VOLUME I
Segmental and Subsegmental Phonology
Edited by
Marc van Oostendorp
Colin J. Ewen
Elizabeth Hume
Keren Rice
THE BLACKWELL COMPANION TO
Phonology
WILEY-BLACKWELL
VOLUME II
Suprasegmental Phonology

This edition first published 2011

Blackwell Publishing was acquired by John Wiley & Sons in February 2007. Blackwell's publishing program has been merged with Wiley's global Scientific, Technical, and Medical business to form Wiley-Blackwell.

Registered Office
John Wiley & Sons Ltd, The Atrium, Southern Gate, Chichester, West Sussex, PO19 8SQ, United Kingdom

Editorial Offices
350 Main Street, Malden, MA 02148-5020, USA

Library of Congress Cataloging-in-Publication Data

The Blackwell companion to phonology / edited by Marc van Oostendorp . . . [et al.].
p. cm. — (Blackwell companions to linguistics series)
Includes bibliographical references and index.
ISBN 978-1-4051-8423-6 (hardcover : alk. paper)
1. Phonetics. 2. Grammar, Comparative and general—Phonology.
I. Oostendorp, Marc van, 1967–
P217.B53 2011
414—dc22 2010042206

A catalogue record for this book is available from the British Library.

Set in 10/12pt Palatino by Graphicraft Limited, Hong Kong

Volume I

Volume II

Suprasegmental and Prosodic Phonology

Volume III

Phonological Processes

Volume IV

Phonological Interfaces

Volume V

Phonology across Languages

Contributors

Akinbiyi Akinlabi is Professor of Linguistics at Rutgers University, New Brunswick. He is the current President of the World Congress of African Linguistics, and serves on the councils of both the West African Languages Congress and the Annual Conference on African Linguistics (USA). His expertise lies primarily in the phonologies of the Benue–Congo languages of West Africa. He has published articles in leading journals of theoretical and descriptive linguistics, including *Linguistic Inquiry*, *Journal of Linguistics*, and *Journal of African Languages and Linguistics*. His forthcoming book is titled: *Yoruba: A phonological grammar*.

Adam Albright is an Associate Professor (Anshen-Chomsky Professorship in Language, and Mind Career Development Chair) at MIT. His research interests include phonology, morphology, and learnability, with an emphasis on using computational modeling and experimental techniques to investigate issues in phonological theory.

Stephen R. Anderson is Dorothy R. Diebold Professor of Linguistics at Yale University. After receiving his Ph.D. from MIT in 1969, he taught at Harvard, UCLA, Stanford, and Johns Hopkins Universities before coming to Yale in 1994. He is the author of numerous articles and six books, including *Aspects of the theory of clitics* (2005). He has done field research on several languages, most recently the Surmiran form of Rumantsch. In addition to phonology and morphology, his research interests include animal communication systems and the evolution of human language.

Diana Archangeli received her Ph.D. from MIT in 1984. She has been a faculty member at the University of Arizona since 1985 and was a Fellow at the Center for Advanced Study in the Behavioral Sciences at Stanford in 2007–8. She co-authored *Grounded phonology* (1994) with Douglas Pulleyblank, and co-edited *Optimality Theory: An over-view* (1997) with D. Terence Langendoen. She is Director of the Arizona Phonological Imaging Lab, used for ultrasound study of the articulation of language sounds.

Amalia Arvaniti is an Associate Professor in the Department of Linguistics at the University of California, San Diego. She received her Ph.D. from the University of Cambridge and has held research and teaching appointments at the Universities of Cambridge, Oxford, Edinburgh, and Cyprus. Her research focuses on the phonetics and phonology of prosody, with special emphasis on the experimental investigation and formal representation of rhythm and intonation.

Bao Zhiming is a linguist working in the Department of English Language and Literature, National University of Singapore. He has two main research interests: Chinese phonology and contact linguistics.

Outi Bat-El is Professor of Linguistics at Tel-Aviv University. She is engaged in the study of Semitic phonology and morphology. In her 1994 *Natural Language & Linguistic Theory* article, she initiated the Semitic root debate, arguing that there is no consonantal root in Semitic morphology. Her subsequent work within the framework of Optimality Theory (*Recherches Linguistiques de Vincennes* 2003) provided further support to this argument. She has also authored articles on Hebrew truncation (*Language* 2002) and reduplication (*Linguistic Inquiry* 2006), on blends (*Phonology* 1996) and hypocoristics (*Phonology* 2005), as well as on language acquisition (*Language Sciences* 2009).

Michael Becker received his Ph.D. from the University of Massachusetts Amherst in 2009, and is currently a lecturer at Harvard University. His work focuses on the grammatical principles that govern lexicon organization, especially as a way to discover Universal biases in the phonological grammar. He also works on the acquisition and learning of lexical patterns.

Ricardo Bermúdez-Otero is Senior Lecturer in Linguistics and English Language at the University of Manchester. He previously held a Postdoctoral Fellowship at the British Academy, followed by a Lectureship in Linguistics at the University of Newcastle upon Tyne. His research focuses on the morphosyntax–phonology and phonology–phonetics interfaces, with particular attention to diachronic issues. His publications include chapters in *Optimality Theory and language change* (2003), *The handbook of English linguistics* (2006), *The Cambridge handbook of phonology* (2007), *Deponency and morphological mismatches* (2007), *Optimality-theoretic studies in Spanish phonology* (2007), and *Morphology and its interfaces* (forthcoming).

Christina Y. Bethin is Professor of Linguistics at Stony Brook University, New York, who works on prosody and syllable structure. She has written numerous articles on the diachronic and synchronic phonology of the Slavic languages, including Polish, Ukrainian, Russian, Belarusian, Serbian and Croatian, Czech, and Slovene, and published two award-winning books, *Polish syllables: The role of prosody in phonology and morphology* (1992) and *Slavic prosody: Language change and phonological theory* (1998).

Geert Booij is Professor of Linguistics at the University of Leiden. He is the author of *The phonology of Dutch* (1995), *The morphology of Dutch* (2002), *The grammar of words* (2005), and *Construction morphology* (2010), and of a number of linguistic articles in a wide range of Dutch and international journals, with focus on the interaction of phonology and morphology, and theoretical issues in morphology.

Anna R. K. Bosch has taught linguistics at the University of Kentucky since 1990, where she is now Associate Dean for Undergraduate Programs and a faculty member of the Linguistics Program and English departments. She has written on

Scottish Gaelic phonology and dialectology, and is currently working on a new project on the history of phonetic transcription in European dialect studies.

Bert Botma is associate professor at the Leiden University Centre of Linguistics (LUCL) and a research fellow at the Netherlands Organization of Scientific Research (NWO). His main research interest is segmental phonology. He has published on such topics as nasal harmony, English syllable structure, and on the phonological contrast between obstruents and sonorants.

Diane Brentari is Professor of Linguistics and Director of the ASL Program at Purdue University. She has published widely in the area of sign language phonology and morphology. She is the author of *A prosodic model of sign language phonology* (1998) and editor of *Sign languages: A Cambridge language survey* (2010). Her current research involves the cross-linguistic analysis of sign languages.

Adam Buchwald is an Assistant Professor at New York University in Communicative Sciences and Disorders. He holds a Ph.D. in Cognitive Science from Johns Hopkins University and had a post doctoral fellowship in the Speech Research Lab at Indiana University. His work is interdisciplinary and spans topics in linguistics, psycholinguistics, and communication sciences.

Eugene Buckley is Associate Professor of Linguistics at the University of Pennsylvania. His research interests include metrical and syllable structure, and the proper locus of phonetic and functional explanation. Much of his work focuses on native languages of North America.

Luigi Burzio is Professor Emeritus, Department of Cognitive Science, Johns Hopkins University. He has also taught at Harvard University, Department of Romance Languages and Literatures. His research interests include syntax, phonology and morphology. He is the author of *Italian syntax* (1986) and *Principles of English stress* (1994).

Patrik Bye is currently a researcher with the Center for Advanced Study in Theoretical Linguistics at the University of Tromsø. He has published scholarly articles on a variety of topics including the syllable structure, quantity, and stress systems of the Finno-Ugric Saami languages, North Germanic accentology, and phonologically conditioned allomorphy. With Martin Krämer and Sylvia Blaho he edited *Freedom of analysis?* (2007).

Charles Cairns is Professor Emeritus of Linguistics at the City University of New York. He received his Ph.D. in linguistics from Columbia University in 1968. Author of a number of articles in phonology, his most recent work is a co-edited volume with Eric Raimy, *Contemporary views on architecture and representations in phonology* (2009).

Andrea Calabrese was born in Campi Salentina in the southeastern tip of Italy. He obtained his Ph.D. in linguistics at MIT in 1988 and is currently teaching at the University of Connecticut. His main interests are phonology, morphology, and historical linguistics. He has published more than 50 articles in books and journals such as *Linguistic Inquiry, Linguistic Review, Studies in Language, Brain and Language, Journal of Neuro-Linguistics, and Rivista di Linguistica.* His recent book, *Markedness and economy in a derivational model of phonology* (2005), proposes a theory integrating phonological rules and repairs triggered by markedness constraints into a derivational model of phonology.

Roderic F. Casali's interests include phonetics, phonological theory, and descriptive work on the phonology of African languages. His research has focused primarily on vowel phenomena, especially vowel hiatus resolution and ATR vowel harmony. He has done linguistic fieldwork in Ghana with SIL and currently teaches linguistics at the Canada Institute of Linguistics at Trinity Western University in Langley, British Columbia.

Young-mee Yu Cho is Associate Professor of East Asian Languages and Cultures at Rutgers University and author of *Parameters of consonantal assimilation* (1999), *Integrated Korean* (2000), and *Korean phonology and morphology* (forthcoming). She has written on Korean language and culture, theoretical linguistics, and Korean pedagogy.

Abigail C. Cohn is Professor of Linguistics at Cornell University, Ithaca, New York. Her research addresses the relationship between phonology and phonetics and is informed by laboratory phonology approaches. She also specializes in the description and analysis of a number of Austronesian languages of Indonesia. Her published work includes articles in *Phonology* and a number of edited volumes and she is co-editor of the forthcoming *Oxford handbook of laboratory phonology*.

Jennifer Cole is Professor of Linguistics and Computer Science at the University of Illinois at Urbana-Champaign, and is a member in the Cognitive Science group at the Beckman Institute for Advanced Science and Technology. She is the founding General Editor of *Laboratory Phonology*, and has served on the editorial boards of the journals *Language*, *Linguistic Inquiry*, and *Phonology*.

Bruce Connell is based at York University, Toronto. His research interests include the phonetics of African languages, the relationships between phonetics and phonology, historical linguistics, and language endangerment and documentation. He makes regular fieldtrips to Africa for research and is an authority on languages in the Nigeria–Cameroon borderland. He received his Ph.D. in Linguistics from the University of Edinburgh in 1991. His publications include "The perception of lexical tone in Mambila," *Language and Speech* 43, and "Tone languages and the universality of intrinsic F0: Evidence from Africa," *Journal of Phonetics* 30.

Marie-Hélène Côté is Associate Professor of Linguistics at the University of Ottawa. Much of her research in phonology relates to the role of perceptual factors in phonological processes, the status of the syllable, and the treatment of variation. She also specializes in French phonology, with a focus on Laurentian (Québec) French.

Onno Crasborn is a Senior Researcher at the Deparhnent of Linguistics of Radboud University Nijmegen, where he heads the sign language research theme of the Centre for Language Studies. After completing a dissertation on phonetic variation in Sign Language of the Netherlands (2001) at Leiden University, he has broadened his research interests beyond sign phonetics and phonology to sociolinguistics, discourse, and corpus linguistics. In 2008 he published the Corpus NGT, the first open access sign language corpus in the world.

Megan J. Crowhurst is an Associate Professor in the Department of Linguistics at the University of Texas at Austin. Her publications in theoretical phonology have concentrated on prosodic phenomena related to word stress and reduplication.

In collaboration with Mark Hewitt, she has also contributed to the literature on constraint conjunction. Her current research, conducted in an experimental paradigm, explores the ways in which humans' perception of rhythm might contribute to the form and frequency of stress patterns found in natural languages.

Stuart Davis is Professor of Linguistics at Indiana University, Bloomington. His primary area of research is in phonology and phonological theory with a secondary area of research in the early history of linguistics in the USA. His work in phonology has especially focused on issues related to syllable structure and word-level prosody. His work has appeared in a wide variety of edited volumes and journals including *Linguistic Inquiry*, *Phonology*, *Lingua*, *Linguistics*, and *American Speech*.

Kenneth de Jong is currently Professor of Linguistics, Cognitive Science and Second Language Studies at Indiana University. He has worked extensively on questions of how prosodic organization pervades the details of speech production, and more generally how speech production and perception interact with one another and how this relates to the phonological system. He is author of more than 50 articles on aspects of phonetic behavior and is currently Associate Editor of the *Journal of Phonetics*.

Paul de Lacy is an Associate Professor in the Department of Linguistics at Rutgers University, an Associate of the Rutgers Center for Cognitive Science, Co-director of the Rutgers Phonetics and Fieldwork Laboratory, and editor of the *Cambridge handbook of phonology*. He works on phonology and its interfaces with syntax, morphology, and phonetics.

Laura J. Downing is a research fellow at the ZAS, Berlin, leading projects on the phonology–focus–syntax interface in Bantu languages. She has published several articles on tone and depressor tone, morphologically-conditioned morphology, syllable structure and prosodic morphology in Bantu languages, and a book, *Canonical forms in prosodic morphology* (2006).

B. Elan Dresher is Professor of Linguistics at the University of Toronto. He has published on phonological theory, learnability, historical linguistics, and West Germanic and Biblical Hebrew phonology and prosody. He is the author of *Old English and the theory of phonology* (1985) and "Chomsky and Halle's revolution in phonology" in the *Cambridge companion to Chomsky* (2005). His recent books include *Formal approaches to poetry: Recent developments in generative metrics* (co-ed., with Nila Friedberg, 2006), *Contrast in phonology: Theory, perception, acquisition* (co-ed., with Peter Avery and Keren Rice, 2008), and *The contrastive hierarchy in phonology* (2009).

San Duanmu is Professor of Linguistics, University of Michigan, where he has taught since 1991. He obtained his Ph.D. in linguistics from MIT in 1990 and from 1981 to 1986 held a teaching post at Fudan University in Shanghai.

Amanda Dye is a graduate student in Linguistics at New York University. She holds a B.A. in Linguistics from Harvard University. Her past work has focused on theoretical and experimental study of the morphophonology and syntax of mutation in Welsh. Her research interests are in experimental phonology, segmental phonology, the study of Welsh, and the phonology–semantics interface.

Mirjam Ernestus is an Associate Professor at Radboud University in Nijmegen. She obtained her Ph.D. from the Free University Amsterdam in 2000 and then held several postdoctoral positions at the Max Planck Institute for Psycholinguistics in Nijmegen.

Kathryn Flack Potts received her Ph.D. in linguistics from the University of Massachusetts, Amherst in 2007. She is a Lecturer in Linguistics at Stanford University.

Stefan A. Frisch is an Associate Professor in the Department of Communication Sciences and Disorders at the University of South Florida. He uses the tools of laboratory phonology to examine frequency effects in the lexicon and in metalinguistic judgments of well-formedness. He is also interested in speech articulation and the use of experimentally elicited speech errors in the study of speech production processes.

Adamantios I. Gafos is an Associate Professor at New York University's Linguistics Department and a senior scientist at Haskins Laboratories. His interests lie at the intersection of phonology and cognitive science.

Randall Gess is Associate Professor of Linguistics, Cognitive Science, and French, and Director of the School of Linguistics and Language Studies at Carleton University. His research interests are in historical phonology, the phonetics–phonology interface, and French and Romance phonology.

Heather Goad is an Associate Professor in Linguistics at McGill University. She works principally on the acquisition of phonology. Her work has been published in *Linguistic Review, Lingua, Language Acquisition*, and *Second Language Research*. Her research is currently funded by the Social Sciences and Humanities Research Council of Canada and the Fonds québécois de la recherche sur la société et la culture. She has been an Associate Editor of *Language Acquisition* since 2004.

Matthew Gordon is Professor of Linguistics at the University of California, Santa Barbara. He is the author of *Syllable weight: Phonetics, phonology, typology* (2006) and co-editor of *Topic and focus: Cross-linguistic perspectives on meaning and intonation* (2008). His research focuses on prosody, including stress and intonation, and the phonetic description of endangered languages.

Janet Grijzenhout is Professor of English Linguistics at the University of Konstanz and director of the Baby Speech Lab there. Her research focuses on the phonological representation of voicing and stricture, the phonology–morphology interface, infant speech perception, and the acquisition of prosody and morphology.

Naomi Gurevich received a Ph.D. from the Linguistics Department at the University of Illinois at Urbana-Champaign in 2003. The dissertation was published in the Outstanding Dissertations in Linguistics Series in 2004 under the title *Lenition and contrast: Functional consequences of certain phonetically conditioned sound changes*. Recently Naomi's research interests have shifted from theoretical linguistics to neurologically-based language disorders. She is currently working on a clinical certification in Speech Language Pathology.

Carlos Gussenhoven is Professor of General and Experimental Phonology in the Department of Linguistics at Radboud University, Nijmegen and Professor of Linguistics in the School of Languages, Linguistics, and Film at Queen Mary University of London. One of his research topics is the prosodic structure of English, including word stress and sentence intonation. Other research has focused on stress and tone in a variety of languages, including Dutch, Japanese, Nubi, and a group of Franconian dialects with a lexical tone contrast. Among his publications are *The phonology of tone and intonation* (2004) and *Understanding phonology* (1998, 2005).

Gregory R. Guy (Ph.D., Pennsylvania) is Professor of Linguistics at New York University, and has been on the faculty at Sydney, Temple, Cornell, Stanford, and York. He has taught at five Linguistic Institutes of the Linguistic Society of America, and three Institutes of the Associação Brasileira de Lingüística. He specializes in sociolinguistics and phonological variation and change, and works on Portuguese, English, and Spanish. His current research interests include the treatment of variation in linguistic theory, the relationship between individual and community grammars, and the theoretical treatment of grammatical similarity. His books include *Towards a social science of language* (1996) and *Sociolingüística quantitativa* (2007).

Daniel Currie Hall received his Ph.D. from the University of Toronto in 2007 with a thesis entitled "The role and representation of contrast in phonological theory." He has taught on all three campuses of the University of Toronto and at Queen's University and worked as a researcher at the Meertens Instituut of the Royal Netherlands Academy of Arts and Sciences, and is currently an Assistant Professor at Saint Mary's University in Halifax, Nova Scotia.

Nancy Hall is an Assistant Professor at California State University, Long Beach. She received her Ph.D. from the University of Massachusetts, Amherst in 2003, and has taught at Rutgers University, the University of Haifa, Ben-Gurion University of the Negev, and Roehampton University.

T. A. Hall is Associate Professor of Germanic Studies and Adjunct Associate Professor of Linguistics at Indiana University. He has published widely on a number of topics in general phonological theory and Germanic phonology in journals such as *Linguistics*, *Lingua*, *Natural Language & Linguistic Theory*, *Journal of Germanic Linguistics*, *Phonology*, *Linguistic Review*, *Journal of Comparative Germanic Linguistics*, and *Morphology*.

Michael Hammond is Professor of Linguistics and Department Head at the University of Arizona. He received his Ph.D. in Linguistics from UCLA in 1984. He is the author of numerous books and articles. His research interests are broad, including the metrical theory of stress, Optimality Theory, poetic meter, language games, computational linguistics, psycholinguistics, mathematical linguistics, syllable structure, probabilistic phonotactics, English phonology generally, and Welsh.

S. J. Hannahs is Senior Lecturer in Linguistics at Newcastle University. Co-author of *Introducing phonetics and phonology* (2005), much of his research has focused on prosodic structure, particularly at the interface between phonology and morphology. His recent and ongoing work has concentrated on the phonology and morphophonology of modern Welsh.

John Harris, Professor of Linguistics at University College London, writes on various topics connected with phonology, including phonological theory, the interface with phonetics, language impairment, and variation and change in English. Among his publications are the books *Phonological variation and change* (1985) and *English sound structure* (1994).

Jeffrey Heinz is Assistant Professor in the Department of Linguistics and Cognitive Science at the University of Delaware and has held a joint appointment with the department of Computer and Information Sciences since 2009. He received his Ph.D. in Linguistics from UCLA in 2007 and is keen to help bridge divides between theoretical phonology, computational linguistics, theoretical computer science, and cognitive science.

Ben Hermans is a senior researcher at the Meertens Institute in Amsterdam. He was trained as a Slavist and Germanicist. In 1994 he defended his thesis "The composite nature of accent" at the Free University. He now focuses on the tonal accents of the Limburg dialects, for example, "The phonological structure of the Limburg tonal accents" (2009), and is particularly interested in their formal representation. He also publishes on the history of the phonology of Dutch and its dialects.

José Ignacio Hualde (Ph.D. in Linguistics, 1988, University of Southern California) is Professor in the Department of Spanish, Italian, and Portuguese and the Department of Linguistics at the University of Illinois at Urbana-Champaign. He is author of *Basque phonology* (1991) and *The sounds of Spanish* (2005), co-author of *The Basque dialect of Lekeitio* (1994) and co-editor of *Generative studies in Basque linguistics* (1993), *Towards a history of the Basque language* (1995), *A grammar of Basque* (2003) and *Laboratory phonology 9* (2007), among other books. He has also published a number of articles on synchronic and diachronic issues in Basque and Romance phonology.

Harry van der Hulst is Professor of Linguistics at the University of Connecticut. He has published four books, two textbooks, and over 130 articles, and has edited 20 books and six journal theme issues in areas including feature systems and segmental structure, syllable structure, word accent systems, vowel harmony, and sign language phonology. He has been Editor-in-Chief of the international linguistic journal *The Linguistic Review* since 1990 and he is co-editor of the series Studies in Generative Grammar.

Elizabeth Hume is Professor and Chair of the Department of Linguistics at Ohio State University. She holds a Ph.D. and M.A. in Linguistics from Cornell University, an M.A. in French and Social Psychology of Language from McMaster University (Canada), and a B.A. in French from Université Laval (Quebec). Her research interests lie in language sound systems, cognitive science, language variation, and language change. She has published widely on topics including consonant–vowel interaction, feature theory, geminates, markedness, metathesis, sound change, the interplay of speech perception and phonology, and Maltese phonetics and phonology.

Brett Hyde received his Ph.D. in Linguistics from Rutgers University in 2001 and currently has an appointment at Washington University in St. Louis. His primary research interests are in metrical stress theory and related areas.

Larry M. Hyman is Professor of Linguistics at the University of California, Berkeley. He received a Ph.D. in Linguistics from UCLA in 1972. He has published several books (e.g. *Phonology theory and analysis, A theory of phonological weight*) and numerous theoretical articles in such journals as *Language, Linguistic Inquiry, Natural Language & Linguistic Theory, Phonology, Studies in African Linguistics*, and *Journal of African Languages and Linguistics.*

Sharon Inkelas is Professor of Linguistics at the University of California, Berkeley. She specializes in the phonology–morphology interface and has branched out in recent years into child phonology. With co-author Cheryl Zoll she published *Reduplication: Doubling in morphology* in 2005.

Gregory K. Iverson is Professor of Linguistics at the University of Wisconsin-Milwaukee and Research Professor at the University of Maryland Center for Advanced Study of Language. His research interests span the fields of historical linguistics, especially Germanic, the phonetics and phonology of laryngeal systems, especially Korean, and the acquisition of second language phonological patterns.

Jongho Jun is Professor of Linguistics at Seoul National University. His research interests are phonetics in phonology, variation in phonology, and the formal properties of Optimality Theory.

Barış Kabak is currently an Assistant Professor of English and General Linguistics at the University of Konstanz.

Ellen M. Kaisse is Professor of Linguistics at the University of Washington. She has co-edited the journal *Phonology* since 1988. Her research concentrates on the interactions of phonology with morphology and syntax, on distinctive features, and on the phonology of Modern Greek, Turkish, and Spanish.

Yoonjung Kang is an Assistant Professor in the Department of Humanities at the University of Toronto, Scarborough and the Department of Linguistics at the University of Toronto. Her area of specialization is phonology and its interface with phonetics and morphology, with a special focus on Korean.

Shigeto Kawahara is an Assistant Professor in Linguistics and Rutgers Center for Cognitive Science (RuCCs) at Rutgers University. He was awarded his Ph.D. from the University of Massachusetts, Amherst in 2007. His research focuses on the phonetics–phonology interface, experimental investigations of phonological judgments, corpus-based studies of verbal art, and studies on intonation and accents.

Robert Kennedy is a lecturer in the Department of Linguistics at the University of California, Santa Barbara. His areas of expertise include reduplication, prosodic morphology, hypocoristics, vowel systems of English varieties, and articulatory phonology.

John Kingston is a Professor in the Linguistics Department, University of Massachusetts, Amherst. His publications include: "Phonetic knowledge," *Language* (with R. L. Diehl, 1994); "Lenition," *Proceedings of the Third Conference on Laboratory Approaches to Spanish Phonology* (2007); "The phonetics–phonology interface," *Cambridge handbook of phonology* (2007); "On the internal perceptual structure of distinctive features: The [voice] contrast," *Journal of Phonetics* (with R. L. Diehl, C. J. Kirk, and W. A. Castleman, 2008); "Contextual effects on the perception of duration," *Journal of Phonetics* (with S. Kawahara, D. Chambless, D. Mash, and E. Brenner-Alsop, 2009); "Auditory contrast versus compensation for coarticulation: Data from Japanese and English listeners," *Language and Speech* (with S. Kawahara, D. Mash, and D. Chambless, in press).

Charles W. Kisseberth has just retired from his position as Professor of Linguistics at Tel Aviv University (where he taught from 1996 to 2010) and is also Emeritus Professor at the University of Illinois (where he taught from 1969 to 1996). He is best known for his work in theoretical phonology, where his work on "conspiracies" laid the foundations for Optimality Theory, and his work on Chimwiini prosody helped to lead the way to current studies in the phonology–syntax interface. His work over the last 30 years has focused on Bantu tonal systems, and Optimal Domains Theory has evolved out of that work. He is co-author with Michael Kenstowicz of *Generative phonology* (1979), a standard introduction to classical generative phonology.

Alexei Kochetov is currently an Assistant Professor in the Linguistics Department at the University of Toronto. He received his Ph.D. at the University of Toronto with the thesis "Production, perception, and emergent patterns of palatalization" (published in 2002). His research deals with various issues in the phonetics–phonology interface, cross-language speech production, and Slavic phonology and phonetics.

Astrid Kraehenmann holds a Ph.D. in Theoretical Linguistics from Konstanz University, Germany. Her main research interests are phonology, phonetics, the phonology–phonetics interface, historical linguistics, and Germanic languages.

Haruo Kubozono is Professor and Director at the National Institute for Japanese Language and Linguistics in Tokyo. His main publications include *The organization of Japanese prosody* (1993), "Mora and syllable" (in *The handbook of Japanese linguistics*, 1999), and "Where does loanword prosody come from?" (*Lingua* 116, 2006).

Darlene LaCharité is Professor of Phonetics and Phonology at Laval University. Her areas of research include loanword phonology (in collaboration with Carole Paradis), the L2 acquisition of phonetics and phonology, and creole phonology and morphology (in collaboration with Silvia Kouwenberg). She has published in a variety of linguistics journals, including *Linguistic Inquiry*, *Phonology*, *Journal of Linguistics* and *Journal of Pidgin and Creole Languages*.

William R. Leben is Professor Emeritus of Linguistics at Stanford University. He has worked on the phonology of tone in languages of West Africa and has also co-authored pedagogical works on Hausa. He continues to work on phonology in Kwa languages of Côte d'Ivoire. The second edition of *English vocabulary elements*, a textbook he co-authored, was published in 2007.

Clara C. Levelt is Associate Professor at the Linguistics Department of Leiden University, and affiliated to the Leiden University Centre for Linguistics (LUCL) and the Leiden Institute for Brain and Cognition (LIBC). She received her Ph.D. in 1994, and has worked on child language phonology ever since. In 2007 she received a prestigious research grant from the Netherlands Organization for Scientific Research (NWO), which enabled her to set up a baby lab. Combining insights from perception and production data, phonology and phonetics, she tries to uncover the source of children's deviating productions.

Susannah V. Levi is an Assistant Professor in the Department of Communicative Sciences and Disorders at New York University. She received her Ph.D. in 2004 from the Department of Linguistics at the University of Washington. She then completed a three-year postdoctoral fellowship at Indiana University in the Department of Psychological and Brain Sciences. She has worked on glides, Turkish stress and intonation, and most recently on speech perception and language processing in children and adults.

Yen-Hwei Lin is Professor of Linguistics at Michigan State University, and taught at the 1997 and 2003 Linguistic Society of America Linguistic Institutes. Her research has focused on phonological representations and constraints in the theoretical context of non-linear phonology/morphology and Optimality Theory. She is author of *The sounds of Chinese* (2007) and editor of *Special Issue on Phonetics and Phonology* (*Language and Linguistics* 5.4, 2004).

Anna Łubowicz is Assistant Professor of Linguistics at the University of Southern California. Her research interests lie in the investigation of the role of contrast in phonology and morphology, lexical phonology, and the morphology–phonology interface. She specializes in Slavic languages and holds a Courtesy Appointment in the Department of Slavic Languages at the University of Southern California.

Andrew Martin received his Ph.D. in Linguistics from UCLA in 2007. His research is focused on understanding early phonological and lexical learning. He is also interested in how a language's lexicon changes over time, and how a word's phonological properties affect that word's ability to survive and spread in a speech community. He is currently a post-doctoral researcher at the Laboratory for Language Learning and Development in the RIKEN Brain Science Institute near Tokyo.

Joan Mascaró studied at the Universitat de Barcelona and at MIT where he got his Ph.D. in linguistics in 1976. He has taught at Cornell University and at the Universitat Autònoma de Barcelona, where he is currently full professor. His main research areas are linguistic theory, phonological theory, the phonology–morphology interface, and the phonological and morphological analysis of Romance languages.

April McMahon is Forbes Professor of English Language, and Vice Principal for Planning, Resources and Research Policy, at the University of Edinburgh. She co-edits the journal *English Language and Linguistics*. Her research focuses on the interaction of phonological theory and sound change, and methods for the comparison and classification of accents and languages.

Jacques Mehler is the director of the Language, Cognition, and Development laboratory at the International School for Advanced Studies, Trieste, Italy (SISSA). After obtaining a Ph.D. from Harvard University in 1964, he worked at the National Center for Scientific Research (CNRS) in Paris, France, from 1967 until 2001. In 1972, he founded *Cognition*, an international journal of cognitive science, and acted as Editor-in-Chief until 2007. He became Directeur de Recherche at CNRS in 1980 and was elected Directeur d'Études at the École des Hautes Études en Sciences Sociales in 1982. He has published influential experimental studies of language acquisition in the first year of life, and has also explored early bilingualism. He is a member of the American Academy of Arts and Sciences (2001), the American Philosophical Society (2008) and the Academic Europaea. He was awarded a Doctor Honoris Causa from Utrecht University (2009), and from Université Libre de Bruxelles (1995). His publications are available at: www.sissa.it/cns/lcd/publications.html.

Jeff Mielke is Assistant Professor of Linguistics at the University of Ottawa and Co-director of the Sound Patterns Laboratory. He completed his Ph.D. at Ohio State University in 2004 and undertook postdoctoral research at the Arizona Phonological Imaging Laboratory at the University of Arizona before moving to Ottawa in 2006. His work focuses on the way phonological patterns reflect influences such as physiology, cognition, and social factors. He is the author of *The emergence of distinctive features* (2008).

Amanda Miller is a Visiting Assistant Professor at Ohio State University. Her research focuses on the phonetics and phonology of African languages, particularly Khoesan languages. She has studied gutturals, complex segments (clicks and labial-velars), and contour segments (affricates and airstream contours). She has investigated acoustic voice quality cues and the role of acoustic similarity in a Guttural Obligatory Contour Principle constraint; as well as tongue root retraction in clicks and labial-velars, and its role in C-V co-occurrence patterns. She has also published papers on reduplication and the tonal phonology of Khoesan languages.

Brett Miller is a graduate student at the University of Cambridge. His interests include Indo-European phonology, especially stops; the phonetics–phonology interface; feature contrast, representations, and interaction in rules and constraints; and typology *vis-á-vis* the comparative method.

Bruce Morén-Duolljá is a Senior Researcher at the Center for Advanced Study in Theoretical Linguistics at the University of Tromsø. He has published on synchronic and diachronic phonology, including Slavic palatalization, Icelandic preaspiration and Thai tones. He is the author of *Distinctiveness, coercion and sonority: A unified theory of weight* (2001).

Marina Nespor is Professor of General Linguistics at the University of Milano-Bicocca. She has focused her research on how the phonological shape of an utterance conveys information about its syntactic structure, the so-called theory of prosodic phonology. She has also investigated how prosody is used in comprehension and during language acquisition. Her book *Prosodic phonology* (co-authored with I. Vogel, 1986) is a citation classic and she has numerous articles in peer-reviewed journals.

Andrew Nevins is a Reader in Linguistics at University College London. His research has primarily focused on phonological and morphological theory, and the relations between different modules of the grammar. He has worked on locality, markedness, contrast, reduplication, the nature of underlying representations, and the structure of the morphological component. He is the author of *Locality in vowel harmony* (2010) and the co-editor of two books, with Bert Vaux, *Rules, constraints, and phonological phenomena* (2008), and with Asaf Bachrach, *Inflectional identity* (2008).

David Odden is Professor of Linguistics at Ohio State University. His areas of research specialization include phonological theory and language description, especially the structure of African languages. He served as Editor of *Studies in African Linguistics* from 2003 to 2009 and was Associate Editor of *Phonology* from 1998 to 2008. Recent publications include *Introducing phonology* (2005), "Ordering," in Vaux and Nevins, *Rules, constraints, and phonological phenomena* (2008), and "Tachoni verbal tonology," *Language Sciences* (2009).

Jaye Padgett is Professor of Linguistics at the University of California, Santa Cruz. At the broadest level his research is on the interplay of phonology and phonetics, with special attention to the role that perception plays in shaping phonological patterns. Though his research bears on larger questions it often focuses particularly on Russian phonetics and phonology.

Carole Paradis is Professor of Phonology at Laval University. She proposed a theory of constraints in 1987, as a visiting scholar at MIT. She co-edited a book on the special status of the coronals with J.-F. Prunet in 1991. With R. Béland's collaboration, she has drawn a parallel between aphasic errors and loanword adaptations. This study, extended to other speech error types, has been published in journals such as *Aphasiology* and has led to the construction of more optimal speech pathology exercises.

Steve Parker is a Professor with the Graduate Institute of Applied Linguistics (GIAL) in Dallas. He graduated from the doctoral program in linguistics at the University of Massachusetts, Amherst in 2002. He has served as a teacher and consultant with the Summer Institute of Linguistics (SIL International) for 30 years. In that capacity he has carried out direct fieldwork and research on a number of indigenous languages of South America and Papua New Guinea, two of which are now extinct.

Sharon Peperkamp is a senior researcher in the Laboratoire de Sciences Cognitives et Psycholinguistique at the École Normale Supérieure in Paris. Her main research interests are in experimental and computational approaches to speech perception and phonological acquisition.

Marianne Pouplier obtained her Ph.D. from Yale Linguistics in 2003 and is now a principal investigator of an Emmy-Noether Research Group funded by the Deutsche Forschungsgemeinschaft at the Institute of Phonetics and Speech Processing, University of Munich. She has also been affiliated with Haskins Laboratories for a number of years. Her research focuses on the interaction of speech planning and motor control and the phonetics–phonology interface. In particular, she has worked on speech errors, phonetic correlates of syllable structure, and word boundary assimilation.

Pilar Prieto holds a Ph.D. in Romance Linguistics at the University of Illinois at Urbana-Champaign, and is currently working as the coordinator of the Grup d'Estudis de Prosòdia at the Universitat Pompeu Fabra in Barcelona. Her main research interests focus on how melody and prosody work in language and how they interact with other types of linguistic knowledge. She is also interested in how babies acquire sounds and melody together with grammar, and how these components integrate in the process of language acquisition.

Douglas Pulleyblank is Professor of Linguistics at the University of British Columbia. His research has focused on the phonology and morphology of Nigerian languages, particularly Yoruba. He has worked extensively in autosegmental and optimality-theoretic frameworks, examining phenomena such as tone and vowel harmony.

Eric Raimy is an Associate Professor at the University of Wisconsin-Madison. He received his Ph.D. from the University of Delaware in 1999. He is the author of *The phonology and morphology of reduplication* (2000) and co-edited *Contemporary* *views on architecture and representations in phonology* (2009) and *Handbook of the syllable* (in press) both with Charles Cairns.

Anthi Revithiadou is an Assistant Professor of Linguistics at the Aristotle University of Theory, with emphasis on the structure of phonological representations and the issue of parallel grammars, and has published in journals (*Lingua, Linguistic Review, Journal of Greek Linguistics*) and edited volumes.

Curt Rice is the Vice President (Prorektor) for Research and Development at the University of Tromsø in Tromsø, Norway. He was the founding Director of the Center for Advanced Study in Theoretical Linguistics: A Norwegian Center of Excellence (CASTL) from 2002 to 2008, at the same university.

Keren Rice is University Professor and Canada Research Chair in Linguistics and Aboriginal Studies at the University of Toronto. She holds an M.A. and Ph.D. in Linguistics from the University of Toronto and a B.A. in Linguistics from Cornell University. Her research interests lie in language sound systems, contrast and markedness, interfaces with phonology, language variation and language change, and Athabaskan languages as well as ethics and responsibilities of linguists in fieldwork. She has published on topics including feature theory, sonorants, markedness, language change, and Athabaskan phonology and morphology.

Anastasia K. Riehl is Director of the Strathy Language Unit at Queen's University in Kingston, Canada, where she also teaches in the Linguistics Program. She received a Ph.D. in Linguistics from Cornell University. Her research interests include the phonology–phonetics interface, endangered language documentation, Austronesian languages, and varieties of English.

Jason Riggle is Assistant Professor of Linguistics at the University of Chicago, and his main research areas are phonology, learnability, and computational linguistics. Much of his research focuses on the ways that specific models of grammar, learning, and communication interact to make predictions about linguistic typology with special emphasis on the frequencies with which patterns are observed within and across languages.

Sharon Rose is Associate Professor of Linguistics at the University of California, San Diego. She has published journal articles covering topics such as consonant harmony, syllable contact, Semitic root structure, reduplication, phonotactics, and the interaction between tone and syllable structure. She specializes in African languages spoken in Ethiopia, Eritrea, and Sudan; her current research is an investigation of the Sudanese language, Moro, funded by the National Science Foundation.

Jerzy Rubach holds an appointment as Professor of Linguistics at two universities: the University of Iowa in the United States and the University of Warsaw in Poland. His expertise is primarily in Germanic and Slavic languages. He has published six books and 75 articles. His work has appeared in numerous journals, including *Linguistic Inquiry, Language, Phonology,* and *Natural Language & Linguistic Theory.*

Joseph C. Salmons is Professor of German at the University of Wisconsin–Madison and Executive Editor of *Diachronica: International Journal for Historical Linguistics.* His research interests include language change, sound systems, language contact, and language shift, all often involving data from the Germanic languages.

Wendy Sandler has been investigating the phonology, morphology, and prosody of American Sign Language and Israeli Sign Language for many years, beginning with her graduate work at the University of Texas at Austin, where she earned her Ph.D. Sandler has authored or co-authored three books on sign language linguistics. Currently, with colleagues Mark Aronoff, Irit Meir, and Carol Padden, she is investigating a new sign language that arose in an insulated Bedouin community in the Negev desert of Israel.

Tobias Scheer is currently Directeur de Recherche at the Centre National de la Recherche Scientifique in France. He works at the laboratory Bases, Corpus, Langage (UMR 6039) in Nice, of which he is the director. Being a phonologist, his main interests lie in syllable structure thematically speaking, in the (Western) Slavic family as far as languages are concerned, and in diachronic study. In 2004, he published a book on a particular development of GP, so-called CVCV (or strict CV), and a book on the (history of the) interface of phonology and morpho-syntax.

Misun Seo is an Assistant Professor in the Department of English Language and Literature at Hannam University in Daejeon, Korea. She received her Ph.D. in Linguistics at Ohio State University; her research interests include phonology, its interface with phonetics, and L2 acquisition.

Kimary Shahin is a phonetician/phonologist who specializes in Arabic and Salish. She also investigates first language acquisition and contributes to the documentation and revitalization of indigenous languages in Canada.

Mohinish Shukla has a background in molecular genetics, and holds a Ph.D. in Cognitive Neuroscience from the Scuola Internazionale Superiore di Studi Avanzati (SISSA), Italy. He is currently doing postdoctoral work at the University of Rochester, New York. He is interested in human cognition, with a focus on infant cognitive development, particularly the development of linguistic abilities from phonology to syntax. He is also interested in the neural bases of cognitive behavior, which he primarily explores using near-infrared spectroscopy in infants and adults.

Daniel Silverman earned his degree at UCLA in 1995 under the tutelage of Donca Steriade and Peter Ladefoged. He has published widely on phonology and phonetics, including *A critical introduction to phonology: Of sound, mind, and body* (2006), and *Neutralization: Rhyme and reason in phonology* (forthcoming). He is currently on the faculty of San José State University.

Jennifer L. Smith teaches phonology, phonetics, and Japanese linguistics at the University of North Carolina, Chapel Hill. Her research explores the ways in which interfaces between phonology and other domains of linguistics affect phonological constraints and representations.

Péter Szigetvári gives courses on phonology, linguistics, information technology, and typography at Eötvös Loránd University, Budapest. His main research areas include phonotactics and consonant lenition.

Nina Topintzi has taught as a Teaching Fellow in England and Greece (2006–2010) and will soon commence her appointment as Assistant Professor in Phonology at the English Department, Aristotle University of Thessaloniki. She has published in journals including *Natural Language & Linguistic Theory* and the

Journal of Greek Linguistics. Beyond onsets, her research interests include stress, the syllable, and various weight-based phenomena from a typological perspective.

Miklós Törkenczy is a Professor at the Department of English Linguistics and the Theoretical Linguistics Department of Eötvös Loránd University Budapest and a senior researcher at the Research Institute for Linguistics of the Hungarian Academy of Sciences. He is co-author of *The phonology of Hungarian* (2000).

Jochen Trommer received his Ph.D. from the University of Potsdam, has worked as lecturer at the University of Osnabrück and is currently Lecturer in Phonology at the Department of Linguistics at the University of Leipzig. His work focuses on the theoretical and typological aspects of phonology and morphology, especially prosody, non-concatenative morphology, hierarchy effects in agreement morphology, and affix order. His publications include "Case suffixes, postpositions, and the phonological word in Hungarian," *Linguistics* 46(1) (2008); "Hierarchy-based competition and emergence of two-argument agreement in Dumi," *Linguistics* 44(5) (2006); and "The interaction of morphology and syntax in affix order," *Yearbook of Morphology 2002* (2003).

Suzanne Urbanczyk is an Associate Professor in the Linguistics Department at the University of Victoria. She received her Ph.D. from the University of Massachusetts, Amherst and has published on Salish reduplication and non-concatenative morphology in *Natural Language and Linguistic Theory* and *Linguistic Inquiry*. Her current research focuses on the role repetition plays in structuring language, and she is developing a model of morphology which is grounded in the mental lexicon, with an empirical focus on word-formation in Salish and Wakashan languages.

Adam Ussishkin is an Associate Professor in the Linguistics Department at the University of Arizona, where he also holds joint appointments in Cognitive Science and Near Eastern Studies. His areas of research include phonology, morphology, and lexical access, with an empirical focus on Semitic languages.

Bert Vaux is University Reader in Phonology and Morphology at the University of Cambridge and a Fellow of King's College, Cambridge. He is primarily interested in phenomena that shed light on the structure and origins of the phonological component of the grammar, especially in the realms of psychophonology, historical linguistics, and sociolinguistics. He also enjoys working with native speakers to document endangered languages, especially dialects of Armenian, Abkhaz, and English.

Rachel Walker is Associate Professor of Linguistics at the University of Southern California. She is the author of *Nasalization, neutral segments and opacity effects* (2000) and *Vowel patterns in language* (forthcoming). She has published widely on topics involving long-distance assimilation and copy, as seen in systems of harmony and reduplication. Her current research investigates the interaction of vowel patterns with positions of prominence in the word.

Natasha Warner has been a faculty member in Linguistics at the University of Arizona since 2001 and has worked at the Max Planck Institute for Psycholinguistics. Her interests are in the three-way interface of phonetics, experimental phonology, and psycholinguistics, with language interests in Dutch, Japanese, Korean, and English. She also works on revitalization of the Mutsun language.

Janet C. E. Watson is Professor of Arabic Linguistics at the University of Salford, UK. She has previously worked at the universities of Edinburgh and Durham, and held visiting posts at the universities of Heidelberg and Oslo. She has published extensively on Yemeni Arabic, and since 2006 has been working on the documentation of the Modern South Arabian language, Mehri. She is currently preparing a syntax of Mehri for publication. Her publications include *Phonology and morphology of Arabic* (2002) and *A syntax of San'ani Arabic* (1993).

Andrew Wedel is on the faculty of the Department of Linguistics and the Cognitive Science Program at the University of Arizona. His primary interests lie in exploring the causes for, and the interaction of, two opposing tendencies evident in language change: a tendency toward pattern-coherence, and a tendency to preserve semantically relevant contrasts. Relevant work in this domain includes "Feedback and regularity in the lexicon," *Phonology* 24, and with Juliette Blevins, "Inhibited sound change: An evolutionary approach to lexical competition," *Diachronica* 26 (2009).

Jeroen van de Weijer is Full Professor of English Linguistics at Shanghai International Studies University (College of English Language and Literature) within the Chinese "211-Project." He is a Distinguished University Professor of Shanghai (Oriental Scholar), an award bestowed by the Shanghai Municipal Education Commission. He has published widely on segmental structure, Optimality Theory, English phonology, and East Asian languages. His current research is focused on combining phonological and psycholinguistic theories.

Richard Wiese has been a Professor of German Linguistics at the Philipps-Universität, Marburg, Germany, since 1996. His work concentrates on theoretical linguistics, phonology, and psycholinguistics. He has written a monograph, *The phonology of German* (2000) and numerous articles on issues of (German) phonology, morphology, psycholinguistics, and orthography, and is Co-editor of the book series Linguistische Arbeiten.

Ronnie Wilbur, Professor and Director of Linguistics and Professor of Speech, Language, and Hearing Sciences, received her Ph.D. in Linguistics at the University of Illinois, Urbana-Champaign. She has taught at the University of Southern California, Boston University, University of Amsterdam, University of Graz, Austria, and University of Zagreb. Her 1973 dissertation "The phonology of reduplication" was reissued as a "Classic in Linguistics" in 1997. She was Founding Editor of the journal *Sign Language & Linguistics* and Editor from 1998 to 2006.

Matthew Wolf received his Ph.D. in 2008 from the University of Massachusetts, Amherst. After having been a Visiting Assistant Professor at Georgetown University and a Visiting Lecturer at Yale University, he is currently a Postdoctoral Associate at Yale. His research has focused primarily on aspects of the phonology–morphology interface, including process morphology, allomorph selection, and paradigm gaps, as well as on opacity and serial versions of Optimality Theory.

Moira Yip is Professor of Linguistics (Emerita) at University College London. Previously she was at the University of California, Irvine, and Brandeis University. She received her Ph.D. from MIT in 1980, studying under Morris Halle. She has published extensively on tone, reduplication, distinctive feature theory, and loanword phonology. Much of her work has been on Chinese languages. Recently she has become interested in comparisons between birdsong and human phonology, and is now publishing in this area.

Alan C. L. Yu is Associate Professor of Linguistics at the University of Chicago. He is the author of *A natural history of infixation* (2007) and co-editor (with John Goldsmith and Jason Riggle) of the *Handbook of phonological theory*, 2nd edition (forthcoming). His work on phonetics and phonology has appeared in *Language*, *Phonology*, *Journal of Phonetics*, and *PLoS One*.

Draga Zec is Professor of Linguistics at Cornell University. She has worked in several areas of phonology and its interfaces: the moraic theory of syllable structure, the representation of pitch accent, and both the phonology-morphology and the phonology–syntax interfaces.

Elizabeth C. Zsiga is an Associate Professor in the Department of Linguistics at Georgetown University. Her research primarily addresses the phonetic and phonological patterns that occur at and across word boundaries in connected speech. Her publications have examined a range of processes in different languages, including final consonant deletion and palatalization in English, vowel assimilation in Igbo, palatalization in Russian, tone simplification in Thai, voicing in Setswana, pitch accent in Serbian, and most recently nasalization and voicing in Korean and Korean-accented English.

Preface

Progress in phonology, like other disciplines, grows out of debate. Every journal article, every conference paper, every book chapter, every book on phonology, can be seen as a contribution to one or more discussions on some theoretical topic. New data are sought to sharpen theoretical claims and new theories are proposed to accommodate previously undescribed data. Already familiar data paradigms are frequently appealed to in arguing that some new theory fares better than its competitors in the description of various phenomena.

Arguably, the synchronic study of phonology is currently celebrating its first centenary: Ferdinand de Saussure was teaching his *Cours de linguistique générale* up to his death in 1913 (it was published posthumously in 1916). One hundred years of debates have yielded many insights into the sound structure of human language. We now know much more about a whole range of specific phonological phenomena, including topics such as vowel harmony, the typology of word stress systems, and the structure of affricate sounds. We know more about how sound systems interact with morphological and syntactic systems, and about the importance of taking factors like variation and frequency into account in the study of phonology. Phonologists have not developed a theory which completely captures each of those phenomena (let alone one which captures every aspect of all of them in a uniform way). But at least we have a much better picture of some of the properties which a successful theory of phonology should have.

Alongside external and universal challenges, such as university administrators who do not see the importance of something as esoteric as the study of sound systems, we can identify at least two internal dangers which challenge our field.

The first is that many debates are abandoned at some point, and then forgotten, with the issues involved sometimes being rediscovered much later, without the earlier research necessarily being known to the new generation of researchers. The reasons for this are often perfectly understandable, and there is probably no way to avoid this state of affairs completely. After lengthy discussions in the literature on, say, the relationship between continuancy and place of articulation, apparently involving arguments for and against almost every logically possible view on the issue, the topic may seem to be intractable, and scholars may tire of it and move on to new topics of debate. Thus we may avoid unfruitful attempts to solve problems for which we just do not have the right tools at that particular moment.

However, these discussions will frequently have led to at least partial agreement on important properties of the phenomenon at hand, even if only that the phenomenon is extremely complicated: just positing, for instance, some feature-geometric structure in which continuancy and place of articulation are in an unambiguous universal relation to each other will encounter many problems that help us better understand the phenomenon, even if they do not lead to a generally accepted solution. However, by abandoning the debate on the topic, we run the risk of losing that knowledge. The danger is that new generations will have to rediscover the subtleties of the phenomenon when the topic is taken up again.

The second danger is over-specialization. Saussure was an all-round linguist, with a deep understanding of much of (Western) linguistics as it was known at the time. Today there are very few, if any, people who can make such a claim. Scholars with a thorough understanding of phonology may have some knowledge of neighboring disciplines such as morphology or phonetics, but usually not even of both of those. There are many more phonology talks given every year at specialized phonology conferences than there are phonology talks at general linguistics conferences. And even within the field itself there are fairly well-established dividing lines: an expert on intonation is unlikely to be completely up to date on the literature on coronals; somebody who studies the Iambic–Trochaic Law may skip the talks on sign language phonology in the local phonology workshop; somebody who works on stress may have little knowledge of segmental phonology. This means that crucial insights within one sub-discipline of phonology are becoming less and less accessible to phonologists working within other sub-disciplines.

The Blackwell Companion to Phonology does not have the ambition to offer solutions to these problems; indeed, they are probably unavoidable. Yet a tool such as this allows us to document at least some of the many insights into human language that phonologists have gathered in the past decades, and also to give an overview of what at present seem to be the major issues that those interested in sound structure are thinking and arguing about.

The *Companion* is in essence an encyclopedia of case studies. Each chapter addresses some topic which has been debated in one way or another in the history of our field. Authors were invited to concentrate primarily on the empirical arguments that have been put forward by the various sides in such debates. Because of this concentration on case studies, there are many topics we have ignored. For instance, there is a chapter on coronals, but not one on labials, simply because there has been much more discussion in the phonological literature on the internal structure and the behavior of coronal sounds than on their labial counterparts. Similarly, there is a chapter on palatalization, but not one on labialization, again because the former has been discussed broadly in the phonology literature while the latter has not.

Some chapters have turned out more like the case studies we originally had in mind than others. Inevitably, some chapters had to be organized differently, for instance those concentrating more on a specific theoretical device (such as constraint conjunction or rule ordering) than on some empirical phenomenon. However, even the authors of these chapters were asked to provide some discussion of the data which led scholars to develop such theoretical concepts in the first place.

We are, of course, conscious of the fact that the reader will find that many possible topics are missing from the *Companion*, including some hotly debated ones

– the 124 case studies included could easily have been doubled in number. There are various reasons for this, perhaps most importantly the need to keep an already substantial enterprise within reasonable bounds, so that many topics which had a good claim to be included had to be discarded. Sometimes, too, chapters have taken a rather different direction from that originally anticipated – in such cases the editors generally felt that including such chapters was preferable to imposing an over-rigid framework into which the authors would have to fit their material. It may, however, prove possible to add further topics to the online version of the *Companion* (www.companiontophonology.com), which will provide features not available in the print version, and which is anticipated to grow in the next few years.

In spite of this, a great deal of ground is covered in this first print edition. Phonology as a discipline is theoretically and methodologically in a period of great change, making it a very exciting time to be a phonologist. We find scholars constructing formal theories working alongside others who apply statistical methods adopted from the social and computational sciences, while those who prefer to test ideas with the use of experimental techniques may be working along-side those who collect their data in the field.

This diversity is reflected in the group of authors. Altogether, almost 150 phonologists have been involved in the production of this reference work – a significant sample of the population of phonologists. The insights of many major frameworks of the beginning of the twenty-first century, such as Articulatory Phonology, Evolutionary Phonology, Government Phonology, Laboratory Phonology, and Optimality Theory, are presented in various chapters, and in some cases compared explicitly. Where appropriate, authors were also invited to end their chapters by presenting their own views on the topic under discussion, and sometimes their own analyses of particular phenomena, and many have done so. As well as being a collection of case studies, then, the *Companion* can also be read as an overview of theoretical positions within phonology at the beginning of the twenty-first century.

As already noted, the *Companion to Phonology* comes in two different shapes. One is a traditional print edition. The other is an electronic edition, published online, and convenient for searching and downloading individual papers. The chapters in the print edition are organized thematically into five volumes of more or less equal size.

The first volume opens with a number of chapters on general phonological topics, for example markedness and learnability, which will be of wide general interest to those working in the field. The bulk of this volume is devoted to chapters on topics in segmental phonology, and includes studies of individual classes of sounds, such as the chapters on clicks and fricatives, as well as more general discussions on the organization and structure of speech sounds (for example the chapter on distinctive features).

The chapters in Volume II contain discussion of topics in suprasegmental phonology as well as prosody (which, at least on some views, amount to the same thing). The division between Volumes I and II – and indeed the organization of the volumes in general – has not always been straightforward, as there are so many intersecting parameters involved; the chapter on geminates has been included in the volume dealing with suprasegmental phonology, although, as noted in the chapter, consonantal length is considered by some to be a segmental property.

Volume III deals with phonological processes. Again, many of these chapters could have found a home in Volume I or II, as the processes considered in them typically involve segmental or suprasegmental phonology.

The chapters in Volume IV are concerned with interfaces with other branches of linguistics, for example morphosyntax or phonetics, and also with topics which some might consider to be at least partly extralinguistic (such as frequency or variability).

Volume V contains language-specific issues, concentrating in particular on the discussion of processes and phenomena in individual languages or language families which have played a major role in general phonological discussion and the development of theories and analyses with a wider scope than the particular phenomena dealt with here. Chapters have been included on topics such as vowel harmony in Hungarian and Turkish and flapping in English, but in this volume, in particular, there were many more potential topics than could in the end be included.

The division into volumes is thus to some extent arbitrary. However, we do not anticipate that readers will make use of the material in the *Companion* on a volume-by-volume basis, but rather as a complete reference work. To this end, every chapter contains a substantial number of cross-references to other chapters in the five volumes dealing with related topics.

We have been working on *The Blackwell Companion to Phonology* for roughly five years. During this period we have been heartened by the enthusiasm with which many of our colleagues have reacted to the plans for the project, both those who have contributed chapters and those who were not able to take part in the project for one reason or another. It appears that the phonological community at large believes that a reference work of this size will be valuable for progress in the field. We believe that the *Companion* shows how healthy and lively the field of phonology currently is. A great deal of knowledge has been accumulated, and many insights have been gained. Vast numbers of questions are still unanswered; the debate goes on.

That an enterprise of this magnitude has come to fruition in a comparatively short period of time is primarily due to the help of a great number of people, primarily, of course, the authors of the 124 chapters, nearly all of whom also acted as reviewers of other contributions to the *Companion*. We thank them all for their willingness to participate in the project, even when confronted with impossible deadlines for submitting chapters, writing reviews, and responding to editorial queries. We are very happy that April McMahon is one of those authors; it was April who, as prospective editor-in-chief, first developed the plans for this *Companion* in conjunction with the publishers, and set up the rest of the editorial team – unfortunately her many administrative obligations meant that she had to withdraw from editing the project at a fairly early stage.

We are extremely grateful to Tessa Obbens, who took on the task of editing and making uniform the large number of references (over 10,000) in the 124 chapters.

We also would like to thank Martin Everaert and Henk van Riemsdijk, who are general editors of the series of Blackwell Companions to Linguistics, of which *The Blackwell Companion to Phonology* is the second, and who also edited *The Blackwell Companion to Syntax*. We have benefited from their helpful comments.

We are grateful to everyone at Wiley-Blackwell for their support and patience, in particular the commissioning editor, Danielle Descoteaux, who took over the

project from her predecessor, Ada Brunstein, before the editorial team was complete, and has been an invaluable source of enthusiastic support ever since. Barbara Duke, production editor in Oxford, has managed to keep us on the straight and narrow even when we fell so far behind schedule that final deadlines threatened to be missed. The project managers, initially Louise Spencely and thereafter Janey Fisher, together with their large team of copyeditors and proofreaders, have been of invaluable help in preparing these volumes, and in guiding us through some of the more esoteric conventions of the publishing world. We thank them for their unfailing good humor and efficiency in the face of our persistent questions, and hope that they will be pleased with the final result.

Language is acquired and experienced primarily through the medium of speech or the manually signed signal. A primary goal of phonology, restricted here to the context of spoken language, is to discover the elements that serve as the building blocks of speech. Considering that languages differ in their spoken forms, two further questions for an understanding of phonology concern the relations between the sound elements that give shape to the phonological system of an individual language, and the constraints that determine how these sound elements may pattern in the formation of words and phrases in that language.

Over many centuries of scholarship and across continents, linguists have pursued answers to these questions for the practical purpose of providing a straightforward orthography for particular languages (see Pike 1947), explicating a method for describing the phonological component of individual languages, or for the scientific purpose of identifying the mental encoding of phonological form in the minds of the native speaker/hearer. Differences in the relative priority accorded to practical and scientific purposes have resulted in differences in the principles and methods of competing schools of phonology. But all approaches, from the work of the Sanskrit scholar Patanjali in the second century BCE to the theories that emerged during the heyday of European and American phonology in the twentieth century, presume that the basic elements of spoken language are at some level of abstraction from the physical form of speech as experienced by the speaker/hearer. The representation of words in terms of abstract elements is posited as a *basic* or *underlying representation* (UR) in nearly every phonological theory to the present day. Theories differ in the status of the UR (as an artifact of descriptive analysis, or part of the cognitive system of language), its relation to morphological form and phonetics, and whether it may encode morphosyntactic context, reflecting differences among theories in the kinds of data considered as primary evidence for phonological form. Different proposals for UR also reflect differences in the scope of the proposed theory, e.g. in modeling diachronic or synchronic phenomena, dialectal or style-dependent variation, corpus data, speaker intuitions, child productions, or instances of the intentional, creative manipulation of phonology in poetry or language games.

1 Underlying representations in phonemic theories

Phonological theories of the late nineteenth and early twentieth century take the *phoneme* as the basic element of phonological analysis (see CHAPTER 11: THE PHONEME). Jan Niecislaw Baudouin de Courtenay and his student Mikołaj Kruszewski of the Kazan school (established in the mid-1870s) introduced the phoneme as a mental construct encoding the "image" of a sound as it is perceived and recognized, and as the abstract units with which phonological alternations may be characterized (Baudouin de Courtenay 1871). The notion of the phoneme as an abstraction from the acoustic and articulatory manifestation of speech was also expressed in the contemporaneous work of Ferdinand de Saussure, published posthumously in 1916, and recognized as the origin of structuralist linguistic analysis. De Saussure's "sound images," corresponding to what other scholars would term "phonemes" (Anderson 1985: 38–40), were characterized in terms of the properties that distinguish between the abstract sound units. And while Baudouin de Courtenay's view evolved to assign psychological reality to the phoneme as a unit of representation, de Saussure did not share this attribution, emphasizing instead the importance of the rules that relate sound representations (Anderson 1985: 53, 68). Despite de Saussure's rejection of the phoneme as constituting a distinct level of representation – an underlying form – his work profoundly influenced a later generation of scholars who focused intensely on the question of phonemes as units of representation, notably in the work of Trubetzkoy (1939) and Jakobson (1949) of the Prague School and of American structuralist linguists such as Bloomfield (1933) and Harris (1944, 1960).

Both the Prague School and American structuralism adopted de Saussure's view of phonemes as being characterized in terms of a system of contrast (see CHAPTER 2: CONTRAST). The Prague School notion was that phonemes are elements that are related to one another in a system of oppositions that define lexical contrast. Similarly, Jones (1967: 10) defines the phoneme as "a family of sounds in a given language which are related in character and are used in such a way that no one member ever occurs in a word in the same phonetic context as any other member," and explains that what phonemes do "is to distinguish words from one another" (1967: 265). The American structuralists held a similar notion, and focused on the method for determining the phonemic representation of words based on observations of phonetic form.

In a first sense, any representation of the utterances of a language in terms of contrasting phonemes can be construed as providing an *underlying* representation of those utterances. Thus, the form **'fonim**, which we find in Kenyon and Knott's (1953) *Pronouncing dictionary of American English* for what is conventionally written *phoneme*, is to be taken as the representation that underlies the infinitely diverse actual and potential productions of this word by native speakers of American English. This UR is in terms of the contrasting segment-sized units of the language.

An important claim behind phonemic theories, by and large borne out by everyday experience, is that, given an adequate phonemic representation, a native speaker of the language will know how to pronounce a previously unknown word accurately, in all phonetic detail. That is, a native speaker of American English who encounters, say, the word *phoneme* for the first time in an English text will know how to pronounce it accurately upon consulting Kenyon and Knott's dictionary. Words containing the same sequence of phonemes cannot differ in any detail of their pronunciation. If they do, that would indicate that they have been incorrectly transcribed as having identical underlying phonemic representations. In the case of a language whose conventional orthography follows the phonemic principle to a greater extent than English, such as Spanish, it is not unusual for very small children to convincingly read the newspaper aloud even though a great percentage of the words that they are reading may be unknown to them (so that, in fact, they may not understand much of what they are reading).

A first hypothesis of the theory of phonemic transcription is thus that all utterances in a language can be analyzed as combinations of a small set of phonemes (consonants, vowels, and prosodic phonemes). Often there is an important additional hypothesis that there is a universal set of sounds among which each actual language chooses its set of contrasting phonemes. The International Phonetic Alphabet (IPA) represents an explicit proposal about the nature of this universal set. As stated in the *Handbook of the International Phonetic Association* (IPA 1999), "[t]he IPA is intended to be a set of symbols to represent all the possible sounds of the world's languages [. . .]. The sounds that are represented by the symbols are primarily those that serve to distinguish one word from another in a language" (IPA 1999: 159).

Everyday experience shows that, on the other hand, there is no universal phonetics. To give a trivial example, one of the authors of this chapter is a native speaker of American English and the other one is a native speaker of Spanish who learned English in adulthood. Both authors have a good understanding of what sounds the symbols of the IPA are intended to represent. Chances are that both authors' renditions of a given word in American English, say, **'fonim**, would be identified as the same sequence of phonemes, that is, as the word that is normally written *phoneme*. One of them, however, would be perceived as having been produced with a foreign accent (i.e. with non-native phonetics).

The implicit hypothesis of phonemic transcription, e.g. as reflected in Kenyon and Knott, is, then, that speakers' knowledge of the sounds of their language can be characterized as (a) knowledge of the phonemes and sequences of phonemes of their language (drawn form a larger potential set of contrastive sounds, as expressed in the IPA), and (b) knowledge of how to articulate those phonemes in the different phonological environments in which they can be found. Importantly, phonetic detail can be abstracted away from individual lexical entries. Given a UR consisting of a string of phonemes, a native speaker will know how to pronounce it in all contexts.

2 Indeterminacy in phonemic representations

Experience has shown that establishing the phonemic inventory of a language is for the most part a straightforward matter, but also that in any language there usually remain a few cases of unclear or ambiguous phonemicization (cf. for instance, Hualde 2004). Difficulties often arise in situations where the mapping between allophones and phonemes is not one-to-one (i.e. the *bi-uniqueness condition* of Harris 1944, 1951 breaks down). Some of the commonly attested types of problems for phonemicization are discussed in this section.

2.1 English flaps as "fuzzy" phonemes

Indeterminacy in phonemic analysis arises when a single surface segment can be analyzed as deriving from a sequence of two phonemes and when segmentation as one or two phonemes is unclear. There are well-known examples of this sort in English, such as the case of the rhotacized vowel that occurs in words like *bird* – is it an independent phoneme or a sequence of vowel followed by /r/? A similar question occurs for the velar nasal – is it an independent phoneme with defective distribution (banned from syllable-initial position) or the phoneme sequence /ng/? Another notorious problem for segmentation is posed by the tense, diphthongizing vowels, variously transcribed with one or two symbols by different authors. A distinct kind of problem for phonemicization concerns the treatment of schwa – should it be analyzed as an allophone of /ʌ/ (a phonetically similar vowel) that occurs in unstressed syllables? Or, in cases where there is a morphologically related word in which stress occurs on a different syllable (e.g. *'tel*[ə]*phone, te'l*[ɛ]*phony*), should the phonemicization of schwa depend on the value of the corresponding vowel in the related word? We will come back to this topic.

A different issue for phonemic analysis is that of the status of the flap [ɾ] in American English (see also CHAPTER 113: FLAPPING IN AMERICAN ENGLISH). Replacing [ɾ] with [tʰ] in *better, but again,* or *positive* does not result in a difference in lexical meaning, so by an analysis based on the test of lexical contrast, [ɾ] should be an allophone of /t/. But under Harris's (1951) criterion of the native speaker's judgment, the flap may qualify as a phoneme, since native speakers are aware that these are two different sounds (as reflected, for instance, in informal spellings such as *geddout of here, forgeddabouddit,* etc.).[1] The perceived difference may be associated with formality or personal choice (in *better, positive*), or with phrasing (in *but again*). If we consider the phoneme as a sound category, then the flap in American English appears to be an example of a "fuzzy" or quasi-phoneme that shares some but not all of the properties of more robust phonemes (see Janda 1999 and Hall 2009 for related discussion). This view treats phonemicization as being akin to other categorization phenomena (Taylor 2006), and may allow for more complexity in the relationships among linguistic sounds than that implied in any of the twentieth-century phonemic theories.

2.2 Neutralization

2.2.1 English obstruent sequences

As noted, phonemic theory invokes lexical contrast as a primary criterion for establishing the phonemic status of a sound relative to other sounds in the language. Problems for this approach arise when contrast relations between two or more sounds are not consistent throughout the language. For instance, in many languages, two or more sounds that contrast in some positions in a syllable or word fail to contrast in others. This phenomenon is known as the *neutralization* of contrast, and its resolution in phonemic analysis has led to increased abstraction in URs in several theories.

Consider the case of obstruent voicing in English. In English, coda sequences of obstruents always agree in voicing. Thus we observe obstruent voicing agreement

[1] Flapping causes neutralization of /t/ and /d/. Speakers also seem to be aware that the flap is different from /d/, although we don't have the same kind of evidence.

in words like *act* and *tasks*, while the corresponding disagreeing tautosyllabic sequences are unattested, */-kd/, */-zks/, etc. In a simple phonemic analysis (i.e. one that expresses only phonemes and allophones and a direct mapping between the two), the absence of clusters with disagreeing voicing results in a pattern of defective distribution of obstruents: only voiced obstruents occur adjacent to a tautosyllabic voiced obstruent, with a parallel restriction for voiceless obstruents. The defective distribution does not, in this simple phonemic analysis, have any implications for URs, nor is it explicitly treated in the phonemic analysis.

Prague School phonology, on the other hand, offers an explicit model of neutralization by positing an archiphoneme in the phonological representation (the UR) in contexts of neutralization. An archiphoneme is a unit that represents the common features of phonemes whose contrastive property is neutralized in specific contexts. The archiphoneme appears in only those contexts of neutralization, substituting as it were for any one of the specific phonemes it covers. In the English example under discussion here, in a sequence of obstruents in the syllable coda, archiphonemes unspecified for voicing (represented by capital letters) replace any occurrence of an obstruent phoneme after another obstruent. In English we would thus have representations such as *desks* /dɛsGZ/, *texts* /tɛkZDZ/, *adze*, *ads*, *adds* /ædZ/, etc., where the surface voice properties of the archiphoneme are predictable from the preceding context. The inclusion of archiphonemes renders URs somewhat more abstract than a simple phonemic representation, and anticipates future developments advocating abstractness of URs. But before leaving this example, notice that since the neutralization of obstruent voicing may affect consonants across morpheme boundaries in coda clusters, as in *texts*, *ads*, and *adds*, it leads to alternations in the shape of suffixes including the regular plural nominal suffix and the 3rd person verbal agreement, a topic to which we will return in §3.

2.2.2 *Japanese sibilants*

The treatment of neutralization in phonemic theory has further implications for the abstractness of URs, illustrated here in an example from Japanese. In Japanese [s] and [ʃ] appear to be in phonemic contrast in all contexts except before /i/, where only [ʃ] is found, and before /e/, where only /s/ is found, excluding recent borrowings. Thus Japanese presents another case of the defective distribution of phonemes due to the neutralization of contrast in specific contexts. In a Prague School analysis the archiphoneme /S/ would replace the two phonemes /s/ and /ʃ/ before a front vowel, where the contrast is neutralized.

There is another possible solution to phonemicization in cases of defective distribution such as the Japanese example, which does not involve archiphonemes. The solution allows the specification in UR of abstract phonemes that fail to map to surface allophones.[2] We refer to this here as the Abstract Phonemic analysis. For the Japanese case, an Abstract Phonemic analysis posits the phoneme /s/, relegating [ʃ] to the status of an allophone: /s/ maps onto the allophone [ʃ] in surface realization when it precedes phonemic /i/ and also before the glide /j/, a kind of "ghost" phoneme that serves to condition the palatal sibilant and is simultaneously absorbed into that consonant (see Table 1.1). In fact, there is a romanization of Japanese that assumes this second phonemicization, and this is essentially the representation that we also find in the native kana orthography.

[2] Goldsmith (2008) presents an insightful discussion of the historic precedent for this type of analysis in the work of Harris (1951).

Table 1.1 Phonemicization of Japanese surface allophones [s ʃ] in three phonemic analyses. Representations in parentheses are excluded from the set of possible URs

Surface allophones		*Simple phonemic*		*Prague School*		*Abstract phonemic*	
		phonemes: /s ʃ/		*phonemes:* /s ʃ/ *archiphoneme:* /S/		*phonemes:* /s/	
[sa]	[ʃa]	/sa/	/ʃa/	/sa/	/ʃa/	/sa/	/sja/
[se]	—	/se/	(*/ʃe/)	/Se/	(*/se ʃi/)	/se/	(*/sje/)
—	[ʃi]	(*/si/)	/ʃi/	/Si/	(*/si ʃi/)	/si/	(*/sji/)
[so]	[ʃo]	/so/	/ʃo/	/so/	/ʃo/	/so/	/sjo/
[sɯ]	[ʃɯ]	/sɯ/	/ʃɯ/	/sɯ/	/ʃɯ/	/sɯ/	/sjɯ/

2.3 *Basque palatal sonorants and the question of the "free ride"*

A similar situation arises in Basque. In some Basque dialects /l/ and /n/ historically became [ʎ] and [ɲ], respectively, when preceded by /i/, syllabic or non-syllabic, and followed by another vowel; e.g. [mutila] > [mutiʎa] 'the boy', [mina] > [miɲa] 'the pain'. When the trigger was a glide, it was absorbed: [sajna] > [saɲa] 'the vein'. Since, in the relevant varieties, /l/ and /n/ were not palatalized in the coda, this has resulted in numerous alternations in morpheme-final position: [mutil] 'boy', [mutiʎa] 'the boy'; [min] 'pain', [miɲa] 'the pain'; [sajl] 'difficult', [saʎa] 'the difficult one'; [sajn] 'vein', [saɲa] 'the vein' (in other dialects we find palatalization also in the coda). In a phonemic analysis with ordered rules, this mapping between phonemic and allophonic representation could be handled by the following ordered rules (glides are allophones of the high vowels and another rule would account for their distribution; see CHAPTER 15: GLIDES):[3]

(1) *Basque palatalization*

Palatalization: /l n/ → [ʎ ɲ] in contexts following /i j/ and preceding a vowel
Glide absorption: /j/ deletes in contexts preceding (intermediate) [ʎ ɲ]
e.g. /mina/ → [miɲa]
/saila/ → sajla → sajʎa → [saʎa]

Once we have these rules, we may let them apply also in the morpheme-internal context, where palatals do not participate in any alternations. Thus, [iʎe] 'hair', [oʎo] 'chicken', [iɲor] 'anybody', and [baɲatu] 'bathe' can be analyzed as /ile/, /oilo/, /inor/, and /bainatu/. The rules in (1) will successfully derive palatal sonorants from all positions except perhaps word-initially (where the context for the added rule of glide formation would not obtain); since word-initial palatal sonorants are found only in a very small number of words (mostly borrowings),

[3] Phonemic analyses with ordered rules mapping phonemes to surface allophonic representations are found in Bloomfield (1939), and, as highlighted in Goldsmith's recent work (2008), are again taken up by Wells (1949) in work that presages the major development in Generative Phonology a decade later.

this dynamic phonemic analysis may allow us to dispense with two phonemes, /ʎ ɲ/, from the underlying phoneme inventory for the language. The question for phonemic theory is whether this analysis should be allowed, where morpheme-internal palatal sonorants get a "free ride" on the analysis motivated for cross-morpheme contexts (Oñederra 1991). In this particular case, we have some evidence in favor of the abstract analysis that allows "free ride" derivations, in the form of some subsequent developments. In a couple of regional dialects palatal sonorants have undergone depalatalization, and this has affected both morpheme-final and morpheme-internal palatals. Indeed, palatals which did not have their historical origin in the palatalization process have also been depalatalized, generating a preceding glide when not following /i/: e.g. *teila* 'tile' < Romance *teʎa; *ladrilu* 'brick' < Spanish *ladrillo*; *dainu* 'damage' < Spanish *daño* (Zuazo 2010: 61-62). Although the explanation for this second sound change may be found in a hypercorrection process, it is consistent with the abstract URs of the "free ride" analysis.

2.4 *Summary*

The examples discussed above illustrate the challenge in determining the correct UR for a given word or phrase in a phonemic analysis. While there has been widespread support for the notion that the basic elements of phonology are units, such as phonemes, that are abstractions over detailed phonetic forms, there are still many questions remaining about the degree of abstraction that is appropriate in UR. A frequent problem arises when two sounds that contrast in some contexts do not contrast in other contexts, as in the Japanese example that we have considered. Further issues arise from the possibility of reducing the size of the phoneme inventory at the expense of greater abstractness in underlying phonemic representation, as in the case of Basque palatal sonorants, or the several problematic cases mentioned from English. Yet another challenge arises from cases where different criteria for phonemicization result in conflicting phonemicization, as in the case of the English flap as a fuzzy phoneme. Yet other challenges arise when the contrast between lexical items involves overlapping segments, and cannot be reduced to an analysis in terms of one-to-one correspondence between phones and phonemes (for further discussion see Lass 1984: ch. 2).

3 Underlying representations in morphophonemic theories

A different approach to phonemic analysis in cases of neutralization can be found in the work of American structuralist phonologists who tackle the problem of determining the underlying segments in cases of neutralization by taking into consideration the phonological form of inflectionally or derivationally related words. A classic demonstration of this approach is in the analysis of the underlying voicing of word-final plosives in German, based on their realization in inflected forms of the same paradigm. For instance, the final voiceless consonant of *Bund* [bʊnt] 'association' may be analyzed as the realization of an underlying voiced phoneme /d/, because the genitive *Bundes* [bʊndəs] appears with the voiced phoneme, as does the plural *Bunde* [bʊndə] (see CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). Similarly, American English *atom* [ærəm] may be represented as /ætam/ because the underlying nature of the neutralized segments is revealed in *atomic* [ətʰamɪk]. This view, which makes use of morphophonological considerations to determine underlying forms, was already present in the work of Baudouin de Courtenay (see Anderson 1985: 67–68), but is explicitly rejected by Jones (1967: 104–107) and other authors who maintain that phonemic representations of words should be established using purely phonological information.

In American structuralist approaches, a phonemic representation is based on observations of the distribution of sounds in phonetic form, and is distinguished from a separate morphophonological representation, where relations between words containing the same morpheme are considered. Thus, German *Bund* [bʊnt] would have the phonemic representation /bʊnt/ and the morphophonemic representation //bʊnd//. The admittance of a morphophonological level of representation raises the question of whether this representation should be considered as the underlying representation of words, and accorded status as psychologically real. A phonemic theory with no morphophonological level must resort to an explicit listing of the allomorphs as multiple URs for alternating morphemes, while in a theory with distinct levels of morphophonological and phonemic representations, allomorphs can be defined by the mapping between the two. The morphophonemic analysis is illustrated here with the English regular plural suffix. This morpheme can be said to possess three allomorphs in complementary distribution: /-z/, /-s/, and /-əz/. (In a Prague School analysis, it would have the allomorph /-Z/ after an obstruent, where there is no contrast between /s/ and /z/, as in *cats, dogs*, and the allomorph /-z/ after a sonorant, as in *boys, hens*, where it contrasts with /s/, cf. *voice, hence*). Since the distribution of the allomorphs is phonologically conditioned (see CHAPTER 99: PHONOLOGICALLY CONDITIONED ALLOMORPH SELECTION), and furthermore, essentially the same alternation is found with other suffixes such as the genitive and the regular past tense, one possibility is to choose a single underlying morphophonemic representation for each suffix, from which (phonemic and) surface forms could be derived by the application of general rules. The morphophonemic analysis is summarized in (2), in contrast to a phonemic analysis with a listing of allomorphs. Note that the analyses shown here are offered as concrete examples of the phonemic and morphophonemic approaches, and exist alongside other possible analyses of the specification of phonemic or morphophonemic form.

(2) *The English plural suffix in "simple" phonemic, Prague School phonemic, and morphophonemic analyses*

	"simple" phonemic	Prague School phonemic	morpho-phonemic
morphophonemic level:	—	—	//-z// (=UR) *hens, cats, dogs, kisses*
phonemic level:	/-z/ *hens, dogs* /-s/ *cats* /-az/ *kisses* (=UR)	/-z/ *hens* /-Z/ *cats, dogs* /-az/ *kisses* (=UR)	/-z/ *hens, dogs* /-s/ *cats* /-əz/ *kisses*

Relevant to our focus here on URs, the critical distinction between the phonemic and morphophonemic analyses illustrated in (2) is whether there is a unique representation specifying the phonological form of all surface realizations of the morpheme (the morphophonemic analysis), or whether each allomorph has an independent phonological representation (the phonemic analyses). The morphophonemic solution is also adopted in Generative Phonology, the theory that supplanted structuralism as the dominant school of American phonology, but with the important difference that the Generative Phonology model of grammar bypasses the "classical" phonemic level.

4 Underlying representations in Generative Phonology

In modern practice the term "underlying representation" (UR) has become associated with the underlying phonological representations of Chomsky and Halle's Generative Phonology, the major development in phonological theory following Bloomfield and his successors in American structuralism. As Chomsky and Halle (1968: 11) explain, their phonological representations are essentially equivalent to the morphophonemic representations of American structuralist phonology. They further make clear that they, however, prefer not to use the term *morphophonemic representation*, because this term seems to imply the existence of a different, *phonemic* level, which they do not believe to be necessary or useful as a level or representation.[4]

Chomsky and Halle's adoption of the morphophonemic level as input for the operation of phonological rules is mostly justified in terms of Chomsky's overall conception of grammar, where the phonology operates on the output of syntactic structures. Since the morphemes that compose a word may appear under different syntactic nodes, morphemes, not words, must be the units of lexical encoding. To use their example, the syntax provides sequences such as $[[sing]_V\ past]_V$ and $[[mend]\ past]_V$, which, after the operation of readjustment rules, become, respectively, the underlying phonological representations $[s^*ng]_V$ and $[[mend]_V\ d]_V$ (where * represents the addition to the feature specification of *i* of a new feature "indicating that it is subject to a later phonological rule which, among other things, happens to convert *i* to æ"; 1968: 11).

In Chomsky and Halle's framework the units in URs contain segments which are further decomposed into phonological distinctive features, including morphological and syntactic juncture features, and in some instances, such as the examples discussed above, specific diacritic features. URs are mapped onto surface forms through the application of phonological (transformational) rules. These rules apply in a linear order, and the output of a rule yields an *intermediate* form that is the input for subsequent rules, until the final ordered rule applies to yield the surface form.

[4] In denying the status of a distinct level of phonemic representation, Chomsky and Halle were essentially in agreement with Bloomfield (1933), as noted by Koerner (2003). Chomsky and Halle's rejection of structuralism, and phonemic analysis in particular, is directed at the taxonomic phonemic analysis of Twaddell, Bloch, and other post-Bloomfield structuralists (Odden 2005: ch. 3, supplement).

4.1 The criterion of maximizing grammatical generalization

The URs of Generative Phonology, like the phonemic representations of structuralist theories, abstract away from the detail of phonetic form. There is no explicit limit on the degree to which the UR diverges from the phonetic form, and the UR of a given morpheme is not constrained to be identical or even similar to the surface form of any of its allomorphs. For example, Kenstowicz and Kisseberth (1979: 204) propose an analysis of Russian vowel alternations in which the noun "head" is assigned the UR /golov/ 'head', with two full vowels. These vowels never occur simultaneously in the surface form of any word containing this root morpheme, but each occurs in stressed position in different words: ['goləvu] (ACC SG) and [gʌ'lof] (GEN PL).[5] The full vowels in the UR surface intact only in the presence of stress, which is assigned by morphophonological rules, and are otherwise transformed by rule into the reduced vowels [ə ʌ] in unstressed syllables.

URs specify lexically contrastive features (see CHAPTER 17: DISTINCTIVE FEATURES), and leave out any feature that is predictable from the phonological content (including juncture features), but the criterion of contrast is not the sole basis for determining URs in Generative Phonology. Another important criterion is maximizing grammatical generalization. The UR is the form that provides an optimal mapping to *all* the observed surface forms of the morpheme, maximizing the function of phonological rules in specifying predictable information, and in expressing regularities in the distribution of sounds in the language overall.

For example, consider the representation of nasal consonants in a language like Catalan (Herrick 2002; see also Bonet and Lloret 1998: 127–155; Wheeler 2005: 166–219). In certain phrasal contexts, the alveolar nasal /n/ assimilates in place of articulation to a following consonant, as in (3a). The rule of Nasal Assimilation (4), formulated using the notation of Chomsky and Halle (1968), operates on word-final /n/ to change the place of articulation feature in the appropriate contexts. There is a similar pattern of homorganicity in NC clusters that can be observed within words, shown in (3b), i.e. [n] is never found in heterorganic clusters morpheme-internally. These word-internal clusters do not participate in any morpho-phonological alternations involving nasal place of articulation, but allowing the rule of Nasal Assimilation to apply word-internally to /nC/ sequences offers the maximal generalization, permitting URs like /kanp-ɛt/ 'little field' to be mapped onto surface representations with homorganic NC clusters like [kamp-ɛt]. Under this account, the underlying structure /. . . np . . ./ may be posited even in the absence of any direct evidence for that structure from alternations in surface form, e.g. when the rule system operates to transform the underlying structure in every surface instance.

[5] This also applies to the vowels in the English example *atom, atomic*, mentioned in §3.

(3) *Catalan nasal assimilation with /n/*

a.	*son*	[n]	'they are'
	son amics	[n]	'they are friends'
	son pocs	[mp]	'they are few'
	son feliços	[ɱf]	'they are happy'
	son dos	[n̪d̪]	'there are two'
	son rics	[ɳr]	'they are rich'
	son germans	[nʲʒ]	'they are brothers'
	son lliures	[nʲʎ]	'they are free'
	son grans	[ŋg]	'they are big'
b.	*campet*	[mp]	'field (DIM)'
	tombet	[mb]	'walk, stroll (DIM)'
	puntet	[n̪t̪]	'point (DIM)'
	banquet	[ŋk]	'bank (DIM)'

(4) *Catalan nasal place assimilation*

$$\begin{bmatrix} \text{+nasal} \\ \text{+coronal} \\ \text{+anterior} \end{bmatrix} \rightarrow [\alpha\text{place}] \ / \ \_\_ \ \# \ [-\text{syllabic}, \alpha\text{place}]$$

4.2 *Underspecification in underlying representation*

An alternative analysis of the Catalan data that avoids positing /n/ as the UR in monomorphemic NC clusters is to allow the nasal consonant to be underspecified for place features in UR. Underspecification in UR was proposed by Kiparsky in an unpublished (1981) manuscript on vowel harmony, and further developed in Kiparsky (1982), Archangeli (1984), Steriade (1987), and Pulleyblank (1988), among others (see Steriade 1995 and CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION for an overview). The proposal is an elaboration of a basic tenet of Generative Phonology as put forth by Chomsky and Halle (1968), namely that URs are devoid of all predictable phonological information (which as noted above is also a core principle of phonemic representation in most phonemic theories). For Chomsky and Halle, segments are specified as bundles of distinctive features, and thus any non-contrastive feature, such as aspiration on voiceless plosives in American English, is omitted from UR. Taking this idea one step further, features that do not function to distinguish contrastive sounds may also be omitted from those contexts in UR, in what is termed *Contrastive Underspecification* (Steriade 1987). Notice that the solutions adopted for underlying representations in generative analysis with underspecification can be very similar or identical to Prague School representations incorporating archiphonemes. This will be the case when features are left underspecified only in contexts of neutralization and the features that are left unspecified are those that in other contexts serve to distinguish two or more segments, as in Catalan *campet* /kaNpɛt/ 'little field', *puntet* /puNtɛt/ 'little point'. A more extreme version of underspecification theory, termed *Radical Underspecification*, holds that for every binary distinctive feature, only one value (the *marked* value) is specified in UR, while the opposite value (the *unmarked* value) is filled in during the course of derivation by either context-sensitive or default phonological rules (Kiparsky 1985; Archangeli 1988).

Applied to Catalan, the principle of contrastive specification in UR means that the place of articulation feature will *not* be specified for nasals in NC clusters, where it is predictable from the following C even though in other contexts, where place features cannot be predicted, they are obligatorily included in UR. This analysis would be identical to a Prague School analysis. In Radical Underspecification analysis, on the other hand, one of the nasals may be left unspecified for place even in contexts where place distinctions are not neutralized, such as word-finally before pause or a vowel. Thus, *són* 'they are' would be represented as /soN/ in Radical Underspecification models even though in this context there is a contrast with the bilabial nasal of *som* /som/ 'we are'. An advantage of the Radical Underspecification approach, in which /n/ is systematically unspecified for place, as /N/, is that its representation accounts for why it is only /n/ that undergoes (major) place assimilation. Nasals with marked place features can occur in heterorganic clusters, e.g. *som dos* 'we are two', *a*[ɲ] *feliç* 'happy year'.

Needless to say, the adoption of underspecification of any sort renders URs more abstract. At the extreme, a segment may lack all distinctive feature content, being defined in UR with no more than a bare syllable position. For example, featureless vowels have been proposed by Choi (1995) for the analysis of Marshallese, and for the analysis of schwa (e.g. Anderson 1982; see also CHAPTER 26: SCHWA).[6]

With this development of underspecification in Generative Phonology in the 1980s, we have reached a zenith with respect to phonological theories with abstract and minimally specified URs. In §7 and §8 we return to consider subsequent developments in phonological theory, which pull URs in the opposite direction, away from abstractness and toward full specification.

4.3 *URs and novel word formation*

Some evidence in support of a theory that posits URs as a means to maximize grammatical generalization comes from observations about novel word formation (Kenstowicz and Kisseberth 1979: 26ff.). Consider for example the analysis of the English plural in terms of URs (as in (2) above). By positing the underlying form of the plural suffix as /-z/, with phonological rules mapping this UR to its surface reflexes in [-z], [-s], and [-əz], we have a ready account of the behavior of native speakers in forming novel plural words. As shown by Berko (1958), even young children show a preference for novel plurals that conform to familiar lexical patterns (e.g. the plural of *wug* is given with [-z]), which is consistent with the application of a general phonological rule to a common UR for the plural suffix.

The productivity of phonological patterns to novel words may be handled in a theory without URs by explicitly listing each allomorph in the lexicon along with its conditioning environment. Mechanisms of analogical extension can then select the correct allomorph for a novel word form based on its similarity to an existing word form. But, as discussed by Kenstowicz and Kisseberth (1979: 29ff.), the lexical listing alternative is not available for productive phonological rules that

[6] The featureless vowel lacks phonological place features, acquiring place specification only in phonetic implementation. Manner features are typically non-contrastive for vowels, and the major class features that distinguish vowels from consonants can be predicted on the basis of a minimal syllable structure that encodes the vowel as a syllable nucleus. Alternatively, syllable structure itself can be omitted from UR if the vowel is specified for the major class features [−consonantal, +syllabic].

are conditioned by phrasal context, as in the case of Chimwiini vowel length. More recently, Albright and Hayes (2003) present experimental evidence against an account of novel word formation that draws only on analogical extension of existing lexical patterns, based on data from novel word formation in English. They propose that English speakers' ratings of novel past tense forms reflect the operation of rules learned by induction over lexical patterns, but only if rules are constrained to encode phonological structural similarities between lexical items. However, we note that although Albright and Hayes argue for phonological rules as the mechanism for expressing phonological patterns over word forms, their analysis does not require abstract URs and does not give absolute priority to maximizing phonological generalization. Rather, they advocate a model of grammar that allows multiple rules governing morphophonological alternations that are formulated at varying degrees of specificity, reflecting "islands" of morphophonological regularity in the lexicon.

5 Indeterminacy in morphophonemic representations

In a framework with morphophonemic URs, including Generative Phonology in addition to some earlier American structuralist approaches, the problem of determining the most appropriate or optimal UR is even greater than in a simple phonemic theory that lacks a morphophonemic representation. Some issues that arise relate to: (a) the choice of UR when a morpheme has different allomorphs, (b) constraints regarding how abstract URs may be, and (c) determining which words are related.

5.1 *Indeterminacy in UR selection*

When we have distinct allomorphs of a morpheme, the choice of UR is sometimes less than obvious. Even in the relatively simple case of allomorphy in the English plural and other inflectional suffixes, there is a surprising variety of possible analyses, many of which have been explicitly proposed (see Zwicky 1975; Kenstowicz and Kisseberth 1979: 181; CHAPTER 99: PHONOLOGICALLY CONDITIONED ALLOMORPH SELECTION). For instance, different generative phonologists have proposed analyses where the UR of the plural suffix in English is /-z/, /s/, or /-ɪz/. In Spanish, the plural is generally formed adding /-s/ to stems ending in a vowel, as in *casa*, *casas* 'house, houses', and adding /-es/ to stems ending in a consonant, as in *amor*, *amores* 'love, loves'. Whereas generative phonologists appear to agree in taking /-s/ as the UR of the suffix, there has been much debate on the relative merits of an epenthesis analysis, where *amores* would be derived from /amor+s/ by a rule of vowel insertion (Saltarelli 1970), and a deletion analysis, where all consonant-final stems are provided with a final vowel in their UR, which is deleted in word-final position by rule (Foley 1967; Harris 1969), so that *amor* is /amore/ and *amores* is /amore+s/. In principle, nothing would rule out a third analysis where the UR of the plural suffix is /-es/, with deletion of the suffix-initial vowel in *casas* /kasa+es/.

There are few explicitly stated principles governing the analysis of URs. Deciding on a UR can require careful phonological argumentation, taking many kinds of facts into account and, as we see, different phonologists may come up with different solutions. It remains unclear what principles of Universal Grammar guide the language learner to a unique correct analysis in indeterminate cases such as these. Note that the issue of choosing the correct UR is especially acute in Generative Phonology, where, barring suppletion, all allomorphs of a given morpheme *must* derive from a unique underlying phonological representation. A theory that does not treat morphophonemic URs as mental constructs has the option of handling alternations of this type simply by lexical listing of each alternant.

5.2 *Abstractness in underlying representations*

The problems in the selection of UR are complicated by the possibility of having indeterminately abstract URs. URs assume a certain degree of abstraction just for adopting phonemic (i.e. phonetically underspecified) representations. When we identify a phoneme /t/ in English which is realized as aspirated [tʰ], unaspirated [t], glottalized [tˀ], flap [ɾ], or glottal stop [ʔ] in different contexts or instances, we are proposing an invariant abstract phonological unit underlying quite different phonetic realizations. But the issue of abstractness and its limits are even more vivid in Generative Phonology precisely because this theory takes the strong position that the relevant units of lexical encoding are morphemes. Since morphemes may appear in quite different shapes in different words, the URs of Generative Phonology can be considerably more abstract than the phonemic representations of words. Again using Chomsky and Halle's example for this point, the underlying representation of *telegraph* must be one from which the surface phonetic representation of *telegraph, telegraphic,* and *telegraphy* can be derived. They thus choose +tele+græf+. Elsewhere in the same work, they propose URs that differ quite radically from the surface form of words. Some of the early generative work by other authors also includes very abstract representations. We will consider a couple of examples below, in connection with the issue of word-relatedness.

5.2.1 *Constraining abstractness: The Alternation Condition*

A reaction to the abstractness of URs in Generative Phonology is found in the work of Kiparsky (1968), whose Alternation Condition is nevertheless too restrictive for some scholars (e.g. Kenstowicz and Kisseberth 1979; Kenstowicz 1994; Odden 2005). Hooper's (1976) True Generalization Condition amounts to a wholesale rejection of the theory behind morphophonemic URs, since the condition essentially limits the scope of phonological rules to phonotactics. Whereas in more recent times there has been a tendency to disfavor very abstract morphophonological URs, the fact is that the issue has not been explicitly resolved so much as sidestepped in contemporary work in Generative Phonology.

Because of its historiographic importance, we will briefly review Kiparsky's (1968) proposal here. In formulating the Alternation Condition, Kiparsky's focus is on analyses within the framework of Generative Phonology that posit underlying forms that contain elements that never surface as such, but which serve to condition the application of a phonological rule whose output could not otherwise be predicted on the basis of the surface forms that actually do appear. The Alternation Condition prohibits analyses in which all phonological derivations of an underlying form (a morpheme) result in the neutralization of a contrastive element, termed an "absolute" neutralization. The offending analyses posit different underlying representations for what appears in surface form as the same segment, in order to account for differences in phonological behavior conditioned by that segment, in different words. Generally these are cases where two historically distinct phonemes have merged. We will briefly consider one of the examples treated by Kiparsky.

A synchronic statement about Sanskrit is that velars palatalize before /i/ and before some, but not all, instances of /a/. The historical explanation for this state of affairs is that palatalization took place before the front vowels /i e/, but subsequently in the diachronic development of the language, all non-high /e a o/ vowels merged in /a/ (Hock 1991: 149; see also CHAPTER 71: PALATALIZATION).

(5) *Sanskrit velar palatalization*

*gegome	>	/ʤagaːma/	'went'
*giwo	>	/ʤiːva/	'alive'
*penke	>	/paɲʧa/	'five'

A possible synchronic analysis in a Generative Phonology approach would postulate underlying /e/ as distinct from /a/ and formulate the rule as palatalization of /k g/ before front vowels. This would be followed by another rule converting all instances of /e/ into /a/: /ke/ → /ʧe/ → [ʧa]. This derivation involves absolute neutralization, since underlying /e/ never surfaces as such in the morphemes that condition palatalization. In every instance it is neutralized with /a/ after the application of the palatalization rule. The /e/ vowel is posited in the underlying representations only to make the palatalization rule appear to be regular. This exemplifies the diacritic use of phonological content that Kiparsky's Alternation Condition is intended to disallow.

As mentioned, some generative phonologists argued that Kiparsky's constraint is too restrictive. For instance, Kenstowicz (1994: 113), following Chomsky and Halle (1968), claims that the alternation between [aj] and [ɪ] in words like *divine* and *divinity* derives from a common source in "underlying long [iː]." He points out that the putative underlying vowel does not surface as such in any surface realization of the root morpheme. Rather, the underlying vowel /iː/ is either diphthongized as in *divine* or undergoes shortening as in *divinity*. Kenstowicz reasons that the merits of the phonological analysis of Vowel Shift in these examples (and extending to certain other alternations between long and short vowels) favor rejecting the Alternation Condition. For Kenstowicz, the critical criterion for judging the validity of an abstract UR is whether positing such a form results in a simpler grammar (i.e. one with fewer and less complex rules), and achieves broader generalization in characterizing the sound patterns across the lexicon. These criteria require an evaluation method for measuring complexity and generalization, which is in itself problematic, but do not require any constraints on abstractness in UR per se, or methods for measuring the degree of abstractness in UR.

5.2.2 *Abstract URs and opacity*

A sound pattern that arises due to a phonotactic constraint or through morphophonological alternation is said to be *opaque* if its conditioning environment is not present in surface form, but can be identified in a UR. Kenstowicz and Kisseberth (1979) show that certain opaque patterns can be successfully and succinctly characterized in Generative Phonological analyses that involve abstract URs set up to contain appropriate triggering conditions for the opaque sound pattern, only to have the triggering elements subsequently modified or eliminated by rules that apply later in the derivation. An example is the analysis of Palestinian Arabic word stress (Kenstowicz and Kisseberth 1979: 229–231; see also CHAPTER 124: WORD STRESS IN ARABIC), which is described by the following rule:

(6) *Stress in Palestinian Arabic*

a. Stress the final syllable if it contains a long vowel or ends in a consonant cluster: [ka'maːn] 'also', [dara'stiː] 'you (FEM) studied it', [da'rast] 'I studied'; or else:
b. Stress the penultimate if heavy: [da'rasti] 'you (FEM) studied', [ba'tˤaːtˤa] 'potato'; or else:
c. Stress the antepenult: [da'rasatu] 'he studied it'.

There are two sets of surface exceptions to the pattern defined by these rules. In one group of words stress is antepenultimate even though the penultimate is heavy. A second group of exceptions have final stress even though the last syllable does not have a long vowel and does not end in a consonant cluster:

(7) *Surface exceptions to the stress rules*

a.	['btudursi]	'you (FEM) study'
	['simismu]	'his sesame seeds'
	['zuʔurtu]	'his bees'
b.	[bji'trin]	'string (3MASC)'
	[bji'trudʒ]	'shake (3MASC)'
	[bji'tam]	'persist (3MASC)'

Kenstowicz and Kisserberth argue that all these exceptions can be explained if the stress rules take morphophonemic URs into account. The set of words in (7a) have roots whose segments appear in a different order in contexts when they are not followed by a vowel-initial suffix; e.g. ['btudrus] 'you (MASC) study'. The stress assignment in these words would be regular if stress were assigned to the URs before a systematic rule of metathesis: /b-tudrus-i/ stress assignment → /'btudrusi/ metathesis → /'btudursi/. As for the examples in (7b), other forms in the paradigms of these words show that the UR of the stem ends in a geminate, e.g. [bi'trinni] 'ring (2SG FEM)'. The surface forms in (7b) would be derived by a totally general rule that simplifies geminates at the end of a word, applying after stress assignment.

In a theory that eschewed abstract URs in favor of representations that are transparent to surface phonetic form, the facts in (7) would be treated as true exceptions to the otherwise systematic, syllable-dependent distribution of stress in Palestinian Arabic. The possibility of the systematic analysis of opaque systems, as above, makes a compelling case for allowing URs to contain elements that don't survive in surface forms. But the question arises whether the problem justifies the solution. Are opaque sound patterns sufficiently robust and productive to warrant an analysis in terms of regular grammatical rules or constraints? Or do speakers of the language treat such patterns as localized exceptions, in which case an analysis in terms of lexical exceptions to a regular pattern would be more appropriate? Productivity may be implemented as analogical patterns without the need for abstract, morphophonemic URs (see Cole and Hualde 1998 for discussion).

5.3 *Indeterminacy in word relatedness*

In order to provide consistent underlying representations at the morpheme level, a phonologist (and a language learner) should be able to determine in some principled way which words contain the same morpheme. It should be obvious, however, that, except for inflectional paradigms – and even there we may have suppletion – deciding which sets of words are related in terms of underlying phonological representations becomes very much a subjective decision of the analyst in many cases. Phonological theory has yet to offer a principled way to decide these issues.

Two examples suffice to illustrate the problem in determining morphophonological relatedness. As an example of early work in the Generative Phonology framework, Harris (1969: 169) considers that the Spanish noun *eje* /'exe/ 'axle, axis' and the adjective *axial* /ak'sial/ 'axial' are related – as they surely are from a historical point of view – and proposes an underlying form /akse/ for ['exe]. Similarly, he analyzes *leche* ['letʃe] 'milk' as /'lakte/ to capture its relationship with the adjective *láctico* 'lactic'. More than a decade later, Lightner (1983: 205), after arguing that the root of English *long* and *length* should be given a single UR in synchronic analysis, suggests that, since the adjective *dolichocephalic* 'long-headed' is surely also related to these other words, a better UR for the root morpheme may be /dl-/, followed by a suffix in /dl-nkʰ/ *long*. An exceptionless phonological rule of English would simplify the initial group /dl/. The problem for this method lies in deciding how much derivation is appropriate in a synchronic grammar – are there any practical limits that constrain the language learner in establishing a shared component of UR for a pair of words? Adding the possibility of diacritic features and abstract URs only further broadens the range of possible analysis. We are faced with many plausible or possible analyses, and few if any criteria for deciding which one is correct. Much seems to depend on which sets of words the analyst is willing to consider as containing the same morpheme. Odden (2005: 273) explicitly addresses this concern, concluding that "[t]he question of how to judge formal word-relatedness remains controversial to this day, and with it, many issues pertaining to phonological abstractness."

An independent but related problem, given claims of psychological realism, is that the theory must allow for constant updating of underlying representations as new words are learned. Chomsky and Halle (1968: 233) propose that in order to account for both the lack of vowel laxing and the presence of the affricate [tʃ] instead of [ʃ] in *righteous* (from *right*), the UR of the root should be /rixt/. That is, the UR of *right* is altered after the learner encounters the word *righteous*. Likewise, the Spanish-speaking child may need to wait until her school years, when she may learn the word *láctico*, to determine the ultimate underlying representation of the word *leche* 'milk' and may have to wait until late adulthood to learn the word *axial*, which would trigger a change in UR from /exe/ to /akse/ for the word *eje* 'axle' that she learned in childhood (see also Janda 2003: 419). In the analytic framework of Generative Phonology, the consequences of even small changes in the UR of established words could have very large ramifications for the grammar as a whole, with ripple effects possibly extending throughout the rule system. We are not aware of any work that explores this prediction, testing for effects of large-scale grammatical restructuring in late stages of language acquisition or in adulthood.

On the positive side, morphophonological URs can be a useful mechanism for capturing speakers' intuitions regarding word-relatedness. For instance, speakers may have the intuition that two words that are phonetically identical (homophones) are different if they show different behavior under suffixation. This knowledge can be represented in morphophonological URs.

5.4 *Summary*

In this section we have seen that the validity of a phonological theory that posits morphophonological forms as URs depends on a successful and constrained method for determining URs, and that such a process will necessarily involve the determination of word relatedness. Indeterminacy about the level of abstractness in URs, together with indeterminacy in establishing which words are related through a common morpheme in UR, can render the analysis opaque, which leaves us to wonder how the phonologist can arrive at the correct analysis, or beyond that, how language learners converge on a common, correct analysis of the URs of their target language. Despite serious efforts to resolve some of these issues in the years since the publication of Chomsky and Halle's seminal work (1968), notably in Kiparsky's (1968) work on constraining abstractness, and his later work on Lexical Phonology (1985), the problem of the indeterminacy of URs remains largely unresolved today.

6 Underlying representations in Optimality Theory

In Generative Phonology, as proposed by Chomsky and Halle (1968), the phonological rules that map URs to surface forms in successive steps are "input-oriented"; they apply only if the necessary conditioning environments are present in the representation that is the input to the rule (i.e. the underlying or intermediate form), and are not sensitive to properties of the output form. Optimality Theory (Prince and Smolensky 1993) is a development from Generative Phonology in which input-oriented rules are eliminated in favor of constraints on surface form. Optimality Theory maintains the morphophonological URs of Generative Phonology, but in place of a stepwise derivation that maps URs onto surface forms through the application of ordered rules, Optimality Theory invokes static constraints that evaluate surface forms for their adherence to phonotactic constraints and for the "faithful" correspondence between the UR and a candidate surface realization of that form.

A principle of Optimality Theory is the claim that URs are entirely unconstrained ("Richness of the Base"): any structure that can be defined through the legal combination of phonological elements is a potential UR in any language. Like its predecessors in Generative Phonology, Optimality Theory maintains the claim of a unique UR for each morpheme, and many analyses employ the same kinds of morphophonological URs as in rule-based Generative Phonology. Optimality Theory inherits many of the concerns discussed above related to abstractness of representations and indeterminacy in identifying morphological relatedness. To constrain the process of selecting a UR from the vast set of possible forms allowed under Richness of the Base, Optimality Theory introduces a principle of Lexicon Optimization, which aids in the specification of a UR by forcing the selection of the underlying representation that gives the most harmonic mapping between UR and surface form, which is calculated by comparing the number of constraint violations for equally ranked constraints (see McCarthy 2002: 23, 77).

The architecture of Optimality Theory, with constraints that evaluate the identity between two phonological representations, allows for the possibility of eliminating URs altogether, in a purely surface-oriented grammar, as noted by authors such as Burzio (1996). Making no reference to URs, surface phonological patterns can be modeled through constraints that evaluate the identity between distinct surface forms of words under specific morphological conditions (e.g. when two surface forms share the same morpheme, or in the presence of a reduplicating morpheme).

The emphasis on surface constraints as the source of explanation in Optimality Theory has also led to analyses with URs that are phonetically specified, and to the formulation of constraints that refer to non-contrastive phonetic detail. The "surface-oriented" approach of Optimality Theory has invited a greater focus on the phonetic factors that shape phonological systems (as illustrated by many of the papers in Hayes *et al.* 2004), a trend that extends also to Exemplar Phonology and Articulatory Phonology, to which we now turn.

7 Phonetic detail in lexical representations: Exemplar Phonology

The preceding sections document the long history of the notion that the building blocks of speech, i.e. the basic elements of phonological form, are abstractions over detailed phonetic form, but in the period of scholarship that predates Generative Phonology there was substantial disagreement between scholars about the psychological reality of abstract (phonemic or morphophonemic) representations. Thus, while Baudouin de Courtenay and Kruszewski of the Kazan School emphasized the status of phonemes as mental entities, Bloomfield asserted a behaviorist view of the independence of linguistic analysis from any psychological assumptions about the status of linguistic constructs, a position that goes back to Saussure, and was shared by Twaddell (1935), among others (see Anderson 1985 for further discussion of mentalism in the works of these and other phonologists).

The strongest claim for the psychological reality of phonological representations is made in Generative Phonology, where abstract morphophonemic representations are the basis of lexical encoding. URs, which are composed of discrete distinctive feature specifications and, as we have seen, are often highly abstract relative to phonetic form, comprise the representations of spoken language that are stored in long-term memory, and thus they are the units that serve the physical processes of speech production and perception.

This view, which went largely unchallenged for several decades after the seminal papers in Generative Phonology (including Halle 1959 and Chomsky and Halle 1968), has been revisited in recent years. A rapid expansion of research using methods from experimental and computational sciences and corpus linguistics provides converging evidence that phonetic detail is part of the information that is stored in the long-term memory of words, influencing processes of speech production and perception, and ultimately shaping patterns of sound change (Pierrehumbert 2002). Evidence that phonetic detail influences lexical representation is offered by Bybee (2000, 2001), based on her findings that the incidence of lenition or deletion of word-final /t d/ in English is related to the frequency of occurrence of individual words in everyday language use. High-frequency words are more likely to exhibit lenition or deletion than low-frequency words (see also Bell *et al.* 2003). Bybee argues that small changes in the phonetic realization of a phoneme, however they may be conditioned, are reflected in the phonetically detailed lexical representation, which may be construed as a cluster of exemplars or a specification of the distribution of continuous-valued features in phonetic space. High-frequency words are more frequently "updated"; any contextually driven lenition affecting the most frequent forms will yield an incremental process of phonetic reduction which, over time, and in the appropriate sociolinguistic context, can result in sound change. Even phonetic detail that is not related to linguistic form, such as the phonetic detail that distinguishes one speaker's voice from another, can influence the long-term memory representation of a specific word spoken by that speaker, as shown in work by Goldinger, Pisoni, and their collaborators, among others (e.g. Palmeri *et al.* 1998; Goldinger 2000).

These are only some examples from a growing variety of studies that raise questions about the traditional division between phonetics and phonology (Pierrehumbert *et al.* 2000; see also CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY and CHAPTER 90: FREQUENCY EFFECTS). The findings are at odds with the assumption that phonetic detail is removed from phonological representation, and are incompatible with theories in which phonetic detail plays no role in phonological representation or in the functioning of rules and constraints of phonological grammar.

The presence of phonetic effects on phonology can be better modeled in exemplar theory, originating in psychological theories of categorization. Whereas in other approaches to phonology, and Generative Phonology in particular, the phonetic detail that arises in speech production derives from an abstract lexical representation, in Exemplar Phonology it is the abstract elements that are formed on the basis of statistical patterning of phonetic detail as experienced by the speaker/hearer (e.g. Pierrehumbert 2001; Johnson 2007; Cole 2009). It follows then that higher-level phonological structures (features, phonemes, syllables, etc.) may differ from word to word, and from speaker to hearer. In Exemplar Phonology there is no single, discrete UR that identifies the sound representation for each word in the language; rather, the mental encoding (i.e. lexical form) consists of a patchwork representation that links together information at different levels of granularity, from abstract category-level information (e.g. specifying the syllable structure of a word) to fine detail (e.g. specifying the range of VOT values of a plosive occurring in the word). And even though exemplar models do not explicitly recognize distinct levels of representation, relationships between words that share morphemes (e.g. *telegraph, telegraphy*) can be modeled in Exemplar Phonology without recourse to an explicit, abstract morphophonological form.

The status of abstract elements in phonological representation is still very much a matter of debate in phonology, as researchers continue to investigate the evidence for the role of phonetic detail in shaping phonological systems and influencing speech behavior on one hand, and the evidence for the priority of abstract phonological structures on the other.

8 A non-segment-based theory of UR: Articulatory Phonology

Many theories of phonology refer to phonetic properties as the basis of phonemic (or lexical) contrasts between sounds. Jakobson's distinctive features (Jakobson *et al.* 1952) incorporated both acoustic and articulatory features, while subsequent work in Generative Phonology emphasized the articulatory basis of phonological features, assigning features to hierarchically grouped classes (Clements and Hume 1995). But despite the phonetic attributes associated with phonological features, they are not equated with the actual articulatory or acoustic parameters that specify phonetic form.

As one of the first among contemporary works that integrate phonetic and phonological analysis, Browman and Goldstein (1986) introduced a model of phonology in which the atoms of phonological encoding are articulatory gestures (see also CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS). In their theory of Articulatory Phonology, gestures are the low-dimensional features that encode the dynamic actions of the speech articulators in the lexical form of words. Gestures represent the actions of the lips, tongue, and jaw in the formation of constrictions along the length of the vocal tract, and are coordinated in "ensembles." Segments have no direct representation in this model, but may be emergent from stable and recurring gesture ensembles.

The mapping from abstract gestures to their implementation in physical actions of the articulators is achieved with a mathematically explicit mechanical model rather than a formal symbolic grammar. Articulatory gestures differ from the segments and distinctive features of earlier theories in that they have inherent temporal and size dimensions. The phonological and phonetic content of words is represented using a set of gestures whose relative timing is coordinated in a limited number of patterns (e.g. in-phase or anti-phase) (Goldstein *et al.* 2006). These timing patterns result in sequences of gestures that may overlap in time and reduce in magnitude. Familiar phonological phenomena such as assimilation and lenition are some of the phonological effects that are modeled through patterns of gesture overlap and reduction in this approach.

Articulatory Phonology, like Exemplar Phonology, does not recognize explicit, distinct levels of phonological representation, and does not attempt to model morphophonemic alternation beyond cases that have a transparent basis in articulation, such as assimilation to an adjacent speech gesture. At the same time, Articulatory Phonology is distinguished from Exemplar Phonology in its strong claim that phonological encoding is articulatory and not acoustic, and by the characterization of phonological form as a distinct and singular representation, not a cluster of individual instances of spoken words.

9 Conclusion

A recurrent theme throughout the history of phonological theory is that in each language there is a representation of the spoken form of a word that specifies the essential contrastive elements that distinguish that word in its spoken form from all other non-homophonous words in the language. In the preceding pages we have traced the development of this notion through the European and American theories of phonology over approximately the last century, where we observe an historical progression toward representations that are increasingly abstract relative to the physically experienced spoken word. Not all theories attribute psychological reality to these abstract phonological forms, but since the introduction of Generative Phonology in the 1960s, the focus of phonological theory has been precisely on the matter of representations and grammar as components of the uniquely human cognitive system.

The trend toward increasingly abstract representations has reversed in much of the work in phonology since around 1990, and continuing to the present day. In theories as divergent as Optimality Theory, Exemplar Theory, and Articulatory Phonology, there is an increasing acceptance of the notion that phonetic detail of the sort typically relegated to a phonetic component plays a role in defining the properties of individual phonological systems, and, by extension, partly determines properties of phonological typology across languages. Contemporary theories differ in whether phonetic factors play a role in synchronic grammar, e.g. in some work in Optimality Theory, or only in diachrony as the basis for sound change, as claimed in Evolutionary Phonology (Blevins 2004; see also Hale and Reiss 2000). But both views require a theory where phonetic detail is available to phonological generalization, and a rejection of the strict separation of phonetic and phonological levels.

We observe two factors that have driven the move to abstraction in URs. First is the problem of determining the identity of the phonological units (phonemes) in contexts of neutralization, where there is not a one-to-one mapping between phonetic and phonological units. This concern marked the development of the Prague School phonemic theory with archiphonemes, and was also seen as one motivation for the distinction between morphophonemic and phonemic levels in American structuralist theory. A concern for the mapping between phonetic and phonological form is a factor in contemporary theories, and is a primary motivation for the adoption in Articulatory Phonology of gestural features, which are abstractions over the phonetic variability of different instances of the same word.

A second factor behind the adoption of abstract URs was the treatment of morphological alternations, and the perceived need to provide a common phonological representation for (non-suppletive) allomorphs of the same morpheme. To unify the phonological representation of systematically related allomorphs, structuralist theories and Generative Phonology alike rely on abstract morphophonological representations (though as noted earlier, the current focus in Generative Phonology has shifted away from questions of morphophonological representation and toward the question of the link between phonetics and phonology). The adoption of abstract morphophonological URs in Generative Phonology is necessitated by the adherence to a principle of compactness of phonological grammars. The overriding goal of phonological analysis in classical, rule-based Generative Phonology is to arrive at a set of URs and a set of grammatical rules that maximally express generalizations about phonotactics and alternations. The optimal analysis will be compact, with fewer URs and fewer rules, which are specified with minimum phonological structure, necessitating abstract URs.

Theories that lack morphophonological representations must resort to specifying a distinct phonological form for each allomorph of any given morpheme. This is the case for simple phonemic theory (without a morphophonological level), and also for some contemporary theories. For instance, in Articulatory Phonology the phonological representation specifies gestures, which are directly mapped onto articulatory actions. Any two words that comprise different gestures must have different phonological representations, including many instances of morphologically related words that contain different allomorphs of the same morpheme, e.g. *cats* and *dogs* in English, which contain different allomorphs of the plural suffix. Articulatory Phonology does not address how in the general case the phonological relationship between allomorphs should be modeled in the mind of the speaker/hearer.

A solution to the problem of how to model the phonological relatedness of morphologically related words while allowing phonetically detailed mental representations is offered in Exemplar Theory. Beckman and Pierrehumbert (2003) argue that words are related to other words through two different kinds of connections: those based on shared meaning (e.g. due to shared morphological content) and those based on shared sound structure (due to shared phonological or phonetic content). The two sets of connections don't have to converge on a common representation; phonological relations are formed over phonetic units, while morphological relations are formed over units that encode structural and semantic information related to morphemes. The mental representation of a word consists, then, of a family of interconnected forms coding different linguistic properties of the word, which Beckman and Pierrehumbert describe in terms of a connectionist network. This model falls within the family of exemplar models in that words are represented in the mind of the speaker/hearer in terms of units of phonetic experience, preserving predictable and idiosyncratic phonetic detail alike. Abstract units such as phonemes are viewed as categories formed over phonetic units (and other kinds of units), and are considered as formal syntactic objects in the overall language system.

The association between the physical experience of spoken language and its mental representation will continue to be the focus of research in phonology, as many questions remain to be answered. What is clear from the treatment of URs in phonological theory over the last century is that a complete account of phonology must model both the phonetic and the morphological relationships between words, based on evidence from a rich variety of languages, and on observations about human behavior related to spoken language.

2 Contrast

Daniel Currie Hall

1 Twixt Ptydepe and Chorukor

Václav Havel's play *The memorandum* (Havel 1966) imagines a dysfunctional bureaucracy that suffers from, among other things, the imposition of two quite different but equally perverse artificial languages. The first of these, called Ptydepe, is designed to maximize redundancy, and thus distinctiveness. Every word of Ptydepe must differ from every other word of the same length by at least 60 percent. To mitigate the sesquipedalian consequences of this restriction, forms are allocated to meanings according to frequency; the shortest word of Ptydepe is *gh*, which means 'whatever' (Czech *cokoliv*). Ptydepe is eventually deposed as the official medium of communication, and replaced by Chorukor, which represents something like the opposite extreme. Words in Chorukor are minimally distinct, and semantically related words cluster particularly closely together; for example, the names of the days of the week differ from one another by only a single vowel. If a typographical error should cause a meeting scheduled for Friday to happen on Tuesday instead, then, the rationalization goes, that is only all the more efficient.

No natural human language is quite like either Ptydepe or Chorukor, but contrast and redundancy have been the subjects of considerable attention, and controversy, in the study of natural language phonology. In 1985, for example, Stephen Anderson's influential history of the discipline, *Phonology in the twentieth century*, suggested that the field as a whole had lately been sailing dangerously close to Chorukor in assuming that redundant features are excluded from underlying representations. This assumption was, in Anderson's view, a poorly motivated one, driven by an uncritical acceptance of Saussure's (1916: 166) assertion that "dans la langue, il n'y a que des différences," and by a misguided appeal to efficiency of encoding. Cherry *et al.* (1953), for example, had presented a theory of minimal contrastive specifications as a means of quantifying the information content of Russian phonemes; this exercise, Anderson points out, does not in itself give us any reason to believe that only unpredictable features are in fact stored in the Russian lexicon, particularly in light of subsequent revelations about "the sheer bulk and internal redundancy of mental storage of information" (Anderson 1985: 13).

The current state of the field – approximately a quarter of a century after Anderson's history – is rather different. One of the major changes in the intervening years has been the development of Optimality Theory (OT; Prince and Smolensky 1993) as a prominent and influential approach to phonology. The optimality-theoretic device of Lexicon Optimization, which maximizes the faithfulness of underlying representations to their corresponding surface forms, effectively bans underspecification in most contexts in which it is not necessary to account for surface alternations. (See Inkelas 1995, 1996, McCarthy 2005 and Hall 2007a for more detailed discussion.) The principle of Richness of the Base, meanwhile, excludes the possibility of language-specific restrictions on input forms, and thus preemptively rules out a great many of the ways in which contrastive underspecification might be put to explanatory use. These principles are important to Optimality Theory: Richness of the Base sets a rigorous standard under which the constraint hierarchy must take responsibility for static phonotactic patterns and dynamic alternations alike, and Lexicon Optimization is a key element of optimality-theoretic accounts of acquisition. A side-effect of these principles, however, is that input forms are now widely assumed to contain quite a lot of non-contrastive information and, because this is a side-effect, it has not been the subject of much direct scrutiny. The prevailing view of underlying representations has swung back toward the richly redundant style of Ptydepe, but not as the result of the kind of re-evaluation Anderson felt that contrast was due for (see also CHAPTER 1: UNDERLYING REPRESENTATIONS). The purpose of this chapter is not to provide such a thorough evaluation of the role of contrast as is still needed (an undertaking of rather greater scope, for which the reader is referred to Hall 2007b and Dresher 2009), but rather to provide a sense of some of the ways in which contrast and redundancy are relevant to current phonological theory, and vice versa. §2 provides a brief overview of phonemic and phonetic contrast, §3 takes a more detailed look at phonemic contrast and the notion of a contrastive hierarchy, §4 discusses the treatment of (primarily phonetic) contrast in Optimality Theory and §5 offers some concluding remarks.

2 Phonemic and phonetic contrast

Contrast in the sound systems of natural languages may be said to exist at two levels: the phonemic and the phonetic. At the phonemic level, more or less abstract contrasts exist among segments of the underlying inventory. These contrasts have traditionally been held to be categorical (although cf. Goldsmith 1995 and Hall 2009 for discussion of the notion of a "cline" of phonemic contrastiveness), and they are classically defined as having the potential to distinguish one word or morpheme from another. Contrasts at the phonetic level are concrete articulatory, acoustic, and auditory differences between sounds, and are clearly gradient, although the question of how best to quantify their degree is far from trivial.

In phonological theory, these two levels are connected through the use of distinctive features, which encode contrasts among phonemes by dividing them into natural classes that are typically defined in terms of phonetic properties. However, as Keating (1984: 289) argues, "while we want the phonological features to have some phonetic basis, we also want to distinguish possible [phonological] contrasts from possible [phonetic] differences." Moreover, many of the phenomena with which phonology concerns itself involve some kind of mismatch between phonemic and phonetic contrast.

Phonetic contrast without phonemic contrast exists most obviously in cases of allophony, in which a single underlying segment has phonetically distinct surface realizations. For example, Russian makes no phonemic contrast between /ʧ/ and /ʤ/, having only the former in its underlying inventory, but a surface contrast arises between [ʧ] and [ʤ] through regressive voicing assimilation, as in [ʒeʧʲ lʲi] 'should one burn?' *vs.* [ʒeʤ bɨ] 'were one to burn' (Halle 1959: 22).[1]

Not all such phonetic differences are allophonic in precisely the traditional sense. For example, Trubetzkoy (1939: 32) observes that tone is not phonemically contrastive in German, but that phonetic differences in pitch can be used "for the function of appeal" (*Appell*, on which see Bühler 1934). Into this category we might also put sociolinguistically or dialectally conditioned variants of phonemes, which could be seen as allophones from the perspective of the language as a whole, but which do not necessarily exist as such in the mental grammar of any one speaker. Phonetic contrasts also enable listeners to distinguish one speaker's voice from another's. Phonetic contrasts can thus be not only perceptible but even informative without necessarily corresponding to any phonemic contrast. In this connection, Trubetzkoy (1939: 51–52) speaks of multiple "sieves" (*Siebe*) that extract meaningful differences from the phonetic signal, of which the phonological sieve is only one. In recent exemplar-based models, on the other hand, phonological and metalinguistic information are extracted from the signal by mechanisms that are not necessarily distinct or separate; see e.g. Johnson 2006 for an exemplar-based model of the perception of gender in speech.

Phonemic contrast without phonetic contrast exists in cases of neutralization. In Classical Manchu, for example, the underlying contrast between /u/ and /ʊ/ is neutralized to [u] at the surface everywhere except after dorsal consonants (Dresher and Zhang 2005). The extreme case of phonemic contrast without phonetic contrast is, of course, absolute neutralization, in which an underlying contrast is eliminated in all surface environments. Kiparsky's (1968) Alternation Condition holds that absolute neutralization should not occur at all (or, in a weaker formulation, that absolute neutralization has a high cost in complexity), but arguments for such processes have been advanced (and disputed) with some frequency in the phonological literature.

The combination of allophony and neutralization can produce phonetic displacement of phonemic contrast, as in the opaque interaction of raising and flapping in the pair *writer* [ɹʌjɾɚ] – *rider* [ɹajɾɚ] in Canadian English (Joos 1942; Chambers 1973). Here the underlying voicing contrast between /t/ and /d/ conditions an allophonic contrast in the immediately preceding diphthong, but is itself neutralized;

[1] For the sake of consistency, I have used the symbols of the International Phonetic Alphabet (IPA) in all transcriptions in this chapter, converting from various other systems where necessary in material drawn from other sources. Here, for example, I have replaced the traditional Slavicist's symbols [č ǯ ž] used by Halle (1959) with their IPA counterparts [ʧ ʤ ʒ].

a phonemic contrast on one segment surfaces as a phonetic contrast on another. Because such patterns often involve some form of phonological opacity, they are of particular interest in investigations of the mechanisms through which opacity arises. It has been pointed out (see e.g. Kaye 1974; Gussmann 1976; Kisseberth 1976) that although such displacement makes phonological rules opaque (Kiparsky 1973), it also makes underlying representations more easily recoverable than they would be in cases of simple neutralization. This idea has been taken up by some recent work in Optimality Theory (e.g. Łubowicz 2003, 2007; Tessier 2004; Barrie 2006), in which the functional utility of recoverability plays a direct role in selecting optimal output forms; see CHAPTER 73: CHAIN SHIFTS for further discussion.

Cases in which absolute neutralization has been argued for necessarily involve some sort of displacement; in the absence of effects on surrounding material, there would be no reason to posit the existence of an underlying contrast that never appears at the surface.[2] For example, Hyman (1970) suggests that Nupe is best analyzed as having underlying /ɛ/ and /ɔ/ that are neutralized to [a] in all environments (in addition to an underlying /a/, which also surfaces as [a]). The primary motivation for positing this underlying contrast is the effect of /ɛ/ and /ɔ/ on immediately preceding consonants: /ɛ/ triggers palatalization, and /ɔ/ triggers labialization, while underlying /a/ triggers neither. The absolute neutralization analysis, which is further supported by evidence from loanword adaptation, offers a way of avoiding the inference that Nupe has phonemically contrastive series of palatalized and labialized consonants that contrast phonetically only before [a]. A small number of abstract contrasts thus obviates the need for a large number of concrete but marginal contrasts.[3]

It should be clear from this brief summary that phonemic and phonetic contrast and the relations between them have been at the root of some of the most basic – and some of the most controversial – questions in phonology. In current phonological theory, there are two major lines of inquiry that explicitly focus on contrast. Phonetic contrast features crucially in work on phonetically driven approaches to phonology, particularly as they apply to neutralization and to typological predictions about the shapes of phonological inventories. Phonemic contrast, on the other hand, is central to investigations into the specification and underspecification of features. These two areas of research form the foci of the following sections of this chapter. As in the foregoing discussion, the main phenomena considered in both of the following sections involve contrast at the segmental and featural levels of structure; however, it is worth bearing in mind that similar kinds of issues arise in suprasegmental structure as well.

[2] In Optimality Theory, Richness of the Base (Prince and Smolensky 1993: §9.3) implies that, in principle, every language must neutralize some input contrasts absolutely. However, Lexicon Optimization (in its original formulation by Prince and Smolensky 1993: §9.3 and in the refined version proposed by Inkelas 1995 as Alternant Optimization) ensures that an input segment that never surfaces faithfully and that is not recoverable from any effects it has on other aspects of the surface form will never be listed in any actual lexical entry, and thus will never be phonemically contrastive in the relevant sense.

[3] See Harms (1973) for counterproposals in which /ɛ/ and /ɔ/ are analyzed as /ɪa/ and /ua/ or /ja/ and /wa/, and Hyman (1973) for a rebuttal.

3 Phonemic contrast and the contrastive hierarchy

3.1 *Challenges to contrastive specification*

Over the course of modern phonological theory, there have been various proposals for restricting the content of lexical representations to exclude redundant information. (Some of these are outlined in this section, but see CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION and Dresher 2009 for further discussion and additional references.) One challenge that Anderson (1985: 11) identifies for such theories is the existence of "reciprocally dependent properties." If a feature value [αF] always entails the presence of some other feature value [βG], and the presence of [βG] always entails the presence of [αF], does this mean that both [αF] and [βG] are redundant, and that both should be omitted from the lexicon?

For example, consider the vowel inventory of Arapaho, which Goddard (1974: 115) transcribes as /i e o u/. Full specifications of these vowels for the binary features [±high], [±back], and [±round] are shown in (1).

(1) *Full specifications for Arapaho vowels*

	i	e	o	u
[±high]	+	−	−	+
[±back]	−	−	+	+
[±round]	−	−	+	+

In this system, any vowel that has the feature value [α back] also has the value [α round], and vice versa.[4] This could be taken to mean that neither [±back] nor [±round] is contrastive, but eliminating both of these supposedly redundant features leads to a set of representations that fails to distinguish /i/ from /u/ or /e/ from /o/:

(2) *Inadequate "contrastive" specifications for Arapaho vowels*

	i	e	o	u
[±high]	+	−	−	+
[±back]				
[±round]				

Archangeli (1988) presents a similar case in arguing against the theory of Contrastive Specification advanced by Steriade (1987) and Clements (1987). As an explicit means of identifying and removing redundant feature values, Archangeli (1988: 192) presents the algorithm in (3) (dubbed the Pairwise Algorithm by Dresher 2003, 2009).

(3) *The Pairwise Algorithm* (Archangeli 1988: 192)

a. Fully specify all segments.
b. Isolate all pairs of segments.
c. Determine which segment pairs differ by a single feature specification.

[4] Indeed, Arapaho is one of the languages that Rice (1995, 2002) cites in arguing that vowel place in general should be encoded phonologically with just two privative features: Peripheral (which encompasses both Dorsal and Labial) and Coronal.

d. Designate such feature specifications as "contrastive" on the members of that pair.
e. Once all pairs have been examined and appropriate feature specifications have been marked "contrastive," delete all unmarked feature specifications on each segment.

The Pairwise Algorithm fails to produce adequate feature specifications in cases of reciprocally dependent feature values, as in Arapaho; applied to the inventory in (1), it yields the specifications in (2). It produces similarly inadequate specifications for other types of inventories as well, such as the Maranungku vowel inventory in (4).

(4) *Full specifications for Maranungku vowels* (Archangeli 1988: 201, citing Tryon 1970)

	i	ɑ	ə	æ	ʊ
[±high]	+	−	−	−	+
[±low]	−	+	−	+	−
[±back]	−	+	+	−	+

Given the specifications in (4), the algorithm in (3) will identify the following minimal pairs of segments: /ə/ and /ʊ/ differ only in [±high]; /ɑ/ and /ə/ differ only in [±low]; /i/ and /ʊ/ differ only in [±back]; /æ/ and /ɑ/ differ only in [±back]. Accordingly, the Pairwise Algorithm will identify the feature specifications in (5) as contrastive, and eliminate all the others.

(5) *Inadequate "contrastive" specifications for Maranungku vowels* (Archangeli 1988: 202)

	i	ɑ	ə	æ	ʊ
[±high]			−		+
[±low]		+	−		
[±back]	−	+		−	+

The system of specifications in (5) includes identical representations for /i/ and /æ/; each of these phonemes is specified only as [−back] because each enters into only one minimal pair, and each is the [−back] member of the pair in which it appears. This by itself makes the representations inadequate, but it is perhaps also worth noting that the specifications for /ɑ/ and /ʊ/ are not distinct from each other, nor is the representation of /ə/ distinct from the representation shared by /i/ and /æ/, in the sense defined by Halle's (1959: 32) Distinctness Condition, quoted in (6). In other words, the feature system in (5) is essentially a ternary-valued one: /ɑ/ is different from /ʊ/ only if positive values are considered distinct from zero, while /ə/ is different from /i/ and /æ/ only if negative values are considered distinct from zero.

(6) *The Distinctness Condition* (Halle 1959: 32)

Segment-type {A} will be said to be different from segment-type {B}, if and only if at least one feature which is phonemic in both has a different value in {A} than in {B}; i.e. plus in the former and minus in the latter, or vice versa.

Furthermore, the putatively "full" specifications shown for Arapaho in (1) and for Maranungku in (4) in fact omit some potentially relevant features. If the feature value [+low] applies to the Arapaho vowels /e/ and /o/, as in (7a), then there will be no minimal pairs at all, and the Pairwise Algorithm will produce the totally unspecifiied representations in (7b).

(7) a. *Fuller feature specifications for Arapaho vowels*

	i	e	o	u
[±high]	+	−	−	+
[±low]	−	+	+	−
[±back]	−	−	+	+
[±round]	−	−	+	+

b. *"Contrastive" (total) underspecification of Arapaho vowels*

	i	e	o	u
[±high]				
[±low]				
[±back]				
[±round]				

Similarly, adding the feature [±round] to the specifications for Maranungku, as in (8a), will eliminate the two minimal pairs involving /ʊ/, leading to the "contrastive" specifications in (8b).

(8) a. *Fuller feature specifications for Maranungku vowels*

	i	ɑ	ɔ	æ	ʊ
[±high]	+	−	−	−	+
[±low]	−	+	−	+	−
[±back]	−	+	+	−	+
[±round]	−	−	−	−	+

b. *"Contrastive" specifications for Maranungku vowels, based on* (8a)

	i	ɑ	ə	æ	ʊ
[±high]					
[±low]		+	−		
[±back]		+		−	
[±round]					

The Pairwise Algorithm is clearly not a viable means of assigning phonological feature specifications. This is perhaps not surprising, in light of the fact that Archangeli (1988) formulated it specifically to serve as a straw man in her argument against Contrastive Specification. However, as Dresher (2009) demonstrates, this approach to identifying contrastive feature values has been put to serious use in influential works of phonological theory, although not always explicitly or consistently. The examples cited by Dresher include Trubetzkoy (1939) on French and German, Jakobson (1949) on Serbo-Croatian, Martinet (1964) on French, and, more recently, Nevins (2004).

3.2 *The contrastive hierarchy and its uses*

There is, however, another approach to identifying contrastive features that avoids the pitfalls of the Pairwise Algorithm. In this approach, features – and thus contrasts – are organized into a hierarchy, so that some contrasts take scope over others. Dresher *et al.* (1994: x) present a version of this approach that they term the Continuous Dichotomy Hypothesis, which is based on Jakobson and Halle's (1956) account of phonological acquisition:

(9) *The Continuous Dichotomy Hypothesis* (Dresher *et al.* 1994: x)

a. In the initial state, all sounds are assumed to be variants of a single phoneme.
b. An initial binary distinction (dichotomy) is made on the basis of one [member] of the universal set of distinctive features.
c. Keep applying the dichotomy to each remaining set until all distinctive sounds have been differentiated.

Dresher (2009) offers a more formally explicit procedure, which he terms the Successive Division Algorithm. This version is also more general, in that it does not assume that the features (and the divisions they make) will necessarily be binary:

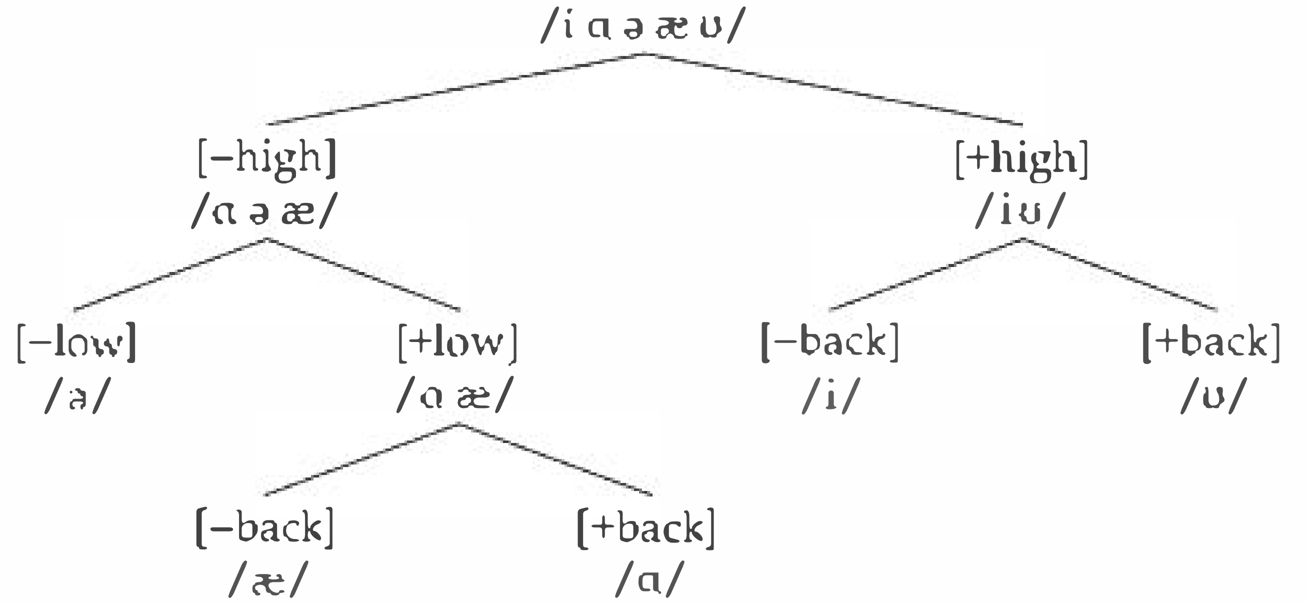
(10) *The Successive Division Algorithm* (Dresher 2009: 17)

a. In the initial state, all tokens in inventory I are assumed to be variants of a single member. Set I = S, the set of all members.
b. i. If S is found to have more than one member, proceed to (c).
   ii. Otherwise, stop. If a member, M, has not been designated contrastive with respect to a feature, G, then G is *redundant* for M.
c. Select a new *n*-ary feature, F, from the set of distinctive features. F splits members of the input set, S, into *n* sets, F_1–F_n, depending on what value of F is true of each member of S.
d. i. If all but one of F_1–F_n is empty, then loop back to (c). (That is, if all members of S have the same value of F, then F is not contrastive in this set.)
   ii. Otherwise, F is *contrastive* for all members of S.
e. For each set F_i, loop back to (b), replacing S by F_i.

Unlike the Pairwise Algorithm, the Successive Division Algorithm will necessarily produce a set of feature specifications that is sufficient to distinguish all segments in the input inventory, because it proceeds by assigning features to differentiate segments, and does not terminate until all segments are adequately specified, rather than starting with full specifications and deleting ones that appear to be redundant. By organizing features into scopal relations, the Successive Division Algorithm resolves the question raised by reciprocally dependent properties: if two feature values are mutually predictable, then the feature that takes higher scope will be assigned as a contrastive specification, and the other one will be considered redundant.

For example, suppose that the Maranungku vowel inventory in (8) is specified using the Successive Division Algorithm, with features taking scope in the following order: [±high] >> [±low] >> [±back] >> [±round]. The divisions made by the algorithm can be represented in a tree structure, as in (11a), yielding the feature specifications summarized in (11b), which suffice to distinguish the Maranungku vowels in accordance with Halle's (1959) Distinctness Condition.

(11) a. *Dividing the Maranungku vowel inventory*



b. *Feature specifications assigned by* (11a)

	i	ɑ	ə	æ	ʊ
[±high]	+	−	−	−	+
[±low]		+	−	+	
[±back]	−	+		−	+
[±round]					

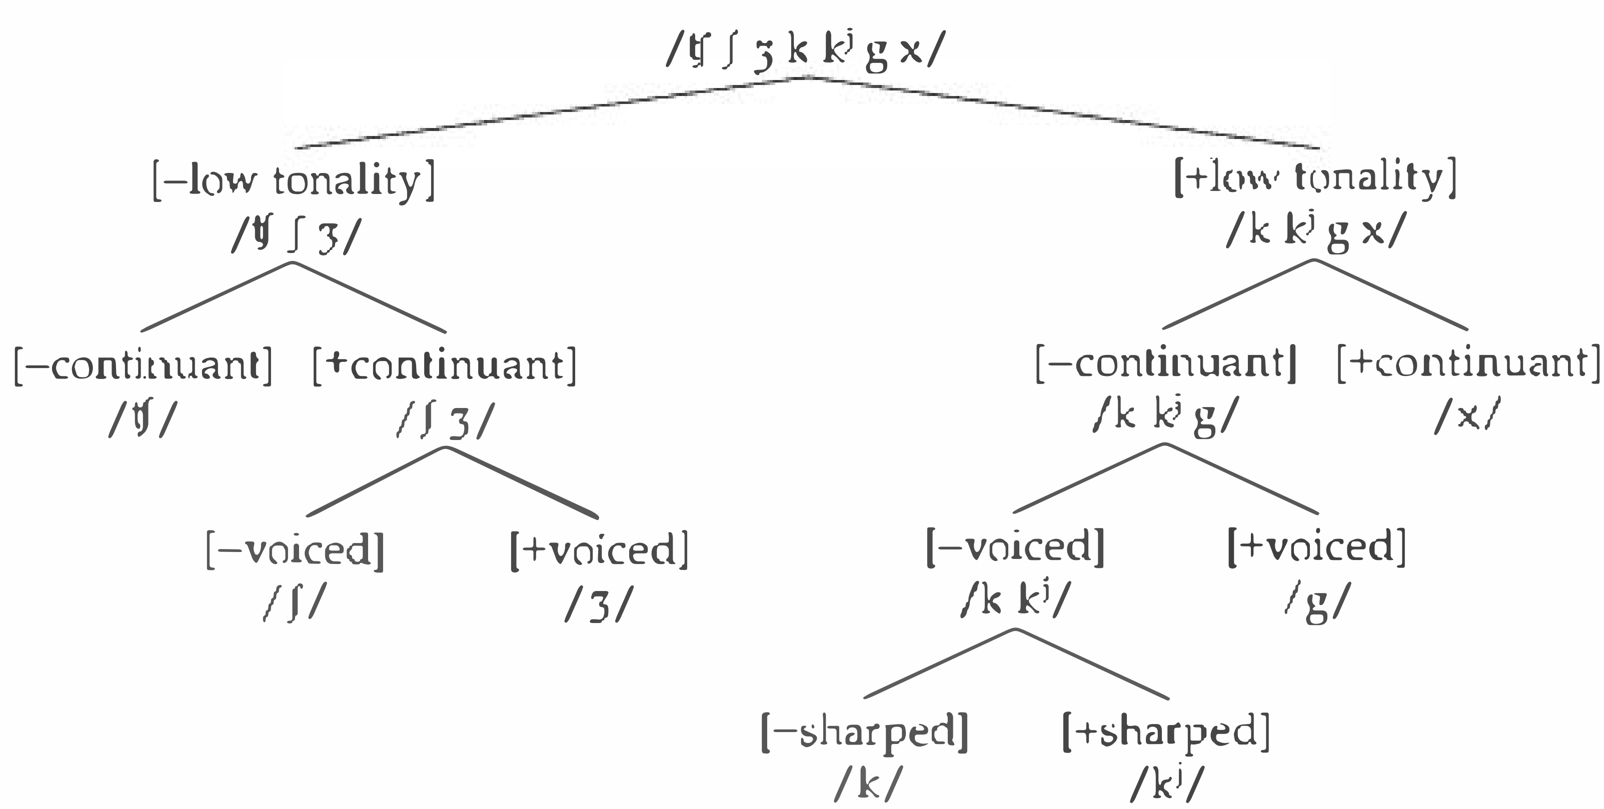
In the example in (11), all five vowels are specified for [±high], because this feature has scope over the entire inventory. The feature [±low] does not divide the [+high] vowels, so it is not contrastive for them, but it does divide the [−high] vowels, and so this feature is included in the specifications assigned to /ɑ ə æ/. Because the specification [+low] entails [−high], the value [−high] on /ɑ æ/ would be considered redundant by a post hoc approach to contrast such as the Pairwise Algorithm. Under the Successive Division Algorithm, however, the assignment of a lower-ranking feature (such as [±low] in this case) cannot erase any specifications that have already been assigned (such as [−high]), even if the higher-ranking features are logically predictable from the lower-ranking ones.

The Successive Division Algorithm requires that features be assigned in order according to a hierarchy, but it does not itself specify what orderings are possible. Unlike the Pairwise Algorithm, the Successive Division Algorithm can produce different sets of specifications for the same inventory, depending on the scope assigned to each feature. For example, the feature [±round] is not used at all in (11) because it is placed so low in the hierarchy that all the segments have been fully distinguished before [±round] is brought to bear on them. If [±round] were given scope over [±back], then [±round] would distinguish /i/ and /ʊ/, and [±back] would be redundant for those segments, although [±back] would still be contrastive elsewhere in the system, distinguishing /æ/ from /ɑ/.

Researchers working within this general approach to identifying contrastive features have proposed different ways of determining or restricting the order of features in the contrastive hierarchy. Jakobson and Halle (1956) proposed a universal partial ordering of features based on observations of the order in which children acquire the corresponding contrasts. Halle (1959), in using a contrastive hierarchy to establish underlying representations for Russian morphonemes, suggests that an ordering should be chosen in such a way as to minimize the number of specified values. More recent work, particularly in the framework referred to as Modified Contrastive Specification by Paradis and Prunet (1991), has focused on the role that specifications assigned in this manner can play in accounting for the phonological activity or inactivity of features. For example, Dyck (1995) offers evidence, based primarily on the phonological behavior of vowels in Spanish and Italian dialects, that the feature [low] consistently takes scope over [high] in Romance, and perhaps more generally as well. The papers collected in Hall (2003) offer additional examples of this approach, in which only contrastive features are predicted to be active in (at least some well-defined component of) the phonological computation.

Not all work that makes use of the contrastive hierarchy posits a correlation between phonological activity and contrastiveness. Consider, for example, the specifications assigned by Halle (1959: 45–46) to the palatal and velar obstruents of Russian:

(12) a. *Partial contrastive hierarchy for Russian* (Halle 1959: 46)



b. *Features assigned by* (12a) (Halle 1959: 45)

	ʧ	ʃ	ʒ	k	kʲ	g	x
[±low tonality]	−	−	−	+	+	+	+
[±continuant]	−	+	+	−	−	−	+
[±voiced]		−	+	−	−	+	
[±sharped]				−	+		

By giving [±continuant] scope over [±voiced], Halle (1959) ensures that the unpaired voiceless segments /ʧ/ and /x/ – as well as /ts/, in the dental series, not shown in (12) – will be unspecified for the latter feature. These segments do, however, pattern together with the contrastively voiceless obstruents of Russian with respect to regressive voicing assimilation; indeed, Halle (1959) famously used this fact to argue against the strict structuralist distinction between morphophonemic and phonemic rules, under which Russian voicing assimilation would have to be treated as two separate processes with suspiciously similar effects. In order to ensure that /ts ʧ x/ correctly trigger regressive assimilatory devoicing of other obstruents, Halle (1959) requires another rule, ordered before the assimilation rule, which fills in the predictable value [−voiced] on these segments. As Dresher (2009) points out, however, this redundancy rule would not be needed if the positions of [±continuant] and [±voiced] in the contrastive hierarchy were reversed. If [±voiced] were ranked above [±continuant] and below [±nasal], it would be possible to say that voicing is contrastive among Russian obstruents in general, and that all segments underlyingly specified for [±voiced] participate in the assimilation rule.

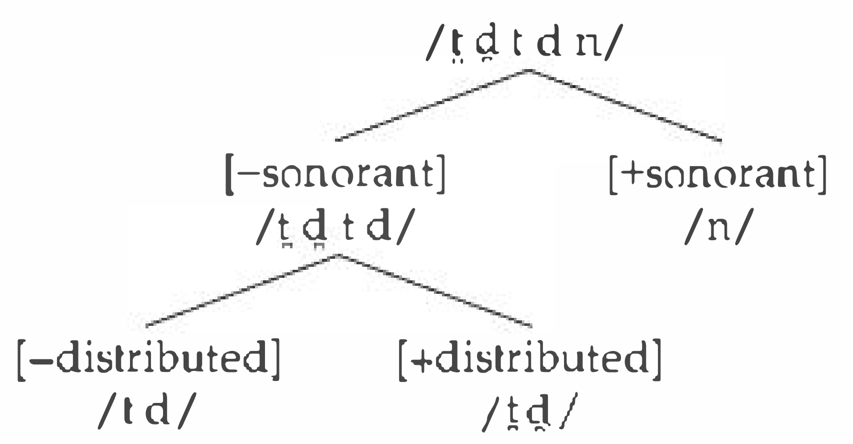
For Halle (1959), then, the contrastive hierarchy serves mainly to eliminate redundant features from the lexicon, a goal whose utility is disputed by Anderson (1985), as noted above. In the framework of Modified Contrastive Specification, however, the Successive Division Algorithm has been used to restrict the role of redundant features in phonology more generally. A particularly compelling example is offered by Mackenzie (2005, 2009) in her analysis of dental harmony in Luo and Anywa. Each of these two languages has a coronal stop inventory that includes the segments shown in (13).[5]

(13) *Dental and alveolar stops in Luo and Anywa* (Mackenzie 2009: 36)

	voiceless plosive	voiced plosive	nasal
alveolar	t	d	n
dental	t̪	d̪	

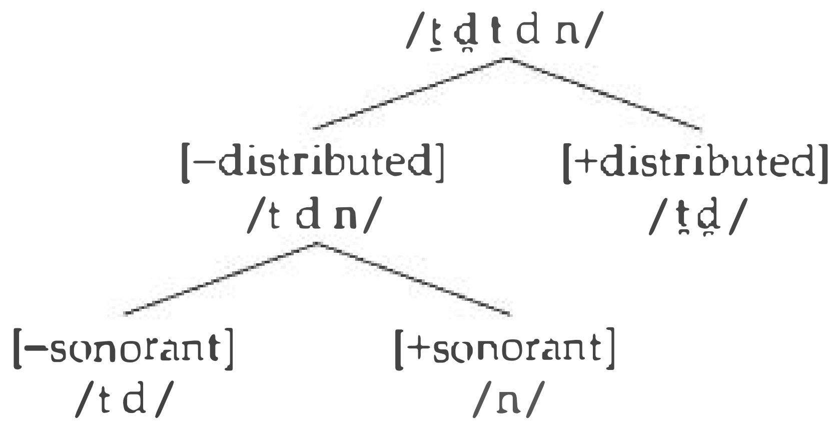
In Luo, the nasal /n/ is ignored by dental harmony, and occurs freely with dental and alveolar plosives (although these cannot co-occur with each other). In Anywa, on the other hand, /n/ is targeted by dental harmony, being realized allophonically as [n̪] in words containing dentals and as [n] elsewhere. Mackenzie argues that this difference can be attributed to different contrastive hierarchies in the two languages: in Luo, [±sonorant] takes scope over [±distributed], while in Anywa the reverse ordering applies.

(14) a. *Partial contrastive hierarchy for Luo* (Mackenzie 2009: 43)



[5] For the sake of simplicity, I set aside the Luo prenasalized stops /ⁿd ⁿd̪/, which participate in dental harmony as expected.

b. *Partial contrastive hierarchy for Anywa* (Mackenzie 2009: 42)



In both languages, dental harmony applies to segments that are specified for [±distributed]. In Anywa, this set includes /n/; in Luo it does not. Because the Successive Division Algorithm allows for cross-linguistic variation in feature scope, the shape of the inventory in (13) only partially determines the possible feature specifications. The unpaired alveolar /n/ is the only segment that can be unspecified for [±distributed], but if the feature is given wide enough scope, it will be contrastive on /n/ as well. Mackenzie's analysis accommodates the attested cross-linguistic variation while supporting the strong hypothesis that non-contrastive features are absent from the phonological computation.

4 Phonetic contrast and Optimality Theory

The rise of Optimality Theory in phonology has brought with it an interest in exploring the extent to which it is possible to characterize phonological patterns in terms of interactions between constraints that express potentially conflicting formal or functional ideals. These constraints are generally held to be surface oriented, in that the desiderata they encode have to do either with the form of the output itself (in the case of markedness constraints) or with the relation between the output and the input (in the case of faithfulness constraints).[6] Per the principle of Richness of the Base, inputs themselves are not directly constrained. A large part of the conceptual appeal of Optimality Theory is that it offers the prospect of explaining all mismatches between phonemic and phonetic contrast by means of the same markedness constraints that enforce static phonotactic generalizations.

In accordance with the generally surface-oriented character of Optimality Theory, much of the work on contrast in this framework focuses on phonetic contrast. In particular, there has been much interest in the role of phonetic distinctiveness in determining the environments in which underlying contrasts are preserved or neutralized, and in phonetic contrast as an explanation for the shapes of sound inventories.

4.1 *Phonetic contrast and neutralization*

The preservation and neutralization of underlying contrasts can be seen within Optimality Theory as arising from a basic conflict between constraints that favor

[6] Some work in Optimality Theory has proposed various additions to these two basic types of constraints; see in particular Archangeli and Suzuki (1997).

phonetically robust realization of contrasts and constraints that favor the elimination of contrasts. Input contrasts are preserved or enhanced to the extent that constraints of the former type dominate constraints of the latter type; contrasts are neutralized to the extent that constraints of the latter type predominate.

4.1.1 Formal and functional constraints

There are several different possible instantiations of each of these two types of constraint. For one thing, each type of constraint can be formulated in either formal or functional terms. A constraint that favors neutralization may be a markedness constraint in the purely formal sense of the term: e.g. the constraint *[*xxx*Place] (de Lacy 2002: 180) penalizes segments with a dorsal place of articulation (represented formally as three degrees of markedness in the Place dimension), and will have the effect of neutralizing dorsal–non-dorsal contrasts to the extent that it prevails over conflicting faithfulness constraints. On the other hand, a constraint such as *Gesture(body) (Boersma 1998: 230), which also penalizes dorsals, does so in terms of functional markedness by penalizing the articulatory effort involved in moving the tongue body to make a dorsal articulation.

Among constraints that preserve contrast, formal and functional versions also exist. On the formal side are constraints such as Ident[*xx*Place] (de Lacy 2002: 180), which says that all segments with at least two degrees of markedness in the Place dimension in the input (i.e. segments that are underlyingly labial or dorsal) must have their place features preserved in the output. As an example of an explicitly functionalist faithfulness constraint, we could take *Replace(|a|, /ɛ/, ≥30%) (Boersma 2000: 37), which relates faithful production to accurate perception by penalizing any realization of |a| that will be perceived at least 30 percent of the time as /ɛ/. While the functional utility of faithfulness in general is intuitively obvious, it is perhaps worth noting that in a framework that assumes Richness of the Base, there is no guarantee that the contrast whose preservation is mandated by any given faithfulness constraint actually carries any functional load. Rather, the connection between faithfulness constraints and the use of contrasts to mark lexical distinctions must run in the opposite direction: per Lexicon Optimization, a contrast will exist in the lexicon only if the constraints that mandate its preservation are ranked sufficiently high. (Furthermore, even the inclusion of different representations in the lexicon does not necessarily mean that the distinctions between them carry any functional load; Lexicon Optimization will ensure that all non-alternating aspects of form are stored, even if they are redundant.) Faithfulness constraints can be seen as functional in a more general information-theoretic sense, however, in that increasing the number of contrasts present in the output increases the rate at which the signal is capable of transmitting information. (See e.g. Shannon 1956 for the information-theoretic point, and Boersma 1998: 184–185 for some comments on its relevance to functionalist optimality-theoretic phonology; also chapter 63: markedness and faithfulness constraints for further discussion of the differences between markedness and faithfulness constraints.)

4.1.2 Positional licensing and positional faithfulness

Another point of difference among optimality-theoretic accounts of the preservation and neutralization of contrast is which set of constraints is held to be responsible for identifying the relevant environments. The Licensing by Cue approach presented by Steriade (1997), for example, captures the generalization that laryngeal contrasts are most likely to be neutralized in contexts in which they are least perceptible by means of the fixed ranking of markedness constraints in (15) (see also CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS):

(15) *Hierarchy of markedness constraints penalizing surface specifications for voicing* (Steriade 1997: 11, 35)

a. *[α voice] / [−son] __ [−son], [−son] __ #, # __ [−son]
b. *[α voice] / V __ [−son]
c. *[α voice] / V __ #
d. *[α voice] / V __ R[−son]
e. *[α voice] / V __ R#
f. *[α voice] / V __ R̥, V __ RV, V __ V

This is one instantiation of the notion of positional licensing, in which marked features are penalized unless they are licensed by virtue of occupying a particular position. In Steriade's (1997) approach, this positional licensing is phonetically grounded, in that the licensing environments are identified as those providing the best acoustic or auditory cues for perception of the contrast being licensed.

An alternative to positional licensing is positional faithfulness, as proposed by Beckman (1998). In this approach, the relevant environments are defined not by the markedness constraints, but by the faithfulness constraints, as in the example in (16):

(16) *Hierarchy of positional faithfulness constraints preserving underlying specifications for voicing* (Beckman 1998: 35)

a. IDENTONSET(voice)
b. IDENT(voice)

Other differences between Steriade's (1997) and Beckman's (1998) approaches are orthogonal to the choice between positional licensing and positional faithfulness, and to each other. The constraints in (16) are formulated so that (16a) applies to a subset of the forms for which (16b) is relevant; Beckman (1998: 35) hypothesizes that their ranking is fixed, so that the more specific constraint universally dominates the more general one. The constraints in (15), on the other hand, are not in a subset relation, and their ranking is fixed by alignment to the relative phonetic perceptibility of voicing in the environments to which they refer. Additionally, the environments taken to be relevant by the constraints in (15) are defined in terms of segmental adjacency, while (16) refers to syllable structure instead.

One potential drawback of the positional licensing approach is that although a hierarchy of constraints like the one in (15), with the faithfulness constraint PRESERVE(voice) (Steriade 1997: 12) ranked somewhere in its midst, can predict *where* voicing neutralization will occur, it does not necessarily determine *how* it will occur. In Lithuanian, for example, voicing on obstruents is neutralized by regressive assimilation in obstruent clusters, and by devoicing word-finally, while voicing contrasts are preserved before sonorants:

(17) *Voicing neutralization in Lithuanian* (Steriade 1997: 18)

a. *at+gal* [dg] 'back'
b. *dirb+ti* [pt] 'work (INF)'
c. *daug* [k#] 'much'
d. *silpnas* [pn] 'weak'
e. *liūdnas* [dn] 'sad'

These facts indicate that in Lithuanian, PRESERVE(voice) is ranked below *[α voice] / V __ [–son] and *[α voice] / V __ #, but above *[α voice] / V __ RV, which is consistent with the hierarchy in (15). However, the resulting grammar does not predict which instances of neutralization will result in assimilation and which in devoicing; the *[α voice] constraints indicate only that underlying voicing specifications are not to be respected. One possibility would be to say that the output of the phonological computation includes segments that are unspecified for voicing where dictated by *[α voice] constraints, and that the actual realization of these segments as voiced (as in (17a)) or voiceless (as in (17b) and (17c)) is a matter of phonetic implementation. This, however, would seem to run counter to the aim of incorporating phonetic explanations into the phonological constraint grammar.

The positional faithfulness account of similar voicing facts in Polish offered by Lombardi (1999) does not suffer from the same difficulty, because in this model the constraints that motivate unfaithfulness to underlying voicing specifications also determine the appropriate surface voicing values in each context.

Lombardi's (1999) account of final devoicing and regressive voicing assimilation in Polish is based on the constraints in (18):

(18) *Constraints relevant for voicing patterns in Polish* (Lombardi 1999: 270–272)

a. AGREE: Obstruent clusters should agree in voicing.
b. IDENTONSET(Laryngeal): Consonants in onset position should be faithful to their underlying laryngeal specifications.
c. *LAR: Segments should not have marked laryngeal features.[7]
d. IDENT(Laryngeal): Consonants should be faithful to their underlying laryngeal specifications.

Ranked in the order AGREE, IDENTONSET(Laryngeal) >> *LAR >> IDENT(Laryngeal), these constraints will generate final devoicing and regressive assimilation, and respect underlying voicing specifications of onset obstruents, as illustrated in (19):

(19) *Tableaux for Polish laryngeal neutralization* (Lombardi 1999: 282)

a. *klub* [p] 'club'

Input: /klub/	AGREE	IDONS(Lar)	*LAR	ID(Lar)
a. [klub]			*!	
☞ b. [klup]				*

[7] In the tableaux in (19), I assume that this constraint penalizes all and only voiced obstruents; Lombardi (1999: 271, fn. 2) suggests that the constraint can be taken to be more general than this, but only its ability to penalize [voice] on obstruents is relevant here.

b. *żabka* [pk] 'frog (DIM)'

Input: /ʐabka/	AGREE	IDONS(Lar)	*LAR	ID(Lar)
a. [ʐabka]	*!		**	
☞ b. [ʐapka]			*	*
c. [ʐabga]		*!	***	*
d. [ɕapka]		*!		**

c. *prosba* [zb] 'request (N)'

Input: /prosba/	AGREE	IDONS(Lar)	*LAR	ID(Lar)
a. [prosba]	*!		*	
☞ b. [prozba]			**	*
c. [prospa]		*!		*

d. *nigdy* [gd] 'never'

Input: /ɲigdi/	AGREE	IDONS(Lar)	*LAR	ID(Lar)
☞ a. [ɲigdi]			**	
b. [ɲikdi]	*!		*	*
c. [ɲikti]		*!		**

Under the positional faithfulness approach, then, faithfulness constraints determine where contrasts should be preserved, and markedness constraints are largely responsible for dictating what happens when they are not.

4.2 Phonetic contrast and inventories

Another significant way in which Optimality Theory has been brought to bear on questions of contrast is in accounting for cross-linguistic patterns in the shapes of phonological inventories. In much optimality-theoretic work, inventories are regarded as essentially epiphenomenal, having no theoretical status of their own: a surface inventory is simply the set of segments the grammar happens to permit in output forms, and an underlying inventory is simply the set of segments Lexicon Optimization leads the learner to posit in input forms. (See e.g. Kirchner 1995, 1997 on the derivability of contrastiveness in Optimality Theory.) Generalizations about inventories might therefore be expected to fall out automatically from a successful theory of the constraints that govern everything else in phonology. Dispersion Theory (Flemming 1995, 2002, among others), however, addresses inventories more directly, through the use of constraints that explicitly refer to the number or robustness of contrasts in the system as a whole, rather than only to individual forms.

4.2.1 *Dispersion Theory*

Flemming's Dispersion Theory offers an optimality-theoretic implementation of some of the insights of Lindblom's (1986, 1990) Theory of Adaptive Dispersion. Under this approach, the shapes of inventories emerge from competition among three types of constraints (Flemming 2002: 4):

- constraints that require the presence of particular numbers of surface contrasts, e.g. MAXIMIZECONTRASTS (Flemming 2002), NWORDS (Ní Chiosáin and Padgett 1997, 2001), *MERGE (Padgett 2003), CONTRAST (Bradley 2001), 𝒥-constraints (Sanders 2003);
- constraints that require surface contrasts to be phonetically robust, e.g. MINDIST (Flemming 2002), CONTRAST (Ni Chiosáin & Padgett 1997), SPACE (Ní Chiosáin and Padgett 2001; Padgett 2003), DISP (Kirchner 1998), 𝒟-constraints (Sanders 2003);
- constraints that penalize articulatorily effortful (or otherwise marked) surface forms, e.g. MINIMIZEEFFORT (Flemming 2002), LAZY (Kirchner 1997, 1998), ℳ-constraints (Sanders 2003).

Each of these three types potentially conflicts with the other two; for example, a contrast can be made more distinct either through the application of additional effort in the articulation of one or more of its members, or through the removal of one or more members from the set of contrasting forms.

If the constraints referring to contrasts are to be part of the evaluation, the grammar must consider sets of contrasting forms together; in principle, the evaluation may apply to an entire language of forms, although for expository purposes, tableaux are restricted to representative sets of forms illustrating how the grammar treats a particular type of contrast.

For example, consider the following dispersion-theoretic account of voice onset time (VOT) contrasts in English, adapted from a sketch presented by Flemming (2002: 47–48).[8] English stops exhibit a two-way contrast in VOT, but this contrast is realized differently in different positions. Foot-medially, the contrast is between voiced and voiceless unaspirated stops, as in *ogre* [ogɚ] *vs. ochre* [okɚ]. Word-initially, the voiced stops are partially devoiced, and the voiceless stops are aspirated, as in *goal* [g̊oɫ] *vs. coal* [kʰoɫ]. A dispersion-theoretic account of these facts requires the following constraints:

- MAXIMIZEVOT CONTRASTS gives preference to candidate systems with larger numbers of surface forms that are distinct in VOT. As Flemming (2002: 27) explains, MAXIMIZECONTRASTS constraints are positive scalar constraints; rather than assigning asterisks to candidates for violations, they assign check marks to candidates according to how many contrasting forms they include.

[8] I have departed from Flemming (2002) primarily in representing voiceless unaspirated [k] and partially devoiced [g̊] as (very slightly) phonetically distinct from each other, largely for the sake of providing an example in which the MINDIST constraints make a crucial contribution to the outcome. Flemming's (2002) constraint hierarchy also appears to predict that English should have a three-way VOT contrast, which is not the case in this adaptation.

- MinDist=VOT constraints require forms that contrast in VOT to do so by at least a certain degree. For this particular example, we can consider the range of potentially contrasting segments in (20), and say that the crucial MinDist constraint here, MinDist=VOT:2, requires contrasting forms to differ at least as much as do [k^h] and [g̊], or [k] and [g]. A more stringent constraint, MinDist=VOT:3, which would require forms to differ as much as [g] and [k^h], is ranked too low to have an effect.

(20) *Stops potentially contrasting in VOT*

g	g̊ k	k^h
negative VOT	VOT *circa* 0	positive VOT

- Markedness constraints penalize effortful articulations:
  *InitialVoicedStop penalizes prevoicing of word-initial plosives.
  *Aspiration penalizes aspirated stops.

Ranking MinDist=VOT:2 over MaximizeVOT Contrasts at the top of the hierarchy will mean that in both medial and initial positions the optimal system will have two contrasting forms. A system with more than two forms cannot satisfy MinDist=VOT:2, and a system with only one form will be ruled out by MaximizeVOT Contrasts.

As the tableau in (21) illustrates, the forms chosen in medial position will have [g] and [k]. Any other pair of forms that fares at least as well on the MinDist constraints will be ruled out by the constraint against aspirates. A pair with [g̊] and [k] is harmonically bounded by the winning candidate because it violates MinDist=VOT:2.

(21) *English VOT contrasts in medial position*

	MinDist =VOT:2	Max Contrasts	*IVS	*Asp	MinDist =VOT:3
☞ a. [ogɚ] [okɚ]		✓✓			*
b. [ogɚ] [ok^{h}ɚ]		✓✓		*!	
c. [og̊ɚ] [ok^{h}ɚ]		✓✓		*!	*
d. [ogɚ]		✓!			
e. [og̊ɚ] [okɚ]	*!	✓✓			*
f. [ogɚ] [og̊ɚ] [okɚ]	*!*	✓✓✓			***
g. [ogɚ] [og̊ɚ] [okɚ] [ok^{h}ɚ]	*!**	✓✓✓✓		*	*****

The corresponding tableau for word-initial position is shown in (22). Here, the winning candidate has forms with [g̊] and [kʰ]. Any other set of forms that is at least equally dispersed is eliminated by *INITIALVOICEDSTOP; any set of forms that is less dispersed is eliminated by MINDIST=VOT:2.

(22) *English VOT contrasts in initial position*

As this example illustrates, Dispersion Theory deals not only with the overall shapes of inventories, but also with the ways in which syntagmatic patterns interact with the paradigmatic system of contrasts, and it does so in a way that is very much independent of underlying representations. In this treatment, it makes no difference whether the English VOT contrast is represented in the input as a voicing contrast (/g/ *vs.* /k/), or as an aspiration contrast (/k/ *vs.* /kʰ), or both, in part because faithfulness constraints do not play a crucial role in determining the surface forms. Because Dispersion Theory treats the system of contrasts as a whole, a markedness constraint that directly affects one form may indirectly affect another; for example, when a markedness constraint requires devoicing of the lenis member of the pair, the fortis member must be realized as aspirated in order to satisfy MINDIST=VOT:2.

4.2.2 *Dispersion and diachrony*

Padgett (2003) uses Dispersion Theory to account for a diachronic change that involves a system of contrasts, namely post-velar fronting of [ɨ] to [i] in Russian. This change, Padgett argues, was driven by constraints mandating robust phonetic contrast: the change from [kɨ] to [kʲi] resulted in a greater contrast with [ku], taking advantage of a gap that had been left by the First Velar Palatalization, in which [kʲi] had become [ʧʲi]. The tableau in (23) shows the essential components of Padgett's account of post-velar fronting.

(23) *Post-velar fronting in Russian* (Padgett 2003: 74)[9]

/pʲi/$_1$ /pɨ/$_2$ /pu/$_3$ /kɨ/$_5$ /ku/$_6$ /tʃʲi/$_4$	*MERGE	SPACE$_{COLOR}$≥½	IDENT(color)
☞ a. [pʲi]$_1$ [pɨ]$_2$ [pu]$_3$ [kʲi]$_5$ [ku]$_6$ [tʃʲi]$_4$		**	*
b. [pʲi]$_1$ [pɨ]$_2$ [pu]$_3$ [kɨ]$_5$ [ku]$_6$ [tʃʲi]$_4$		***!	
c. [pʲi]$_1$ [pɨ]$_2$ [pu]$_3$ [kʲi]$_5$ [kɨ]$_6$ [tʃʲi]$_4$		***!	**
d. [pʲi]$_{1,2}$ [pu]$_3$ [kʲi]$_5$ [ku]$_6$ [tʃʲi]$_4$	*!		**

Maintenance of contrasts here is driven by the faithfulness constraint *MERGE, which requires that separate forms in the input have distinct realizations in the output; input–output correspondence is indicated by subscript numerals. This constraint is violated by the last candidate, in which the input forms /pʲi/ and /pi/ are collapsed into [pʲi]. This is also the only candidate that fully satisfies SPACE$_{COLOR}$≥½, which requires that minimal pairs distinguished only by vowel color (backness and/or rounding) must each have at least half of the range of possible vowel colors available to them. This constraint thus imposes restrictions on both the number and the phonetic realization of contrasting vowels. If n vowels are evenly distributed in the available space, each vowel has $1/n$ of the space, as schematized in (24a). A system with more than two vowels cannot satisfy SPACE$_{COLOR}$≥½, but neither will a two-vowel system in which the vowels are unevenly spaced, such as the system in (24b).

(24) a. *Equal allocation of vowel color space* (Padgett 2003: 55)

i	ɨ̟	ɨ̠	u	Each vowel has ¼ of the available space.
i	ɨ	u		Each vowel has ⅓ of the available space.
i	u			Each vowel has ½ of the available space.
ɨ				Each vowel has all of the available space.

b. *Unequal allocation of vowel color space*

ɨ	u	/u/ has less than ½ of the available space.

[9] The tableau in (23) differs slightly from Padgett's (2003) original, in that I have omitted the constraint *au, which plays no role in this evaluation (although it was important at an earlier diachronic stage), and included the palatalization of [p] before [i].

The winning candidate in (23) improves upon the perfectly faithful candidate by realizing /ki/ as [kʲi], eliminating the violation of SPACE$_{COLOR}$≥½ in the [kV] series at the expense of the low-ranking faithfulness constraint IDENT(color). The two violations of SPACE$_{COLOR}$≥½ incurred by the [pV] series, however, cannot be eliminated without violating *MERGE, so the labial series is realized faithfully.

It is crucial to Padgett's account that SPACE$_{COLOR}$≥½ evaluates words, rather than segments; in order for the realization of /kɨ/ as [kʲi] to be useful, the [kV] series must be evaluated independently from the [pV] series. Hence Padgett's (2003: 56) definition of the SPACE constraint family explicitly refers to (potential) minimal pairs. This definition, however, allows for a rather counterintuitive repair strategy for forms with phonetically weak underlying contrasts. If some other faithfulness constraint (e.g. DEP) is ranked sufficiently low, then the forms could be made to satisfy SPACE vacuously by violating that constraint in such a way as to ensure that they are no longer minimal pairs (e.g. by inserting additional segments elsewhere in the form). The tableau in (25) suggests that if DEP were ranked below IDENT(color) in some language that otherwise resembles Russian at the stage at which post-velar fronting applied, a candidate in which several forms undergo epenthesis will be preferred over the winning candidate from (23):

(25) *Enhancing contrast through epenthesis*

/pʲi/$_1$ /pi/$_2$ /pu/$_3$ /kɨ/$_5$ /ku/$_6$ /tʃʲi/$_4$	*MERGE	SPACE$_{COLOR}$≥½	IDENT(color)	DEP
a. [pʲi]$_1$ [pi]$_2$ [pu]$_3$ [kʲi]$_5$ [ku]$_6$ [tʃʲi]$_4$		*!*	*	
☞ b. [spʲi]$_1$ [pɨ]$_2$ [plu]$_3$ [kɨn]$_5$ [ku]$_6$ [tʃʲi]$_4$				***

The obvious objection to this tableau is that, by restricting the input to these six forms, it conceals some violations of *MERGE. If [spʲi], [ki] and [plu] are phonotactically licit "words," then they should also be part of the input language, and the apparently successful candidate in (25) will be penalized for conflating them with /pʲi/, /kɨ/ and /pu/. However, if DEP is ranked sufficiently low, then the ideal way of avoiding these violations of *MERGE may be to epenthesize additional segments in the output correspondents of /spʲi/, /kin/ and /plu/ as well. Of course this, in turn, may collapse still other underlying distinctions, and so the truly optimal candidate would involve a massive chain shift of augmented words.[10]

In addition to being quite unlike any attested historical change, a shift of this sort would render intractable Padgett's (2003: §3.1) simplifying assumption that a language can be represented in a tableau as a small set of idealized forms. Because

[10] This scenario owes its inspiration to Cantor's (1892) diagonalization argument demonstrating the uncountability of the real numbers.

the forms in question represent phonotactically possible words rather than actual words, the full set of forms is, unlike an actual lexicon, at least potentially infinite. So long as the only changes contemplated in the tableau are substitutions, it is feasible to focus on small clusters of similar forms. However, if each form under consideration must be compared to one that is one segment longer, the candidate languages may need to be evaluated in their entirety.

This example may seem far-fetched, perhaps in part because it involves an unusually low ranking of a major faithfulness constraint. However, a system that includes constraints designed to evaluate the phonetic distinctiveness of entire words does open up the possibility that marginal contrasts may be "enhanced" by the introduction of apparently irrelevant changes. If such constraints exist and are freely rankable with respect to faithfulness constraints, then something very much like Ptydepe becomes a typological possibility.[11]

5 Concluding remarks

As the range of work touched on in the preceding sections suggests, there is considerable support among phonologists for the proposition that contrast is important, but there is rather less agreement about *how* it is important, or even about what, precisely, contrast is. Phonological theories that may be broadly described as based on the notion of contrast include formal algorithms for deriving minimally specified underlying representations (e.g. the Successive Division Algorithm of Dresher 2009), constraints that evaluate surface forms in minute phonetic detail (e.g. Dispersion Theory), and many things in between. Faced with the diversity not only of these theories themselves, but of their goals, it can be difficult to imagine a way of synthesizing them, or even of drawing meaningful comparisons among them.

There are, however, at least some areas in which these disparate theories may be brought to bear on similar sorts of questions. One of these is the shape of phonological inventories, discussed above in §4.2.1 in connection with Dispersion Theory. While the notion of a contrastive hierarchy, as described in §3.2, applies specifically to contrasts at the phonemic level, this approach to phonological feature specifications can also make significant predictions about the phonetic shape of inventories, particularly if it is used in combination with some theory of phonetic enhancement (on which see e.g. Keyser and Stevens 2001). Consider, for example, the highly implausible three-vowel inventory in (26), which represents a segmental analogue to the word-level indistinctness of Chorukor.

(26) *An unlikely three-vowel inventory*

ɨ	ʉ
ɘ	

The inventory in (26) is unlikely because, as noted by some of the work discussed in §4.2.1, contrasting segments tend to distribute themselves in such a way as to

[11] See also Dresher (2009: §8.3) for some other objections to Padgett's (2003) analysis of post-velar fronting and an alternative account based on the notion of a contrastive hierarchy.

take maximal advantage of the phonetic space available to them, as in the widely attested three-vowel inventory /i a u/. Dispersion Theory addresses this fact by positing constraints that evaluate the phonetic robustness of an entire system of contrasting segments or words.

The Successive Division Algorithm, as Hall (2007b: §4.3.2) points out, offers an alternative explanation. If the algorithm is used to assign features to the segments in (26), there will not be very many ways of doing so: the only features that can divide this inventory are [±high] and [±round]. If [±high] takes wider scope, the features will be assigned as in (27a); if [±round] is applied first, the features will be as in (27b).

(27) a. *Specifications for* (26) *with* [±high] >> [±round]

	ɨ	ɘ	ʉ
[±high]	+	−	+
[±round]	−		+

b. *Specifications for* (26) *with* [±round] >> [±high]

	ɨ	ɘ	ʉ
[±round]	−	−	+
[±high]	+	−	

What is noteworthy about the sets of specifications in (27) is that they are both entirely compatible with the inventory /i a u/. In a theory of full specification, the vowels in (26) would be identifiable as /ɨ ɘ ʉ/, because they would be specified for all the features they have in common as well as for the features that differentiate them; the Successive Division Algorithm can mark only how they differ from one another. If the Successive Division Algorithm is combined with some simple rules for robust phonetic implementation – e.g. a [−high] vowel is realized as low unless it is specified as [−low]; a [+round] vowel is realized as back unless it is specified to the contrary; etc. – then the inventory as specified in (27) will not only be phonologically indistinguishable from /i a u/, but it will even be pronounced as [i a u] or some other similarly dispersed set of surface forms. While the Successive Division Algorithm by itself does not guarantee phonetic dispersedness, it does guarantee that every specified feature serves to distinguish a segment from some other member or members of the inventory. If no redundant features are specified, then enhancement of specified features will contribute to surface dispersedness. Under this view, minimal representation of phonemic contrasts in underlying forms is a crucial part of a system that generates enhanced phonetic contrasts at the surface level, but that does so without making any explicit comparison between the surface forms themselves.

One theme that occurs repeatedly in the disparate treatments of phonological contrast is the relevance of information theory to phonology. As mentioned in §1, it was information theory that inspired Cherry *et al.* (1953) to apply a contrastive hierarchy to the phonemic inventory of Russian. For contemporary functionalist theories, the ability of the phonetic signal to communicate information is one of the major forces driving all phonological patterns. For Hall (2007b: §4.3.1) and Dresher (2009: §2.5.3) diagrams similar to the adjacency graphs of Shannon (1956) help to identify the type of inventory for which the Pairwise Algorithm (discussed above in §3.1) is inadequate. Broe (1993) uses information theory in constructing a theory of phonological similarity, the converse of phonological contrast. For Hume (2005), the information-theoretic concept of predictability provides new insight into phonological phenomena previously attributed to markedness (see also CHAPTER 4: MARKEDNESS). Hall (2009) uses entropy – Shannon and Weaver's (1949) formal measure of uncertainty – as a means of quantifying the degree to which two phones contrast with each other, thereby creating a non-categorical theory of phonemic contrast.

While there is, at this point, no overarching consensus on the role of contrast in phonology, or even on what the right questions to ask about it are, there are some interesting points of tangency, and sometimes agreement, among the contrasting views of contrast. There is reason, then, to think that the tensions among them – between phonemic and phonetic, formal and functional, abstract and concrete – are productive ones, and that, as Aristotle (1991: 240) suggested, "understanding is made greater by contrast." *Vivent les différences!*

ACKNOWLEDGMENTS

I am grateful to the editors and two anonymous reviewers for their helpful comments and suggestions. This chapter has also benefiited from discussions with Elan Dresher, Elizabeth Cowper, Marc van Oostendorp, Aleksei Nazarov, and Oliver Lenz. Any remaining errors, omissions or other infelicities are entirely my own fault.

3 Learnability

Jeffrey Heinz
Jason Riggle

1 Introduction

How can anything (such as a child or any other computing device) automatically acquire (any aspect of) a phonological grammar on the basis of its experience?

This is the fundamental (and unresolved) question of phonological learnability, and it is essentially independent of whether the grammar is taken to be the best description of the cognitive state of the language faculty, or whether the grammar is taken to be the best description of a language pattern, independent of its cognitive status. The problem of learning a general pattern from a finite set of observations has roots in the philosophical problem of inductive logic (Popper 1959; Sober 2008). Though language learning is simply a specific instance of this problem, it has played a perennially central role in the discussion. In fact, the modern formal study of learnability was inspired by the problem of language acquisition and much of the learnability literature is couched in formal language theory, whose early period was also influenced by the founding of generative linguistics. There have been many developments in formal learning theory and related disciplines, such as grammatical inference, computational learning theory, and machine learning. For the purposes of this chapter we will refer to all of these areas with the term *learning theory*.

All characterizations of learning – whether the domain is syntax, phonology, or gardening, and whether the models are connectionist, Bayesian, or symbolic – are subject to the results of learning theory. Even if they are not intended as such, answers to the question posed at the outset of this chapter constitute hypotheses about the broad characteristics of the computations that humans perform in learning the phonology of their language(s). Our goal in this chapter is to motivate the applicability of learning theory to the problem of learning phonological grammars. In this pursuit, we discuss but a fraction of the many grammatical formalisms and models of phonological learning that have been proposed (space does not permit a comprehensive survey, so we apologize in advance to those whose work is omitted in our brief discussion of the literature). Our main points are that learning theory: (i) makes clear *what* it is that is being learned; (ii) reveals little conceptual difference in the problems of learning gradient *vs.* categorical distinctions; (iii) makes a theory of universal grammar inevitable; (iv) can make clear which properties of phonological patterns are important for learnability; (v) emphasizes understanding the *general behavior* of learning models.

§2 reviews the foundations of formal language theory and its relevance to phonology. §3 covers the main contributions of a few of the theoretical learning frameworks to our understanding of the problem of learning phonological grammars. §4 examines the role of structure in generalization. §5 reviews several phonological learning models from the perspective of learning theory.

2 Formal language theory and phonology

How do we represent the patterns (i.e. languages) that a learner might attempt to learn? (See also CHAPTER 101: THE INTERPRETATION OF PHONOLOGICAL PATTERNS IN FIRST LANGUAGE ACQUISITION for a different perspective.) In formal language theory, languages are characterized as sets, relations, or, equivalently, functions (Harrison 1978; Hopcroft *et al.* 1979). This abstraction focuses attention on the patterns themselves rather than the particular grammars that describe the patterns. Though grammars typically reflect the generalizations that we are interested in, there can be many different ways to describe the same language.

2.1 *Phonotactic patterns*

For a concrete example, consider the set of all and only the words that obey a given phonotactic pattern. In this case, the phonotactic pattern makes a binary distinction between well-formed and ill-formed words (gradient distinctions are discussed later). For example, suppose that (1) designates all and only those words which obey the constraint that obstruents in codas do not disagree in voice.

(1) {fɪst, dæft, rabd, . . .}

Already the connection between the foundations of generative grammar and formal language theory are apparent. If the "three dots" in (1) are meant to include only actual English words, then clearly the set is finite. Generative phonologists reject such finite "list" representations, because the evidence is overwhelming that phonological competence goes beyond the finitely many words a speaker actually knows. In other words, the "three dots" are meant to include every conceivable word which includes many things that are not words of English, such as those in (2).

(2) {plɪst, θæft, wabd, . . . , peifɪst, . . .}

The fact that these sets can be infinite is what necessitates a generative grammar – that is, some finite device capable of generating all and only those *logically possible* words which obey the phonotactic pattern.

2.2 *Alternations*

(Morpho)phonological alternations can be represented as *relations* (i.e. sets consisting of all and only the pairs of words that obey the alternation). The example in (3) represents word-final obstruent devoicing found in languages like Dutch (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). Again, *all* logically possible pairs that obey the alternation are included (which, in the case of Dutch, includes pairs like (ag, ak) even though Dutch lacks /g/).

(3) {(ab, ap), (ad, at), (ag, ak), . . . , (bab, bap), (bad, bat), (bag, bak), . . .}

The pairs can be taken to mean that underlying /ab/ is realized as [ap], and so on. When an underlying form *u* is paired with a surface form s, we write ⟨*u*, *s*⟩. Again, much depends on how the "three dots" are interpreted. If they are interpreted as strictly as possible, then the alternation could be generated by the *SPE* rule:

(4) $\begin{bmatrix} \text{+voice} \\ \text{−son} \end{bmatrix} \rightarrow [\text{−voice}] \;/\; \_\_ \#$

In introductory phonology, it is often pointed out that the feature [+voice] in the target of the rule is unnecessary. In the interests of having shorter rules and rules which apply maximally without being falsified, the feature [+voice] is omitted in favor of the following.

(5) $[\text{−son}] \rightarrow [\text{−voice}] \;/\; \_\_ \#$

This would mean that the "three dots" are intended to include pairs like those in (6).

(6) {(ap, ap), (at, at), (ak, ak), . . .}

Thus the rule in (5) applies even to hypothetical form like /ap/, mapping it to [ap]. Koskenniemi (1983) takes this one step further, and considers the "three dots" to include pairs like those in (7).

(7) {(a, a), (as, as), (af, af), (ar, ar), (an, an), . . .}

In other words, all hypothetical underlying forms are included in the left-hand side of some pair. The corresponding *SPE* rule could be said to apply to all possible underlying forms, though in most cases its application is vacuous. The application only results in a change when the final consonant is a voiced obstruent. Mainstream phonology never adopted this perspective, for two reasons: it made the standard *SPE* rules more difficult to write (and sometimes more complex according to the *SPE* simplicity metric), and there were some discouraging complexity results (Barton 1986; Barton *et al.* 1987). But Koskenniemi observes a conceptual shift when thinking of the patterns in this way: rules can be thought of as constraints on alternations.

Note that all phonological knowledge can be deduced from the alternation pattern. In the case of phonotactic knowledge, this is straightforward: the set of forms in the right-hand side (the "surface forms") of the alternation pattern constitutes the infinite set of all forms that obey the surface phonotactic constraints of the language. Similarly, the set of forms in the left-hand side (the "underlying forms") is an infinite set which constitutes all forms that obey the Morpheme Structure Constraints (MSCs) of the language (CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS). If the notion of the rich base is adopted, there are no morpheme structure constraints, and the left-hand side becomes all logically possible underlying forms. Finally, the alternation pattern itself determines the contrasts. Generally, any two segments that are mapped to the same surface segment in all contexts (i.e. are neutralized) are not contrastive. Because knowledge of MSCs, phonotactics, and contrasts can all be deduced from alternations, the problem of devising learners for phonological alternations is one of the most important frontiers of phonological learnability.

2.3 *Gradience*

The above discussion only makes binary distinctions of well-formedness. Recently, however, many phonologists have argued for the importance of gradient distinctions (Coleman and Pierrehumbert 1997; Zuraw 2000; Albright and Hayes 2003; Coetzee 2008; Hayes and Wilson 2008). Gradient distinctions have been used to model the confidence of speakers in the face of lexical exceptions, variation in the productions of individual speakers, and variation across speakers in experimental settings.

The scope of formal language theory is not limited to binary distinctions. The sets and relations above can be thought of as functions whose domain is all logically possible words, or pairs of words, and whose co-domain is simply 0 and 1, for "ill-formed" and "well-formed," respectively; i.e. as *indicator functions*. Phonological patterns can also be thought of as functions whose co-domain is real-valued. Moreover, if these values sum to one, then the function is a probability distribution.[1]

From the perspective of formal language theory and learning theories, the differences between indicator functions and distributions are not particularly significant. Consider the Chomsky Hierarchy:

(8) finite $\subset$ regular $\subset$ context-free $\subset$ context-sensitive $\subset$ recursively enumerable

This inclusion hierarchy classifies patterns (e.g. sets of (pairs of) forms) in terms of the complexity of the kinds of formal devices (e.g. grammars) needed to generate them (see, e.g. Harrison 1978; Hopcroft *et al.* 1979; Thomas 1997). A remarkable range of ways to characterize complexity all converge on the distinctions in (8), which is why the hierarchy is considered to be so illuminating.

Crucially, the place of a function in the Chomsky Hierarchy is entirely independent of whether its co-domain is Boolean or real-valued. For learning theory – and the central problem of generalization – the co-domain matters little. Vapnik (1998: 8) writes:

[1] Formally, let Σ^* be the set of all logically possible words given a finite alphabet Σ. A pattern L is an indicator function if $L : \Sigma^* \rightarrow \{0, 1\}$. It is real-valued if $L : \Sigma^* \rightarrow \Re$ and it is a probability distribution iff $\sum_{w \in \Sigma^*} L(w) = 1$. If Δ is another alphabet, then $L : \Sigma^* \times \Delta^* \rightarrow \{0, 1\}$ is a Boolean alternation and $L : \Sigma^* \times \Delta^* \rightarrow \Re$ is a real-valued one.

> Generalizing the results obtained for estimating indicator functions (pattern recognition) to the problem of estimating real-valued functions (regressions, density functions, etc.) was a purely technical achievement. To obtain these generalizations, no additional concepts needed to be introduced.

Thus the choice of binary *vs.* gradient distinctions should depend simply on *what* one is trying to model.

2.4 Properties of phonological patterns

What are the properties of phonological patterns? When we consider alternations, it is the case that they can be described with any grammar capable of describing regular relations (Johnson 1972; Kaplan and Kay 1981, 1994; Karttunen 1993, 1998; Eisner 1997a, 1997b; Riggle 2004).[2] It is known that all regular relations have regular domains and co-domains, so it follows that all phonotactic patterns are regular as well. This is a striking hypothesis in light of the fact that some syntactic patterns appear to belong to higher levels of the Chomsky Hierarchy (Chomsky 1956; Joshi 1985; Shieber 1985; Kobele 2006).

Though limiting phonology to regular patterns is a significant restriction, it is not nearly restrictive enough. For instance, consider a hypothetical stress pattern consisting of all forms with an even number of stressed syllables. This pattern is regular, but it is wildly unlike those observed in natural language (see e.g. Hayes 1995; Gordon 2002; CHAPTER 41: THE REPRESENTATION OF WORD STRESS). Furthermore, though assuming that phonology is regular provides significant structure to the hypothesis space, there are many learning frameworks where this is still too little structure to guarantee learnability.

Learning theorists are interested in the properties that make patterns learnable. Linguistic properties are just now beginning to be investigated for their contributions to learnability. In the case of phonological patterns, it seems likely that the relevant properties will be subregular; that is, properties that carve out some proper subclass of the regular languages. Rogers and Pullum (2007) draw attention to the Subregular Hierarchy (McNaughton and Papert 1971), which classifies regular patterns according to the properties of different kinds of grammars capable of generating them. Additional recent work which attempts to relate phonological patterns to their place in the Subregular Hierarchy include Edlefsen *et al.* (2008), Graf (2010), and Heinz (2010).

3 Learning theory

3.1 Goals

There are many good resources on formal learning theory for phonologists. Nowak *et al.* (2002) provides an excellent, short introduction. Niyogi (2006) and de la Higuera (2010) provide detailed, accessible treatments, and Anthony and

[2] The notable exception to this is reduplication (CHAPTER 100: REDUPLICATION; CHAPTER 119: REDUPLICATION IN SANSKRIT), which is arguably a morphological process (Inkelas and Zoll 2005). For regular (finite-state) approaches to reduplication, see Roark and Sproat (2007).

Biggs (1992), Kearns and Vazirani (1994), and Jain *et al.* (1999) provide technical introductions. Here we summarize some of the main ideas and common results.

Learning theory characterizes learning, and the necessary and sufficient conditions required for learning strategies to be successful, or to exhibit some other particular behavior. This focus on characterizing a learner's behavior helps us understand precisely *why* a particular learning strategy succeeds in some cases, and helps us to characterize the class of cases where it may fail.

Learning theory defines learners as functions which map experience to grammars. The experience of the learner is necessarily finite, but the target languages typically are not. Any learning procedure can be characterized in this way, including learners that are connectionist (e.g. Rumelhart and McClelland 1986) or Bayesian (Griffiths *et al.* 2008), and learners based on maximum entropy (e.g. Goldwater and Johnson 2003), as well as those embedded within generative models such as Recursive Constraint Demotion (Tesar 1995; Tesar and Smolensky 1998) and minimal generalization (Albright and Hayes 2002; Albright 2009). Results of formal learning theory apply to all of these particular proposals and many others.

By characterizing learning algorithms as functions, it is possible to focus on the functional behavior of a learning strategy rather than its procedural description. This allows one to identify relevant properties of the mapping – like the linguistic typology predicted by a function's range – that are independent of the algorithm's implementation. Moreover, these properties are often crucial in understanding precisely what kinds of patterns learners are guaranteed to learn, and where they can fail.

Learning functions can also be characterized in terms of their computational complexity. Some learning procedures may require unreasonable resources and time. The exact meaning of "unreasonable" is studied in a number of works, including Pitt (1989) and de la Higuera (1997).

3.2 Learning frameworks

In §3.2.1–§3.3 we survey three learning frameworks: Identification in the Limit from Positive Data (Gold 1967), Probably Approximately Correct learning (Valiant 1984), and the Mistake Bounds model (Littlestone 1988). Other frameworks are discussed in §3.3.1, and the major results of learning theory are given in §3.4. Across the frameworks, precisely the same conclusion explicates the necessity of (some form of) Universal Grammar: namely, without a structured, restricted hypothesis space, feasible learning is impossible.

3.2.1 Identification in the Limit from Positive Data

In the Identification in the Limit from Positive Data (ILPD) framework, there are no limits on the learner's computational resources or time, and the input is assumed to consist of an infinitely long noise-free text that contains at least one instance of every form in the target pattern. Learners are partial functions, which map initial finite portions of these texts to grammars. A learner is said to *converge* to a grammar G if and only if at some finite point every future hypothesis is G. The learner is said to identify a language (or class of languages) in the limit just in case the learner converges to a grammar that generates the target language for *any* text from the target language (for any member of the class of languages).

Though the learner's input is generously assumed to include every potentially useful finite collection of forms from the target, the criterion for success is very strict: for *any* logically possible text for the language, the learner must find a grammar that generates the target pattern without a single deviation. This scenario focuses the learning problem squarely on generalization. Given as much *finite* experience as desired, can any learning device, no matter how powerful, exactly learn some language pattern, which may be *infinite* in size? How can the learning device cover the gap between its finite experience and the infinite set which represents the capacity of a normal speaker?

3.2.2 *Probably Approximately Correct learning*

Another model that has received a great deal of attention in learning theory is the Probably Approximately Correct (PAC) framework, first introduced by Valiant (1984) and subsequently developed by Kearns *et al.* (1987), Angluin (1988a), and Blumer *et al.* (1989), among others.[3] This model offers a probabilistic perspective on efficiently learning a class of languages in terms of the probability of attaining a hypothesis that has a low likelihood of making errors modulo the number of training samples observed.

The input to the learners is determined by drawing elements from the instance space X of data points, according to a probability distribution Π. Instead of exact identification, the quality of a learner's hypothesis h is evaluated in terms of the probability that h disagrees with the target language l for any $x \in X$, randomly drawn according to distribution Π. The ingenious aspect of the PAC model is that it does not matter what the distribution is, only that the same distribution Π is used for training and for evaluation.

The *error* of a hypothesis, denoted *error(h)*, is the sum of the probability that Π assigns to data points where h disagrees with the target. Analysis of learnability in the PAC model centers on the following question:

(9) For a given level of error ε, if a learner is presented with m samples drawn from X at random according to Π, what is our confidence δ that *error(h)* of the learner's hypothesis h is less than ε?

For a language class $\mathcal{L}$ and any given learning strategy, the *sample complexity* is the number of samples m needed to ensure that, for any $l \in \mathcal{L}$ and *any* distribution Π, the likelihood is at least δ that a learner will generate a hypothesis whose error is at most ε. This leads to the following definition of PAC-learnability:

(10) $\mathcal{L}$ is PAC-learnable iff the sample complexity of $\mathcal{L}$ is a polynomial function of ε and δ.

The PAC-learning framework differs from IDLP in two important respects. In one sense, the PAC model is more stringent because the required training data and computation must be *feasible* (i.e. polynomial). But, in another sense, the PAC model

3 See Haussler *et al.* (1992) and Haussler (1995) for overviews of work in learnability theory and insights into the deep connections between the PAC, Bayesian, and mistake-bound perspectives.

is less stringent than the Gold model, in that it loosens the definition of success from exact identification of a language to *approximate* identification that is likely to be correct *most* of the time.

3.3 Mistake bounds

Littlestone (1988) observes that, in many cases of interest, learnability can be characterized by the fact that the number of mistaken classifications – and subsequent corrections – is bounded. In this online framework, a learning algorithm $\mathcal{A}$ must classify each form it observes according to its current hypothesis h, which may be updated after the correct classification is revealed. The *mistake bound* for $\mathcal{A}$ on language class $\mathcal{L}$, denoted $M_{\mathcal{A}}(\mathcal{L})$, is the number of mistaken classifications that $\mathcal{A}$ might make when facing a diabolical adversary who knows $\mathcal{A}$'s strategy and has boundless computing resources to choose the hardest language in $\mathcal{L}$, and the least helpful presentation of examples. The *optimal mistake bound* for $\mathcal{L}$, denoted $Opt(\mathcal{L})$, is the smallest $M_{\mathcal{A}}(\mathcal{L})$ for any possible $\mathcal{A}$.

Littlestone (1988) shows that if $Opt(\mathcal{L})$ is finite, then it is the case that the class $\mathcal{L}$ is both identifiable in the limit and PAC-learnable. The converse, however, does not hold; neither PAC nor Gold learnability guarantees a finite mistake bound. In the former case there might be an infinite sequence of imperfect hypotheses that all have error less than ε, and in the latter case one might be able to guarantee that the number of mistakes will be finite without being able to give a specific bound.

3.3.1 *Other frameworks*

There are other learning frameworks. Some enrich the learner's input in particular ways, which gives the learner more information and generally leads to stronger positive results. For example, Gold (1967) also considers the case of learning from positive and negative data. In this scenario, the entire class of recursively enumerable languages is learnable in principle, though no learner is efficiently computable for even the regular languages (Gold 1978). Gold also shows that restricting texts to those with certain useful kinds of structure (for example, by only allowing texts whose structure is describable with primitive recursive functions; see also Rogers 1967) can also guarantee the learnability of the recursively enumerable languages. This means that knowing crucial properties of the presentations of the data can, like negative evidence, make a huge contribution to pattern learning. However, it is highly doubtful that the natural language data children observe have either of these properties (note that occasional overt corrections do not necessarily constitute negative evidence).

Similarly, Horning (1969) shows that, when learning stochastic languages (distribution learning), if it is the case that learners are required to succeed only on texts generable by the target distribution then it follows that probabilistic context-free languages can be learned (see also Osherson *et al.* 1986). Angluin (1988b) supersedes Horning's result, and shows that the entire class of recursively enumerable distributions is in fact learnable in this sense. Like Gold's result above, these results suggest that knowing properties of the presentations of the input data dramatically increases what is learnable in principle. Crucially, however, the learners in these proofs are not remotely feasible, so these results do not inform human language learning.

3.4 *Main results*

In the ILPD, PAC, and MB frameworks surveyed above, there are significant negative results: none of the major classes in the Chomsky Hierarchy is learnable. In the case of identification in the limit from positive data, no class which is a proper superset of the finite languages is learnable. In the PAC and MB models, not even the finite class of languages is learnable. In other words, there is no learner, not even in principle, that can PAC-learn or identify in the limit from positive data all regular, context-free, or context-sensitive language patterns.

There are many ways to interpret this result (see, for example, Pinker 1979). Gold mentions restricting the problem so that not *all* regular (or context-sensitive) patterns are permitted in natural language. This possibility is promising for three reasons. First, the field of grammatical inference has identified many classes of languages that are ILDP and PAC-learnable (Angluin 1982; Muggleton 1990; Clark and Eyraud 2007; Heinz 2008; de la Higuera 2010). Many of these classes contain infinitely many patterns, and some include context-free, even context-sensitive patterns. In virtually every case, the successes occur because the language classes *are non-arbitrary* in important ways: the hypothesis space is structured. Secondly, this possibility makes sense from the studies of distribution learning above: while recursively enumerable distributions are learnable in principle they are not feasibly learnable in practice. The efficiency issues can be overcome by restricting the class of distributions to be learned (if doing so adds sufficient structure to the hypothesis space). Finally, this possibility also matches well with language typologists' repeated observations that the extensive variation that exists in natural languages appears to be limited, though stating exact universals is difficult (Greenberg 1963, 1978; Mairal and Gil 2006; Stabler 2009).

The results surveyed above lead to the following conclusion: structure matters. In particular, if the collection of language patterns to be learned has the right kind of structure – the right kind of properties – then learning is possible. The most interesting learners will use the structure or properties in the language class to license the right generalizations from their finite experience to an infinite pattern. Conversely, these results show that there is essentially no hope of learning in cases where the range of possible patterns is too unstructured.

4 The role of structure in generalization

The *structure* of the hypothesis space is what allows for generalization. In this section, we discuss very general structural properties important to learnability. We begin with a discussion of finite hypothesis spaces, then turn to structure related to what has been called the *subset problem*, and conclude with a general metric of structure known as the Vapnik-Chervonenkis Dimension.

4.1 *Finiteness as a kind of structure*

Many linguistic theories, such as Principles and Parameters and Optimality Theory, only allow finitely much variation in the typology, thereby providing a finite collection of languages. This property of hypothesis spaces is a sufficient property for success in many frameworks, including PAC and IDLP. A common brute-force strategy for any finite hypothesis space is to essentially match all grammars with the learning data, and choose the one that is the most consistent.

Although it is a sufficient property for learning, finiteness is hardly an interesting property. To see why, recall the earlier discussion of quantity insensitive (QI) stress patterns, and let us artificially place an upper bound on word length so that we only have finitely many patterns to consider. For ease of illustration we set the bound at four). If we restrict ourselves to just one string of each length, then there are 2^{10} = 1,024 logically possible patterns, of which eight are shown in (11).

(11) *Some logically possible stress patterns over 1–4 syllables*

	natural QI stress systems	*unnatural systems*
Initial	1 10 100 1000	0 01 100 0101
Final	1 01 001 0001	1 10 101 0110
Edges	1 11 101 1001	1 00 000 1010
Binary-initial	1 10 101 1010	1 01 101 1100

The artificial bound limits the class in a very significant but uninteresting way, because almost all of these 1,024 patterns belong in the "unnatural" column. The properties that determine which patterns belong to the "natural" column are going to be precisely those same linguistic properties that hold regardless of whether the class is finite or infinite. It is of far greater interest how those properties – and not finiteness – structure the hypothesis space.

Finiteness is hardly a necessary property for learnability – many infinite language classes are efficiently learnable because they have structure that learners can utilize (Jain *et al.* 1999; de la Higuera 2010). On the other hand, brute-force learners that simply traverse an enumeration of all hypotheses are not generally feasible (since finite classes can still be very large). Even for the finite case, the interesting learners are those that make use of structure (see e.g. Recursive Constraint Demotion; Tesar and Smolensky 2000).

4.2 Tell-tale sets and the subset problem

Angluin (1980) provides one benchmark for necessary and sufficient structure in a hypothesis space. If every language pattern L in the hypothesis space contains a finite set S, such that no other language pattern L' in the hypothesis space is simultaneously a superset of S and proper subset of L (see Figure 3.1), then this hypothesis space is sufficiently structured to be identified in the limit from positive data. The finite set S is called a *tell-tale set*, and we call the above property of hypothesis spaces the *tell-tale property*.

The tell-tale property is sufficient for learning, because a learner that guesses L after exposure to its tell-tale set is guaranteed to have hypothesized the smallest language in the class consistent with the sample. Characterizing the tell-tale sets of a hypothesis space – and more generally, characterizing the finite experience a learner needs to generalize correctly to the language patterns in a hypothesis space – is one of the important lessons of learning theory. It adds to the functional characterization of the learner. This is because once the tell-tale sets are characterized, when given a learner and a language pattern L from the learner's

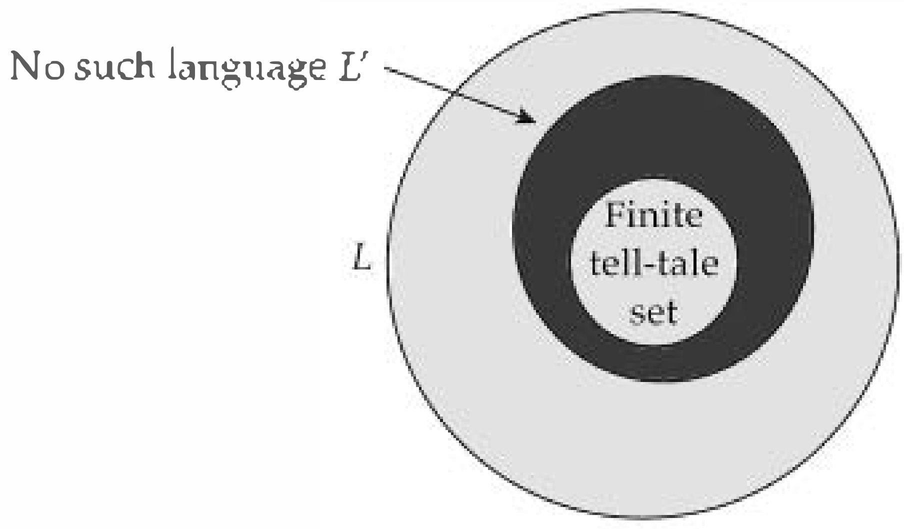

Figure 3.1 The tell-tale property

hypothesis space, one knows whether the learner will succeed given some finite sample S (by checking whether S is a tell-tale set).

Identifying properties of the tell-tale sets is important to phonologists for two reasons. First, it provides an additional way to evaluate learning proposals, since the tell-tale sets can be compared with the actual linguistic forms available to children. Secondly, knowledge of the properties of tell-tale sets allows one to understand how the learner generalizes, and may provide insight into stages of the learning process.

4.3 The Vapnik–Chervonenkis dimension

One particularly simple and robust metric of structure for concept classes is the combinatorial measure of complexity known as the Vapnik–Chervonenkis (VC) dimension (Vapnik 1998; Vapnik and Chervonenkis 1971). For a given concept class $\mathcal{L}$, the VC dimension (VCD) of $\mathcal{L}$ is the cardinality of the largest set of data S such that there is at least one language in $\mathcal{L}$ for each of the $2^{|S|}$ possible ways of labeling the data points in S as "ungrammatical" or "grammatical." If S has this property it is said to be *shattered* by $\mathcal{L}$.[4] If sets of arbitrary size are shatterable then the VCD is said to be infinite.

For an illustration, suppose that we represent coda clusters as points in $\mathcal{R}^2$ (the x–y plane) where the x-axis encodes the sonority of the second consonant and the y-axis the sonority of the first. Suppose further that $\mathcal{L}$ is the (infinite) set of languages corresponding to "half-spaces" defined by straight lines that split $\mathcal{R}^2$ into two regions, one for licit clusters and the other for illicit clusters. Figure 3.2 provides a rough example that situates the clusters *sn*, *pl*, *pt* in $\mathcal{R}^2$. In this example, a grammar that includes all three clusters can be obtained by drawing a line off to one side so that the illicit (shaded) area does not include the points. Grammars that include any two of the points can be obtained by drawing a line between the point to be excluded and the other two, and shading the side with the excluded point. These four possibilities make up the top row of Figure 3.2. The other four possibilities are illustrated in the bottom row of Figure 3.2; these are obtained by inverting the grammars in the top row. Since there is a grammar (i.e. a half-space)

[4] Formally, sample $S = \{x_1, \ldots, x_n\} \subseteq \mathcal{X}_n$ is shatterable if $\forall (v_1, \ldots, v_n) \in \{0, 1\}^n$, $\exists l \in \mathcal{L}$ such that $\forall i\ c(xi) = v_i$. The VC dimension of $\mathcal{L}$ is the cardinality of the largest shatterable sample: $vcd(L) = max\{|S| : S \text{ is shatterable}\}$.

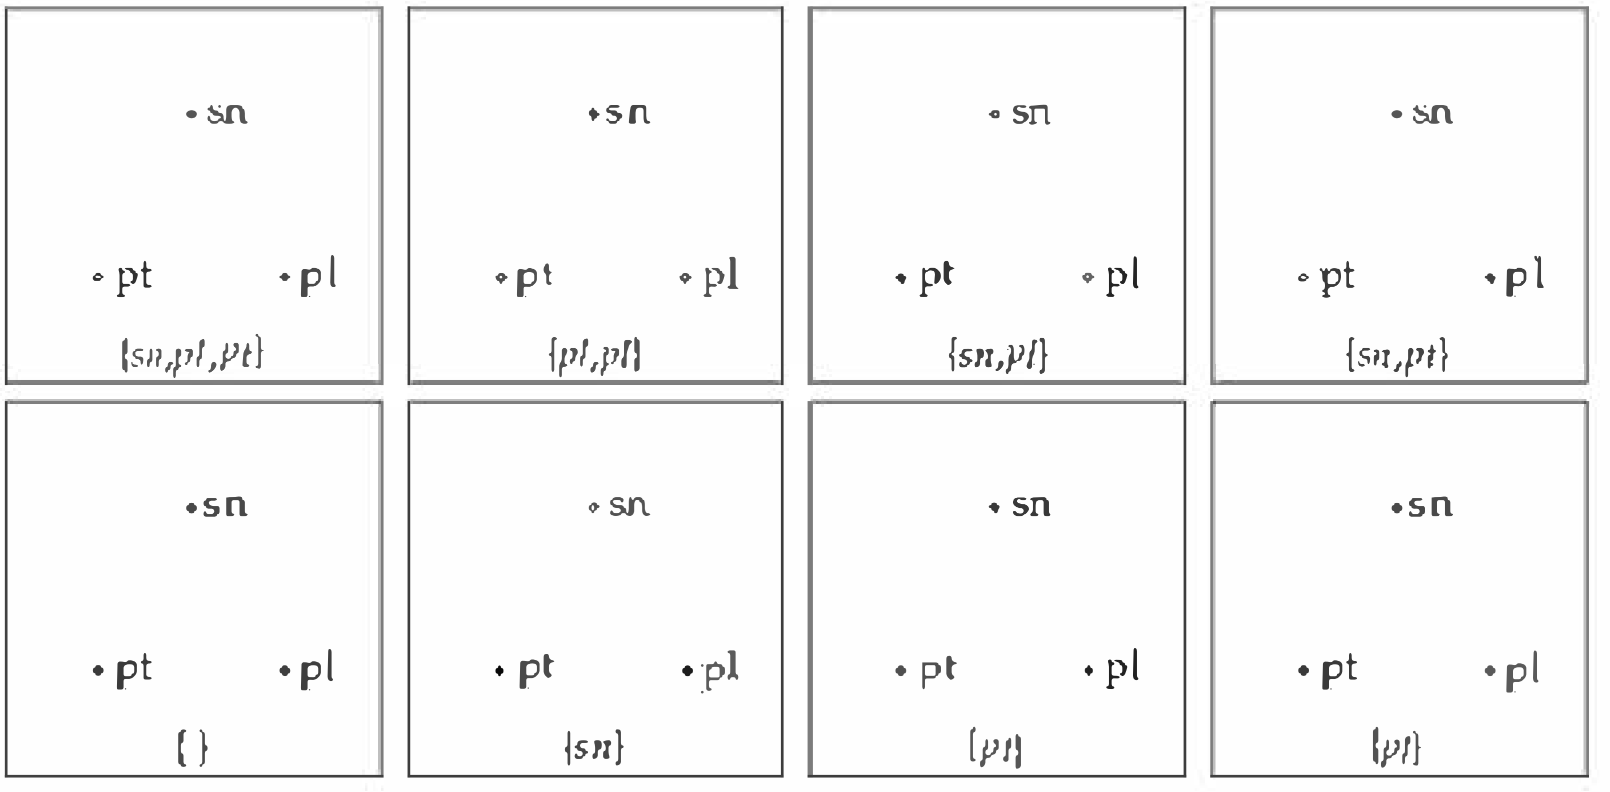

Figure 3.2 A set of three points that is shatterable by half-spaces in $\mathcal{R}^2$

for each of the eight logically possible grammatical/ungrammatical distinctions over these three points, we say that this set of points is shattered by the class $\mathcal{L}$.

Because there is a shatterable set of three points, the VC dimension of $\mathcal{L}$ is at least three. This does not entail that *every* set of three points is shatterable. For instance, any set of three collinear points cannot be shattered, because one of the points lies directly between the other two and thus cannot be separated by a half-space. This same logic explains why no set of four points in $\mathcal{R}^2$ is shatterable; either one point is inside a triangle whose corners are the other points, or the four points are the corners of a convex polygon. In the former case, no hyperplane can include the interior point while excluding all the points at the corners and, in the latter case, no hyperplane can include two opposing corners while excluding both points at the other corners. The fact that there are shatterable sets of three points, but no shatterable sets of four, places the VC dimension of half-spaces in $\mathcal{R}^2$ at three (for $\mathcal{R}^n$ it is n+1). What this means in terms of learnability is that, for any dataset with more than three points, there *must* be points whose grammaticality is interdependent.

To understand the role this structure plays in learning, consider a class $\mathcal{L}$ whose VC dimension is d and a learner with m data points. As long as $m \leq d$, it is possible that the labeling of every point is totally independent of the others. But, as soon as $m > d$, some generalization/prediction is always possible, because there are fewer than 2^m distinct ways to label the data points as grammatical or ungrammatical according to languages in $\mathcal{L}$ (otherwise the VCD would be higher). Furthermore, it turns out that when $m > d$, the number of possible labelings is a *polynomial* function of m. In essence, there is a sort of "phase transition" from exponentially many labelings when $m \leq d$ to only polynomially many when $m > d$, which makes the complexity of the hypothesis space a polynomial function of m when the VCD is finite.[5]

[5] By complexity, we mean information-theoretic complexity in the sense that $\mathcal{L}$ makes it possible to describe any labeling of $m > d$ data points with fewer than $\log_2 m$ bits. See Kearns and Vazirani (1994) for more discussion and for proofs.

A finite VCD is both necessary and sufficient for PAC-learnability (Blumer *et al.* 1989), and thus not even the class of finite languages (which has infinite VCD) is learnable in the PAC framework. It follows that none of the major classes of the Chomsky Hierarchy are PAC-learnable, which again suggests that the right characterization of the class of patterns in phonology is some class that cross-cuts the Chomsky Hierarchy.

Finally, we should note that substantive linguistic restrictions will shrink the VC dimension below the upper bound that follows from more general structural properties of the class. For example, in the grammars of Figure 3.2, phonetic factors such as ease of articulation or perception might rule out the possibility of languages that admit [pt] clusters while excluding [sl] and [sn] clusters. When additional properties such as implicational universals over sonority sequencing restrict a concept class, the VCD can quantify the structure that such factors bring to the learning problem.

4.4 Summary

The three kinds of structure surveyed here – finiteness, the tell-tale property, and the VC dimension – provide a foundation for phonologists to investigate the contribution phonological properties make to learning. Phonologists widely agree that there is intricate structure in phonological patterns. How this phonological structure relates to the structures that are relevant to learnability is a promising new research area.

5 Phonological learners

5.1 Learning rule-based alternations from pairs

Johnson (1984) presents an algorithm that takes as input a set of $\langle u, s\rangle$ pairs and returns segment substitution rules and their orderings that are logically consistent with the data. The class $\mathcal{L}$ of all languages (sets of $\langle u, s\rangle$ pairs) that are representable by ordered sequences of substitution rules is superfinite, and thus we know that this strategy cannot identify $\mathcal{L}$ in the limit from positive data. Johnson notes that this set of induced rules and orderings can be reduced via evaluation metrics and other heuristics grounded in language universals. The need for the latter shows that, while logical properties of phonological rules can restrict the hypothesis space, additional structure in linguistic systems must play a role in choosing among hypotheses.

Gildea and Jurafsky (1996) present an algorithm that takes as input $\langle u, s\rangle$ pairs from a dataset with some alternation, and returns a rule, which unlike Johnson's system can include deletion and epenthesis. Their work begins with a result from Oncina *et al.* (1993), who present an algorithm dubbed OSTIA, which identifies in the limit from positive data a subclass of regular relations describable by subsequential finite state transducers. Since the flapping rule of English can be represented this way, Gildea and Jurafsky ask whether OSTIA will acquire the

[6] Since the CMU dictionary does not include allophonic information, Gildea and Jurafsky modified the dictionary to replace [t] and [d] with [ɾ] in every instance where the rule would apply.

flapping rule from an appropriately modified version of the *Carnegie Mellon University Pronouncing Dictionary* (CMU 1993).[6] Essentially, they ask whether the CMU contains a tell-tale set (for OSTIA). Because OSTIA fails to learn the flapping rule from the CMU dictionary, the answer is no, probably because a tell-tale set would need to include non-English forms like *ttt*.[7]

Gildea and Jurafsky then augment OSTIA with three phonologically motivated principles. These are Faithfulness: underlying–surface pairs tend to be similar; Community: similar segments tend to behave similarly; and Context: phonological rules can access variables in their context. This modified OSTIA algorithm gets much closer to acquiring a rule that represents the English flapping alternation. Gildea and Jurafsky conclude that these biases aid learning, and argue for a research program for evaluating the contributions of such biases. We agree wholeheartedly; domain-appropriate biases that add structure to or otherwise reduce the hypothesis space are likely to aid learning by also reducing the size of tell-tale sets. However, it is critical to ask exactly how and why this occurs, and most crucially what class of rules are learnable with the biases in place. To our knowledge, neither of these interesting questions has been addressed.

Albright and Hayes (2003) also aim to learn alternations expressed by phonological rules. Their algorithm takes as input $\langle u, s\rangle$ pairs and returns a set of rewrite rules with confidence scores. A central idea in their rule construction procedure is a strategy called minimal generalization. The idea is that if two sounds are known to undergo some alternation, then one may conclude that all sounds in the smallest natural class containing those two sounds also undergoes the alternation (cf. the Community principle). In addition, the algorithm assigns a confidence score to each rule based on the frequency of the rule's application in the corpus. The confidence score can be used to analyze free variation, or phonologically conditioned allomorphy (as with the irregular English past tense).

Albright and Hayes do not focus on an analytical characterization of the class of languages that their algorithm can learn, but instead compare the behavior of their algorithm to the judgments of native speakers on "wug" tests (Berko 1958; CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY). These comparisons reveal intriguing correlations, but they are somewhat difficult to interpret. On the one hand, a shift in focus from the analysis of properties that define various learnable classes of languages to the behavior of humans is undoubtedly appealing to any who feel that the results of learnability theory are too abstract and remote from real-world learning problems. On the other hand, having observed that an algorithm $\mathcal{A}$ and human subject $\mathcal{H}$ give similar responses for a particular set of test items T after being exposed to a set of training data D, it is not clear what we can conclude about $\mathcal{H}$ or the relationship between $\mathcal{A}$ and $\mathcal{H}$, because they might wildly diverge for some other data T' and D'. The goal of determining which properties of the data critically underlie learnability – or in this case the correlation between $\mathcal{A}$ and $\mathcal{H}$ – is precisely why learning theory focuses mainly on the

[7] It should be emphasized that OSTIA learns a rule that is consistent with the data. It is just that the alternation that this rule describes is not the same infinite set of ⟨underlying form, surface form⟩ pairs that phonologists think the flapping rule ought to describe.

properties of classes of languages or the *general behavior of specific algorithms*, as opposed to the specific behavior of specific algorithms.

5.2 *Learning OT grammars*

Optimality Theory (Prince and Smolensky 1993) is a theory of grammar which characterizes alternations by a strict ranking of constraints which evaluate possible $\langle u, s\rangle$ pairs. A $\langle u, s\rangle$ pair belongs to the alternation just in case it is optimal among the (possibly infinite) range of $\langle u, s'\rangle$ pairs according to the ranked constraints. (CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS).

For a fixed (universal) set of k constraints there are at most $k!$ languages and thus any set of constraints defines a finite class of languages that is learnable in the limit. Though the members of any finite class of languages can be identified in the limit by enumerating the languages, such an approach is not feasible in practice. An early positive result for OT learning was provided by Tesar and Smolensky's (1993) Recursive Constraint Demotion (RCD) algorithm. Tesar and Smolensky (1996: 26) subsequently showed that the structure that ranked constraints given to the hypothesis space guarantees that RCD will successfully identify languages with a polynomial mistake bound (unlike a brute-force enumeration).

5.3 *The VC dimension of OT and HG*

As mentioned earlier, finitude is itself a very simple kind of structure for concept classes. With regard to the VC dimension, this is reflected by the fact that the VCD of any finite set of grammars is at most $\log_2$ of the cardinality of the set. This follows because it takes at least 2^n concepts to shatter a set of n data points. Hence the VCD of any set of OT grammars over a fixed set of k constraints is at most $\log_2 k!$, because there are only $k!$ possible rankings. By contrast, if we take the same constraints and consider grammars defined by real-valued *weightings* (as in Harmonic Grammar; HC)[8] there are infinitely many possible grammars and thus no a priori bound on the VCD.

This pair of cases proves to be quite illuminating. Though the finitude of $\mathcal{L}$ (or lack thereof) provides some information about its learnability, the characterization is both coarse and incomplete. In the case of OT, the finitude of the concept class bounds the VC dimension at $\log_2$ of $k!$ (which is on the order of $k \log_2 k$). Unsurprisingly, the hypothesis space has more structure than its mere finitude, and this structure bounds OT's VC dimension at $k-1$ (Riggle 2009). By contrast, one might expect the infinite hypothesis space of HG to have much less structure, but it turns out that learning weightings can be represented as the problem of learning half-spaces in $\mathcal{R}^k$ (as in Figure 3.2), so the VC dimension cannot be greater than $k+1$ and in fact is $k-1$ (Bane *et al.* 2010). This parity means not only that both models are efficiently learnable, but that the learning problems are essentially of equal complexity (recalling Vapnik's observation in §2.3).

[8] In addition to HG (Legendre *et al.* 1990; Smolensky and Legendre 2006; Pater 2009), a range of weighted models have been proposed by Goldsmith (1990, 1991, 1993a, 1993b) and a few others.

5.4 *PAC learning of rankings and weightings in OT and HG*

Both OT and HG have the same VC dimension: k–1 for grammars with k constraints. For a concrete example of what this means in terms of learnability, consider the three hypothetical tableaux in (12).

(12)

input 1	c_1	c_2	c_3	c_4	
Cand *a*		*			implication: $a > b$ iff $w_1 > w_2$ in HG or $c_1 >> c_2$ in OT
Cand *b*	*				implication: $b > a$ iff $w_2 > w_1$ in HG or $c_2 >> c_1$ in OT

input 2	c_1	c_2	c_3	c_4	
Cand *c*			*		implication: $c > d$ iff $w_2 > w_3$ in HG or $c_2 >> c_3$ in OT
Cand *d*		*			implication: $d > c$ iff $w_3 > w_2$ in HG or $c_3 >> c_2$ in OT

input3	c_1	c_2	c_3	c_4	
Cand *e*				*	implication: $e > f$ iff $w_3 > w_4$ in HG or $c_3 >> c_4$ in OT
Cand *f*			*		implication: $f > e$ iff $w_4 > w_3$ in HG or $c_4 >> c_3$ in OT

In both OT and HG it is possible to formulate sets of k–1 binary tableaux like those in (12), in which each of the exponentially many (i.e. 2^{k-1}) ways to choose a set of winners is possible under some grammar. However, as soon as a learner has seen k or more tableaux – in either model – there are only polynomially many ways to choose a set of winners (i.e. there is no set of four tableaux in which all patterns of winners are possible). The remarkable consequence of this fact is that any learner that meets the simple condition that its hypotheses are always consistent with all previous observations is guaranteed to PAC-learn a ranking/weighting from a set of training data whose size is a linear in the number of constraints.[9]

Given a constraint set and a dataset comprising ⟨winner, loser⟩ pairs, Recursive Constraint Demotion (Tesar and Smolensky 1993, 1998, 2000; Tesar 1995, 1997, 1998a, 1998b) constructs a stratified hierarchy $\mathcal{H}$ (i.e. a weak ordering) that is consistent with the data by constructing strata consisting of constraints for which, in each remaining ⟨w, l⟩ pair, w has no more violations than l, and then discarding any pair in which w is optimal according to the $\mathcal{H}$ constructed thus far. This process is reiterated until all ⟨w, l⟩ pairs are gone (or until no constraint favors a winner, in which case no ranking is consistent with the data). If, in addition to $\mathcal{H}$, RCD records the ranking conditions that support its correct predictions, then it can generate hypotheses consistent with all previous observations and thereby be guaranteed to PAC-learn rankings from in the order of k random samples (the extra record-keeping is needed to ensure consistency because "accidentally" correct predictions can be undone by subsequent updates to $\mathcal{H}$).

[9] The bound on sample complexity m, according to VC dimension d, is $m \leq \lceil (4/\varepsilon)\ (d \ln (12/\varepsilon) + \ln (2/\delta)) \rceil$; see e.g. Blumer *et al.* (1989).

For HG grammars, Potts *et al.* (2010) propose a consistent learner that finds a constraint-weighting $w = \langle w_1, w_2, \ldots, w_k \rangle \in \mathcal{R}^k$ that simultaneously satisfies all the linear inequalities that correspond to a set of ⟨winner, loser⟩ pairs – such as those in (12) – using a technique from linear programming called the *simplex algorithm* (see e.g. Papadimitriou and Steiglitz 1998: chapter 2). Though their learner is intended to operate over batches of $\langle w, l \rangle$ pairs, they could conceivably be recast as an "error-driven" learner, so that, rather than generating a new hypothesis for each new datum based on all prior observations, a new hypothesis would be generated only in the event of an erroneous prediction.

RCD also has an error-driven formulation, and an especially useful property of error-driven learners is that they only need to "remember" data points that they misclassified (often called "supports") in order to faithfully reconstruct correct predictions for all forms in the training sequence. This allows a mistake bound to double as a memory bound on the amount of information that a learner could ever need to store.

Pater (2008) observes that Rosenblatt's (1958) "perceptron" can be straightforwardly applied to HG learning. The perceptron is an error-driven learner that maintains a weighting $w = \langle w_1, w_2, \ldots, w_k \rangle \in \mathcal{R}^k$, with which they make predictions as follows. For candidates a and b, the value $\Delta(a, b) \in \mathcal{Z}^k$ is the result of subtracting b's violations from a's violations (e.g. in (10), $\Delta(a, b) = \langle -1, 1, 0, 0 \rangle$). This point in k-dimensional space is "in" just in case it lies within the half-space described by w (i.e. if the inner product $w \cdot \Delta(a, b)$ is greater than zero; this is a linear-classifier like the ones in Figure 3.2). Upon misclassifying a data point, the hyperplane represented by the weight-vector w is nudged in the direction of $\Delta(a, b)$. Though multiple errors on the same data point are possible (i.e. the update rule is non-corrective), the perceptron is guaranteed to eventually converge to a correct weighting if one exists. In the general case, the perceptron is not a PAC-learner, because the sample complexity can be exponential in k when the probability mass of Π is concentrated on positive and negative data points that are packed too close to the hyperplane that separates them. Moreover, though the perceptron will converge eventually, it is precisely these "hard" probability distributions that lead to many mistakes.

5.5 Mistake bounds in OT and HG

Regarding optimal mistake bounds, Littlestone (1988) shows that, while a lower bound on $Opt(\mathcal{L})$ is set by $\mathcal{L}$'s VC dimension, in cases where $\mathcal{L}$ is finite, the upper bound of $Opt(\mathcal{L})$ is $\log_2|\mathcal{L}|$. This follows because the strategy of making predictions that accord with a plurality of the hypotheses consistent with previous observations only errs on data points that half or fewer of the remaining hypotheses correctly classify (else the correct prediction would have been made) and, as such, each error halves the set of viable hypotheses which allows no more than $\log_2|\mathcal{L}|$ errors.

This suggests room for improvement over RCD's quadratic mistake bound of $k(k-1)/2$, which follows from the maximum number of stratified hierarchies that RCD can entertain on the way from all k constraints in a single stratum to a total order (Tesar and Smolensky 1996: 26). To implement Littlestone's halving algorithm for OT, Riggle (2008) proposes a recursive function for calculating the fraction of the space of possible rankings that are consistent with a set of optimal candidates, a quantity he calls the r-volume. For just two candidates a and b, if A denotes the constraints for which *a* has fewer violations and *B* those for which *b* has fewer violations, then the fraction of rankings that select *a* is precisely |A| / (|A|+|B|).

(13)

input	c_1	c_2	c_3	c_4	
Cand *a*		*	*	*	the *r*-volume of candidate *a* is ⅓ (i.e. 8 rankings)
Cand *b*	**		*		the *r*-volume of candidate *a* is ⅔ (i.e. 16 rankings)

Unfortunately, though computing *r*-volume for larger sets of candidates can often be done in ways vastly more efficient than exhaustive search, there are "hard" cases where computation will always be intractable.[10] This highlights the core tension between power and efficiency in learning; RCD's mistake bound may be sub-optimal but it is still polynomial and it is obtainable at amazingly low computational cost, whereas the halving algorithm yields a nearly optimal mistake bound (i.e. within a logarithmic factor of $k-1$), but does so by introducing computation that is intractable in the worst case.

Analysis of mistake bounds illuminates a significant point of divergence between OT and HG. Though the two models have the same VC dimension, the mistake bound of the former is finite, while the mistake bound of the latter is not. This is so because it is possible to construct a sample sequence of arbitrary length in which each new data point causes an error that leads to an ever smaller change in the weighting. Thus, though learners that use strategies such as the perceptron algorithm will eventually converge to a correct constraint weighting for any HG grammar (see Pater 2008), there is no general bound on the rate of convergence (i.e. the number of mistakes along the way) that holds for all possible sets of training data.

Partially due to this fact, much of the work on learning linear classifiers has focused on the way that specific properties of samples affect learnability. For instance, the quantity γ, known as the *margin*, measures the distance (in high dimensional space) between the grammatical and ungrammatical points and the line that separates them. Given γ, one can derive bounds on the number of mistakes and the rate of convergence. In fact, if the margin is large enough, it supplants the dimensionality of the sample space in determining the VC dimension of the learning problem. Thus, with large margins, HG grammars with thousands of constraints might nonetheless have very low mistake bounds and sample complexity, suggesting that searching for so-called large-margin classifiers might provide linguistic insights.

5.6 *Learning segmental adjacency patterns*

Hayes and Wilson (2008) develop a learner that takes as input a list of words and outputs a maximum entropy grammar consisting of a finite set of weighted constraints that define a probability distribution over forms. The algorithm has several properties of interest. First, the constraints it returns are essentially *n*-grams and thus, in its simplest form, the algorithm can learn adjacency patterns, but not harmony patterns. Secondly, the units in these constraints are feature bundles denoting natural classes. Thirdly, the algorithm is designed to first search for more general constraints (i.e. those with smaller *n* and fewer features). Fourthly, following the

[10] This follows from the fact that pairs of candidates can be used to define partial orders over the constraints and the fact that the problem of counting the linear extensions of partial orders is #*P*-Complete.

principle of maximum entropy, the model weights constraints so that their observed number of violations in the training data matches the expected number.

The authors provide case studies using corpus data suggesting that phonological features play a crucial role in generalization. However, Albright (2009) explores feature-based generalization in Hayes and Wilson's model, as well as one based on minimal generalization, and shows that the specific contribution features make to learning remains unclear (CHAPTER 17: DISTINCTIVE FEATURES). This is an interesting class of models, and the phonological biases with the hypothesis space are in many ways appealing. However, as with the biases in Gildea and Jurafsky (1996), formal analysis of their contribution is needed.

5.7 *Learning Harmony Patterns*

Hayes and Wilson (2008) show that when representations are enriched by allowing segments with certain features to project onto tiers (where segments without such features are not projected) (see CHAPTER 14: AUTOSEGMENTS; CHAPTER 105: TIER SEGREGATION), if the algorithm is allowed to search for *n*-gram-like constraints on these additional levels of representation then it is possible to learn long-distance phonotactic constraints (i.e. harmony; see CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS). Hayes and Wilson (2008: 32) conclude that "in controlled comparative simulations, [tiers] makes phonotactic learning possible where it would not otherwise be so." It is, however, critical to bear in mind that this result tells us something about a particular *algorithm*, and not something about the linguistic phenomenon of *harmony* (i.e. a class of languages). Indeed, Heinz (2007, 2010) shows that long-distance phonotactic constraints can be learned without tiers (see below). Furthermore, the tiers that are critical to the success of the algorithm are taken by Hayes and Wilson to be antecedently given, but this does not entail (nor do the authors claim) that they must be antecedently given. Goldsmith and Riggle (forthcoming) offer a strategy for learning long-distance patterns that has many similarities to Hayes and Wilson's approach, but begins with an algorithm from Goldsmith and Xanthos (2009) for "discovering" tiers via unsupervised categorization of the sounds of corpus into vowels and consonants.

Heinz (2007, 2010) shows that phonotactic patterns derived from long-distance agreement patterns (Hansson 2001; Rose and Walker 2004) can be learned without tiers, using the notion of a discontiguous subsequence of length two. This idea is similar to bigram learning where learners keep track of contiguous subsequences of length two. Heinz provides proofs and formal analysis of classes of patterns this algorithm is able to identify in the limit. Unfortunately, the absence of analysis of what classes are learnable by the previously discussed phonotactic learners hinders comparisons of the models.

5.8 *Learning stress patterns*

Stress patterns can be thought of as word-well-formedness conditions, and hence a kind of phonotactic pattern. Since stress typologies are diverse and well established, learning stress patterns has become a popular and challenging proving ground for learning algorithms (CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE; CHAPTER 41: THE REPRESENTATION OF WORD STRESS; CHAPTER 44: THE IAMBIC–TROCHAIC LAW; CHAPTER 57: QUANTITY-SENSITIVITY).

Dresher and Kaye (1990) propose a learning model in the Principles and Parameters framework for learning stress patterns. In this framework, a grammar is a vector of parameters. The learner takes as input a list of words, and for each word, sets parameters as determined by checking whether the word consists of particular properties, called cues. Gillis *et al.* (1995) implement the model with interesting discussion regarding what constitutes an appropriate cue. They only provide input words up to four syllables in length, and demonstrate that the learner succeeded in learning 75 percent of the patterns. Related work includes Gibson and Wexler's (1994) Triggering Learning Algorithm (see also Frank and Kapur 1996 and Niyogi 2006: chapter 3 for discussion).

Goldsmith (1994) and Gupta and Touretzky (1994) investigate how quantity-insensitive stress patterns can be learned using dynamic networks. Although the models differ in their specifics – Goldsmith employs a different updating procedure than Gupta and Touretzky, who use a standard perceptron – these methods achieve a certain level of success in learning the patterns for which data is presented.

Tesar and Smolensky (2000) discuss twelve OT constraints which yield a typology of quantity-sensitive stress patterns. The OT constraints make reference to feet (CHAPTER 40: THE FOOT), which are not part of the learning input. Consequently, another procedure is necessary to parse the learner's input data, so that it can be processed by RCD (the underlying form is assumed to be a string of the right number of unstressed syllables). This procedure is non-trivial, as there may be different parses (i.e. foot assignments) for a given stress pattern. Tesar (1998a) proposes a procedure called *robust interpretive parsing*. To test their system, Tesar and Smolensky hand-selected a test set consisting of 124 languages containing most of the "familiar metrical phenomena" analyzable with their constraints (Tesar and Smolensky 2000: 68). Note, however, that they acknowledge this set is not necessarily representative of the whole typology generated by their constraints. Using robust interpretive parsing, they report that if the initial state of the learner is monostratal – that is, no a priori ranking – then the learner succeeds on about 60 percent of the languages in the test set. When a particular initial constraint hierarchy is adopted, the learner achieves ~97 percent success. So in this case, robust interpretive parsing (mostly) addresses the problem RCD has with hidden structure (for this particular set of test data).

Heinz (2007, 2009) proposes that all phonotactic patterns are neighborhood-distinct, which is a locality condition defined in automata-theoretic terms. It is shown that all but two of 109 descriptions of the world's stress patterns are neighborhood-distinct and that a particular learner that uses this property can learn 100 of these 109 patterns exactly. Although not every pattern can be learned, the patterns acquired in the "failure" cases differ only slightly from the target patterns. Heinz concludes that this particular notion of locality structures the hypothesis space in a way that makes a significant contribution to phonotactic learning.

6 Conclusions

We have argued that learning theory affirms the role of structure as a solution to the problem of generalization, and that there are ideas and methods within learning theory that allow one to measure this structure and the class of languages which have such structure. These tools offer phonologists a way to characterize the contribution various structural properties of phonological patterns can make to learning.

With the exception of a substantial amount of work on learning in Optimality Theory (and Heinz 2010, on phonotactics), it is striking that most proposed learning algorithms have been evaluated only with case studies. Though such studies are suggestive and can be vital in the development of models, in order to know whether a given case study illustrates general properties of a problem we need analytical results that show *why* the algorithm succeeds, what properties of the training sample are critical to success, and how the algorithm maps experience to grammars.

Finally, we have emphasized what we believe to be the most fruitful direction for future research. Phonologists ought to identify properties of phonological patterns that structure the hypothesis space or reduce its size (cf. Heinz 2009; Tesar, forthcoming). This approach works in tandem with, rather than in lieu of, formal analysis.

4 Markedness

Elizabeth Hume

1 Introduction

Markedness is one of the most widely used concepts in phonology and other areas of linguistics. The picture is complicated, however, by the fact that the term is used in different ways, as summarized in (1) (see also Haspelmath 2006).

(1) *Markedness usages*

a. *Descriptive markedness*
An abstract relation holding over members of a set of observations displaying asymmetry, such that one subset is unmarked and the other is marked.

b. *Theoretical markedness*
A universal principle or laws that guide language acquisition, loss, inventory structure, processes, rules, etc. toward the unmarked form.

c. *Markedness constraints*
A technical term in Optimality Theory referring to a category of constraints that evaluate the well-formedness of output structures.

As stated in (1c), one usage of markedness appears in Optimality Theory (OT), where the term describes a category of constraints that evaluate output structures. The technical use of markedness in OT is distinct from other usages: "A markedness constraint in OT may produce results related to [the] descriptive or typological sense of markedness, but the formal constraint and the typological observation are two different things" (McCarthy 2002: 15). Markedness constraints are not discussed in this chapter; the reader is referred to CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS, where the topic is addressed in detail.

A more common usage of the term, given in (1a), is descriptive in nature, referring to an abstract relation holding over a set of language observations. Descriptive markedness has served as an analytic tool to categorize sounds and other linguistic elements. It has also been commonly used as an instrument for comparing different language systems leading to the creation of language typologies. This concept of markedness dates back to linguists from the Prague School, most notably Nikolai Trubetzkoy and Roman Jakobson. Trubetzkoy (1939) used the term in order to describe the relations among members of a sound opposition: one member of the opposition bears some property or "mark" that the other member lacks. For example, given the set of consonants [m n b d], the nasal sounds [m n] can be described as being in opposition to the oral sounds [b d] regarding the property *nasal*: [m n] bear the "mark" of nasality, while [b d] do not. Thus, nasal consonants can be referred to as the marked category and oral consonants the unmarked category (see also Jakobson 1932; Jakobson and Pomorska 1990; CHAPTER 11: THE PHONEME).

In contemporary linguistics, the terms "marked" and "unmarked" have come to carry much more meaning than simply "bearing some property," as exemplified in (2) by terms drawn from the literature. (See §5 for discussion of some of these terms, including the noted contradiction regarding perceptual salience.) Thus, describing an observation as *unmarked* is often taken to mean that it is, for example, more frequent, natural, simple, and predictable than the marked observation of the comparison set. The unmarked is also often referred to as the *default* member of a class; that is, it is the member to be assumed, the most basic member of the set, barring further requirements or information.

(2) *Markedness descriptors*

unmarked	*marked*
natural	less natural
normal	less normal
general	specialized
simple	complex
inactive	active
more frequent	less frequent
optimal	less optimal
predictable	unpredictable
acquired earlier	acquired later
more phonetically variable	less phonetically variable
articulatorily simple	articulatorily difficult
perceptually strong	perceptually weak
perceptually weak	perceptually strong
universal	language-specific
ubiquitous	parochial

A further meaning of the term "markedness" is theoretical in nature, referring to a universal principle or laws that guide language toward the unmarked, (1b). The theoretical use of markedness has been at the core of modern phonology and the focus of much debate. It is also the main focus of this chapter. Some key areas of controversy are listed in (3), though it should be pointed out that given the enormity of this topic, it is difficult to do justice in a single chapter to all the debates surrounding markedness. Consequently, the reader is encouraged to consult the references cited throughout and related *Companion* chapters for additional discussion.

(3) *Some key areas of controversy*

a. General approaches to predicting markedness patterns.
b. The relation of markedness to phonological theory.
c. The formal expression of markedness.
d. Criteria for predicting markedness patterns.

2 General approaches to predicting markedness patterns

It is uncontroversial that asymmetrical patterns exist within and across languages. Consider vowel epenthesis, for example (CHAPTER 67: VOWEL EPENTHESIS). It has been widely observed that in some languages, one vowel from the language's inventory is consistently used by speakers to break up ill-formed consonant clusters. In English, this vowel is typically schwa or [ɪ] (CHAPTER 26: SCHWA). For example, as a native English speaker, I pronounce the Polish city name *Gdansk* as [gədænsk], with schwa inserted in the [gd] cluster, rather than [i e a o] or any other English vowel. Thus, we can say that, given the set of English vowels, schwa patterns asymmetrically from other vowels within that set. Expanding our investigation to include other languages, we observe that the epenthetic vowel is [i] in Maltese, [e] in Spanish, and [œ/ø] in French. By defining the set of observations as the epenthetic vowels in English, French, Maltese, and Spanish, we can observe a further asymmetry (among possibly others) having to do with the nature of the vowel selected: in three languages (English, Maltese, Spanish) the epenthetic vowel is unrounded, and in one (French) it is rounded (see §5.5 for additional discussion). Asymmetrical patterns such as these are commonly called markedness observations. That asymmetries such as these exist is not in question; the controversy surrounds how to predict them.

There are two general approaches to this issue. The first draws on markedness itself as the explanation for the asymmetries. In this sense, markedness laws form part of a person's innate knowledge of language (i.e. *competence*; Chomsky 1965, 1986), the position widely adopted by generative phonologists. In this view, markedness forms part of Universal Grammar, and is thus predetermined for speakers of all languages. Further, markedness is a formal issue, in that markedness patterns are predicted from the formalism. For simplicity, I will refer to this as the *markedness-through-formalism* approach.

An alternative, which I will call the *markedness-through-mechanism* approach, attributes markedness patterns to a confluence of factors that interact with grammatical systems, and relate to physical, cognitive, and social mechanisms shared by all humans (e.g. Lass 1975; Stampe 1979; Comrie 1983; Menn 1983; Boersma 1998; Blevins 2004; Hume 2004b; Mielke 2008; Bybee, forthcoming). Comrie (1983), for example, argues that markedness can be explained in terms of human interaction with other humans and with the world, and not as an accidentally inherited or a purely formal property of language. Since independent factors are able to explain the patterns, he argues, there is no need for recourse to Universal Grammar, and markedness as a universal guiding principle need not exist.

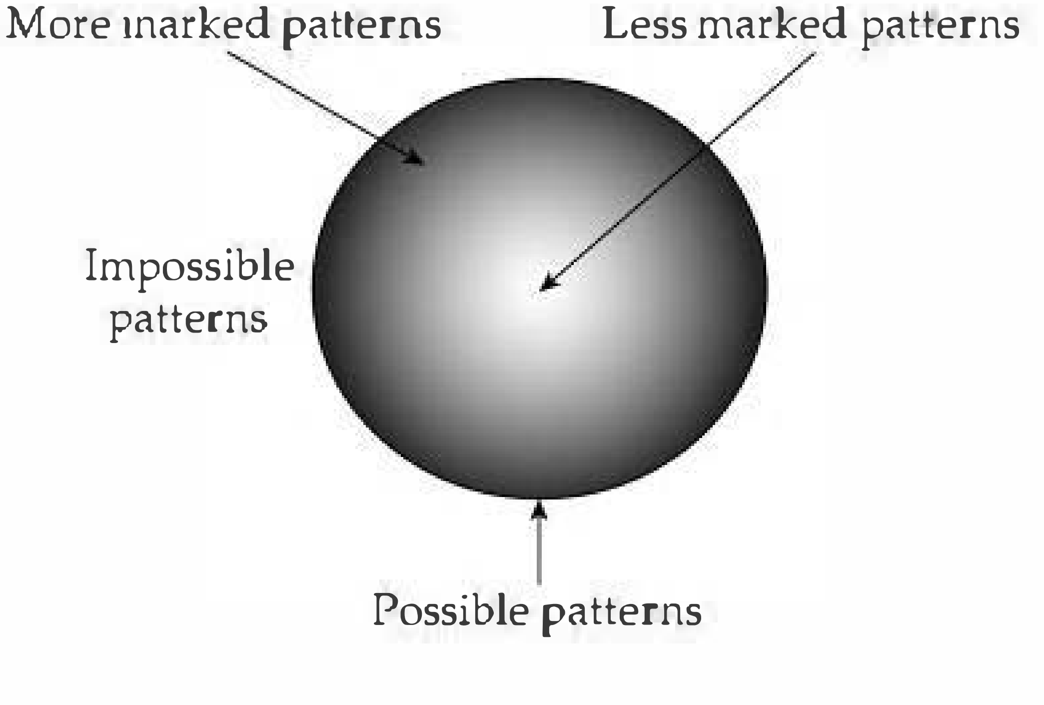
Asymmetrical patterns in syllable structure exemplify the nature of the debate. It has long been observed that there are preferred syllable types cross-linguistically (e.g. Cairns and Feinstein 1982; Vennemann 1988). For example, onsets with sonority rising into the nucleus (e.g. [blV]) are more common than those with sonority falling into the nucleus (e.g. [lbV]) (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE; CHAPTER 49: SONORITY; CHAPTER 55: ONSETS). Such cross-linguistic preferences for syllable type are commonly described in markedness terms: an onset cluster with rising sonority is less marked than one with falling sonority. Berent *et al.* (2007) tested the claim that listeners have innate knowledge of such patterns. Results from their perception experiments indicate that the asymmetrical patterning of syllable types observed cross-linguistically is reflected in the linguistic behavior of their English listeners: the more an onset cluster is marked (i.e. onsets with sonority falling into the nucleus), the more likely it is to be perceived with an illusory epenthetic vowel (presumably as a means of creating a less marked onset) (see also CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). Their interpretation of the findings is in keeping with the markedness-through-formalism approach to predicting markedness patterns: the results provide evidence that knowledge about the markedness of onset clusters is part of Universal Grammar (UG). Proponents of the markedness-through-mechanism approach would interpret the findings differently, as expressed in Peperkamp's (2007: 634) response to Berent *et al.*'s conclusion: "A possible account of the reported markedness effect that makes no appeal to innate knowledge lies with phonetic differences across onset clusters with varying sonority profiles." In particular, the human perceptual mechanism is responsible for a human's ability to detect phonetic differences, rather than assuming that the individual is born with knowledge about these differences.

It is important to note that it is not the notion of innateness that differentiates these approaches; both assume innateness. Rather, the difference lies in *what* is considered innate. In the markedness-through-mechanism approach, it is the physical, cognitive, and, for some, social mechanisms guiding language acquisition, loss, and usage that are innate. In the markedness-through-formalism approach, on the other hand, it is the formalism from which markedness patterns are derived that is innate. Depending on the particular theory, the formalism may be rooted in the physical and cognitive mechanisms assumed in the former approach.

3 The relation of markedness to phonological theory

Markedness has played an important role in the development of phonological theories; however, approaches have differed with regards to where the domain of explanation for markedness patterns resides. In one approach, markedness observations are directly expressed in a theory of phonology, while in another, they are the basis for a separate theory of markedness. By means of illustration, assume that the sphere in (4) contains all possible sound patterns; impossible patterns reside outside of the sphere. Further, the space within the sphere is graded, with more marked patterns occurring further away from the core.

(4) *Language patterns*



One approach assumes separate theories to account for the set of language patterns in (4): a theory of markedness and a formal theory of phonology (or grammar). Examples include Chomsky and Halle (1968: ch. 9), Kean (1975), Cairns and Feinstein (1982), Mohanan (1993), Calabrese (1995), Steriade (1995), and Boersma (1998). The goal of markedness theory, according to Chomsky and Halle (1968), is to distinguish between more and less natural segments and rules, and to determine the degree of admissibility of a given lexical item. In other words, the domain of markedness theory is internal to the sphere in (4). A theory of grammar serves a different purpose: to distinguish between possible and impossible items, i.e. between elements that do and do not occur within the sphere (see Mohanan 1993 and Calabrese 1995 for related discussion).

This model of markedness was first proposed for phonology in chapter 9 of Chomsky and Halle (1968; *SPE*). Like Jakobson (1971a) and Greenberg (1966), *SPE* treats markedness as a universal principle which guides language acquisition and the formation of phoneme inventories. In addition, it serves as an evaluation metric on the selection of analytic options in the formulation of phonological rules and underlying representations: "children construct grammars to account for the data they are exposed to within the constraints imposed by the formalism, and an evaluation metric selects the simplest possible grammar for the given data" (Mohanan 1992: 639, based on *SPE*). Marked options impose a cost on an analysis, while unmarked ones do not; qualifiers such as *simpler, preferred, optimal,* and *more highly valued* are commonly used to convey the less costly nature of the unmarked option. Steriade (1995: 118) suggests that a theory of markedness should also be able to "document the validity of . . . universal statements" such as feature co-occurrence constraints, "and seek an explanation for their universal status."

A second approach to predicting markedness patterns assumes a single theory. In this view, the goal of an adequate theory of grammar is to be able to predict not only possible grammars (inside *vs.* outside the sphere), but markedness observations as well (gradations within the sphere). Such an approach is seen in, for example, Archangeli (1984), Prince and Smolensky (1993), Calabrese (1995), Rice (1996), de Lacy (2002, 2006), and made explicit in Sagey's (1986: 9) influential dissertation on feature organization:

> It should be possible to represent within [a theory of phonology] any phonological process or form that is a possible human language, and it should be impossible to represent phonological forms and processes that do not exist in human language . . . Another requirement on the theory is that the relative simplicity of describing in the representation each process or form that occurs should reflect its relative naturalness, in the sense of its frequency of occurrence in the languages of the world. That is, more marked forms and processes should be correlated with more marked representations.

As discussed further below, this perspective is fundamental to some theories of underspecification (e.g. Archangeli 1984; CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION) and feature organization (e.g. Clements 1985; Avery and Rice 1989; CHAPTER 27: THE ORGANIZATION OF FEATURES).

4 The formal expression of markedness

The representation of markedness, in a theory of markedness or grammar, typically assumes two components: (i) a formal device denoting whether an element is marked or unmarked, and (ii) a mechanism encoding the relative markedness of the elements in question. Examples of each are given in (5). Implicational statements (§5.2) can be viewed as incorporating both components.

(5) *Representing markedness*

a. *Formal devices*
Feature values (e.g. Jakobson *et al.* 1952; Jakobson 1971a; *SPE*)
Diacritics (e.g. *SPE*; Calabrese 1995)
Distributional statements (e.g. Mohanan 1993)
Redundancy rules (e.g. *SPE*; Archangeli 1984)
Constraints (e.g. Prince and Smolensky 1993; Calabrese 1995; Boersma 1998; Causley 1999; de Lacy 2002, 2006)

b. *Relational mechanisms*
Ordering (e.g. Calabrese 1995; CHAPTER 74: RULE ORDERING)
Constraint ranking (e.g. Prince and Smolensky 1993)
Subset relations (de Lacy 2002, 2006)
Quantitative measures (e.g. *SPE*; Archangeli 1984; Clements 1985; Kiparsky 1985; Avery and Rice 1989).

Given space limitations, the discussion below provides an overview of only some of these components.

In *SPE*, the diacritics *m* and *u* are formal devices assigned to features in order to indicate whether a feature value is intrinsically "marked" or "unmarked," respectively. All phonemes are assigned a value for each feature, thus *m* and *u* values are present in the lexicon. The combination of feature values within a segment determines whether that sound is marked or unmarked. Prior to the application of phonological rules, markedness conventions, as in (6), translate *m* and *u* into the values + and –. For example, the redundancy rule in (6a) states that the unmarked value of the feature [high] for vowels is [+high], while (6b) states that the unmarked value for [back] when coupled with [+low] is [+back]. Importantly, unmarked rules are considered universal statements that cannot be violated, while marked rules can be violated, but add a cost to the grammar; unmarked values do not contribute to the complexity of a grammar.

(6) *Sample marking conventions for vowels*

a. [u high] → [+high]

b. [u back] → [+back] / $\begin{bmatrix} \overline{} \\ \text{+low} \end{bmatrix}$

In *SPE*, the relative markedness among elements in a system is a quantitative issue, in that the complexity of a system is equal to the sum of the marked features of its members. However, as the authors point out (Chomsky and Halle 1968: 409ff.), counting features alone is not sufficient to predict optimal systems; other considerations, such as system symmetry and simplicity, also need to be taken into account.

Correlating markedness with quantity is also central to some theories of underspecification, in that the least marked element is represented with the least amount of theoretical machinery (e.g. Kiparsky 1982; Archangeli 1984; Pulleyblank 1988; Archangeli and Pulleyblank 1989; CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION). Most models of feature geometry adopt a similar approach (Clements 1985; McCarthy 1988; Avery and Rice 1989; Clements and Hume 1995), as exemplified by Clements's (1985) proposal that natural (unmarked) phonological rules are expressed as single operations. As such, an unmarked rule of assimilation involves the addition of a single association line (CHAPTER 81: LOCAL ASSIMILATION), and an unmarked deletion rule is presented by the delinking of a single line (CHAPTER 68: DELETION). In this light, predicting markedness patterns is a representational problem (Rice 1999).

Associating quantity of structure with unmarkedness is generally linked to the view that unmarked feature values are absent in underlying representation (for discussion see, e.g. Archangeli 1984; Steriade 1987, 1995; Clements 1988, 1993; Odden 1992; Rice 1992; Mohanan 1993; Calabrese 1995; CHAPTER 1: UNDERLYING REPRESENTATIONS; CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION; CHAPTER 27: THE ORGANIZATION OF FEATURES). Thus, underlying representations provide the vehicle for determining markedness relations. For example, Paradis and Prunet (1991: 3) argue that "the special status of coronals lies in the fact that they lack specifications for place features in UR" (see also CHAPTER 12: CORONALS). Similarly, Rice (1992: 64) remarks: "Segment structure combined with absence of universally unmarked features at a node . . . indicates markedness relations, with more structure indicating a more marked segment and less structure a less marked segment." This approach can be traced to early writings by Jakobson and colleagues (e.g. Cherry *et al.* 1953; see §5.5), who sought to maximize the efficiency of phoneme systems by minimizing redundant information, a view reflected in *SPE*. These ideas are further developed in Kiparsky (1982), Archangeli (1984), Pulleyblank (1988), and Archangeli and Pulleyblank (1989), and is expressed in the following quote (Kiparsky 1982: 54–55) (see also CHAPTER 8: SONORANTS):

> The theory of grammar will provide a set of universal redundancy rules functionally analogous to the markedness principles of Chomsky and Halle (1968), but formally identical to ordinary phonological rules. In particular, assume that for every feature F there is minimally a rule
>
> (42) [ ] → [α F]
>
> Where α (+ or −) is the "unmarked" value. In addition, other rules may be applicable in specific syntagmatic or paradigmatic contexts. For example, for voicing we may have the rules
>
> (43) a. [ ] → [+voiced]
> b. [+obst] → [−voiced]
>
> putting the unmarked value as [−voiced] for obstruents and [+voiced] elsewhere. We now say that voiceless obstruents and voiced sonorants are represented as [0 voiced], that is, unspecified for voicing, and that their respective specifications for voicing are filled in by the application of rule (43). This much is quite in the spirit of traditional markedness theory.

Critical discussion of the connection between underspecification and markedness can be found in e.g. Mohanan (1993) and Steriade (1995). Among the critiques, Steriade (1995: 199–200) questions:

> whether the asymmetric distribution between the marked and the unmarked value justifies eliminating the unmarked value from underlying structure. Is underlying privativity the faithful representation of markedness facts? . . . Should the unmarked value be represented at all on the surface?

In response to these questions, she suggests that there are segments in most languages that start out and end up without features, such as place of articulation in the case of the laryngeal consonants [h] and [ʔ] and schwa-like vowels.

A further issue concerns the assumption that only one member of a class can be unmarked and thus least specified. For example, Kiparsky (1985) argues that coronal nasals are unmarked for place in Catalan, since only coronals assimilate to the place of articulation of any following consonant (Mascaró 1976). Rice (2007), however, points out that this approach is untenable, a claim supported by evidence in Hume (2003) showing that virtually any combination of dorsal, labial, and coronal can be unmarked, given their patterning as targets of assimilation, a common markedness diagnostic (see §5).

In the 1990s, the shift in focus from underlying to surface representations further impacted the use of underspecification as a means of expressing markedness. Instead, surface-oriented devices were developed. Calabrese (1995: 374) proposes the use of marking statements, similar to the marking conventions of *SPE*, though formalized as constraints rather than rules. He argues that "the structure of inventories is determined by restrictions on phonological segments in the form of constraints on pairs of features." Co-occurrence restrictions occur within marking statements, as shown in (7). The property of being marked is encoded by underlining of the relevant feature in the statement, as is the case for value β of feature G in combination with another feature value αF, where α and β range over + and –.

(7) *Marking statement* (Calabrese 1995)

$[\alpha F, \underline{\beta G}]$

Constraints are also central to accounts of markedness developed within the framework of Optimality Theory (e.g. Prince and Smolensky 1993; Steriade 1995; Hamilton 1996; Lombardi 1997; Causley 1999; de Lacy 2002, 2006; Hayes and Steriade 2004). For example, Hayes and Steriade (2004: 1) propose that "markedness laws characterising the typology of sound systems play a role, as grammatical constraints, in the linguistic competence of individual speakers."

In some constraint-based approaches, degrees of markedness are expressed through formal devices that organize constraints hierarchically. Calabrese, for instance, draws on constraint ordering to create a hierarchy of markedness statements. In some OT approaches, markedness relations are expressed through the harmonic ordering of members of a correlational set which imposes a universally fixed order on a set of constraints (Prince and Smolensky 1993). For example, as shown in (8), it is claimed that the harmonic ordering for place of articulation expresses the markedness relations provided by UG, such that dorsal is more marked than labial, which is more marked than coronal, and so forth. The corresponding grammatical constraints and ranking appear in (8b). Despite the assumed universality of such rankings, this approach also provides a formal means for describing the observation that a given feature need not be unmarked in all languages: an additional constraint may dominate the fixed ranking, thus having the effect of overruling the unmarked status of a lower-ranked constraint (see e.g. Lombardi 1997 for an analysis along these lines; also CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION).

(8) a. *Harmonic ordering for place of articulation* (> = "is less marked than")
glottal > coronal > labial > dorsal

b. *Corresponding fixed universal ranking* (>> = "is ranked above")
*dorsal >> *labial >> *coronal >> *glottal

De Lacy's (2002, 2006) OT-based theory of markedness makes use of markedness hierarchies tied to sets of constraints. Place of articulation features are represented by the hierarchy in (9a), which projects onto the output constraint sets in (9b).

(9) a. *Markedness hierarchy*
(hierarchy enclosed by | |; > = "is more marked than")
| dorsal > labial > coronal > glottal |

b. *Each hierarchy is related to a set of constraints:*

i. *[dorsal]
Assign a violation for each [dorsal] feature.

ii. *[dorsal, labial]
Assign a violation for each [dorsal] and each [labial] feature.

iii. *[dorsal, labial, coronal]
Assign a violation for each [dorsal], each [labial], and each [coronal] feature.

iv. *[dorsal, labial, coronal, glottal]
Assign a violation for each [dorsal], each [labial], each [coronal], and each [glottal] feature.

Unlike (8b), the ranking of the constraint sets in (9b) is not fixed. Instead, de Lacy proposes that markedness patterns are generated by virtue of the subset relations present in each set of constraints. For example, since in (9) the marked feature [dorsal] is listed in each constraint of the entire set, a violation of any of the constraints will necessarily target [dorsal]. Conversely, the absence of [glottal] in all constraints but *[dorsal, labial, coronal, glottal] preserves the feature, except when all other feature types are involved. In other words, [dorsal] is least preferred, while [glottal] is most preferred. I refer the reader to de Lacy (2006) for discussion concerning the predictive power of the approaches represented in (8) and (9).

5 Criteria for predicting markedness patterns

Determining what constitutes reliable evidence for markedness relations remains an area of controversy. One issue concerns whether one can actually diagnose markedness: are markedness diagnostics to be treated as "criterial for determining asymmetry or as merely correlative" Battistella (1996: 14)? Generative phonological approaches have tended to view markedness diagnostics as criterial.

Others view such diagnostics as correlative, to the extent that they reveal reliable statistical tendencies (e.g. Lass 1975; Menn 1983; Ohala 1990; Bybee 2001; Hume 2004a, 2004b; Haspelmath 2006; Mielke 2008).

Controversy also surrounds the issue of whether evidence for markedness comes from synchrony or diachrony (CHAPTER 93: SOUND CHANGE). In theories of generative phonology, the status of synchronic patterns is considered paramount, given the fundamental premise that such observations provide a window into an individual's innate knowledge of language. Further, since the individual does not have direct access to knowledge of changes from the past, only synchrony can provide valid sources of evidence for markedness patterns (see e.g. Rice 1999; de Lacy 2002, 2006). Conversely, Blevins (2004: 20) argues that

> there is no clear role for markedness within synchronic phonology. Absolute universals and universal tendencies in sound patterns emerge from general pathways of language change, and have no independent status in the grammar . . . most proposed universals and their counterexamples have straightforward diachronic explanations.

(See also Mielke 2008; CHAPTER 17: DISTINCTIVE FEATURES.)

Another area of debate concerns which criteria are appropriate for determining the markedness value of a given element. The types of evidence used to support claims about phonological markedness include those in (10).

(10) *Types of evidence for predicting markedness patterns*

a. Acquisition.
b. Phonological patterns, e.g. alternations, inventory structure, distribution, implicational relations.
c. Phonetics, e.g. quality of acoustic/auditory cues to the identification of a pattern, articulatory difficulty in producing a pattern.
d. Usage factors, e.g. statistical patterns.
e. Cognitive factors, e.g. information content, entropy.

In the remainder of this section we take a closer look at these criteria.

5.1 *Language acquisition*

Since Jakobson's seminal papers on language acquisition (1971a, 1971b), the view that there are universal principles, such as markedness, that guide the order in which a child learns language has been highly influential (CHAPTER 101: THE INTERPRETATION OF PHONOLOGICAL PATTERNS IN FIRST LANGUAGE ACQUISITION). Central to this approach is the proposal that acquisition of a marked sound category, defined in terms of distinctive features, presupposes the acquisition of the corresponding unmarked category (see implicational relations: §5.2). According to Jakobson (1971b: 11), the order in which children acquire sound categories "corresponds exactly to the general laws of irreversible solidarity (implication) which govern the synchrony of the languages of the world." For example, under the assumption that dorsal place of articulation is more marked than coronal, the acquisition of dorsals presupposes that of coronals. Jakobson (1971b: 7) acknowledges in places that the term *general laws* might be "more prudently formulated" as *tendencies*, though his proposed orders of acquisition have typically been interpreted as absolutes: all children acquire sounds in the same order, regardless of the language that they are learning.

Controversy has surrounded at least two issues arising from the proposed link between acquisition and markedness: (i) the extent to which there is a universal order of acquisition such that the marked implies the unmarked; and (ii) whether acquisition data should be used as evidence for claims regarding markedness.

With regard to the first point, experimental evidence indicates that there is considerable variability in the order of acquisition across languages. For example, Morrisette *et al.* (2003) tested the claim that dorsal place of articulation is more marked than coronal by examining inventory structure and substitution patterns from 211 English-learning children. They found that

> the full range of logical possibilities was found to occur with regard to inventory structure; that is, some children included both coronals and dorsals in their inventories, others included coronals but not dorsals, and yet others included dorsals but not coronals. In terms of the children's substitution patterns, dorsals were replaced by coronals . . . in a large proportion of the cases. However, a small proportion of the children replaced coronals with dorsals. (Morrisette *et al.* 2003: 351)

(See also Menn 1983; Vihman 1993; Beckman *et al.* 2003.)

Beckman *et al.*'s (2003) study of the acquisition of place of articulation also challenges the view that there is a universal order of acquisition for place of articulation. Japanese-learning children made more than twice as many "backing" errors for /t/ (i.e. /t/ pronounced as /k/) as they made "fronting" errors for /k/ (/k/ pronounced as /t/), which runs counter to the claim that back consonants like /k/ are universally marked and likely to be replaced by front consonants like /t/.

However, Beckman *et al.* (2003) also suggest that some universals may exist, "if we take the term 'universal' to mean a strong numerical tendency rather than an absolute rule." They suggest that the best example involves laryngeal features, thus supporting Jakobson's claim that voiceless unaspirated stops are mastered before aspirated or voiced stops. Drawing on evidence from Kewley-Port and Preston (1974), they propose that this universal of acquisition is phonetically grounded in the relative diffiiculty of satisfying aerodynamic requirements for the different stop types.

A second issue concerns whether or not observations from acquisition, including second language acquisition, should be used as evidence for a theory of markedness at all. In other words, if there is empirical evidence that children acquire one class of sounds prior to another, should these observations be used as evidence for or against a theory of markedness? There has been less of an overt debate regarding this issue; rather, authors typically assume one position or the other. For example, Calabrese (1995) draws on the order of acquisition of segments (and segment loss) in his markedness theory to establish the order of marking statements. Conversely, de Lacy (2006) assumes that acquisition data do not in and of themselves provide evidence for a markedness pattern. He takes issue with the findings of Beckman *et al.* (2003), who argue that velar /k/ patterns are unmarked among Japanese-learning children, claiming that in the absence of synchronic alternations in the language that also attest to the unmarked status of velars, the apparent unmarked behavior of velars could be explained by phonetic factors. A crucial difference between de Lacy's and Beckman *et al.*'s approaches is that in the former, markedness constitutes a fundamental part of an individual's grammatical competence, independent of performance factors. In this view, any observations that might be explained by factors external to the grammar and not supported by synchronic processes do not constitute empirical evidence for a formal theory of markedness. Conversely, in the latter approach, there is no strict division between competence and performance; linguistic knowledge comprises and is influenced by both types of information.

5.2 *Phonological patterns*

From the earliest discussion of markedness in Trubetzkoy (1939) to more recent research on the topic, the asymmetrical patterning of features and sounds in inventories and phonological processes has served as the basis for predicting markedness relations. Indeed, in Rice's (1999) evaluation of markedness criteria, she concludes that the strongest and most compelling arguments come from phonological processes (see also de Lacy 2006). Thus, when comparing features within a class, if one feature patterns asymmetrically with respect to the others, it is this feature that is deemed the unmarked member of the relation. Consider an example from Yoruba. There are three tones in the language's tonal inventory (High, Mid, Low) (CHAPTER 45: THE REPRESENTATION OF TONE). The Mid tone, unlike High and Low, never appears in the structural descriptions or changes of phonological rules. Mid thus patterns asymmetrically with respect to other members of the tonal class and, as a result, is considered the unmarked member (Akinlabi 1985). The following discussion provides an overview of the types of evidence used in diagnosing markedness, but cannot do justice to the vast literature that has been devoted to this topic. Additional works that discuss the different types of evidence include Battistella (1990, 1996); Rice (1999, 2007); de Lacy (2002, 2006); Hume (2004b, 2006, 2008); Haspelmath (2006).

In terms of phonological patterning, it is widely assumed that, to the extent that there is asymmetry, the unmarked member of an opposition patterns differently than other members in being the *target* of phonological processes, such as reduction, deletion, and assimilation (though cf. de Lacy 2006). With regard to assimilation (CHAPTER 81: LOCAL ASSIMILATION; CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS), for example, Rice (1999: 4) points out:

> the unmarked pole of an opposition is lost or obscured, with the marked pole remaining . . . In assimilation, the marked features within a class are active . . . the unmarked features, on the other hand, are passive, or inert . . . overridden by other features.

Put another way, marked features are assumed to resist modification, while unmarked features are subject to change. Rice (1999, 2007) labels this criterion "submergence of the unmarked." Recall the Catalan example from above, in which only coronals assimilate to the place of articulation of a following consonant (Mascaró 1976); in this case, coronal is considered unmarked. A more complex yet frequently cited example comes from place assimilation in Korean, as shown in (11), where a final obstruent stop assimilates in place to a following consonant, with the following restrictions. A morpheme-final coronal assimilates to a following dorsal or labial consonant (11a). A morpheme-final labial also assimilates to a following dorsal, but fails to assimilate to a following coronal, as in (11b). As the examples in (11c) show, a final dorsal consonant does not assimilate to either a following labial or coronal consonant. According to the view that markedness is correlated with resistance to modification, the dorsal consonant is considered most marked, followed by labial, then coronal (Iverson and Kim 1987), i.e. dorsal > labial > coronal.

(11) *Korean place assimilation*

a.	/mit+ko/	[mikk'o]		'believe and'
	/mit^h+pota/	[mipp'ota]		'more than the bottom'
b.	/ip+ko/	[ikk'o]		'wear and'
	/nop+ta/	[nopt'a]	*[nott'a]	'high'
c.	/nok+ta/	[nokt'a]	*[nott'a]	'melt'
	/kuk+pota/	[kukp'ota]	*[kupp'ota]	'more than soup'

The *output* of certain phonological processes including epenthesis and neutralization has also been drawn on as evidence for identifying the unmarked member of a class. The output of *neutralization* (CHAPTER 80: MERGERS AND NEUTRALIZATION) is one of the original diagnostics for markedness, proposed in Trubetzkoy (1939): the result of neutralization does not bear the mark of the relevant property, i.e. it is unmarked. For example, in languages with final devoicing such as German, Maltese, Polish, and Russian, the contrast between voiced and voiceless consonants is arguably neutralized in word-final or coda position; only one member of the opposition survives, the voiceless consonant, and thus this member is considered unmarked. There is lack of consensus, however, regarding the use of the output of neutralization as evidence for the unmarked. Croft (2003), for example, claims that there is no uniformity across languages concerning which value is to be considered unmarked (see also de Lacy 2002, 2006; Vaux and Samuels 2005). And for epenthesis, de Lacy (2002, 2006) considers consonant, but not vowel, epenthesis to be a valid criterion for markedness.

Distributional evidence has also long been considered a criterion for determining markedness relations. Battistella (1990) distinguishes between paradigmatic distribution and syntagmatic distribution. With regard to the former, it is claimed that the unmarked category of a contrastive pair is used to distinguish more words than the marked category (see also Waugh and Lafford 1994). As for syntagmatic distribution, it is widely held that the unmarked segment (or feature) is more widely distributed than its marked counterpart (see, e.g. Trubetzkoy 1939; Hockett 1955; Greenberg 1966; Battistella 1990; Stemberger 1992; for related discussion, see Rice 1999). In fact, Hockett (1955: 166) proposes that distributional differences underlie the unmarkedness (simplicity, in his terms) associated with the result of neutralization (see also Trubetzkoy 1939; Hume 2004b). In this light, the view that voiceless obstruents in languages such as Russian are simpler (unmarked) as compared to their voiced counterparts is explained in terms of their wider distribution: the voiceless member of the contrast occurs in non-final contexts, as does the voiced member, but also in word-final or coda positions.

One of the original sources of evidence for markedness comes from *implicational relations*, as noted in §5.1: the presence of *x* implies the presence of *y* (Trubetzkoy

1939; Greenberg 1966; Jakobson 1971a). Jakobson (1971a) treats implicational relations as a cornerstone of markedness, in that they state a compulsory connection between two related properties of language; for example, the occurrence of nasal vowels implies that of nasal consonants. Implicational relations have been claimed to reveal markedness patterns in sound change, acquisition, and inventories. Thus, in sound change, the loss of a marked category implies the loss of the corresponding unmarked one (Bailey 1973). Similarly, in child language acquisition, the acquisition of a marked category implies prior acquisition of the corresponding unmarked category (Jakobson 1971a).

Yet it has been in phoneme inventories that implicational relations have been most widely cited as evidence for markedness patterns (see e.g. Chomsky and Halle 1968; Kean 1975; Lass 1975; Cairns and Feinstein 1982; Calabrese 1995; Hamilton 1996; Causley 1999; de Lacy 2002, 2006). For example, Kean (1975) claims that if a language has voiced obstruents, it also has voiceless obstruents. Conversely, Rice (1999) considers implication problematic as evidence for markedness relations given the assumption that language learners do not have access to implicational relationships between segments in consonant and vowel inventories. Rather than being a part of an individual's knowledge of language, implication in Rice's view is a consequence of properties relating to phonetics and usage.

Interestingly, Lass (1975: 501), who opposes the claim that markedness observations provide evidence for innate properties of language, nonetheless views implicational relations as relevant for a theory of "universal phonetics." He suggests that there is a hierarchy made up of

> necessary choices which appear to be universal, and a larger (unordered) set of contingent choices which any language can make after it has made the non-contingent ones. This reflects such facts as the apparent lack of languages without vowels, the lack of languages with nasalized vowels but no oral ones, or glottalized consonant but no non-glottalized one . . . and so on. . . . Under this view we return to something very like the Praguian notion of "marking," in which (at least in some cases) the relation U : M presupposes not "optimalness" or "simplicity" vs. "non-optimalness" or "complexity," but rather (irreflexive) implication: If M, then U; but not vice versa.

Structural asymmetries in phoneme inventories have also been used to identify the unmarked member of the inventory (e.g. Rice and Avery 1993; Rice and Causley 1998; Causley 1999). Building on insights from Trubetzkoy (1939) and Jakobson (see Battistella 1990), Rice and Causley argue that non-contrastive features are inactive, and that such inactivity signals the unmarked status of features and segments. To illustrate, compare two hypothetical sound systems in (12). System A is comprised of six segments; we may assume that each of the following pairs are distinguished by some feature [F]: /a – d/, /b – e/, and /c – f/. System B is made up of five segments; like system A, feature [F] is contrastive for /b – e/ and /c – f/, but not for segment /a/.

(12) *Structural asymmetries*

System A			*System B*		
a	b	c	a	b	c
d	e	f		e	f

Dyck (1995) proposes that phonological patterns occur in which the /a/-like segment in system A triggers processes, whereas the /a/-like segment in system B does not (see the discussion in Rice 2007). Further, there is some support for the role of contrast in predicting markedness in vowel place specifications. Causley (1999: 76–77) argues that vowel systems that

> lack a central vowel have a front or back vowel patterning as unmarked. When a language has a front–central–back contrast, the central vowel is chosen as the least marked. Thus the markedness status of different vowel specifications is linked to the inventory.

Using contrast as a predictor of markedness values is not consistently reliable, however. Rice (2007) presents a number of cases showing variation in the segment that emerges as unmarked among languages with similar systems of contrast.

5.3 *Phonetic properties*

There is general consensus that phonetic factors play a role in predicting markedness patterns, a view dating back to the earliest writings on the topic (e.g. Trubetzkoy 1939; Jakobson and Halle 1956; Greenberg 1966; Chomsky and Halle 1968). Acceptance of this view is seemingly independent of whether or not one associates markedness with Universal Grammar. Hayes and Steriade (2004) note that universal markedness laws are rooted in phonetic knowledge. Consistent with this view, Mohanan (1993) assumes that phonological patterns are influenced by three phonetic principles: minimize the number of articulatory gestures; minimize the deviation of articulatory gestures from configurations of least effort; maintain the phonetic distinctions that distinguish between different words. Similarly, Boersma (2000: 18) notes that markedness, in the sense of cross-linguistic rarity, "emerges from an interaction between principles of articulatory effort and perceptual confusion, and [are] not encoded directly in our phonological language device." Further, Bybee (2001: 14) proposes that the "underlying explanation for sound changes that create markedness relations is phonetic in nature." A more nuanced approach appears in de Lacy (2002, 2006: 1), where two theories of markedness are assumed: a performance theory and a competence theory. "Markedness is part of grammatical Competence (I-language). Markedness in Competence is distinct from sometimes apparently similar Performance-related phenomena." While asymmetrical patterns are assumed to exist in both competence markedness and performance markedness, according to de Lacy their explanations lie in different domains: the former are explained in terms of Universal Grammar, and the latter by factors external to the grammar, such as those relating to phonetics and usage.

The remainder of this section focuses on the phonetic factors most commonly used as criteria for identifying markedness values, as listed in (13).

(13) *Phonetic factors*

a. phonetic variability in production
b. articulatory simplicity
c. perceptual distinctiveness

5.3.1 *Phonetic variability in production*

The unmarked member of an opposition has been claimed to be produced with greater phonetic variability than the marked counterpart, a view first attributed to Trubetzkoy (1939). Similarly, Greenberg (1966) considers greater allophonic variability to be a criterion of the unmarked category, and Rice (1999: 19) suggests that fixedness of phonetic realization correlates with markedness such that the marked pole is more clearly defined: marked members show little variation, while unmarked members show more.

5.3.2 *Articulatory factors*

The unmarked member of an opposition is widely considered to be easier and less complex than the marked counterpart in terms of production. Calabrese (1995: 376), for example, states that the less marked nature of certain feature combinations can be explained by ease of articulation and perceptual saliency: for instance, he claims that

> the [+continuant, −strident] coronal fricatives [θ, ð] are complex because of the articulatory adjustments needed to maintain absence of stridency in fricatives. Still other combinations are phonologically simple. For example, the combination [+continuant, +strident] is simple, since stridency is a natural consequence of the type of constriction found in fricatives.

Similar assumptions hold for sequences of sounds. Along these lines, Hamilton (1996: ii) proposes that

> each phonotactic constraint is phonetically grounded. Unmarked clusters correspond to structures which are gesturally and/or perceptually simple and marked structures are gesturally and/or perceptually complex.

For related discussion, see Archangeli and Pulleyblank (1994), Jun (1995), and Boersma (1998), among others.

The use of articulatory simplicity to predict markedness patterns is not without issues. For example, despite wide acknowledgment in the phonological literature that such factors play an important role, the actual phonetic evidence showing *x* to be simpler than *y* is often not rigorously demonstrated. Further, while it may seem intuitively evident in some cases that two elements are appreciatively different in terms of articulatory complexity (e.g. [p] *vs.* [pʕ]), gradations of difficulty are less evident among more similar elements (e.g. [p] *vs.* [t] *vs.* [k]), particularly for adult speakers with years of experience producing the sounds (see Stampe 1979: 10 for related discussion). An additional issue concerns the interaction between articulatory and perceptual factors, a point returned to in the following section.

5.3.3 *Perceptual distinctiveness*

The perceptual distinctiveness of sounds and strings of speech has also been drawn on to predict observed asymmetries in phonological systems (e.g. Trubetzkoy 1939; Jakobson and Waugh 1987; Lindblom 1990; Flemming 1995; Jun 1995; Steriade 1995; Boersma 1998; Hume 1999, 2004a; Hume and Johnson 2001; Blevins 2004; Bybee, forthcoming; CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). It is clear that distinctiveness is important for the correct identification of sounds and strings of speech (e.g. Ohala 1981; Kawasaki 1982; Lindblom 1990). In this regard, Kawasaki (1982) proposes that sharper changes in the speech signal serve to increase the salience of cues in the portion of the signal where the modulation takes place: the greater the magnitude of the modulation, the better a given signal is detected. Interestingly, this proposal relates to claims regarding phonological markedness in two seemingly conflicting ways.

The first concerns the observation that patterns with *larger modulations* tend to recur across languages, since they are more resistant to change than those with smaller modulations. In this case greater syntagmatic distinctiveness correlates with unmarkedness, an interpretation consistent with the common assumption that the CV syllable is universally preferred over other syllable types, e.g. V, CVC, VC (Cairns and Feinstein 1982; Clements and Keyser 1983). Paradigmatically, strong perceptual distinctiveness has also been proposed as the explanation for recurring phonological inventories. Liljencrants and Lindblom (1972) propose that the structure of vowel systems is determined largely by the principle of maximal perceptual contrast, thus favoring systems in which vowels are perceptually distinct, e.g. [i a u] (see Flemming 1995). Perceptual distinctiveness has also been drawn on extensively to account for asymmetries in phonological patterns. As Hamilton (1996: 12ff.) observes, following Jun (1995) and Steriade (1995),

> Simple percepts are unmarked and complex percepts are marked . . . simple speech sounds in perceptual terms are those with robust spectral cues . . . The empirical correlate to this is that perceptually robust speech sounds are highly valued cross-linguistically, while languages only grudgingly elaborate perceptually opaque structures.

The flip side of the coin is that structures with *small modulations* due to weak acoustic/auditory cues will tend to be modified more often than those with larger modulations (Kawasaki 1982). As a result, sounds lacking distinctiveness are subject to phonological processes such as assimilation, reduction, and deletion to a greater degree than sounds with robust cues (see e.g. Kohler 1990; Hura *et al.* 1992; Jun 1995; Steriade 1997; Boersma 1998; Hayes *et al.* 2004). Thus weak perceptual distinctiveness is also correlated with being unmarked. This interpretation is consistent with the claim that the target of phonological processes such as deletion is the unmarked member of the comparison set.

The use of perceptual distinctiveness thus appears contradictory as a markedness diagnostic: unmarkedness is associated with *strong* perceptual distinctiveness as well as *weak* perceptual distinctiveness. Consequently, it is seemingly impossible to predict a priori whether a sound is marked or unmarked given its salience. Hume (2006), and Hume and Mailhot (forthcoming) propose that these observations are consistent with a model of markedness conceptualized in terms of entropy, a measure of the uncertainty in a system (Shannon and Weaver 1949); see §5.5 for discussion.

A further issue concerns the interaction between production and perceptual demands, and the role of these interactions in predicting markedness observations. Given the complexity of this issue, it is understandable that the topic has received less attention in the literature than the roles of perception and production in markedness independently. The subject is addressed in considerable detail in Boersma (1998), who proposes a production theory of markedness and a perception theory of markedness. He observes (Boersma 1998: 17) that production and perceptual constraints can make conflicting predictions regarding markedness, citing fricatives as an example:

> In gestural terms, fricatives are complex, since the correct spatial relationship between the active and passive articulators must be very precisely controlled in order to maintain turbulent airflow . . . At the same time, fricatives are spectrally very robust. Their random high frequency energy patterns are very distinct from the spectral properties of the other manners of articulation, and also act as a very salient cue to place of articulation.

To resolve such conflicts, Boersma claims (1998: 17) that languages adopt different strategies:

> They may follow the [production theory of markedness] and elaborate gesturally harmonic features, or follow the [perception theory of markedness] and elaborate perceptually harmonic features, or opt for some combination of the two. Therefore in the case of fricatives some languages have more stops than fricatives while others (including English) have fricatives which lack stop counterparts.

5.4 Usage

The most common usage factor cited in relation to markedness is the statistical frequency with which a particular pattern occurs, a criterion dating back to Zipf (1932), Trubetzkoy (1939), Hockett (1955), and Greenberg (1966), among others. The claim is that the unmarked is more frequent cross-linguistically than the marked (CHAPTER 90: FREQUENCY EFFECTS). Despite its long history, the relation between frequency and markedness remains controversial. Three of the main issues are given in (14).

(14) *Issues regarding frequency and markedness*

a. whether or not frequency should play a role in predicting markedness patterns;
b. to the extent that frequency is used as a predictor of markedness, whether frequency should be calculated across all languages, within a single language, or involve both calculations; and
c. what type of frequency measure is relevant.

Trubetzkoy (1939), inspired by Zipf (1932), drew a link between unmarked status and frequency: since the unmarked member of an opposition emerges in cases of neutralization, the distributional asymmetry would contribute to the unmarked sound's greater frequency over the marked sound (see also Hume 2004b). For Jakobson, frequency was foundational to the use of markedness in modern linguistics, reflected in the frequency of a sound across languages, and through implicational relations. This view continues to be commonly accepted today, though not uniformly so. Hume and Tserdanelis (2002) point to the higher frequency of labial place in Sri Lankan Portuguese Creole nasals as support for the unmarkedness of the labial nasal in that language. Rice (1999), however, considers a pattern's frequency to be a consequence of emergent properties (i.e. factors influencing language change), rather than a diagnostic for markedness (see also de Lacy 2002, 2006).

Nonetheless, the link between frequency and markedness is widely attested in the generative phonology literature. Citing cross-linguistic frequency as evidence for markedness, Kean (1975) states that since almost all languages have [t a] but fewer have [kp y], [t a] are unmarked and [kp y] are marked. Further, as noted in §4, Sagey (1986: 9) claims that a requirement of a theory of phonology

> is that the relative simplicity of describing in the representation each process or form that occurs should reflect its relative naturalness, in the sense of its frequency of occurrence in the languages of the world. That is, more marked forms and processes should be correlated with more marked representations.

Similarly, Paradis and Prunet (1991: 10) point to three types of statistical patterns which, they argue, support the view of the feature coronal being unmarked. As listed in (15), the evidence comes from cross-linguistic measures (typological frequency) as well as language-specific ones (inventory frequency, token frequency).

(15) *Evidence from frequency for the unmarked status of coronal* (Paradis and Prunet 1991: 10)

a. Inventory frequency: the number of coronals in the consonant inventory of a given language.
b. Typological frequency: the number of coronals attested in a universal phonemic inventory.
c. Occurrence frequency (i.e. token frequency): the number of times coronals are produced in a representative speech corpus.

Paradis and Prunet's broad use of frequency measures relates to another area of controversy: whether frequency should be calculated across all languages, within a single language, or both. Trubetzkoy (1939) considered the frequency of one member of an opposition within a language as a signal of unmarked status. Greenberg (1966) used statistical methods to claim that the frequencies with which phonemes show up in languages are the expression of a universal tendency to avoid marked phonemes; unmarked phonemes have higher cross-linguistic frequencies. This view is also reflected in more recent literature; Hamilton (1996: 5–6) states that "unmarked features are more frequent than marked features . . . features with a wider cross-linguistic distribution also occur at higher frequencies language-internally." Yet Meier (1999) challenges the view that cross-linguistic frequency is a valid criterion for markedness, arguing that "presumably marked values (e.g. glottality in stop consonants) have a very different distribution in different languages" (cited in Elšík and Matras 2006: 16). In this view, frequency is best calculated on a language-specific basis (see also Hume 2006).

The use of statistical measures is complicated by a number of issues. One has to do with what the appropriate measure is, e.g. type or token frequency. Type frequencies are calculated over a lexicon, for example, how frequently a phoneme occurs in the dictionary of a language; see for example Trubetzkoy (1939). Token frequency is calculated over a written or spoken corpus, for example, how frequently a phoneme occurs in a corpus of natural speech. Type frequencies generally provide more information about the structure of a language, whereas token frequency reveals patterns of usage. The extent to which the two properties affect phonological patterns differently remains an empirical question (see e.g. Munson 2000 for related discussion). A further issue concerns which elements and levels of language frequency should be measured over, for example, features, segments, syllables, words. Does frequency affect all elements of language uniformly? If not, what are the empirical consequences for a language's phonological system? A further issue concerns the interaction of statistical patterns with other factors such as production, perception, word structure, and word similarity. For additional discussion see, for example, Bybee (2001), Phillips (2006), and CHAPTER 90: FREQUENCY EFFECTS.

5.5 *Entropy and information content*

The concepts of entropy and information content have been connected to markedness in at least two ways: as a foundational concept for the dichotomous view of the unmarked and marked, and as a predictor of markedness patterns. Information content and the more widely used term "entropy" are tools of Information Theory (IT; Shannon and Weaver 1949), and well established in the field of computational linguistics. IT is concerned with representing mathematically how much information, measured in terms of binary choices (bits), is needed to efficiently convey a message given the constraints imposed on the system. Entropy is a measure of the amount of uncertainty associated with selecting outcomes in a given system. A higher entropy value is associated with greater uncertainty among a set of possible outcomes; those outcomes that are relatively unexpected contribute more information, or complexity, to a message.

Jakobson's theory of distinctive features and the binary nature of markedness were inspired by Information Theory. According to Cherry *et al.* (1953: 34), analyzing a language requires that "we must determine the minimum set of [distinctive] features that the listener needs in order to recognize and distinguish all except homonymic morphemes, without help from context or situation." Each binary feature represents a choice regarding a particular sound (is it voiced? is it nasal?), with the response encoded as plus (yes) and minus (no) (zero indicates redundant information). A plus value is generally interpreted as marked, and minus as unmarked. The goal of this approach was to determine how many binary choices were needed to identify a given phoneme within the language system. Consistent with Information Theory, the most efficient system was the one that required the fewest number of binary questions (i.e. features) to convey the identity of a particular phoneme. Many of these ideas became cornerstones of subsequent theories of feature specification, and the information-theoretic concept of binarity emerged as a fundamental assumption of markedness theories.

Entropy has also been applied to other aspects of phonological knowledge; for applications of information-theoretic concepts to sound patterns, see Hockett (1955), Broe (1996), Goldsmith (1998, 2002), Hume and Bromberg (2005), Hume (2006), Hall (2009), Goldsmith and Riggle (forthcoming), Hall *et al.* (forthcoming), Hume and Mailhot (forthcoming); also CHAPTER 6: SELF-ORGANIZATION IN PHONOLOGY. For example, Hume (2006), Hall *et al.* (forthcoming), and Hume and Mailhot (forthcoming) suggest that entropy and information content can be used to make predictions about the preferred contexts and likely outcomes of a range of phonological processes, hence markedness patterns. Specifically, the most likely targets are predicted to be those that contribute little to the total entropy of the system, or in the case of repair processes, those that would significantly increase entropy if left unrepaired. The most likely outcomes are predicted to be ones that result in the least change in the pre-existing entropy of the system. One consequence of this approach is that it unites a range of otherwise disparate observations regarding influences on phonological patterns within a given system. For instance, Hall *et al.* (forthcoming) argue that in cognition, the information content of an element is influenced not only by its frequency, but also by its phonetic salience and by the attention a language user allocates to it in context. These are factors that linguists have independently argued influence phonological patterns. Laboratory studies of a number of languages show that listeners tend to allocate more attention to beginnings of words. Correspondingly, many languages restrict marked elements or structures to initial syllables of words (e.g. Beckman 1997).

To briefly illustrate, consider a language system L with a set of elements $X = \{x_i, x_{ii}, \ldots x_n\}$. Predicting which element will occur in a given context can be measured as a function of its probability, determined in part by its frequency of occurrence (see below for the role of acoustic salience in defining information content). Each element thus has its own probability of occurrence: sound x_i has probability $p(x_i)$. The information content of an element x_i is the negative logarithm base 2 of its probability p. This corresponds to our intuition that elements with higher probability are more expected than elements with lower probability; in information-theoretic terms, it takes less information (fewer binary decisions) to determine whether or not it will occur. In the vowel epenthesis example below, for instance, information content is used to compare the probability that a particular vowel occurs in a given context with the probabilities for all vowels in the system that comprise the relevant probability distribution.

Comparisons can also be made at the level of systems, rather than individual items: the total entropy of a system, or its complexity, is the sum of the information contributed by all members. To the extent that systems from different languages are compared, this measure can address questions relating to universal markedness patterns. To measure the contribution of a particular element to the entropy of the system, its information content is multiplied by the probability of its occurrence in that system, that is, $-p(x_i) \log_2 p(x_i)$. Note that an element's probability appears twice in this expression, with opposite effects. As a result, elements with either very high or very low probability contribute little to total system entropy: elements with very low probability have high information content, but contribute little because of their low rate of occurrence; conversely, elements that occur very frequently contribute little because their information content is correspondingly low. Elements with intermediate probability contribute relatively more to the complexity of the system, that is, its entropy, through their balance of moderate information content and frequency of occurrence.

The common markedness diagnostic, epenthesis, illustrates how these concepts can be used to answer the questions: (i) why epenthesize?; and (ii) why epenthesize a particular vowel? Consider the case of English vowel epenthesis as used to repair a non-occurring word-initial cluster. As noted above, a word-initial [gd] cluster as in the Polish city name Gdansk is often repaired as [gəd] (or [gɪd]). The first question concerns the motivation for epenthesis. In this approach, the answer is that adding [gd] to the language would, all else being equal, increase the complexity of the system, measured as entropy. This conclusion derives from considering the information content of the structures [gd] and [gəd], measured as the negative $\log_2$ of the conditional probability of the respective phonotactic sequences in English and the contribution of each to the entropy of the system. (In this simple case, information content can be approximated solely in terms of the type or token frequency of each sequence in a corpus of English.) Prior to borrowing, [gd] has a probability of zero, and contributes nothing to the entropy of the system; adding this sequence increases systemic entropy sharply. In contrast, increasing the frequency of an already occurring element such as [gəd] has less of an effect on the entropy of the system.

Parallel reasoning can be used to predict why one segment is the preferred epenthetic vowel in a given context over other vowels in the language. Why, for example, is the initial [gd] cluster typically repaired in English as [gəd] or [gɪd], as opposed to [gad], [god], [gid], among other possibilities? Common explanations point to the epenthetic vowel as unmarked, less salient, more frequent, predictable or somehow simpler than other vowels in the language. The information-based approach is consistent with these insights. A simple model takes into account the probability of each vowel in the system as a function of frequency and mutual information (context-dependent frequencies), and the phonetic nature of the sound in the relevant context, measured in terms of the quality of its acoustic cues. In this model, the information content of a given vowel is a function of both its probability of occurrence and its acoustic salience. The results indicate that [ə ɪ] have the lowest information content of all vowels in the system, consistent with the observation that these vowels commonly emerge as epenthetic.

While English epenthesis provides a relatively straightforward example, the approach extends to cases such as vowel epenthesis in French where, as noted above, a mid front rounded vowel serves as the epenthetic vowel; as such, the initial [gd] cluster of *Gdansk* would commonly be repaired as [gød] or [gœd]. French epenthesis is of particular interest, given the widely held view that front rounded vowels are universally marked (Chomsky and Halle 1968; Causley 1999; de Lacy 2006). However, the front rounded vowels are not only among the most frequent vowels in French, but also have been shown to be the most confusable with other vowels in the system. The information-based approach correctly predicts the mid front rounded vowels to have the lowest information content among vowels in the language, and to be the preferred epenthetic vowels (Hume and Bromberg 2005).

This approach provides an answer to the conflict regarding perceptual salience noted above: unmarked status is associated both with patterns with strong salience and those with weak salience. The salience of sounds in a system can be calculated as the probability of a given element being correctly identified. To the extent that the probability distribution is asymmetrical such that some sounds have a high probability of being misidentified (weak salience), these sounds will have a low value for information content and thus contribute little to the entropy of the system (as defined by the relevant probability distribution). All else being equal, such sounds are likely candidates for reduction and deletion. Interestingly, the observation that sounds with low information content are prone to deletion as well as epenthesis also addresses another apparent conflict among markedness criteria: the unmarked segment is not only the most likely to be deleted, it is also the most likely to be inserted. As noted above, the proposed explanation is because changes to the entropy of the system would be minimally affected by those elements that contribute little to its complexity. Sound patterns with strong salience, on the other hand, have higher information content; as a result, their loss would result in a more drastic change to the system. Thus, all else being equal, patterns with stronger salience are predicted to be more stable and avoid change.

6 Conclusion

As should be evident from the discussion above, the concept of markedness has had a long and controversial history in phonology. The goal of understanding why some elements pattern differently from others is at the heart of the linguistic and, more generally, cognitive enterprise. As a result, I suspect that markedness, whatever "it" is, will continue to be a much debated topic for years to come.

ACKNOWLEDGMENTS

My sincere thanks to Marc van Oostendorp, Keren Rice, and an anonymous reviewer, whose valuable comments strengthened this chapter. I would also like to thank Colin Ewen for his assistance in preparing the final version. This chapter is dedicated to the memory of G. Nick Clements who, on my generals exam at graduate school, posed the question of what markedness is, thus starting me on my quest to get to the bottom of it.

5 The Atoms of Phonological Representations

Marianne Pouplier

1 Introduction

Phonology describes spoken language as a combinatorial system typically comprising 30–40 basic units. The smallest known inventories make use of about 10 contrastive units, the largest no more than 150 (Maddieson 1984). Phonological theories capture, on the one hand, the nature of these basic units themselves (the atoms of speech production and perception) and, on the other hand, the language-specific patterns that the units show when they combine into larger structures. One of the key problems in relating this combinatorial system to the phonetic, physical side of speaking lies in the spatio-temporal structure of speech, which does not seem to mirror the units of linguistic analysis. When we inspect instrumental records of speech, the discrete combinatorial system that underlies these records is by no means obvious. We see continuously changing, highly context-dependent articulator motion and spectral energy patterns, with no clear boundaries between the individual sounds. The discrepancy between the symbolic units used to capture grammatical regularities and the dynamic complexities of speech as a motor act is so fundamental that some researchers have adopted the view that phonology and phonetics best be studied as separate sciences, since it seems difficult to see how the insights of each discipline could be relevant for the other. Current phonological and phonetic theories are, however, informed by the insight that phonetics and phonology are intertwined to such an extent that one cannot be understood without the other. How the relationship between phonetics and phonology can be negotiated has therefore been one of the key research topics in both disciplines (Pierrehumbert 1990; Boersma 1998; Flemming 2001; Hume and Johnson 2001; Keating *et al.* 2003; Hayes *et al.* 2004; Prince and Smolensky 2004; to name but a few); see also Kingston and Beckman (1990) and subsequent Laboratory Phonology volumes.

Several theories have tackled this issue in a new fashion since the 1980s, most prominently by positing the phonetic grounding of constraints in optimality-theoretic approaches and by recasting phonological primitives as dynamic entities within gestural theories. Within the optimality-theoretic framework, phonological constraints can directly encode speakers' knowledge of the kinematics of speech production and of characteristics of the auditory system. For instance, sounds can be ranked according to a scale of articulatory effort, and constraints may target different points along that scale (in particular so in the functional phonology school, e.g. Jun 1995; Boersma 1998; Flemming 2001; Steriade 2009). In addition, the perceptibility of sounds can directly be referred to in phonological constraints, often in the form of a requirement of contrast maintenance (CHAPTER 2: CONTRAST). Assimilation patterns (CHAPTER 81: LOCAL ASSIMILATION) have for instance been modeled as affecting primarily the least perceptible segments. In this view, speakers conserve articulatory effort (reduce a given articulation) if they know that it is likely to go undetected by a listener or if the perception of a phonological contrast is not endangered (Hura *et al.* 1992; Steriade 2001). Continuous constraint evaluation is also used to predict undershoot and hyper- or hypoarticulation in the sense of Lindblom (1963, 1990); see Boersma (1998) and Jun (2004). These theoretical frameworks capture how phonological constraints exploit the physiological givens of speech production and perception, but many accounts still rely on discrete phonological units that are implemented phonetically at some unspecified later translation stage.

Flemming (2001) advocates that these phonetically informed constraints also operate on continuous, phonetically enriched representations. Category effects arise from constraints requiring maximal contrast, i.e. contrast will only arise if there is sufficient phonetic distinctiveness. He assumes that consonants and vowels have acoustic targets that are fixed in terms of formants and duration. Contextual deviations from the target fall out from effort avoidance constraints and the interaction of effort avoidance with constraints requiring the maintenance of contrast. Flemming (2001) illustrates his account with an example using an F2 target; how the account could be expanded to the full wealth of acoustic cues and their trading relations remains open. He further relies on a direct correlation between extent of articulator movement and acoustic change, but, due to the many nonlinearities in the acoustic–articulatory relationship (Stevens 1989), this can only be a first approximation (for the general controversy surrounding the assumption of acoustic targets in speech production see Fowler 1980, 1986; Guenther *et al.* 1998). Flemming's model shows how in principle both gradient and categorical effects may arise from the same representations. His model remains incomplete, however, in that it fails to incorporate the relative timing of articulatory events beyond a linear sequencing of target specifications.

A full-fledged model of how the temporal orchestration of articulatory events is shaped by linguistic structure and how phonological representations can carry temporal specifications while still providing means for expressing phonological contrast has been developed by gestural approaches. Gestural theories like Articulatory Phonology (Browman and Goldstein 1985) have departed from the assumption of symbolic representations: the basic units (gestures) are dynamically specified, goal-directed movements in the vocal tract and are coordinated with respect to one another to form larger molecules. Coupling provides the "glue" that makes gestures cohere into larger molecules. Phonology, in this view, directly governs coordination relationships (relative timing) among articulatory gestures.

We can quickly appreciate why the claim that phonological units should be abstract dynamic specifications of articulator motion provides a formidable theoretical challenge (and has been by no means uncontroversial) when we consider that the generation of any single sound as much as of any utterance requires a highly skilled coordination among numerous components of the respiratory, laryngeal, and supralaryngeal systems. For the production of a single sound, it has been estimated that 70–80 pairs of muscles are required; for instance, 12 muscle pairs alone participate in lip movement (Hardcastle 1976). The physical production of speech, in contrast to the phonological inventory of a language, involves a large number of subcomponents. Yet numbers express only a (perhaps small) part of the complexity issue: the temporal discreteness of phonological representations ("beads on a string") can only predict the temporal orchestration of articulatory events in the vocal tract to a limited extent.

Just prior to the development of the gestural approach, Autosegmental Phonology (Goldsmith 1976, 1990) (see also CHAPTER 14: AUTOSEGMENTS) was a major phonological development driven by the insight that the absolute linearity of phonological representations (Chomsky and Halle 1968) does not do justice to the temporal structure of phonological specifications. Goldsmith (1976) refers to this as the "Absolute Slicing Hypothesis," meaning that feature matrices belonging to each segment all have exactly the same domain. Autosegmental Phonology abandoned the idea of absolute slicing or absolute linearity (see also CHAPTER 54: THE SKELETON). Instead, Goldsmith used the analogy of a musical score that represents different information channels simultaneously. Non-linear phonology was motivated by the insight that the domains of linguistic specifications (e.g. the sequence of feature columns specifying the CV content of a word and the tonal specifiications of a word) do not necessarily line up in a 1:1 fashion. Temporal complexity of phonological representations was therefore expanded by introducing different tiers, which allow each linguistic specification to have a larger or smaller scope than a feature column on another tier (smaller in that, for example, two tonal features can be associated with a single vowel for a contour tone). Yet Autosegmental Phonology was not concerned with the translation problem: the basic units of representation remain symbolic and a-temporal. Non-linear phonologies still assume some unspecified translation stage that converts phonological symbols into the physics of speech.[1]

Articulatory Phonology, which spearheaded the gestural approach in the 1980s, is a much more radical departure from absolute linearity, by virtue of its claim that phonological representations are dynamic specifications of articulatory goals. Articulatory Phonology and Task Dynamics, as well as Motor Theory and Direct Realism, all belong to the early group of gestural theories. These theories have provided insights into different aspects of a skilled action approach to speech: Articulatory Phonology is a theory of how phonological processes can be understood by reference to the physical act of producing speech, and Task Dynamics provides a theory of speech motor control that enables us to understand how a continuous speech stream can arise from underlying combinatorial action units (Fowler 1980, 1984, 1996; Browman and Goldstein 1985, 1989, 1990a, 1992, 1995a; Liberman and Mattingly 1985; Fowler and Smith 1986; Kelso *et al.* 1986; Saltzman 1986; Saltzman and Munhall 1989; Liberman 1997; Goldstein *et al.* 2006). A treatment of Direct Realism and Motor Theory – the theoretical approaches that seek to explain how listeners parse these combinatorial action units from the continuous

[1] Another way to represent categorical temporal differences in phonological representations is Moraic Theory (Hayes 1989). Moraic Theory, however, does not provide an account of articulatory timing; furthermore, the mora needs to be translated into a phonetic-physical specification. For a gestural re-interpretation of moras as units of syllable weight, see the section on split-gesture dynamics.

speech stream – is outside the scope of this chapter, but useful overviews can be found in Hawkins (1999), Jusczyk and Luce (2002), and Galantucci *et al.* (2006).

We will elaborate on the basic concepts of gestural approaches in more detail in this chapter, and review some aspects of the controversies surrounding such a conceptualization of phonological representations. Recent theoretical proposals regarding the nature of gestures will also be presented. We will then discuss the modeling of syllable structure, as well as fluent speech phenomena as case studies illustrating the difference between segmental and gestural views. The last section discusses work that has combined gestural representations with optimality-theoretic constraints.

2 Gestures as units of action: Task Dynamics

Task Dynamics draws on the principles and insights from general motor behavior; the general model of skilled movement control has been adopted from non-speech domains to linguistics by Elliot Saltzman and colleagues (Saltzman 1979, 1986, 1991, 1995; Kelso and Tuller 1984; Browman and Goldstein 1985; Kelso *et al.* 1986; Saltzman and Kelso 1987; Saltzman and Munhall 1989; Turvey 1990). Task Dynamics provides a model of speech motor control showing how a continuous speech stream can arise from underlyingly discrete (action) units, without positing intrinsically timeless (symbolic) entities. These underlying units are called *gestures*. Task Dynamics addresses the nature of these primitive action units, the consequences of their partial or complete spatial and temporal overlap, and how coupling provides cohesion for larger units consisting of multiple gestures (gestural molecules).

The central problem in movement control – in speech as much as in any other area of skilled action – lies in the numerous degrees of freedoms that need to be controlled in an abstract fashion. Turvey *et al.* (1978) illustrate this on the basis of the five hinged parts controlling the spatial orientation of an airplane: to control the positioning of these parts individually would be a task stretching the limits of human information processing. By yoking the individual parts such that they move in a coordinated fashion, the angle of ascent/descent and the turn of a plane can be controlled by simply moving a joystick forward/backward or left/right. Also complex movements (skilled actions) in biological systems can be controlled macroscopically on the basis of so-called coordinative structures that yoke together many subparts into a single action unit (Bernstein 1967; Kelso and Tuller 1984; Kugler and Turvey 1987; Kay 1988; Kelso 1995). Action units are discrete, but their parameter settings (see below) give rise to continuous movement in time and space. Coordinative structures are functionally specific in that they are flexibly assembled depending on the requirements of a particular task; they are not hard-wired. In terms of speech, a speech task or gesture (e.g. Lip Closure) calls on several articulators (e.g. upper lip, lower lip, jaw) as a single coordinative structure; the articulators are grouped temporarily and flexibly into a functional unit that will accomplish the linguistic task. In this manner, gestures macroscopically govern the formation and release of local constrictions in the vocal tract. The task dynamic model importantly distinguishes *gestures* from *articulators* as two distinct but interacting levels. Put simply, gestures are phonological units, while articulators are not. To reach their tasks (Lip Closure), gestures call on several articulators (upper lip, lower lip, jaw) as a single coordinative structure. In this sense, gestures are abstract: they define global tasks (Lip Closure), not point-by-point movement. Each gesture is associated with a set of tract variables, specifying constriction location and degree, and a set of articulators that will act to perform the task (Saltzman and Munhall 1989).

Which articulatory component should be specified at the gestural level and which at the coordinative structure/articulator level is open to debate. For example, Mooshammer *et al.* (2007) propose that at least some consonants (specifically sibilants) should be specified for a jaw gesture, instead of the contribution of the jaw arising only by virtue of it being part of the coordinative structure. The authors base their argument on the fact that consonants with different manners of articulation differ systematically in the relative contribution of the jaw (Keating *et al.* 1994). However, which vocal-tract control component should be specified at the gestural or articulator level will usually be a phonological matter. Phonological processes like assimilation (CHAPTER 81: LOCAL ASSIMILATION) or harmony patterns (CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY) probably do not refer to the jaw, and for these reasons the jaw component should be relegated to the articulator level.

Tasks are modeled as dynamical systems (hence the name Task Dynamics). A dynamical system provides us with the simplest and most abstract description of the forms of motion over time produced by a system on the basis of an invariant control structure. Note that tasks are abstract, but they are not symbolic: the gestural task is modeled as a virtual mass-spring system whose rest position depends on the linguistic task. For Lip Closure, the rest position is set to the Euclidean distance between the lips being zero. The position of the individual articulators may vary by context but the lip closure corresponds to the rest position of the task that the virtual springs will inevitably return to, irrespective of initial conditions or perturbation on the way. Motor skills are generally modeled on the basis of critically damped mass-spring systems precisely because they provide a good model of this *equifinality* (the rest position/target is reached independently of the initial position, the amount of displacement, or number of perturbations along the way). Coordinative structures allow for the necessary context-specific variability; the task can be reached with many different articulator configurations (a relative lower jaw position, but more raising of the lower lip, etc.) without the details of the configuration requiring central replanning or a task-level reparameterization (Turvey 1977; Abbs and Gracco 1984; Kelso and Tuller 1984; Kelso *et al.* 1984).

Task Dynamics is an intrinsic timing theory, meaning that the proposed units themselves carry inherently a temporal dimension. In contrast, extrinsic timing theories posit that the dimension of time is irrelevant for defining the phonological units themselves, or their relations in planned utterances. Symbolic segmental representations do not carry an intrinsic temporal component; the temporal evolution of segments during their phonetic implementation is provided externally through a timekeeper that is extrinsic to the units themselves and not explicitly represented in the plan (Fowler 1980). In Task Dynamics, however, the extension of sounds in time and their relative timing are intrinsic consequences of the system's dynamical organization. Distinct gestures for a given vocal organ are associated with a distinct set of dynamical parameter values that are fixed over time. A gesture's activation interval refers to the time interval during which these specifications are active. Each tract variable is associated with linear second order dynamics, that is, activation of a tract variable entails a specific damping ratio, a natural frequency (stiffness), and a target position (Saltzman and Munhall 1989). Gestures therefore carry temporal specifications in several ways: they have an *activation interval* during which they control the vocal tract; second, *intragestural timing* refers to each gesture's intrinsic temporal properties; and third, *intergestural timing* refers to the temporal coordination of multiple gestures with respect to each other.

Serial order arises in two ways. First, the different intrinsic temporal properties of gestures may give rise to serial order. For example, vowels are "slower" compared to consonants (they have a lower stiffness parameter setting): for a production of /ba/, for example, the vowel gesture may start before the lip gesture has reached its target (Perkell 1969; Löfqvist and Gracco 1999), but the vowel extends temporally beyond the consonant. Allophonic variation may also arise as a consequence of this temporal overlap of gestures. The allophonic variation of English /k/ in a front and back vowel context arise due to the velar constriction being blended with the co-occurring vowel constriction, since both vowels and /k/ control the tongue body (Öhman 1966); the temporal overlap of gestures is seen as the cause of co-articulation (Fowler and Saltzman 1993).

The other way to capture serial order is through coupling between multiple gestures; coupling provides the glue that makes gestures cohere into larger molecular structures. These coupling relations between gestures are expressed as relative timing or phase relations between gestures (intergestural timing). Since gestures are conceptualized as underlyingly oscillatory systems, larger gestural structures such as segments, syllables, and lexical items are modeled as coupled dynamical systems. Two specific coupling modes have a privileged status: it is well known that coupled dynamical systems in general exhibit naturally preferred coordination modes in terms of stability (Strogatz and Stewart 1993; Turvey 1990): Most stable is synchronous coordination (in-phase, 1:1 frequency) followed by a coordination 180° out-of-phase. Synchronous coordination has been observed to emerge spontaneously when skilled actions fail to be produced accurately, for example under increasing speed. While humans routinely perform highly complex patterns of coordination, these take time to learn and will, under the right conditions, revert to the stable synchronous coordination. There has also been some evidence for the significance of these preferred coordination modes in speech. For example, when subjects are instructed to repeated /ip/ at increasing speaking rate, we observe a spontaneous phase shift to the timing pattern characteristic for /pi/ (Kelso *et al.* 1986). Speech errors have also been argued to arise from a dynamic synchronization of articulatory gestures: they may result in the gestures for two consonants being produced on top of each other (Goldstein *et al.* 2007; Pouplier and Goldstein 2010). Gestural theories argue that these coordination patterns are not only part of speech motor control, but they are part of grammar and provide the basis for expressing cross-linguistic preferences such as a preference of CV over VC. They also constitute the basis of the gestural account of syllable structure (Browman and Goldstein 1988, 2000), speech errors (Goldstein *et al.* 2007; Pouplier 2008), and moraic structure (Nam 2006). Certain aspects of phonological development in language acquisition have likewise been modeled on the basis of in-phase and out-of-phase coordination (Studdert-Kennedy and Goldstein 2003).

Task Dynamics is a theory of how continuous articulator motion can be divided into discrete underlying action units (gestures). These action units can provide the small inventory of discrete units required for phonological contrasts. How gestures can function as combinatorial phonological units was first developed in the theory of Articulatory Phonology and will be detailed in the next section.

3 Gestures as units of phonological contrast

The gestural structure is the most abstract representation level of gestural planning. It captures the gestural tasks, the underlying coordination or coupling relationships, and the shapes and duration of each gesture's activation function that gives rise to the gestural score (Goldstein *et al.* 2006). The activation of gestures is not on-or-off; gestural activation rises and falls gradually (Byrd and Saltzman 1998). The dynamic parameterization (target, stiffness, and damping) of a gesture as lexically specified in the gestural score is invariant and context-independent, although there seems to be some notion that speaking rate or prosodic boundaries can affect the stiffness parameterization of a gesture. Crucially, however, due to the temporal co-existence of gestures, the articulator movement that the gestural score gives rise to is ***not*** invariant but varies with context (Browman and Goldstein 1990b; Fowler and Saltzman 1993). The gestural score is the driving input for the articulator level (although the levels interact), and the activation waves serve to insert a gesture's parameter settings (constriction location and degree) into the articulator dynamical system. Figure 5.1 shows an example gestural structure and score. The relatively independent articulatory subsystems (termed "vocal organs" by Browman and Goldstein) are arranged on separate tiers. The gestural structure

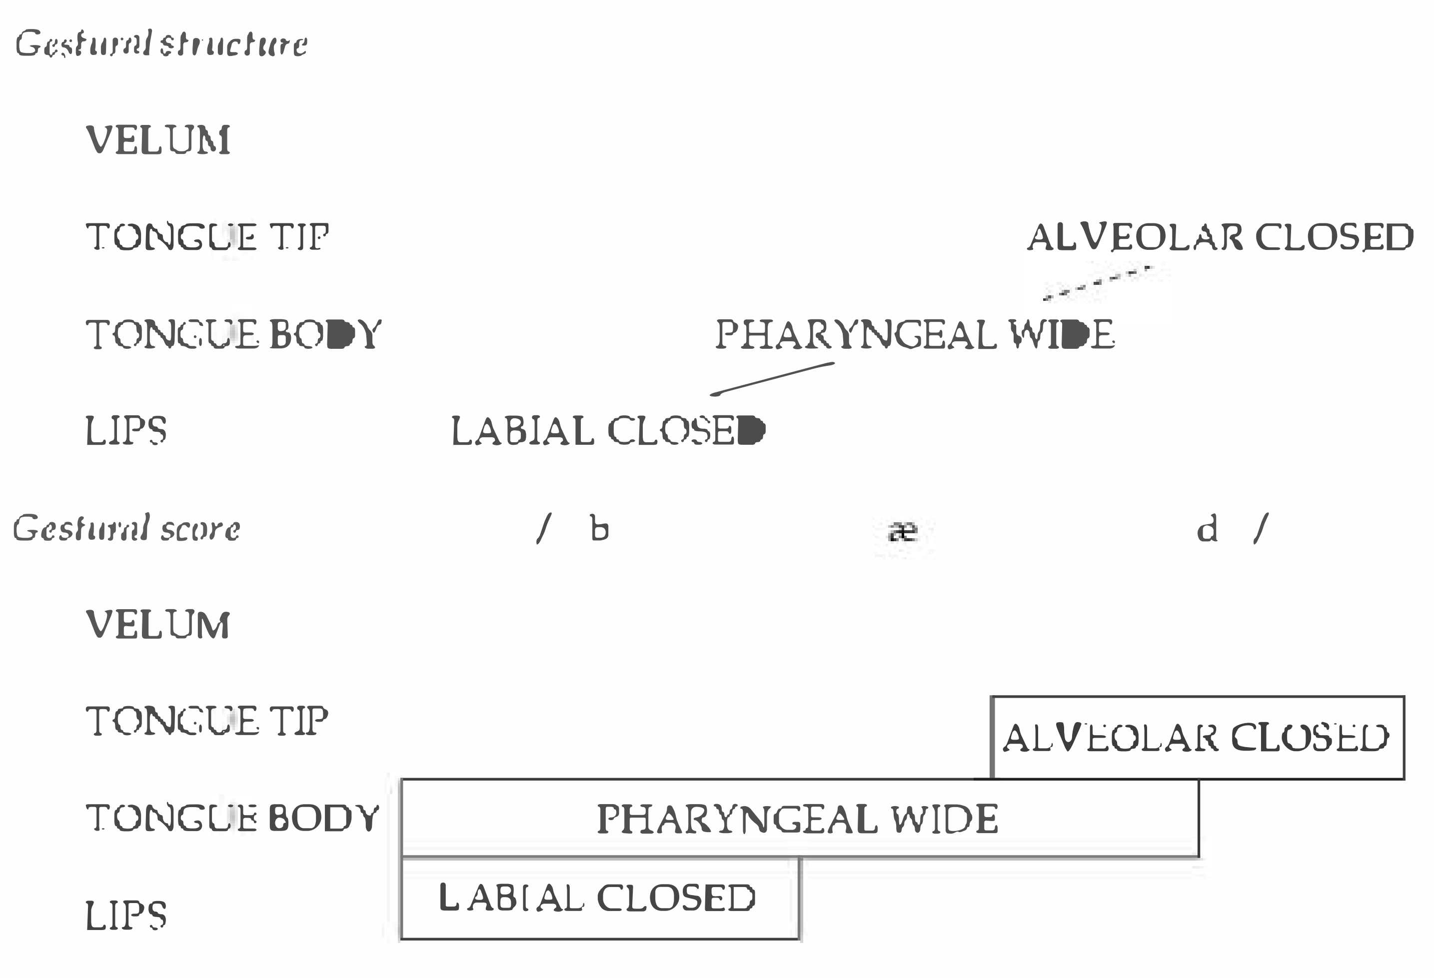

Figure 5.1 Gestural structure (top) and gestural score (bottom) for the English word *bad*. In the gestural structure, dashed lines indicate anti-phase coupling relations, while solid lines indicate in-phase coupling relations

specifies the coupling relations between the gestures of a lexical item. The gestural score is the relative timing pattern of gestures that arises from the gestural structure. Again, the vocal organs are arranged on separate tiers. The boxes indicate the time interval during which a given gesture actively controls the vocal tract.

The visual impression of the gestural structure highlights the metaphor of gestural atoms and molecules that both gestural and non-linear phonologies have used. Atoms that are bound together in a molecule are arranged geometrically, not in the linear sequence in which chemical formulas are written (Browman and Goldstein 2001). Similarly, gestures are arranged temporally in a complex manner to each other by means of different coordination relationships (see also Goldsmith's 1976 terminology of the "musical score," even though, as noted above, autosegmental association lines provide a domain specification rather than a specification of physical time).

The basis for discrete combinatorial units is provided by those vocal organs or constricting devices of the vocal tract that can perform constrictions relatively independently from each other (cf. relatedly the functional grouping of features in feature geometry: Clements 1985; Sagey 1986; Keyser and Stevens 1994; and the "information channels" in Goldsmith 1976): the tongue tip, tongue blade, tongue root, larynx, velum, and the lips. The parallels and differences to a feature-geometric approach are discussed in detail in Browman and Goldstein (1989; see also Padgett 1994). The six vocal organs are hypothesized to be inherently discrete and provide a small set which we can use as discrete, context-invariant units of phonological contrast (Browman and Goldstein 1989; Goldstein *et al.* 2006). Supporting evidence comes for instance from typological considerations: the typologically most widespread contrasts have been argued to involve distinct vocal organs as opposed to within-organ contrasts (Browman and Goldstein 2001; Goldstein and Fowler 2003). Tongue movement data also support a functional discretization of the parts of the tongue (Stone *et al.* 2004; Iskarous 2005; see further Studdert-Kennedy and Goldstein 2003 for arguments from phonological development).

Gestures can serve as the units of a combinatorial system in three basic ways. First, the presence or absence of a gesture is a categorical distinction. This is assumed to be the most basic type of contrast, since it involves the presence of a constriction of one of the six basic vocal organs. For example, *mad* has a velum opening gesture, while *bad* has no such velum gesture, *pad* has a glottal opening gesture while *bad* has no such gesture, etc. Note that glottal adduction ([+voice] in featural terms) and a closed velum ([−nasal]) are assumed to be default articulatory settings that do not need to be specified at the gestural level (Browman and Goldstein 1992; Goldstein and Browman 1986), so there is no glottal adduction and no velum closing gesture.

A second way in which gestures encode linguistic contrast is by differences in the dynamical parameters that define the spatio-temporal properties of a gesture (within-organ contrasts). Gestures employing the same vocal organ may differ parametrically in constriction location, constriction degree, and stiffness; for example, vowels and consonants differ in stiffness (and in constriction degree). A tongue tip gesture may be specified for a constriction degree value of "closure" (stops) or "critical" (fricatives). It is argued that there are stable ranges in these continuous parameter values that tend to contrast with one another cross-linguistically (cf. Quantal Theory; Stevens 1989). The third way in which gestures express phonological contrast lies in the relative coordination of different gestures to one another.

For example, the opposition between unaspirated, aspirated, and breathy stops is rooted in differences in gestural timing (and in size of the glottal gesture): for an unaspirated stop, the peak glottal opening occurs synchronously with the maximal closure, while for an aspirated stop the peak glottal opening gesture occurs at the consonant release with the consequence of a positive voice onset time. In breathy stops, the onset of the glottal opening gesture is timed to occur at the release (Sawashima and Hirose 1980). Some phonotactic rules can also be expressed as timing relations. English /s/ + stop cluster phonotactics (see CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS) have been described in gestural terms as allowing only a single glottal opening gesture, the peak of which is presumably timed with respect to the maximal constriction of the /s/. As a consequence, the stops in such clusters are unaspirated. Phonological units in general (including segments) are all understood as characteristic patterns of temporal coordination among multiple gestures, as will be discussed in more detail next.

4 Atoms of speech production: Gestures, segments and split-gesture dynamics

It is important to note that in Browman and Goldstein's view (most explicitly stated in Browman and Goldstein 1986) the segment does not have a privileged status (CHAPTER 11: THE PHONEME; CHAPTER 54: THE SKELETON); segments are gestural molecules, just like onset clusters or syllables, for example. Gestures may sometimes be similar in grain size to segments or features, but they differ from both. A gesture corresponds to a feature in *bad vs. mad*. Presence/absence of a gesture corresponds to a segment in *bad vs. add*. For other features, such as [consonantal] or [sonorant] (CHAPTER 13: THE STRICTURE FEATURES), there is no corresponding gesture; these are generalizations over constriction degree, i.e. one of the dimensions of gestural parameterization (Browman and Goldstein 1989). The cluster /sp/ consists of two segments, yet gesturally it is composed of a tongue tip gesture and a labial gesture, as well as a single glottal opening gesture whose maximum opening is timed to occur at mid-frication; but see Saltzman and Munhall (1989) for alternative data and interpretations, and Hoole (2006) for a detailed investigation of the gestural timing of laryngeal and oral gestures in consonant sequences and a discussion of the question of what timepoints should best be considered for alignment.

Scobbie and Pouplier (2010) provide evidence for the gestural constellation view of segments in their investigation of British English /l/ (CHAPTER 31: LATERAL CONSONANTS). English /l/ is known to have two gestures: a tongue tip raising gesture and a tongue dorsum retraction gesture, and the timing and spatial magnitude of the gesture varies systematically with syllable position (Giles and Moll 1975). Scobbie and Pouplier report that the two gestures of English /l/ behave like two elements of a cluster rather than a single segment, in that the two gestures may behave independently of each other in external *l*-sandhi. There is also some evidence from speech errors supporting a gestural rather than a segmental view (Goldstein *et al.* 2007b). Other gestural approaches do recognize segmental levels of organization. Byrd has argued that segmental molecules have a particularly high degree of stability; thus, intra-segmental phase relationships (e.g. the phase relationships binding together the oral and glottal gestures of a voiceless consonant) have a privileged (more stable) status compared to inter-segmental phasing relationships (e.g. the phase relationship binding together the /s/ and /k/ of a /sk/ cluster: Saltzman and Munhall 1989; Byrd 1996; Byrd *et al.* 2009).

Moving a step further away from segmental level of organization, Browman (1994) argues that the release of a gesture needs to be actively controlled; the assumption of the initial gestural model that the release is governed by a return of the articulators to a neutral position (Browman and Goldstein 1985) was shown to be insufficient to predict articulator kinematics. This insight has consequently been implemented in Nam's recent theory of split-gesture dynamics (Nam and Saltzman 2003; Nam 2006, 2007). Nam extends the principles of the molecular composition of clusters to single gestures by modeling each "gesture" on the basis of a separate constriction formation and a separate release gesture. Each consonantal gesture is now conceived of as a gestural molecule or cluster in which formation and release gestures can enter different phonologically specified coupling relations. Singleton consonants and consonant clusters differ only in the number of components and coupling relations that form the molecular structure, but in principle they are both clusters. Empirical underpinnings come from a variety of areas: asymmetries in the kinematics of articulator motion into and out of a constriction have long been noted, and seem to necessitate a separate modeling of release and closure formation (Gracco 1988; Browman 1994). Further, the assumption of split gestures allows the modeling of different types of releases, such as released *vs.* unreleased stops (cf. also Steriade 1993). In addition, differences in articulatory timing and in timing variability in CV *vs.* VC sequences (Byrd 1994) can appropriately be captured by this model. The influence of prosodic factors on articulator kinematics has also previously been modeled as the movement into the constriction being truncated by the movement out of the constriction (Munhall *et al.* 1992; Harrington *et al.* 1995). On the phonological side, several facts about moraic structure and geminate inseparability (CHAPTER 37: GEMINATES) have been mustered as arguments for a separate representation of a release (Nam 2006, 2007). Nam (2006) gives the mora a gestural interpretation, and thus provides an account for the weightlessness of onsets (CHAPTER 55: ONSETS; CHAPTER 57: QUANTITY-SENSITIVITY) in terms of different coordination relations governing prevocalic and post-vocalic positions (cf. §5 on syllables). Nam conceptualizes moraic structure as differences in the complexity of coordination relationships, moraic weight becoming thus a continuous phenomenon, a step that may ultimately increase our understanding of typological timing or rhythm class differences between languages. Note that in the current task dynamic model of Nam *et al.* (2004) only oral consonantal gestures are hypothesized to carry split-gesture dynamics. For glottal, velic, and vocalic gestures, the whole movement cycle into and out of the constriction is modeled on the basis of a single gestural task.

Preceding Nam's work, there had been suggestions to account for the tense–lax opposition in the German vowel system by modeling the movement into and out of the vowel constriction on the basis of split vowel gestures by Hoole, Mooshammer, and colleagues (Kroos *et al.* 1997; Hoole and Mooshammer 2000) in an articulatory interpretation of Vennemann's syllable-cut hypothesis (Vennemann 1991). The authors argue that the difference between tense and lax vowels lies in their dynamic properties, namely the coupling of the opening to the closing gesture (with a relative tighter coupling of the split vowel gestures to each other for the lax vowels) and the kinematics of the opening movement. Lax vowels are more centralized, because the opening gesture into the vowel differs in its dynamics from the tense vowels, such that the lax vowel opening gesture is produced with a bigger amplitude and different acceleration profile. The idea that vowel inventory oppositions such as tense–lax pairs can be modeled on the basis of split-gesture dynamics has not as yet been developed any further (but see Restle 2003).

After reporting these different views on what grain size the atoms of speech production have, we will now consider syllable structure and assimilation as case studies of how gestural approaches model these core phonological phenomena with gestural rather than symbolic atoms.

5 Prosodic structure: Syllables as phonological molecules

In phonological theory, prosodic structure is defined in terms of a symbolic hierarchy of prosodic constituents (Nespor and Vogel 1986; Selkirk 1982; see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE; CHAPTER 40: THE FOOT; CHAPTER 51: THE PHONOLOGICAL WORD; CHAPTER 84: CLITICS; CHAPTER 50: TONAL ALIGNMENT). Gestural theories have modeled the syllable hierarchy, and the serial order provided by the different syllable positions on the basis of different intergestural coupling relations, that is, syllables are viewed as characteristic patterns of temporal coordination among multiple gestures (Krakow 1993; Browman and Goldstein 1995b, 2000). By hypothesis, the behavior of a gestural constellation in different syllable positions is governed by the two preferred coordination modes (in-phase, out-of-phase). Syllabic organization is therefore assumed to reflect the preferred coordination modes, typical for skilled action, in speech, whereby the onset carries the intrinsically less marked in-phase relationship.

Empirical evidence for the coordination theory of syllable structure comes from systematic differences in relative timing that can be observed as a function of syllable position. For example, in syllable-initial position, the two gestures of the initial /l/ in *leap* reach their target with a small lag, with the vocalic dorsal gesture being typically closer to the onset. Syllable-finally, e.g. in the word *peal*, the two gestures of /l/ show a different pattern: the tongue body retraction gesture begins early during the vowel (resulting in an audibly darkened vowel), while tongue tip raising lags behind the retraction gesture (Browman and Goldstein 1990b; Sproat and Fujimura 1993), although this may differ between languages (Gick *et al.* 2006). Similarly, for nasal consonants, the oral and velic gestures achieve their targets simultaneously initially, but the velic opening gesture precedes the oral gesture syllable-finally, resulting in a nasalized vowel (Krakow 1993, 1999; Byrd *et al.* 2009). It is assumed that these timing relationships are consequences of the underlying in-phase (onset) and out-of-phase (coda) coordination relationships.

Browman and Goldstein (1988, 2000) argue that in onset clusters, consonants *cannot* all be coordinated synchronously with the vowel; they would not be perceptually recoverable. It is thus assumed that onset consonants are coordinated sequentially with each other, yet each consonant is coordinated synchronously with the vowel, as illustrated in Figure 5.2. These incompatible phasing relationships yield a blended output in which the onset cluster as a whole retains the same stable temporal relationship with the vowel, independently of how many consonants the cluster contains. This stable temporal center of the ensemble of onset consonants has been termed the c-center. According to Browman and Goldstein,

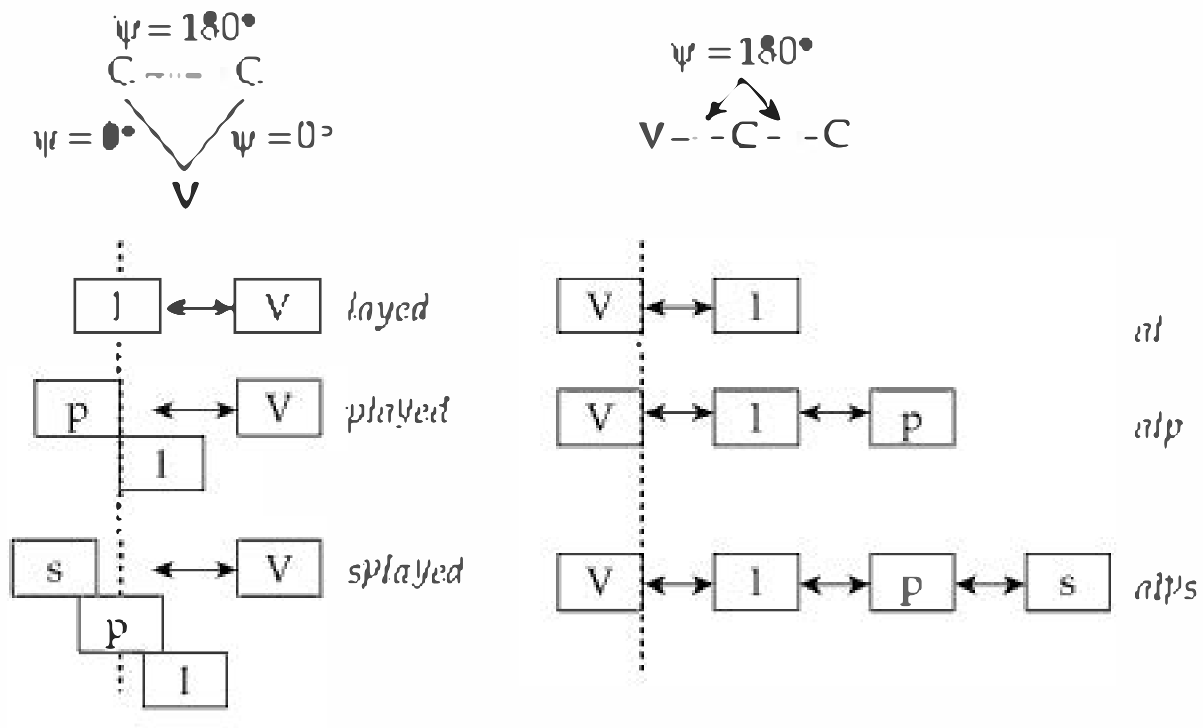

Figure 5.2 Schematic representation of c-centre coordination and the observed timing relationships in onset (left) *vs.* left-edge coordination in coda (right). The dashed vertical line indicates the stable timing point measured in articulatory data that is due to the underlying phase relationships (c-centre in onset; pairwise-sequential coupling in coda)

at least in English, the c-center is observed only in onsets, not in codas. In a $VC_1C_2C_3$ coda, pairwise-sequential phasing, also referred to as left-edge coordination, will be observed: C_1 will be coordinated 180° out of phase with the vowel, C_2 180° out of phase with C_1, etc.

That the onset exhibits predominantly the preferred in-phase coordination mode has been used to explain a variety of phonological phenomena, such as the primacy of onsets in language acquisition, the unmarked status of the CV syllable (but see Tabain *et al.* 2004; Butcher 2006), and the moraic weightlessness of onsets (Nam 2006). The coupled oscillator model of syllable structure further predicts that onsets should cross-linguistically exhibit c-center organization. Studies on English, Italian, and Georgian have confirmed c-center organization for onsets; the c-center has also been used as a diagnostic for syllable structure in Arabic and Berber (Honorof and Browman 1995; Goldstein *et al.* 2007a; Hermes *et al.* 2008; Shaw *et al.* 2009). Fewer studies have investigated coda clusters, and the results are less consistent than for onsets (Byrd 1995; Kochetov 2006; Marin and Pouplier 2010). The coherence of syllables into words and larger constituents has received only a limited amount of attention in gestural approaches so far. Smith (1995) proposed that stress- and mora-timing can be modeled on the basis of different cross-word coupling structures, but much work remains to be done in this area (cf. also Barbosa 2002a, 2002b; Yanagawa 2006; Tilsen 2009). For recent work modeling the prosodic hierarchy based on a hierarchy of coupled oscillators see Byrd and Choi (2010), Byrd and Saltzman (2003), and Saltzman *et al.* (2008).

6 Assimilation, overlap, and reduction

In connected speech we observe a variety of sandhi phenomena, such as assimilation. Describing and predicting patterns of assimilation has been one of the major motivations for non-linear phonologies, and remains a touchstone issue for theories modeling the phonetics–phonology interface. In a non-linear approach to phonology, assimilation has been captured on the basis of feature linking and delinking. For example in fluent speech, the cross-word [kt#m] cluster in the phrase *perfect memory* may be pronounced as [km], with the final coronal being assimilated to the following labial, schematically exemplified in (1):

(1) /t/ /m/ (→ [m])

Place Place

coronal labial

However, articulatory recordings of assimilated sequences revealed that a delinking of features may not accurately capture place assimilation. Articulatory recordings of the phrase *perfect memory* showed that although perceptually the final [t] was completely assimilated to the following nasal, the coronal constriction for the [t] was in fact still produced; it was only perceptually hidden by the temporally overlapping labial articulation (Figure 5.3). This example illustrates the consequences of a particular case of gestural overlap, namely when overlapping gestures control different vocal organs and tract variables. The articulations of coronal and labial

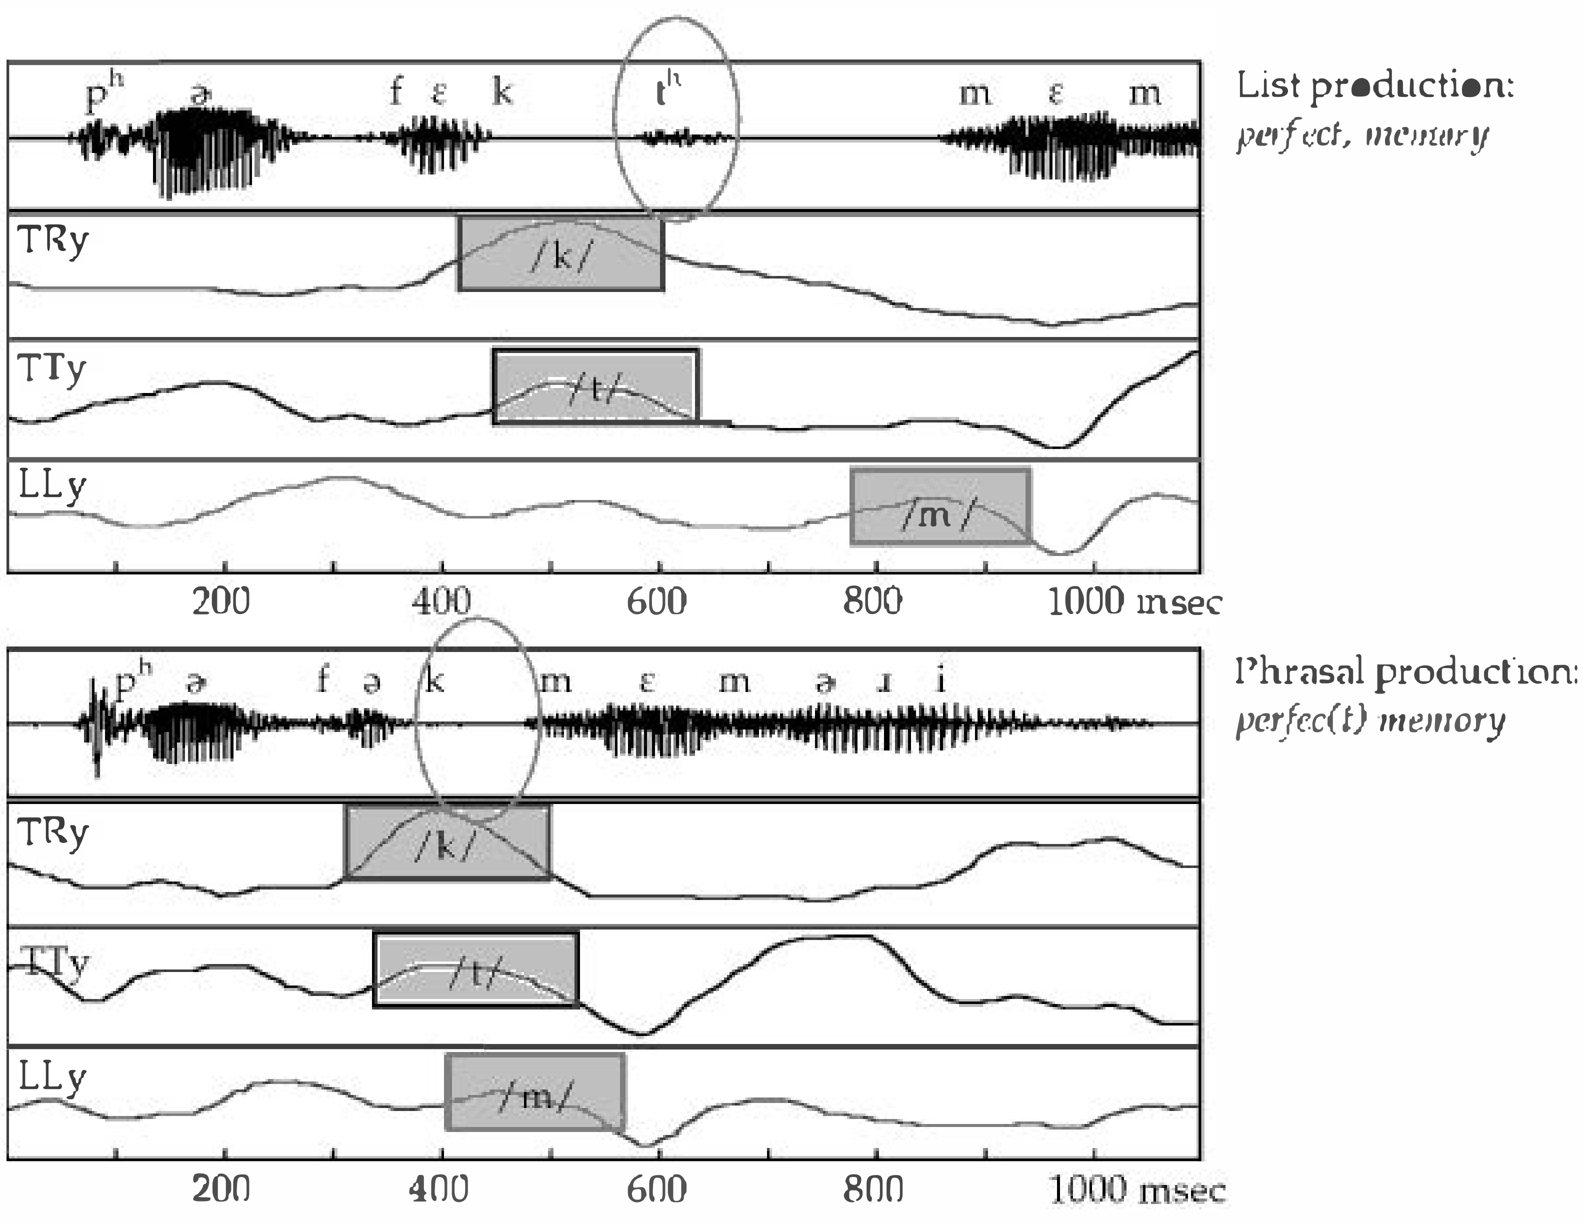

Figure 5.3 Articulatory data showing vertical tongue rear (TRy), tongue tip (TTy), and lower lip (LLy) movement over time. Boxes indicate the kinematic realization of the /k/, /t/, and /m/ gestures. The phrasal production illustrates how increased temporal overlap between gestures may lead to perceptual hiding of a gesture (/t/), although articulatorily the coronal constriction is produced in both cases. From Tiede *et al.* (2001). Used with permission

constrictions are largely independent, and do not affect each other significantly in the case of temporal overlap.

In other cases, articulatory place assimilation at word boundaries could be shown to be gradient, in that the spatial magnitude of the tongue tip gesture is reduced along a continuum of values (Surprenant and Goldstein 1998), yet articulatory assimilation may also be categorical, in that the assimilated gestures may be consistently and categorically absent (i.e. not produced: Honorof 1999; Son *et al.* 2007). For example, the tongue tip gesture for word-final alveolar /n/ in Castilian Spanish (e.g. in *diga*[m] *paja* 'say straw (FORM PL)'; cf. *diga*[n]) is categorically absent, and the lip aperture gesture is temporally extended (Honorof 1999).

Furthermore, if the overlap of gestures involves not stops, but continuants, the temporal overlap may have quite clearly audible consequences, as in *miss you*. In fluent speech, the phrase will be pronounced as [mɪʃju]. The tongue tip gesture for /s/ is overlapped by the tongue body raising gesture for /j/, leading to a production perceptually similar to [ʃ]. Articulatorily and acoustically, the assimilated sequence differs from an underlying [ʃ] (Zsiga 1995). However, for lexically derived forms such as *impression*, she finds no evidence of [ʃ] arising from a co-production of /s#j/ gestures. For lexically derived forms, Zsiga therefore assumes a symbolic (de)linking of features, and a gestural overlap account only for post-lexical assimilation.

The hypothesis that fluent speech phenomena do not involve a symbolic restructuring of phonological units and their affiliations to segmental timing slots, but can be exclusively understood as variation in timing and spatial magnitude (see especially Browman and Goldstein 1992: 173), sparked a heated debate. A vigorous exchange concerned English sibilant assimilation as it occurs in phrases such as *Paris show*. Nolan and colleagues (Holst and Nolan 1995; Nolan *et al.* 1996) investigated phrases like *claps Shawn*, and found evidence for gradient assimilation as well as categorical assimilation, and argued that the latter would more appropriately be described as a symbolic linking and delinking process rather than in terms of gestural overlap. Interestingly, for many tokens Nolan and colleagues also observe intermediate assimilation patterns, as expected for gestural overlap, but they do not offer an account of these assimilation patterns or of how the occurrence of one or the other type of assimilation might be conditioned. In other studies that have been conducted since (for several different languages), we likewise see a wide range of speaker behavior, and assimilation patterns consonant with a symbolic restructuring view (linking–delinking as sketched above) have emerged side-by-side with gradient assimilation and gestural hiding and blending phenomena as first described by Browman and Goldstein (Barry 1991; Farnetani and Busà 1994; Recasens and Pallarès 2001; Ellis and Hardcastle 2002; Kühnert and Hoole 2004; Kochetov and Pouplier 2008).

Overall, it has become clear over the years that a plethora of factors inflluence the degree of overlap found for any given utterance, such as the types of segments and (types of) lexical items, word frequency, and the (hypothesized) casualness of speech; also there are systematic differences in the degree of overlap between languages (Gibbon *et al.* 1993; Zsiga 2000; Chitoran *et al.* 2002; Kochetov 2006; Kochetov *et al.* 2007). There has to date been no deeper account that lets us predict which factors may condition the presence or absence of articulatory place assimilation in the form of a reduction of the final consonant, and under what circumstances any present place assimilation will be categorical or gradient in nature.

In this context, Zsiga (2009) advocates a combined autosegmental–gestural view: in her view gestural coupling relations can be manipulated by phonology; just like autosegmental association lines, they can be linked or delinked as a categorical phonological process. In her approach, the autosegmental association lines specify timing relationships in terms of in-phase or out-of-phase coupling of the associated gestures. Phonetic processes may then influence the timing of gestures within the association lines (in-phase, out-of-phase) provided by phonology. The phonetic fine-tuning of gestural timing leads to gradient assimilation caused by gestural overlap.

Most of the early work done in a gestural approach focused on the consequences of gestural temporal overlap for connected speech processes and on developing a theory of co-articulation as a coproduction of gestures. Gafos (2002) argues that the temporal organization of gestures is also relevant for discrete morphophonological alternations, and proposes a theory in which grammatical constraints govern the temporal coordination of gestures. Gafos's central hypothesis is that grammatical principles and constraints refer to temporal relations between gestures in terms of overlap patterns. He illustrates his argument with template satisfaction in Moroccan Colloquial Arabic. Markedness (CHAPTER 4: MARKEDNESS) is expressed in terms of different gestural coordination relations: for example, Gafos posits a constraint expressing a preference for a specific temporal alignment or phase relationship: CC-Coord = Align(C1, C-Center; C2, onset) requires alignment of the temporal midpoint (timepoint of maximal strength) of the gesture for C1 with the beginning of the activation for gesture C2. However, a second markedness constraint disallows the preferred coordination mode for homorganic consonants; this is a gestural interpretation of Leben's (1973) Obligatory Contour Principle. Motivation for this constraint is recoverability: if two homorganic stops are timed closely together, there will be no release of C1 leading to difficulties with its perceptual recovery. The interaction of these two constraints, together with various repair strategies to avoid their violation, leads to a unified account of template filling processes in Moroccan Colloquial Arabic. Gafos's insightful work was the first to show how new generalizations from seemingly disparate surface phenomena in morphophonological processes (glide insertion, medial C duplication, stability of epenthetic schwa to speaking rate, geminate (in)separability) can be gained under the assumption that all these surface phenomena are the result of constraint interactions that govern the temporal organization of gestures.

Other theoretical approaches seeking a connection between gestural representations and grammatical processes have been presented by Beňuš and Gafos (Gafos and Beňuš 2006; Beňuš and Gafos 2007) in the context of Hungarian vowel harmony (see also Gafos 1999). Davidson's (2006a, 2006b) work on non-native cluster phonotactics and Jun's work on place assimilation (Jun 2004) should be mentioned here. Marin (2007) has presented a gestural model of stress-conditioned vowel alternations in Romanian. There have further been some recent studies on the temporal alignment of intonation to articulatory gestures (Gao 2008; Mücke *et al.* 2009).

7 Concluding remarks

Recent phonological theories have taken an integrated view on the relationship between phonetics and phonology: phonological constraints may express speakers' knowledge of the physics of speech production and perception. Going even further, gestural models have rigorously integrated articulatory timing in both the phonological and phonetic aspects of spoken language by assuming dynamically specified atoms of speech production. These approaches thereby explicitly model the temporal coordination of gestures, and thus allow us to formulate and empirically test hypotheses about the relation of the observable, physical principles of speech to underlying cognitive representations.

ACKNOWLEDGMENTS

The writing of the chapter was supported by the Deutsche Forschungsgemeinschaft (DFG PO 1269/1-1). Thanks to Mark Tiede for permitting the use of Figure 5.3. I am much indebted to Khalil Iskarous and Stefania Marin for many interesting discussions and helpful comments on an earlier version of the chapter.

49 Sonority

Steve Parker

1 Introduction

If an interface between phonetics and phonology really exists (*pace* Ohala 1990b), then one topic having a long and controversial history in that domain is sonority. Sonority can be defined as a unique type of relative, *n*-ary (non-binary) feature-like phonological element that potentially categorizes all speech sounds into a hierarchical scale. For example, vowels are more sonorous than liquids, which are higher in sonority than nasals, with obstruents being the least sonorous of all segments. In terms of traditional phonetic systems for categorizing natural classes of sounds, then, the feature encoded by sonority most closely corresponds to the notion *manner of articulation* (see CHAPTER 13: THE STRICTURE FEATURES). In this sense, sonority is like most other features: it demarcates groups of segments that behave similarly in cross-linguistically common processes. At the same time, however, sonority is unlike most features in that it exhaustively encompasses all speech sounds simultaneously, i.e. every type of segment has some inherent incremental value for this feature. Sonority is also unique in that it has never been observed to spread (assimilate), in and of itself.

A major function of sonority is to organize (order) segments within syllables. Specifically, more sonorous sounds, such as vowels, tend to occur in the nucleus, while less sonorous sounds normally appear in the marginal (non-peak) positions – onsets and codas. This concept has engendered several chronic and frequently discussed research questions:

(1) a. What role, if any, does sonority play in Universal Grammar?
    b. How many and what kinds of natural class distinctions need to be made in the sonority hierarchy?
    c. Are its rankings fixed or permutable (reversible)?
    d. Which distinctions in the sonority scale, if any, are universal and which, if any, are language-particular?
    e. Is sonority an abstract phonological mechanism only, or does it also have a consistent, measurable phonetic basis?

To answer (1e) briefly, the main acoustic correlate of sonority is intensity. As Ladefoged (1975: 219) notes, "The sonority of a sound is its loudness relative to that of other sounds with the same length, stress, and pitch." Nevertheless, although much progress has been made in addressing the issues in (1), little consensus has emerged in understanding many of them. This chapter touches on each of the questions in (1), although not necessarily in the same order or to the same degree. The goal is to summarize the debates and document the types of empirical data that have been presented in arguing for the different positions. This chapter is organized as follows: §2 reviews the cross-linguistic phonological evidence for sonority. Thus §2.1 discusses the Sonority Sequencing Principle, §2.2 Minimum Sonority Distance effects, §2.3 the Syllable Contact Law, and §2.4 the contribution of sonority to the relative weight of the rhyme. §3 describes the Sonority Dispersion Principle, while §4 presents several desirable characteristics that a complete sonority hierarchy should ideally display. Finally, §5 examines the physical basis of sonority, as demonstrated experimentally.

2 Phonological evidence for sonority

This section describes various phonological phenomena that demonstrate that sonority is active in many languages. The exposition summarizes works discussing the issues in more depth, such as Parker (2002) and Cser (2003). Phonotactic constraints and morphophonemic alternations provide the most compelling evidence for establishing the divisions in the sonority hierarchy. Consequently, most of the argumentation here relies on these two factors. Several patterns are attested in enough languages to motivate the hypothesis that some notion of sonority should be considered part of Universal Grammar (UG; the innate linguistic faculty shared by all humans; Chomsky and Halle 1968; Kenstowicz 1994). How sonority is best expressed in UG is a separate topic, not discussed in detail here. In many cases, opposing points of view exist, with some linguists denying that sonority is actually involved in these phenomena. See e.g. Ohala (1974, 1990a, 1990b) and Kawasaki (1982) for arguments against appealing to sonority as an explanation for these data.

2.1 The Sonority Sequencing Principle

The domain in which sonority is most often invoked is the syllable, and related notions such as permissible consonant clusters in onset or coda position. This reflects the analogy that the syllable is like a wave of energy (Sievers 1893; Pike 1943). Specifically, syllables universally tend to abide by the following constraint:

(2) Every syllable exhibits exactly one peak of sonority, contained in the nucleus.

This is known as the Sonority Sequencing Principle (SSP) or the Sonority Sequencing Generalization. Key works assuming this principle as a basis for analysis include Hooper (1976), Selkirk (1984), Blevins (1995), and, in Optimality Theory, Cho and King (2003) and Zec (2007). Ohala (1990a, 1990b) and Wright (2004) note that a rudimentary notion of the SSP is observed in the work of de Brosses (1765). For the purpose of formally encoding and testing the SSP, the most frequently cited sonority scale is the following:

Table 49.1 Cross-linguistic variation in syllabic segments based on sonority

	Vowels	*Liquids*	*Nasals*	*Obstruents*
Bulgarian, Hawaiian, Kabardian, Latin, Spanish	✓	–	–	–
Lendu, Sanskrit, Slovak	✓	✓	–	–
English	✓	✓	✓	–
(Central) Carrier, (Imdlawn) Tachelhit (Berber)	✓	✓	✓	✓

(3) *Modal sonority hierarchy* (e.g. Clements 1990; Kenstowicz 1994; Smolensky 1995)

vowels > glides > liquids > nasals > obstruents

⟵⟶

higher in sonority   lower in sonority

In terms of sonority, the five natural classes in (3) are the easiest ones to motivate and the most useful ones to employ. Assuming the SSP and the hierarchy in (3), hypothetical syllables like [ta], [kɾu], [wos], and [pʰlænt] are well formed, since their sonority slope uniformly rises from the beginning of the syllable to the nuclear vowel, and falls from the nucleus to the end of the syllable. Conversely, syllables containing "sonority reversals" such as [lpa] and [odm] violate (2) and are therefore illicit in most languages.

One argument for the SSP is that cross-linguistically the inventory of [+syllabic] segments in particular languages normally forms a continuous range based on a scale like (3). Thus, the propensity for a sound to occur in nuclear position is correlated with how sonorous it is. The typology of permissible syllabic segments across languages is illustrated in Table 49.1, adapted from Blevins (1995) and Zec (2007).[1] The generalization is that if a language permits syllabic segments from a lower sonority class, it also allows nuclei from all higher sonority classes. In Tachelhit even voiceless stops occur in nuclear position. However, glides are omitted here since by definition they are non-nuclear. The following example lists forms containing syllabic consonants from two of these languages, where [.] marks a syllable boundary (Parker 2002; Zec 2007; Ridouane 2008).[2]

(4) a. *Slovak*

[kr̩.vi] 'blood'
[vl̩.ka] 'wolf'

b. *Tachelhit*

[tz̩.dm̩t] 'gather wood'
[tr̩.gl̩t] 'lock'
[tʃ̩.tk̩.ts̩tt] 'you sprained it (FEM)'

Nevertheless, while the pattern in Table 49.1 is a strong tendency, it is not universally obeyed. For example, many languages (especially in Africa) attest syllabic

[1] Language names and genetic affiliations follow the *Ethnologue* (Lewis 2009). In the online version of this chapter, the appendix provides more details about the languages cited here: country, linguistic phylum, primary source of data, etc.

[2] The online version of this chapter contains more illustrative data throughout.

nasals but not syllabic liquids: e.g. Djeebbana, Lele (Chad), and Swahili (Blevins 2006). Thus, factors other than sonority must also be appealed to in some cases.

Besides syllabic consonants, another reason to adopt the SSP is that it accounts for tautosyllabic consonant clusters in most languages. The following example illustrates three languages that strictly follow the SSP in onsets and codas (Blevins 2006):

(5) a. *Cheke Holo*
[kai.ka.fl.i] 'flash on and off'
[kmai.kma.ji] 'eat a varied meal (reduplicated)'

b. *Djeebbana*
[n̩.ka.la] 'fork'
[kalk.bet] 'northern black wallaroo'

c. *Spanish*
[plan] 'plan'
[trans.kri.βir] 'to transcribe'

Again there are exceptions; (6) shows data from two languages in which the underlined consonant clusters apparently violate the SSP (Blevins 2006):

(6) a. *Leti* (Indonesia)
[pni.nu] 'fool'
[sra:t] 'main road'
[rka:.lu] 'they shout'
[rstp.le] 'they sail'

b. *Yir Yoront*
[melt] 'animal, bird'
[patl] 'clean, bald'

Counterexamples to the SSP also occur in some Indo-European languages, such as Czech, Romanian, and Russian. Extreme cases are found in Georgian, a Kartvelian language attesting the word-initial clusters /zrd/, /mkrt/, /msxv/ and /mt͡svrtn/ (Blevins 2006). Such exceptions have led some researchers to conclude that analyses based on sonority are circular in nature (Ohala 1990b: 160). However, no studies exist in which the proportion of languages with sonority reversals is tabulated among a statistically reliable and balanced sample. Therefore, based on available data, it seems safe to conclude that a large percentage of the world's languages do conform to the SSP. Furthermore, purported counterexamples like Georgian /mt͡svrtn/ are dubious if the onset cluster in question occurs only word-initially, but not word-internally. This is crucial since, in a given language, a consonant cluster should appear in a position other than at a word edge in order to count as a canonical syllable type. Otherwise, when a greater number of consonants show up next to a word boundary, it is debatable whether this constitutes a true syllable margin. A more principled explanation is to analyze the SSP-violating segment(s) as a degenerate syllable or an extrasyllabic appendix licensed by the prosodic word. See Cho and King (2003) for further discussion. Finally, some alleged SSP violations cannot withstand further scrutiny. For example, Blevins (2006) lists Leti [rka:lu] in (6) above. However, van Engelenhoven (2004) states that word-initially before another consonant the trilled /r/, nasals, /l/ and /s/ are lengthened and "syllabic." Thus, a more accurate transcription of this word is [r̩.ka:.lu]. Since the /r/ and the /k/

Table 49.2 Typological range of languages containing sC clusters

s +	*Spanish*	*French, Western Keres*	*Greek*	*English*	*Dutch*	*German*	*Russian*
stop	–	✓	✓	✓	✓	✓	✓
fricative	–	–	✓	–	✓	–	✓
nasal	–	–	(–)	✓	✓	✓	✓
lateral	–	–	–	✓	✓	✓	✓
rhotic	–	–	–	–	(–)	✓	✓

are not tautosyllabic, this is not a counterexample to the SSP. Rather, it confirms it.

Cross-linguistically, the most frequent exceptions to the SSP involve initial /s/ followed by a plosive, as in the English words *spill*, *still*, and *skill*. Morelli (2003) and Goad (CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS) focus on this phenomenon. Table 49.2 is adapted from the latter.

Summarizing this table, Goad observes that the lower a consonant is in sonority, the more preferred it is after an initial /s/. She thus posits that s + stop > s + nasal > s + lateral > s + rhotic, where ">" = "is more harmonic than." This scale (minus the s) follows many sonority hierarchies that posit more natural class distinctions than (3), such as the maximally detailed scale in §4.

Morelli (2003) reaches a similar conclusion. She notes that many languages have onset cluster inventories comprising three main types: (1) stop + sonorant, (2) fricative + sonorant and (3) fricative + stop. These first two satisfy the SSP, while the third reverses it (assuming that fricatives are more sonorous than stops; see below). Illustrative languages include Haida, Hindi, Hungarian, Isthmus Zapotec, Italian, Mohave, Swedish, Telugu, Yecuatla Totonac, and Yuchi. To her knowledge, however, no language exists that is analogous to these, yet completely follows the SSP: hypothetically, (1) stop + sonorant, (2) fricative + sonorant, and, crucially, (3) stop + fricative (not counting affricates). Consequently, she posits that among onset clusters consisting of two obstruents, the unmarked type is fricative + stop, where "unmarked" = phonologically default and most common (Kenstowicz and Kisseberth 1973: 3; de Lacy 2006).

Summarizing thus far, the SSP is a strong universal tendency but has exceptions. In some cases the reversals in the sonority slope are of the largest possible degree: an onset consisting of a glide followed by a voiceless stop. To illustrate, Santa María Quiegolani Zapotec exhibits many words like the following (Regnier 1993):

(7) [wkit] 'game'
[wtóːʔ] 'sell (COMPLETIVE)'
[jkǎ] 'buy (POTENTIAL)'

Nevertheless, typological generalizations can still be made. For example, most languages have more consonant cluster types and tokens obeying the SSP than violating it. Furthermore, more languages attest obstruent + liquid (OL) onset clusters, for instance, than the opposite (LO). This can be stated even more forcefully as an implicational universal: if a language allows complex onsets of the type

LO, it must permit OL clusters as well, whereas the inverse is not necessarily true (Greenberg 1978). However, this kind of observation cannot be extended to include all possible natural class combinations. For instance, Texistepec Popoluca does not permit obstruent + nasal (ON) syllable initially, yet it does allow NO clusters: [mbak] 'my bone' (Wichmann 2002).[3] Consequently, absolute claims about the SSP tend to break down given enough languages. Nevertheless, one apparently exceptionless statement is the following:

(8) No language exists in which all tautosyllabic consonant clusters reverse the SSP.

Returning to the five-category sonority hierarchy in (3), many phonologists expand this by making subdivisions within three of the natural classes: vowels, liquids, and obstruents (cf. (27) in §4). For example, fricatives are often claimed to be more sonorous than stops (Hankamer and Aissen 1974; Steriade 1982, 1988; Kager 1999). To illustrate, in Sanskrit reduplication, when a verb base begins with a consonant cluster, the prefix retains the less sonorous of these two sounds. Thus, in (9), when a stop and a continuant are adjacent in either order, the reduplicant invariably surfaces with the stop:

(9) *Sanskrit* (from Whitney 1889)

/praʧʰ/	→	[pa-praʧʰ]	'ask'
/swar/	→	[sa-swar]	'sound'
/tsar/	→	[ta-tsar]	'approach stealthily'
/stʰaː/	→	[ta-stʰaː]	'stand'
/tjaʤ/	→	[ta-tjaʤ]	'forsake'
/ʃratʰ/	→	[ʃa-ʃratʰ]	'slacken'
/druw/	→	[du-druw]	'run'
/mluʧ/	→	[mu-mluʧ]	'set'
/rdʰ/	→	[aːr-di-dʰam][4]	

In (9) the obvious generalization is that the reduplicant copies the less sonorous consonant from the onset of the base, regardless of its relative position within the cluster. Otherwise, if all obstruents are equal in sonority, the analysis of this process is more complicated to express (Benua 1997; Hironymous 1999). For further data and discussion of Sanskrit reduplication, see CHAPTER 119: REDUPLICATION IN SANSKRIT. While the full details are complex, the pattern whereby the least sonorous segment emerges in the prefix is very regular. For a mathematical explanation of this effect, see §3.

When underlying representations juxtapose sounds violating the SSP, these are repaired in four different ways cross-linguistically: (1) vowel epenthesis, (2) deletion, (3) syllabic consonants, and (4) metathesis. First, a vowel can be inserted to rescue the unsyllabifiable consonant, a process called stray epenthesis (Itô 1986). This occurs in Serbo-Croatian (Kenstowicz 1994):

[3] Prenasalized stops (common in African languages) do not violate the SSP, since they are single phonemic units, not true sequences. Syllabic nasals, such as in hypothetical [n̩.da], do not constitute tautosyllabic onsets either.

[4] Whitney does not gloss this root, but notes that the form is aorist.

(10)

		masculine	*neuter*	
	a.	pust	pusto	'empty'
		zelen	zeleno	'green'
	b.	dobar	dobro	'good'
		jasan	jasno	'clear'
	c.	bogat	bogato	'rich'
		kriʒan	kriʒano	'cross'

In the adjective paradigm in (10), the neuter is marked by the suffix /-o/. The masculine column displays no overt morphological marking. In (10b), [a] alternates with Ø. This vowel surfaces phonetically in the final syllable of the masculine forms, between the last two consonants, but is absent in the neuter column. The contrasting forms in (10c) contain an [a] in the second syllable in both columns. This demonstrates that the alternation in (10b) involves epenthesis of [a] in the masculine forms, not syncope of underlying /a/ in the neuter column. The underlying representations of the roots in (10b) are /dobr/ and /jasn/. These underlying representations end with a consonant cluster consisting of an obstruent followed by a sonorant. If these were syllabified directly into a complex coda, they would violate the SSP. In contrast, the root /pust/ in (10a) ends with a cluster in which sonority falls. Therefore stray epenthesis is not needed since the sequence /pust/ can be exhaustively syllabified while respecting the SSP. The sonority profile of two of these contrasting roots is displayed in the following metrical-like grids (Jespersen 1904; Zec 1988; Clements 1990; Kenstowicz 1994):

(11)

vowel		*					*		
glide		*					*		
liquid		*					*		*
nasal		*					*		*
fricative		*	*				*		*
stop	*	*	*	*		*	*	*	*
	p	u	s	t		d	o	b	r

These grids employ the five-category sonority hierarchy in (3), supplemented by obstruents being split between fricatives and stops, motivated by the Sanskrit data in (9). As these figures show, the morpheme /pust/ in isolation (in the masculine column) contains one peak of sonority (the /u/), whereas /dobr/ contains two (the /o/ and the /r/). Consequently, the motivation for inserting a vowel in the second case ([dobar]) is to rescue the /r/, which cannot be incorporated into the same syllable as the /b/ without violating the SSP.

A second process used to fix SSP violations is the deletion of an unlicensed (unsyllabifiable) consonant, known as stray erasure (Itô 1986). This process is illustrated by Ancient Greek. The following data show that complex onset and coda clusters are permitted, including word-medially (Steriade 1982; Kenstowicz 1994):

(12)

	klep^h	'to steal'
	smerd.nos	'power, force'
	am.blus	'dull'

as.tron	'star'
a.elp.tos	'unhoped for'
t^{h}elk.tron	'charm'
pemp.tos	'sent'

The form [t^{h}elk.tron] demonstrates that up to four consonants can be concatenated intervocalically, providing the SSP is respected. However, in the reduplicated form /CV-grap^h-st^{h}ai/ → [gegrap^{h}t^{h}ai] 'to have been written', the underlying /s/ at the beginning of the infinitival suffix occurs between two stops. If this word were assigned a sonority profile as in (11), the /s/ would constitute a peak of sonority. However, this /s/ is not syllabic, nor can it be incorporated into a syllable with the preceding /p^h/ or the following /t^h/ without violating the SSP. Consequently, since it is prosodically unparsable, it is elided. According to Steriade (1982) and Itô (1986), this phenomenon is a default universal mechanism automatically applying at the end of the derivation to clean up any remaining problems (see CHAPTER 68: DELETION).

A third strategy for dealing with SSP violations is to simply retain the offending consonant, in which case it is automatically realized phonetically as syllabic. English illustrates this with unstressed sonorant consonants in word-final clusters: *prism, button, pickle, manner*. Another example is Chamicuro (Parker 1989):

(13)	[w-usm-i]	'I sing'	[w-usm̩-kati]	'I sang'
	1SG-sing-EPENTHETIC		1SG-sing-PAST	

Fourth, and most rarely, SSP violations are resolved by metathesis. The most convincing case of this to date is Western Farsi. When a final vowel is deleted by a general process of apocope, an obstruent or nasal in a potential coda cluster metathesizes with a following liquid. Otherwise (without metathesis), the final liquid would constitute a separate sonority peak, which this language does not allow (Hock 1985):

(14)	ʧaxra	→	ʧarx	'wheel'	
	suxra	→	surx	'red'	(cf. suhr-ab 'ruddy goose')
	vafra	→	barf	'snow, ice'	
	asru	→	ars	'tear'	
	vazra	→	gurz	'club'	
	*namra[5]	→	narm	'soft'	

Hock (1985) attributes this alternation to the SSP. However, from his description this is primarily a historical process, so it may no longer be synchronically active.

2.2 *Minimum Sonority Distance*

While the SSP rules out many of the prohibited syllable types in most languages, it is not the full story. For example, the three syllables [kna], [kla], and [kwa] equally

[5] The form /namra/ is preceded by *, since it is reconstructed.

Table 49.3 Minimal Sonority Distance language types

	Maximal inventory of permissible onset clusters	*Languages*
MSD = 0	OO, ON, OL, OG, NN, NL, NG, LL, LG, GG	Bulgarian, Leti
MSD = 1	ON, OL, OG, NL, NG, LG	Chukchee
MSD = 2	OL, OG, NG	Cizrra, Kurdish, Spanish
MSD = 3	OG	Mono, Panobo, Japanese (?), Mandarin Chinese (?)

satisfy the SSP. Nevertheless, although many languages permit onset clusters such as [kl] and/or [kw], syllables like [kna] are much less common. One explanation for this asymmetry is a language-specific parametric requirement that the members of a tautosyllabic consonant cluster be separated by a minimum number of ranks on the sonority scale (Steriade 1982; Selkirk 1984). For example, /k/ and /l/ are sufficiently distinct in relative sonority and may therefore be combined. However, /k/ and /n/ are too close along this scale, and this is not tolerated in many languages. Conversely, a language like Russian, which permits words like /kniga/ 'book', has a lower threshold on this parameter. This condition is captured by the following principle:

(15) *Minimal Sonority Distance* (MSD)

Given an onset composed of two segments, C_1 and C_2, if a = Sonority Index of C_1 and $b = \mathrm{SI}(C_2)$, then $b - a \geq x$, where $x \in \{0, 1, 2, 3\}$.

Assuming the sonority hierarchy in (3), the typology of possible languages shown in Table 49.3 is generated (cf. Zec 2007). The generalization is that if a language permits clusters with a lower sonority distance, it allows clusters of all higher sonority distances as well, *ceteris paribus*. The inverse of this is not true. The reversed counterparts of these onsets, such as *LO, can be excluded by the independently motivated SSP when necessary (§2.1). The data in (16) illustrate typical consonant sequences from each of the four language types in Table 49.3. Naturally, not every cluster type is fully productive for all phoneme combinations in these languages. Nevertheless, enough representative examples occur to justify the general trends.

(16) a. *Leti* (van Engelenhoven 2004)

[ptu.na]	'star'
[tmu.ra]	'tin'
[kru.ki]	'crab (sp.)'
[m̩.kwo.ri]	'you (SG) lift'

b. *Chukchee* (Kämpfe and Volodin 1995)

[plətkuk]	'end, finish, conclude'
[qlikkin]	'twenty'
[tretʃejwaɣʔe]	'I will go'
[ljur]	'suddenly'

c. *Gizrra* (van Bodegraven and van Bodegraven 2005)
[glɛs] 'dew'
[ta.praz.də] 'on (his) fangs'
[djao] 'palm (sp.)'
[ur.mjao] 'tree (sp.)'

d. *Panobo* (Parker 1992)
[hwĩn.ti] 'heart'
[βwi.ni.kæ̃j] 'they are taking, carrying'
[pja.ka] 'nephew, niece'
[wa.ta.tjan] 'last year'

As Table 49.3 displays, a significant implication of the MSD approach is that the ideal onset cluster consists of an obstruent plus a glide, all else being equal. Thus, if a language allows complex onsets and has glides in its phonemic inventory, it must permit stop + glide clusters. This is the only onset sequence occurring in all four language types in Table 49.3. An explanation for this is that these two natural classes (stops and glides) are maximally separated in terms of their relative sonority, since they occupy the extreme ends of the scale (among consonants). Baertsch (2002) proposes one way to capture MSD effects in Optimality Theory (OT: Prince and Smolensky 1993). The corresponding prediction is that some languages should exist which permit OG but no other onsets. Two such cases are Mono (Democratic Republic of the Congo; Olson 2005) and Panobo. Other possibilities are Japanese (Vance 1987, 2008) and Mandarin Chinese (Yuan 1989). The latter two are listed in Table 49.3, followed by question marks to highlight their controversial status. Also, in Hindi (Ohala 1983) and Koluwawa (Guderian and Guderian 2005), the only initial clusters are OG and NG, but not *OL. There is, however, a problem. In a sequence like [kwa], the [w] is potentially ambiguous since it allows different phonological interpretations. A priori it could pertain to a diphthongal nucleus rather than the onset: [kʊ͡a]. Alternatively, it might be a secondary articulation (labialization) of the preceding /k/: [kʷa]. If so, then there really is no consonant cluster, just a single complex phonemic unit. The third possibility is that [kw] simply constitutes a true onset cluster, as in Panobo. Teasing apart these different conclusions is complicated, and often the language-specific evidence is not compelling either way. Unfortunately, then, when no other canonical onset clusters (such as OL) exist in a language, the argumentation is in danger of circularity regardless of which segmentation is posited. See §3 for an alternative model that claims that the unmarked initial cluster is not OG but OL. Finally, in the MSD approach, the sonority distance between the second onset consonant and the vowel is not crucial, because phonotactic restrictions rarely obtain across onset–nucleus junctures (Blevins 1995). However, see §3 for an approach in which the nature of this sequence (C_2 + V) does matter. See also CHAPTER 15: GLIDES for further discussion of glides, and CHAPTER 55: ONSETS for an expanded treatment of onsets.

2.3 *The Syllable Contact Law*

Another sonority-based principle active in many languages is the Syllable Contact Law (SCL). Some seminal references are Hooper (1976), Murray and Vennemann (1983), and Clements (1990). More recent treatments of the SCL as a

Table 49.4 Alternations motivated by the Syllable Contact Law

Process	*Illustration*	*Language*	*Example*
coda weakening	g.n → w.n	Hausa	/hagni/ → [haw.ni] 'left side'
onset strengthening (desonorization)	k.l → k.t	Kyrgyz	/konok-lar/ → [konok.tar] 'guest-PL'
	l.l → l.d	Kazakh	/kol-lar/ → [kol.dar] 'hand-PL'
	z.l → z.d	Kazakh	/koŋuz-lar/ → [koŋuz.dar] 'bug-PL'
	z.m → z.b	Kazakh	/koŋuz-ma/ → [koŋuz.ba] 'bug-INT'
tautosyllabification	k.l → .kl	Germanic	[tēk-.lıç] 'daily', [e.klıç] 'disgusting'
gemination	b.r → b.br	Latin > Italian	/labrum/ → [lab.bro] 'lip'
epenthesis	n.ɾ → n.dr	Spanish	/benir-a/ → [ben.dra] '(s/he) will come'
regressive assimilation	k.m → ŋ.m	Korean	/kuk-mul/ → [kuŋ.mul] 'broth'
progressive total assimilation	g.n → g.g	Pali	/lag-na/ → [lag.ga] 'attach (PAST PART)'
regressive total assimilation	n.l → l.l	Korean	/non-li/ → [nol.li] 'logic'
anaptyxis	p.r → pV.r	Ho-Chunk	/hipres/ → [hiperes] 'know'
metathesis	d.n → n.d	Sidamo	/gud-nonni/ → [gun.donni] 'they finished'

family of OT constraints include Davis (1998), Gouskova (2004), and Zec (2007). The following are two typical formulations of the SCL:

(17) *Syllable Contact Law*

a. A heterosyllabic juncture of two consonants *A.B* is more harmonic (ideal) the higher the sonority of *A* and the lower the sonority of *B*.
b. In any heterosyllabic sequence of two consonants *A.B*, the sonority of *A* is preferably greater than the sonority of *B*.

By (17), for example, the sequence [l.k] is inherently less marked than [k.l]. Vennemann (1988: 50) provides a list of sample repair strategies that languages employ to improve satisfaction of the SCL. These are summarized in Table 49.4, as annotated by Davis (1998: 183) and supplemented by Seo (CHAPTER 53: SYLLABLE CONTACT), which offers more data and discussion. Based on a survey of 31 languages with SCL effects, her results give a better idea of the range of typological generalizations and their relative robustness. For example, Kazakh tolerates a /j-l/ juncture, as in [mandaj.lar] 'foreheads', since sonority drops slightly from /j/ to /l/. Kyrgyz, nevertheless, requires a greater fall in sonority and maps /aj-lar/ to [aj.dar] 'moons' (Davis 1998).

Examining the details of SCL phenomena in particular languages allows us to establish subtle differences in sonority ranks. For instance, Spanish attests words such as [per.la] 'pearl' and [al.re.ðe.ðor] 'around', yet the hypothetical sequence *[l.ɾ] systematically does not occur. When such a juncture would be created, an intrusive stop appears instead. This happens when the future tense is derived by dropping the infinitival theme vowel: /salir/ 'to leave' → *[sal.ɾa] → [sal.dra] '(s/he) will leave'. These facts motivate the following sonority hierarchy among Spanish liquids, based on the second of the two definitions in (17): flap > lateral > trill (Bonet and Mascaró 1997; Parker 2008).

Nevertheless, there are problems with the SCL too. For example, it predicts that obstruent + sonorant junctures should be "fixed" more often than sonorant + sonorant clusters, *ceteris paribus*. The opposite in fact is true (CHAPTER 53: SYLLABLE CONTACT). Furthermore, in Akan both /O-N/ and /N-O/ sequences result in phonetic [NN]. The latter is a mirror image of Korean nasal assimilation (Table 49.4), even though this makes syllable contact worse: /óń-dú/ → [óń.núʔ] 'he should arrive' (Schachter and Fromkin 1968).

2.4 *Rhyme weight*

It is well known that the heavier a syllable is, the more it tends to attract stress (Hayes 1980; Prince 1990). For example, open syllables are light, but closed syllables are usually bimoraic. Thus, they may be obligatorily stressed (see also CHAPTER 57: QUANTITY-SENSITIVITY). Also, in some languages, rhymes headed by /e/ or /o/ attract stress more than those with /i/ and /u/, indicating that mid vowels have more weight than high vowels in these systems. Furthermore, the propensity for a coda consonant to project a mora is correlated with how sonorous it is (Zec 1988, 1995). An adequate theory of phonology should provide a unified (non-accidental) explanation for these facts. Appealing to a scalar feature like sonority allows us to do that. Based on case studies examining the relationship between segmental quality and syllable weight effects, the following hierarchy of vowel sonority has been posited (Kenstowicz 1997; de Lacy 2002, 2004, 2006, 2007a). Specific languages may choose to exploit different subsets among these natural classes:

(18) *Relative sonority of vowels*

a > e, o > i, u > ə > ɨ

To illustrate, Kobon vowels are divided into four groups in terms of stress assignment: /a/ > /e o/ > /i u/ > /ə ɨ/. In this case the potential distinction between /ɨ/ and /ə/ is underexploited. In unaffixed Kobon words, stress predictably falls on the most sonorous nucleus within a disyllabic window at the right edge (Davies 1980, 1981):

(19)	a > e	[haŋ'gaβe]	'blood'
	a > i	[kʰi.'a]	'tree (sp.)'
	a > ə	[kʰəβə'ja]	'rat'
	a > i	['aɲ'ɨm-'aɲɨm]	'lightning'
	o > u	['mo.u]	'thus'
	o > i	[si.'oŋkʰ]	'bird (sp.)'
	o > i	[gɨ'ɾo-gɨ'ɾo]	'talk (mother pig to piglet)'
	i > ə	[ga'ɽinəŋ]	'bird (sp.)'
	i > ɨ	['jimbɨɽ]	'very'

The generalization in (18) and (19) is that vowels which are more peripheral in the acoustic space are more sonorous than central ones. Furthermore, within these two sets, segments involving a lower jaw configuration outrank their higher counterparts (Coetzee 2006). At the bottom of this hierarchy, /ə/ is higher in sonority than /ɨ/. This is due to languages such as Lushootseed, in which /ə/ can be stressed (unlike English) when it is the only nucleus in a root. Stress falls on the first "full" vowel of the stem; otherwise on the first schwa (Urbanczyk 2006):

(20) *Stressable /ə/ in Lushootseed*

['ʔitut]	'sleep'
[dzə'ɬixʷ]	'creek'
['ʧuqʷu-d]	'to whittle something'
[ʧə'gʷas]	'wife'
[k'ə'daju]	'rat'
['ʤəsəd]	'foot'
['bəʧ]	'fall down'

Other languages in which sonority is crucial to stress assignment include Pichis Ashéninka (Payne 1990; Hayes 1995), Komi (Hayes 1995; de Lacy 1997), and Finnish (Anttila 1995; Hayes 1995). However, a reviewer notes that contrastive /ə/ in languages like Lushootseed may be different in quality from phonetic [ə] resulting from reduction in English and analogous languages. For example, the former is probably longer in duration than the latter. This is a valid point that must be controled for in cross-linguistic comparisons of this sort. For Lushootseed, Urbanczyk posits a phonemic /ə/ in underlying forms. In motivating a constraint against stressed schwas she writes:

> *ə́ has the distributional hallmarks of a markedness constraint because there are languages which never stress schwa, languages which avoid stressing schwa, and languages which permit schwa, along with other vowels, to be stressed, but no language enforces the stressing of schwa in preference to other vowels. (Urbanczyk 2006: 210)

She then lists other Salishan languages in which this prohibition is active (2006: 211, fn. 24). See CHAPTER 26: SCHWA for further discussion of schwa in general.

Concerning the relative weight of coda consonants, the typological range of languages is also dependent on sonority. Table 49.5 is adapted from Zec (1995, 2007). The generalization is that if a lower-sonority class is moraic in a particular language, then all higher-sonority categories are also moraic in syllable-final position. Zec (2007) knows of no language in which coda liquids count as heavy but nasals do not; she considers this an accidental gap. In addition to stress attraction, other diagnostics for consonant moraicity are: (1) the ability to bear a contrastive tone (Tiv; Zec 1995), (2) prosodic minimality (Fijian; Dixon 1988), and

Table 49.5 Inventories of moraic segments

Natural classes contributing to syllable weight	*Languages*
vowels only	Fijian, Halh Mongolian, Lardil, Yidiny
vowels and liquids	?
vowels, liquids, and nasals	Gonja, Kwakiutl, Lithuanian, Tiv
vowels, liquids, nasals, and obstruents	Egyptian Arabic, English, Latin, Maithili

(3) blocking of processes such as vowel reduction (Maithili; Hayes 1995) (see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE). (21) gives sample data from the three attested language types in Table 49.5:

(21) a. *Fijian* (Dixon 1988)
Stress the syllable containing the penultimate mora (closed syllables do not occur).

[ˈsiŋa]	'day'
[ᵐbuˈtaʔo]	'steal'
[ᵐbutaˈʔoða]	'steal-TRANS'
[ʔiˈlaa]	'know-TRANS'
[ˈraiða]	'see-TRANS'
[ˈlu.a]	'vomit (VB)'

b. *Tiv* (Zec 1995)
Only sonorant consonants occur in codas, where they bear tone.

[báŕ]	'salt'
[fáˈḿ]	'rainy season'
[rùmùr̀]	'agreed, confessed'

c. *Egyptian (Cairene) Arabic* (Hayes 1995)
Stress the ultima if superheavy (trimoraic), otherwise the penult if heavy, otherwise the antepenult.

[kaˈtabt]	'I wrote'
[hadʒˈdʒaːt]	'pilgrimages'
[ˈbeːtak]	'your (MASC SG) house'
[kaˈtab.ta]	'you (MASC SG) wrote'
[muˈdar.ris]	'teacher'
[ʔinˈkasara]	'it got broken'
[ˈkataba]	'he wrote'

If fricatives are more sonorous than stops (§2.1), by implication some languages should exist in which fricatives occur in coda position but stops do not. This is exemplified by Panobo. Syllable-final consonants include glides, nasals, and fricatives. However, this is complicated by the fact that the flap /ɾ/ occurs in onsets, yet not in codas. Evidence that coda consonants are moraic in Panobo is that in word-final position they attract stress. Otherwise, the default quantity-sensitive foot type, a moraic trochee, assigns stress to the penultimate syllable (Parker 1992):

(22) *Heavy final syllables in Panobo*

[ˈatsa]	'manioc'
[kaˈnoti]	'bow (weapon)'
[jaˈwiʃ]	'opossum'
[tahˈpõŋ]	'root'
[pihˈkæ̃j]	'(they) will eat'

3 The Sonority Dispersion Principle

Clements (1990) proposes an approach to syllable phonotactics that is also based on sonority. In his model, syllables are divided into two parts. The initial demisyllable consists of any onset consonants (if present) plus the nucleus, and the final demisyllable contains the nucleus plus the coda, i.e. the rhyme. The term demisyllable is borrowed from Fujimura and Lovins (1978). The nucleus crucially resides in both demisyllables simultaneously. For example, the word /plom/ contains the demisyllables /plo/ and /om/. The essence of the Sonority Dispersion Principle (SDP) is that initial demisyllables are preferred when their constituents are maximally and evenly dispersed in sonority; e.g. /ta/. The same tendency is inverted for final demisyllables, favoring open rhymes (those ending with a vowel). More precisely, initial demisyllables of the same length (number of segments) are more harmonic to the degree that they minimize *D* in (23) below. Conversely, final demisyllables are more harmonic to the degree that they maximize *D*, all else being equal. The formula for *D* comes from the realms of physics and geometry, where it governs the distribution of mutually repelling forces in potential fields (like electrons). Its linguistic use originates with the work of Liljencrants and Lindblom (1972) on perceptual distance between segments in the acoustic vowel space. Hooper (1976) and Vennemann (1988: 13–14) anticipate its application to sonority and syllable structure.

(23) *Sonority Dispersion Principle*

$$D = \sum_{i=1}^{m} \frac{1}{d_i^2}$$

where d = distance between the sonority indices of each pair of segments, and m = number of pairs of segments (including non-adjacent ones), where $m = n(n-1)/2$, and where n = number of segments.

Clements (1990: 304) paraphrases (23) as follows: "D . . . varies according to the sum of the inverse of the squared values of the sonority distances between the members of each pair of segments within" a demisyllable. *D*, then, is the reciprocal of dispersion. To illustrate the application of (23), Clements assumes a sonority scale with the five categories from (3):

(24)

		sonority index
vowels	(V)	5
glides	(G)	4
liquids	(L)	3
nasals	(N)	2
obstruents	(O)	1

When *D* is computed for demisyllables containing exactly one or two consonants, it yields the following values (ignoring types that violate the SSP):

(25) *Sonority Dispersion demisyllable values*

a.			b.
OV = .06	most natural onset		OLV = .56
NV = .11	↑		OGV = 1.17
LV = .25			ONV = 1.17
GV = 1.00			NGV = 1.36
	↓		NLV = 1.36
	least natural onset		LGV = 2.25

c.	VO = .06	least natural coda	d.	VLO = .56
	VN = .11	↑		VGO = 1.17
	VL = .25			VNO= 1.17
	VG = 1.00			VGN = 1.36
		↓		VLN = 1.36
		most natural coda		VGL = 2.25

In (25a) the SDP favors a single syllable-initial consonant that maximizes the sonority slope between the onset and the vowel. Therefore, it correctly predicts that the preferred syllable of type CV has an onset consonant as low in sonority as possible ($D = .06$). This results in the following scale of relative unmarkedness: /ta/ > /na/ > /la/ > /ja/. This is foreshadowed in the discussion of Sanskrit reduplication (§2.1). Recall that the pattern there demonstrates that fricatives can outrank stops in sonority. Therefore, not all obstruents are necessarily equal in sonority (see §4).

Summarizing thus far, a unique consequence of the formula for *D* is that in an initial demisyllable of two segments (CV), the segments should differ from each other in sonority as much as possible. This is somewhat analogous to the MSD approach for onset clusters (§2.2). However, when the initial demisyllable contains three segments (CCV), what matters (given *D*) is that the aggregate total of the sonority distances between all of these together be maximized. This is accomplished by spacing apart the segments as evenly as possible (in sonority). This results in the best evaluation for OLV in (25b), since it has the lowest obtained value (.56). This is because liquids fall precisely midway between obstruents and vowels in terms of their sonority indices in Clements's five-category scale in (24). As evidence for the SDP, Clements notes that underlyingly French permits complex demisyllables of the type OLV only. However, in surface forms, some instances of OGV also exist. This raises an important typological question: which onset cluster is universally unmarked, OL or OG? On the one hand (as noted in §2.2), the MSD principle predicts that some languages should permit OG but not *OL. This seems to be correct, but see the caveats in §2.2. On the other hand, the SDP claims that OL is preferred. One piece of evidence that could help resolve this would be an alternation mapping underlying OLV to OGV, or vice versa. Unfortunately, no such process has yet been observed. A cross-linguistic survey documenting the number of languages with one type of cluster but not the other would also be enlightening. It may be that both kinds of onsets (OG and OL) need to be optimal simultaneously, i.e. in the grammars of different languages. Rod Casali and Ken Olson (personal communication) note that apparent OG-only languages are especially common in Africa.

Finally, the SDP assigns an equal evaluation to the two demisyllable types OGV and ONV in (25b). This may be problematic, since many languages exhibit the initial sequence OG, but not *ON. For example, Table 49.3 mentions Gizrra, Kurdish, Mono, Panobo, and Spanish. However, Clements does not claim that demisyllables of the same rank necessarily co-occur in any language containing one of them. At the same time, no languages appear to allow ONV but not *OGV. If this is a systematic gap, it is troubling for the predictions of the SDP.

4 The complete sonority hierarchy

Perhaps no issue in phonological theory has led to more competing proposals than the internal structure of the sonority hierarchy, i.e. the numbers and types of natural classes, and their corresponding ranks. Parker (2002) notes that more than 100 distinct sonority scales are found in the literature. The purpose of this section is to lay out several desirable characteristics that a full and final sonority hierarchy should possess, and then present one specific model that arguably comes closest to fulfilling those goals. Briefly, an adequate sonority scale should display the a priori traits in (26). In principle these criteria apply not just to sonority, but to all phonological features, that is, classic binary features like [±voice], [±round], etc.

(26) All else being equal, an ideal sonority scale would have these characteristics:

a. *Universal:* It potentially applies to all languages.
b. *Exhaustive:* It encompasses all categories of speech sounds.
c. *Impermutable:* Its rankings cannot be reversed (although they may be collapsed or ignored).
d. *Phonetically grounded:* It corresponds to some consistent, measurable physical parameter shared by all languages.

Each of the points in (26) will now be discussed. First, ideally we can establish a single, unique sonority hierarchy to analyze all known languages. This is not to say that any particular language actually exploits every one of the natural class rankings in the sonority scale. On the contrary, it would be quite amazing (although fortuitous) to discover such a case. Nevertheless, the explanatory power of sonority is maximized if we ascribe it to UG, making it equally available to all humans.

Second, an adequate theory of sonority should include every known type of phonological segment. Many hierarchies omit recalcitrant natural classes such as glottal consonants (/h/ and /ʔ/), affricates, etc., perhaps because of their inherent complications. Such scales then cannot apply to all languages. This undermines their universality.

Third, the rankings in the sonority scale should be impermutable. This is a beneficial characteristic since it is the most restrictive hypothesis possible, i.e. it severely limits the types of processes directly attributable to sonority. In addition to avoiding overgeneration of non-attested language types, impermutability makes claims about sonority easier to falsify. This in turn reduces the danger of circular argumentation. For example, once it is established that laterals, for instance, are more sonorous than nasals, the entailment is that there is no language in which nasals pattern as more sonorous than laterals by the same criteria. At the same time, however, potential divisions between sonority ranks are frequently underexploited in many languages. See de Lacy (2002, 2004, 2006, 2007a) for a formal approach to "underspecification" of sonority classes in OT.

Fourth, in an ideal world we can show that sonority is based on concrete articulatory gestures and/or their acoustic counterparts. This is the topic of the next section.

Although no sonority scale to date perfectly fulfills every desideratum sketched above, one that perhaps comes closest is that of Parker (2008), reproduced below:

(27) *Final hierarchy of relative sonority*

Natural class	*Sonority index*
low vowels	17
mid peripheral vowels (not [ə])	16
high peripheral vowels (not [ɨ])	15
mid interior vowels ([ə])	14
high interior vowels ([ɨ])	13
glides	12
rhotic approximants ([ɹ])	11
flaps	10
laterals	9
trills	8
nasals	7
voiced fricatives	6
voiced affricates	5
voiced stops	4
voiceless fricatives (including [h])	3
voiceless affricates	2
voiceless stops (including [ʔ])	1

Space does not permit a detailed justification of (27). Nevertheless, to highlight a few positive aspects of this scale, the evidence for most of the natural classes is fairly robust and secure. Parker (2002, 2008) summarizes the debates and provides at least one argument to motivate every ranking in this hierarchy (every pair of adjacent categories). Much of this is reviewed in §2 of this chapter. To give another example, Koine (Ancient) Greek permits the clusters /pn/ and /kn/ (/pniktos/ '(things) strangled', /kneθo/ 'have itching, tickled'; Mounce 1993), but proscribes */bn/ and */dn/. This can be explained as an MSD effect if voiced stops are closer to nasals (in sonority) than voiceless stops are. Furthermore, flaps are higher in sonority than trills in Spanish, as established by the SCL in §2.3. Three other facts confirm this. First, in word-initial position the contrast between /r/ and /ɾ/ is neutralized to /r/ ([rana] 'frog'). Second, in codas it is neutralized in favor of /ɾ/: [ʧaɾlaɾ] 'to chat'. These two points follow from the SDP (Bonet and Mascaró 1997). Third, /ɾ/ and /l/ appear as the second member of complex onsets, yet /r/ does not (see (5)). This is another MSD effect if /r/ is less sonorous than /ɾ/ and /l/ (Baković 1994). These distributional facts indicate that liquids do not always pattern as a monolithic class in Spanish. Finally, the rhotic approximant /ɹ/ is higher in sonority than /l/ in English: (1) the contrast between *Carl* (one syllable) *vs. caller* (two syllables) follows from the SSP if /ɹ/ outranks /l/ (Borowsky 1986); (2) /ɹ/ is the default epenthetic coda in Eastern Massachusetts speech (McCarthy 1993). This follows from the SDP if /ɹ/ is the most sonorous consonant available in this position. And (3) syllabic /ɹ/ may bear stress (*bird, curtain*), but /l/ never does (Zec 2003).

Another strength of the scale in (27) is its breadth, i.e. the number of different types of segment classes it encompasses. Nevertheless, it is still not exhaustive, because it leaves out a few rarer kinds of sounds, such as clicks and implosives. Since no known sonority hierarchy includes these, more research in this area would be welcome. A third advantage of (27) is that it has been rigorously tested and found to provide a good fit with all phonetic segments in seven specific languages. This is discussed in §5.

However, a few problems persist. For example, the placement of affricates between stops and fricatives is a controversial issue, remaining open to disagreement. Many scales either leave affricates out entirely or group them with plosives, using a term such as *stops*. Such proposals may simply assume that affricates behave phonologically like stops, as they do in many languages. For instance, Kang (CHAPTER 95: LOANWORD PHONOLOGY) concludes that affricates are just stops with a special place specification, e.g. [strident]. See CHAPTER 16: AFFRICATES for more discussion of affricates in general. Similarly, the ranking of voiced stops over voiceless fricatives is harder to justify than most aspects of this hierarchy. A major reason for this is that many languages require consonant clusters to agree in voicing. Therefore, crucial diagnostic examples are rare, but one such token is the English word *midst*. Since this form is monosyllabic, /d/ is higher in sonority than /s/ by the SSP since /d/ is closer to the nucleus. Finally, the question of whether glottal consonants are sonorants or obstruents is also contested. Clearly /h/ and /ʔ/ pattern phonologically with prototypical sonorants in some languages, yet behave like obstruents in others. In (27) they are classified as obstruents. One piece of evidence supporting this is that in Panobo, /h/ groups with /β p t/ in exclusively obstruent + glide clusters (see (16)). Also, in many languages [ʔ] is inserted as a default onset, where segments of low sonority are preferred by the SDP (Lombardi 2002). Finally, in the P-base sample of 549 languages, there are 65 distinct phonological processes in which /h/ and/or /ʔ/ pattern solely with consonants that are unambiguously obstruents. In 21 other cases they group with sonorants (Mielke 2008).[6]

In the scale in (27) the tendency is obviously to "split" rather than to "lump together" natural classes. The motivation for this is as follows. There is ample evidence that fine-grade distinctions in sonority need to be made in some languages, such as between fricatives and stops in Sanskrit (§2.1). UG then must allow for these options, and hence the potential exists for other languages to exploit them as well. If we start with a hierarchy that assigns a unique rank to every distinct manner of articulation (like (27)), it is a trivial matter to formally compress (conflate) ranks together in order to analyze languages not invoking those splits. This procedure applies to every language in one way or another. However, if we assume a maximal sonority hierarchy with just the five groups in (3), no mechanism exists to "decompose" these, making more narrow distinctions in the scale when necessary. Consequently, only a fully detailed hierarchy such as (27) is flexible enough to generate the range of variation attested among the languages of the world with respect to processes involving sonority.

Nevertheless, based on acoustic studies of many languages, Zhang (2001) and Gordon (2006) deny that a universal sonority scale is theoretically the most parsimonious option. Rather, they reject the existence of invariant sound classes. Gordon, for instance, concludes that syllable weight effects are not a unified

[6] Thanks to Jeff Mielke (personal communication) for these counts.

phenomenon. He claims that nasals, for example, display slightly different phonetic behavior from one language to another. This can then influence their phonological patterning in terms of sonority.

5 The physical substance of sonority

As summarized in §2, the function of sonority in phonological systems is fairly well understood. Nevertheless, these phenomena raise an important, related question that has provoked much contention and speculation: is there any coherent notion of sonority grounded in evidence external to the phonotactic facts that sonority is assumed to account for? In other words, what is the articulatory, acoustic, and/or perceptual source of sonority in the speech signal? To date at least 98 different correlates of sonority have been posited, documented in Parker (2002). The most frequently proposed phonetic definition of sonority is probably openness (of the vocal tract) or (supralaryngeal) aperture (Bloomfield 1914; Jespersen 1922; Goldsmith 1990; Kirchner 1998), or its inverse, (supraglottal) stricture, closure, impedance, etc. (Halle and Clements 1983; Kenstowicz 1994; Hume and Odden 1996). However, notions such as impedance are difficult to quantify. A more promising correlate of sonority is amplitude/intensity, or its perceptual counterpart, loudness (Bloomfield 1914; Laver 1994; cf. §1 and see also CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). Recently a major instrumental study was carried out measuring relative sound levels or RMS (root mean square) intensity of all phonemes of Peruvian Spanish, Cusco Quechua, and Midwestern American English (Parker 2008). See Jany *et al.* (2007) for a similar investigation of four other languages (Egyptian Arabic, Hindi, Mongolian, and Malayalam). In Parker (2008), the obtained intensity values for all segments yield an overall mean Spearman's correlation of .91 with the sonority indices proposed in (27). Given those results, it is proposed there that the best way to characterize the physical basis of sonority is via a linear regression equation such as (28) below. This is calculated from the mean intensity measurements of all English coda consonants pertaining to nine of the natural classes from (27). These were pronounced five times each by five male native speakers of English.

(28) $sonority = 13.9 + .48 \times dB$ (dB = decibel; $r^2 = .95$)

This formula predicts an estimated sonority index based on a hypothetical intensity value. It characterizes the best-fitting line corresponding to the relative sonority of English coda consonants in phrasally stressed words. The obtained intensity value of each of these segments was compared to that of a stressed, utterance-initial low vowel (/ɑ/) in a fixed carrier sentence. In (28) the Y intercept is 13.9. This is the projected value of Y (sonority) when X (dB) equals 0. Here it is significantly higher than the theoretical null value. This is because the obtained intensity of the reference vowel /ɑ/, whose sonority index is 17, was subtracted from that of the target consonant for each utterance measured. This is a type of normalization procedure often performed to control for random fluctuations in loudness across speakers and tokens. The slope in (28), .48, indicates the rate of change in the dependent variable Y (sonority) per unit change in the independent variable X (dB). Its obtained value allows us to approximate the mathematical nature of the relationship between intensity and sonority. Specifically, for every decibel by which the relative sound level is increased, the corresponding sonority rank increases by about .48 units (for this sample of five English speakers). Also in (28), $r^2 = .95$. This is the coefficient of determination. It indicates the proportional reduction of error gained by using the linear regression model. Given this r^2 value, we can conclude that the single factor *sonority* accounts for (predicts) about 95 percent of the systematic variability in the intensity measurements of that dataset.

Compared with previous accounts of sonority, the definition in (28) has several advantages (Parker 2008): (1) it is precise; (2) it is non-arbitrary; (3) it is phonetically grounded; (4) it is empirically verifiable and replicable; (5) it can be calculated for other speakers and languages; and (6) the underlying methodology (regression) is compatible with different (competing) sonority scales. However, while studies of this type represent progress, some problems remain. For example, in Parker (2008) the majority of the mismatches between sonority ranks and segmental intensity values (in all three languages) involve the sonorant consonants, particularly the approximants (laterals and glides). The reason for this is not clear at this point and merits further investigation.

Finally, other researchers appeal to more functional aspects of the speech signal to avoid invoking sonority altogether. For example, building on the phonetically based work of Mattingly (1981) and Silverman (1995), Wright (2004: 35) reformulates the SSP as "a perceptually motivated and scalar constraint in which an optimal ordering of segments is one that maximises robustness of encoding of perceptual cues to the segmental make-up of the utterance." Similarly, Ohala (1990a) claims that what drives the phonological phenomena discussed here is not really sonority but simply a need for adequate modulation in the acoustic wave.

6 Conclusion

Despite its problems, sonority makes sense. If it did not exist, it would be invented (Parker 2008). In this chapter a number of important issues have been examined. Nevertheless, certain topics need to be left for future work. For example, in §3 a possible contradiction between the claims of the MSD approach and the SSP is noted, involving the relative unmarkedness of OGV *vs.* OLV demisyllables. An in-depth typological study of these clusters would be helpful. Also, more attention should be given to the phonetic and/or functional bases of principles such as the SSP, the SCL, and the MSD. The question of why these hold true is potentially intriguing. Finally, another interesting point not discussed here is whether sonority scales are necessarily the same across different domains, such as phonotactics *vs.* the calculation of syllable weight.

50 Tonal Alignment

PILAR PRIETO

1 Introduction

In recent decades, the issue of *tonal alignment* has been at the forefront of several phonological and phonetic debates in the analysis of intonation. Since the groundbreaking work of Bruce (1977), the autosegmental metrical approach to intonation proposed that intonational patterns were to be represented as autosegmental tone melodies (Pierrehumbert 1980; Beckman and Pierrehumbert 1986; Ladd 1996; and others). Given that melodies are independent from the segments which realize them in this theory (CHAPTER 45: THE REPRESENTATION OF TONE; CHAPTER 14: AUTOSEGMENTS), and since the tones are realized potentially over quite long strings, it is a central research issue to find a set of principles for mapping tones to segments. The term tonal alignment thus refers to the temporal implementation of fundamental frequency (F0) movements with respect to the segmental string. Tonal alignment has not only been used in crucial ways as an argument in favor of a given phonological framework, but has also been the focus of debate in itself. This notion has played an important role in current theories of intonational phonology, since relative alignment of tones with the segmentals has been shown to be a crucial piece of information when describing the phonological make-up of the melodic contour. This chapter reviews four important topics in the recent history of phonology in the discussion of which tonal alignment has been a crucial component.

One of the important issues in intonational phonology is the investigation of the acoustic correlates that encode *intonational categories*. Since the beginning of the autosegmental metrical approach to intonation, tonal alignment has been claimed to play a central role in encoding intonational contrasts. Pierrehumbert (1980) and Pierrehumbert and Steele (1989) showed that the timing of F0 peaks or valleys with segments functions contrastively in English, and that early-aligned pitch accents are phonologically distinct from late-aligned pitch accents. In the decades since the publication of these studies, a body of experimental research has shown that tonal alignment cues semantic distinctions in a number of languages and that it can be perceived in a near-categorical fashion (e.g. Kohler 1987; Niebuhr 2007 for German; D'Imperio and House 1997 and D'Imperio 2000 for Neapolitan Italian; Gili-Fivela 2009 for Pisa Italian; Pierrehumbert and Steele

1989 and Dilley 2007 for English). In §2 we will review recent experimental evidence that elucidates the role of tonal alignment in encoding intonational distinctions in a number of languages.

The relationship between *tonal association* and *tonal alignment* has been a central issue in the tonal representation debates within the autosegmental metrical theory of intonation. Though the autosegmental metrical representational proposal has met with considerable success in accounting for melodic patterns in a variety of languages, the literature on tonal representation has identified a few phenomena that resist transparent analysis. Two such phenomena have to do with the metrical part of the model and the standard interpretation of the relationship between phonological association and phonetic alignment. It has recently been claimed that the theoretical concept of starredness is somewhat unclear and that its definition cannot be based solely on phonetic alignment (Arvaniti *et al.* 2000; Prieto *et al.* 2005). In §3 we describe the standard view of the relationship between phonological association of tones and phonetic alignment and then review some recent proposals on the topic.

Another important goal of several models of intonation has been to develop a *phonetic model of tonal alignment*. Within these models, it is a central issue to determine what part of the variation in the realization of the tune-to-text mapping is due to phonetic implementation and what part is phonological and is accounted for in a phonological representation (either of the tone melodies or of prosodic or segmental anchors for tones). A body of work on tune–text alignment has shown that, apart from phonological distinctions in alignment, a variety of phonetic factors, such as tonal crowding, speech rate and syllable structure influence the fine-grained patterns of F0 location in predictable ways. For example, it has been demonstrated that time pressure from the right-hand prosodic context (i.e. the proximity of an upcoming accent or boundary tones) is crucial in determining the location of H peaks (see e.g. Silverman and Pierrehumbert 1990 for English and Prieto *et al.* 1995 for Spanish). Recent work has shown that when such right-hand prosodic effects are excluded (i.e. when the tonal features under investigation are not in the vicinity of pitch accents or boundary tones), the alignment of F0 peak targets is consistently governed by *segmental anchoring* (Arvaniti *et al.* 1998 for Greek; Ladd *et al.* 1999 for English). Similarly, other work on production and perception supports the hypothesis that prosodic structure must play an essential part in our understanding of the coordination of pitch gestures with the segmentals and that listeners are able to employ these fine details of H tonal alignment due to syllable structure or within-word position to identify lexical items (D'Imperio *et al.* 2007b; Prieto *et al.*, forthcoming). In §4 we review recent proposals regarding phonetic models of tonal alignment and the role of prosodic structure in the implementation of F0 tonal alignment patterns.

Finally, tonal alignment studies have also been used to test specific predictions by different *phonological models* of prosody and intonation. Arvaniti and Ladd (2009) provide a useful example of how a production study on alignment can be used to test specific predictions by *target-based vs. configuration-based* models of intonation (CHAPTER 32: THE REPRESENTATION OF INTONATION). As we will see below, Arvaniti and Ladd undertook a very detailed phonetic study of the intonation of Greek wh-questions and tested different predictions about tonal implementation. The F0 alignment data showed predictable adjustments in alignment depending on the location of adjacent tonal targets. The authors conclude that models that specify the F0 of all syllables, and models that specify F0 by superposing contour shapes for shorter and longer domains, cannot account for predictable variation without resorting to ad hoc tonal specifications, which, in turn, do not allow for phonological generalizations about contours applying to utterances of different lengths. In §5 we review the evidence coming from a variety of tonal alignment studies that test specific predictions from different phonological models of intonation.

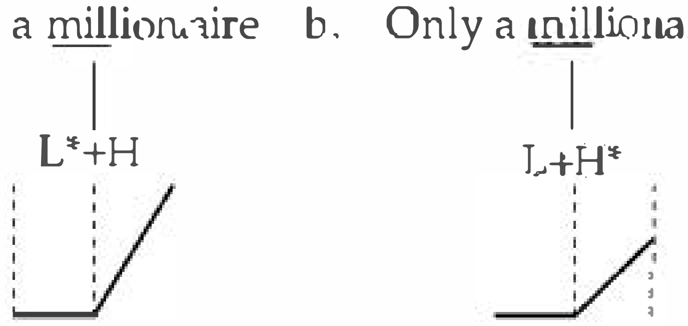
In the following sections, we present and discuss each of these four topics, providing the relevant data and highlighting some of the unresolved issues.

2 The role of tonal alignment in distinguishing intonational categories

One of the key discoveries within work on intonation is the fact that tones in intonational languages are associated with either metrically prominent syllables (*pitch accents*) or prosodic edges (*boundary tones*). Many theories of intonational phonology thus draw a clear distinction between the two sorts of tonal units, i.e. tonal entities associated with prominent or metrically strong syllables and tonal entities associated with edges of prosodic domains. Within the autosegmental metrical (AM) approach to intonation initially developed by Pierrehumbert (1980), she argues that the English intonation system consists of an inventory of tonal units, each consisting of either one or two tones, which can be High (H) or Low (L) (see CHAPTER 14: AUTOSEGMENTS; CHAPTER 116: SENTENTIAL PROMINENCE IN ENGLISH). These tones can either be associated with metrically strong syllables (and represented with a *, i.e. H* and L*) or be associated with prosodic edges (and represented with a %, i.e. H% and L%).

Tonal units can be monotonal or bitonal. In the case of tonal units associated with prominent syllables, or pitch accents, Pierrehumbert proposed a phonological inventory of six pitch-accent shapes for English (H*, L*, H*+L, H+L*, L*+H, L+H*), some of them encoding alignment differences. Crucially, the AM model started to make use of the star notation (*) in bitonal pitch accents to indicate tonal association with metrically strong syllables and relative alignment – see §3 for a review of the starredness concept. The autosegmental representations in (1) capture the fact that the LH shape is aligned differently in the two contrastive pitch accents exemplified in figure 50.1. While L*+H has a low tone (L) on the stressed syllable and a high tone (H) trailing it, L+H* has a high tone on the stressed syllable with a low tone leading it:

(1) a. Only a <u>mill</u>ionaire b. Only a <u>mill</u>ionaire



In sum, an important proposal of the AM model of intonation, based on Bruce's (1977) analysis of the tonal alignment contrast between Accent I and Accent II in

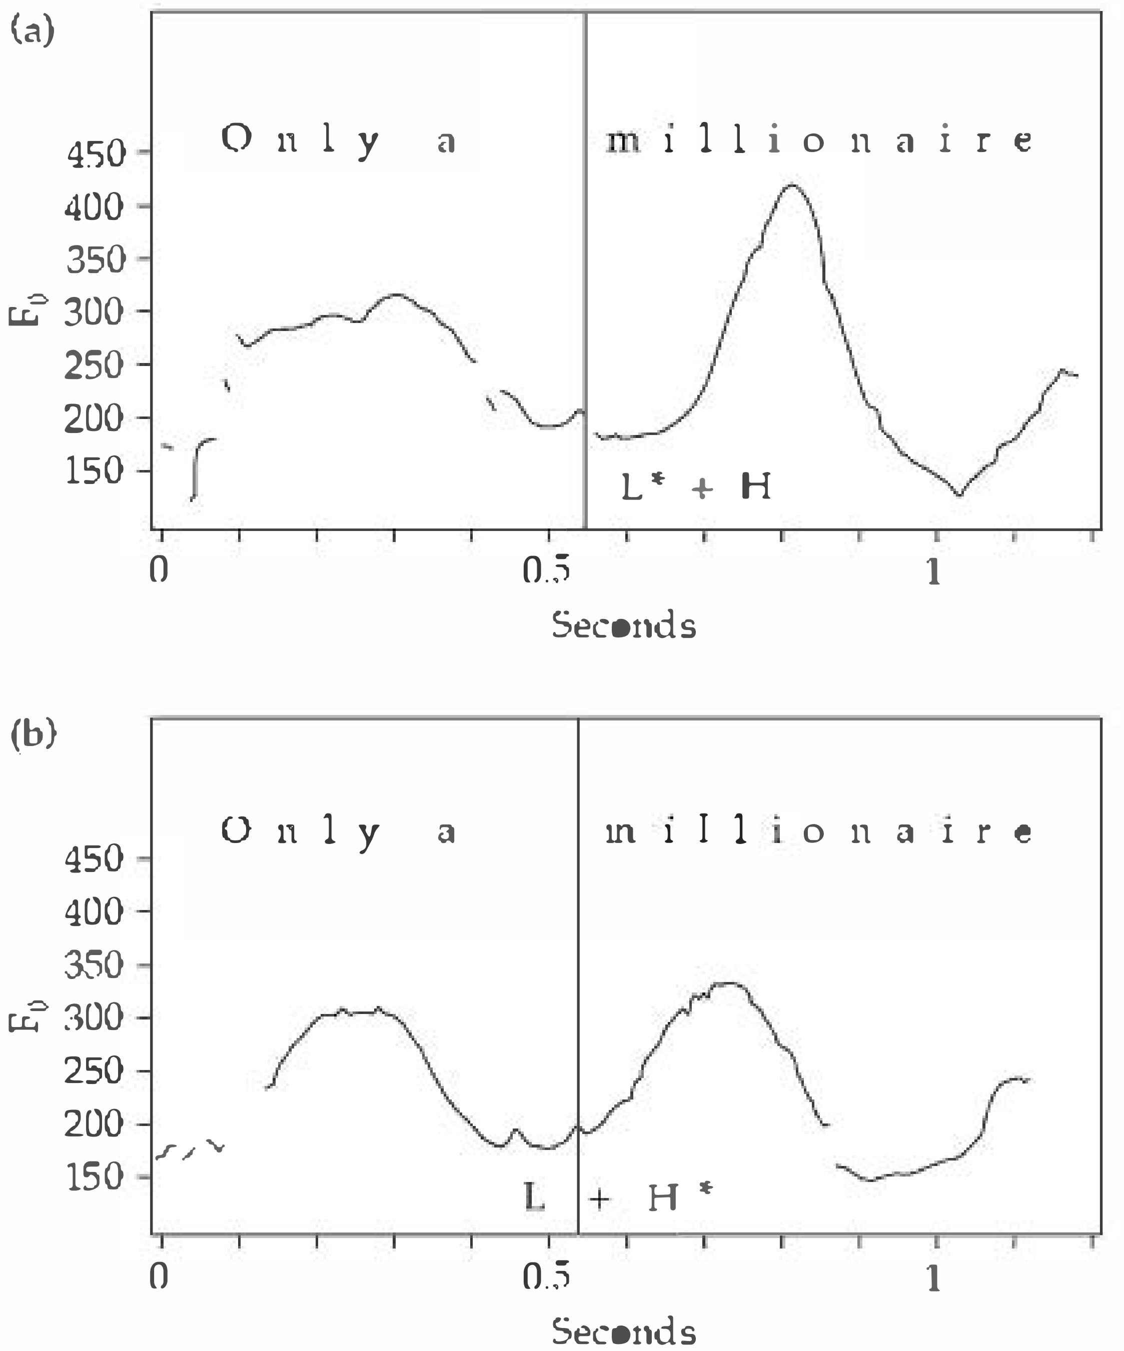


Figure 50.1 The fundamental frequency contour of the utterance *Only a millionaire* spoken with two different pitch accents on *millionaire*: the late-aligned pitch accent, which indicates incredulity or uncertainty (a), and the early-aligned pitch pattern, which indicates assertion (b). The vertical cursor is placed at the [m] release in *millionaire*. Figure reproduced from Pierrehumbert and Steele (1989: 182)

Swedish, is that pitch accent types can be phonologically distinguished by their *relative alignment* with the metrically prominent syllable. Pierrehumbert (1980) shows that tonal alignment functions contrastively in English and that early-aligned pitch accents are phonologically distinct from late-aligned pitch accents. Figure 50.1 shows two intonation patterns of the utterance *Only a millionaire* spoken with two different pitch accents on *millionaire*: the late-aligned pitch accent, which indicates incredulity or uncertainty (a), and the early-aligned pitch pattern, which indicates assertion (b).

In their seminal paper, Pierrehumbert and Steele (1989) performed an *imitation task* with the two intonation patterns of the abovementioned utterance *Only a millionaire* (see Figure 50.1). They created a synthesized continuum of several steps of alignment between the two, and asked subjects to imitate the utterance. The results of the imitation task revealed the existence of two separate phonological categories. The authors argued that if the subjects had been able to reproduce the full range of the continuum in their imitation, peak alignment differences could be regarded as gradient. However, since they found that by and large the distribution of peak alignment was bimodal in the imitation data, they therefore concluded that the distinction between early and late peak alignment was categorically distinct.

Pierrehumbert and Steele's paper represented an important first step in a series of experimental investigations on the perception of tonal alignment (see CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). Since then, a body of experimental research has demonstrated that tonal alignment cues *intonational meaning distinctions* in a number of languages (e.g. Kohler 1987 and Niebuhr 2007 for German; D'Imperio and House 1997 and D'Imperio 2000 for Neapolitan Italian; Gili-Fivela 2009 for Pisa Italian; Dilley 2007 for English). The issue of whether a certain pair of intonational contrasts can be accompanied by categorical differences in meaning and whether these contrasts are perceived in a discrete or a gradient fashion has been an important research question in the field of intonation. A number of experimental methods have been used to study what is categorical or linguistic in intonation and what is paralinguistic and gradient (see the reviews in Gussenhoven 2004, 2006; also CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). In what follows we review recent studies that have provided evidence from a number of languages on the role of tonal alignment in encoding intonational distinctions. All in all, these articles provide robust experimental evidence for the claim that changes in F0 alignment of peaks and valleys are especially salient and cue phonological distinctions across languages. This evidence has been generally interpreted as direct support for AM theory, as tonal alignment differences in this model are encoded phonologically at the pitch accent level.

Kohler's (1987) paper was the first to apply the *Categorical Perception* paradigm to alignment data and to show that alignment contrasts can be perceived categorically. The Categorical Perception paradigm involves firstly an identification/classification task in which the listeners have to categorize stimuli taken from a continuum, and secondly a discrimination task in which listeners are asked to judge pairs of stimuli as being either the same or different. For perception to be considered categorical, a peak of discrimination is expected at the point in the acoustic domain that separates the two categories (for a review, see Dilley 2007). Kohler (1987) employed the complete paradigm to investigate the perception of a set of F0 contours in German involving rises with a continuum created between early and medial peaks. He found that the early peak was associated with finality ("knowing," "coming to the end of an argument"), and the medial peak with openness ("observing," "starting a new argument"). The results of both tasks of the paradigm revealed categorical changes in the identification of early *vs.* medial peaks, with a discrimination maximum across the category boundary. More recently, Niebuhr (2007) carried out a series of perception experiments with the same German alignment contrasts and showed that the function-based identification of the peak categories is influenced not only by peak synchronization, but also by peak shape and height. In general, though, his findings corroborate the existence of the two categories in German intonation and support the idea that the timing of the peak movements with regard to the accented vowel is important for their perceptual differentiation.

Similar results have been obtained for American English tonal alignment contrasts. Following Pierrehumbert and Steele's (1989) investigation, a number of studies have examined the distinction between an early-aligned pitch accent (L+H*) and a late-aligned pitch accent (L*+H) in American English. In the most comprehensive study, Dilley (2007) conducted a series of perception experiments with the two pairs of accents attested in American English (H* and H+L*, and L* and L+H*), an identification task, two types of discrimination tasks and an imitation task. Evidence of discrimination maxima that aligned well with identification crossover points in the identification task demonstrated categorical perception for intonation and provided converging evidence with earlier results by Kohler (1987). Moreover, converging evidence for the categorical perception of intonation categories was obtained from the imitation study.

Though Kohler (1987) and Dilley (2007) are advocates of the application of the Categorical Perception paradigm to intonation, few other studies have shown clear evidence of categorical perception, i.e. with a clear discrimination peak in the expected position. The discrimination functions observed differ between studies, and in the majority of cases no discrimination peaks appear at the category crossover point revealed by the identification test. One such example is described in Gili-Fivela's (2009) article. She investigated the contrast between narrow focus and narrow contrastive focus in Pisa Italian, represented as H* and H*+L. In Pisa Italian, as in other languages, narrow contrastive focus is expressed through the use of retracted pitch peaks and an increase in pitch height. Gili-Fivela applied the Categorical Perception paradigm to the data, with both identification and discrimination tasks being performed, and also an imitation task. She manipulated both the alignment and scaling patterns of a rising pitch accent in narrow focus and a rising-falling pitch accent in contrastive narrow focus. The results showed that while there is a clear difference between a narrow focus pattern and a contrastive focus pattern in production, the contrast might not be categorically perceived, as the identification and discrimination functions do not correspond to an abrupt shift in identification aligned with a discrimination peak.

Other studies have shown that the slope of the rise and the shape of the peak also contribute to tonal contrast identification. D'Imperio and House (1997) and D'Imperio (2000) investigated the distinction between questions and statements in Neapolitan Italian. In Neapolitan Italian, questions and statements are characterized by a rise in pitch that occurs in the vicinity of the accented syllable. The materials in D'Imperio and House (1997) consisted of a series of stimuli in which the F0 peak of a rising-falling pitch accent was shifted forward and backwards within the accented syllable. Neapolitan listeners performed an identification task in which they listened to the stimuli and then classified each of them as either a question or a statement. The results showed that questions and statements are primarily distinguished by the relative alignment of the rise in a rise-fall pattern in the accented syllable. In subsequent experiments using this same contrast, D'Imperio (2000) showed that both details of the temporal alignment of target tones and the shape of the peak contribute to the identification of the contrast between questions and statements in this language. Moreover, she found that syllable structure detail modifies acoustic target alignment but does not modify the crossover point between the two categories (for more details, see §4).

New experimental paradigms have been recently applied to study the role of tonal alignment in spoken language processing. Chen *et al.* (2007) adopted the *eye-tracking paradigm* to investigate the role of pitch accent type and deaccentuation in online processing of information status in British English.[1] It was found that

[1] For a review of the eye-tracking paradigm applied to prosody research, see Watson *et al.* (2006) and Watson *et al.* (2008).

two types of pitch accents (H*L and L*HL) create a strong bias toward newness, whereas deaccentuation and the L*H pitch accent create a strong bias toward givenness. Watson *et al.* (2008) also used the eye-tracking paradigm to investigate whether the presence of a pitch accent difference between L+H* and H* in English biases listeners toward interpreting a temporarily ambiguous noun as referring to either a discourse-given or a discourse-new entity. Participants had to perform a word-recognition task (for example, *candle vs. candy*) and pick up one of the two competing objects, while their eye movements were being monitored. They found that although listeners interpreted these accents differently, their interpretive domains overlapped. L+H* created a strong bias toward contrast referents, whereas H* was compatible with both new and contrast referents.

The electro-encephalography (EEG) technique, a procedure which measures electrical activity of the brain and which allows for the non-invasive measuring of brain activity during cognitive processing, has also been used to study pitch processing. For example, Fournier *et al.* (2010) used this technique to investigate the tonal and intonational pitch processing of some tonal contrasts (some of them alignment contrasts) by native speakers of the tonal dialect of Roermond Dutch as compared to a control group of speakers of Standard Dutch, a non-tone language. A set of words with identical phoneme sequences but distinct pitch contours, which represented different lexical meanings or discourse meanings (e.g. statement *vs.* question), were presented to both groups. The stimuli were arranged in a mismatch paradigm, under several experimental conditions: in the first condition (lexical), the pitch contour differences between stimuli reflected differences between lexical meanings; in the second condition (intonational), the stimuli differed in their discourse meaning. In these two conditions, both native and non-native responses showed a clear magnetic mismatch negativity in a time window from 150 to 250 msecs after the divergence point of standard and deviant pitch contours. In the lexical condition, a stronger response was found over the left temporal cortex of speakers of standard as well as non-standard Dutch. Crucially, in the intonational condition, the same activation pattern was observed in the control group, but not in the group of Roermond Dutch speakers, who showed a right-hemisphere dominance instead. Thus the lateralization of pitch processing was condition-dependent in the Roermond Dutch group only, suggesting that processes are distributed over both temporal cortices according to the functions available in the grammar.

Finally, researchers have begun to consider the role of potential *articulatory landmarks* and the coordination or alignment between *tonal gestures* (measured as F0 turning points) and *oral constriction gestures*. Recent work by Mücke *et al.* (2006), D'Imperio *et al.* (2007a), and Mücke *et al.* (2009) has investigated alignment patterns for three different languages (Italian, German, and Catalan) by using electromagnetic mid-sagittal articulography (EMMA) for capturing oral constriction gestures alongside acoustic recordings. The end of pitch movements in bitonal pitch accents co-occurs with the minima and maxima of the closing gesture of C_2 in $C_1V.C_2$ and C_1VC_2 sequences. In all these studies, such pitch targets were seen to be more closely aligned in time with articulatory landmarks than with acoustic ones. However, there was some variation as to the articulatory landmark which served as an anchor for the tonal target. For example, in German nuclear LH accents, the H peaks co-occurred with the intervocalic C target, whereas in pre-nuclear accents peaks co-occurred with the target for the following vowel (what is called "accent shift"; Mücke *et al.* 2009). In Catalan it was the consonantal peak velocity rather than the consonantal target which served as the landmark. Such an apparently small alignment difference in the articulatory anchor type may be used by speakers to make (or contribute toward making) phonological distinctions, as in Neapolitan, where H in L*+H (questions) aligns with the maximum constriction, and H in L+H* (statements) aligns with peak velocity (see D'Imperio *et al.* 2007a).

3 Phonological encoding: Tonal association and tonal alignment

The topic of this section is the relation between phonological association and phonetic alignment of tones and how it is encoded in a representational system. The starting point is provided by the autosegmental metrical approach to intonation, which has developed an explicit phonological representational approach that has been applied to a variety of languages (Pierrehumbert 1980; Pierrehumbert and Beckman 1988; Ladd 1996; Gussenhoven 2004; among others). Though the AM representational proposal can account for melodic patterns in a variety of languages, there are a number of areas that remain unresolved. Two of these issues relate to how to interpret the relationship between tones and metrically strong syllables in the AM model, namely the concept of starredness on the one hand and the interpretation of the relationship between phonological association and phonetic alignment on the other.

The AM phonological representation of pitch accents encodes "autosegmental" information (or pitch accent shapes, LH or HL) and "metrical" information, i.e. information about the association of tones with metrical constituents and the relative alignment of tones with the metrically prominent syllable. The surface alignment of tones is basically derived from the use of the star notation (*). The star notation encodes two complementary things: (i) phonological association between pitch accent shapes and stressed syllables – in other words, a tone gets a star when it is associated to a metrically strong position; (ii) relative alignment in bitonal pitch accents – i.e. the tone that gets the star is the one that is directly linked to the metrically strong position. In bitonal accents, the question of which tone in LH or HL accent shapes should be assigned a star is not completely straightforward. On this issue, Pierrehumbert's original definition states that "a strength relationship is defined on the two tones of bitonal accents and that it is the stronger tone which lines up with the accented syllable" (Pierrehumbert 1980: 76–77). According to this definition, it is ambiguous whether the star notation * indicates phonetic alignment between the tonal unit and the stressed syllable or just a "looser" phonological association. Similarly, Pierrehumbert and Beckman (1988: 234) note that "the * diacritic marks which tone of a bitonal accent is aligned with stress." Arvaniti *et al.* (2000: 120) state that "phonetically this use of the star is to be interpreted as signifying that the starred tone is aligned in time with the stressed syllable." In subsequent work, one of the most common interpretations of the star notation is that the starred tone is phonetically aligned with the stressed syllable, and thus a strict temporal alignment between the tone and its tone-bearing unit is expected.

Recently, attention has been drawn to the various problems created by the representational ambiguity of the star notation. One of them is that it can be difficult to decide between competing AM analyses of bitonal accents, because the same contours can be transcribed in different ways (Prieto *et al.* 2005). For example, let us compare the surface alignment of the tones described by the English and Spanish L+H* – L*+H contrasts according to, respectively, Pierrehumbert (1980) and Sosa (1999). Even though the two phonological units capture the two-way phonological contrast present in both languages, the same labels L+H* and L*+H refer to different phonetic realizations (or alignment patterns) in the two languages. In fact, English L+H* corresponds to Spanish L*+H. This difference between the notational systems is caused by different interpretations of the star notion: while in the English notation the star is interpreted as an indication of phonological association between the tone and the prominent syllable, in Spanish it is interpreted as phonetic alignment, that is, the star is indicating whether the H peak is aligned (H*) or not aligned (L*) with the stressed syllable.

(2) *Schematic representation of* L+H* *and* L*+H

a. *English* (after Pierrehumbert 1980) b. *Spanish* (after Sosa 1999)

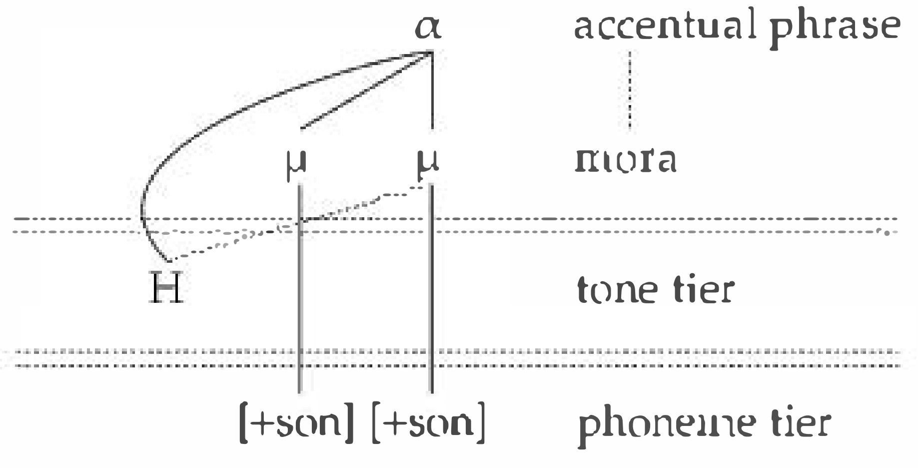
In addition, some authors have pointed out that the theoretical concept of starredness is ill-defined and cannot be based solely on phonetic alignment (Arvaniti *et al.* 2000). Arvaniti *et al.* present evidence from Greek of the types of problems that arise when phonetic alignment to the accented syllable is taken to be the exponent of association of tones with segments. As they note:

> we show that there exist pitch accents that are clearly bitonal but neither tone is, strictly speaking, aligned with the accented syllable. We argue from this fact that association cannot be based on phonetic alignment in any straightforward way and that a more abstract and rigorously defined notion of starredness is required.

In Greek rising pitch accents in pre-nuclear position, typically, neither L nor H is phonetically aligned with the stressed syllable: in most cases, the L is consistently aligned before the beginning of the accented syllable (5 msecs on average before the onset), and H displays more variability and is typically located in the post-tonic. Thus, these authors conclude that "if alignment is the sole exponent of the association of tones to segments, phonetic variability in this domain becomes a crucial issue when the phonological structure of a bitonal accent is in question" (Arvaniti *et al.* 2000: 121). We take it as essentially correct that a one-to-one relationship between phonological association and phonetic alignment is difficult to maintain in the current AM model.

In a recent proposal, Prieto *et al.* (2005) describe the contrastive possibilities of alignment of rising accents in three Romance languages, Central Catalan, Neapolitan Italian, and Pisa Italian (see also CHAPTER 2: CONTRAST). According to these authors, these Romance languages provide evidence that small differences in alignment in rising accents must be encoded phonologically. To account for such facts within the AM model, they develop the notion of "phonological anchoring" as an extension of the concept of secondary association originally proposed by Pierrehumbert and Beckman (1988). They propose that the phonological representation of pitch accents needs to include two independent mechanisms to encode alignment properties with metrical structure: (i) encoding of the primary phonological association (or affiliation) between the tone and its tone-bearing unit; and (ii), for some specific cases, encoding of the secondary phonological anchoring of tones to prosodic edges (i.e. moras, syllables, and prosodic words). (3) shows the schematic representation of the primary and secondary associations of a phrasal H within the accentual phrase in Japanese (Pierrehumbert and Beckman 1988: 129). The solid line indicates primary association to the accentual phrase α and the dashed line secondary association to the second sonorant mora μ within the accentual phrase.

(3) *Japanese* (after Pierrehumbert and Beckman 1988: 129)



The Romance data provide crucial evidence of mora-edge, syllable-edge, and word-edge H tonal associations and suggest that not only peripheral edge tones seek secondary associations. In this way, the specification of metrical anchoring points in the phonological representation offers a more transparent analysis of the alignment contrasts found in Romance languages and, ultimately, can help in the task of defining a more transparent pitch accent typology. Finally, Prieto *et al.* (2005) argue that such an approach makes the mapping from phonological representation to surface alignment patterns more explicit, and that it thus allows for more straightforward cross-linguistic comparisons.

The evidence described above shows that even though AM representations are adequate when it comes to characterizing the minimal contrasts in pitch accent types found in different languages, the proper procedures by which to map phonological representations and the surface alignment of tones (through the use of the star notation) are still somewhat unclear. This is because the specific details of the coordination between tones and the segments that are linked to the structural unit are not part of the phonological representation itself. We thus agree with Arvaniti *et al.*'s (2000: 130) suggestion "that the task for the future is to refine the notion of the phonological association of tones in intonational systems." In the near future, the contrastive possibilities of alignment found cross-linguistically need to be explored. This will provide firm ground from which to advocate a further refinement of the metrical side of the AM model.

4 Phonetic models of tonal alignment

Apart from changes in tonal alignment which have phonological effects, i.e. which encode a difference in meaning (see §2 and §3), tonal alignment is influenced by a variety of phonetic factors, such as tonal crowding, speech rate, segmental composition, and syllable structure composition. These fine-grained F0 alignment differences do not affect meaning or representation, and are instead considered to arise from differences in phonetic implementation rather than phonological representation. In this section we review some of the production studies that have investigated the influence of such factors on tonal alignment patterns and the perception studies that have demonstrated that some of these effects are employed by native speakers in lexical access tasks.

Cross-linguistically, the location of fundamental frequency peaks (or H values) has been shown to be greatly affected by the right-hand prosodic context, in such a way that the peak is retracted before upcoming pitch accents and boundary tones (see Silverman and Pierrehumbert 1990 for English and Prieto *et al.* 1995 for Spanish, for example). Prieto *et al.* (1995) examined the peak placement patterns in rising accents in Spanish and found the following: (i) the location of the start of the F0 rise is fairly constant (generally at the onset of the accented syllable); (ii) as in English, the duration of the rising gesture is highly correlated with syllable duration. These results show that the slope and/or duration of a speech F0 movement are not constant, as claimed by the *fixed rise-time hypothesis* (Fujisaki 1983; 't Hart *et al.* 1990; and others), but are instead governed by the coordination of the movement with the segmental string. Both studies demonstrated that a successful quantitative model of peak placement must contain at least two factors, namely the duration of the accented syllable and the distance in syllables to upcoming pitch accents or boundary tones.

The *Segmental Anchoring Hypothesis* (henceforth SAH), as articulated by Ladd *et al.* (1999) on the basis of work by Prieto *et al.* (1995) and Arvaniti *et al.* (1998), refers to the idea that the slope of tonal movements is not invariant, but rather is specifically related to segmental anchors. Arvaniti *et al.* (1998) found an unexpected and consistent stability effect when little or no tonal pressure was exerted on the pitch accent. In a Greek word such as [pa'ranoma] 'illegal', the H target in the LH pitch accent associated with the test stressed syllable ['ra] was consistently aligned over – or "anchored to" – the frontier between the post-accentual onset and the following vowel ([n] and [o]). This clearly contradicts the traditional "constant slope" and "constant duration" hypotheses (i.e. the fixed rise-time hypothesis: Fujisaki 1983; 't Hart *et al.* 1990; and others). The SAH says that both the beginning and the end of a rising or falling F0 movement are anchored to specific points in the segmental string, such as the beginning of the stressed syllable or the following unstressed vowel, and consequently the duration of the F0 movement is strongly dependent on the duration of the segmental interval between the anchor points. As we will see below, work on the effects of lower prosodic structure levels such as the syllable or the prosodic word on tonal alignment shows that we need to refine the SAH to incorporate these findings.

Recent work on tonal alignment in different languages has shown that the position of the peak tends to change across syllable structure types (e.g. Rietveld and Gussenhoven 1995 for Dutch; D'Imperio 2000 for Neapolitan Italian; Prieto and Torreira 2007 for Peninsular Spanish; Prieto 2009 for Catalan). For example, D'Imperio (2000) found that the peak was located closer to the vowel offset in closed syllables in Neapolitan Italian. While in open syllables the peak was aligned with the end of the accented vowel, in closed syllables the peak was somewhat retracted and located within the coda consonant. This same effect of coda consonants on alignment has been detected in both rising accents in various languages (see citations above) and falling nuclear accents in Catalan (Prieto 2009). The results indicate that while the beginning of the falling accent gesture (H) is tightly synchronized with the onset of the accented syllable, the end of the falling gesture (L) is more variable and is affected by syllable structure: in general, while in open syllables the end of the fall is aligned roughly with the end of the accented syllable, in closed syllables it is aligned well before the coda consonant.

D'Imperio *et al.* (2007b) hypothesized that Neapolitan listeners might capitalize on the alignment regularity for the perception of lexical contrast. Specifically, their hypothesis was that listeners of Neapolitan Italian might identify more closed syllable items when tonal alignment details are congruent with those for this type of syllable structure (see also Petrone 2008). In order to test this hypothesis, two natural productions of the words *nono* 'ninth' and *nonno* 'grandfather', both carrying a yes/no question nuclear accent, were manipulated in two ways. First, the researchers modified the length of the stressed vowel and the following consonant in five steps, in order to shift the perception of each item from *nono* to *nonno* and *vice versa*. Then, tonal alignment was shifted earlier, in four steps, without changing the percept of the question to that of a statement but merely creating question patterns that would be more or less congruent with the syllabic structure of the base. Thirteen Neapolitan listeners identified the stimuli as either *nono* or *nonno*. Significantly, the results showed that the alignment manipulation produced a category boundary shift in the *nonno* base stimulus series, but no effect in the open syllable series, supporting the hypothesis that fine detail of tonal alignment not only is employed to signal pragmatic contrast but may also be stored as part of the phonological specification of lexical items.

Similarly, acoustic work on a variety of languages has shown that H peaks are consistently affected by the position of the accented syllable within the word (for English, see Silverman and Pierrehumbert 1990, and for Spanish Prieto *et al.* 1995). In general, peaks tend to shift backwards as their associated syllables approach the end of the word: in other words, the distance from the beginning of the accented syllable to the peak is longer in words with antepenultimate stress than in words with penultimate stress, which in turn show a longer distance than in words with final stress. In order to correct for the potentially confounding effects of stress clash (or distance to the next accented syllable), Prieto *et al.* (1995) analyzed a subset of the data obtained from test syllables in different positions in the word (e.g. *<u>nú</u>mero* 'number', *nu<u>me</u>ro* 'I number', *nume<u>ró</u>* '(s)he numbered'). Their materials consisted of word sequences in which there was a distance of two unstressed syllables between one accented syllable and the next (e.g. *<u>nú</u>mero <u>rá</u>pido* 'quick number', *nu<u>me</u>ro ner<u>vio</u>so* 'I number nervously', and *nume<u>ró</u> regu<u>lar</u>* '(s)he numbered in a regular way'). The three diagrams in Figure 50.2 show a schematic representation of the difference in F0 timing patterns in the three conditions, *número rápido*, *numero nervioso*, and *numeró regular*. A significant effect of word position on different measures of peak alignment was found in all the comparisons. Similarly, in Silverman and Pierrehumbert's (1990) model of F0 peak location, the dropping of the variable "Word-Boundary" (while leaving the variable "Stress Clash" as a main predictor) significantly worsened the fit of the model.

Prosodic word effects seem to suggest the possibility that the end of the word (and not only the presence of upcoming accents or boundary tones) is acting as a kind of prosodic boundary that exerts prosodic pressure on H tonal targets and

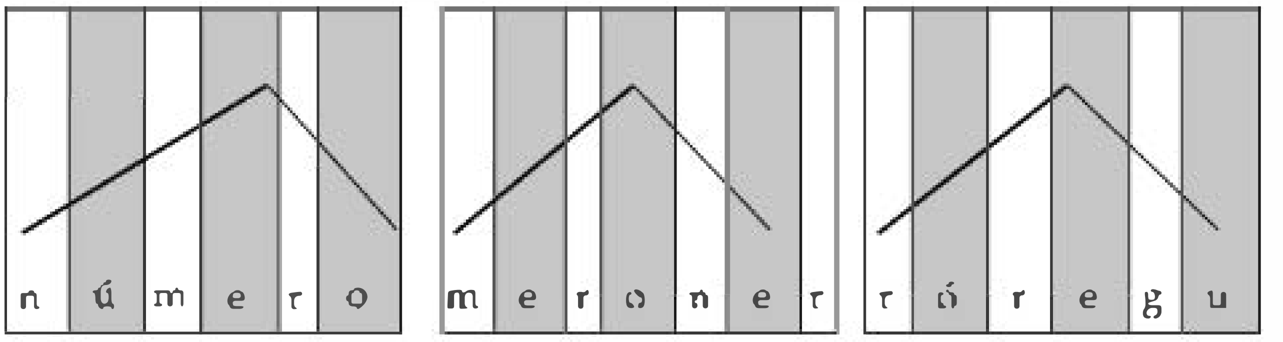


Figure 50.2 A schematic representation of the difference in F0 timing patterns in the three conditions, *número rápido*, *numero nervioso*, and *numeró regular*

that this effect can be exploited in word boundary identification tasks. Prieto *et al.* (forthcoming) performed a set of production and perception experiments that dealt with potentially ambiguous utterances distinguished by word boundary location in Catalan and Spanish (e.g. Catalan *mirà batalles* '(s)he looked at battles' *vs.* *mirava talles* 'I/(s)he used to look at carvings'; Spanish *da balazos* '(s)he fires shots' *vs.* *daba lazos* 'I/(s)he gave ribbons'). For the perception experiments, they hypothesized that relative peak location would help Catalan and Spanish listeners in terms of lexical access. The results of the production experiments showed that the prosodic word domain has a significant shifting effect on F0 peak location, and the results of the perception experiments showed that these alignment patterns are actively used by listeners in word identification tasks.

In general, the results of studies on lexical access (D'Imperio *et al.* 2007b; Prieto *et al.*, forthcoming) support the hypothesis that listeners are able to employ fine allophonic details of H tonal alignment due to syllable structure or within-word position to identify lexical items. This empirical evidence demonstrates that prosodic structure must play an essential role in our understanding of the coordination of pitch gestures with the segmentals and argues in favor of a view supported by other work that prosodic structure is manifested in details of articulation.

5 Tonal alignment: Evidence for target- *vs.* configuration-based theories of intonation

As pointed out in §2, work on tonal alignment has provided robust experimental evidence that changes in the synchronization of peaks and valleys with segmental landmarks are key perceptual cues for phonological distinctions across languages. This evidence has been interpreted as direct support for AM theory, which is widely held to afford a number of advantages over other discrete tone theories, as tonal alignment differences in this model are encoded phonologically in pitch accent units.

Alignment studies have also been used to test specific predictions about different phonological models of prosody and intonation. For example, one of the old controversies in intonation studies surrounds the relative merits of the *target-based vs. configuration-based* theories of intonational primitives (see Ladd 1996: §1.2 for a review; also Arvaniti and Ladd 2009). The target-based model (also called *target-and-interpolation model* by Arvaniti and Ladd 2009) is the phonetic basis of AM intonational phonology, which has become the dominant phonological framework for analyzing intonation. This model assumes that certain points in the contour (e.g. local targets or F0 maxima and F0 minima) reflect phonologically specified targets and thus derive the intonational contour by defining the tonal targets and then connecting those through an interpolating F0 curve that goes from one target to the next. In recent years there has been accumulating evidence from tonal alignment studies that L and H tones behave as static targets and that they align with the segmental string in extremely consistent ways. Typically, in a variety of languages, the L valley of pre-nuclear rises is precisely aligned with the beginning of the accented syllable (see Prieto *et al.* 1995 for Spanish, Arvaniti *et al.* 1998 for Greek, and Ladd *et al.* 1999 for English, for example). Moreover, some studies have shown that this precise L intonational alignment with word or syllable boundaries is used by listeners in lexical identification tasks. For example, Ladd and Schepman (2003) showed that the different alignment of L in minimal pairs like *Norman Elson/Norma Nelson* is a useful cue to the word-boundary distinction between them. If L alignment was modified experimentally in such ambiguous phrases, this affected the listeners' judgments in the identification task. Similarly, a recent study on the tonal marking of the French Accentual Phrase (AP) by Welby (2003) showed that the L tone associated with the left edge of the first content word of the AP is aligned at the boundary between the last function word and the first syllable of the first content word. Welby's results for perception showed that French listeners use the alignment of the L tone as a cue for lexical access (in pairs such as *mes galops* 'my gallops' and *mégalo* 'megalomaniac'). All in all, these alignment results, as well as many scaling results, have been interpreted in favor of the target-based hypothesis (for a review, see Ladd 1996).

On the other hand, *configuration-based theories* (also called *concatenation models* by Arvaniti and Ladd 2009) treat the contour as the result of stringing together entire tonal sequences (not necessarily straight lines) of various lengths. Traditional intonational descriptions of the so-called "British school" (e.g. Crystal 1969; O'Connor and Arnold 1973) and the approach adopted by the Eindhoven-based *Instituut voor Perceptie Onderzoek* (IPO; e.g. 't Hart *et al.* 1990) are of this sort, as is the more recent syllable-concatenation model proposed by Xu and colleagues (e.g. Xu and Wang 2001; Xu and Xu 2005). There have been several results reported in the literature that provide support for a configuration-based theory of intonation. For example, as mentioned above, D'Imperio and House (1997) undertook a perception experiment that investigated the contrast between questions and statements in Neapolitan Italian. They wanted to determine whether the major perceptual cue to this category distinction involved only the temporal alignment of the high-level target with the syllable or if instead the category percept also depended on the presence of a rising or falling melodic movement within the syllable nucleus. The results showed that the primary perceptual cue for questions is a rise through the vowel, while the primary cue for statements is a fall through the vowel. D'Imperio and House claimed that their results confirmed the second hypothesis, in that perceptually a rise in the vowel was the most important cue for the question, while a fall in the vowel was the most important cue for the statement, thus supporting the notion that pitch movements through areas of stability are perceptually important for identifying tonal categories.

Contrasting results were obtained by Arvaniti and Ladd (2009), who carried out a production study in which they used acoustic alignment measures to test specific predictions about different phonological models of intonation. This involved

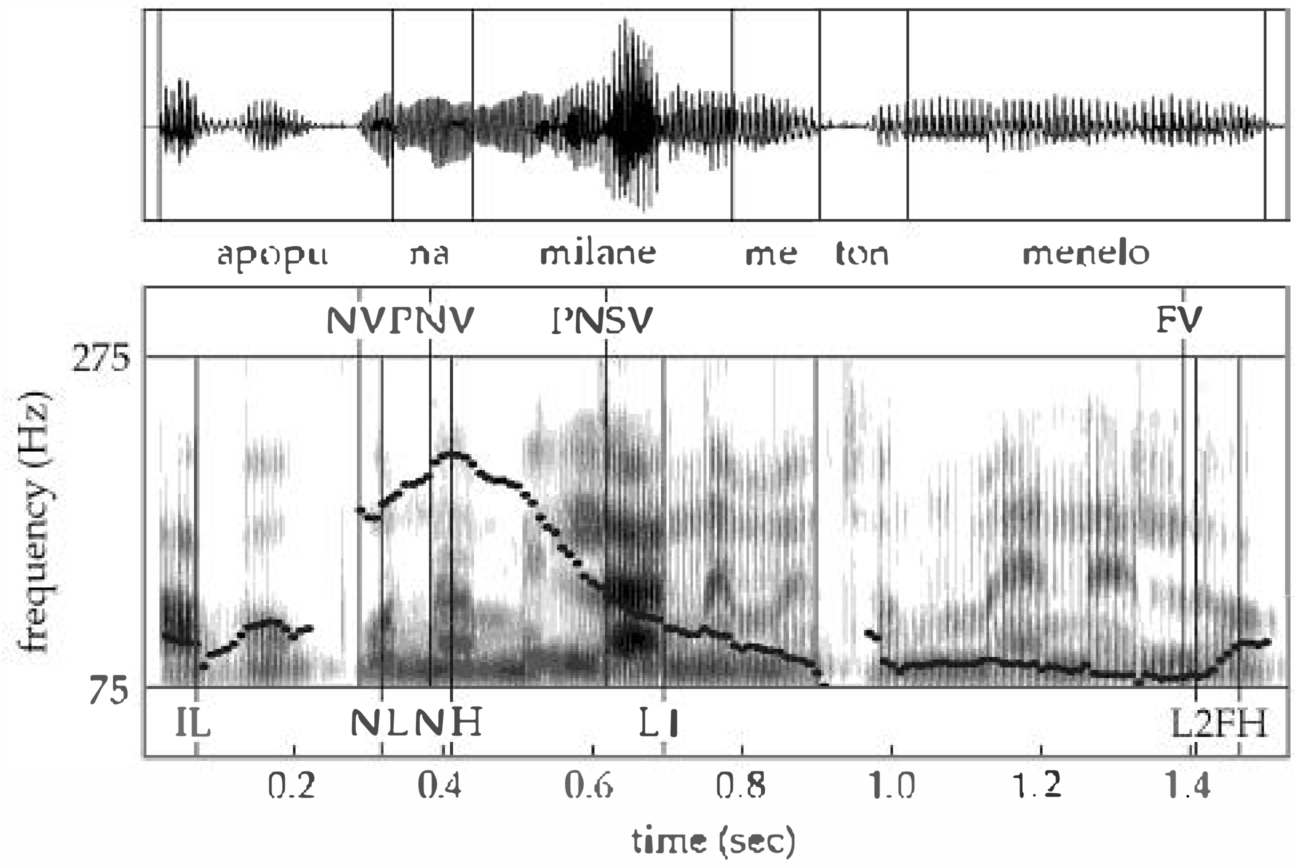

Figure 50.3 The waveform, spectrogram, and F0 contour of [apo'pu na mi'lane me ton 'menelo] 'Where could they be speaking to Menelos from?' (speaker KP), illustrating the measurements taken on the F0 contour and relevant segmental onsets. Figure reproduced from Arvaniti and Ladd (2009: 55)

undertaking a very detailed phonetic study of the Greek wh-question melody. According to their results, certain points in the Greek wh-question melody show little variability in scaling and predictable variability in alignment. A close analysis of the F0 alignment data showed that (i) the exact contour shape depended on the length of the question, and (ii) the position of the first peak and the low plateau depended on the position of the prominent anchor syllables. The study also showed predictable adjustments in alignment depending on the proximity of adjacent tonal targets. Figure 50.3 shows the F0 contour of a long wh-question. In long wh-questions, the contour starts with a rise from a low F0 point, the fall from the peak is relatively shallow, and the following low F0 stretch is long. By contrast, short wh-questions consist of a high tone associated in time with the stressed syllable of the wh-word, followed by a rapid fall to a stretch of low F0, followed by a small rise.

Arvaniti and Ladd (2009) argue that the Greek wh-question data strongly argue in favor of a *target-based model* of intonational phonology like that proposed by the autosegmental metrical framework of intonational phonology, and in particular in favor of the notion of sparse tonal specification. This is because one key assumption of the autosegmental metrical framework is that there is not necessarily any role for the syllable in modeling utterance contours. Rather, F0 targets can be temporally anchored to the segmental string in a variety of ways. This is exactly what we find in the wh-contour data in Greek, as the alignment and scaling adjustments observed in the contour are totally predictable, and depend on the length and tonal crowding manipulations in the target utterance. Arvaniti and Ladd claim that these predictable effects cannot be explained by superposition models of intonation, such as Fujisaki's (1983) command–response model, or by configuration-based models that specify F0 by superposing contour shapes for shorter and longer domains, since both of them lack the mechanisms to account for effects such as the truncation of targets or asymmetrical adjustments to the larger tonal domains. Similarly, models that specify the F0 of all syllables (like Xu and colleagues' model), and thus assume that all syllables are specified for tone, cannot account for lawful variation except by using ad hoc tonal specifications, which, in turn, do not allow for phonological generalizations about contours applying to utterances of different lengths.

6 Conclusion

In recent decades, the issue of tonal alignment has been a key focus of phonological research in intonational phonology. We now have solid evidence coming from different languages that F0 alignment differences can convey intonational contrasts, and that these alignment differences can be perceived in a near-categorical way. In this chapter, we have reviewed this work, and the use of several techniques in the investigation of tonal alignment processing (§2). As we have seen, a wide range of methodological paradigms have been applied to alignment research, including acoustic and articulatory analyses of speech productions, judgments and reaction times obtained during identification and discrimination tasks, measurements of brain activity, and eye movements.

A recent debate within the autosegmental metrical approach to intonation has been how to represent these phonological contrasts in tonal alignment. As has been reported before, this theory does an especially good job of accounting for why tone alignment differences can convey intonational contrasts. In the AM framework, the star notation encodes both phonological association of the tones with a stressed syllable and the relative alignment in bitonal pitch accents. However, though the AM representations can adequately characterize the minimal contrasts in pitch accent types found in different languages, the procedures for mapping the surface alignment of tones through the use of the star notation onto phonological representations are still somewhat unclear. This chapter has reviewed some recent proposals regarding this issue which highlight the need to further investigate the contrastive possibilities of alignment found cross-linguistically.

Apart from the phonological contrasts induced by tonal alignment, F0 tonal patterns are influenced by a variety of phonetic factors, such as prosodic crowding, speech rate, segmental composition, upcoming syllable structure, and prosodic word boundaries. In this case these fine-grained F0 alignment differences do not affect intonational meaning. This chapter has reviewed some of the production and perception studies that have informed the current phonetic models of tonal alignment. This work has highlighted principles of stability and also of adaptation to neighboring prosodic structure as basic pillars of phonetic models of tonal alignment. Importantly, some of these alignment patterns have been shown to be actively used by listeners in word identification tasks and lexical access.

Finally, tonal alignment issues have historically been used as arguments to test the predictions of phonological models of intonation and to bear upon current theories of intonational phonology. The last section of this chapter has offered a selection of the arguments put forth in favor of the target-based model of intonation. As a final note, we believe that the full exploitation of recent methodological advances will provide important answers to the role of tonal alignment in phonological and phonetic models of intonation.

ACKNOWLEDGMENTS

Preparation of this chapter was supported by two grants awarded by the Spanish Ministerio de Ciencia e Innovación: projects FFI2009-07648/FILO and CONSOLIDER-INGENIO 2010 "Bilingüismo y Neurociencia Cognitiva CSD2007-00012." I am grateful to Rafèu Sichel, two anonymous reviewers, and the editors of this volume, Colin Ewen, Beth Hume, Marc van Oostendorp, and Keren Rice, for all their help and very useful comments on an earlier version of the manuscript.

51 The Phonological Word

ANTHI REVITHIADOU

1 Introduction

In the past few decades, the field of phonology has witnessed the development of an assortment of phonological theories and their offshoots. Seminal among them is the theory of *Prosodic Phonology*, which explores how prosodic structure is built in relation to morphosyntactic structure. Prosodic Phonology employs mapping rules that aim at organizing chunks of structure (e.g. strings smaller or larger than the grammatical word) into hierarchically ordered layers of prosodic units which, in turn, form the domains within which phonological rules apply. Such *phonological domains* need not be isomorphic to morphosyntactic constituents. More importantly, the existence of a mapping mechanism entails that rules of phonology proper (i.e. rules inducing changes in the phonological shape and pattern of a string of elements) do not make direct reference to morphosyntactic constituents.[1] In general, the basic tenet of Prosodic Phonology is that phonological rules cannot see nor refer to any structure other than the units of the *Prosodic Hierarchy* (Selkirk 1978b, 1980, 1981a, 1981b, 1984, 1986, 1995; Nespor and Vogel 1982, 1986; Hayes 1989; see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE, CHAPTER 40: THE FOOT, CHAPTER 48: STRESS-TIMED *VS.* SYLLABLE-TIMED LANGUAGES, CHAPTER 54: THE SKELETON, CHAPTER 104: ROOT–AFFIX ASYMMETRIES, and CHAPTER 56: SIGN SYLLABLES for some other aspects of the Prosodic Hierarchy):

[1] In this sense, therefore, Prosodic Phonology sharply contrasts with *direct reference* approaches to the interface, most articulately expressed in the work of Kaisse (1983, 1985) and Odden (1987, 1990).

The *Phonological Word* (PW) is one of the best-established constituents of the Prosodic Hierarchy, and has received a great deal of attention. Despite its wide acceptance, certain aspects of the PW are still under debate in the literature. Part of the controversy surrounding its name pertains to the fact that the PW has broadly been established as the constituent that mediates the interface of phonology with morphology (i.e. lexical component) and syntax (i.e. post-lexical component), even though originally it was not intended to encapsulate both aspects of the interface. Moreover, it is the prosodic constituent which, roughly, corresponds to a grammatical word, and hence, naturally, cannot escape the conflicts and ambiguities associated with this notion.

This chapter, therefore, aims to address all the major issues pertaining to the PW. More specifically, I will first explore the exact nature of the mapping mechanism(s) involved in the construction of this prosodic constituent. The pivotal questions center on the ways the mapping rules operate to group a specific chunk of morphosyntactic structure into a PW and the way this is formally expressed. It will become apparent from the discussion that, despite the thirty or so years of research in this area, certain aspects of the mapping mechanism are still poorly understood. Second, I will present the methodology and, in particular, the diagnostic criteria employed by researchers in identifying the domain of the PW. This survey will provide the opportunity to investigate and, more importantly, assess the amount of knowledge that has been accumulated over the years regarding the nature of rules that identify this prosodic constituent. Third, I will review the empirical situation and, more specifically, whether cross-linguistic evidence renders the PW universally viable or not. To this end, alternative proposals – which range from the formation of extended versions of the PW to the introduction of smaller or larger reincarnations of it (e.g. the small word, etc.) – will also be reviewed. Such enriched versions of the Prosodic Hierarchy have been proposed to accommodate

[2] The CG is the most debatable prosodic constituent, and is usually not included in the Prosodic Hierarchy. It was originally introduced by Hayes (1989) and later adopted and further established by Nespor and Vogel (1986) (see also CHAPTER 84: CLITICS).

complex constructions involving function elements (e.g. particles, clitics, etc.), compounds, and complex predicates, which yield somewhat "looser" versions of the notion "word" and hence raise challenging questions for the mode in which the mapping is performed.

The remainder of this chapter is organized as follows: §2 sketches out the main advancements that led to the development of a hierarchical model of prosodic constituency, an integral part of which is the PW. §3 examines how prosodic units relate to constituents of morphosyntactic structure and the places where this mapping is performed. §4 sets out the diagnostic criteria for identifying phonological wordhood. §5 focuses on the properties of an extended version of the PW, and §6 concludes this chapter.

2 The birth of the Prosodic Hierarchy: From boundaries to prosodic domains

In the *Sound Pattern of English* (*SPE*; Chomsky and Halle 1968) two concepts of syntactic surface structure are acknowledged: (a) output of the syntactic component, and (b) input to the phonological component. Re-adjustment rules are employed to handle discrepancies between these two types of structure. Their main task is to convert the syntactic string into a form that can later be read off and interpreted by phonology. More specifically, syntactic information is encoded in phonology by rules that insert *boundary* symbols at the edges of syntactic constituents. Such boundaries are considered to be segment-like elements that lack any phonetic manifestation. Two are relevant for the discussion here: (a) the syntactic boundary, #, used to indicate edges of major syntactic categories (N, V, A, etc.), phrasal categories (e.g. NP, VP, etc.) and stress-neutral affixes (Chomsky and Halle 1968: 12, 366), and (b) the morphological boundary, +, which indicates lexically assigned morphological boundaries (Chomsky and Halle 1968: 94). Essentially, the introduction of boundaries initiates an indirect mode of interaction between the components of grammar: phonological rules can either refer to boundaries in their structural description or be blocked by them, but they can never refer directly to syntactic edges.

Much of the post-*SPE* era has been devoted to defining the exact number of boundaries and their relative strength prominence (e.g. McCawley 1968; Selkirk 1972). Gradually, however, the focus of attention shifted from linearly ordered boundary-defined domains to hierarchically organized prosodic ones.[3] Based on the seminal work of Liberman (1975) and Liberman and Prince (1977), Selkirk (1978b, 1980, 1981a) proposes that phonological representations, like syntactic ones, are hierarchical in nature. She provides compelling arguments in favor of a "suprasegmental, hierarchically arranged organization" of the utterance (Selkirk 1981a: 111). Selkirk aptly points out the "problem of nestedness": a phonological rule that applies across a "stronger" boundary can also apply across all "weaker" ones. Analogously, a phonological rule that applies before or after a certain

[3] The increasing debate against boundaries was also stimulated by their clearly diacritic character. Boundaries do not constitute linguistic objects and, as such, lack any formal existence in mental representations (see e.g. Pyle 1972; Rotenberg 1978).

boundary can do so with all stronger ones. For instance, in Sanskrit a rule of voicing affects stops in intervocalic position (Selkirk 1980: 115). Crucially, the rule applies at the domain of the Utterance and affects only consonants at # boundaries (2b), ignoring the ones residing at a + boundary (2a).

(2) a. #marut+i# → maruti
  b. #parivraṭ# #ajam# → parivraḍ ajam

In the boundary theory, the typological predictions in the domain of application of phonological rules described above are a mere stipulation. However, they come for free in a theory that assumes a hierarchically organized set of *prosodic categories*, i.e. sub-units of prosodic structure such as the syllable, the foot, the phonological word, the phonological phrase, the intonational phrase, and the utterance. This hierarchical constellation, the Prosodic Hierarchy, signals the birth of *Prosodic Phonology*. The advantage of the new theory is that the principle in (3) (Selkirk 1984; Hayes 1989) can easily capture the "nested" effect in the application of phonological rules mentioned above.

(3) *Strict Layer Hypothesis (SLH)* (Hayes 1989: 204)

The categories of the Prosodic Hierarchy may be ranked in a sequence C_1, C_2, . . . C_n, such that
a. all segmental material is directly dominated by the category C_n, and
b. for all categories C_i, $i \neq n$, C_i directly dominates all and only constituents of the category C_{i+1}.

Selkirk strengthens the argumentation in favor of prosodic constituency by showing that prosodic domains have independent motivation, besides the interface (Selkirk 1980: 110, 126–129; 1981a: 125; 1984: 8ff.). For instance, the PW in English is a category with an internal organization that yields patterns of relative (i.e. strong *vs.* weak) stress prominence, e.g. (ˌɪrɪ)$_{F_w}$ (ˈspɛktɪv)$_{F_s}$, while at the same time constituting the domain of application of various phonological rules (e.g. non-low vowels are tensed in PW-final position).

After an exploratory period (Nespor and Vogel 1982, 1983; Nespor 1985, 1986; Vogel 1985, 1986), Nespor and Vogel (1986) extended Selkirk's work and further enriched it with novel data from a wide array of languages (e.g. Hungarian, Greek, Turkish, and Italian). The focus of research in the following years was on defining the basic premises of Prosodic Phonology (e.g. the nature of the mapping algorithm, the way it is performed, etc.) and lending further support to the theory with empirical evidence from cross-linguistic research (e.g. Booij 1983, 1985a, 1985b; Booij and Rubach 1984; Hayes 1989; Itô and Mester 2003).

In the Prosodic Phonology literature, however, the main motivation for prosodic constituency is non-isomorphism, most commonly expressed as a mismatch between phonological and morphosyntactic boundaries (e.g. Selkirk 1981a; Nespor and Vogel 1982). Nespor and Vogel (1986) argue that in Hungarian, for instance, vowel harmony takes place within a stem and a string of suffixes – (4a) and (4b) – but fails to apply in strings that contain sequences of stems (4c) or a prefix plus a stem (4d) (see CHAPTER 123: HUNGARIAN VOWEL HARMONY). The reason for the disparity in the application of the process relies on the nature of the phonological domain formed by the elements involved. Vowel harmony applies within the domain of the PW, and a stem + suffix string is mapped into one PW. Significantly, compounds and prefixed constructions form two separate PWs, as shown in (4c) and (4d), despite the fact that they constitute single grammatical words.

(4) *Hungarian vowel harmony* (Nespor and Vogel 1986)

a.	*ölelés*	[ölelés]$_{PW}$	'embracement'
	hajó	[hajó]$_{PW}$	'ship'
b.	*ölelés-nek*	[ölelésnek]$_{PW}$	'embracement-DAT SG'
	hajó-nak	[hajónak]$_{PW}$	'ship-DAT SG'
c.	*Buda-Pest*	[Buda]$_{PW}$ [Pest]$_{PW}$	'Budapest'
	könyv-tar book-collection	[könyv]$_{PW}$[tar]$_{PW}$	'library'
d.	*be-utazni* in-commute	[be]$_{PW}$ [utazni]$_{PW}$	'to commute in'
	oda-menni there-go	[oda]$_{PW}$ [menni]$_{PW}$	'to go there'

The reference to prosodic constituents such as the PW allows us to describe the rule of vowel harmony in a unified way. The issue of (non-)isomorphism is central in defining and exploring the nature of phonological wordhood and is addressed in detail in subsequent sections of this chapter.

To summarize, each one of the prosodic categories in the Prosodic Hierarchy is governed by its own principles of internal constituency, and each one forms a domain for the application of phonological rules. Moreover, certain prosodic domains are introduced in order to capture the non-isomorphic character of the interface. Boundaries, on the other hand, are entities that "assist" the interface but have a strong diacritic flavor. The ensuing sections explore the mode in which a particular prosodic constituent, namely the PW, relates to constituents of the morphosyntactic structure and the place this mapping occurs.

3 The Phonological Word at the interface

The classical Prosodic Phonology theory (Selkirk 1981a, 1981b, 1984, 1986, 1995; Nespor and Vogel 1982, 1986) assumes the organization of grammar in (5). Thus, the rules that undertake the mapping of morphosyntactic structure into a PW are part of the *post-lexical* phonology. Selkirk (1984: 82) dubs this a *syntax-first* model.

(5) syntactic surface structure → mapping rules → prosodic representations → phonological rules → phonetic representations

This view, however, has been challenged by several researchers (e.g. Booij 1983, 1988; van der Hulst 1984; Inkelas 1989; Booij and Lieber 1993). Nowadays it is widely accepted that constituents up to the level of the PW are built lexically, and that phonological and morphological structure is constructed at the same time, from bottom up. This issue is addressed in detail in §3.3.

3.1 *Mapping rules under the Strict Layer Hypothesis*

Nespor and Vogel (1986) recognize that there are several options available for the definition of PW. They attribute the attested variation to an assortment of morphological notions that mapping rules can be sensitive to (e.g. stems, roots, sequences of stems, and suffixes, etc.). There are languages, like Greek for instance, in which a lexical word, i.e. the terminal element of the syntactic tree, whether a compound or simple word, is mapped into a PW. On the other hand, there are languages like Hungarian, in which mapping rules are sensitive to smaller elements such as stems, prefixes, or sequences of stems and suffixes. Finally, there are languages such as Dutch, in which certain elements (e.g. suffixes or prefixes) are endowed with a diacritic that grants them independent PW status regardless of the general dictates of the mapping mechanism. For instance, in Italian vowel-final prefixes are assigned independent PW status due to language-specific syllable well-formedness conditions, a restriction that the mapping rule must read and comply with. In Nespor and Vogel's (1986) model of mapping there is yet another source of phonological wordhood, namely the SLH in (3). The principle of proper nesting requires all "unparsed" elements to prosodify into a PW in the absence of a neighboring host. The definition of PW in (6) encapsulates the aforementioned mapping possibilities.

(6) *PW domain* (Nespor and Vogel 1986: 141)

A. The domain of PW is Q (= any terminal element of the syntactic tree).

or

B. I. The domain of PW consists of
   a. a stem;
   b. any element identified by specific phonological and /or morphological criteria;
   c. any element marked with the diacritic [+W].

II. Any unattached elements within Q form part of the adjacent PW closest to the stem; if no such PW exists, they form a PW on their own.

The above set of statements on the application of mapping rules makes some predictions. First, PWs cannot be larger than a terminal element in the syntactic tree. Second, no single stem can be mapped into more than one PW, and, third, affixes will always be part of the PW of their base unless they bear a diacritic. Interestingly, the definition in (6) encompasses diacritic information as well as special restrictions imposed by the phonological and/or morphological components of the grammar. Such a mapping algorithm, therefore, is far too powerful to be insightfully implemented in an interface theory which aspires at advancing the understanding of the factors involved in PW formation.

Selkirk (1986), based on Chen (1987), proposes an *end-based* mapping theory, which operates on the edges of X-bar constituents. The basic idea is that a prosodic constituent is demarcated by the right or the left edge of selected syntactic constituents (i.e. X^0, X', X'') (Selkirk and Shen 1990: 319):

(7) *The syntax–phonology mapping*

For each category C^n of the prosodic structure of a language there is a two-part parameter of the form

C^n: {*Right/Left*; X^m}, where X^m is a category type in the X-bar hierarchy.

It is a parametric choice of a language as to which edge of the X^0 (= word), for instance, will serve as the beginning or the end point of the PW domain. An advantage of the model is that the mapping algorithm is cross-categorical: the end rules can apply at some level of the X-bar hierarchy in order to form the appropriate prosodic domains. For instance, they apply at the X^0 to derive PWs and at the X′ or X″ to derive PPhs.

A comparison between the two algorithms reveals a significant difference in their descriptive and predictive power. The prosodic patterns established between a PW and a *morphological word* (MW)[4] by Nespor and Vogel's (1986) algorithm are given in (8). Recall that this algorithm grants independent PW status to sub-minimal elements such as function words (fnc), prefixes (prf), etc., either as a result of a diacritic or due to the SLH. Crucially, a PW can never be larger than an MW.

(8) a. PW = MW or *x* where *x* = fnc/prf
b. PW < MW
c. *PW > MW

Selkirk's (1986) end-based mapping algorithm, on the other hand, assigns a PW status to MWs but, importantly, permits a PW larger than an MW as a prosodic output. This domain can be derived when function elements are trapped in between two MWs, as shown in (9). Selkirk (1986, 1995) explicitly states that only lexical categories – not functional ones – and their projections are visible to the mapping rules. This entails, therefore, that, depending on the end rule parameter setting, the function words will prosodify together with the preceding or the following MW (= X^0). In the following abstract example, the PW will extend from the left (9b) or the right (9c) edge of one lexical item to the left or the right edge, respectively, of the next, incorporating in the process any intervening function words.

(9) a. X^0 fnc fnc X^0
b. $[X^0$ fnc fnc$]_{PW}$ $[X^0]_{PW}$ end rule: left
c. $[X^0]_{PW}$ [fnc fnc $X^0]_{PW}$ end rule: right

Importantly, the original formulation of the end-based mapping rule does not allow elements that are smaller than the MW to constitute independent PWs. As a consequence, clitics, prefixes, and suffixes are deprived of this prosodic possibility. Given the SLH, only one option is available: incorporation of the sub-minimal element into the PW of a neighboring MW. The parsing options for PWs derived by the end-based algorithm are summarized in (10):

(10) a. PW = MW
b. *PW < MW
c. PW > MW

[4] In linguistics, the notion "morphological or grammatical word" is not uncontroversial. Dixon and Aikhenvald (2002: 18ff.) provide different types of criteria to define it and also distinguish it from PW. The most important three are that the elements a grammatical word consists of must always occur together, in a fixed order, and have a conventionalized coherence and meaning.

Interestingly, the two models diverge in the cases of non-isomorphism: Nespor and Vogel's algorithm allows a PW to be smaller but not larger than an MW, whereas the end-based mapping sanctions the opposite. Furthermore, each theory makes different predictions with respect to the prosodization of sub-minimal elements. Due to the SLH, the end-based algorithm will force such elements to incorporate into an adjacent PW, whereas Nespor and Vogel's algorithm will allow them to form an independent PW. The end-based algorithm is silent regarding the prosodization of non-terminal syntactic elements such as stems, prefixes, and suffixes.

The empirical facts provide only partial support for each model. Let us start with the pattern PW < MW, predicted only by Nespor and Vogel's algorithm. In northern Italian, prefixes and the stems of compounds, but not suffixes, form separate PW-domains for the rule of intervocalic s-voicing (Nespor and Vogel 1986: 125). As evidenced by the examples in (11), this rule applies in monomorphemic and inflected words, (11a) and (11b), which constitute one PW. It is blocked, however, between a prefix and stem (11c) or between the stems of a compound (11d), suggesting that such constructions are parsed into two PWs.

(11) *Northern Italian: Intervocalic* s-*voicing*

a.	*a/s/ola*	*a*[z]*ola*	$[\text{azola}]_{PW}$	'button hole'
b.	*ca/s/-e*	*ca*[z]*e*	$[\text{caze}]_{PW}$	'house-PL'
c.	*a-/s/ociale*	*a*[s]*ociale*	$[\text{a}]_{PW}$ $[\text{sociale}]_{PW}$	'asocial'
d.	*tocca-/s/ana*	*tocca*[s]*ana*	$[\text{tocca}]_{PW}$ $[\text{sana}]_{PW}$	'cure all'

During the exploratory period of Prosodic Phonology, a growing body of cross-linguistic evidence revealed that affixes may form independent PWs (e.g. Booij and Rubach 1984 for Polish and English; Hannahs 1991, 1995a, 1995b for French; amongst many others). Cross-linguistic evidence, therefore, gives an empirical advantage to the Nespor and Vogel mapping algorithm compared to the end-based one. However, several researchers have shown that the latter can easily handle these facts if end rules are appropriately modified so that they can read off edges of elements smaller than the word, such as stems (Kang 1992), or even edges of functional categories, e.g. agreement (Rice 1993).

Furthermore, the end-based algorithm seems to have the advantage on the empirical side in cases where the PW is larger than the MW. Booij (1988) draws attention to clitic constructions from Latin and Dutch where clitics – even though they are independent grammatical words – are phonologically dependent on an adjacent word. This mapping is predicted by the end-based algorithm, but not by the Nespor and Vogel one. It is important to emphasize here that Nespor and Vogel (1986) posit a different prosodic constituent for the prosodic organization of such clitic constructions, namely the Clitic Group (CG). Within this larger constituent, however, the Nespor and Vogel mapping algorithm, under the dictates of SLH, is forced to elevate each independent element, i.e. clitic, into a PW. Below I exemplify from Greek the results of each model of mapping.

In Greek, weak object pronouns precede the non-imperative verb form (12a) but follow the imperative (12b) (Revithiadou and Spyropoulos 2008, and references cited therein).

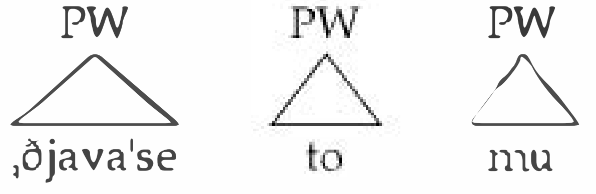
(12) *Greek object clitics*

a. o 'petr-os to 'ðjava-se
the Peter-NOM.SG CLT.3N.SG.ACC read-PST.3SG
'Peter read it.'

b. ˌðjava-'se to (< 'ðjava-se)
read-2SG.IMP CLT.3N.SG.ACC
'Read it!'

Under a Nespor and Vogel-type mapping, each clitic will be granted PW status, as shown in (13). The problem with this structure, however, is that the PW of the clitic exhibits a different behavior from that of the PW of the host element. A clitic may "trigger" stress on the final syllable of the preceding PW (14a) or carry stress itself (14b). More importantly, examples like (14a) pose a serious threat to the SLH. The addition of the clitic causes the form to be further footed so that the three-syllable restriction imposed by the language can be salvaged: (ˌðjava)('se to) mu. The problem now is that the newly formed foot cuts across two PW boundaries: [(ˌðjava)('se]$_{PW}$ [to)]$_{PW}$ [mu]$_{PW}$, in total disrespect of proper containment.[5]

(13)



(14) a. ˌðjava-'se to mu
read-2SG.IMP CLT.3N.SG.ACC CLT.1SG.GEN
'Read it to me!'

b. ˌpar-e 'mu to
take-2SG.IMP CLT.1SG.GEN CLT.3N.SG.ACC
'Take it for me!'

Furthermore, there is compelling evidence that postverbal clitics are incorporated into the PW of the verb (see footnote 5 and Revithiadou and Spyropoulos 2008 for more evidence), as correctly predicted by the end-based algorithm PW: {*Left*; X^0}. Thus, the comparison so far gives a descriptive advantage to the end-based model. A more careful examination of the facts, however, reveals that this algorithm is not unproblematic either. Given the left-end orientation of the rule, pre-verbal clitics are expected to encliticize to the preceding PW, but they do not, as shown in (15). If the clitics incorporated into the PW of the NP /o 'θoðoros/ 'the Theodore-NOM.SG', the window restriction would have forced the development of a new stress on the last syllable of the noun, yielding [o θoðo'ros tu to]$_{PW}$ 'the Theodore-NOM.SG CLT.3SG.GEN CLT.3N.SG.ACC.' Clearly, this expectation is not confirmed by the data.

[5] Nespor and Vogel (1986: 154–155) escape this problem by employing a (grid-based) *Stress Readjustment* rule. There is independent evidence, however, that clitics in Greek are footed. For instance, imperatives opt to incorporate the enclitic by deleting their final vowel, e.g. /ɣrapse ton/ (*'ɣrapston*)$_F$ 'write-IMP.2SG CLT.3M.SG.ACC'. Alternatively, the clitic may be augmented so that it can form its own foot, e.g. (*ˌɣrapse*)$_F$ (*'tone*)$_F$. Similar augmentation phenomena are independently enforced by foot well-formedness conditions, e.g. /ro'ta-n/ (with inherent accent) 'ask-3PL' *ro('tane)* ~ *ro('tan)*.

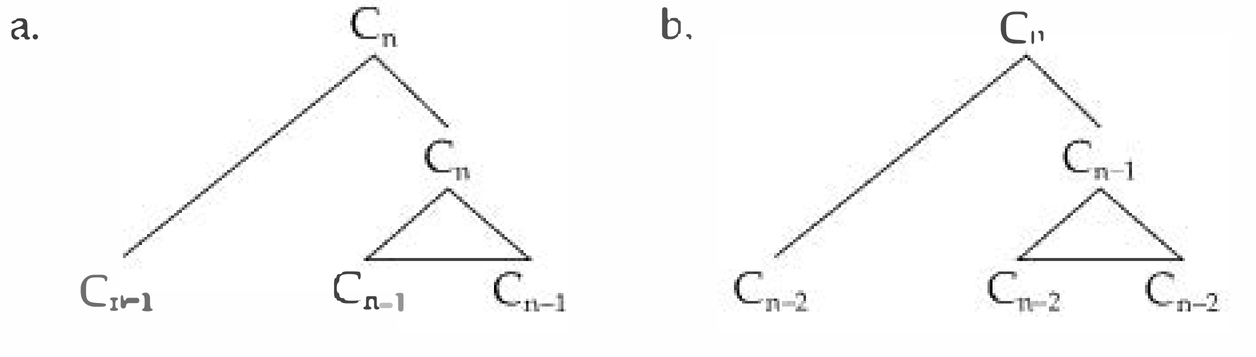
(15) o 'θoðor-os tu to ðja'vaz-i
the Theodore-NOM.SG CLT.3SG.GEN CLT.3N.SG.ACC read-3SG
'Theodore reads it to him.'

Similar cases have been found in a variety of languages, underlining, among other things, the asymmetric behavior often witnessed in the prosodic organization of constructions with function elements (e.g. particles, clitics, etc.), compounds, and other complex expressions (e.g. Inkelas 1989; Booij 1996; Leben and Ahoua 1997; Peperkamp 1997; Vigário 1999, 2003).[6] These findings therefore challenged the descriptive and explanatory efficiency of both mapping algorithms, and opened up new directions for research in this area.

3.2 *The Weak Layer Hypothesis: Mapping as constraint interaction*

A number of researchers have sought a solution to the problems mentioned above in the architecture of the Prosodic Hierarchy. In particular, they questioned the necessity of the SLH as a well-formedness principle of the arboreal prosodic structure. The proposed modifications involve the introduction of (a) *recursive* structures, in which a prosodic constituent of a certain type dominates another constituent of the same type (16a), and (b) *non-exhaustively parsed* structures, in which a constituent of one type is permitted to skip intermediate levels and dominate a constituent of more than one level lower in the Prosodic Hierarchy (16b). The relaxed version of the SLH is referred to as the *Weak Layer Hypothesis* (e.g. Booij 1988, 1995, 1996, 1999; Itô and Mester 2003).

(16) *Weak layering: Recursion and non-exhaustivity*



Under the influence of Optimality Theory (Prince and Smolensky 1993), Selkirk (1995) goes one step further and proposes that the SLH should be decomposed into its primitive components, which take the form of the *prosodic domination* constraints in (17).

(17) *Constraints on prosodic domination* (Selkirk 1995: 443)
(where C^n = some prosodic category)

a. LAYEREDNESS: No C^i dominates a C^j, $j > i$.
b. HEADEDNESS: Any C^i must dominate a C^{i-1}.
c. EXHAUSTIVITY: No C^i immediately dominates C^j, $j < i-1$.
d. NON-RECURSIVITY: No C^i dominates C^j, $j = i$.

6 The asymmetry in the prosodization of weak elements constitutes one of the main arguments against the CG as a prosodic constituent.

Layeredness and Headedness are argued to be universally inviolable and therefore undominated in the constraint ranking of all languages. The structures in (16) result from the relative ranking of Exhaustivity and Non-Recursivity to the other constraints of the system. A significant role in the construction of prosodic constituents has been played by the *alignment* family of constraints, which basically undertakes the mapping of morphosyntactic constituents to prosodic structure (McCarthy and Prince 1993a, 1993b):

(18) *Alignment constraints*

a. MW-Constraint (WCon): Align(MW, L/R; PW, L/R)
b. PW-Constraint (PCon): Align(PW, L/R; MW, L/R)

These interface constraints are translations of Selkirk's (1986) parameterized end-based theory of mapping into Optimality Theory (OT) constraint-based terminology. They have a uniform general scheme, which can easily account for cross-categorical mappings, since units from different levels of the Prosodic Hierarchy can coincide with morphosyntactic units. For instance, the constraint in (18a) requires the left or right edge of every MW to coincide with the left or right edge of some PW.

Differences in the ranking of the relevant constraints and/or the morphosyntactic structure of an input string are taken to be responsible for the attested variation in the prosodization of weak elements (e.g. function words, prefixes, etc.) cross-linguistically. The interaction of the above constraints yields the following prosodic patterns for the abstract string /*x x* V/ (where *x* is a weak element):

(19)

	structures	*typology*	*rankings*
a.	$[[\acute{x}\ x]_{PW}\ [V]_{PW}]_{PPh}$	PW	Exh, NonRec, MCon >> PCon
b.	$[x\,x\ [V]_{PW}]_{PPh}$	free	MCon, PWCon >> NonRec >> Exh
c.	$[x\ x\ [V]_{PW}]_{PW}$	recursive	Exh, MCon >> NonR, PCon
d.	$[x\,x\ V]_{PW}$	internal	Exh, NonRec >> MCon, PWCon

It remains an open question whether all predicted typologies receive empirical support or whether they lead to vast overgeneration of PW patterns. There is, however, ample cross-linguistic evidence in support of the typology of function words in (19). In a cross-dialectal study of Italian clitics, for example, Peperkamp (1997) shows that the patterns in (19b) and (19d) correspond to specific Italian dialects. Similarly, Revithiadou (2008) provides evidence from a cross-dialectal survey of object clitics in Greek that all four prosodic patterns are empirically attested. Moreover, she demonstrates on the basis of diachronic evidence that there is a transition from "looser" types of constructions – e.g. patterns (19a) and (19b) – to nested ones – pattern (19c) – and from there to total integration of the clitic to its host, pattern (19d) (see also chapter 84: clitics).

3.3 *Split between two worlds*

After discussing various approaches as to how a mapping rule assigns a PW make-up to a portion of the morphosyntactic string, I now turn to addressing where and when the mapping takes place. Such questions are of course meaningful only within a theory that assumes a division of labor between the components of grammar and a procedural view of the interface.[7]

Selkirk takes a clear stance on this issue and argues that both word structure and sentence structure are sensitive to the same mechanism, and must therefore be treated alike, i.e. after syntax at the post-lexical component (Selkirk 1984: 415). Any additional tools would simply lead to an unnecessary proliferation of the machinery phonology has at its disposal. Nespor and Vogel (1986), on the other hand, take a more moderate approach. They draw a distinction between two sets of rules: (a) those that refer to phonological domains only and (b) those that make *direct reference* to morphological information. By doing so, they implicitly adopt a compartmentalized view of phonology. First, there is a section of phonology that may access directly "morphological structure and/or specific morphological elements" (Nespor and Vogel 1986: 18). Its rules are handled by a different mechanism, possibly *Lexical Phonology* (Kiparsky 1982a, 1982b; Mohanan 1982; CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME). Second, there is another section that accesses the interface indirectly, via the constituents of the Prosodic Hierarchy, and operates strictly on Prosodic Phonology rules proper. The question as to how these blocks of rules are ordered is left open to further research (see also CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE).

Inkelas (1989) attempts to salvage the indirect nature of the interface alluded to by Nespor and Vogel (1986) with the introduction of a radical move: she eliminates the σ and the F from the Prosodic Hierarchy and introduces prosodic constituency below the PW in the Lexicon. The ranks below the PW in (1), which roughly correspond to levels in Lexical Phonology, can now accommodate strings of structure into prosodic units that are smaller than the PW. They basically provide the appropriate domain within which phonological rules can apply without having to directly refer to morphological constituents.

Booij and Rubach (1984) and Booij (1988) concur that a lexically constructed PW is necessitated on empirical grounds, e.g. the prefix *a-* in Italian; see example (11). They further argue that it can offer solutions to bracketing paradoxes, special rules of allomorphy, and so on. For instance, the word $[[un[grammatical]_A]_A ity]_N$ poses a problem, because the prefix *un-* is stress-neutral (i.e. level 2 in Lexical Phonology terminology), and hence should be added *after* the stress-shifting suffix *-ity* (i.e. level 1). This implies, however, that the prefix *un-* should attach to *grammaticality* and not to *grammatical*, which is also problematic, because *un-* attaches only to adjectival bases. At the phonological level, the suffix *-ity* shifts the stress of the base *ungrammatical*, which nevertheless contains a stress-neutral prefix. This is problematic too, because only stress-neutral suffixes can be added after that prefix (i.e. a level 1 affix may not follow a level 2 affix). This bracketing paradox receives a straightforward explanation once a prefix is assigned an independent PW status: $[un]_{PW}$ $[grammaticality]_{PW}$. Each PW constitutes an independent domain of stress assignment. As a result, the shifting property of the suffix can never interfere with the prefix, simply because the latter belongs to a different PW. Elements that impose such prosodic restrictions are often called *non-cohering*.

[7] In non-serial theories of phonology such as OT, where mapping is the job of interface constraints that operate simultaneously on both modules, such questions are almost redundant, unless one embraces the distinction between a lexical and a post-lexical component in phonology.

If this property is not derivable from the size and the segmental shape of the morpheme in question, it must be specified in the subcategorization frame of the relevant lexical item (Booij and Lieber 1993). Clitics may have similar prosodic selection requirements. For instance, *ie* 'he' in Dutch subcategorizes for a right PW boundary: $]_{PW}$ __ (Booij and Lieber 1993: 39).

However, there is a major drawback in assigning PW status to morphological elements in the lexicon: it reintroduces via the back door the problem of the PW boundary as a diacritic, thus posing a serious threat to the very nature of the Prosodic Hierarchy. Another major consequence of moving the construction of PWs into the lexicon is that the mapping now applies twice: once in the lexicon and again after syntax, i.e. post-lexically. This suggests that there are two types of PWs, lexical and post-lexical, and, consequently, the interface between phonology and morphology is of a different nature than that between phonology and syntax. If we admit this, we need to jettison the idea of a unified phonology that Prosodic Phonology – especially through the work of Selkirk – originally pursued. Yet another problem with implementing prosodic rules in the lexicon is that it blurs the division between Prosodic Phonology and Lexical Phonology (see CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME). The former theory is designed to deal with the interface of phonology and morphosyntax post-lexically; the latter relies on a procedural mode of interaction of phonology and morphology in order to account for "idiosyncratic," morphology-dependent phonological behavior. If the two models meet in the lexicon, then one may wonder which type of phenomenon each model targets and, moreover, on which grounds the division of labor is decided. Do their rules apply simultaneously or in an ordered fashion?

Even though the model of Lexical Phonology has gradually lost headway, the distinction between lexical and post-lexical PW has endured over time (Booij and Lieber 1993; see also Booij 1999 for Dutch; Nespor 1990, Vogel 1991, Peperkamp 1997 for Italian; amongst others). The lasting nature of this division emphasizes all the more the truly interface nature of PW and further establishes it as the prosodic constituent that intersects the interface of phonology with morphology and syntax. However, more work needs to be done in order to acquire a better understanding of the factors that dictate the formation of PWs, and the workspace where this is done.

4 Diagnostics for the Phonological Word as a prosodic constituent

In the previous sections, we examined ways and places within which PWs are built. Here, the focus will be on what type of phonological evidence has been put forward to substantiate the PW as an integral part of the Prosodic Hierarchy. Nespor and Vogel (1986: 58ff.) identify certain diagnostics for establishing the concept of *constituent* in phonology. Phonological rules must refer to a string of elements in their formulation and have this string as their domain of application. The same piece of structure may also serve as the domain of phonotactic restrictions and stress prominence relations. Vogel (2009) aptly remarks that in establishing a prosodic constituent a number of phenomena must cluster together in using a particular string of elements as their domain. In the almost thirty years of research on Prosodic Phonology, various diagnostic criteria have been put forward to identify the domain of the PW. In the ensuing paragraphs, we will closely examine the most important ones, at the same time drawing attention to the existence of conflicting evidence and its repercussions for the status of PW as part of Universal Grammar.

4.1 *Segmental rules*

In previous sections, we have seen that it has been proposed that both vowel harmony in Hungarian and intervocalic *s*-voicing in Italian apply within the domain of the PW. The Prosodic Phonology literature is replete with examples of segmental rules used as diagnostics for the definition of the PW domain in a variety of languages (see e.g. Hannahs 1991, 1995a, 1995b; Kang 1992; Peperkamp 1997; Kleinhenz 1998; Hall and Kleinhenz 1999; Vigário 1999, 2003). To illustrate with an example from French, Hannahs (1995a, 1995b) argues that glide formation and vowel nasalization can be safely used as diagnostics of the PW domain. For instance, underlying high vowels such as /i y/ semi-vocalize intervocalically to [j] and [ɥ], respectively. Crucially, this rule applies only in stem + suffix strings (20a) but never when the vowel in question occurs at the end of a prefix (20b) or the first element of a compound (20c) (Hannahs 1995b: 1131). The blocking of the rule in the latter environments is taken as evidence that the stem plus suffix string constitutes a different PW from the remainder of the word. This is a typical example of non-isomorphism between prosodic and morphological structure.

(20)	a.	*colonie*	[kɔlɔni]	'colony'
		colonial	[kɔlɔnjal]	'colonial'
	b.	*anti-alcoolique*	[ãtialkɔlik]	'anti-alcohol'
			*[ãtjalkɔlik]	
	c.	*tissue-éponge*	[tisyepɔ̃ʒ]	'terry-cloth'
			*[tisɥepɔ̃ʒ]	

Similarly, Vigário (2003) employs a great variety of both lexical and post-lexical rules to substantiate the existence of the PW in European Portuguese. One such rule is vowel reduction, which affects all stressless vowels of a word except for the word-initial one, e.g. *promo'ver* → *promu'ver* '(to) promote'. A more careful examination of the data nevertheless reveals that the vowel is protected even when it is not in absolute word-initial position (21b). For Vigário (1999: 272–273), this constitutes evidence for the presence of a PW boundary at the left of the base *ocu'par*. The exact prosodic structure of such prefixed formations will be discussed in §5.

(21)	a.	ocu'par	'(to) occupy'
	b.	desocu'par	'(to) not occupy'

4.2 *Stress and tone*

Stress is prototypically considered to be an infallible diagnostic for the PW domain: a PW must bear only one primary word stress (see CHAPTER 41: THE REPRESENTATION

OF WORD STRESS). In Greek, for example, the phonological wordhood of lexical words and stem–word compounds is signaled by the presence of one primary stress:

(22) a. /anθrop-os/ ['anθropos] 'man'
man-NOM.SG
b. /pali-o-maɣaz-o/ [paljo'maɣazo] 'lousy shop'
bad-LINKV-shop-NOM.SG

Dixon (2002) reports that in Jarawara, a Madi dialect of the Arawá family of southern Amazonian, primary stress is on the penultimate syllable, and rhythmic stress occurs on every other syllable to the left of the main-stressed foot (23a). Curiously, compounds and reduplicative formations display two stress peaks, which, crucially, are not on the second and the fourth mora from the end of the complex word but rather on the penultimate syllable of each of their constituents; (23b) and (23c). The attested stress patterns, therefore, suggest that the relevant formations form two PWs, e.g. ['bani]$_{PW}$ [ka'sako]$_{PW}$ (Dixon 2002: 128).

(23) a. to-'wa-ka-'tima-'maro
away-APPLIC-in.motion-upstream-FPEF 'took upstream'
b. 'bani-ka'sako / *ba'nika'sako 'wild dog species'
c. 'kete-ke'tebe / *ke'teke'tebe 'run a lot'
< ke'tebe 'run, follow'

Tonal information may also serve as a criterion for delimiting the PW boundaries (see CHAPTER 42: PITCH ACCENT SYSTEMS). Leben and Ahoua (1997) provide an instructive example from Baule, a Bia language of the central Tano group. The language has both a High and a Low tone. Interestingly, a sequence of High tones shows an upstepping pattern, which involves a gradual rise in pitch from a level phonetically close to Low to a Super-High level. The domain of the upsweep, as this rule is commonly referred to, is the PW. The examples in (24) demonstrate that the rule operates in monomorphemic words (24a) and noun–noun compounds (24b), but it is blocked in possessor–possessed (24c) and subject–predicate phrases (24d) (Leben and Ahoua 1997: 117–118). The difference between these two sets of formations is attributed to a difference in their respective prosodic constituencies. The former constitute a single PW, e.g. [bólí nɔ́nnɔ́n]$_{PW}$ (24b), whereas the latter are organized into two separate PWs, e.g. [bóli]$_{PW}$ [mángún]$_{PW}$ (24c). The proposed prosodic structures are enhanced with additional evidence from segmental processes (Leben and Ahoua 1997: 122ff.).

(24) a. Á k í s í 'Akisi'
[– – ¯]
b. b ó l í n ɔ́ n n ɔ́ n 'goat milk'
[_ – ¯ ¯]
c. b ó l í m á n g ú n 'goat's friend'
[_ ¯][_ ¯]
d. Á y á b ó l i 'Aya is a goat'
[– ¯][_ ¯]

4.3 Phonotactics and syllabification

The PW has been considered an important domain for phonotactic constraints, together with the syllable and the foot. In Dutch, for instance, the schwa as a featureless vowel cannot be preceded and followed by the same consonant; /a:lǝl/, for example, is an impossible morpheme. Across PW boundaries, however, as in compounds, such sequences are tolerated, e.g. *formu*/lǝ-l/*ijst* 'formula list' suggesting that the relevant Obligatory Contour Principle restriction is confined by the PW (Booij 1999: 56–57).

The boundaries of PWs can also be subject to certain restrictions. In German, a lax vowel constraint (i.e. *[−tense, −low, −long]) limits the distributional freedom of vowels that occur at the right edge of the PW (Hall 1999). In European Portuguese (Vigário 2003), a PW cannot begin with a flap [ɾ]. Furthermore, Sanskrit shrinks its consonant clusters at the right edge of the PW (Selkirk 1980), sharply contrasting in this respect with Dutch, which tolerates the occurrence of extra consonants and heavier rhymes in the same position (Booij 1995, 1999).

In several, but not all, languages syllabification is taken to be a reliable diagnostic for establishing the PW domain (e.g. Kang 1992 for Korean; Booij 1995, 1999 for Dutch; Hall 1999 for German; Peperkamp 1997 for Italian; Raffelsiefen 1999 for English). Kang (1992) argues that in Korean, aspirated consonants, which normally neutralize to stops in coda position, syllabify together with derivational suffixes (25a). This option, however, is not available when the relevant segment is in between the two stems of a compound (25b), suggesting that resyllabification is blocked by an intervening PW-boundary.

(25)	a.	$[[\text{kip}^h]_V\,\text{i}]_N$	$[\text{ki.p}^h\text{i}]$	*[kip.i]	$[\text{kip}^h\text{i}]_{PW}$
		deep-NML			'depth'
	b.	$[[[\text{ap}^h]_N\,[\text{ap}^h]_N\,\text{i}]_{Adv}$	$[\text{ap.a.p}^h\text{i}]$	$^*[\text{a.p}^h\text{a.p}^h\text{i}]$	$[\text{ap}]_{PW}\,[\text{ap}^h\text{i}]_{PW}$
		front front ADVS			'to each person'

4.4 Other diagnostics

Given that PWs dominate feet and feet are usually branching constituents, PWs should be minimally either bimoraic or disyllabic depending on whether they are composed of moraic or syllabic feet. Thus, foot binarity together with HEADEDNESS (17b) derive the notion *minimal word* (McCarthy and Prince 1986, 1993a, 1993b, 1998). Prosodic minimality is also enforced in morphological processes such as nickname truncations and various types of clippings (see McCarthy and Prince 1998 and references cited therein). In Greek, for instance, name truncations are minimal words (Topintzi 2003):

(26) a. *Ni'kolaos* 'nikos
b. *Poli'kseni* 'poli, 'kseni
c. *Aspa'sia* 'aspa

An often cited example in the literature for the identification of the PW is reduction under coordination (e.g. Booij 1985b for Dutch; Kleinhenz 1998 for German). For instance, Booij (1985b) demonstrates, on the basis of the examples in (27) that parts of complex words – i.e. compounds (27a) and complex formations with the so-called *non-cohering* affixes (27b) – can be cut off in coordinate constructions:

(27) a. natuur~~kunde~~ en scheikunde
'nature knowledge and analysis knowledge'
b. zicht~~baar~~ en tastbaar
'visible and tangible'

The condition is that this rule applies to trim off only parts of grammatical words which constitute separate PWs. That is, it can never eliminate an affix that is included in the PW of the stem it combines with: **rod~~ig~~ of groenig* 'reddish or greenish'. All that the rule "sees" is phonological structure, i.e. PW boundaries, and not the internal morphonological structure of words.

Language games constitute a resourceful supplier of evidence for the PW. Henderson (2002) reports on a play language called "Rabbit Talk" in Arrernte, a central Australian language. In Rabbit Talk, the first syllable of the word is removed from its original position, and transposed to the end of the PW (28a). Monosyllabic words skip the transposition rule, and the syllable /ej/ is prefixed instead (28b). For the purposes of this discussion, I follow Henderson in assuming that the syllable structure is VC(C). Rabbit Talk suggests that disyllabic case clitics constitute a separate PW. In (28c), the two elements of the construction count as separate domains: the first element is treated as a monosyllabic word and hence receives the /ej/ prefix. The clitic /-akerte/, on the other hand, constitutes a PW by itself and, as such, it is subjected to the transposition rule.

(28)		*ordinary speech*	*Rabbit Talk*
a.	ampangk+eme moan+PRES	/amp.angk.em/	/angk.em.amp/
b.	artwe man	/artw/	/ej.artw/
c.	irlpe-akerte ear-COMIT		/ej.irlp.ert.ak/

4.5 *Conflicting evidence and methodological issues in defining the Phonological Word domain*

Within the Prosodic Phonology framework, the methodology applied in establishing prosodic constituents in general and the PW in particular involves four basic steps: first, discovering the domain within which a given phonological process applies or is blocked; second, establishing that more rules have the same domain as their locus of application; third, matching the string of elements with a particular unit of the Prosodic Hierarchy; and fourth, giving the particulars of the mapping mechanism that determines which chunk of morphosyntactic structure is organized into that particular unit. A good theory should have a mapping mechanism with a certain degree of descriptive power. In practice, however, the weight of investigation falls primarily on substantiating a specific prosodic constituent on the basis of the phonological rules alone, with much less attention paid to the specifics of the morphosyntax. This proves to be quite problematic when the phonological component sends conflicting signals.

Cetnarowska (2000) reports that the distribution of secondary (rhythmic) stress in proclitic + host strings in Polish presumes the existence of a foot that straddles a PW boundary which is established on the basis of segmental evidence (Rubach and Booij 1990). In this case, the stress facts of the language conflict head on with the evidence provided by segmental rules. Likewise, Raffelsiefen (1999) argues that assimilation rules in English do not constitute a reliable criterion for establishing PW structure in English. This lack of agreement among different types of diagnostic criteria has led some researchers to propose units smaller or even larger than the PW in order to accommodate the "problematic" or "misbehaving" data. For instance, Rice (1993) acknowledges the existence of a *small word* in Slave, which is subject to certain rhymal constraints, as opposed to the PW, which is the domain of foot-based processes and various segmental rules.

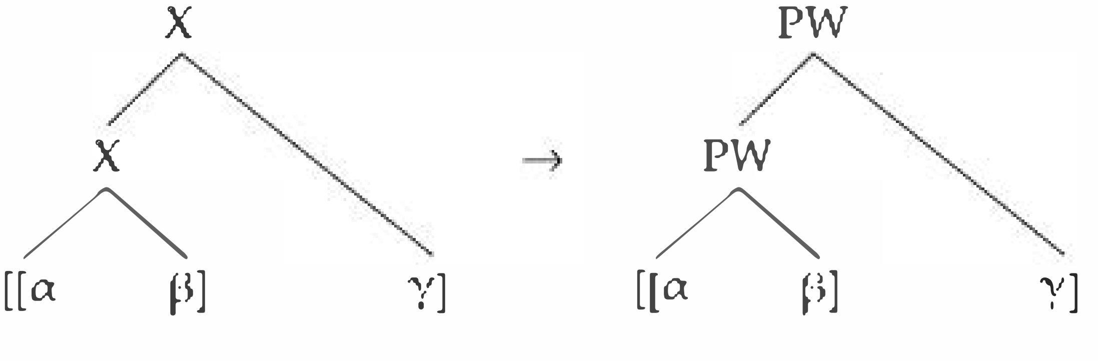
What is clear from the discussion so far is that the proponents of Prosodic Phonology have been confronted with challenging issues, and have opted for different solutions to deal with them. The first solution is to acknowledge that different types of criteria can serve as diagnostics of phonological wordhood in different languages and that each language decides on how to prioritize these criteria or even discard some of them on the basis of some sort of "scale" of relative importance. The question that naturally arises in this case is the way and the context in which this decision is made. The second solution resorts to the proliferation of prosodic domains by inserting pieces of structure with analogous prosodic behavior to distinct slots below the PW. The problem in this case is whether there is an upper bound to the proliferation of domains and, more importantly, whether these domains are universal.

There is a third approach to (partially) tackling the problem described above. Recall from §3.2 that the Weak Layering Hypothesis offers the option of constructing a recursive PW. Such an extended version of the PW has been employed to capture non-isomorphic aspects of the interface from where some (but not all) of the challenging data stem, as we will see in the following section.

5 Extending the Phonological Word

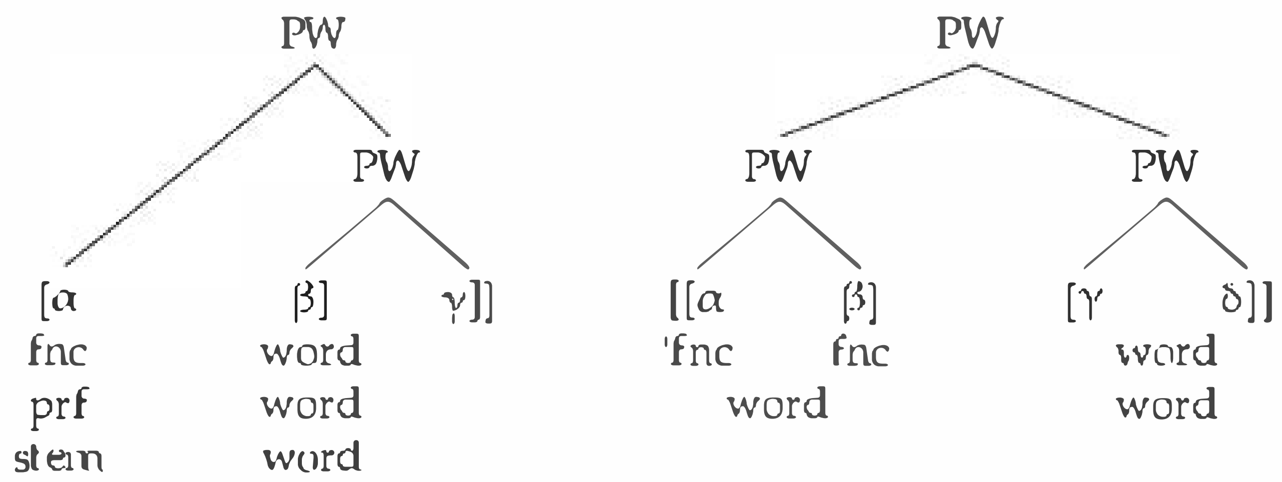
The relaxation of the SLH allowed the emergence of recursive structures. It is doubtful whether constituents lower than the PW can be recursive (Itô and Mester 2009; Kabak and Revithiadou 2009). However, recursion is commonly assumed for higher levels of the Prosodic Hierarchy, such as the PW and the PPh. Selkirk (1995), in a study on the typology of clitics, motivates PW recursion as resulting from morphosyntactic recursion. In (29), phonology "mimics" the nested structure of the morphosyntactic representation by assigning PW boundaries to the edges of constituent X (see also Kabak and Revithiadou 2009 for more examples and argumentation).

(29)



A recursive PW (PW-Rec) comes in two shapes: as a result of *adjunction* (30a) and as a *prosodic compound* (30b). The latter is typically associated with word–word compounds and sequences of function words, the first of which may be inherently stressed or stressed due to binarity.

(30) a. *adjunction* b. *prosodic compound*



In the Prosodic Phonology literature, PW recursion does not always have a morphosyntactic motivation. It is often assumed to arise either as a parsing choice of a particular language or as the result of the subcategorization requirements of individual elements (e.g. Booij and Lieber 1993 on certain Dutch clitics and prefixes). Evidence in support of recursion is primarily drawn from phonology and, specifically, the fashion in which phonological rules apply within the lower and upper PW. The main motivation for the existence of a PW-Rec is the blocking[8] or the optional application of a PW-level phonological process (e.g. Booij 1995, 1996; Peperkamp 1997; Vigário 1999, 2003). In Greek, for example, proclitics and certain prefixes are subject to the same segmental rules that typically apply within the PW (31a), such as s-voicing before a nasal or a voiced fricative:

(31)	a.	/ɣeras-'menos/	ɣera'zmenos
		old-PART	'aged'
	b.	/mas 'ðinis/	maz.'ðinis
		CLT.1PL.GEN give-2SG	'you give us'
	c.	/ðis-'mirii/	ðiz.'mirii
		twice-ten thousand-PL	'twenty thousand ones'

The fact that such sub-minimal elements are part of the extended PW and not of the PW is evidenced by the blocking of resyllabification, e.g. *ɣera.'zme.nos vs. maz.'ði.nis*, which indicates the existence of a boundary at the left edge of the word. The PW boundary prevents the proclitic/prefix from fully incorporating into the PW of its host/base, suggesting that the sub-minimal element adjoins recursively to the PW of the word: [cl/prf $[X^{\mu}]_{PW}]_{PW}$.

The recursive PW has proved to be extremely useful in accounting for attested asymmetries in the degree of cohesion that clitics, affixes, and other dependent elements show in relation to their host. For instance, in many languages enclitics incorporate to their host, whereas proclitics adjoin recursively to it (e.g. Booij 1996 for Dutch; Peperkamp 1997 for Italian; Vigário 2003 for Portuguese; Revithiadou

[8] The blocking of rule application is considered as an immediate result of adjunction. Elements of the outer layer of the PW inherit the properties of the mother constituent, but, because they are not dominated by all of its segments (Chomsky 1986), they can escape (some of) the rules (cf. Booij 1996).

and Spyropoulos 2008 for Greek). Similarly, languages may choose to incorporate suffixes but not prefixes into the PW of their base. Despite its broad use, however, the recursive PW has been called into question as a legitimate prosodic constituent mainly because it is inherently incompatible with the non-recursive nature of phonology (see e.g. Neeleman and Koot 2006; Scheer 2008; Vogel 2009).

6 Conclusions

It is clear from the discussion so far that the PW, as a constituent that lies at the heart of the interface of phonology with morphology and syntax, cannot fully escape the problems naturally associated with the complex nature of the mapping. Four key aspects of PW have been the focus of attention in this chapter: (a) the mechanism that maps a string of elements into a PW and the principles that govern it, (b) the distinction between lexical and post-lexical PW, which essentially reflects the split nature of the mapping itself, (c) the type of criteria used to motivate the PW domain, and (d) the solutions proposed to account for conflicting evidence. The discussion has revealed that all of these issues are surrounded by a number of sometimes thorny problems, and has left numerous questions open for further research. For instance, it is still undecided whether the distinction between lexical and post-lexical PW can be dispensed with or not, or whether certain types of processes are universally associated with the PW.

On the other hand, PW, as a theoretical construct, has been shown to play an important role in language acquisition (e.g. Fikkert 1994; Gerken 1994) and in language change (e.g. Lahiri 2000). Furthermore, psycholinguistic research has established a strong relation between the PW and units of production and perception (Wheeldon and Lahiri 1997, 2002), thus lending further support to the PW as a functionally useful constituent of the Prosodic Hierarchy. Future research will hopefully shed light on less clear aspects of the properties of the PW and the mode in which it is constructed and hence advance our understanding of this pivotal constituent of the Prosodic Hierarchy and, by extension, of the prosodic organization of grammatical elements.

ACKNOWLEDGMENTS

I wish to thank two anonymous reviewers, as well as the editors of the *Companion to Phonology*, especially Marc van Oostendorp and Keren Rice, for their insightful comments. All errors are of course my own.

52 Ternary Rhythm

Curt Rice

1 The facts

Most languages with iterative stress patterns show a simple rhythmic alternation between stressed and unstressed syllables (CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE; CHAPTER 41: THE REPRESENTATION OF WORD STRESS). But in a few cases, stress appears not on every second syllable, but rather on every third one. Patterns of this nature reveal the phenomenon of ternary rhythm.

Ternary rhythm is most easily seen in a language with a stress system that ignores the internal structure of syllables, i.e. a quantity-insensitive system (see CHAPTER 57: QUANTITY-SENSITIVITY). Cayuvava, now extinct, but formerly spoken in parts of Bolivia, is a language well documented in the work of Key (e.g. Key 1961, 1967). It is classified as an isolate, with no established genetic relationship to other languages. Key's fieldwork documents ternary rhythm in Cayuvava and no relevant syllable quantity. Stress in this language appears on every third syllable counting from the right edge of the word. To see the pattern schematically, consider the representations in (1). Each number represents a syllable: "0" represents a syllable with no stress, "1" represents a syllable with primary stress, and "2" represents secondary stress. The pattern is claimed to emanate from the right edge of the word and the representations here are therefore right-justified. The pattern clearly emerges from this schematic representation.

(1) *Ternary alternation patterns of Cayuvava*

a.	10
b.	100
c.	0100
d.	00100
e.	200100
f.	0200100
g.	00200100
h.	200200100
i.	0200200100

The transcribed data from the literature on Cayuvava flesh out the schematic patterns. We can see forms from Key's work in (2), which correspond to the patterns already sketched in (1).

(2) *Cayuvava*

a.	ˈda.pa	'canoe'
b.	ˈto.mo.ho	'small water container'
c.	a.ˈri.po.ro	'he already turned around'
d.	a.ri.ˈpi.ri.to	'already planted'
e.	ˌa.ri.hi.ˈhi.be.e	'I have already put the top on'
f.	ma.ˌra.ha.ha.ˈe.i.ki	'their blankets'
g.	i.ki. ˌta.pa.ra.ˈre.pe.ha	'the water is clean'

To see a more complex instance of ternary rhythm, we turn to Tripura Bangla. Das (2001) describes Tripura Bangla as a dialect of Bangla, resulting from a complicated sociolinguistic situation in the small Indian state of Tripura, where it is a commonly used lingua franca.

One complication in the pattern of Tripura Bangla when compared with Cayuvava is the relevance of syllable structure for stress assignment. Before illustrating this, we can discern the default pattern through a consideration of words consisting only of light syllables. In such strings, we find main stress on the initial syllable and secondary stress emanating rightward in a ternary rhythm. However, a final light syllable cannot bear stress. When the pattern would place stress on a final syllable – e.g. in strings of four or seven syllables – that stress is not realized. This means, for example, that a word consisting of exactly four light syllables will have only one stress, namely the main stress on the word-initial syllable.

(3) *Tripura Bangla default pattern*

a.	ˈra.za	'king'
b.	ˈgo.ra.li	'ankle'
c.	ˈnɛ.ta	'leader'
d.	ˈboi.ra.gi	'mendicant'
e.	ˈbɛ.na.ro.ʃi	'Benaras silk'
f.	ˈbi.βɛ.sɔ.na	'consideration'
g.	ˈʃɔ.ma.lɔ.ˌsɔ.na	'criticism'
h.	ˈo.nu.kɔ.ˌro.ni.jɔ	'imitable'
i.	ˈɔ.no.nu.ˌda.βo.ni.jɔ	'unintelligible'
j.	ˈɔ.no.nu. ˌkɔ.ro.ni.ˌjɔ.ta	'inimitability'

These patterns can be perturbed by closed syllables. Closed syllables can under certain circumstances tolerate stress in word-final position and they can also draw stress off from a word-initial open syllable. A simple generalization is that a stressed light syllable cannot be immediately followed by a closed syllable. When this would happen, the closed syllable bears stress instead. Further complications assign stress to the third syllable when it is heavy and to a word-final closed syllable, unless immediately preceded by a stressed syllable. Providing analyses at this level of detail is not the aspiration here, but both Das (2001) and Houghton (2006) discuss these patterns in detail. The data in (4) have closed syllables in various positions. In positions where we expect stress anyway, the patterns are as in (3). In other cases, the heavy syllable interrupts the default pattern.

(4) *Tripura Bangla quantity effects*

a.	'mal.ʃa	'big metal bowl'
b.	'ɸa.til	'earthen pot'
c.	'ʃɔr.kar	'government'
d.	ɔ.'hɔŋ.kar	'pride'
e.	'ʃɔŋ.rɔk.ˌkɔn	'reservation'
f.	o.'big.ga.ˌɸɔn	'intimation'
g.	'o.nu.ˌbik.kɔn	'microscope'
h.	'baɸ.zaiʈ.ʈa.mi	'adamancy'
i.	'ɔ.no.ˌnu.kɔ.ˌrɔn	'non-imitation'
j.	'ɸɔdʒ.dʒa.lɔ.ˌsɔ.na	'deliberation'
k.	'ʃɔŋ.rɔk.ko.ˌni.jɔ.ta	'preservability'
l.	'ɸa.rɔ.ˌdoʃ.ʃi.kɔ.ta	'expertness'

Ternary rhythm is also visible in Chugach Alutiiq, a Yup'ik language spoken by a small number of individuals in Alaska. This language is most extensively documented in a series of important works by Leer (e.g. 1985a, 1985b). These data and Leer's discussion figure prominently in the literature on ternary rhythm, including many of the theoretical works cited in the present chapter.

Quantity is also relevant for the placement of stress in Chugach Alutiiq, but unlike in Tripura Bangla, a syllable must have a long vowel to perturb the pattern. Closed syllables with short vowels – except when in word-initial position – do not attract stress. Assuming that the default stress pattern is revealed in strings with no relevant quantity distinctions, stress in Chugach appears on the second syllable and then every third syllable thereafter. A word in Chugach Alutiiq with five or six light syllables will have stress on the second and fifth. A word with four, however, will have stress on the second and fourth. Syllables with long vowels always attract stress.

(5) *Chugach Alutiiq*

a.	mu.'lu.kan	'if she takes a long time'
b.	a.'ku.ta.'mek	'*akutaq* (a food) (ABL SG)'
c.	ta.'qa.ma.lu.'ni	'apparently getting done'
d.	a.'ku.tar.tu.'nir.tuq	'he stopped eating *akutaq*'
e.	ma.'ŋar.su.qu.'ta.qu.'ni	'if he (REFL) is going to hunt a porpoise'
f.	'taa.'taa	'her father'
g.	'taa.ta.'qa	'my father'
h.	'naa.ma.ci.'quq	'it will suffice'
i.	'naa.qu.ma.'lu.ku	'apparently reading it'
j.	'naa.ma.'ci.'qua	'I will suffice'
k.	mu.'u.'kuut	'if you take a long time'
l.	u.'lu.te.ku.'ta.'raa	'he's going to watch her'

The three cases presented above are the clearest examples of ternary rhythm that have been uncovered to this point. The languages include some very long words, and even in the quantity-sensitive languages, there are words consisting of long strings of light syllables. Leer's transcriptions of those strings indicate stressed syllables that are separated by two unstressed syllables. This is the empirical basis for the claim that ternary rhythm is a real phenomenon and that a metrical theory of stress assignment must have formal tools that can generate such patterns. While the clearest cases are presented above, there are other languages which have been analyzed as having ternary rhythm, at least in some subset of the data. Most familiar among these are Ho-Chunk, Sentani, and Munster Irish.

Having established the basis for the claim that ternary rhythm is an empirical fact, we turn now to metrical theory and the major strategies that that literature offers for the analysis of these data.

2 Theory and analysis

The preceding section has established that a plausible theory of metrical structure must offer a strategy for modeling ternary rhythm. We turn now to a brief review of the emergence of this issue in the literature and the general tendencies that can be identified.

Hints about the treatment of ternary rhythm can be found very early in the development of a generative theory of stress assignment. As CHAPTER 40: THE FOOT discusses in detail, early work in generative phonology treated stress as the realization of a phonological feature [stress]. In this way, stress was analyzed with tools parallel to those used in the analysis of place of articulation – e.g. [coronal] or [dorsal] – or manner of articulation – e.g. [voice] or [continuant]; cf. Chomsky and Halle (1968) (see CHAPTER 17: DISTINCTIVE FEATURES).

A breakthrough in the study of stress systems came with Liberman's (1975) proposal that stress should be characterized not as a feature with absolute values, but rather as a relation in which two elements differ in their relative prominence. Along with this proposal came hierarchical representations and the introduction of the metrical foot into the generative literature, further developed in Liberman and Prince (1977). The foot naturally invited a more extensive theory of prosodic structure, incorporating segments into syllables, syllables into feet, and so on up the prosodic tree to the phrase or utterance; cf. Nespor and Vogel (2008) (see also CHAPTER 40: THE FOOT; CHAPTER 51: THE PHONOLOGICAL WORD; CHAPTER 84: CLITICS; CHAPTER 50: TONAL ALIGNMENT). This is the context in which any proposed modifications of metrical theory find themselves today. The first extensive typological work on stress systems is found in Hayes (1980). Hayes studies the stress systems of many languages, and identifies a number of parameters that can be used to characterize the variation shown in these languages. Parameters specify points of variation, such as the direction of foot construction, sensitivity to syllable-internal quantitative structure, trochaic or iambic headedness of the feet, whether feet are binary or unbounded, the edge of the word that hosts main stress, and whether or not peripheral material can be excluded from the initial parse through extrametricality. And, indeed, it is precisely the discussion leading up to the proposal of extrametricality that includes the earliest considerations of ternary rhythm. Before turning to the treatment of iterative ternary rhythm in metrical theory and Optimality Theory (OT), the relevance of extrametricality and its competitor are discussed. For a more thorough overview of metrical theory, see van der Hulst (1999) or Hammond (1995).

3 Extrametricality *vs.* ternary feet

Extrametricality as a theoretical tool arose in response to apparent ternary rhythm at the edges of words. The stress pattern of English nouns offers a relevant illustration. In sufficiently long words, we can see that English displays alternating, binary stress assignment, in words such as *Apalachicola, Minnesota, candelabra.* But when we examine the right edges of words more closely, we quickly find that stress is sometimes found not on one of the final two syllables, but rather on the antepenultimate syllable, as in *America, cinema, analysis.* In this way, we identify a fundamentally binary system that has a ternary component, namely a three-syllable window at the right edge of the word. A model that only constructs binary feet over an entire word would not be able to generate this pattern. Specifically, the construction of feet from right to left in English nouns would always result in penultimate stress. How can a binary foot "reach in" far enough to position primary stress on the antepenult? To model antepenultimate stress, two possible enhancements of the theory were entertained early on. One of these is extrametricality.

Extrametricality is a theoretical tool that does not explicitly entail enhancement of the inventory of feet. Instead, it provides a particular strategy for foot construction, or parsing a string of syllables. In particular, extrametricality excludes a peripheral syllable from the string to be parsed into feet. In the case of English nouns, exclusion of the final syllable, followed by construction of a binary left-headed foot, will place stress on the antepenultimate syllable. Extrametricality is also illustrated in CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY. As we will see below, some later work on iterative ternary rhythm relativizes the peripherality requirement, such that syllables can be excluded from the string not only when they are word-peripheral but also, for example, when they are foot-peripheral.

A conceptually different approach from extrametricality would be to enhance the model such that it also includes ternary feet. Data of the type described for English nouns would then be modeled by building a ternary foot at the edge, followed by the construction of binary feet iterating leftward. Since the stress that is found in the three-syllable window is the primary stress, this amounts to a proposal that primary stress can be modeled through the use of one kind of foot while secondary stress requires another. Such proposals can be found for other points of parametric variation for foot construction, as well. For example, primary stress may require the use of a quantity-sensitive foot, while iterative secondary stress seems to be quantity-insensitive (van der Hulst 1984, 1999).

One strategy for modeling an edgemost ternary domain – extrametricality – enhances the parsing strategies available in the theory, while the other strategy – a ternary foot – enhances the inventory of feet available in the theory.

4 Modeling iterative ternary rhythm

The parameters of metrical theory specify the nature of feet and control their construction across words in languages. The feet that are constructed are constituents that create a domain for the assignment of relative prominence. Prince (1983) offers an alternative approach without internal constituency, representing relative prominence instead only with a grid, and reconstruing some of Hayes's parameters such that their effects can be replicated without binary constituents (see also CHAPTER 41: THE REPRESENTATION OF WORD STRESS). The debate about constituency includes argumentation based on sensitivity of non-stress phenomena to feet, as reviewed in Kenstowicz (1993). This debate is present in much of the subsequent literature, finding one of its most extensive and significant considerations in Halle and Vergnaud (1987).

Halle and Vergnaud's constituentized grid representation integrates grids and feet. Grids are built but the gridmarks are grouped and these groupings represent constituents. The construction process implements parameter settings here, too, also in pursuit of a typology of stress systems. And it is here, in Halle and Vergnaud's opus, that we find the first discussion of iterative ternary stress presented in a major work on stress system typology.

Halle and Vergnaud of course draw on papers and presentations regarding ternarity that were floating about in the immediately preceding years, with some issues already nascent in McCarthy (1979). The discussion of iterative ternary rhythm and its implications for the typologies under consideration in the relevant literature was initiated by Levin (1985), which was ultimately published in a significantly modified form as Levin (1988). Levin's work drew on the data from Cayuvava in (2).

Halle and Vergnaud (1987) discuss neither Tripura Bangla nor Chugach Alutiiq. Regarding the latter, Leer's (1985a, 1985b) careful and important results would soon influence the details of the constituentized grid theory. Leer's work was picked up on in Rice (1988), where an analysis in the spirit of Halle and Vergnaud (1987) is advanced. This, in turn, influenced subsequent revisions of the theory, as presented in Halle (1990).

The theory developed by Halle and Vergnaud models ternary rhythm through the construction of ternary feet, extending to the problem of iterative ternary rhythm the spirit of the approach discussed above in the context of word-final three-syllable stress windows.

A competing approach also reflects that earlier debate. This competitor maintains a size limit such that feet are maximally binary. Ternary rhythm is achieved with a parsing strategy that leaves occasional syllables unincorporated into feet, extending the basic notion of extrametricality; cf. Hammond (1990) and Hayes (1995).

These two general approaches, to be illustrated presently, form the heart of the theoretical debate occasioned by ternary stress patterns. As we will see in the discussion of ternary rhythm and OT below, the debate persists there, too. We turn now to the chronologically first approach, namely an analysis of ternary rhythm using ternary feet.

5 Ternary feet

5.1 Amphibrachs

At first glance, the Cayuvava stress patterns in (1) and (2) suggest an analysis with dactylic feet (strong–weak–weak), built from right to left. If we maintain a parametric strategy for constructing feet, then the independently established presence in the theory of a parameter placing heads at the left or right edge of the foot means that the admission of dactyls to the inventory of derivable feet would imply the introduction of anapests (weak–weak–strong) as well. Allowing a ternary foot with its head at the left edge implies via the relevant parameter the possibility of constructing a ternary foot with its head at the right edge. With Cayuvava as the only known case of iterative ternary rhythm at the time of this theoretical work, generating dactyls would lead to the phenomenon of overgeneration, i.e. being able with the tools of the theory to generate patterns not known to exist.

In pursuit of a restrictive theory, Levin (1988) therefore takes a different tack, relaxing metrical theory just enough to allow for exactly one type of ternary foot, instead of two; dactyls and anapests are disallowed, but the theory now permits amphibrachs, i.e. ternary feet with prominence on the middle syllable, employing a strategy described below. When combined with final extrametricality – which can be overridden when necessary to build at least one foot on the (minimal) disyllabic words – the construction of amphibrachs will yield a footing of the schematic patterns in (1) that correctly locates stress, as seen in (6). Parentheses indicate feet and angled brackets mark extrametricality. In longer words, initial lone syllables are left unfooted, by stipulation.

(6) *Ternary alternations parsed into amphibrachs*

a.	(10)
b.	(10)⟨0⟩
c.	(010)⟨0⟩
d.	0(010)⟨0⟩
e.	(20)(010)⟨0⟩
f.	(020)(010)⟨0⟩
g.	0(020)(010)⟨0⟩
h.	(20)(020)(010)⟨0⟩
i.	(020)(020)(010)⟨0⟩

Halle and Vergnaud (1987) adopt Levin's strategy, and also limit Universal Grammar (UG) to this one type of ternary foot. They parameterize the requirement that the head of a constituent be at its edge. When this parameter is set such that the head is not required to be at the edge of a constituent, the only ternary foot that can emerge is an amphibrach; cf. Rice (1988, 1990) for related discussion. The approach developed by Levin and widely discussed in publications by Halle and Vergnaud effectively views iterative ternary rhythm as evidence for expanding the inventory of feet. Constituents may have one head, but as many as two non-heads. For them, there is no hierarchical structure within the foot, so that this approach generates flat ternary feet.

Another main thrust of the literature also sees a proposal with ternary feet, but now with internal hierarchical structure. Early proponents of this include Dresher and Lahiri (1991) and Rice (1992), building on Rice (1990). Leer's (1985b) article offers the leading idea, namely identifying the quantitative equivalence of two light syllables with a single heavy syllable, allowing either of those configurations to be the head of a foot. Taking into account a non-head consisting of a light syllable, a foot might consist of three light syllables, two of which are themselves a subconstituent. Hence, ternary feet become an option.

In the foot typology of Hayes (1980), some languages were identified in which the heads of feet must be heavy, a foot type dubbed the obligatory branching foot.

Rice (1992) in particular draws a parallel between Hayes's obligatory branching feet and the analysis of ternarity under consideration, since the head consisting of one heavy syllable or two light ones could be construed as obligatory branching. That analysis is also relevant to the contrast between (6e) and (6d): in the former case, two word-initial syllables concluding the right-to-left parse are sufficient for a foot, while the single syllable in the latter case is not. The analysis in Rice (1992) suggests that degenerate feet must have a head, and in the case of the ternary feet constructed for Cayuvava, two lights are required to constitute a head, hence the minimal foot (and word) is binary. In the approach with flat ternary feet, it is unclear why a minimum of two syllables is necessary for a degenerate foot. Additional discussion related to this approach can be found in Everett (1988), Hewitt (1992), Rice (1993), Blevins and Harrison (1999), van der Hulst (1999), Rifkin (2003), and other references mentioned below.

5.2 *Weak local parsing*

The appearance of iterative ternary stress patterns in the literature on metrical phonology triggered, as noted above, a second strategy. Instead of increasing the set of possible feet, this second strategy increased the set of possible parsing strategies. This approach is developed in Hayes (1995), drawing on earlier work by Hammond (1990). In Hayes's approach, universal grammar allows only three kinds of feet, as in (7) (see also CHAPTER 44: THE IAMBIC–TROCHAIC LAW).

(7) *The Hayesian foot typology*

a.	Syllabic trochee	(x	.)		
		σ	σ		
b.	Moraic trochee	(x	.)		(x)
		L	L	*or*	H
c.	Iamb	(.	x)		(x)
		L	σ	*or*	H

No exhaustive parsing of a string with any of these feet will give an iterative ternary pattern. But non-exhaustive parsing can do that. Hayes proposes that UG include a weak local parsing parameter that creates the possibility of leaving an unparsed syllable between each foot. The unparsed syllable can by stipulation only be a light one. Having an unparsed light syllable between each foot yields a ternary pattern using only binary feet, as in (8).

(8) *Ternary alternations parsed into non-exhaustive binary feet*

a. (10)
b. (10)(0)
c. 0(10)(0)
d. 00(10)(0)
e. (20)0(10)(0)
f. 0(20)0(10)(0)
g. 00(20)0(10)(0)
h. (20)0(20)0(10)(0)
i. 0(20)0(20)0(10)(0)

For the Cayuvava pattern, trochees are constructed from right to left; whether they are moraic or syllabic trochees is irrelevant, since there is no quantity distinction in this language. The parsing also uses final extrametricality and, of course, weak local parsing. The final syllable in (8c) is extrametrical and the initial syllable is unfooted, because it is too little to be a foot, since no degenerate feet are allowed. In (8d) the influence of weak local parsing is seen; in this form, there is in fact sufficient material at the left edge of the word to form a foot. Since doing so would result in adjacent feet – which is not allowed with weak local parsing – no foot can be formed. Not until we have six syllables, as in (8e), is there sufficient space to build two non-adjacent – i.e. weakly local parsed – feet. A detail beyond the scope of this chapter is that adjacency can be tolerated in the case of adjacent heavy syllables – as in Chugach – suggesting that the requirement to incorporate heavy syllables into feet has priority over the prohibition on adjacent feet under weak local parsing.

5.3 *Summary*

At the level of analysis, we have seen that there are two primary strategies for constructing constituents across strings when the goal is to achieve iterative ternary alternations. One strategy is to expand the inventory of constituents, and here there are also two approaches. In the approach developed by Levin (1988) and Halle and Vergnaud (1987), flat ternary feet are allowed. Any non-head in a foot must be adjacent to its head. This allows exactly one kind of ternary foot, namely an amphibrach, where the head is not found at the edge of the foot, but rather is flanked by two non-heads. The second inventory-expanding approach, as seen primarily in Dresher and Lahiri (1991) and Rice (1992), relaxes the requirement that the head of a foot can span only one syllable. Feet that require heavy heads can draw their material either from one heavy syllable or from two light ones.

The alternative to expanding the foot inventory is expanding the strategies available for constructing binary feet, and the primary representative of this approach is Hayes (1995). In this approach, binary feet are constructed in a new way. There are two necessary properties to the weak local parsing of a string: feet must be non-adjacent and they must be minimally non-adjacent. These requirements lead to iterative construction of feet that are separated by one light syllable.

There was, as noted, an early debate in the metrical literature regarding the need for constituency; perhaps stress systems can be modeled simply with a theory of prominence as represented with a grid, and feet are superfluous. This debate has not shown itself in the context of ternary rhythm, insofar as the literature lacks a grid-only analysis of iterative ternary rhythm.

6 Ternary rhythm in Optimality Theory

The typological enterprise in generative grammar has enjoyed enhanced prominence in the era of OT (McCarthy and Prince 1993; Prince and Smolensky 1993). One of the core foci in the OT literature is typology (Archangeli and Langendoen 1997; Roca 1997; Kager 1999). Classic OT achieves typological insights by having a universally fixed set of constraints. Variation is modeled with constraint reranking. The factorial typology of constraint rankings defines the range of possible grammars.

Stress patterns and metrical theory have played an important role in the construction and exploration of optimality-theoretic approaches to modeling grammar. Indeed, one of the important early discussions of the power of violable constraints was built around the pursuit of a parallelist strategy for achieving the effects of directionality. The insight in this discussion is that minimal violation of a requirement that all feet be at one edge of the word (ALLFT-L or ALLFT-R), when combined with the force of a requirement that all syllables be parsed into feet (PARSE-σ), will yield as optimal a parse identical with serial foot construction from one edge of a string to the other.

Less present in the OT literature, however, has been discussion of ternary rhythm. There has been almost no debate about the contrast between analyses using ternary feet and those using non-exhaustive parsing with binary feet. Indeed, Rice (2007) is to the best of my knowledge the only publication in which the issue is even mentioned, although Hyde (2002) also offers relevant perspectives on the nature of ternary parsing.

The most prominent discussions of ternary rhythm in OT mimic the weak local parsing approach, as in Ishii (1996) and Elenbaas and Kager (1999). Elenbaas and Kager take an important principled position on methodology. In particular, they articulate and adopt the goal of deriving iterative ternary rhythm with tools that are already necessary to account for other phenomena. This laudable position of theirs contrasts with the too frequent practice in OT analyses of positing new constraints to give new analyses. That practice has substantial implications, in light of the methodology of the factorial typology noted above; introducing a new constraint introduces many new grammars, and the restricted typological enterprise as construed in classic OT is substantially challenged with every new constraint that is introduced.

The analysis of ternary rhythm in OT based on underparsing has two crucial components. First, PARSE-σ – which requires that syllables be incorporated into feet – must be relatively low-ranked. This will be important in allowing optimization of an incomplete parse along the lines seen in (8). But simply ranking PARSE below a requirement that all feet align with the right edge of the word will yield a parse with only one foot. Note that ALLFT-R awards a violation for every syllable intervening between the right edge of a foot and the right edge of the word, for each foot.

(9) *Underparsing with low-ranked* PARSE

σσσσσσ	ALLFT-R	PARSE
a. ('σσ)('σσ)('σσ)	*!*****	
b. σ('σσ)σ('σσ)	*!**	**
☞ c. σσσσ('σσ)		****

This brings us to the second crucial component. To counter the pressure of ALLFT-R, parsing of at least some of the other syllables must be rewarded. The solution offered builds on well-established insights that lapses in long parses should be avoided; cf. Selkirk (1984). There are various *LAPSE constraints in the literature (e.g. Kager 1994; Green 1995; Gordon 2002), where the leading idea is that a string of more than two unstressed syllables is disfavored. With *LAPSE ranked above ALLFT-R, the optimal parse will show only as much parsing as is necessary to minimize violations of *LAPSE, and will favor options in which the feet are relatively toward the right.

(10) *Ternary rhythm with* *LAPSE

σσσσσσ	*LAPSE	ALLFT-R	PARSE
a. ('σσ)(σ'σ)(σ'σ)		****!**	
b. (σ'σ)σ(σ'σ)σ		****!*	**
☞ c. σ(σ'σ)σ(σ'σ)		***	**
d. σσ(σ'σ)(σ'σ)	*!	**	**

The OT analysis of ternary stress requires consideration of many more details and much more discussion, which is to be found in the cited works. For present purposes, it is sufficient to note that an analysis akin to Hayes's weak local parsing strategy is achieved through the interaction of *LAPSE and ALLFT-R. Although the methodology of pursuing an analysis built simply on the reranking of independently motivated constraints is commendable, that goal has not yet been achieved. For example, careful study reveals that multiple versions of *LAPSE will be necessary, one of which is specifically designed for the ternary cases; this is made laudably explicit in Houghton (2006). While the use of ternary-specific tools is not an a priori flaw of these analyses, it nonetheless keeps them from clearing the high bar set in pursuit of an analysis by pure reranking of constraints that are not ternary-specific.

In addition to facilitating an illustration of the strategy that has been most thoroughly pursued in providing an analysis of ternary rhythm within OT, the patterns under consideration here raise another important methodological point. Future work in OT that considers the relative merits of the two main types of analyses illustrated above – ternary feet or underparsing – must consider related issues about the division of labor among the modules of the theory. Consider, for example, the possibility that a particular analysis intends to optimize a parse that does not use flat ternary feet, or amphibrachs. How will such feet and their optimization be avoided?

If it is possible that prosodic structure is present in inputs – a possibility required by the richness of the base methodology – then amphibrachs are possibly present in inputs. One way in which these can be prevented from being selected as optimal is with a constraint that rules them out. Introducing an anti-amphibrach constraint, however, implicitly raises the possibility that it could be ranked relatively low, which in turn could open the door to the optimization of such structures. If one's position is that amphibrachs are never optimal, then it is unfortunate to achieve this universal exclusion with a constraint. The alternative is to provide structure to Gen, such that the output of Gen cannot include amphibrachs. The tension between these possibilities is the focus of Rice (2007), and it is one of the general theoretical issues raised in OT by the study of ternary rhythm.

7 Implications and directions for future research

As noted earlier, one strategy for modeling an edgemost ternary domain – extrametricality – enhances the parsing strategies available in the theory, while the other strategy – a ternary foot – enhances the inventory of feet available in the theory. On what basis can a theoretician select the model to be pursued? Are these two options really different from one another in some meaningful sense? Does one approach allow for the description of some kind of situation that the other one does not?

If the approaches do not make different predictions, are there other strategies available for selecting among them? One possibility would be to appeal to general principles of theory construction or to findings in other realms of cognitive science. Such principles or findings may have implications for selecting among competing theories of phonology.

To see one example of argumentation for selecting among competing theories, we can turn to Hayes's (1980) argumentation for extrametricality over ternary feet. This argument is based primarily on identifying differences in the types of systems the competing theories predict. In the cited work, Hayes compares his foot inventory at that point with a proposal made by Morris Halle, attributed to "class notes" (Hayes 1980: 114ff.). Halle had introduced ternary feet into his version of the theory, while Hayes had developed the approach using extrametricality.

Hayes begins his argument against Halle's inventory by stating the following: "I know of no languages whose stress patterns could simply be described using feet of the [ternary] form" (Hayes 1980: 115). This quotation suggests that a gap in the typology – namely the absence of languages with iterative ternary rhythm – can be used as an argument against a theory that could in fact model that.

At the conclusion of the section, we are again encouraged to adopt an inventory with binary feet and peripheral extrametricality, in part because it provides "an explanation for why feet which have [ternary] surface forms . . . are never assigned iteratively" (Hayes 1980: 122).

This example from the early literature on ternary rhythm illustrates an argument based on overgeneration. The theories are evaluated, and the one that generates a pattern not known to exist is dispreferred on those grounds. Gaps in the typology become a criterion for theory selection. However, as we now know from the sections above, this gap was soon revealed to be accidental.

This is not the only example in the generative literature of argumentation based on gaps in the empirical record. We might use this occasion to ask whether such experiences are relevant as we hone our methodology for identifying the properties of UG. The following paragraphs present some of the broader implications that may be explored on the basis of our discussion of ternary rhythm.

The typological enterprise as widely practiced in generative phonology aspires to model grammatical variation through simple formal manipulations of various components of the theory: reranking of constraints, different rules or rule orders, or the setting of parameters to different values.

Generative linguists often see themselves as doing work grounded in a reliable typology of the structures found in natural languages. Our goal – cf. Odden (forthcoming) – is to identify the limits of the human linguistic capacity and to model that knowledge. What is a possible grammar, and what is not? What cognitive structures must be posited to restrict the outcome of the language acquisition process to possible grammars, thereby rendering unattainable the impossible ones? And regarding the case at hand, what does the fact of ternary rhythm force us to posit in our theory?

These questions are sometimes studied from "above." Researchers could take as their starting point a theory of cognitive capacity and build a model of linguistic knowledge within the context of that theory. Demonstrated incompatibility of a conceivable linguistic structure with a known fact about our cognitive system would be an argument for genuine universal ungrammaticality: cf. Odden (2008) and Reiss (2008).

Alternatively, one could develop a theory from "below." In this case, one would approach the matter through a deep study of one language or one family of languages, or through a carefully selected set of unrelated languages. Regardless of the starting point one adopts, any predictive model of linguistic knowledge will be held accountable to facts about natural languages.

We work to enhance the empirical foundation for developing theories of grammars by studying individual languages. The very act of documenting, describing, and analyzing the multifarious properties and subsystems that are found in natural language entails engagement in a typological enterprise; cf. Newmeyer (2005) and Hyman (2009). A model of linguistic knowledge that allows the construction of a particular grammar gains credibility *vis à vis* its competitors when a specific language is identified that requires precisely that grammar.

We might call this the *positive typological enterprise*: certain structures are attested in the set of well-studied natural languages, and any theory of grammar must sanction the generation of such structures.

But there is also a *negative typological enterprise*. Work on this side of the program aspires to model the absence of unattested structures. If we imagine competing models of linguistic knowledge, all of which satisfy the positive side of the enterprise insofar as all of them generate those structures that are known to exist, then we need some criterion for choosing among them. Proposed models of linguistic knowledge are therefore routinely criticized from the negative side, i.e. for allowing the construction of a grammar that is not known to be instantiated by any natural language; this is the state of overgeneration, of which we saw an example above.

A model that overgenerates is in principle inferior to one that does not. A model that completely fails to overgenerate matches the systems that it cannot generate with those that are unattested.

While this seems at first glance to be an important goal, the danger we must guard against when attempting to eliminate aspects of a theory that overgenerates is the equation of *unattested* with *impossible*. How can we know whether a structure that is absent from the empirical database is merely unattested – as was the case with iterative ternary rhythm – or genuinely beyond the grasp of UG?

Finding an answer to this question seems insurmountably forbidding when we realize that distinguishing the merely unattested from the cognitively impossible would be no easier if all languages were thoroughly documented, studied, and analyzed. Those activities, of course, may fill gaps in our knowledge, and they will certainly generate a richer base for our research enterprise, thereby contributing to a deeper understanding of our cognitive capacity. But even if all languages were deeply understood, any linguist would still be able to posit conceivable albeit unattested structures, and all theories that overgenerate would make this challenge easy. Such conceivable but unattested structures can be assumed to be universally ungrammatical only if we assume that all possible structures in fact do appear somewhere in the set of human languages. This assumption, alas, is no more plausible than an assumption that all possible structures for eyes, for example, are attested somewhere in the animal kingdom.

This realization presents a significant confrontation to the bottom-up approach to linguistic theory construction. Building theories on the basis of what is attested and unattested tends to confuse *does not exist* with *cannot exist*. The work of linguists is not to explain linguistic structures that do exist, but rather to explain linguistic structures that can exist. While the starting point may be the empirical record, that cannot be the ending point. The empirical record does not and cannot show us the limits of human linguistic capacity. The empirical record cannot reveal what is necessarily beyond the realm of our grammatical competence; cf. Isac and Reiss (2008).

8 Conclusions

Although it is not the purpose of this chapter to go deeply into methodological issues, it is essential nonetheless to highlight the importance of doing so. The study of ternary rhythm and the history of analyses of this phenomenon in the generative literature raise issues of the kind presented here. The remaining challenge is to take these discussions further, not only in this context, but whenever we enter into discussions arguing for the selection of one theoretical model over another.

There is more work to be done in metrical theory and on ternary rhythm. This must address several issues, both in the context of a specific analysis and with respect to the theory with which that analysis is built. Naturally, any analysis has to satisfy the positive typological enterprise by allowing the generation of those patterns that are attested. An analysis must take a position on the kind of constituents that are constructed. Are they binary or ternary?

If there are ternary feet, i.e. feet with three terminals, is there any internal structure to those constituents, or are they flat ternary structures? If there are not ternary feet, how are binary feet constructed with iterative non-exhaustivity, i.e. periodic non-parsing as with the earlier theory of weak local parsing? What is the fate of those syllables that are left unparsed? How are they incorporated into the prosodic structure of the word, and what implications does this have for a theory of layering in prosodic structure (Selkirk 1984)?

Beyond the basic matter of developing an analysis, future work on this topic should also address the role of typological evidence in the theory being offered, specifically the extent to which patterns absent from the empirical record are considered to be not merely unattested but unattestable. In this way, the typological enterprise will remain an important topic of discussion, and the languages showing ternary rhythm will play their significant role in future refinements of metrical theory and the methodologies of research in generative linguistics.[1]

[1] Works relevant to the study of ternary rhythm that have not been mentioned in this article, but which students of this topic should consult, include the following: Crowhurst (1992); Idsardi (1992); Kager (1993); Green and Kenstowicz (1995); Rowicka (1996); van de Vijver (1998); Elenbaas (1999); Hyde (2001); Gordon (2002); McCartney (2003); Karttunen (2006); Buckley (2009).

ACKNOWLEDGMENTS

For feedback on an early draft of this chapter, I thank Sylvia Blaho, Peter Jurgec, Bruce Morén-Duolljá, Dave Odden, Charles Reiss, Bridget Samuels, and two anonymous reviewers. I also thank Sylvia Blaho for extensive support during the editing process. I am indebted to phonologists too many to name, with whom I have had fruitful discussions about metrical theory and ternarity over the years. Some of the perspectives advanced here owe an intellectual debt to Hale and Reiss (2008), which is hereby gratefully acknowledged.

53 Syllable Contact

Misun Seo

1 Introduction

Syllable contact is a notion introduced to describe the sonority relation between adjacent segments across a syllable boundary, that is, between heterosyllabic coda and onset segments. According to Hooper (1976), Murray and Vennemann (1983), and Vennemann (1988), among others, there is a cross-linguistic preference to avoid rising sonority across a syllable boundary; this tendency is formulated as the Syllable Contact Law (SCL). This law states, for example, that *al.ta*, with falling sonority, is preferred to *at.la*, with rising sonority. This law has been adduced to account for both diachronic and synchronic sound alternations in coda–onset clusters.

In this chapter, I will review the notion of syllable contact by referring to sound alternations involving coda–onset clusters observed in different languages. The chapter is organized as follows. In §2, I offer an overview of sonority and sonority scales on which the SCL is crucially based. In addition, I review previous proposals on syllable contact and different types of diachronic and synchronic phonological changes analyzed as repair strategies for bad syllable contact. In §3, I present the issues and debates on syllable contact such as the necessity of syllable contact, the categorical *vs.* gradient nature of syllable contact, language-specific variation, and problems of syllable contact (see also CHAPTER 49: SONORITY).

2 Syllable contact

The notion of syllable contact is essentially based on the relative sonority of segments. Thus, in §2.1, I first review sonority and then the SCL. In §2.2, I provide examples of different types of diachronic and synchronic phonological changes which have been analyzed using the notion of syllable contact.

2.1 *Sonority and the Syllable Contact Law*

The SCL is based on the concept that speech sounds can be classified into different categories according to their relative sonority. There have been many proposals for the definition of sonority. For example, Ladefoged (1982) defines sonority as the loudness of a sound relative to that of other sounds with the same length, stress, and pitch, and Clements (1990) defines it in terms of a set of major class features. In Venneman (1988), sonority is described as an inverse restatement of strength, which is based on "degree of deviation from unimpeded (voiced) air flow." In addition, Parker (2002, 2008) claims that sonority has a phonetic basis in intensity measured as "sound level differences in decibels between a target segment and a constant reference segment in the environment."

There exist many competing sonority scales, obtained on the basis of different definitions of the sonority. Different sonority scales result from the controversial relative sonority of laterals and rhotics, voiced and voiceless obstruents, stops, fricatives, and affricates, and high, mid, and low vowels. However, it is generally agreed among most researchers that the uncontroversial sonority hierarchy is as follows (Bell and Hooper 1978; Harris 1983; van der Hulst 1984; Clements 1987, 1990; Kenstowicz 1994; Smolensky 1995; Holt 1997; van Oostendorp 1999):

(1) *Sonority hierarchy*

more sonorous
↑ vowels
glides
liquids
nasals
↓ obstruents
less sonorous

For extensive discussion of sonority and sonority scales, see CHAPTER 49: SONORITY.

With reference to the relative sonority of segments, Hooper (1976) proposes a constraint on heterosyllabic coda-onset clusters. According to the principle, the sonority of a coda consonant must exceed that of a following onset consonant. Murray and Vennemann (1983) and Vennemann (1988) extend the principle as follows:

(2) *Syllable Contact Law* (Vennemann 1988: 40)

A syllable contact A.B is the more preferred, the less the consonantal strength of the offset A and the greater the consonantal strength of the onset B.

The SCL can be rephrased as in (3), using the concept of sonority, which is the reverse of strength and more commonly used in current phonology.

(3) *Syllable Contact Law (sonority version)* (Davis and Shin 1999: 286)

A syllable contact A.B is the more preferred, the greater the sonority of the offset A and the less the sonority of the onset B.

The SCL has also been invoked as a family of related OT constraints (Bat-El 1996; Davis 1998; Ham 1998; Davis and Shin 1999; Rose 2000; Baertsch 2002; Gouskova 2004; Holt 2004; Zec 2007).

2.2 *Phonological change as optimization of syllable contact*

2.2.1 *Diachronic change*

The notion of syllable contact has been employed in motivating various diachronic changes attested in coda–onset sequences (see also CHAPTER 93: SOUND CHANGE). For example, Hooper (1976) claims that various phonological processes have applied to the /nr/ sequence diachronically in different Spanish dialects to remedy the sequence violating the SCL, as illustrated below:

(4) *venirá* > *venrá* > *vendrá*	(by stop insertion)	'(it) will come'
verná	(by metathesis)	
verrá	(by assimilation)	

In the example above, after the occurrence of syncope, the resulting form *venrá* is unacceptable since the onset /r/ in the /nr/ sequence is more sonorous than the coda /n/, thus violating the SCL. Therefore, phonological processes such as stop insertion, metathesis, and assimilation apply in different Spanish dialects to improve the less preferred heterosyllabic /nr/ sequence.

Stop insertion also applied to various heterosyllabic consonant–liquid clusters in Old Spanish and Old French, as shown below.

(5) a. *Stop insertion in Old Spanish* (Martínez-Gil 2003)

Latin	Old Spanish	
fem(i)na	*(f)embra*	'female'
hum(e)ru	*hombro*	'shoulder'
trem(u)lare	*temblar*	'to shake, shiver'
ingen(e)rare	*engendrar*	'to engender, beget'
mel(io)rare	*me(l)drar*	'to grow'

b. *Stop insertion in Old French* (Walker 1978; Morin 1980; Wetzels 1985; Picard 1987; Martínez-Gil 2003)

Latin			Old French	
cam(e)ra	(> *chamre*)	>	*chambre*	'room'
sim(u)lare	(> *semler*)	>	*sembler*	'to resemble'
ten(e)ru	(> *tenre*)	>	*tendre*	'tender'
mol(e)re	(> *molre*)	>	*molder*	'to grind'
laz(a)ru	(> *lazre*)	>	*la(z)dre*	'beggar'
ess(e)re	(> *esre*)	>	*estre*	'to be'
spin(u)la	(> *espinle*)	>	*espingle*	'pin'

According to Martínez-Gil (2003), all the heterosyllabic consonant–liquid clusters in the examples above violate the SCL by showing more sonorous onsets than codas, and thus the stop is inserted within the clusters as a strategy to improve bad syllable contact.

Holt (2004) analyzes the metathesis observed in the heterosyllabic /dn/ and /dl/ sequences of Old Spanish as a repair strategy to optimize syllable contact. In Old Spanish, the heterosyllabic /dn/ and /dl/ sequences brought about by syncope in Late Spoken Latin or by morpheme concatenation underwent many repair strategies, such as dissimilation, palatalization, stop insertion, deletion, and strengthening, e.g. *antenatu* (Latin) > *adnado* ~ *andado* ~ *andrado* ~ *alnado* ~ *anado* ~ *annado* (Old Spanish) 'stepchild'. The examples in (6) illustrate that metathesis is optional in Old Spanish forms, while only metathesized forms occur in Modern Spanish.

(6) a. /dn/

Latin	Old Spanish	Modern Spanish	
CAT(E)NATU	*cadnado* ~ *candado*	*candado*	'padlock'
ANTENATU	*adnado* ~ *andado*	*andado*	'stepchild'
LEGITIMU	*lidmo* ~ *lindo*	*lindo*	'pretty'
RETINA	*riedna* ~ *rienda*	*rienda*	'rein'

b. /dl/

Latin	Old Spanish	Modern Spanish	
SPATULA	*espadla* ~ *espalda*	*espalda*	'back'
CAPITULU	*cabidlo* ~ *cabildo*	*cabildo*	'town council'
FOLIATILE	*hojalde* ~ *hojaldre*	*hojaldre*	'puff pastry'
TITULO	*tidle* ~ *tilde*	*tilde*	'written accent'

According to Holt, metathesis applied to /dn/ and /dl/ in Old Spanish, since the sequences have rising sonority over a syllable boundary and thus show bad syllable contact. (See also CHAPTER 59: METATHESIS for a discussion of synchronic metathesis processes in response to phonotactic requirements more generally.)

In addition, West Germanic word-medial gemination after a short vowel and before *j, *r, and *l has been analyzed by Murray and Vennemann (1983) as being driven by the need to avoid an onset which is more sonorous than the coda.

(7) *Gemination in West Germanic*
(Murray and Vennemann 1983; Braune and Eggers 1987; Ham 1998)[1]

	East Germanic	West Germanic	
a.	Go. *skapjan*	OS *skeppian*, OE *scieppan*	'to create'
	Go. *bidjan*	OS *biddian*, OE *biddan*	'to ask for'
	Go. *hafjan*	OHG *heffan*, OE *hebban*	'to lift'
	ON *framja*	OHG *fremmen*, OE *fremman*	'to carry out (a task)'
	Go. *halja*	OHG *hella*, OS *hellia*	'hell'
b.	ON *bitr*	OHG *bittar* (<**bittr*)	'bitter'
	Go. *akrs*	OHG *ackar*, OS *akkar* (<**akr*)	'field'
	VL *facla*	OHG *faccala* (<**faccla*)	'torch'
	ON *epli*	OE *æppel*, OS *appel* (<**appl*)	'apple'

According to Murray and Vennemann, Proto-Germanic had stem-initial accent, suggesting that the Proto-Germanic forms of the examples in (7) were syllabified as *VC.jV, *VC.rV, and *VC.lV in order to maintain a heavy stressed syllable. Murray

[1] Go. = Gothic; OS = Old Saxon; OE = Old English; OHG = Old High German; ON = Old Norse; VL = Vulgar Latin.

and Vennemann argue that West Germanic gemination was triggered by the SCL; that is, by gemination, coda–onset sequences with rising sonority across a syllable boundary (i.e. VC.jV, VC.rV, and VC.lV) were improved to ones with a sonority plateau (i.e. VC.CjV, VC.CrV, and VC.ClV). Ham (1998) also motivates gemination before *r and *l in West Germanic by appeal to the concept of syllable contact, arguing that gemination before *j resulted from the well-attested Germanic avoidance of *j in onset-initial position.

2.2.2 *Synchronic change*

Syllable contact has also been considered as a factor motivating different types of synchronic sound alternations, such as assimilation, metathesis, glide formation, and epenthesis in heterosyllabic coda–onset clusters. For example, Rice and Avery (1991), Rice (1992), Iverson and Sohn (1994), and Davis and Shin (1999) view the assimilation observed in Korean nasal + liquid sequences as being due to the SCL. In Korean, two types of assimilation processes are attested when a liquid is preceded by a nasal. When /n/ is followed by a liquid, the nasal assimilates to the following liquid, resulting in [ll], as the examples in (8a) illustrate. On the other hand, when a liquid is preceded by a non-coronal nasal /m/ or /ŋ/, the liquid assimilates to the previous nasal segment in nasality and thus the /ml/ and /ŋl/ sequences are realized as [mn] and [ŋn], respectively, as shown in (8b).

(8) a. *Assimilation in /nl/*

/non+li/	[nolli]	'logic'
/han+ljaŋ/	[halljaŋ]	'limit'
/cʰɔn+li/	[cʰəlli]	'natural law'

b. *Assimilation in /ml/ and /ŋl/*

/sam+lju/	[samnju]	'third rate'
/tam+ljək/	[tamnjək]	'courage'
/jəŋ+li/	[jəŋni]	'profit'
/saŋ+lju/	[saŋnju]	'the upper stream'

According to Iverson and Sohn (1994) and Davis and Shin (1999), the two types of sonorant assimilations occur in a nasal + liquid sequence in Korean because the sequence is unacceptable due to violating the SCL.

Bradley (2007) analyzes obstruent–nasal metathesis in Sidamo as occurring in order to avoid bad syllable contact.

(9) *Obstruent–nasal metathesis in Sidamo* (Hudson 1975, 1995; Hume 1999)

/hab+nemmo/	[hambemmo]	'we forget'
/gud+nonni/	[gundonni]	'they finished'
/it+noommo/	[intoommo]	'we have eaten'
/has+nemmo/	[hansemmo]	'we look for'
/duk+nanni/	[duŋkanni]	'they carry'
/ag+no/	[aŋgo]	'let's drink'

As can be seen from the examples in (9), a stem-final obstruent metathesizes with a following suffix-initial /n/ in Sidamo and then the nasal assimilates regressively in place. According to Bradley, metathesis applies to obstruent–nasal clusters with rising sonority to produce nasal–obstruent clusters, which do not violate the SCL.[2]

In addition, Bradley (2007) accounts for the metathesis of /nr/ clusters in irregular future and conditional forms of Judeo-Spanish verbs by employing the concept of syllable contact.

(10) *Metathesis of /nr/ in Judeo-Spanish*
(Lamouche 1907; Baruch 1930; Bradley 2007)

terné	'I will have'	cf. tener	'to have'
verné	'I will come'	cf. venire	'to come'

Glide formation in German is also motivated by the SCL. According to Hall (2007), [i] and [j] are in complementary distribution in German and /i/ is realized as [j] when occurring to the left of a vowel as in *labial* [la'bjaːl] 'labial'. In /VCCiV/ sequences, glide formation applies if the two consonants show a sonority fall, as in (11a), while it does not apply if the two consonants show a sonority rise, as in (11b).

(11) a. *Glide formation*

liquid + obstruent	*Skorpion*	[skɔʀpjoːn]	'scorpion'
	Celsius	[tsɛlzjus]	'celsius'
nasal + obstruent	*Indien*	[ɪndjən]	'India'
liquid + nasal	*Kalifornien*	[kalifɔʀnjən]	'California'
	Fermium	[fɛʀmjom]	'fermium'

b. *No glide formation*

obstruent + liquid	*Atrium*	[aːtʀium]	'atrium'
	Bibliothek	[biblioteːk]	'library'
obstruent + nasal	*Hafnium*	[hafniom]	'hafnium'

The notion of syllable contact has also been employed in explaining vowel epenthesis patterns in loanwords. When CVC languages borrow loanwords with complex onsets, a vowel is inserted and, according to Gouskova (2001), the position of the inserted vowel is determined in consideration of syllable contact.

(12) *Epenthesis patterns in loanwords* (Gouskova 2001)

a. *Falling or flat sonority: Edge epenthesis*

		gloss/source
Hindi	ɪskul	'school'
	isfɪər	'sphere'
Bengali	iʃkul	'school'
Central Pahari	ispiitʃ	'speech'
Sinhalese	istri	Sanskrit stri 'woman'
Wolof	estati	'statue'
Uyghur	istatistika	Russian statistika 'statistics'

[2] Hume (1999) accounts for obstruent–nasal metathesis in Sidamo in terms of the perceptibility of the two consonants involved. According to her, metathesis in Sidamo occurs because having distinctive place in both nasals and unreleased stops in pre-consonantal position is perceptually disfavored.

b. *Rising sonority: Internal epenthesis*

		gloss/source
Hindi	fɪrut	'fruit'
	pəfaizər	'Pfizer'
Bengali	gelaʃ	'glass'
Central Pahari	silet	'slate'
Sinhalese	tijage	Sanskrit tjage 'gift'
Wolof	kalas	'class'
Uyghur	kulub	Russian klub 'club'

As shown in (12a), a vowel is inserted before the onset consonants with falling or flat sonority, since the resulting coda–onset clusters do not violate the SCL. However, as illustrated in (12b), a vowel is inserted between the two consonants of the onset with rising sonority to avoid the coda-onset clusters violating the SCL.

According to Rose (2000), syllable contact plays a role in determining the position of an epenthetic vowel in Chaha (see CHAPTER 67: VOWEL EPENTHESIS). For example, when [i] is epenthesized in /VCCCV/ for structural reasons, either [VCCɨCV] or [VCɨCCV] can surface with the aim of achieving good syllable contact. Thus, /t-n-k'rət'm-nə/ 'while we are cutting' surfaces as [tink'irət'imnə], since the alternative form *[tɨnɨk'rət'ɨmnə] has the coda–onset cluster [k'.r], with bad syllable contact. On the other hand, /t-n-msəkr-nə/ 'while we are testifying' is realized as [tinimsəkinnə] rather than *[tinmɨsəkinnə], with a coda-onset cluster with flat sonority, which is avoided in the language.

In addition, epenthesis in Picard clitics (Auger 2003) is said to be influenced by the preference for achieving good syllable contact, and Pons (2005) argues that regressive manner assimilation, rhotacism, gliding, onset strengthening, epenthesis, and deletion attested in Romance languages are strategies triggered to avoid bad syllable contact.

3 Issues and debates on syllable contact

3.1 *Sonority Dispersion Principle and the Syllable Contact Law*

As seen in §2.2, the notion of syllable contact has been employed in motivating different types of diachronic and synchronic sound changes. However, there have been debates regarding whether or not it is necessary to posit a separate law just for coda-onset sequences. Clements (1990) claims that the Sonority Dispersion Principle makes the SCL dispensable. According to the Sonority Dispersion Principle, sonority rise is required to be maximal from the onset to the nucleus and sonority drop is required to be minimal from the nucleus to the coda. Thus, for example, the principle says that [ta] is more preferred than [la] as the onset and [al] is more preferred than [at] as the coda. From the Sonority Dispersion Principle, it can be predicted that maximal sonority drop is preferred across syllable boundaries, as stated in the SCL. Thus, Clements proposes that the SCL follows from the more general Sonority Dispersion Principle.

However, based on the data from Kazakh in (13), Davis (1998) and Gouskova (2004) argue that the SCL cannot be reduced to the Sonority Dispersion Principle.

(13) *Syllable contact in Kazakh* (Davis 1998)

a. *No onset desonorization*

/alma-lar/	[al.ma.lar]	'apples'
/mandaj-lar/	[man.daj.lar]	'foreheads'
/kijar-lar/	[kijar.lar]	'cucumbers'
/kol-ma/	[kol.ma]	'hand-INTERROG'
/kijar-ma/	[ki.jar.ma]	'cucumber-INTERROG'

b. *Onset desonorization*

/kol-lar/	[kol.dar]	'hands'
/murin-lar/	[mu.rin.dar]	'noses'
/koŋɯz-lar/	[ko.ŋɯz.dar]	'bugs'
/murin-ma/	[mu.rin.ba]	'nose-INTERROG'
/koŋɯz-ma/	[ko.ŋɯz.ba]	'bug-INTERROG'

In Kazakh, consonants of any sonority can be onsets if they are preceded by vowels or by consonants of higher sonority. Thus, no onset desonorization is attested in the examples of (13a). However, when the onset is preceded by a consonant with lower or the same sonority, it desonorizes, as shown in (13b). Therefore, to explain the sound alternations of onsets in the Kazakh examples, it is essential to refer to the sonority relation of the coda and the following onset. For this reason, both Davis and Gouskova claim that the Sonority Dispersion Principle cannot completely replace the SCL.

3.2 Nature of syllable contact: Categorical vs. gradient

Since Hooper (1976), the SCL has been extended to account for more cross-linguistic data, and the nature of syllable contact is now viewed as gradient rather than categorical (see CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). Hooper (1976) originally proposed the SCL for Spanish, where the sonority of a syllable-final consonant must exceed that of a following syllable-initial consonant. According to this, the syllable contact is categorical in nature. Different types of coda–onset clusters are equally fine as long as the sonority of the coda exceeds that of the onset. Thus, although the sonority distance between the coda and the onset is greater in *al.ta* than in *al.na*, both are equally fine clusters with respect to syllable contact since the coda is more sonorous than the onset. Likewise, both *at.la* and *an.la* are equally non-optimal since the coda is less sonorous than the onset.

Murray and Vennemann (1983) and Vennemann (1988) propose an extended version of the SCL whose nature is gradient: two adjacent heterosyllabic segments are more preferred, the greater the sonority of the first segment and the less the sonority of the second segment. Clements (1990) paraphrases the extended SCL as follows:

(14) *The extended Syllable Contact Law* (Clements 1990: 319)

The preference for a syllabic structure A.B, where A and B are segments and *a* and *b* are the sonority values of A and B respectively, increases with the value of *a* minus *b*.

Davis and Shin's (1999) version of the SCL in (3) is also a gradient one. In the gradient view of the syllable contact phenomenon, coda-onset clusters with falling sonority are not considered to exhibit the same degree of optimality. In addition, not all violations of the SCL by clusters with rising sonority are considered equally serious. Depending on the relative sonority distance between the coda and the onset, one cluster is more optimal or less non-optimal than the others. For example, *al.ta* is more optimal than *al.na*, since the sonority distance between the coda and onset is greater in *al.ta* than in *al.na*. In addition, a sequence such as *at.la* constitutes a more severe violation of the law than a sequence such as *an.la*.

In line with this, Clements (1990) provides the following aggregate complexity score of each of the coda–onset sequences by summing the complexity values of each of the demisyllables (nucleus-coda and onset–nucleus sequences) that constitute it.

(15)

C1 \ C2	obstruent	nasal	liquid	glide
obstruent	5	6	7	8
nasal	4	5	6	7
liquid	3	4	5	6
glide	2	3	4	5

According to Clements (1990), obstruent–glide sequences such as *at.wa* violate the SCL most seriously and glide–obstruent sequences such as *aw.ta* satisfy the law most faithfully.

A more fine-grained syllable contact scale is proposed by Gouskova (2004), based on Jespersen's (1904) sonority scale.

(16) a. *Sonority scale* (Jespersen 1904)
glides > rhotics > laterals > nasals > voiced fricatives > voiced stops > voiceless fricatives > voiceless stops
(abbreviated as: w > r > l > n > z > d > s > t)

b. *Syllable contact scale* (Gouskova 2004)
more harmonic ←——————→ less harmonic

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
w.t	w.s	w.d	w.z	w.n	w.l	w.r	w.w	r.w	l.w	n.w	z.w	d.w	s.w	t.w
	r.t	r.s	r.d	r.z	r.n	r.l	r.r	l.r	n.r	z.r	d.r	s.r	t.r	
		l.t	l.s	l.d	l.z	l.n	l.l	n.l	z.l	d.l	s.l	t.l		
			n.t	n.s	n.d	n.z	n.n	z.n	d.n	s.n	t.n			
				z.t	z.s	z.d	z.z	d.z	s.z	t.z				
					d.t	d.s	d.d	s.d	t.d					
						s.t	s.s	t.s						
							t.t							
–7	–6	–5	–4	–3	–2	–1	0	+1	+2	+3	+4	+5	+6	+7

←—— drop ——————— flat ——————— rise ——→

In Gouskova's syllable contact scale in (16b), glide + voiceless stop clusters (represented as *w.t*), for example, are characterized as sequences with a sonority drop of –7, since the sonority of the voiceless stop is lower than that of the glide by seven steps according to Jespersen's sonority scale in (16a). As can be seen in (16b), Gouskova proposes that the syllable contact scale has 15 strata, with glide + voiceless stop sequences (represented as *w.t*) on stratum 1 the most harmonic, and voiceless stop + glide sequences (represented as *t.w*) on stratum 15 the least harmonic.

Clements and Gouskova employ different sonority hierarchies, and thus propose different gradient versions of the sonority contact scale. Gouskova's more fine-grained syllable contact scale can account for the different patterning of /ll/ and /rl/ in Kazakh, while this is not possible within Clements' syllable contact scale. According to Davis (1998), coda-onset sequences with flat or rising sonority undergo desonorization in Kazakh in order to improve syllable contact, as in /murin-lar/ → [murindar] 'noses'. On the other hand, no desonorization applies to coda-onset sequences with falling sonority, as can be seen from /mandaj-ga/ → [mandajga] 'forehead + DIRECT'. In the case of /ll/ with flat sonority, desonorization applies, as in /kol-lar/ → [kol.dar] 'hands', while /rl/ surfaces as [rl], as in /kijar-lar/ → [kijarlar] 'cucumbers'. The different phonological patterning of /ll/ and /rl/ in Kazakh suggests that /r/ is more sonorous than /l/, and that /rl/ is the sequence with falling sonority, as in Gouskova's syllable contact scale. Note that Clements' syllable contact scale cannot account for the different patterning of /ll/ and /rl/ in Kazakh, since /r/ is assumed to be as sonorous as /l/.

The gradient nature of syllable contact makes it possible to explain language-specific patterns of the syllable contact phenomenon. According to Gouskova (2004), languages differ in the level of complexity they tolerate, and thus language-specific patterns of syllable contact are attested. For example, Kirghiz and Kazakh require sonority to drop from the coda to the onset but the two languages are different in the thresholds of acceptable sonority drop. In Kazakh, sonority is merely required to drop from the coda to the onset and need not be maximal. Thus, as can be seen in (13b), onset desonorization applies to coda–onset sequences with flat or rising sonority, but not to coda–onset sequences with falling sonority, as in (13a). On the other hand, as can be seen from the examples in (17), sonority drop alone is not sufficient in Kirghiz, which requires maximal sonority drop.

(17) *Syllable contact in Kirghiz*
(Hebert and Poppe 1964; Kasymova *et al.* 1991; Gouskova 2004)

/konok-lar/	+5	konok.tar	0	'guest (PL)'
/taʃ-lar/	+4	taʃ.tar	−1	'stone (PL)'
/konok-nu/	+4	konok.tu	0	'guest (OBJ)'
/taʃ-nu/	+3	taʃ.tɯ	−1	'stone (OBJ)'
/atan-lar/	+1	atan.dar	−2	'gelded camel (PL)'
/rol-lar/	0	rol.dar	−3	'role (PL)'
/atan-nu/	0	atan.dɯ	−2	'gelded camel (OBJ)'
/kar-lar/	−1	kar.dar	−4	'snow (PL)'
/rol-nu/	−1	rol.du	−3	'role (OBJ)'
/aj-lar/	−2	aj.dar	−5	'moon (PL)'
/aj-nu/	−3	aj.dɯ	−5	'moon (OBJ)'
/kar-du/	−4	kar.dɯ	−4	'snow (OBJ)'
/too-lar/	—	too.lar	—	'mountain (PL)'
/too-nu/	—	too.nu	—	'mountain (OBJ)'

As can be seen from the examples above, desonorization in Kirghiz applies to suffix-initial sonorants after any consonant, in order for sonority to drop maximally from the coda to the onset. Note that the Kazakh and Kirghiz data above cannot be explained properly within the categorical version of the SCL, which predicts that all coda-onset clusters with falling sonority are equally acceptable.

3.3 *Syllable contact as a language-specific constraint on minimal sonority distance*

With respect to syllable contact phenomena, language-specific variations can be observed. First, some languages respecting the SCL allow coda-onset clusters with flat sonority while others disallow them. For example, as shown in (8), Korean prohibits coda-onset clusters with rising sonority. However, a coda can be as sonorous as a following onset, as can be seen from /sallim/ → [sallim] 'housekeeping', /simmun/ → [simmun] 'interrogation', etc. On the other hand, as shown in (13), coda–onset clusters with flat sonority as well as rising sonority are not sanctioned in Kazakh. Thus, /kol-lar/ is realized as [kol.dar] 'hands', to improve syllable contact.

Such syllable contact variation of coda–onset sequences with equal sonority has been accounted for by positing two versions of the SCL.

(18) a. *Syllable Contact Law (strict)* (Rose 2000: 401)
The first segment of the onset of a syllable must be lower in sonority than the last segment in the immediately preceding syllable.

b. *Syllable Contact Law (loose)* (Bat-El 1996; Davis and Shin 1999)
The first segment of the onset of a syllable must not be of greater sonority than the last segment of the immediately preceding syllable.

Coda–onset sequences of equal sonority are not allowed within the SCL in (18a), while they are permitted within the loose version of the SCL in (18b).

Syllable contact variations that cannot be explained by the two versions of the SCL are also found. The SCL has generally been employed to constrain coda–onset clusters with rising sonority. However, languages which allow only falling sonority from a coda to a following onset can vary with respect to minimal sonority distance. According to Gouskova (2004), both Kirghiz and Sidamo allow coda–onset sequences with falling sonority, forbidding sequences with flat or rising sonority. However, the thresholds of acceptable sonority drop are different in the two languages. As can be seen from the examples in (17), minimal sonority drop required in Kirghiz is −4, and coda–onset sequences with sonority drop of less than −4 undergo phonological change of desonorization to remedy bad syllable contact. Thus, desonorization applies to /aj-nu/ 'moon (OBJ)', which is realized as [aj.dɯ], with a sonority drop of −3. On the other hand, /kar-du/ 'snow (OBJ)', with a sonority drop of −4, is not targeted by any phonological process in order to remedy bad syllable contact, and surfaces as [kar.dɯ]. In the case of Sidamo, unlike Kirghiz, the acceptable minimal sonority drop is −2.

(19) *Syllable contact in Sidamo* (Moreno 1940; Gouskova 2004)

a. *Sonority rises: Metathesis*

/duk-nanni/	+4	duŋ.kanni	−4	'they carry'
/huʧ-nanni/	+4	hun.ʧanni	−4	'they pray/beg/request'
/has-nemmo/	+3	han.seemo	−3	'we look for'
/hab-nemmo/	+2	ham.bemmo	−2	'we forget'

b. *Sonority drops less than −2 or is flat: Gemination*

/af-tinonni/	−1	affinonni	—	'you (PL) have seen'
/lelliʃ-toti/	−1	lelliʃʃoti	—	'don't show!'
/ful-nemmo/	−1	fullemmo	—	'we go out'
/um-nommo/	[illegible]	ummommo	—	'we have dug'

c. *Sonority drops more than −2: Place assimilation only*

/mar-toti/	−5	mar.toti	−5	'don't go'
/ful-te/	−5	ful.te	−5	'your having gone out'
/qaram-tino/	−4	qaran.tino	−4	'she worried'

In Sidamo, coda-onset clusters with rising sonority are repaired by metathesis, as in (19a), and the clusters with flat sonority or sonority drop of less than −2 are modified by gemination, as in (19b). On the other hand, when coda–onset sequences have a sonority drop of −2 or above, no modification applies to improve syllable contact, although the sequences undergo place assimilation, as in (19c).

In addition, different languages can permit different degrees of minimal sonority rise, which cannot be explained within the SCL in (18). For example, Faroese and Icelandic set different acceptable sonority distances between a coda and a following onset. According to Gouskova (2004), Faroese permits a sonority rise of +4 or below, as illustrated in (20).

(20) *Syllable contact in Faroese* (Gouskova 2004)

a. *Sonority rise of 5 points or more: Complex onsets*

aː.ʰkvamarɪn	+7	'beryl'
vɛaː.ʰkrɪr	+6	'beautiful (MASC PL)'
aiː.ʰtrantɪ	+6	'poisonous'
d̥ɛaː.ʰprɪr	+6	'sad'
miː.ʰkhr	+5	'great (MASC PL)'
eː.ʰplɪ	+5	'potato'

b. *Sonority rise of fewer than 5 points: Heterosyllabic coda–onset clusters*

sɪg̊.rɪ	+4	'further south'
b̥aʰt.na	+4	'to improve'
ɪd̥.la	+3	'or'
vɛs.na	+3	'to worsen'
ʝar.na	+2	'gladly'
rɔʰk.tɪ	0	'smoked (SG)'
vɛs.tur	−1	'west'
hɛn.d̥ur	−2	'hands'
ʝœr.d̥ɪ	−4	'did (SG)'
nod̥.d̥ɪ	—	'approached (SG)'

In Faroese, where initial syllables are always stressed and heavy, syllable contact plays a crucial role in syllabification. As can be seen in (20a), when two intervocalic consonants show a sonority rise of +5 or more, the two consonants are syllabified into a complex onset and the preceding vowel is long. On the other hand, when two intervocalic consonants exhibit a sonority rise of +4 or less, the two consonants are syllabified as heterosyllabic and the preceding vowel is short, as in (20b). Thus, the examples in (20) show that the maximal sonority rise from a coda to a following onset permitted in Faroese is +4 or less.

In Icelandic, unlike Faroese, the acceptable sonority distance between a coda and a following onset is +5 or less.

(21) *Syllable contact in Icelandic* (Gouskova 2004)

a. *Sonority rise of 6 points or more: Complex onsets*

vɪː.t⁽ʰ⁾ja	+7	'to visit'	skɔː.p⁽ʰ⁾ra	+6	'to roll'
vœː.k⁽ʰ⁾va	+7	'to water'	tvɪː.svar	+6	'twice'
aː.k⁽ʰ⁾rar	+6	'fields'	ɛː.sja	+6	'the mountain Esja'
tʰɪː.t⁽ʰ⁾ra	+6	'to vibrate'			

b. *Sonority rise of fewer than 6 points: Heterosyllabic coda–onset clusters*

ɛʰp.lɪ	+5	'apple'	tʰɛm.ja	+3	'to domesticate'
ɛʰk.la	+5	'lack'	vɛl.ja	+2	'to choose'
ăɪʰt.la	+5	'to intend'	vɛr.ja	+1	'to defend'
b̥ɪð.ra	+4	'to ask'	tʰɛv.ja	0	'to delay'
stœð.va	+4	'to stop'	hɛs.tʏr	−1	'horse'
hăiɣ.rɪ	+3	'right'	ɛv.rɪ	−1	'upper'
b̥lað.ra	+3	'balloon'	av.laɣa	−2	'to bend out of shape'
sɪg̊.la	+3	'to sail'	d̥vɛr.g̊ʏr	−4	'dwarf'
vɪs.na	+3	'to wither'			

As can be seen from the examples in (21a), two consonants with a sonority rise of +6 or more are syllabified as a complex onset and the preceding vowel is lengthened to make the first stressed syllable heavy. On the other hand, when two consonants show a sonority rise of +5 or less, as in (21b), they are syllabified as heterosyllabic, and the preceding vowel is realized as a short vowel since the first stressed syllable is heavy, due to the coda.

According to Gouskova (2004), the language-specific patterns of syllable contact discussed above suggest that languages differ in the thresholds of acceptable sonority distance between a coda and a following onset and that the SCL is not a single constraint forbidding rising sonority. To account for such language variations within Optimality Theory, Gouskova reformulates the SCL as a hierarchy of constraints derived from sonority scales, which target negative, flat, or positive sonority distance across a syllable boundary.

3.4 *Problems with the Syllable Contact Law*

Seo (2003) points out that the SCL has two problems. First of all, the SCL is problematic, since it cannot explain why a consonant + liquid cluster is targeted by a phonological process when a syllable boundary cannot be assumed between two segments in the cluster, for example, in word-initial position. Recall that the SCL crucially refers to a syllable boundary in explaining phonological change of a consonant + liquid cluster by assuming that the change is motivated to avoid cases where the onset B has higher sonority than the coda A in a heterosyllabic A.B sequence.

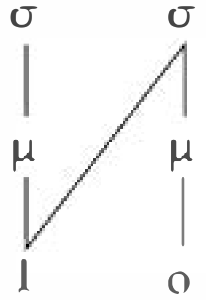
As illustrated below, in Leti an /nl/ sequence is realized as [ll], whether it occurs word-initially or intervocalically. Note that vowel deletion occurs in the examples given.

(22) *Leti* (van Engelenhoven 1995; Hume *et al.* 1997)

/na+losir/	→	[llosir]	'3SG-to follow'
/a:na+leti/	→	[a:lleti]	'Alety (clan)' (child + Leti)

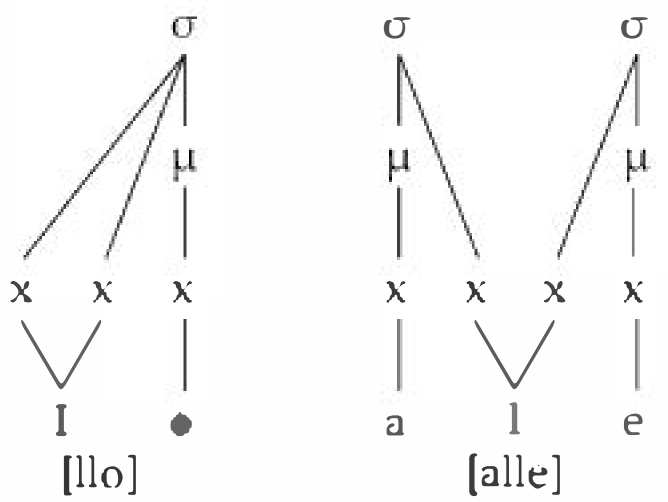
In line with the view that the change of a consonant + liquid cluster is motivated due to the SCL, the word-initial geminate [ll] in [llosir] might be considered to be bisyllabic, as represented below (see also CHAPTER 37: GEMINATES):

(23)



However, as discussed in Hume *et al.* (1997), there is a problem with the representation in (23). Leti has a minimal word requirement that lexical words must be minimally bimoraic. With the representation of the geminate in (23), the minimal word requirement is satisfied in words consisting of an initial geminate and a vowel, for example [p.pe]. Thus, it is expected that there will exist words with such a structure in Leti. However, none are attested. On the other hand, if word-initial geminates are assumed to be part of the onset of a single syllable, words containing initial geminates such as [ppu.na] 'nest' are bisyllabic, conforming to the dominant tendency that lexical words are made up of two syllables in Leti. Thus, Hume *et al.* (1997) propose that geminates in Leti have phonological structure with a root node multiply linked to two timing slots, as in (24).

(24) *Geminates and long vowels in Leti* (Hume *et al.* 1997)



In view of the minimal word requirement, it cannot be assumed that an initial geminate is bisyllabic in Leti. Therefore, the modification of the word-initial tautosyllabic /nl/ sequence in Leti cannot be motivated by the SCL since a syllable boundary cannot be referred to. On the other hand, phonological change of the intervocalic /nl/ sequence in Leti could be accounted for by relying on the avoidance of rising sonority over a syllable boundary. Thus, even though both heterosyllabic and tautosyllabic /nl/ sequences show the same pattern in Leti, the syllable contact account cannot provide a unified account of the modification.

The SCL is also argued to be problematic in Seo (2003), since it cannot provide a unified account of the same types of phonological changes found in nasal + liquid and liquid + nasal sequences in Korean.

(25) *Modifications of nasal/liquid sequences in Korean* (Davis and Shin 1999)

/nl/	→	[ll]	/non-li/	→	[nolli]	'logic'
/ln/	→	[ll]	/səl+nal/	→	[səllal]	'New Year's Day'
cf. /lm/	→	[lm]	/pul+mjən/	→	[pulmjən]	'insomnia'

As illustrated in (25), in Korean /nl/ surfaces as [ll]. According to the SCL, this change is expected since the sequence violates the law. However, the same change applies to /ln/, while /lm/ (with the same sonority distance as /ln/) does not undergo any change. Thus it must be assumed within the syllable contact account that the modification of a nasal + liquid sequence and that of a liquid + nasal sequence result from different factors, although the same types of phonological changes occur in both types of sequence. Korean is not the only language that has the same types of alternations in nasal/liquid sequences. As shown in (26), the same type of phonological change applies to both /nl/ and /ln/ sequences in Leti, Toba Batak, and Boraana Oromo.

(26) *Modifications of nasal/liquid sequences*

a. *Leti* (van Engelenhoven 1995; Hume *et al.* 1997)

/nl/	→	[ll]	/aːna+leti/	→	[aːlleti]	'Alety (clan)'
/ln/	→	[ll]	/vulan/	→	[vulla]	'moon'

b. *Toba Batak* (Nababan 1981)

/nl/	→	[ll]	/laɔn+laɔn/	→	[laɔllaɔn]	'eventually'
/ln/	→	[ll]	/bal+na/	→	[balla]	'his ball'

c. *Boraana Oromo* (Stroomer 1995)

/nl/	→	[ll]	/hin+lool+a/	→	[hilloola]	'I/he will fight'
/ln/	→	[ll]	/kofl+na/	→	[kofalla]	'we smile'

Within the syllable contact account, the modification of /ln/ would have to be motivated by a factor other than syllable contact, although both /ln/ and /nl/ undergo the same type of phonological change.

Seo (2003) proposes that the phonological processes found in phonological modifications of heterosyllabic coda-onset sequences could be viewed as resulting from a segment contact phenomenon which is closely related to speech perception, rather than from the SCL (see CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). According to Seo, contrasts of weak perceptibility triggered by phonetic similarity between two members of a cluster are a key factor in motivating the alternations in the cluster. Thus it is expected that phonological modifications will apply when two consonants are perceptually similar to each other, and when they occur in a sequence, regardless of the presence or absence of a syllable boundary and the order of the two consonants.

4 Conclusion

In this chapter, I have reviewed four major issues concerning the SCL. First, different opinions regarding the necessity of the SCL were discussed – while Clements (1990) claims that the SCL is not required with the Sonority Dispersion Principle, Davis (1998) and Gouskova (2004) argue that the SCL cannot be reduced to the Sonority Dispersion Principle based on the Kazakh data. Second, the change in viewpoint on the nature of syllable contact was reviewed, and it was shown that a gradient of syllable contact makes it possible to explain language-specific syllable contact patterns while a categorical view does not. Third, after providing examples illustrating cross-linguistic variations of syllable contact, I introduced Gouskova's (2004) proposal of the SCL as a language-specific constraint on minimal sonority distance. Finally, based on Seo (2003), after pointing out problems associated with the SCL, I argued that phonological modifications of heterosyllabic coda-onset sequences could be viewed as a segment contact phenomenon, which is closely related to speech perception.

54 The Skeleton

Péter Szigetvári

Only theories of phonology that attach significance to representations of phonological objects and, in addition, subscribe to an autosegmental version of these representations face the question of what the phonological skeleton looks like. Therefore, this chapter presupposes an autosegmental view of phonological representations.

The motivation for the autosegmental model is the fact that the segmentation of the speech signal can never result in absolutely discrete segments. Here segmentation is taken to mean practically the conversion of the continuous speech signal into the alphabetical symbols of the IPA. Some of these symbols pertain to more than one segment: for example, the stress mark to the syllable after it, tones potentially to even longer stretches. Take the question *you live by the sea?* Its last word, carrying the most prominent stress in the sentence, the tonic, might be transcribed as [↑siː]. In this transcription, the tone mark has a scope lasting all through the word (basically its only vowel): the pitch rises on steadily until the end of the utterance. The same holds if the string after the tone mark is longer, for example, as in *you live by the* | ↑*seaside, Martin?* It would take a very complicated mechanism to maintain that pitch was a property of individual segments and in some cases this rising pitch was realized on a single vowel, while in others it was split into low, higher, even higher, and highest pitch and added to several other vowels following. Tone is clearly not an immanent property of a vowel; it is an ephemeral phenomenon (from the point of view of a vowel) controlled by syntactic and pragmatic factors. If so, it is useful to represent it separately from the rest of the properties of the sound string. Such autonomous sound properties came to be known as autosegments.

If the phonological shape of an utterance is represented as a string of discrete feature bundles, the only option of representing the rising pitch in ↑*sea* includes a feature [rising tone] (here R) in the set of features corresponding to the vowel, as in (1a). In ↑*seaside, Martin*, on the other hand, a set of features [low tone], [higher tone], [even higher tone], etc. (here 0H, 1H, etc.) has to be assigned to the vowels following the tonic, as in (1b).

(1) a. siː^{R}
    b. siː^{0H} $\text{saɪ}^{\text{1H}}\text{d}$ $\text{mɑː}^{\text{2H}}\text{tɪ}^{\text{3H}}\text{n}$

One flaw of such representations is obvious: there appears to be nothing in common between the two rising tones, i.e. nothing to indicate their relationship. It is clear that the same tone is spread over the available vowels, but this is not shown in (1b).

Not only tone but many other sound properties turn out to be similarly promiscuous, with the potential of simultaneously belonging to several segments, and being manipulable independently of the segment(s) they belong to. (For further discussion, see CHAPTER 45: THE REPRESENTATION OF TONE and CHAPTER 14: AUTOSEGMENTS.)

The more sound properties extracted from their feature bundles, the fewer there remain. There are two widespread views on how many: according to one – historically the earlier – one feature, [syllabic], remains in the "bundle" (e.g. McCarthy 1979; Halle and Vergnaud 1980; Clements and Keyser 1983); according to the other, no feature remains (e.g. Levin 1985; Lowenstamm and Kaye 1986). The string of segmental positions thus vacated is called the phonological skeleton (a name suggested by Halle and Vergnaud 1980: 83) – or, alternatively, the timing tier or skeletal tier. The former type, in which the skeletal positions hold the feature [syllabic], is the CV skeleton (discussed in §2); the latter one, which is completely empty, is the X skeleton (discussed in §3). A non-segment-based framework involving only syllables and moras is introduced in §4. I will then argue that there is a way of incorporating moras in the old CV skeleton with clear advantages over the moraic framework (§5).

To begin with, let us examine the types of relation that may exist between skeletal positions and phonetic features associable to them.

1 Melody–skeleton relations

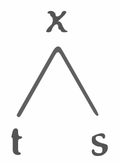
Skeletal positions represent the presence of a segment, and serve as an anchoring site for the phonetic properties associated with that portion of the speech signal. If the relationship of feature bundles – referred to as melody, again following Halle and Vergnaud (1980), among many others – and skeletal positions were always one to one, the latter would be superfluous. But, as we have already seen in the case of tone, this is not so. Let us take the non-trivial options one by one.

1.1 *One-to-many relations*

The standard textbook examples for this type of skeleton–melody relationship are affricates and prenasalized plosives (see CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION). With respect to the former, there has been much debate among phonologists about the feature [±delayed release] (and the marginal oppositions it creates), which Chomsky and Halle (1968) introduced to distinguish affricates from plosives. An alternative approach, that affricates are bisegmental (discussed by Gimson 1989: 172f. and Roca 1994: 3, among others), as suggested by the IPA symbols used to represent them, is undermined by many facts. In most cases, the distribution of affricates shows that they are not clusters, but single segments. It is even possible that an affricate in a system does not contrast with a homorganic fricative (e.g. Castilian Spanish has [ʧ], but not [ʃ]), rendering a cluster analysis improbable.

The separation of quantity (skeleton) and quality (melody) offers an opportunity for handling the quantitatively simplex, but qualitatively complex, affricates in an intuitive way, as so-called contour segments. (2) depicts the view of the affricate [ts] along these lines. (The skeletal slot is represented as "x", but this is not meant to indicate a standpoint in the CV *vs.* X skeleton debate.)

(2) *An affricate as a contour segment*

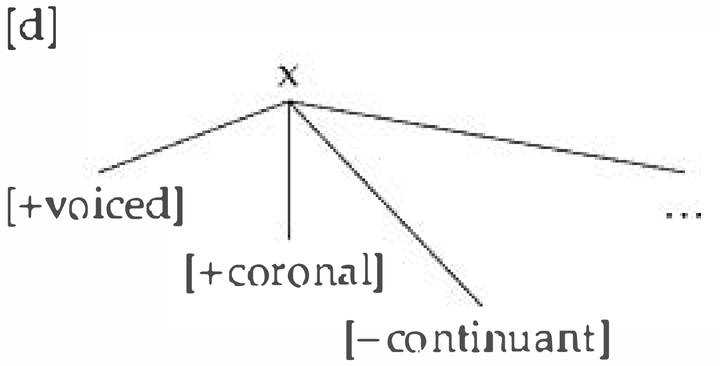


The representation in (2), however, incorporates a misconception, namely, that the melody of segments, without the slot they attach to, forms some kind of unit, two of which are here associated with a single skeletal slot. In reality, the symbols "t" and "s" above have no theoretical status. What exist in an autosegmental framework (or for that matter any other phonological theory since the middle of the twentieth century) are features, many of which occur in both parts of the affricate (e.g. place of articulation, laryngeal properties). Another difficulty with the contour model of affricates lies in the interpretation of autosegmental representations. Any melody linked to a slot of the skeleton – also known as the timing tier – is interpreted simultaneously. Temporal sequencing is managed by the skeleton, i.e. what is linked to an earlier slot is interpreted earlier than what is linked to a later slot. Associating the stop part of the affricate to the left leg of the contour segment and the fricative part to the right is then no more than a graphical trick, which cannot have any realizational consequences. The standard solution to this problem, involving root nodes, is discussed in §4. As Clements (1999) and Lin (CHAPTER 16: AFFRICATES) argue, affricates are best thought of as non-contour segments (strident stops), as Jakobson *et al.* (1952) have proposed.

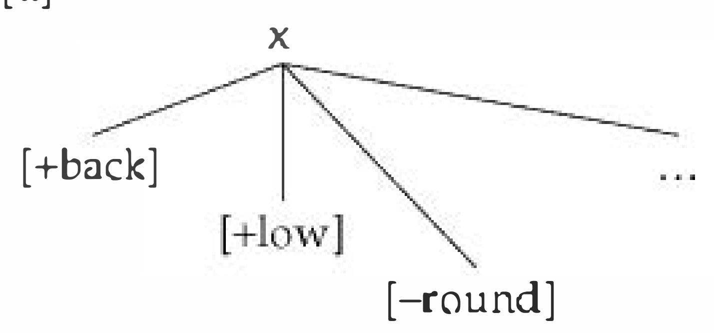
It seems then that we are left without one-to-many relations between the skeleton and melodic material. In fact, such relations are the most common occurrences in representations, since it is not segments but features that are associated with the slots of the skeleton. Thus most segments embody the one-to-many relation, as the partial representations of two very common segments, [d] and [ɑ], show in (3).

(3) *Partial autosegmental representations*

a. [d]



b. [ɑ]



1.2 *Many-to-one relations*

The long–short contrast of a vowel could be encoded in a feature [long], so that the long vowel is [+long] and the short one [–long]. It is evident, however, that this is not an adequate way of modeling length contrasts. Vowel length (or consonant length for that matter, on which see CHAPTER 37: GEMINATES) is not a property like vowel height (or the voicing of obstruents): it does not harmonize or trigger or undergo assimilation of any type (see CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH). Furthermore, changes in segmental length are usually unlike common assimilatory changes. Take, for example, the Rhythmic Law of Slovak, which shortens a suffixal long vowel after a long vowel in the stem. The agentive *-ník* (the acute accent marks length) inherently contains a long vowel (e.g. *rol-ník* [roljniːk] 'farmer'), which shortens when added to a long-vowelled stem (e.g. *stráž-nik* [straːʒɲik] 'guard'; Kenstowicz and Rubach 1987). The rule could be categorized as a dissimilatory process. What is conspicuously missing in languages is any assimilation of this type: i.e. changes where a short vowel would lengthen in the vicinity of a long vowel, and, crucially, because of that long vowel, or a long vowel would shorten purely because of the shortness of a neighboring vowel.

An even more telling phenomenon is compensatory lengthening (see also CHAPTER 64: COMPENSATORY LENGTHENING).[1] A synchronic comparison of the forms of the 1st singular copula in two varieties of Ancient Greek, Attic [eːmi] and Aeolic [emːi] 'I am', suggests a simple shift in the host of the alleged feature [+long]. In light of the reconstructed Proto-Greek etymon *[esmi], however, a different analysis is called for. The loss of the [s] triggers the lengthening of one of the neighboring segments, the preceding vowel in Attic and the following consonant in Aeolic. If length were encoded by a feature, the change could only be described by a pair of rules applying simultaneously, one deleting the coda consonant, the other lengthening the segment next to the deletion site. It is clear that the two rules are interrelated: spontaneously, open syllable lengthening is not attested in Attic, nor is intervocalic gemination in Aeolic – these changes only occur in tandem with the loss of the coda consonant. It is therefore difficult to understand why these two rules so commonly co-occur. If the quantity of segments is stored separately from their quality, this process, and any similar one, has a very neat explanation: it is only the quality (melody) of the coda [s] that is lost (more precisely, only its association with the skeleton); its place, that is, the time it occupied in the string of sounds, is retained (cf. e.g. Ingría 1980; Steriade 1982; Hock 1986; Hayes 1989). It is this empty place that one of the neighboring segments fills in, as shown in (4).

(4) *Compensatory lengthening: The stability of the skeleton*

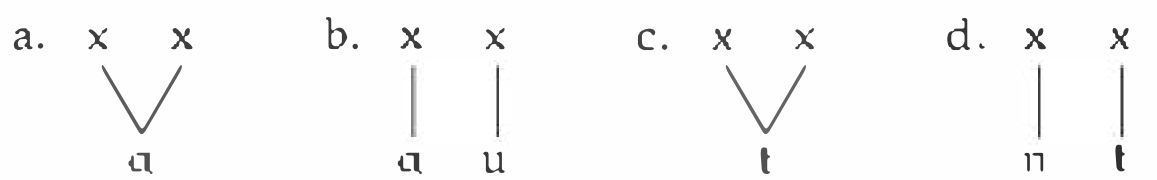
a. *Attic* b. *Aeolic*

[1] Much of the literature limits the term *compensatory lengthening* to cases involving the lengthening of a vowel. The lengthening of a consonant is called inverse compensatory lengthening by Hayes (1989: 280–281). Here I will refer to both processes by the same name.

While cases like the above could also be analyzed as the total assimilation of the [s] to the preceding vowel or the following consonant, there are more complicated types of compensatory lengthening, for which such an analysis is not at all viable. Cases in point include Middle English *tale* [talə] > [taːl] (Minkova 1982), Old Church Slavonic *bógŭ* > pre-Serbo-Croatian *bôg* [bóog] 'god', *bobŭ* > *bôb* [boób] 'bean' (Hock 1986: 435), and Old Hungarian [hida] > *híd* [hiːd] 'bridge', [lɛvɛlɛ] > [lɛvɛːl] (Modern Hungarian *levél* [lɛveːl] 'leaf', with subsequent closing of the second vowel; E. Abaffy 2003: 331). The English case is controversial (see Lahiri and Dresher 1999 for a different analysis), but for the others there is evidence that they are not cases of open syllable lengthening ensued by apocope. In Slavonic the original bisyllabic stress pattern is preserved on the long vowel of the monosyllabic forms. In Hungarian no lengthening takes place before suffixes that retain the stem-final vowel: Modern Hungarian *hídam* [hidɑm] 'my bridge', *levelek* [lɛvɛlɛk] 'leaves'. Lengthening due to a minimal word constraint is also excluded by the last example: the process takes place in monosyllabic and polysyllabic words alike.

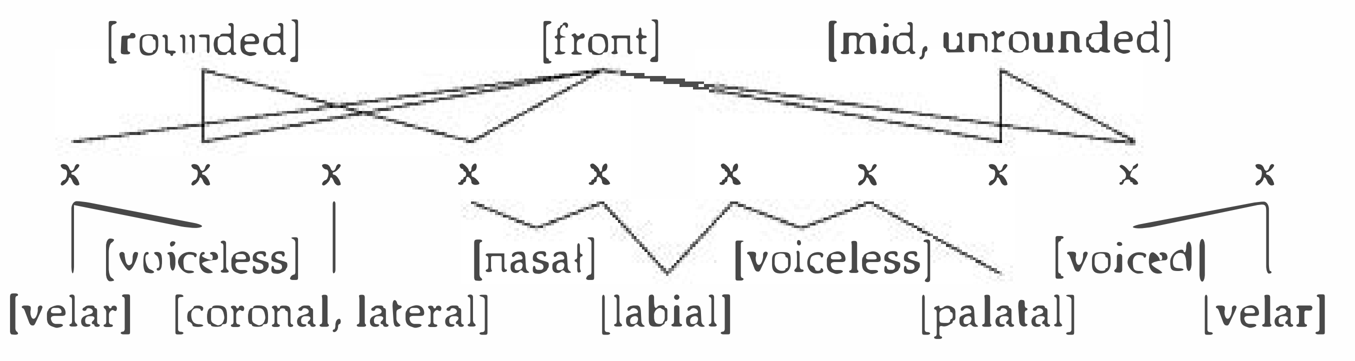
The bipositional analyis of long vowels is also made likely by the fact that they behave similarly to "vowel clusters," i.e. diphthongs. In English, for example, neither category occurs before non-coronal consonant clusters, and both occur word-finally, unlike short monophthongs (Fudge 1969: 272f.; Harris 1994: 37; Gussmann 2002: 20–23; see Prince 1984 for the same conclusion in Finnish for both vowels and consonants). Accordingly, there is a general consensus that long vowels ought to be represented as in (5a), and long (i.e. geminate) consonants as in (5c). The representation of diphthongs and other consonant clusters is given in (5b) and (5d), for comparison.

(5) *The autosegmental representation of vowel and consonant clusters*



It is not only complete segments that may be linked to more than one skeletal position. The standard situation in fact is that features (autosegments) are multiply linked. Take, for example, the Hungarian word *különbség* [k̟ylø̃mpʃeːg] 'difference', depicted in (6). (The features only serve illustrative purposes; their exact identity and location is irrelevant here.)

(6) *Multiply linked features in the representation of* [k̟ylø̃mpʃeːg]



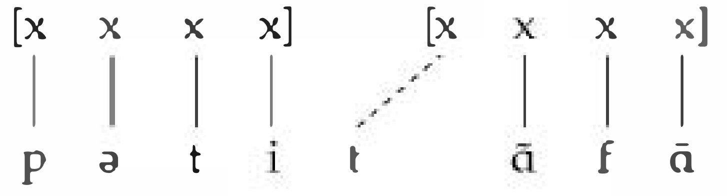
Chaotic as it seems, the diagram in (6) does not contain all the relevant features specifying the segmental content of the string [k̟ylø̃mpʃeːg] – manner of articulation features, for example, are lacking. Nevertheless, it can clearly be seen that it is more common for a feature to be associated with several skeletal slots than to be associated exclusively with one. In (6) this is because of voicing, place of articulation assimilations, vowel nasalization, and consonant fronting, as well as vowel harmony. Even when feature sharing is not a result of such phonological processes, i.e. in monomorphemic items, the multiple association of a single feature is dictated by the Obligatory Contour Principle (Leben 1973; McCarthy 1986; Odden 1986).

1.3 One-to-zero and zero-to-one relations

As we have seen, many-to-one and one-to-many relations between the skeleton and melody are very common. Two further options are discussed in this section. It is possible that a skeletal position is not associated with any melodic material. The opposite case may also occur: features unlinked to any point on the skeleton.

French liaison exemplifies both of these possibilities (see CHAPTER 112: FRENCH LIAISON). In this phenomenon, a word-final consonant is pronounced when the next word begins with a vowel, but not when it begins with a consonant. (The syntactic conditions on liaison need not concern us here.) Thus in the phrase *petit garçon* 'little boy' the first element ends in a vowel ([pəti garsõ]), in *petit enfant* 'little child' a [t] is pronounced ([pətit ɑ̃fɑ̃]). According to one analysis (Prunet 1987: 226) *petit* comes with only four skeletal slots, but five segments; *enfant*, on the other hand, has an extra skeletal slot – it begins with an initial consonantal slot which is empty. The situation is shown in (7).

(7) *Liaison*



The [t] at the end of *petit* is not associated to the skeleton; it is said to be floating. Floating melody fails to be pronounced unless it is able to associate to the skeleton. Vowel-initial words supply an empty skeletal position that the floating melody can associate to. The floating [t] at the end of *petit* must be lexically determined: there are other liaison consonants besides [t], whose identity is unpredictable (e.g. *gros enfant* [groz ɑ̃fɑ̃] 'fat child', *mon enfant* [mõn ɑ̃fɑ̃] 'my child', *gentil enfant* [ʒɑ̃tij ɑ̃fɑ̃] 'nice child', *long article* [lõg artikl] 'long article', etc., where the consonant before the space appears only if the next word begins with a vowel). Therefore this consonant must be included in the lexical representation. It is also not unjustified to suppose that vowel-initial words carry an empty skeletal slot at their left side. It is true for all languages that at least some words (and syllables) begin with a consonant (CHAPTER 55: ONSETS). For some languages this is not optional, but obligatory; crucially, though, there are no languages where an onset is not possible. One may argue that a syllable-initial consonantal position is in fact obligatory in all languages, the optionality lying in whether this position may or may not be left empty (see e.g. Kaye 1989: 134). Thus consonant-initial words do not carry an empty skeletal slot to their left, while vowel-initial words do, and as a result, the latter can host the floating consonantal melody at the end of the preceding word. Apparently, even languages that allow syllable-initial consonantal positions to be empty prefer them to be filled.

Hypothesizing that there is an empty skeletal position between two vowels in hiatus and that languages make an effort to fill it also explains the common phenomenon of hiatus filling (CHAPTER 61: HIATUS RESOLUTION). Unless a language manages to get rid of this consonantal position (often together with one of the neighboring vowels), an intervocalic consonantal position is filled by some melody associating to it from one of the vowels. (8) illustrates this with English *skier* and Hungarian *síel* [ʃiːɛl] 's/he skies'.

(8) *Hiatus filling*

The hiatus between [iː] and [ə] or [ɛ] is filled by the melody of the first vowel, resulting in the forms [skiːjə] (Gimson 1989: 215, 2001: 213) and [ʃiːjɛl] (Siptár and Törkenczy 2000: 283).

The possibility of vocalic positions being empty is considerably more controversial; this issue will be taken up in §5.

2 The CV skeleton

The notion of the CV tier was originally developed for the analysis of the non-concatenative morphology of Classical Arabic by McCarthy (1979, 1981). As in other Semitic languages, a large number of morphological categories are not expressed by linking morphemes after one another, but by fusing individually unpronounceable components into one. A similar, but much less elaborate case is the ablaut found in Germanic languages, e.g. English *sing*, *sang*, *sung*, and *song*, where the consonants carry the lexical entry and the vowel the grammatical category. (See also CHAPTER 105: TIER SEGREGATION and CHAPTER 108: SEMITIC TEMPLATES.)

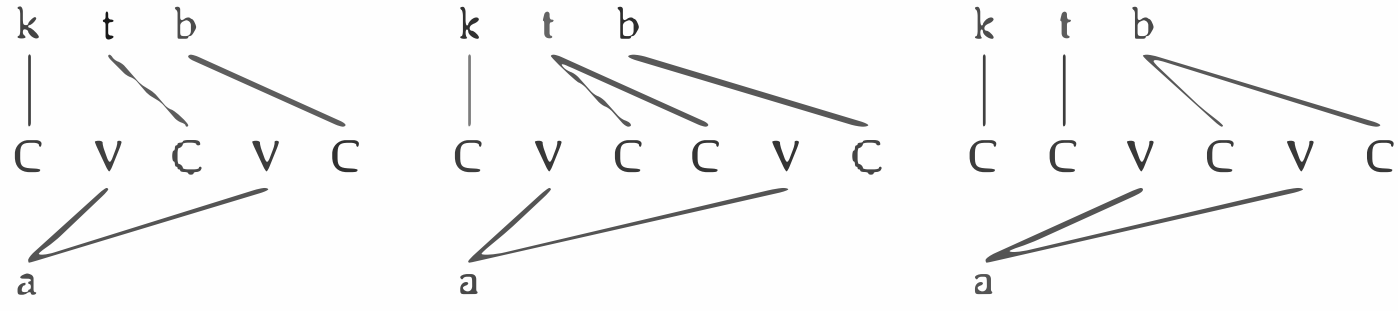
Paradigms in Arabic are classified into groups traditionally called conjugations – or, as McCarthy refers to them, binyans. The prime phonological property of a binyan is the order in which consonants and vowels are arranged. Roots of three (sometimes two or four) consonants contribute a lexical field to the meaning; the vowels are often responsible for grammatical categories like tense and voice. A portion of McCarthy's (1979: 244) table depicting the forms for the root /ktb/ 'to write' is given in (9).

(9) *Some forms of* /ktb/

binyan	*perf act*	*perf pass*
I	katab	kutib
II	kattab	kuttib
III	kaatab	kuutib
...		
IX	ktabab	—

The CV skeletons of the first three binyans are CVCVC, CVCCVC, and CVVCVC, respectively; that of binyan IX is CCVCVC. The root consonants and the vowels supplied by the grammatical category are mapped onto this skeleton more or less according to the association conventions elaborated by Goldsmith (1976). Three cases are shown in (10).

(10) a. katab b. kattab c. ktabab

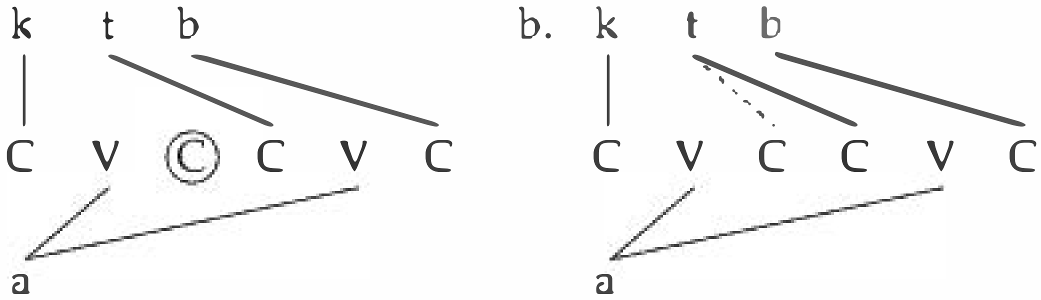


In (10a), the consonants are linked to the C slots of the skeleton, one by one. It is vital that the consonantal and vocalic skeletal slots be distinguished, since the linking of the root consonants and the vowel(s) can be done as required only thus. The case of (10c) shows that association takes place from left to right: with three consonants to four positions, the last consonant is linked to the surplus position ([ktabab]). (10b) poses a problem in this respect: either association is idiosyncratically edge-in in this case, or some extra mechanism is needed. McCarthy (1979: 256) uses brute force here: he assumes the expected *[katbab] in the first round, with a later rule delinking the first linkage of [b] ([katCab], where C represents the slot from which the melody of the [b] is delinked). This is automatically followed by the spreading of the [t] ([kattab]), much like an instance of compensatory lengthening (see §1.2).

A slightly less powerful solution is proposed by Lowenstamm and Kaye (1986: 117–118), who claim that association to the first position is inhibited from the start, thus each consonant of the root occupies its final position in the first round, as shown in (11a). The resulting configuration (empty C followed by filled C) is interpreted as a geminate, as in (11b). I have adapted the original to the previous diagrams of this chapter to aid comparison. We will see below (§3) that Lowenstamm and Kaye use a significantly different scheme.

(11) *The mapping of a geminate* ([kattab])

a. b.



Note that McCarthy's second-round-spreading solution cannot apply after Lowenstamm and Kaye's first-round blocking, since this would yield the unattested form *[kaktab].[2]

[2] Neither analysis gives a reason for delinking or inhibiting the association of the consonant encircled in (11a), so that the unattested form *[katbab] is avoided. Following Hoberman (1988), we may assume that long-distance geminates (those separated by a vowel) are more marked (their inhibition is ranked higher) than local ones and that word-initial geminates are even more marked. This explains why [kattab] is preferred to *[katbab], but [ktabab] to *[kkatab].

In McCarthy's analysis, the CV skeleton of Arabic words is a morpheme (a prosodic template, in his words), identifying the binyan of the word form, contributing to the semantic elements of the specific binyan (as if the Attic–Aeolic difference between [eːmi] and [emːi] represented a difference in morphological categories).

Clements and Keyser (1983: 11) apply the CV skeleton as a universal phonological device, the mediator between the syllable and autosegments, its two types of members, C and V representing "the useful but ill-defined notion of 'phonological segment'." The C for them is an anchor for anything [−syllabic] and the V for [+syllabic] segments. Prince (1984) shows that such impoverished representations adequately capture the templates of, for example, verbal person endings in Finnish, which are -C in the singular and -CC[e] in the plural, with the melody [m] in the 1st, and [t] in the 2nd person. The surface forms are thus 1st singular [-n] (by an independently motivated rule turning [m] to [n] word-finally), 2nd singular [-t], 1st plural [-mme] and 2nd plural [-tte].

3 The X skeleton

Simultaneously with the development of theories of the CV skeleton there evolved an alternative view that considered the distinction of C and V slots redundant, and argued that skeletal slots are uniform, usually marked with dots or x's (e.g. Lowenstamm and Kaye 1986; Levin 1985). Proponents of the X skeleton have put forward a number of arguments against skeletal positions predestined for syllabicity.

3.1 Reduplication in Mokilese

Levin (1985: 35–41) shows some unusual cases of reduplication from Mokilese, which, she believes, are analyzable only with an X skeleton. The point is that the reduplicant is a copy of the first three segments of the first syllable of the stem, irrespective of their being consonants or vowels. Levin argues that the template of the reduplicant must therefore also lack this information. The relevant data are given in (12).

(12) *Mokilese reduplication*

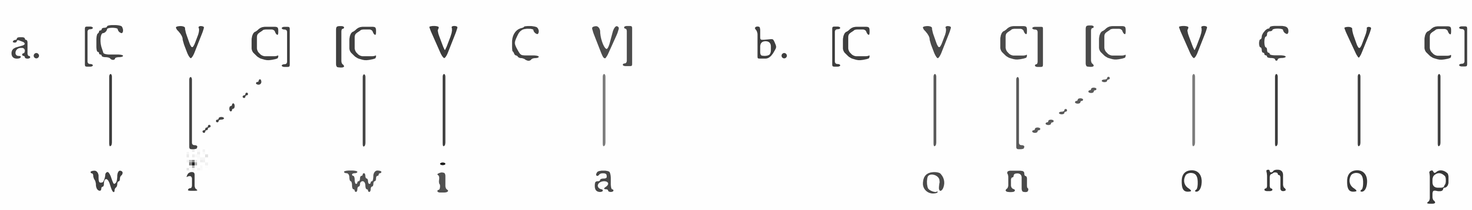
	stem	*progressive*	
a.	pɔdok	pɔdpɔdok	'plant'
b.	kasɔ	kaskasɔ	'throw'
c.	pa	paːpa	'weave'
d.	wia	wiːwia	'do'
e.	caːk	caːcaːk	'bend'
f.	onop	onnonop	'prepare'
g.	andip	andandip	'spit'

Levin contends that the reduplicant must be a totally specificationless skeleton, $_{\sigma}$[xxx], to which the copy of the melody of the stem is associated following universal conventions. The case of (12a), (12b), and (12g) is now straightforward. When the stem is too short, as in [pa], (12c), the last melody is multiply linked. The fact that the reduplicant is a single syllable inhibits the second vowels of [wia] and [onop] from associating to the skeleton (12d) and (12f). As a result, the preceding vowel or consonant is lengthened again. There is a problem with the stem [caːk] though, (12e). The melody of the stem comprises three segments, "|c|", "|a|", and "|k|", and the expected reduplicated form is therefore *[cakcaːk] rather than the attested [caːcaːk]. Levin has to stipulate that multiple melodic associations like that of the long [aː] are transferred in reduplication. A further problem of this analysis lies in the interpretation of the reduplicant: it is specified as a syllable, but it is not one in [on.n-onop] or [an.d-andip] (where the hyphen indicates the boundary between the reduplicant and the stem), since a word-internal pre-vocalic consonant forms a syllable with the following vowel, as the universal onset maximalization principle requires. Yet the constraint on the reduplicant being a syllable cannot be relaxed, because if the first three segments were copied without reference to a syllable, undesirable results like *[wi.a-wia] or *[o.no-onop] would emerge. In fact, Moravcsik says that in her survey of reduplication types she has never come across formulations like "reduplicate the first two [or, in our case, three – szp] segments (regardless of whether they are consonants or vowels)" (1978: 307–308). If in a language reduplication copies the first CVC part of the stem for consonant-initial stems, it will copy VC (not VCV) of vowel-initial stems.

Actually, a simpler account is available for the data in (12). Theoretically it is no more plausible than Levin's, but needs fewer stipulations, and thus invalidates her analysis *as an argument* for the X skeleton. Suppose, as in §1.3 above, that syllable onsets are always represented on the skeleton, either as a filled or as an empty C position. (This immediately explains Moravcsik's observation.) The reduplicant then is a copy of the first CVC part of the stem, melody and skeleton included. The cases of (12a–c) are obvious. The third slot for (12c) is automatically filled by the vowel of the reduplicant, just as for Levin. The objection (also put forward by Broselow 1995: 184) that vowels cannot spread onto a consonantal slot is mistaken: a C slot is not meant to host consonants exclusively, but non-syllabic segments. If a syllable has one syllabic segment, then a long vowel is hosted by a VC sequence on the skeleton, as Clements and Keyser (1983: 12) argue.

In (12d), the empty intervocalic C position is involved in the copying, but, as it is preconsonantal in the reduplicant, it serves as an anchor for the preceding vowel, unlike in the stem, where it is pre-vocalic. This is shown in (13a). Pre-vocalic stems blindly copy the initial empty C position, and so only the first two "real" segments form the reduplicant. (12g) seems to cause a problem now: here the reduplicant appears to be [and-], i.e. VCC, instead of the expected VC. Raimy (1999) suggests an obvious solution: if [nd] is analysed as [ⁿdd], a geminate pre-nasalized stop, then the situation is identical to that in (12f). The stem-initial empty C must be filled to satisfy onset maximalization: it is impossible to have a coda consonant followed by an empty onset. This is illustrated in (13b). (The reduplicant and the stem are enclosed in brackets for easier identification.)

(13) *Reduplication and empty onsets*



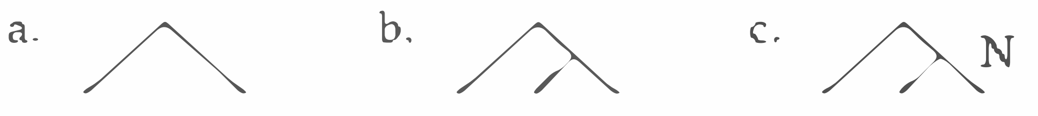
In fact, Levin herself suggests the empty-C-slot analysis as an escape hatch for the CV skeleton, but rejects the idea on the grounds that the vowel of the causative prefix [ka-] does not lengthen when prefixed to vowel-initial stems (e.g.

[ka+adanki] > [ka:danki] 'to name', [ka+uru:r] > [kauru:r] 'to be funny'). Vowels do not usually lengthen by filling a pre-vocalic empty C position (cf. Hayes 1989: 281); what is more, it is hard to expect a long vowel or a diphthong to further lengthen. The conclusive test, the prefix [ak-], which is expected to geminate its consonant if prefixed to a vowel-initial stem if there was an empty consonantal slot, "was only found prefixed to C-initial stems" (Levin 1985: 40). We can conclude that the hypothesis that vowel-initial stems carry an empty consonantal position at their left edge is not refuted by Levin's data.

3.2 *Redundancy of C and V*

A better argument against CV skeletons is that specifying syllabicity on the skeleton is redundant if the same information can be read off higher prosodic structures, like syllabic constituents, especially the nucleus. Lowenstamm and Kaye (1986) argue that simple syllable trees, like those in (14), adequately define the slots of the skeleton.

(14) *Syllable trees*

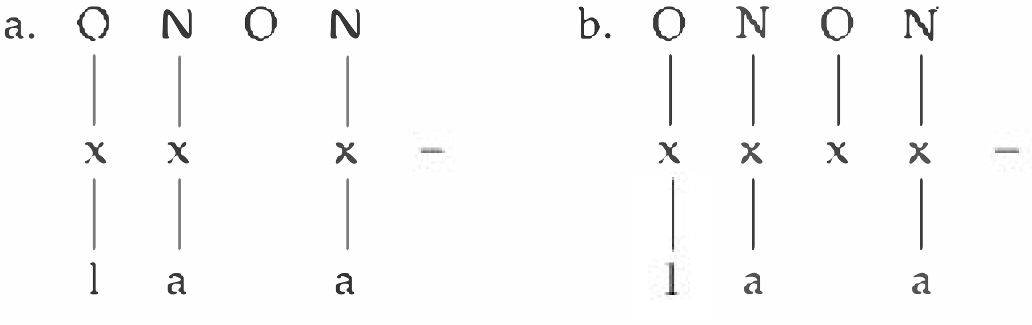


They suggest that labeling the trees is unnecessary since this information also follows from the configuration. Nevertheless, some minimal labeling (N, i.e. "nucleus") is necessary to distinguish CVC, (14b), and CVV, (14c), syllables – consider, for example, the Arabic templates of binyans II ([kattab]) and III ([kaatab]) (see (9)).

Lowenstamm and Kaye (1986) raise the issue of whether the skeleton is an independent level in phonological representations, or merely a projection of higher prosodic structure, in particular syllable structure. A consequence of this assumption is that the nodes representing syllabic constituents (like onset or nucleus) cannot be distinguished from the skeletal position(s) that they dominate. That is, it is impossible to conceive of skeletal positions not dominated by higher prosodic structure, or of a syllabic constituent that does not dominate a skeletal position.

Charette utilizes "pointless onsets" in an analysis of h-*aspiré* words in French (1991: 90f). She claims that "normal" vowel-initial words begin with an onset that does not dominate any skeletal position, while those which contain h-*aspiré* – words that phonetically begin with a vowel, but phonologically behave as consonant-initial – begin with a regular "pointful" onset, dominating a skeletal position which is not associated with any melody. The vowel of the definite article is unpronounced before vowel-initial words, but it is pronounced before consonant- and h-*aspiré*-initial words. (15) illustrates the first part of the two cases using Charette's examples: *l'amie* [lami] 'the girlfriend' and *la hache* [la aʃ] 'the axe'.

(15) *Two types of empty onset*



According to Charette's analysis, the vowel of the article is deleted before a pointless onset as a result of the Obligatory Contour Principle, since the two nuclei are "adjacent" if the onset between them lacks a skeletal slot, as in (15a). When such an onset is linked to a skeletal slot, it inhibits the deletion process, as in (15b). This analysis faces difficulties on several counts. On the one hand, the Obligatory Contour Principle controls the appearance of identical *melodic elements* linked to adjacent skeletal positions. The nodes labeled "nucleus" do not qualify as such. On the other hand, liaison calls for the opposite representation of the two types of vowel-initial words. As mentioned in §1.3, some morphemes that are vowel-final preconsonantally exhibit a consonant when followed by a vowel-initial word. The plural of the definite article is an example: *les amies* [lez ami] 'the girlfriends' *vs. les haches* [le aʃ] 'the axes' (recall that h-*aspiré*-initial words behave as if they were consonant-initial). The final [z] of the cliticized article is pronounced when there is no skeletal position for it to anchor to, and it is not pronounced when there is one, i.e. without further stipulations, Charette's analysis predicts just the opposite of the attested liaison facts. The impoverished structures of (14) are also impossible if labels like "onset" and "nucleus" are treated separately from what they label: the skeletal slots.

To summarize, there is no compelling reason to distinguish skeletal points and the syllabic constituents containing them. Allowing pointless constituents or constituentless skeletal points makes unnecessary contrasts possible. But then, if prosodic nodes like onset and nucleus are not distinct from skeletal slots, then skeletal slots do carry the basic information of syllabic status: such a skeleton does contain Cs and Vs, irrespective of whether this is penciled on paper as Cs and Vs, Os and Ns, or something else. The two levels must, nevertheless, be kept distinct if more than one skeletal slot can be associated with a single syllabic constituent, i.e. if branching onsets and nuclei are posited. §5 discusses a model where even these are claimed not to exist.

4 Moras

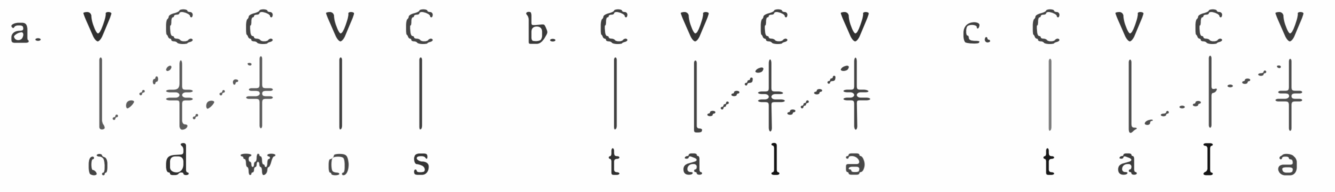
As we have seen in the case of Mokilese reduplication (§3.1), preconsonantal empty C positions are available as targets for the spreading of a preceding vowel; intervocalic ones are not. In many languages, a similar asymmetry characterizes these two consonantal positions. Stress processes, for example, may treat a preconsonantal consonant as being on a par with vowels, but not pre-vocalic consonants.[3]

Hock (1986) argues that the notion of mora must be (re)introduced into phonological theory. The mora has been around in linguistic discussions for at least two centuries (see Allen 1974: 100); it is its theoretical status that is at issue here (see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE). Hock's proposal is to introduce

[3] It is common at this point to offer a disclaimer with respect to Everett and Everett (1984) (who claim that Pirahã is different in this respect) or to Davis (1988) (who collects cases where the quality of the onset seems to play a role in stress assignment). However, as Hayes states: "I believe that the ability of Moraic Theory to account for wide-spread patterns of markedness should be given more weight in assessing the evidence than any particular awkwardness in the analysis of individual languages" (1989: 303). This is probably true for any theory. Furthermore, some of the very few onset-sensitive systems have been shown to be re-analyzable so that they are not onset-sensitive (Goedemans 1996; Takahashi 1999).

the mora as an autosegment, rather similar to tones: in his proposal tones are indeed linked to moras. If compensatory lengthening could only lengthen a vowel in compensation for the loss of a tautosyllabic consonant, the "standard" CV or X skeleton would be fully capable of dealing with the process. We have seen, however, that compensatory lengthening also occurs at a distance: the loss of a vowel in the following syllable may lead to lengthening across an intervening onset consonant. Relevant cases are Greek glide loss (e.g. Proto-Greek [odwos] > Ionic [oːdos] 'threshold'; Steriade 1982: 118) and Middle English schwa apocope (e.g. [talə] > [taːl] 'tale'; Minkova 1982). In both cases the melody delinks and the vowel spreading is separated by a consonant that apparently remains linked to the skeleton.

(16) *Problematic cases of compensatory lengthening*



Actually, as (16a, b) show, the consonant standing in the way of compensatory lengthening is shifted to the right by one slot in both cases. This process, proposed by Steriade (1982: 126–128), is referred to as "double flop" by Hayes (1989: 265–267). The Greek case in (16a) can be explained by universal principles: the loss of [w] leaves us with an empty onset (provided that the syllabification is [od.wos]). The resulting [od.os] violates the onset maximalization principle, thus resyllabification ensues. But the skeletal position does not resyllabify, since there is an empty onset slot, recently vacated by [w]. It is to this slot that the [d] associates, leaving its original slot empty, triggering the lengthening of the preceding vowel.

The lengthening triggered by apocope, exemplified by Middle English [talə] > [taːl] in (16b), is more problematic for a theory which lacks moras. The mechanism appears to be the same as in (16a), but now the consonant before the disappearing word-final vowel is supposed to flop to a vocalic position, to the nuclear slot of the last syllable. In addition, the position it leaves is not one that should cause lengthening of the preceding vowel. The alternative, whereby the vowel spreads out immediately to the vacated vocalic slot, as in (16c), is even worse, as it violates the axiomatic constraint inhibiting the crossing of association lines.[4]

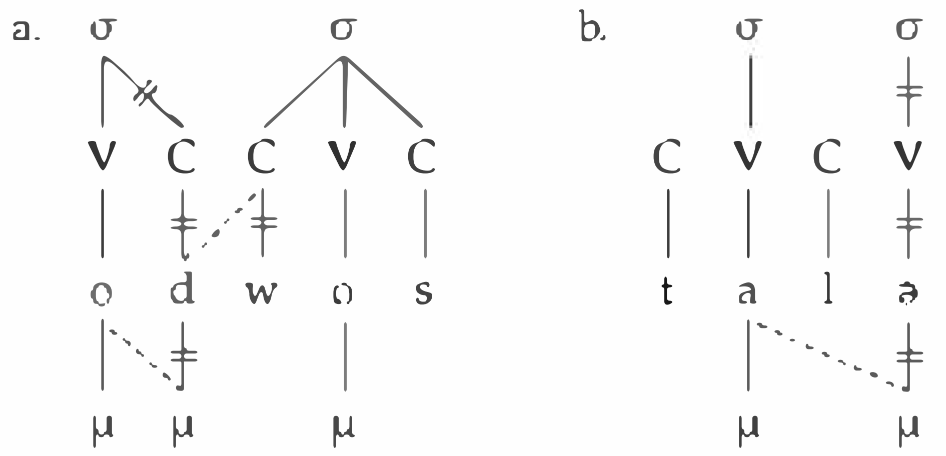
In fact, with both CV and X skeletons it is hard to explain why the spreading of a vowel to some consonantal slots should cause lengthening, while in other cases an apparently similar vowel spreading does not. For example, the empty onset in Hungarian *pia* [pijɑ] 'drink' is filled by the spreading of the melody of the preceding vowel, as in (8).[5] Yet the result is not a long vowel, which it is in *film* 'film', for which the pronunciation [fiːm] is possible (Siptár and Törkenczy 2000: 281) (cf. Hayes 1989: 281–283).

[4] This problem could be avoided by placing vowels and consonants on separate autosegmental planes (as in (10) and (11)); however, such a modification would loosen the theory beyond desirable limits: we would now find it hard to explain why so many processes deemed possible by the framework never occur.

[5] While it may be argued that *pia* is underlyingly [pijɑ], the question still holds why the same structure, the melody of [i] doubly linked to a V and a C slot, is [ij] in one case and [iː] in the other.

Hock's (1986) proposal is to attach a mora (μ) to each weight-bearing position, that is, to each vocalic position, as well as to some consonantal positions, notably codas. The two cases are shown in (17).

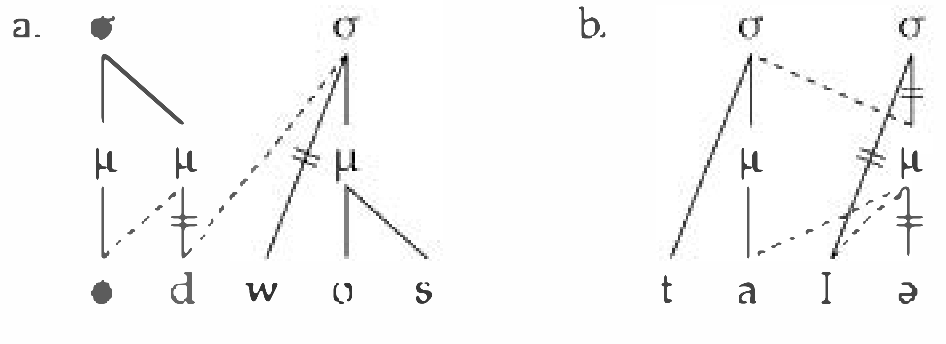
(17) *Double flop with moras*



The moraic analysis of [odwos] > [oːdos] in (17a) is not significantly different from the moraless one, shown in (16a). It nevertheless suggests a reason for the asymmetry between onset and coda consonants: the former do not possess a mora, while the latter do. The advantage of the mora analysis becomes clear in the lengthening of a vowel caused by apocope: [talə] > [taːl], (17b). The intervening onset consonant is not affected by the process at all, since it is not associated with a mora. Thus, the mora left floating after the final vowel is lost can associate to the stem internal vowel "above the head" (or rather "below the foot") of the intervening moraless consonant, much like in a vowel harmony process, where intervening consonants not possessing the relevant vocalic feature are transparent.

Hayes (1989) rearranges the relationship of the syllable and the mora by making the latter an integral part of prosodic structure, dominated by the syllable node. In a more radical innovation he also gets rid of the skeleton as previously conceived. In his view, the function of the skeleton is taken over by moras, and moraless consonants are either associated directly with the syllable node or share a mora with the moraic segment. Accordingly, the two processes displayed in (16) and (17) would be represented as in (18).

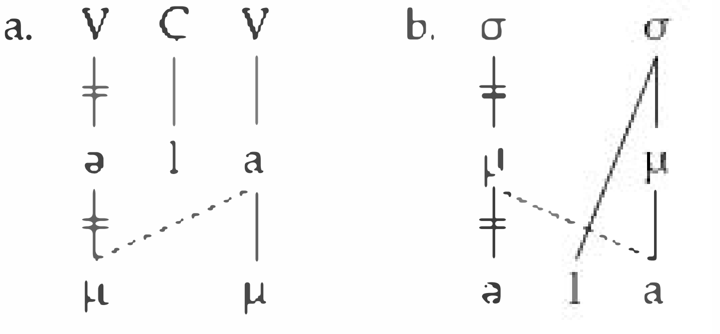
(18) *Moras as the skeleton*



The simple double-flop case of Greek glide deletion in (18a) does not require much comment, as the mechanism is the same as before. For Middle English apocope, however, Hayes needs an extra stipulation, called parasitic delinking: the loss of an overt nucleus in a syllable entails the dissolution of the whole syllable. What is now left of the last syllable, a mora and an [l], is joined to the first one, yielding the correct result. In Hock's analysis, on the other hand, the [l] remains in place, and does not have to be delinked and relinked, as can be seen in (17b).

Despite this complication, Hayes's model has definite advantages over Hock's use of moras. On the theoretical count, it is simpler in that it lacks the CV or X skeleton. On the empirical count, it predicts that compensatory lengthening of a vowel is only caused by the loss of a moraic segment that follows the vowel, never by the loss of one that precedes it. As (19a) shows, Hock's representations easily allow the latter case, which is not attested according to Hayes. His hypothetical example is [əla] > [la:].

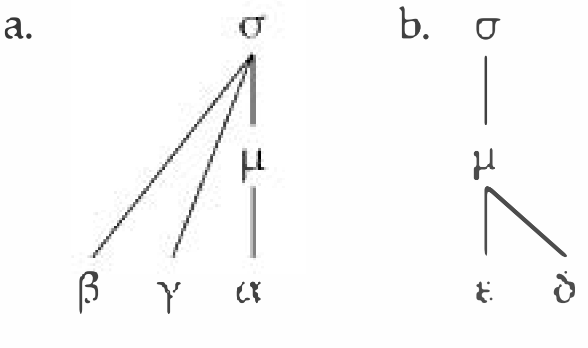
(19) *Compensatory lengthening triggered by loss of preceding vowel*



In Hayes's model, (19b), the freed mora of the first syllable cannot be captured by the second mora, because the onset consonant inhibits this. The price to pay for this solution is the stipulative parasitic delinking mentioned above: if the moraic segment of a syllable is delinked, the onset consonant is also delinked, as in (18b). Without this an onset will always block the linking of a heterosyllabic mora. Note that in Hock's model not only the loss of a vowel, but also the loss of a moraic consonant, could lead to the lengthening of a following vowel (e.g. Proto-Greek [esmi] > hypothetical *[emi:]). Such changes also seem to be unattested, as predicted by Hayes.

While theoretically attractive, dispensing with the skeleton has serious repercussions. Recall that linking IPA symbols to elements of higher prosodic structure (slots of the skeleton, moras, syllables) is misleading, since segments are not atomic. In partial trees like those in (20), where the Greek letters α–ε stand for (auto)segments, the temporal order of these autosegments is not specified. The string βγ is usually referred to as a branching onset; δ is a moraless coda, which may occur word finally even in languages with moraic codas, like English.

(20) *Autosegmental representations without a timing tier*



Accordingly, the order of two adjacent tautosyllabic or tautomoraic segments must be given by some stipulation. Kaye, for example, provides such a stipulation: "By universal convention the less sonorous of the two elements associated to the same point is produced first in the speech chain" (1985: 289). It remains to be seen if this can be maintained. For syllable-initial consonants, (20a), this is exactly what the sonority sequencing principle dictates. In the domain of single segments, affricates follow this convention, but the existence of prenasalized stops casts some doubt on its validity. Apart from light diphthongs (like French [wa] in *trois* [trwa] 'three'), monomoraic rhymal sequences, as in (20b), obviously cannot be subject to this generalization, since they are invariably ordered in the opposite way, with the more sonorous (vowel) first and the less sonorous (consonant) second. Be that as it may, without some similar (set of) principle(s) an autosegmental representation without a timing tier is uninterpretable.

To overcome this difficulty, one might wish to introduce root nodes, a notion familiar from frameworks organizing features into hierarchical structures, "feature geometries" (Clements 1985; Sagey 1986; McCarthy 1988; CHAPTER 27: THE ORGANIZATION OF FEATURES). The root node is the topmost node of such a hierarchy, containing all of the features making up the given segment, that is, the entirety of the segment. If the graphical order of root nodes specified their temporal order as well – as assumed in the contour-segment model of affricates – then "root node" would be just another name for "skeletal slot," i.e. one would simply reintroduce the skeleton into the representation. The skeleton is apparently indispensable.

5 A return to the CV skeleton

The modern career of the mora was launched by the need to distinguish onset consonants from coda consonants. Only the latter are capable of contributing to the weight of a syllable, that is, of behaving like a vowel; onsets are not (CHAPTER 55: ONSETS and CHAPTER 57: QUANTITY-SENSITIVITY). A mora is therefore assigned to consonants in the rhyme, but not to those in the onset. Note, however, that the reasoning is circular: codas are equipped with a mora because we observe that they behave differently, and then refer to these moras to explain their difference. But we could just as well imagine an alternative world in which onsets were moraic and codas were not. There is no inherent property of coda consonants that means they are fated to be moraic, as opposed to onset consonants. To make things worse, we will see that it is not exactly true that onset consonants are never moraic, or at least that their loss never entails compensatory lengthening. It turns out to be an oversimplification to tie diverse phenomena like compensatory lengthening, stress assignment algorithms, the assignment of tone-bearing units, etc. to a single property of the representation, i.e. moras (Hayes 1995: 299; Gordon 2004).

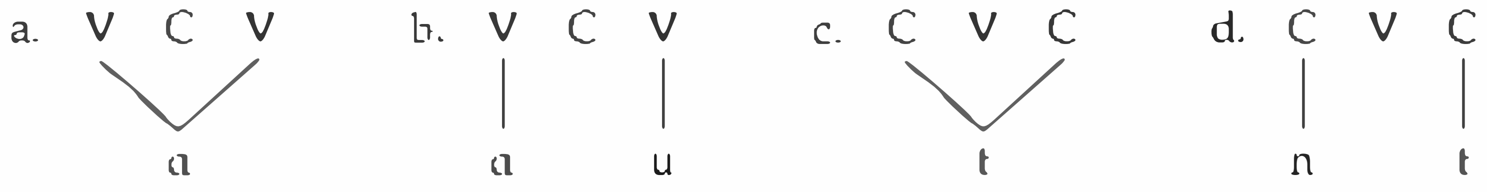
It is a version of the once rejected CV skeleton that might bring us closer to understanding this asymmetry in the behavior of consonants at the two edges of the syllable. To distinguish it from the McCarthy and Clements and Keyser type of CV skeleton, I will refer to it as the "strict CV skeleton." In §1.3 and §3.1, we saw why it is useful to suppose that some skeletal positions are empty. So far, we have only seen empty consonantal positions, but there is no particular reason why emptiness, i.e. the state of not being associated to any melodic material, should be limited to consonantal positions. The claim that the host of the vowel (the nucleus) is the head of the syllable, and therefore cannot be missing, is not a very strong one. Syntactic heads, for example the complementizer of a complementizer phrase, may remain empty (e.g. *I know* [$_{CP}$ [$_{C}$ Ø] *she'll come*]).[6] But other prosodic units like the foot may also exist without an overt head: in the previous sentence

[6] In fact, in English it is by default empty in non-questions, that is, there is an empty complementizer at the beginning of the matrix clause too.

the first headed foot begins with *know*, and the pronoun *I* before it forms a headless, degenerate foot. Feet and syllables are similar types of prosodic units, and headless syllables are therefore not inconceivable entities.

If nuclei may remain unpronounced, a very restricted syllable structure becomes available.[7] Lowenstamm (1996) proposes that underlyingly all languages have the same skeleton, the simplest one available, comprising non-branching onsets and non-branching nuclei in strict alternation. Accordingly, no two consonants and no two vowels are adjacent on the skeleton, as they are always separated by a position of the opposite type. (21) gives the four cluster types of (5) in a strict CV model.

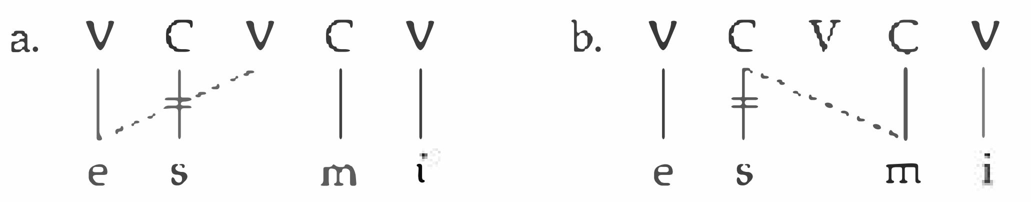
(21) *The strict CV representation of vowel and consonant clusters*



Recall the discussion in §3.2: the CV skeleton contains redundant information that can be read off higher prosodic structures. But this only holds if there is any higher prosodic structure. In fact, strict CV analyses generally do not call for the recognition of such structure, and certainly not of any further syllabic constituency.

The two cases of compensatory lengthening in Greek – Proto-Greek [esmi] > Attic [eːmi] and Aeolic [emːi] – are illustrated in (22).

(22) *Compensatory lengthening in a strict CV skeleton*

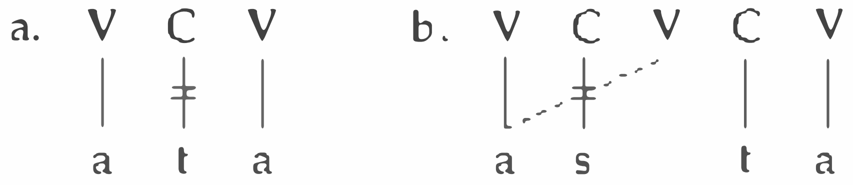


With the delinking of the [s], two skeletal slots are opened up for association: both the consonantal slot of the delinked coda and the vocalic slot enclosed within the original [sm] cluster. The choice is apparently controlled by a dialect-specific parameter, just as in any other theory of the skeleton.

The mora of moraic theories is an independent entity, which can be assigned to segments as the analyst needs it – it is only empirical considerations that stop them from assigning a mora to onsets. In the strict CV approach, moras are an inevitable consequence of the way the skeleton is built up (Scheer and Szigetvári 2005). A coda consonant is moraic because it is followed by an unpronounced vocalic slot. That is, the moraicness of the coda is only apparent: it is the following vocalic slot that carries weight. In this view, only vocalic slots are moraic. The loss of an intervocalic consonant does not free any "buried" empty vocalic slot, as (23a) shows. The loss of a preconsonantal consonant, on the other hand, makes an otherwise unreachable vocalic slot available as a target for spreading, as in (23b).

[7] Note that "empty" and "unpronounced" are not equivalent. In a privative feature framework, empty skeletal positions may be phonetically interpreted, as a sound maximally lacking any contrast, like e.g. [ə] or [ʔ]. Some empty skeletal positions may thus be pronounced; others may remain unpronounced if they satisfy certain conditions. See Kaye *et al.* (1985, 1990), Charette (1991), and Harris (1994) for details.

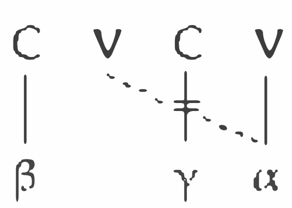
(23) *The loss of an intervocalic and a preconsonantal consonant*



The weight of closed syllables containing a short vowel is language-specific. For example, in English and Cairene Arabic such syllables count as heavy, while in Khalkha Mongolian and Yidin[y] they count as light (Zec 1995: 89). This parametric variation is trivially encoded in moraic frameworks: coda consonants are sometimes assigned a mora, and sometimes not. In the strict CV model, the same fact is encoded by parameterizing whether or not an unpronounced vocalic slot is counted by the relevant process. Crucially, however, since the shape of the skeleton is constant – it is always a strict alternation of vocalic and consonantal positions – the uncounted vocalic slot is there even when it is not counted by a certain process (say, stress assignment). One prediction running counter to those of Moraic Theory follows from this fact: compensatory lengthening of a vowel should be possible even if coda consonants are not moraic in a language. Kavitskaya (2002) claims that at least two languages, Piro and Ngajan, are exactly like this. One could claim that the mora associated with the coda in such languages is one which does not contribute to weight but does allow compensatory lengthening (as an anonymous reviewer points out). This then means that there are two types of mora, a "weight mora" and a "compensatory lengthening mora." The strict CV model predicts exactly this: there are two types of Vs. Pronounced Vs obligatorily contribute to weight, unpronounced ones are parameterizable.

In the strict CV framework, when an empty vocalic position enclosed between two consonants is "unearthed," compensatory lengthening may ensue, irrespective of whether this target of spreading is to the left or to the right of the vowel to lengthen. That is, the loss of an onset consonant may result in the lengthening of the vowel that follows it, as (24) shows.

(24) *Onset loss yielding compensatory lengthening*



The theory dictates that this option is available only for postconsonantal onsets, not for intervocalic ones (see (23a)). Confirmation of this prediction comes from southwestern dialects of Finnish where gradated [k] is lost, with compensatory lengthening. The data in (25) come from Kiparsky (2008); doubled vowels are long, as in standard Finnish orthography.

(25) *Compensatory lengthening in southwestern Finnish dialects*

input	*SW dialect*	*standard*	
/jalka-t/	jalaat	jalat	'legs'
/nælæ-n/	nælææn	næljæn	'hunger-GEN'
/halko-t/	haloot	halvot	'logs'

In the Finnish data, the lost consonant is always preceded by another consonant, and is never intervocalic. This is important, because the empty vocalic slot is available *between* two consonants, but not after a vowel, as (23a) shows.

Samothraki Greek exhibits a similar type of compensatory lengthening. In this dialect, pre-vocalic [r] is lost, and is only retained in preconsonantal position – a mirror image of the distribution in non-rhotic dialects of English. The loss of postconsonantal [r] is illustrated in (26a). Intervocalic [r] is lost without trace, as in (26b), as expected. (The data are from Topintzi 2006, who attributes them to Katsanis 1996.)

(26) *Loss of /r/ in Samothraki Greek*

	input	*output*	
a.	/'protos/	['po:tus]	'first'
	/'frena/	['fe:na]	'brakes'
	/'xroma/	['xo:ma]	'color'
	/'ɣrafo/	['ɣa:fu]	'I write'
b.	/'leftirus/	['leftius]	'free'
	/va'reʎ/	[va'eʎ]	'barrel'
	/'mera/	['mia]	'day'
	/'skara/	['skaa]	'grill'

To provide the missing mora, Hayes (1989: 283) has to hypothesize an epenthesis stage before the loss of the [r]: ['frena] > [fe'rena] > [fe'ena] > ['fe:na]. The strict CV analysis is rather similar, though the only difference is a very important one: the slot of the "epenthetic" vowel is lexically available, since any two consonants are always separated by such an empty slot. The relevance of this difference between the two analyses is that there is no empirical evidence for epenthesis in this case. Furthermore, this assumption creates a paradox in the ordering of the historical events (Kavitskaya 2002: 98), and Hayes's hypothesis is therefore not plausible. The strict CV skeleton, however, has a vocalic position to which the vowel can spread without any extra process.

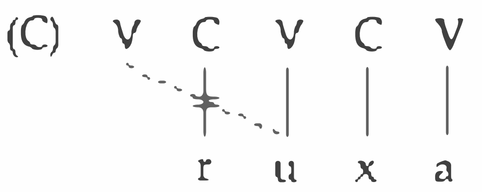
But even the strict CV model seems to be taken by surprise when it comes to the loss of word-initial [r]: this loss also triggers compensatory lengthening, as the words in (27) show.

(27) *Loss of /r/ in Samothraki Greek*

input	*output*	
/'ruxa/	['u:xa]	'clothes'
/'rema/	['e:ma]	'stream'

Scheer and Ségéral (2001) introduce the notion of "coda mirror." The coda is a typical lenition environment, being the position in the word that is not followed by a vowel, i.e. a preconsonantal or word-final position. The coda mirror is the opposite case: it is the position not preceded by a vowel, i.e. a postconsonantal or word-initial position, which is claimed to be the strong position, where lenition is unlikely. Scheer and Ségéral's theory is built on the strict CV skeleton: for them, "not followed by a vowel" means followed by an unpronounced vowel, and "not preceded by a vowel" means preceded by an unpronounced vowel. It is this empty vocalic position that causes the lengthening of the vowel in the Finnish and the Greek data discussed here. Not only postconsonantal, but also word-initial consonants are assumed to be preceded by an empty vowel, a proposal first argued for by Lowenstamm (1999). Accordingly, the loss of a word-initial consonant may also cause compensatory lengthening, as shown in (28).

(28) *Word-initial consonant loss yielding compensatory lengthening*



Since consonant loss is not common in the coda mirror position, compensatory lengthening is also rare in this environment. The peculiarity of Samothraki Greek, then, is that it unexpectedly exhibits [r] loss in the coda mirror position and not in the expected coda position. The ensuing compensatory lengthening is a consequence predicted by the strict CV skeleton.

6 Conclusion

The phonological skeleton evolved as a result of the autosegmental idea taken to its logical conclusion: segments, after autosegmentalizion of all their melodic content, leave behind "traces" that encode their relative temporal order. The debates concerning the phonological skeleton are (i) whether skeletal slots specify any phonetic property (consonantalness *vs.* vocalicness) or none, i.e. whether the skeleton contains Cs and Vs or uniform Xs; and (ii) whether the mora can replace skeletal slots, with moraless consonants linked directly to the syllable node. This chapter has argued that skeletal slots are Cs and Vs, not merely Xs, but there is no further prosodic constituency (e.g. onsets, nuclei, or syllables). Furthermore, it has been claimed that the mora is not an independent element of the representation, but a consequence of parametrical settings on vocalic skeletal slots: pronounced V slots are universally moraic; unpronounced ones are moraic in some, but not in other languages. Consonants, on the other hand, are never moraic.

ACKNOWLEDGMENTS

I acknowledge useful comments and advice from two anonymous reviewers, Marc van Oostendorp, Ádám Nádasdy, Péter Siptár, and László Varga. I thank them all. Remaining errors are mine.

55 Onsets

NINA TOPINTZI

Onsets are obligatory in the most typical syllable found cross-linguistically, the consonant–vowel (CV) syllable, and as such, are found ubiquitously across languages. This chapter explores various aspects of onsets, covering much of their structural, segmental, and suprasegmental behavior. Using empirical data as a point of departure, various stances and theoretical views will be addressed on a number of issues. These include the presence of the onset in unmarked CV syllables (§1), onset clusters and the role of sonority in their formation (§2), and the structure and representation of the onset within the syllable (§3). The focus will then shift to the onset's often disregarded role in suprasegmental phonology with reference to several weight-based phenomena (§4). The chapter closes by briefly reviewing approaches that tackle the onset–coda asymmetry (§5).

1 Onsets in unmarked syllables

Most phonologists agree that the most unmarked syllable universally is a CV syllable (Jakobson 1962: 526; CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE), i.e. a syllable that consists of a nucleus and a preceding consonant, the onset. When the onset consists of a single segment then it is simplex; when it contains a consonant cluster then it is complex. The present section deals with the former.

Evidence for the unmarkedness of CV syllables comes from a variety of sources. First, CV syllables exist in all languages (unlike other syllable types, which only occur in some) and indeed there may be languages whose sole syllable type is CV, e.g. Hua (Blevins 1995) or Senoufo (Zec 2007). While it is the case that every language will have CV syllables, it is not equally true that every syllable in a language will have an onset. Unlike Totonak and Dakota (and of course Hua and Senoufo), where onsets are obligatory, in many other languages they are optional, e.g. Greek, English, and Fijian (Zec 2007).

The naturalness of CV syllables is also indicated by the fact that they are the first syllables produced by children during the initial stages of language acquisition (CHAPTER 101: THE INTERPRETATION OF PHONOLOGICAL PATTERNS IN FIRST LANGUAGE ACQUISITION).

(1) *CV outputs by a Dutch child at age 1;5,2* (Levelt *et al.* 2000)

/pus/	[pu]	'cat'
/klar/	[ka]	'finished'
/oto/	[toto]	'car'
/api/	[tapi]	'monkey'

As Buckley (2003) shows, however, children's initial productions may also involve VC syllables. Importantly though, these never seem to arise independently, i.e. without CV syllables also being present in the language.

The dominance of CV syllables is seemingly contradicted by Arrernte (also known as Aranda; Breen and Pensalfini 1999), Barra Gaelic, and Kunjen – especially its dialect Oykangand – whose syllables are claimed to be of the VC type (with extra codas if need be) and not of the CV type (Blevins 1995 and references therein). These cases are rather weak, however, since for the most part alternative explanations that actually make use of the CV syllable type have been proposed. For instance, Blevins (1995: 230–231) observes that in Kunjen, aspiration only appears prevocalically. In principle, this could be understood as occurring either syllable-initially or syllable-finally, but empirical facts suggest that only the former analysis is viable. If aspiration were to apply syllable-finally, then it should also emerge word-finally, something that never occurs. The facts are thus only compatible with syllabification in the onset. Perhaps the strongest argument in favor of the existence of CV syllables, though, comes from a rule of utterance-initial reduction that deletes initial onsetless syllables, presumably as a means to achieve more well-formed onsetful syllables, as in (2).

(2) *Oykangand reduction in utterance-initial position* (Sommer 1981: 240)

unreduced	*reduced*		*deleted material*
igigun	gigun	'keeps going'	[i]
amamaŋ	mamaŋ	'mother (voc)'	[a]
uŋgul	gul	'there'	[uŋ]

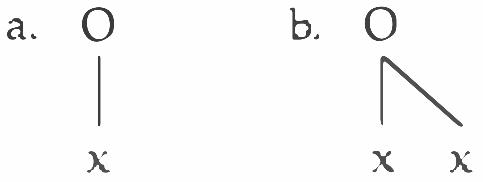
2 Complex onsets

As well as simplex onsets, onsets can also be complex, usually composed of two segments and hence considered maximally binary (Blevins 1995; Morelli 1999; Baertsch 2002; among many others), as in Greek ['tre.xo] 'I run', ['pe.tra] 'stone', ['vli.ma] 'missile', or ['tu.vlo] 'brick'. Longer sequences such as [str] or [spl] are also commonly allowed, as in English [streɪ] *stray* or [splɪt] *split*, but usually these are not considered to exceed the binarity maximum, as there is evidence that the [s] here is not part of the onset (see CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS).

Yet in some work, the existence of complex clusters is denied altogether. For example, Lowenstamm (1996) and Scheer (2004) claim that all surface syllable types are subsumed under the CV matrix with the addition of empty positions, e.g. English [dØ][ri][mØ] *dream*. Duanmu (2008) interprets complex onsets such as *pl, fr, kl, kr* as complex sounds under a single timing slot, on the assumption that such sounds are possible if the articulatory gestures of two sounds can overlap (CHAPTER 54: THE SKELETON).

Most phonological models, however, allow complex onsets and provide relevant analyses to account for them. In government phonology (van der Hulst and Ritter 1999; Kaye 2000), for example, binarity is explicitly integrated within the model through the Binarity Theorem (Kaye 1990, 2000), which states that constituents cannot dominate more than two positions, so that onsets may either exhibit single association to a skeletal point (3a) or be maximally binary branching (3b).

(3) *Onsets within government phonology* (van der Hulst and Ritter 1999)



More commonly, the binarity of the onset and the combinatorial possibilities among segments within it are attributed to co-occurrence restrictions between adjacent segments (Clements 1990; Zec 2007: 164). In fact, a number of proposals subscribe to the idea that onset syllabification – like the other components of the syllable – is governed by sonority considerations (e.g. Hooper 1976; Steriade 1982; Selkirk 1984; Clements 1990; among others). Briefly, in this approach, more sonorous segments are preferred toward the center of the syllable, whereas less sonorous ones make better syllable margins, i.e. onsets and codas (Clements 1990).[1] Despite certain objections to sonority (see below; and also Parker 2002; CHAPTER 49: SONORITY), its importance for phonological theory is generally acknowledged (Steriade 1982; Selkirk 1984; Clements 1990; Rice 1992; Kenstowicz 1994; Zec 1995). One fairly standard version of the sonority hierarchy is shown below (after Clements 1990).

(4) *Sonority scale* (>= more sonorous than)

vowels > glides > liquids > nasals > obstruents[2]

One principle that makes use of this scale is the Sonority Sequencing Principle (SSP; Clements 1990), which states that the sonority profile of a syllable must be such that sonority rises sharply toward the peak and gradually lowers after it.

Evidence for the SSP comes from various sources. One example is Imdlawn Tashlhiyt Berber (e.g. Dell and Elmedlaoui 1985), known for its long sequences of consonants. Indeed, there may be words that consist of no vowel at all, e.g. [tftkt] 'you suffered a sprain'. These seemingly highly complicated strings can, however, be easily analyzed if one utilizes the SSP, plus a few other assumptions. Bearing in mind that in Imdlawn Tashlhiyt Berber: (i) any segment can be a syllable nucleus, (ii) onsetless syllables are only allowed word-initially, (iii) codas may appear word-finally, and (iv) complex onsets are banned, the following examples are syllabified in such a way that the nucleus of each syllable comprises a sonority peak.

1 For more detailed discussion on the Sonority Sequencing Principle and the Minimal Sonority Distance, see CHAPTER 49: SONORITY.

2 For a discussion of other variants see Parker (2002).

(5) *Imdlawn Tashlhiyt Berber syllabification*

/ut-x-k/	[u.tχ̩k]	'I struck you'
/rks-x/	[r̩.ks̩x]	'I hid'
/t-msx-t/	[tm̩.sχ̩ːt]	'you have transformed'

Additional evidence for the SSP comes from onset cluster simplification processes, as in Sanskrit (see Steriade 1988 and CHAPTER 119: REDUPLICATION IN SANSKRIT for relevant data) or Attic Greek (Steriade 1982), whereby C_1C_2 onset strings are reduced to simplex onsets in reduplication. Notably, the surviving C is the least sonorous one, resulting in a more abruptly rising slope toward the nucleus. Similar facts arise in child speech (CHAPTER 101: THE INTERPRETATION OF PHONOLOGICAL PATTERNS IN FIRST LANGUAGE ACQUISITION), as is evident in the outputs of an English-learning girl aged 2;9 reported on by Gnanadesikan (1995).

(6) *Cluster simplification to the least sonorous consonant*

clean	[kin]
snow	[so]
friend	[fɛn]
sky	[kaj][3]

Not all languages admit the same inventory of complex onsets. It is generally held to be true that the larger the distance in sonority between C_1 and C_2, the more well-formed the onset cluster. Thus, obstruent (O) + glide (G) clusters are highly favored, followed by O + liquid (L), O + nasal (N), and so on. Onset clusters preferably satisfy a *Minimal Sonority Distance* restriction in order to be allowed in a language (Vennemann 1972; Hooper 1976; Steriade 1982; Selkirk 1984; Baertsch 2002). In Bulgarian, no distance at all is necessary, thus all of OL, NL, ON, LL, NN, and OO clusters are admitted (Zec 2007); in other languages, different degrees of Minimal Sonority Distance are applicable: in Chuckchee, only OL, NL, and ON clusters are well-formed (Levin 1985); in Spanish, only OL onset clusters (Baertsch 2002); and in Huariapano (Parker 1994), only OG clusters.

In a sense, Minimal Sonority Distance generates the expectation that if a language allows C_1C_2 onset clusters where C_2 is of sonority X, then it should also admit onset clusters with a C_2 whose sonority is higher than X. But as we have just seen, this is not always the case: e.g. Spanish, which bans *OG clusters. To make things worse, many languages also allow sonority plateaus and even reversals. For example, Greek plateaus like [kt], [fθ], and [vɣ] are tolerated, as in [ktirio] 'building', [akti] 'coast', [fθiro] 'impair', [afθonos] 'abundant', [vɣazo] 'remove', [avɣo] 'egg'. Russian also permits reversals, e.g. [rtut] 'mercury' and [lvov] (city name) (Gouskova 2001), which, however, are often considered not to be complex

[3] Under the assumption that [sk] is a complex onset, the fricative [s] must be more sonorous than the stop [k] (cf. Dell and Eldmedlaoui 1985; de Lacy 2006; among others). In the sonority hierarchy I have adopted here, this distinction is not made. On the other hand, a difference in sonority of fricatives as opposed to stops would yield incorrect results in other accounts, e.g. Kreitman (2006). If [s], however, is not part of the onset (cf. CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS), this issue does not arise in the first place.

onsets; rather, the segment(s) violating the SSP can be realized as syllabic, e.g. [r̩.tut], or even extrasyllabic, attaching to some higher level of prosodic structure, e.g. the foot or prosodic word (see CHAPTER 40: THE FOOT and CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS for more discussion). Such data partly explain why the validity of sonority is sometimes contested.

Other objections to sonority include the lack of a clear way to phonetically define and measure it, and its inability to explain the frequent ban on sequences of the type *ji*, *wu*, *bw*, or *dl* (quite likely an Obligatory Contour Principle effect). Some researchers have therefore gone as far as to discard sonority. For example, Ohala (1990) and Harris (2006) claim that attested sequences in languages can be best captured through the perceptual distance between neighboring sounds in terms of a number of different acoustic properties, including amplitude, periodicity, spectral shape, and fundamental frequency (F0) (Ohala 1990: 334). As Ohala (1990: 334–335) admits, however, this view explains which sequences should be found in languages, but does not explain how and why they are grouped into syllables.

This is perhaps why – despite criticism – sonority still remains highly influential in current work on syllabification (cf. Baertsch 2002; Gouskova 2004; Zec 2007; among many others). But there is yet another possibility. Rather than completely endorsing or abandoning sonority, we can accept it, but loosen somewhat the predictions and generalizations it makes. Berent *et al.* (2007) put forward a proposal along these lines. In particular, they suggest a more flexible version of sonority-based generalizations regarding the profile of onset clusters. They state that:

> In any given language:
> (a) The presence of a small sonority rise in the onset implies that of a large one.
> (b) The presence of a sonority plateau in the onset implies that of some sonority rise.
> (c) The presence of a sonority fall in the onset implies that of a plateau. (Berent *et al.* 2007: 594)[4]

On this view, Spanish is no longer problematic (since OL clusters involve high sonority, there is no reason that there should be OG clusters too), and the plateaus of Greek are expected, given that it also has sonority rises, while Russian has falls only because it also has plateaus. More generally, Berent *et al.* (2007) test the statements above against the sample of Greenberg (1978) and find that they overwhelmingly hold true typologically.

Other typological surveys on onset clusters also tend to employ sonority, usually with some modification or enrichment of the theory. For instance, Morelli (2003) investigates the patterns of obstruent onset clusters and proposes implicational relationships between them, as schematized in (7), where fricative + stop (FT) clusters are the least marked, TT the most marked, and TF somewhere in between. FF clusters merely imply the existence of FT, without further implicational relationship with other clusters.

[4] Berent *et al.* (2007) seem to adopt Greenberg's (1978) characterization of small and high sonority. High-sonority rises are OL clusters; low-sonority rises are NL and ON; plateaus are OO, and falls are LN and NO clusters.

(7) *Implicational relationships between obstruent onset clusters* (Morelli 2003)[5]

$$\begin{array}{r} TT \\ \Downarrow \\ TF \\ \Downarrow \\ FF \Rightarrow FT \end{array}$$

Kreitman (2006) focuses on sonorant (S) and obstruent (O) clusters and proposes the implicational hierarchy SO ⇒ SS ⇒ OO ⇒ OS, with OS clusters being the most unmarked, and SO ones the most marked. These are respectively the most and least favored clusters as far as sonority is concerned. SS and OO clusters involve sonority plateaus, but do not randomly appear in languages as one would expect; instead, the presence of SS systematically implies OO. To account for this fact, Kreitman points to the increased salience of obstruents as opposed to sonorants (cf. Ohala 1983: 193). Since obstruents are considered to carry more information, due to their acoustic form, they are easier to distinguish from non-obstruents. Thus, combinations between obstruents should be perceptually favored over those between sonorants.

What all these studies highlight is that removing sonority from the equation is not useful; rather it seems that consideration of other factors, e.g. the role of perceptual salience, may enhance the role of sonority conceptually and improve its empirical coverage.

3 The status of the onset within the syllable

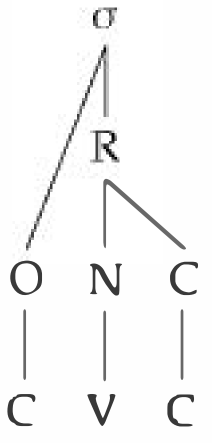
Moving away from the principles that regulate onset syllabification, let us consider the representation of the onset within the syllable. Various models of the syllable have been proposed throughout the years (see Blevins 1995; van der Hulst and Ritter 1999 for overviews; see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE), which due to lack of space will not be discussed here in detail. Nonetheless, reference will be made to those that are especially relevant to onsets. Broadly speaking, we can identify two major theories: (i) those that distinguish between onsets and rimes (Pike and Pike 1947; Kuryłowicz 1948; Fudge 1969; Selkirk 1982; Levin 1985; Kaye *et al.* 1990; Blevins 1995), and (ii) moraic models that do away with the rime, i.e. the nucleus + coda string, as a separate constituent (Hyman 1985; Hayes 1989; Morén 2001).

3.1 *Onset–rime models*

No single version of the onset–rime model is available, and there are significant divergences between models. For instance, Fudge (1969) accepts the syllable as a constituent, whereas Kaye *et al.* (1990) explicitly do away with it, but nonetheless treat the onset and rime as "an inseparable package" (van der Hulst and Ritter 1999: 23).

[5] Inclusion of sC clusters among the FT clusters and their treatment as onset clusters, at least word-initially, is quite problematic for Morelli, however, in light of evidence showing how sC clusters differ from true branching onsets in various ways (see CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS).

(8) *A typical representation of the onset–rime model* (Blevins 1995)



Specific syllable models make different claims about constituenthood. For instance, Blevins (1995) essentially only recognizes the rimal constituent and sees no strong argument for an onset constituent – and for that matter, a coda constituent. For government phonology (van der Hulst and Ritter 1999; Kaye 2000), on the other hand, onsets, nuclei, and rimes are constituents.

The basic argument for the rime hinges on the idea that co-occurrence restrictions are always more likely to occur between nuclei and codas, rather than between either onsets and nuclei or onsets and codas. The strongest argument for the rime though comes from weight facts (Blevins 1995; van der Hulst and Ritter 1999: 23). Consider stress, for example. As is well known, in many languages heavy syllables attract stress in contrast to light syllables (e.g. Hopi; Jeanne 1982). Importantly, heaviness implies a binary rime, $[VV]_R$ or $[VC]_R$, or both, depending on the language. Since the presence of onsets is disregarded in such an evaluation, it must mean that rimes form a constituent that clearly excludes the onset.

Nonetheless, each of the arguments in support of the rime has been challenged. Davis (1985) attacks the reliability of co-occurrence and phonotactic restrictions, given that those are not exclusive to nuclei and codas, but are also found between onsets and nuclei or onsets and codas. For instance, in Korean (Cho 1967), fronted vowels do not appear after labial onsets, while in Yindjibarndi (Wordick 1982), the presence of /r/ in both the onset and a coda of a syllable is banned. Another objection to the onset–rime distinction is found in Yip (2003), who claims that if it were valid, then the boundary between the two constituents should be clear and consistent, and thus segments should uniformly belong to either the onset or the rime, but not to both. English and Mandarin pre-nuclear glides, however, behave sometimes like onsets and sometimes as rimes. As for the weight effects induced by the rime, it is possible to capture them in a different manner without reference to the rime per se. This is what moraic theory does, as we will see in a moment.

Before moving on, though, it is notable that the onset–rime debate is also predominant in psycholinguistic studies that explore the onset–rime boundary in terms of implicit and explicit, i.e. non-conscious *vs.* conscious, phonological awareness. Work by Treiman (1986 and references therein) on various segmentation and substitution tasks in both adults and children suggests that there is a closer connection between VC than CV, thus offering support for the onset–rime boundary. In the same vein, Uhry and Ehri (1999) show that English-speaking kindergarten children preferred to keep VC, rather than CV, intact during segmentation. The opposite result, however, was found by Lewkowicz and Low (1979).

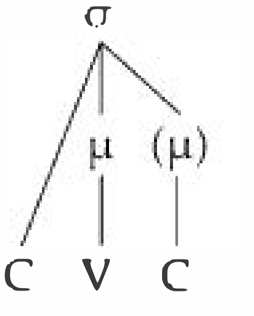
More recently, Geudens and Sandra (2003), in a series of four experiments on Dutch-speaking pre-readers and beginning readers, found no support for the onset–rime boundary. Importantly, they applied strict criteria regarding the selection of items under investigation, such that they could control for distributional and sonority effects. In particular, they used items of different sonority equally often and found that syllables with obstruents were easier to perceive and segment than syllables with sonorants (2003: 172); see also CHAPTER 8: SONORANTS. The influence of sonority may in fact explain some of the findings of previous studies, such as Schreuder and van Bon's (1989) finding that Dutch first-graders break up a CV string more easily than a VC one. In their study, sonorants were mainly used, but sonorants undergo more vocalization in coda rather than onset position, possibly explaining why children find it harder to break them up in a VC environment rather than a CV one.

All in all, psycholinguistic experimentation also reflects contradictory evidence with regard to the onset–rime boundary debate. What this absence of consensus at the very least suggests is that the boundary dispute is well grounded.

3.2 *Moraic model*

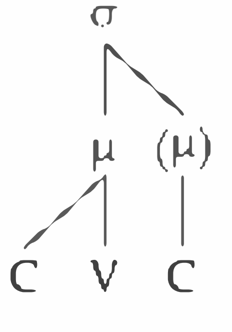
A common response to criticism against the rime has been to dispense with it as a constituent altogether and to replace it with the concept of mora. In moraic theory (Hyman 1985; Hayes 1989), only segments under – what used to be – the rime node may bear moras. Since the latter are needed independently to account for a number of phenomena related to syllable weight, the natural conclusion has been to structurally eliminate the rime from representations. The representation of a CVC syllable in this model is presented next (compare with (8)). Note that the bracket around the mora of the coda indicates that this may be moraic or not on a language-specific basis (cf. Weight-by-Position; Hayes 1989).

(9) *Moraic model* (Hayes 1989)



Within moraic theory, there is no definite agreement as to where exactly the onset associates to. According to Hayes, it directly adjoins to the syllable as in (9). For Hyman (1985), Itô (1989), and Buckley (1992), though, it attaches to the following mora, as in (10).

(10) *Onset association* (Hyman 1985)



In both these versions of moraic theory, the onset is not recognized as a constituent. This is much more clearly shown in (9), where it directly links to the syllable node, but it is visible even in (10), since the mora is shared between the onset and the nucleus.

While Hayes's representation is the most widely employed, there is nevertheless some evidence for (10). Katada (1990) describes the Japanese chain language game *shiritori*, in which players say a word that must begin with the final mora of the previous player's word. If the word ends in a CV syllable, as in [tu.ba.me] 'swallow', then the next word can be something like [me.da.ka] 'killfish'. If the word ends in a long vowel, then the last mora is the second half of the vowel, to the exclusion of the first half, as well as the onset. Thus [bu.doo] 'grapes' can be followed by [o.ri.ga.mi] 'folding paper' but not by *[doo.bu.tu] 'animal'. Importantly, a word like [riN.go] 'apple' (where N is a moraic nasal) cannot be followed by *[o.ri.ga.mi], but must begin with [go]. This is easily explained if the final mora in [go] also associates to the onset, as claimed by (10), rather than linking directly to the syllable (9). The game ends if the final mora cannot form a proper onset, as happens when it is a moraic nasal, e.g. [ki.riN] 'giraffe'.

Since the moraic model identifies no rime constituent, it bypasses the problems faced by the onset–rime model with regard to the extension of co-occurrence restrictions beyond the rimal node, as well as the absence of a clear boundary between the onset and the rime. Superficially, however, it does equally well as the onset–rime model in accounting for syllable weight, simply by stating or – more accurately, stipulating – that moras are strictly limited to nuclei and codas. But even this assertion has been contested. Work by Hajek and Goedemans (2003), Gordon (2005), and Topintzi (2006, 2010) has shown that there is good evidence for the existence of onset weight. We explore this issue next.

4 The suprasegmental phonology of onsets

Contrary to popular belief, onsets do seem to be prosodically active, albeit in a limited number of languages. Their effects become evident in a range of phenomena, including stress, compensatory lengthening, gemination, word minimality, and tone. This section examines the relevant data and theoretical issues that stem from them.

4.1 Stress

Of all these phenomena, onset-sensitive stress has received the most extensive attention. In brief, three patterns are attested: (i) onset effects due to the presence of an onset, (ii) onset effects due to the quality of an onset, and (iii) patterns (i) and (ii) combined.

Starting from (i), we find that in a number of languages onsetful syllables attract stress more than onsetless ones. Languages of this type include Arrernte (Strehlow 1944), Alyawarra (Yallop 1977), and other Australian languages, such as Lamalama, Mbabaram, Umbuygamu, Umbindhamu, Linngithig, Uradhi, Kuku-Thaypan, Kaytetj, and Agwamin (most of them are Cape York and Arandic languages; see Davis 1985, Goedemans 1998, and Blevins 2001 for more details). Beyond Australia, this pattern is attested in unrelated languages of North and

South America, Iowa-Oto (Robinson 1975), Banawá (Buller *et al.* 1993), and Juma (Abrahamson and Abrahamson 1984).[6]

In Arrernte, C-initial words receive stress on the first syllable (11a), but V-initial ones have stress on the second syllable (11b). One exception is disyllabic words, where stress is word-initial regardless of whether the word begins with a vowel or a consonant (11c). This is probably attributed to Arrernte's avoidance of final stress or preference for creating binary feet, as the lack of final secondary stress in words like *[a('ralka)(ˌma)] reveals.

(11) *Arrernte stress* (Strehlow 1944)

a. *consonant-initial words of three or more syllables*

'ra:tama	'to emerge'
'kutunˌgula	'ceremonial assistant'
'lelanˌtinama	'to walk along'

b. *vowel-initial words of three or more syllables*

er'guma	'to seize'
a'ralkama	'to yawn'
u'lambuˌlamba	'water-fowl'

c. *words of two syllables (C- or V- initial)*

'ilba	'ear'
'a:twa	'man'
'kala	'already'
'gura	'bandicoot'

A common denominator is that stress may shift – albeit very locally – to dock on a syllable with an onset. This is not the only possibility, however. In other languages, the stress location remains constant, but if it falls on an onsetless syllable, this acquires an onset. Consider Dutch (Booij 1995: 65). In instances of hiatus where the first vowel is /a/, a glottal stop is inserted before the second vowel, but only if this is stressed by the normal algorithm, e.g. /paɛlja/ → [pa.'ʔɛl.ja] 'paella', /aɔrta/ → [a.'ʔɔr.ta] 'aorta'. Otherwise, no insertion is applicable: /xaɔs/ → ['xa:.ɔs] 'chaos', /farao/ → ['fa:.ra.o:] 'Pharaoh'. Most analyses view this as a prominence (Smith 2005) or alignment (Goedemans 1998; Topintzi 2010) effect.

In yet other languages, the mere presence of an onset is not the issue (see Topintzi 2010: 48 for details on Karo); it is the quality of the onset that matters. This is the case in Karo (Gabas 1999) and possibly Arabela (Payne and Rich 1988). In the former, stress falls on the final syllable, except when the penultimate syllable is a better stress bearer. Better stress bearers are, in order of priority, a syllable with (i) a high tone, (ii) a nasal vowel, or (iii) a voiceless or sonorant onset. When (i) and (ii) are irrelevant, (iii) is taken into consideration and stress falls on the final syllable if the onset is a sonorant (12a) or voiceless (12b) or a voiced obstruent preceded by another voiced obstruent onset (12c).

[6] However, the case of Juma should be treated with caution, because only a handful of data are available and because it is possible to re-analyze it. In particular, words like [pe'jikɔ'pia] 'bird (sp.)' may be argued to contain a final diphthong, i.e. [pe.'ji.kɔ.'pia], rather than a sequence of heterosyllabic vowels, i.e. [pe.'ji.kɔ.'pi.a], which would lend support to the onset effect. Interestingly, Juma is the sole language where the effect appears at the right edge of the word and not at the left. This may perhaps be an additional indication that it is not truly onset-sensitive.

(12) *Karo final stress and onset voicing* (Gabas 1999: 14, 39–41)[7]

a. *final syllable with sonorant onset*
kɔ'jɔ 'crab'
ja'ʔ'mᵇɔ 'yam (sp.)'
kiɾi'wɛp˺ 'butterfly'

b. *final syllable with voiceless onset*
pa'kːɔ 'fontanel'
maʔ'pɛ 'gourd'
kuɾuʔ'cu 'saliva'

c. *final and prefinal syllables with voiced obstruent onsets*
kiɾi'bɔp˺ 'frog (sp.)'
miɾi'ɾij 'toad (sp.)'

Stress, however, falls on the penult if the final syllable has a voiced obstruent onset and the previous one does not, indicating the stress-attracting nature of the voiceless obstruents and the sonorants in this language.

(13) *Karo penult stress and onset voicing* (Gabas 1999: 14, 39–41)

'jaba	'rodent (sp.)'	'pibɛʔ	'foot'
'wɛɾɛ	'frog'	'kaɾo	'macaw'
'mɔga	'mouse'	iʔ'cɔgɔ	'quati (sp.)'

Nonetheless, other cases where stress is seemingly sensitive to the onset quality have been shown to be much less robust or even wrong. One example of the latter arises in Mathimathi, where stress is normally word-initial unless attracted by the second syllable when it begins with a coronal onset. Davis (1988) attributes this to genuine onset-sensitivity. Gahl (1996), on the other hand, shows that another account is more plausible, namely one that considers Mathimathi stress to be morphologically based. She claims that stress is located on the last stem syllable of the word (or better, last stem vowel). Stems are generally monosyllabic or bisyllabic. It so happens that apparent stress shift appears on stems of the type $C_1VC_2VC_3$, where the medial consonant is invariably coronal (Gahl 1996: 329). Evidence for Gahl's analysis comes from monosyllabic C_1VC_2 stems, where C_2 is again coronal. Addition of a suffix to such stems renders C_2 an onset of the second syllable. If Davis were right, then stress here should also be peninitial. However, it is initial, as predicted by Gahl's morphological account; cf. peninitial stress in bisyllabic stems such as [ˌgu.'ra.g+i] 'sand' *vs.* initial stress in monosyllabic stems such as ['wa.d̪+a.d̪+a] 'to come'. In both cases, C_2 is coronal. Thus, re-examination of the facts in light of morphological considerations may reveal the lack of true onset-sensitive effects (see also Nanni 1977 on the English suffix *-ative* or Davis *et al.* 1987 on Italian infinitives).

A final pattern that emerges involves the combination of true onset-presence and onset-quality effects. A well-known example is Pirahã (Everett and Everett 1984; Everett 1988), an Amazonian language where codas are banned. Onsetless light syllables (V) do not occur, and stress may only dock on one of the three final

[7] Note that [ɾ] in Karo behaves like [d], which is otherwise missing from the inventory (Gabas 1999: 12).

syllables of the word. The weight and stress hierarchy the language motivates is: PVV > BVV > VV > PV > BV (P = voiceless; B = voiced). In particular, VV nuclei attract stress more than V ones (14c), and voiceless onsets have the same effect as opposed to voiced ones (14a) and (14d). Crucially, and unlike Karo, Pirahã 'voiced' consonants also include sonorants, which appear as allophones of voiced stops, e.g. /b/ may surface as [b], [m], or the bilabial trill [ʙ]. Consequently, in this language, only voiceless obstruents attract stress. Between equally heavy syllables in terms of nucleic weight, onsetful ones attract stress over onsetless (14b). Finally, if there is more than one equal contender for stress, the rightmost one receives it (14e).

(14) *Pirahã examples* (Everett and Everett 1984; Everett 1988)

a.	PVV > BVV			
	'káo.bá.bai	'almost fell'		(1988: 239)
	pa.'hai.bií	'proper name'		(1984: 708)
b.	BVV > VV			
	'bii.oá.ii	'tired (lit.: being without blood)'		(Everett, p.c.)
	poo.'gáí.hi.aí	'banana'		(1984: 709)
c.	VV > PV			
	pia.hao.gi.so.'ai.pi	'cooking banana'		(1984: 710)
d.	PV > BV			
	ti.'po.gi	'species of bird'		(1984: 710)
	'ʔí.ʙo.gi	'milk'		(Everett, p.c.)
e.	*rightmost heaviest stress*			
	ho.áo.'íi	'shotgun'	*ho.'áo.íi	(1984: 710)
	ti.'po.gi	'species of bird'	*'ti.po.gi	(1984: 710)
	paó.hoa.'hai	'anaconda'	*paó.'hoa.hai *'paó.hoa.hai	(1984: 707)

What is common to all these examples is that the voiceless obstruent onsets systematically attract stress, contrary to the voiced obstruent ones. Various analyses have been offered to account for the Pirahã facts (and many fewer for Karo). These are examined in Topintzi (2010). Some make use of the increased prominence of onsetful syllables and voiceless onsets over onsetless syllables and voiced onsets respectively (Everett and Everett 1984; Hayes 1995; Goedemans 1998; Smith 2005). Some treat certain onsets as weightful and some as weightless (Topintzi 2006, 2010), and others offer a mixed system that utilizes weight but sees it as a function of prominence (Gordon 2005). Due to space limitations, these proposals will not be reviewed here. However, there is one important empirical argument that favors the onset weight approach, namely the existence of other phenomena beyond stress that are weight-related and influenced by onsets.

4.2 *Compensatory lengthening, geminates, and word minimality*

An explicit prediction of the onset–rime and the moraic models is that onsets will never participate in weight-related processes. For the former, this is because onsets are excluded from the prosodic hierarchy (van der Hulst and Ritter 1999: 31). For the latter, it is because onsets never bear moras (Hayes 1989). However, both assertions are entirely stipulative and subject to modifications given the existence of counterevidence.

First, consider compensatory lengthening (CHAPTER 64: COMPENSATORY LENGTHENING), a phenomenon widely utilized in support of standard moraic theory. In standard moraic theory (Hayes 1989), it is predicted that onsets will neither induce compensatory lengthening (through deletion) nor undergo it (through lengthening). Yet several cases of both types have been reported.

In Samothraki Greek, the onset /r/ deletes and generally leads to lengthening of the following vowel, e.g. /'rema/ > ['eːma] 'stream', /'ruxa/ > ['uːxa] 'clothes', /'ðedru/ > ['ðeduː] 'tree', /kra'to/ > [kaː'to] 'I hold' (Katsanis 1996: 50–51). Onondaga (Michelson 1988) is somewhat similar, although /r/-deletion leads to lengthening, whether it is in an onset or a coda originally. Numerous other examples have been reported (Rialland 1993; Beltzung 2007), all of which, however, are highly morphologized. For instance, in Romanesco Italian, the initial /l/ of the definite article and of the object clitic /lo la li le/ optionally deletes (Loporcaro 1991: 280), causing lengthening of the unstressed vowel that follows, e.g. [lo 'stupido] > [oː 'stupido] 'the stupid (MASC)' or [la 'bruːʃo] > [aː 'bruːʃo] 'I burn her'. Beyond this environment, such compensatory lengthening does not appear. Analogous effects are observed in Anuak/Anywa, Lango, Gyore, Turkana, and Ntcham (see Beltzung 2007; Topintzi 2010 and references therein).

Nonetheless, one could question the validity of this approach in terms of onset weight structure and instead provide a more phonetic explanation, as done by Kavitskaya (2002). She observes that vowels in CVC syllables are phonetically longer when followed by certain consonants whose transitions can be misheard as part of the vowel (i.e. sonorants, approximants). On deletion of such consonants, the 'excess' length of the preceding vowels can be phonologized, so that listeners reinterpret them as phonemically longer. Thus vowels are reinterpreted by listeners as phonemically longer. This approach also extends to compensatory lengthening induced by onsets, but only works when highly sonorous consonants are deleted. In principle, this is appropriate for some of the cases, e.g. Samothraki Greek or Romanesco Italian, but is nevertheless problematic. For instance, it cannot explain why the same phonologization of length has not occurred with regard to the Samothraki coda *r*, especially since this is the prototypical position for compensatory lengthening. More troublesome, though, is the inability to account for cases like Ntcham, where the onset that is lost is the highly *non*-sonorous /k/.

More strikingly, onsets also can serve as the target of compensatory lengthening. This means that a segment deletes and the preceding onset lengthens, i.e. geminates in order to compensate for its loss.[8] For instance, Pattani Malay (Yupho 1989; Topintzi 2008) contrasts singletons and geminates in onsets, but only word-initially (on initial geminates see CHAPTER 47: INITIAL GEMINATES), e.g. [ˌbu'wɔh] 'fruit' *vs.* ['bːuˌwɔh] 'to bear fruit', [ˌɟa'lɛ] 'road' *vs.* ['ɟːaˌlɛ] 'to walk' (Yupho 1989: 135). Moreover, it exemplifies a case of compensatory lengthening (Michael Kenstowicz, personal communication). In instances of free variation, one variant involves loss of the word-initial syllable and gemination of the second

[8] This characterization is unavoidably linked to a broader discussion of what exactly constitutes a geminate. Briefly, the debate relates to whether geminates are inherently moraic (i.e. heavy) or involve double linking to higher structure (i.e. long). This issue is thoroughly examined in CHAPTER 37: GEMINATES and CHAPTER 47: INITIAL GEMINATES.

onset, as in e.g. [buwi] ~ [wːi] 'give', [sidadu] ~ [dːadu] 'police', [pɨmatɔ] ~ [mːatɔ] 'jewelry' (Yupho 1989: 130).

That these geminates are moraic is supported by another fact of the language, namely stress. Primary stress is word-final, unless the word begins with a geminate, in which case it shifts to the initial syllable (the other syllables receive secondary stress). We can easily understand this effect by claiming that the syllable hosting a geminate is bimoraic and therefore heavy, and as such, attracts stress in preference to monomoraic syllables.

(15) *Stress in Pattani Malay* (Yupho 1989: 133–135)

a. *words lacking geminates*

ˌa'lɛ	'road path'
ˌda'lɛ	'in, deep'
ˌmãˌkɛ'nɛ̃	'food'

b. *words with initial geminates*

'mːaˌtɔ	'jewelry'
'ɟːaˌlɛ	'to walk'

As well as Pattani Malay, Trukese provides evidence that onset geminates are moraic (see also CHAPTER 37: GEMINATES for discussion). First, Trukese words are minimally (C)VV, e.g. [maa] 'behavior', [oo] 'omen', or C_iC_iV, i.e. a geminate plus a short vowel, e.g. [tto] 'clam (sp.)', [ʧʧa] 'blood' (Davis and Torretta 1998; Muller 1999).[9] CVC and CV words are not allowed (Davis 1999), thus singleton codas contribute no mora (Muller 1999). Presumably, minimality is satisfied by bimoraic words, provided of course that geminates add a mora to their syllable. An additional process of compensatory lengthening following the deletion of the final mora in a word corroborates the moraicity of onset geminates (CHAPTER 37: GEMINATES).

Various proposals within the standard moraic theory tradition have been put forward to account for initial moraic geminates (Davis 1999; Curtis 2003), common to which has been the lack of any association between the geminate's mora and the onset, in line with a major tenet of the theory, namely the ban on onset moraicity. Crucially, to achieve this effect, these approaches link the geminate's mora to some position other than the onset, which is made possible by the double linking commonly assigned to geminates (see CHAPTER 37: GEMINATES). But this solution is not available in cases of moraic initial consonants that are singletons rather than geminates. Such cases exist.

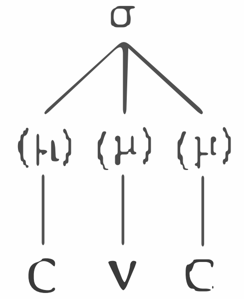
In Bella Coola (Bagemihl 1998) the minimality criterion is fulfilled by VV, VC, and CV words, but crucially not by V words.[10] Topintzi (2006, 2010) argues that the easiest way to uniformly understand these data and place them alongside the root-maximality facts of the language – that make reference to mora structure – is by stating a bimoraic word minimum and by allowing onsets to bear moras.

[9] Many languages impose a minimum size for words to be well-formed. Commonly, words are required to be at least bimoraic (C)VV as in Ket or Mocha, or (C)VV/(C)VC as in English or Evenki (Gordon 2006), or bisyllabic, e.g. Pitta-Pitta (Hayes 1995: 201).

[10] In fact, minimal words with two unsyllabified consonants CC are also allowed. Evidence for the existence of unsyllabified consonants would take us too far afield; see Bagemihl (1998) and Topintzi (2006) for details.

To capture these facts, Topintzi (2006, 2010) puts forward a flatter syllable structure (reminiscent of Davis 1985), whereby all syllable constituents come in either moraic or non-moraic versions. This is hardly surprising for codas; cf. moraic codas in Latin, Delaware, English, Kiowa, and Turkish *vs.* non-moraic ones in Wargamay, Lenakel, Eastern Ojibwa, and Khalkha Mongolian (e.g. Hayes 1995; Zec 1995, 2007; Morén 2001). The claim extends to onsets too, e.g. moraic for onset geminates in Trukese or voiceless obstruents in Pirahã *vs.* non-moraic in a host of other languages. Applying the same distinction to nuclei is also not too far-fetched, as it has been suggested that they can occasionally be weightless, for example in Malagasy (Erwin 1996), Kabardian (Peterson 2007), Alamblak (Mellander 2003), and Chuvash and Mari (Hyman 1985). The following representation illustrates the proposal outlined by Topintzi (2006, 2010).[11]

(16)



Even with this modification, though, moraic theory faces problems when it encounters data such as those in Seri and Kikamba (Roberts-Kohno 1995) and Onondaga and Alabama (Broselow 1995 and references therein), and French *h-aspiré* (Boersma 2007 and references therein). In Seri (Marlett and Stemberger 1983; Crowhurst 1988; Broselow 1995), the distal prefix [jo-] attaches to either C- or V-initial stems. In the former, nothing remarkable occurs (17a), but in V-initial stems, things become more complex. In general, when the first vowel of the stem is low back /a/ or low front /æ/ the prefix vowel deletes and compensatory lengthening results (17b). But in some specific stems, no deletion (and consequently no compensatory lengthening) occurs. Instead, a hiatus context is created (17c).

(17) *Seri distal forms*

	stem		*distal*	
a.	*C-initial stems*			
	-mækæ	'be lukewarm'	jo-meke	
	-pokt	'be full'	jo-pokt	
b.	*general pattern of /a, e/-initial stems*			
	-ataχ	'go'	joː-taχ	
	-æmæ	'be used up'	joː-me	
c.	*exceptional pattern of /a, e/-initial stems*			
	-amwx	'be brilliant'	jo-amwx	*joː-mwx
	-ænx	'play stringed instrument'	i-jo-enx	*i-joː-nx

According to Crowhurst (1988), these data support a mixed representation that includes both X slots and moras (CHAPTER 54: THE SKELETON). The idea is that the stems in (17c) are underlyingly specified with an empty slot in the onset, whose

[11] Simultaneous moraicity on all three positions is presumably attested in Karo (see Topintzi 2010: 49).

net effect is to block deletion (and compensatory lengthening), because of its intervening position between the two vowels. Effectively, then, (17c) acts as if it were a C-initial stem (17a). Data of this type can also be easily accommodated in government phonology (Kaye *et al.* 1990), which by its nature allows reference to empty positions.

It is, however, not entirely clear that Seri cannot be accommodated by moraic theory alone (especially if onsets may bear moras). Unlinked moras appear in numerous works (cf. van Oostendorp 2005; Topintzi 2007) and are in fact suggested by Crowhurst herself. We could assume then that the input for [jo-amwx] is /jo-^{M}amwx/, where ^{M} indicates a floating mora. If on the surface this mora remains unassociated but anchored at the left edge of the stem, then it can produce the same blocking effect of deletion that Crowhurst achieves by means of an unassociated x-slot.

Even if this is feasible, it is unlikely that all similar kinds of facts will be subject to reanalysis. One solution would be to reconsider representations that simultaneously use x-slots and moras, as Crowhurst does. This idea has reappeared in Muller's (2001) Composite Model with respect to geminates, and in Vaux (2009) as a more complete model of timing. Whether such enrichment of the theory is justified remains to be seen. Alternatively, one could entertain Itô's suggestion (1989: 255 and references therein) that "the role previously played by lexically empty skeletal slots can be taken over, wholly or in part, by bare melodic root nodes."

4.3 Tone

Another phenomenon where onsets seem to be involved, albeit rarely, is tone (CHAPTER 45: THE REPRESENTATION OF TONE). Relevant cases reported include Musey (Shryock 1995) and Kpelle (Welmers 1962; Hyman 1985).

In Musey, consonants are divided into Type A (or High consonants) and Type B (or Low consonants). Type A consonants include the sonorants and the historically voiceless obstruents. Type B ones correspond to the historically voiced consonants. Both Type A and B obstruents are basically voiceless (Shryock 1995: 68–69), with Type A stops presenting longer positive voice onset time (VOT), less closure voicing, and higher F0 at the onset of the following vowel than the Type B ones.

The rightward displacement of lexical L tone when a suffix is added in (18) shows the genuine contrast between the two types of consonants as well as their tonal effects. When the lexical L tone shifts, the vowel that hosted the tone is interpreted as mid or high if the onset is Type A, but as low if the onset is Type B.

(18) *Rightward displacement of lexical L tone in Musey*

a. *cliticization of* /-na/

Type A	sà → sanà → sānà		'person'
Type B	fìù → fììnà		'goat'

b.

	subjunctive		*subjunctive with affixation*	
Type A	tò	'sweep'	tōm̀	'sweep it'
Type B	dò	'pick'	dòm̀	'pick it'

Thus, at some level of representation, the onset consonants above seem to bear tone – be it by conditioning it or by having it floating in the input – which subsequently surfaces on the neighboring vowel to the right. What is more interesting is that the tone induced depends on the quality of the consonant involved: voiceless obstruents (and sonorants, which I will come back to in a moment) cause M tone, voiced obstruents cause L tone. This fact correlates precisely with data we find in tonogenesis (cf. Vietnamese (Haudricourt 1954) or synchronically in Kammu dialects (Svantesson 1983); see also CHAPTER 97: TONOGENESIS), where the historical contrast between voiceless and voiced obstruents is neutralized in favor of voiceless obstruents and is reinterpreted by means of tone, as shown below.

(19) *Common pattern in tonogenesis*

voicing contrast; no tone		*no voicing contrast; presence of tone*
pa	>	pá
ba	>	pà

This pattern is phonetically grounded: in voiceless obstruents, the cricothyroid muscle stretches the vocal folds to obstruct vocal fold vibration resulting in vocal fold tensing, which in turn leads to a higher F0. In voiced obstruents the larynx and hyoid bone are lower and a lowered larynx results in a lower F0 (Yip 2002: 6–7; Honda 2004). In fact, depression of F0 after voiced stops is very likely universal, as Kingston and Solnit (1988b) state (CHAPTER 114: BANTU TONE). Sonorants, on the other hand, do not automatically perturb the F0 of adjacent vowels, and thus may cause either elevation or depression of the F0 (Kingston and Solnit 1988a: 276). This finding is also in line with the behavior of sonorants in onset-sensitive stress discussed above. Recall that in Karo sonorants act like voiceless obstruents in attracting stress, but in Pirahã like voiced obstruents in avoiding it.

Reviewing the vast literature on the phonological effects of the onset/tone interaction phenomenon is well beyond the goals of the present chapter (see Yip 2002; Gordon 2006; van Oostendorp 2006; Tang 2008 for relevant overviews). For our purposes and in light of the data above, it suffices to say that Musey exhibits mixed behavior. On the one hand, it has not entirely lost the voicing contrast between stops (see the discussion on Type A and B consonants) – since it retains phonetic voicing by means of short *vs.* long VOT – but is moving in that direction, as the facts above reveal; on the other hand, it has introduced tone, which is commonly associated to specific onset quality, but has not (yet?) extended this pattern throughout the system. One thing seems quite clear: onsets in Musey may act as phonological tone bearers. And as expected, voiceless obstruents produce tone raising and voiced ones tone lowering. The more neutral sonorants here pattern with the voiceless obstruents.

Along similar lines, we can understand the data in Kpelle. However, unlike Musey, Kpelle onsets act as surface tone-bearing units (TBUs). First, consider minimal pairs such as (20), where a sonorant onset can appear toneless, L-toned, or H-toned. This is hardly surprising, given the capacity of sonorants to bear any type of tone.

(20) mare-kɛ̂i 'a question'
m̀are kɛ́ 'ask him'
ḿare kɛ́ 'ask me'

Moreover, the possessive form involves an underlyingly H-toned nasal prefix for the 1st singular or a floating L tone for the 3rd singular (plus the independent processes of voicing assimilation in obstruent-initial stems and total assimilation and nasal simplification in sonorant-initial stems),[12] both of which surface on onset positions.

(21) *Kpelle onsets as TBUs* (Hyman 1985: 44)

	stem	'my'	'his/her'	
a.	*initial obstruent*			
	pólù	ḿbólù	b̀ólù	'back'
	túɛ	ńdúɛ́	d̀úɛ́	'front'
	kɔ́ɔ́	ŋ́gɔ́ɔ́	g̀ɔ́ɔ́	'foot, leg'
	fíí	ɱ́víí	v̀íí	'hard breathing'
b.	*initial sonorant*			
	lēē	ńēē	ǹēē	'mother'
	jéé	ɲ́éé	ɲ̀éé	'hand, arm'
	ma̱lóŋ	ḿa̱lóŋ	m̀a̱lóŋ	'misery'
	ɲí̱ŋ	ɲ́í̱ŋ	ɲ̀í̱ŋ	'tooth'

These examples show that sonorants and voiced obstruents may appear as surface TBUs, but the same does not hold for voiceless obstruents. This is entirely expected, given that the physical correlate of tone is F0, thus only voiced segments should be able to present it, i.e. vowels, sonorants, and voiced obstruents (Gordon 2006). The Musey data nonetheless have suggested that voiceless onsets should be allowed to be input phonological TBUs (a similar claim for Kpelle appears in Topintzi 2010); if this view is along the right lines, future investigation should focus on how the phonology–phonetics mapping of onset–tone association is accomplished.

5 Onset–coda weight asymmetry

Finishing this chapter, it should by now be obvious that while there is evidence that onsets participate in at least some of the phenomena that codas do, the frequency with which they do so is indisputably much lower and in some cases exceedingly rare. This issue has been mentioned but barely dealt with in the literature; nevertheless, it deserves some brief discussion. Of course, for those who deny any role for onsets in prosody (cf. the standard moraic theory of Hayes 1989), there is not much to explain in the first place. The asymmetry in behavior is the outcome of the more restricted – moraically speaking – structural representation of onsets, compared to that of codas. However, as we have just seen, this approach is too restrictive when it encounters many of the empirical data presented previously.

[12] A reviewer points out that the input for the 3rd singular could instead include a low-toned nasal that on the surface fuses with the onset consonant, similarly to what happens in sonorant-initial stems. This is certainly a possibility, but not one Hyman seems to assume. In any case, this issue is orthogonal to the point made here.

To my knowledge, the first explicit attempt to account for the rarity of onset weight and hence of the onset–coda prosodic asymmetry was offered by Goedemans (1998). Through a set of perception experiments using synthetic stimuli, Goedemans found that Dutch listeners are more attuned to perceive fluctuations in vowel or coda duration rather than onset duration. He next devised an additional experiment to check for the possibility that there is inherently a human bias against perceiving onset duration, but found no evidence in support of this. He therefore concluded that the effect described above must genuinely be due to the weightlessness of onsets. One problem posed by this account is that Goedemans found that listeners recognize duration shifts in onset sonorants better than obstruents. This implies that the former should be preferred as weight bearers to the latter, *contra* the empirical data, which suggest that in onsets the real difference is between voiced and voiceless obstruents (and that sonorants may pattern with either; cf. Karo *vs.* Pirahã). More troublesome for this proposal is how to accommodate later work by the same author (cf. Hajek and Goedemans 2003), where onset weight is emphatically argued for, albeit for geminates only (Rob Goedemans, personal communication).

Other, more functional accounts of the onset-coda weight asymmetry include Smith (2005) and Gordon (2005), both of which accept onset-sensitivity, but only with regard to stress. To explain why onsets may have a stress-attracting effect, they offer variants of the same idea relating phonological considerations to more general cognitive abilities, such as the sensitivity to auditory stimuli (Viemeister 1980; Delgutte 1982). More specifically, they allude to the evidence of "neural response patterns that the presence of an onset, and specifically a low-sonority onset, does in fact enhance the perceptual response to a syllable" (Smith 2005: 50). Empirically, though, as we know, sonorant onsets may also contribute to weight (or prominence), a fact that both functional accounts fail to capture. Despite this problem, Gordon (2005) claims that in most cases, i.e. most languages, the onset effect is subordinated to the perceptual energy of the rime itself, which is why rimal weight is prioritized over onset weight.

Finally, Topintzi (2006, 2010) does not confront this issue in much detail, but nonetheless claims that instead of a single property, it is a constellation of phonological factors, perhaps complemented by the functional accounts above, which may prove enlightening (for details, see Topintzi 2010: §3.3.3, §5.4.1, §6.2.3). For example, the rarity of onset-sensitive tone is attributed to the fact that tone and onset-weight requirements are incompatible with one another. Tone requires the presence of F0, whereas moras that can bear tone in the onset are best assigned to voiceless onsets, which by nature lack F0.

In spite of the virtues of each approach, none simultaneously manages to combine accurate empirical coverage with a convincing account that acknowledges the onset-coda asymmetry in its correct perspective and offers a plausible explanation. Future research may fill in the missing pieces of the puzzle.

ACKNOWLEDGMENTS

56 Sign Syllables

Ronnie Wilbur

1 Introduction

This chapter focuses on the notion of syllable in sign languages. Although there is now a consensus on the defining feature of a syllable in sign languages, i.e. that there must be a movement, the initial idea of having "syllables" in sign languages met with considerable resistance on its introduction in the early 1980s, in large part because sign languages are fundamentally monosyllabic languages (see Coulter 1982 on American Sign Language (ASL); similar evidence has been provided for Finnish Sign Language by Jantunen 2007). There was also a strong undercurrent that using concepts borrowed from spoken language linguistics for sign language phenomena would be problematic, if not inappropriate. However, I had an opportunity to ask my colleague Ray Kent, a speech researcher who was then editor of the *Journal of Speech and Hearing Research*, what he would require if I were to send his journal a paper on syllables in sign languages. He said he would look for evidence that the concept was linguistically meaningful and could be reliably measured, and his response will begin our tour on this topic. Actually, proving to spoken language researchers that there are syllables in sign languages on those two criteria was remarkably easy (Wilbur and Nolen 1986; Wilbur and Allen 1991). In contrast, the phonological representation of sub-syllabic structure has been under constant and lively debate. Accordingly, the presentation of evidence for the existence of syllables will be brief, and the bulk of the chapter will focus on describing the issues of disagreement and providing evidence for an answer to the question of the representation of syllables in sign languages.

2 Historical background

Early sign language research treated the sign as the unit of analysis. This is best observed in Stokoe (1960), where each sign was treated as a unit. Then, when this unit was analyzed further, it was observed that a sign was composed of a "simultaneous" bundle of aspects/primes/parameters, including the "big four": handshape, location, movement, and orientation (Stokoe 1960; Friedman 1974, 1977; Battison 1978; Siple 1978; Klima and Bellugi 1979; Wilbur 1979; see also

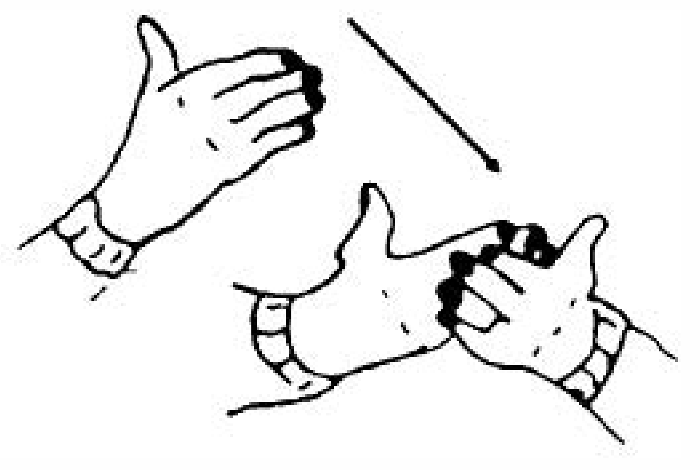

Figure 56.1 ASL ARRIVE is a monosyllabic form (arrow shows direction of movement)

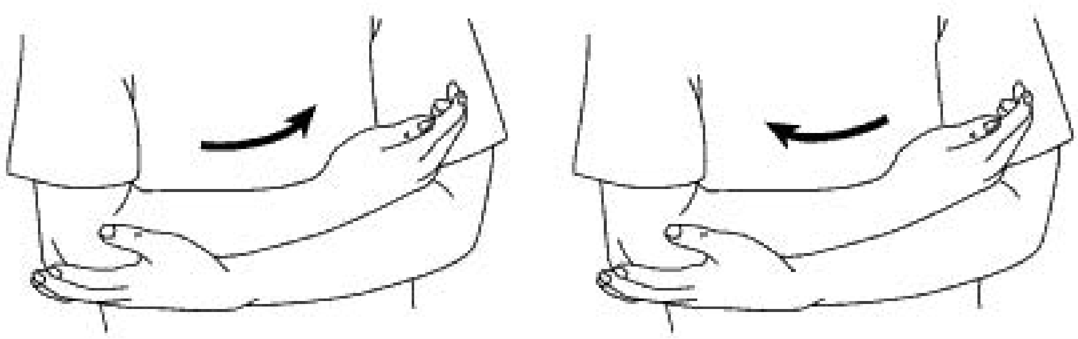

Figure 56.2 ASL BABY has two syllables, i.e. two movements (arrows show direction of movement)

CHAPTER 9: HANDSHAPE IN SIGN LANGUAGE PHONOLOGY; CHAPTER 10: THE OTHER HAND IN SIGN LANGUAGE PHONOLOGY; CHAPTER 24: THE PHONOLOGY OF MOVEMENT IN SIGN LANGUAGE). Several studies suggested that there are syllables in ASL and that these syllables have internal "sequential" organization (Kegl and Wilbur 1976; Chinchor 1978, 1981; Newkirk 1979, 1980, 1981; Liddell 1984). Before addressing the question of internal organization of sign syllables, some clarification of the notion "syllable" in sign languages is necessary.

To better appreciate the status of a syllable in sign languages, we must consider the difference between a syllable and a sign. In many cases, the sign is a single syllable and the boundaries of the two, i.e. a syllable or a sign, coincide (Coulter 1982, 1990). Figure 56.1 is an example of a single-syllable sign.

In other signs, such as BABY in Figure 56.2, there are two syllables in a single sign. The sign BABY is a larger unit than ARRIVE (Figure 56.1). In still other signs, such as MOTHER (Figure 56.3), there are specifications for handshapes, locations, and hand orientations, but, critically, these signs do not have their own movement specifications.

Since every syllable must have a movement, the phonological specification for these lexical items is smaller than a syllable; it has been proposed that the epenthetic/transition movement to, or away from, the target location provides the prosodic feature needed to produce a full syllable (Wilbur 1985; Brentari 1990b, 1998; Geraci 2009).

We have so far sketched sign syllables by providing three groups of signs with different movement specifications, i.e. with single movement, with two movements,

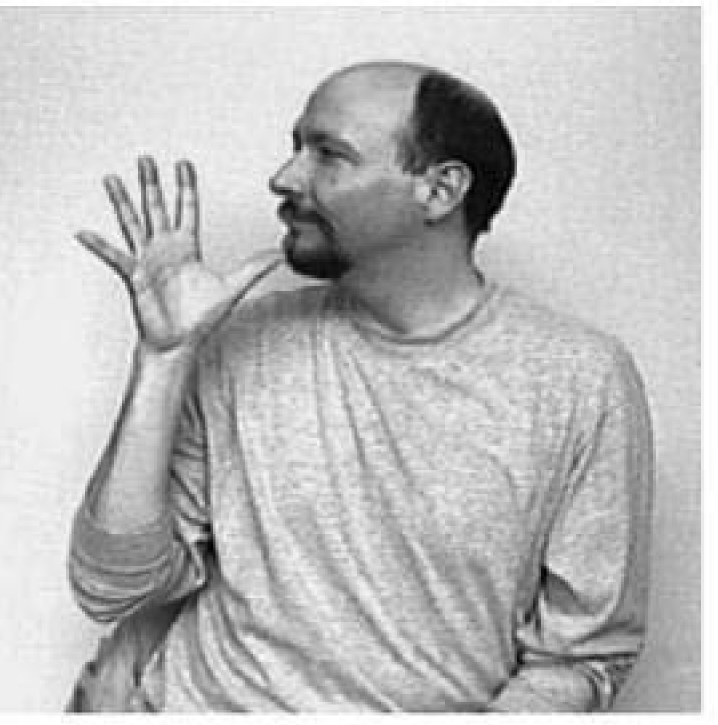

Figure 56.3 ASL MOTHER is a sign without a movement specification. By permission of Dr. Bill Vicars

and without lexical movement. We now consider the difference between a syllable and a morpheme in order to distinguish their functions. A morpheme is defined as the smallest possible unit of meaning. In Figures 56.1–3, each sign is also a single morpheme. In Figure 56.1, the morpheme and the syllable are the same size. In Figure 56.2, the morpheme is larger than the syllable (it has two syllables), and in Figure 56.3, the morpheme is smaller than the syllable (it is missing movement). A morpheme may also be as small as the feature specification for a single handshape, as in classifier constructions (see CHAPTER 9: HANDSHAPE IN SIGN LANGUAGE PHONOLOGY), or location, as in verb agreement.

It should be noted that two-syllable lexical items are highly constrained with respect to their movement specifications: the movement in the second syllable is either the exact opposite (180° rotation) of the movement in the first syllable (as in BABY, Figure 56.2) or it is 90° rotated (Figure 56.4; note transitional movement inserted when the end of the first movement is not the starting position of the second movement) (Wilbur and Petersen 1997).

Clearly movement is central to syllable structure (see CHAPTER 24: THE PHONOLOGY OF MOVEMENT IN SIGN LANGUAGE). The first attempt to break sign movement into smaller sequential pieces was Newkirk (1979, 1980, 1981). Considering rhythmic features of movement, he analyzed them into [onset] [movement] [offset]. Subsequently, a number of sequential and simultaneous proposals were offered. This brings us to the ongoing debate – what is the internal structure of a syllable with respect to sequentiality and simultaneity? In the following section, I provide an overview of what everyone does agree upon, i.e. that syllables in sign languages exist. In the subsequent section, I provide evidence of the behavior of syllables with respect to higher phonological organization. Finally, we dive inside the sign syllable and consider the evidence for the two theoretical options – sequential and simultaneous organization of syllable structure.

Figure 56.4 ASL CANCEL/CORRECT/CRITICIZE and schematic of movement showing second syllable (3 to 4) perpendicular to first (1 to 2)

3 Sign syllables exist

Syllables have been reliably measured, and in conversational contexts they have roughly the same duration as spoken language syllables (Wilbur and Nolen 1986). As will become clear below, there has been no shortage of linguistic uses for the syllable in sign language (morpho-)phonology, hence it is linguistically meaningful. It is fair to say that sign language phonologists now take the notion of sign syllable as a given, and that movement is its nucleus (the carrier of its perceptual salience; Jantunen and Takkinen 2010).

3.1 *Syllable measurements*

Investigators have measured sign duration, including signs that are clearly single syllables (Bellugi and Fischer 1972; Friedman 1976; Liddell 1978, 1984). For those signs which are monosyllabic, the measured duration means range from 233 to 835 msecs as a function of context. Liddell (1978) reported the effects of sentence position and syntactic function on duration of the monosyllabic signs DOG and CAT. His measurements show phrase-final lengthening, as the durations were longest in sentence-final position. Duration in sentence-initial position was next longest, and medial position in relative clauses had the shortest duration. His measurements also show a syntactic effect: objects were shorter than subjects or heads of relative clauses.

My investigation of syllable duration began in 1984, when videotape was "reel to reel," which meant that the tapes could be moved by hand, forward and backward, and measurement was in "fields" – 60 per second. To measure syllables, movements, and holds, we had to provide our own mechanical guidelines and demonstrate that they could be reliably used (Wilbur and Nolen 1986; Wilbur and

Schick 1987). We started with the cues identified by Green (1984) for beginnings and ends of signs, which worked well for signs that were perceptually monosyllabic. These cues included points of contact and changes in facial expressions and eye gaze. However, Green's procedures were not sufficient for determining syllable boundaries when the sign and the syllable are not coterminous, i.e. when we have more than one syllable in a sign. To capture the behavior of multisyllabic signs such as bidirectional signs (Figure 56.2 above), reduplicated forms, and compounds, additional cues were needed. With the aid of native signers, we determined that a change in the direction of movement marked a boundary between two adjacent syllables. For elliptical movements, we accepted Newkirk's (1979, 1980, 1981) argument that they were segmentable into two parts, and then we used the change in direction of movement as the boundary between the two parts. By contrast, circular movements, which show no internal structure, were treated as one syllable per circle. For holds, we established a procedure in which the end of a hold would be marked by one or more of the following cues: start of the next movement, loss of tension in the signing hand(s), change of eye gaze, initiation of signing by the other signer, or change of eye gaze by the other signer (Wilbur and Nolen 1986). Syllables were measured by two people at a time; if they could not agree, a third person was consulted. Over three thousand syllables were measured in four situations – natural conversation, elicited paragraphs, lists of signs, and phrases and compounds.

In conversations, 889 syllables from three signers had a mean of 248 msecs, comparable to the estimated 250 msecs for spoken English (Adams 1979; Hoequist 1983). This similarity may be a reflection of an underlying timing mechanism for motion that may surface not only in speech and signing, but also in non-linguistic motor behaviors. For example, in baseball, a bat swing takes about 200 msecs (Schmidt and Lee 2005).

For the lists, mean syllable duration was 299 msecs for the first production, and 417 msecs for the second. Thus, signers can have different durations at different times. For paragraphs, 14 signers produced paragraphs with either a stressed or unstressed target sign. The stressed target mean was 317 msecs, and the unstressed target mean 299 msecs. There were more syllables in the stressed condition, i.e. repeated syllables and/or resyllabification (similar to English *please* pronounced as *puh-leeze*).

In the last condition, compounds may have two syllables or can be reduced to one (Coulter 1982; Liddell 1984). Eighteen sets of compounds and their two component signs were provided by Ursula Bellugi. In each set, the two signs appeared in a phrase in isolation (e.g. FACE CLEAN) and in context (HE HAS FACE CLEAN 'He has a clean face'). The same morphemes also appeared in a compound (FACE-CLEAN 'handsome') in isolation and in context (HE FACE-CLEAN 'He is handsome'). The compounds had significantly more syllables per sign than simple lexical items (Wilbur and Nolen 1986). Also, the signs in isolation (whether simple lexical items or compounds) had significantly more syllables than in context, reflecting prosodic effects. Thus signers manipulate both syllable duration and number of syllables in their sign productions.

The evidence so far lends support to one of the two criteria that started our discussion, i.e. "Can syllables be reliably measured in sign languages?" We turn now to the other criterion, i.e. "Are syllables linguistically useful?"

4 Phonological applications identified for "syllable"

In this section, I briefly review the arguments that have been offered to show that syllables contribute to the statement of phonological processes and to our understanding of why some processes behave the way they do. The notion of syllables has proven to be useful in the statement of a variety of historical changes (Battison 1978; Frishberg 1978), synchronic morphological processes (Chinchor 1981), and phonological processes (Coulter 1982; Wilbur 1990b, 1993). Blevins (1993), Padden (1993) and the work of Brentari (1990a, 1990b, 1993, 1996, 1998) provide further arguments in favor of the role of syllable structure in ASL phonology. I review only a few, and refer the reader to the original authors for further evidence and discussions.

4.1 *Fingerspelling and fingerspelled loan signs*

Battison's (1978) discussion of the creation of new signs from fingerspelled words provides data to support the notion of syllables. Theoretically, each fingerspelled letter consists of a handshape and, when produced in slow sequences, a transition movement (handshape change) to reach each handshape. Thus, there could potentially be as many syllables as there are letters in the word being fingerspelled, because there could be one movement to make each handshape and each could therefore be a syllable. In actuality, fluent fingerspelling is performed with a phrasal rhythm that smoothes the transition handshape changes and reduces the prominence of certain handshapes while increasing the prominence of others (Akamatsu 1982, 1985; Wilcox 1992). In the process of becoming a lexicalized fingerspelled loan sign, some letters in a word are dropped, and remaining handshapes are associated to syllabic nodes, reducing the number of syllables produced. Fingerspelling the word "sick" (Figure 56.5) involves handshape changes from each letter to the following letter. Since fingerspelling is based on English spelling, each English word will have a different set of handshapes and a corresponding different set of transitional handshape changes. In contrast, in the fingerspelled loan sign #SICK (where # denotes a fingerspelled loan sign (Figure 56.6), the middle letters have been dropped, and the handshape change from S to K has created the movement nucleus of the syllable, to which a slight directional path movement has been added (the arrow does not do justice to this – the middle finger can appear to flick forward from the fist while the index finger straightens up). At the syllable-internal level, the features for

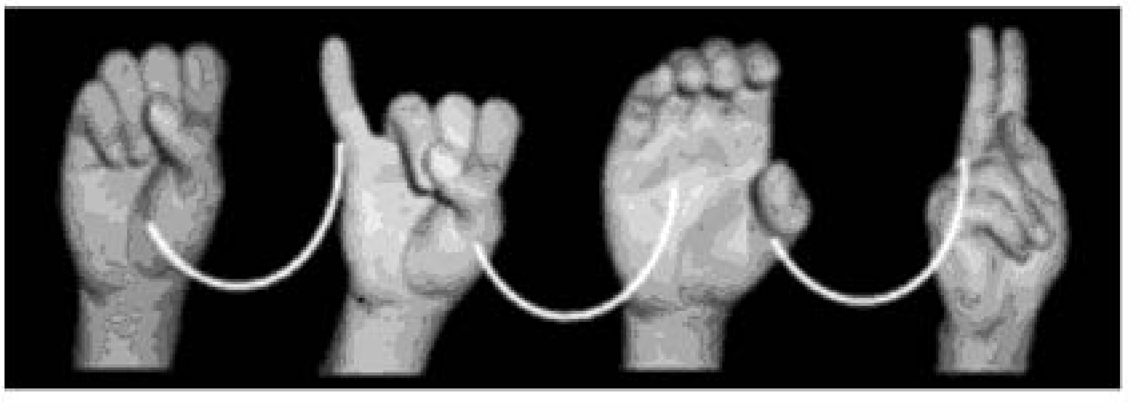

Figure 56.5 Handshapes S, I, C, K, with three transition movements between them

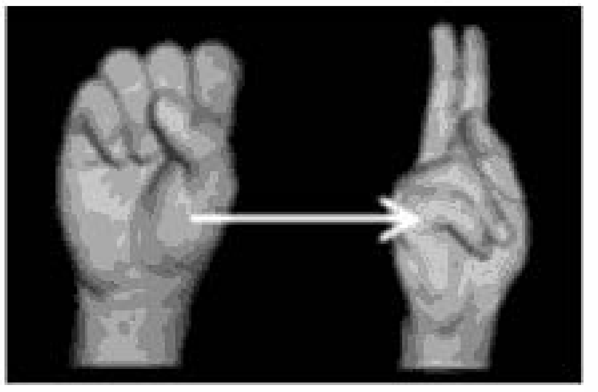

Figure 56.6 Fingerspelled loan sign #SICK, with one lexical movement

the handshapes S and K are associated with the same syllabic node, i.e. the only syllabic node. The handshape change from S to K is not permitted in core lexical items as reflected in Brentari's model, thus this form is clearly identified as of foreign origin from English. Brentari (1994) used the fingerspelled loan signs from published ASL lectures (Valli and Lucas 1992) to determine the processes involved in lexicalization. She found that long fingerspelled words with as many as eight or more letters reduced to fewer handshapes and just two movements. The result is that the newly lexicalized forms fit the phonotactics of ASL, having a maximum of two syllables.

4.2 *Evidence for a sonority hierarchy*

Several researchers have suggested a relationship between visibility and syllable sonority (Corina 1990; Perlmutter 1992; Sandler 1993; Brentari 1998). The sonority hierarchy treats movements made with joints closer/proximal to the body/trunk, such as elbows and shoulders, as more sonorous, because of their visibility in motion when compared to those lower down and more distal, such as hands and fingers, which are considered less visible and hence less sonorous (1) (see CHAPTER 49: SONORITY for an overview of issues surrounding the sonority hierarchy in spoken language):

(1) *Sonority hierarchy with respect to the relevant joints* (from Brentari 1998)

Most sonorous								*Least sonorous*
shoulder joint	>	elbow joint	>	wrist joint	>	base finger joints	>	non-base finger joints

Movements made with the wrist joint have a higher sonority value, i.e. are more visible due to larger movements, than movements made with the use of finger joints. With respect to the development of fingerspelled loan signs above, the addition of the slight path movement in the loan sign #SICK may be viewed as adding a higher sonority value to the less sonorous handshape change from S to K, thereby producing a more sonorous syllable and hence more acceptable lexical item. Thus what we observe is that the proposed prosodic hierarchy provides a rationale for why finger positions are dropped and wrist or elbow movements (depending on how the small path is made) are retained in fingerspelled loan words (CHAPTER 95: LOANWORD PHONOLOGY).

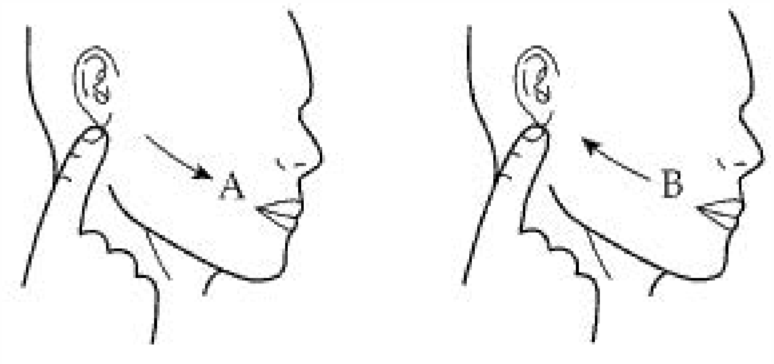

Figure 56.7 Metathesis for the ASL sign DEAF. (a) A-to-B. (b) B-to-A

4.3 Contact metathesis

Another situation where the notion of syllable is phonologically relevant is found with two-location contacting signs, which in certain circumstances can undergo a change that causes the two locations to switch their order (i.e. metathesis; Kegl and Wilbur 1976; Johnson 1986; Sandler 1986; Wilbur 1987; CHAPTER 59: METATHESIS). For example, the location points in signs such as DEAF, PARENTS, and FLOWER may switch from A-to-B to B-to-A (Figure 56.7), depending on preceding phonological context:

The process of metathesis is limited to signs that are both single morphemes and single syllables. Some were originally compounds and may be articulated in a way which reflects their origins. For example, the sign PARENTS might be deliberately made to emphasize its origin from FATHER + MOTHER: movement to contact at the forehead (FATHER) and then movement to contact at the chin (MOTHER). This form would be two syllables, and not subject to metathesis. In the monosyllabic version of PARENTS, the forehead contact is preceded by a transition movement, and the lexical syllable consists of the change in location from the forehead contact to the chin contact. This latter form can undergo metathesis, i.e. the hand can touch the chin first and the forehead second.

The statement of metathesis in terms of syllables greatly simplifies the formalization of the rule. We can see that the statement in terms of syllables is the correct one, as opposed to morphemes or signs. PARENTS can undergo metathesis in one form of production but not in another, so the rule about which signs can undergo metathesis could not refer to "contacts in the same sign" or "contacts in the same morpheme," but only to "contacts in the same syllable."

4.4 Handshape change (change in aperture)

Brentari and Poizner (1994) show that handshape change timing is different within syllables than it is between syllables (CHAPTER 9: HANDSHAPE IN SIGN LANGUAGE PHONOLOGY). Within syllables, if there is path movement and handshape change, the handshape change coordinates with the beginning and end of the path. However, when two signs in sequence have different handshapes, there must be a transitional handshape between the end of the first sign and the beginning of the second (as discussed for fingerspelling, above). In such conditions, the change in handshape is not coordinated with the path movement in the same way as within signs, that is, the timing of the change does not distribute evenly over the transitional path movement.

4.5 *Consistency in movement*

Likewise, Tyrone *et al.* (2007) compare monosyllabic sign movements toward the body to the same location (e.g. forehead) in two conditions: (i) the movement is part of the sign (THINK), and (ii) the movement is transitional prior to the sign (SMART). They report that within-syllable within-sign movements show typical bell-shaped velocity curves for targeted movement, whereas transitional movement between signs is less regular. These findings, along with the handshape change findings above, converge on the necessity of separating phonological syllable movement from phonetic epenthetic/transitional movement.

4.6 *Minimal word*

Simply put, the syllable is the smallest possible well-formed sign/word. Furthermore, two syllables is the maximum for well-formed core lexical signs (Perlmutter 1992; Sandler 1993; Brentari 1998; Jantunen 2007). Alternative formulations without mention of syllables would necessarily be more complex.

4.7 *Prosodic constraints*

Miller (1997) argued, on the basis of Quebec Sign Language (LSQ), that Phonological Phrases require a disyllabic foot. Similarly, van der Kooij and Crasborn (2008) suggest that in Sign Language of the Netherlands (NGT) the phonological constraint on the addition of sentence-final pointing must be stated in syllabic terms: sentence-final pointing is permitted only if the outcome is a disyllabic foot. Wilbur (1999a) observes that ASL pronouns in sentence-final position tend to be extrametrical with respect to stress assignment at the phrase level, supporting prosodic constraints proposed in Halle and Vergnaud (1987) for spoken languages.

5 Syllables and prosody

The last two arguments in favor of syllables also provide evidence for the prosodic hierarchy in sign languages. That is, metrical structure (lexical, phrasal, and clausal stress assignment), rhythmic structure, and intonational phrasing are dependent to some degree on the syllable level. (2) shows the prosodic hierarchy we adopt for further discussions (see CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE; CHAPTER 40: THE FOOT; CHAPTER 51: THE PHONOLOGICAL WORD; CHAPTER 57: QUANTITY-SENSITIVITY; CHAPTER 84: CLITICS for more discussion of the prosodic hierarchy). Prosodic words will be discussed in this chapter; for discussion of Intonational Phrases see Wilbur (1994), Sandler and Lillo-Martin (2006), and Weast (2008).

(2) *Prosodic hierarchy*

syllable < prosodic word < prosodic phrase < intonational phrase

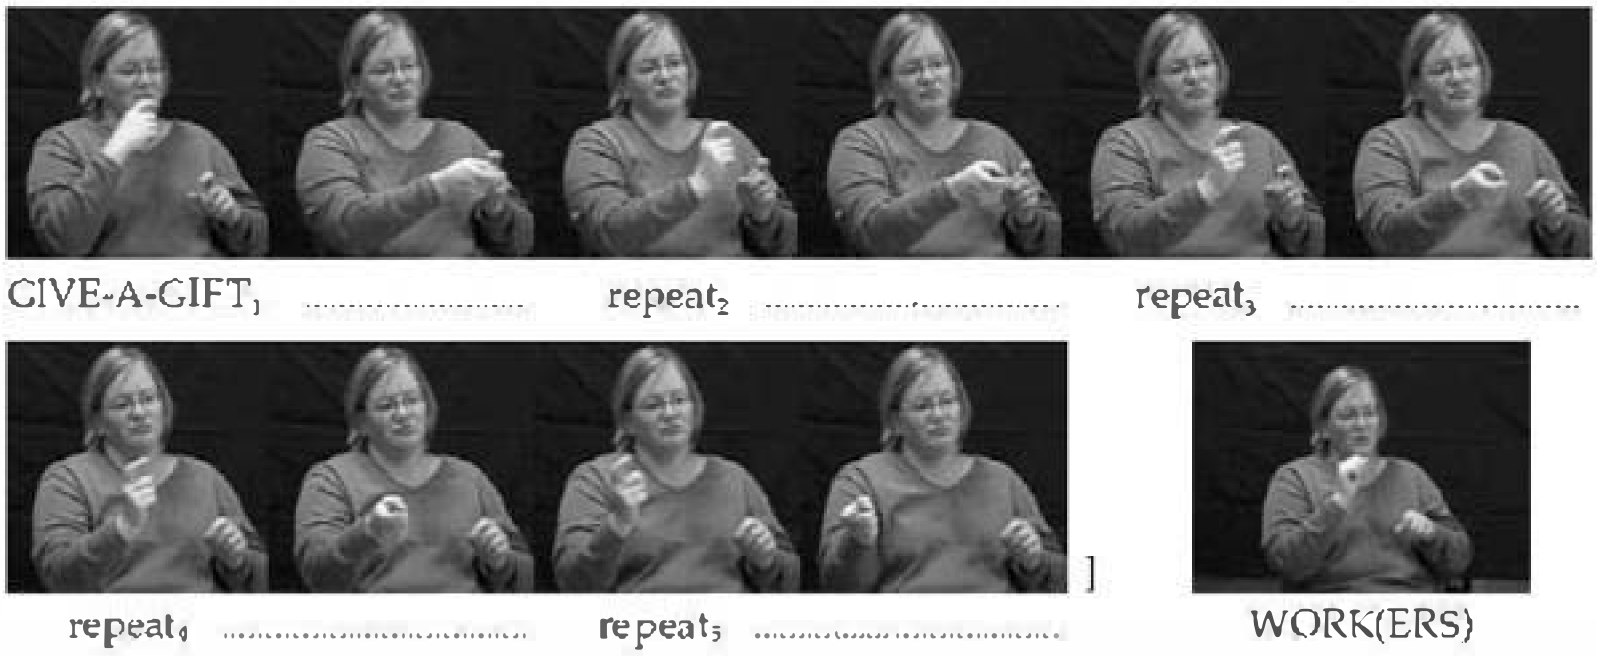

Figure 56.8 One prosodic word, composed of GIVE + distributive aspect, repeated five times, accompanied by one Posture-NM, followed by the next prosodic word, containing WORK

5.1 *Prosodic words*

As indicated, the minimal prosodic word is at least one syllable, and the prosodic constraint on well-formed lexical items is a maximum of two syllables. Brentari and Crossley (2002) demonstrated that changes in lower face tension (mouth and cheeks) mark the end of a prosodic word (PW), which is above the syllable in the prosodic hierarchy. Figure 56.8 shows a single lower face position, i.e. closed mouth with lip corners slightly down, referred to as posture non-manuals (P-NM), which stretches over one long PW, followed by the sign WORK, which has a round mouth and is in a different prosodic word. The context was "every year at Christmas time, the boss gives each of the employees a gift." Note that the single PW contains five syllables (five repetitions of the lexical item GIVE-A-GIFT).

(3) represents the marking of the relevant prosodic words through sign language glossing conventions. The tier above the glosses represents non-manual marking, and the line indicates the spread of the non-manual marker:

(3) *Prosodic grouping for Figure 56.8*

P-NM	P-NM
{GIVE-A-GIFT [Repeat × 5]}$_{PW}$	{WORK(ERS)}$_{PW}$

In contrast, Figure 56.9 shows "one car hits another car three times." The signer produces three mouth changes (Transition-NMs), once for each repetition. These changes result in three PWs, as represented in (4):

(4) *Prosodic grouping for Figure 56.9*

T-NM	T-NM	T-NM
{HIT-CAR}$_{PW}$	{HIT-CAR}$_{PW}$	{HIT-CAR}$_{PW}$

Figure 56.9 Sequence of three CAR-HITs, involving three syllables, three mouth changes, and three PWs

5.2 *Stress assignment*

Stress assignment is a prosodic process, and may occur on lexical items, compounds, and phrases. Early research on ASL stress focused on marking stress on lexical items (Covington 1973; Friedman 1976; Wilbur and Schick 1987; Coulter 1990). Stressed signs can be set off from unstressed signs by several cues: (i) faster/shorter transition movement than between unstressed signs, breaking the rhythmic pattern; (ii) higher in the signing space compared to their unstressed counterparts; (iii) increased repetitions compared to their unstressed counterparts, changing the duration; (iv) increased speed (higher peak instantaneous velocity) compared to their unstressed counterparts; (v) increased muscle tension compared to their unstressed counterparts; and (vi) stressed signs have a following pause (Wilbur and Schick 1987; Wilbur 1990a, 1990b, 1999b, 2009; Allen *et al.* 1991).

5.2.1 *Lexical items*

So far, no sign language has been shown to have distinctive lexical stress, comparable to English *'permit* and *per'mit* (Jantunen and Takkinen 2010). The predominance of monosyllabic lexical items is partly responsible for this absence. Another reason is that polysyllabic signs are restricted to three possibilities:

Lexicalization of repetition: A sign may have more than one syllable if it is formed as a result of lexicalization of a repeated form (e.g. ASL FINGERSPELL; Brentari 1998: 169). The result is a two-movement sign with a Return transition in the middle: A-Return-A. In these forms, only the first syllable is prominent/stressed (Supalla and Newport 1978; Coulter 1990).

Lexical disyllables: A sign may have two syllables if it is a lexical disyllable, i.e. if the morpheme itself requires two syllables. There are two types of disyllables, both of which are subject to constraints on the nature of the movements in each syllable (Wilbur 1990b). In the first type, the movement of the second syllable must be rotated in direction 180° from that of the first, returning the hands to their original location (BABY; Figure 56.2). In the second type, the movement of the second syllable is rotated 90° from the first (creating a crossing movement) (CANCEL; Figure 56.4). Supalla and Newport (1978) discuss the first type, and note that prominence is equal on both syllables. It is also the case that prominence is equal on both syllables in the second type. Thus all lexical disyllables have equal stress on both syllables. Similarly, van der Kooij and Crasborn (2008) show that NGT has both trochaic and iambic stress patterns for disyllabic signs, the type being predictable on the basis of the phonotactics of the rest of the sign. Thus, as for ASL, stress is not distinctive in NGT.

Lexical items have stress on the first, and perhaps only, syllable. Lexical disyllables are exceptional in being specified at the morphemic level for two syllables and in requiring equal prominence on both syllables.

Compounds and phrases: A sign may have two syllables if it is a compound, with the first weaker than the second. Unlike lexical items, the assignment of stress to ASL compounds and syntactic phrases follows a very general pattern. In a compound or phrase, a single stress is assigned to the *most prominent syllable of the rightmost lexical item.*

6 The internal structure of syllables

6.1 *The debate*

Historically, models of the internal structure of syllables (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE) have taken one of two views. The first view is that sign syllables, like spoken syllables, are composed of sequences of segments (CHAPTER 54: THE SKELETON). These segments are of two types (like consonant and vowel in spoken language), namely Movement (M) (the hands are in motion) and a contrasting type with the hands not in motion. Distinctive features are distributed among these phonological segments parallel to spoken language C and V.

Liddell (1984) argued for two types of segments, movements (M) and holds (H). The remaining information – handshape, contact, orientation, location, and facial expression – is represented as features occurring simultaneously with each segment, thus there is a sequence of feature matrices within each sign. Signed syllables could then be of several types, e.g. M, MH, HM, HMH. Sandler (1986, 1989, 2008) proposed a different model, in which the segment opposition is between movement (M) and location (L), with handshape configuration on a separate autosegmental tier. The presence or absence of holds would be characterized by a binary feature in the location feature matrix; rather than having holds underlyingly, there will be some phonetic holds (list rhythm), some phonological holds (at utterance boundary), some morphological holds (ASL aspectual inflections may include final hold as part of their pattern), and some pragmatic holds (end of conversational turn, waiting for back-channel nod). For these models (e.g. Liddell and Johnson 1989; Sandler 1989, 2008; Sandler and Lillo-Martin 2006), the segments are at the top of the phonological trees containing the distinctive features, i.e. the mother nodes in a feature geometry model. That is, the syllable is composed of segments, which are characterized by relevant phonological features.

In the other view, supported in Brentari (1998) for ASL and van der Kooij (2002) for NGT, movements are dynamic prosodic units with similar autosegmental status as tones in contrastive tonal languages (e.g. Mandarin, Cantonese; CHAPTER 45: THE REPRESENTATION OF TONE; CHAPTER 107: CHINESE TONE SANDHI). An important step leading to this alternative view was van der Hulst's (1993) Head–Dependency Model, in which features that did not change during the sign were considered to be heads, with changing features treated as dependents (for detailed discussion see CHAPTER 24: THE PHONOLOGY OF MOVEMENT IN SIGN LANGUAGE). Head features could be location, orientation, the active (selected) fingers, or their configuration. Movement itself was dependent on change of location (path movement) or hand configuration or orientation (local movement) (see similar arguments in Wilbur 1987). Brentari (1998) provides arguments against the notion of dependent/emerging movement, and instead identifies those features that do not change within the syllable as Inherent Features (IF) and those that do change as Prosodic Features (PF). From this perspective, ASL syllables contain distinctive features which may be accessed by phonological rules only in terms of their tiers and syllabic positions (e.g. syllable-initial, syllable-final), without further subdivision or organization. The segments are abstract timing slots at the bottom of the tree, onto which the phonological features are mapped, i.e. the terminal nodes in a feature geometry approach. Thus the question arises of how these two models should be distinguished.

6.2 *Evidence related to syllable structure*

Jantunen and Takkinen (2010) observe that there is no "direct phonetic evidence" to support the sequential segmental models. In fact, evidence against the segmental arrangement of internal syllable structure comes from a variety of experimental sources: tapping, slips of the hand, and backwards signing.

6.2.1 Tapping

Spoken syllables have a rhythmic focus at the onset of the nuclear vowel (Allen 1972). That is, native English speakers who tap in time to speech cluster their taps at the stressed vowel onset. In a comparable study of ASL, native Deaf signers, native hearing signers and sign-naive hearing subjects were asked to "tap the rhythm" of five different three-sentence signed stories. Each story was presented 30 times. One story was repeated as the sixth condition (30 repetitions) for reliability; these conditions represent "tap the rhythm" (Allen *et al.* 1991). Finally, another one of the stories was repeated (30 repetitions) with new instructions to "tap the syllables." Analysis of the tap responses in this condition showed that for all groups, taps are evenly distributed within syllables and do not differ from chance distribution. That is, no syllable-internal rhythmic focus is apparent (Wilbur and Allen 1991). This result is very crucial, and can only be predicted if the sign syllable is composed of constantly changing movement (smoothly changing muscular activity), meaning that there is no single point in time which attracts perceptual attention in the way that the onset of a spoken stressed vowel does, with large changes in muscular and acoustic energy (Allen 1972). The absence of such peaks is consistent with the proposal in the Prosodic Model that there is no further segmentation inside the sign syllable.

6.2.2 Slips of the hand

Additional arguments against segmental models come from sign errors (Meier 1993; Wilbur 1993). English slips of the tongue tend to involve all the features of the segments involved (Fromkin 1971, 1973). If sign phonological features are distributed across segments, as suggested in segmental models, all features associated to each segment should be able to behave as a group. Therefore, parallel to speech, we might expect that the initial segments of two signs could switch with everything else remaining the same. In the corpus of 131 slips of the hand (Klima and Bellugi 1979), the predicted segmental switch did not occur. Instead, observed slips involved handshape, location, orientation, or handedness (one *vs.* two hands) features, with handshape involvement being the most common.

In one slip involving BLACK and WHITE, the handshape sequence in WHITE (open fingers and thumb changing to closed fingers and thumb touching at tips) is anticipated in BLACK, with its regular handshape completely replaced by the handshape change from WHITE, whereas its location (at the forehead) and movement direction (brushing across) remained unaffected (Klima and Bellugi 1979: 139). What did not happen was a complete replacement of the initial handshape, location, and orientation of BLACK with those of WHITE, which would have created a form that started at the chest, not at the forehead. In none of their examples did the features act together as a group, as would be predicted from segmental models.

6.2.3 *Backwards signing*

Backwards signing demonstrates that signers have access both to syllable sequences and to individual features within syllables which can be exchanged in temporal sequence, but not to units corresponding to segments as defined by the segmental models. This contrasts with the evidence from spoken language games and backwards speaking (Sherzer 1970; Cowan and Leavitt 1981, 1990; Cowan *et al.* 1982; Treiman 1983; Cowan *et al.* 1985; Cowan *et al.* 1987; Cowan 1989). Cowan *et al.* (1985: 680) report that fluent backwards talkers segment speech into "phonemic or syllabic" units, and then reverse their order. Their subjects fall into two groups, using either orthography or phonology as the basis for reversal. For example, for 'terrace', orthographic reversers would say /ekaret/, including the final "silent e" and adjusting the pronunciation of the letter "c" followed by back vowels to /k/. Phonological reversers would say /sıret/, simply reversing phonological segment order.

Data from backwards signing (Wilbur and Petersen 1997) provide evidence that signers treat monosyllabic signs in ways that are not compatible with segmental models. For example, Liddell's (1984) representation for THINK in (5) consists of two segments MH, i.e. M-[approach](AP) followed by H with contact. The exchange of these segments should yield HM, i.e. H with contact followed by M-[approach]. Signers actually produce "contact" followed by "move *away*," a result which would be predicted if the starting and ending locations of the movement are exchanged. That is, if movement is represented as a sequence of features, say [–contact] [+contact] (5b) (or [neutral] [forehead] rather than [approach]), then exchanging those features within-syllable to [+contact] [–contact] will result in the correct prediction of movement away from the forehead. Note that in Liddell's model in (5a), there is a sequence of [–contact] [+contact], but these features cannot switch independently of the segments AP and H to which they are assigned. This is what we mean by having the segments at the *top* of the model.

(5) a. *Liddell's model of* THINK

	THINK	
Segment	AP	H
Handshape	1	1
Orientation	TI	TI
Location	FH	FH
Contact	–	+
Non-manual markings	–	–

b. *Feature representation of change seen in backwards signing of* THINK

```
        σ                              σ
      /   \                          /   \
[−contact] [+contact]   →   [+contact] [−contact]
```

Incorrect predictions from segmental models are more obvious with the sign FLY, represented as a single M segment. The predicted backwards version should be the same as the original, because there is nothing available to exchange. Backwards signing shows that the direction of movement of FLY is reversed (Figure 56.10), comparable to the movement reversal in THINK. This remains an inexplicable fact in segmental models which treat movement as a single M segment with its own feature matrix. The only recourse is to change the representation to H_1MH_2 and then reverse the two Hs, but evidence for the presence of those H segments would need to be provided. In any case, the lack of analogy with spoken segment sequences can be seen: the backwards form of *cat* /kæt/ is /tæk/, with the vowel unchanged. But, clearly, in the backwards form of FLY the movement has changed.

Any segmental model containing M segments will have the same problem, because it is the phonological features associated with the movement that must be available to signers to be exchanged. In backwards signing, movements are consistently reversed by exchanging end specification with start specification, as though initial and final features are exchanged on their own tiers: end location with beginning location; end handshape with beginning handshape; end orientation with beginning orientation. Wilbur and Petersen (1997) argue that movement is not *inside* the syllable, but rather that movement *is* the syllable, a conception of "syllable" that takes movement as a dynamic gesture with only starting and ending specifications for the movement trajectory and no further linguistically meaningful internal specifications (see current arguments from gestural phonology approaches, e.g. Mauk and Tyrone 2008; Tyrone and Mauk 2008). For speech, Bagemihl (1989) and Pierrehumbert and Nair (1995) argue that sub-syllabic constituents, such as onset and rime or coda, do not participate in language game behavior, with Pierrehumbert and Nair extending this observation to phonological theory in general, claiming that these sub-syllabic constituents do not exist and that a flat syllable model, such as that proposed by Clements and Keyser (1983), is adequate to account for the facts. Bagemihl (1989: 485f.) notes that language

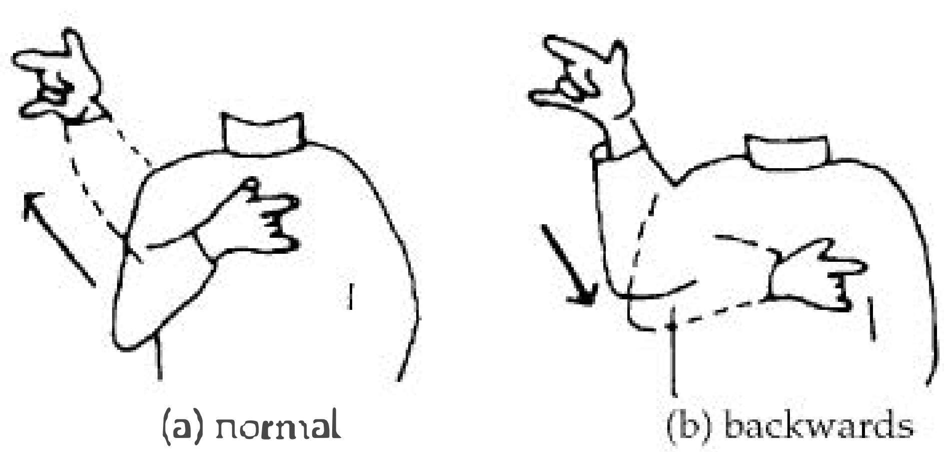

Figure 56.10 The sign FLY, made (a) with normal movement and (b) in backwards signing

games in cultures lacking phonemic alphabet writing systems do not use segments, only syllables. Furthermore, children do not use segmental language games until they are exposed to those writing systems. He suggests that alphabetic writing systems may be necessary for the development of metalinguistic awareness of segments as opposed to syllables.

Brentari (1998) capitalizes on these and other observations by separating the specifications that do not change during a syllable (Inherent Features) from those that do (Prosodic Features). Each syllable has two timing slots, one after the other, representing sequentiality, and the Prosodic Features are associated accordingly. The Inherent Features spread across both slots. Thus, her timing slots (sequentiality) are at the bottom of the tree, whereas for Sandler and Liddell, the sequentiality is at the top of their models. Jantunen and Takkinen (2010) review the sign language studies, and note that there is no evidence for internally structured sequential segmental syllables of the kind found in spoken languages (such as an onset–nucleus-coda distinction). Hence there is no justification for positing an intermediate level between segment (referring here to the timing slots in Brentari's model) and syllable, or more than two segments/slots per syllable. Finally, another benefit of the Prosodic Model for sign languages is that it provides seamless access to the prosodic hierarchy above the syllable.

7 What does simultaneity in syllable structure buy us?

It is time to turn our attention to the benefits of the notion of simultaneity in sign syllables, that is, what it accounts for that the other approaches do not. There are two important concepts that come from this model of syllable representation, namely the notion of *syllable weight* and the analogue to spoken language *sonority*. In addition, aspectual reduplication can be seen to operate prosodically on verb *roots*, whether one or two syllables.

7.1 *Syllable weight*

Consider the difference in speech between syllables of different structures CV, CVC, CVCC, CCVC, CCVCC. It is easy to identify an increase in syllable weight as more consonants are added to these syllables, even without knowing what those consonants are or the type of vowel in the nucleus or whether there is a distinction between short and long vowels or open syllable vowel lengthening (CHAPTER 57: QUANTITY-SENSITIVITY).

If sign syllables do not have the same internal structure as spoken language syllables, then is there a syllable weight distinction in sign languages, and, if so, how does it manifest itself? Brentari (1998) argues that there is a weight distinction in ASL, based on the number of simultaneous movements specified for the syllable. Syllables with one movement are light and those with two are heavy; more technically, a weight unit is constructed for every prosodic foot. With this analysis, she can explain the pattern of verbs that can and cannot take reduplication to form nouns, i.e. respectively light and heavy verbs. For example, the sign FLY in Figure 56.10a above is able to form a repeated nominalization for AIRPLANE because it is a light (one-movement) syllable. In contrast, syllables with complex movements (for example, a path movement combined with a handshape change) cannot undergo reduplicated nominalization, even if the verb qualifies semantically. Similarly, activity verbs that form activity nouns with the addition of the feature [trilled movement] must have light syllable structure to start with (Brentari 1998: 242–243). Brentari also shows the correlation between verb heaviness and preference for sentence-final position, that is, the word order is sensitive to the weight of the verb, which is determined by the number of movements in the syllable (and if reduplicated, the number of syllables).

In Brentari's analysis, the maximum number of weight units per syllable is two. Using data from Finnish Sign Language (FinSL), Jantunen (2005; see also Jantunen and Takkinen 2010) argues that an extended system is necessary for FinSL because more than two weight units per syllable are possible if one takes the non-manual movements into account – in fact, three or four may be possible. For Jantunen, a movement is complex (not simple) if more than one articulator is involved. He is then able to make a weight distinction between two monosyllabic signs, MUSTA 'black' which has only path movement, hence one weight unit, and UJO 'shy', which has local movement accompanied by a head movement, and hence has two weight units. Thus, even though both are monosyllabic, the difference in weight results from the non-manual head specification. Another benefit of this line of reasoning is that in FinSL there are lexical items which are made entirely with non-manual articulation (there are a few in ASL also) – these would be assigned a single weight unit, and that is the desired result. One additional generalization can be stated: both FinSL and ASL prefer syllables with simple movements over complex movements (Brentari 1998; Jantunen and Takkinen 2010). This generalization would be lost from a segmental perspective on syllable structure.

7.2 *Sonority*

Sonority is not built on syllable weight, as a mora-based generalization might suggest (Perlmutter 1992). Brentari suggests that sonority be approached as multidimensional salience. She suggests that sonority is correlated articulatorily with closeness of the articulator to the body's midline, and that articulation closer to the midline has greater visual salience than articulation further away. Thus, strengthening of visual salience (Enhancement Theory; Stevens and Keyser 1989) by choice of articulator higher up on the hierarchy (and likewise, reduction by choice lower down) is captured directly by the Prosodic Model in a way that segmental models cannot (Brentari 1998: 135). She suggests the following hierarchy, repeated here from (1) above:

(6) *Brentari hierarchy*

shoulder joint	>	elbow joint	>	wrist joint	>	base finger joints	>	non-base finger joints

This distinction can be observed in cases where a movement can be articulated by different articulators, that is, if a wrist movement and an elbow movement can convey the same phonology. In such cases, if the movement is made by an articulator that is up the hierarchy, say an elbow joint replacing a wrist movement, then "proximalization" is said to occur, whereas if the articulator used is down the hierarchy, from elbow to wrist, then "distalization" is said to happen (see Mirus *et al.* 2001 for an empirical test of the factors involved). Crasborn (2001) likewise provided evidence in NGT for some of the factors relating to proximalization/distalization. An important methodological aspect of Crasborn's study is that it looked at fluent L1 signers, whereas Mirus *et al.* looked at L2 acquisition, for which the presence of sonority effects might be obscured by developmental performance factors.

Looking at data from British Sign Language and the echoing of manual movements by the signer's mouth, Woll (2001) suggests than non-manual articulations can also provide insight into the sonority hierarchy. Based on detailed investigation of these aspects of Finnish Sign Language, Jantunen (2005, 2006, 2007) suggests that non-manual movement should be included in the hierarchy, as in (7), from Jantunen (2005: 56):

(7) upper body and head > hands (including Brentari's hierarchy) > mouth

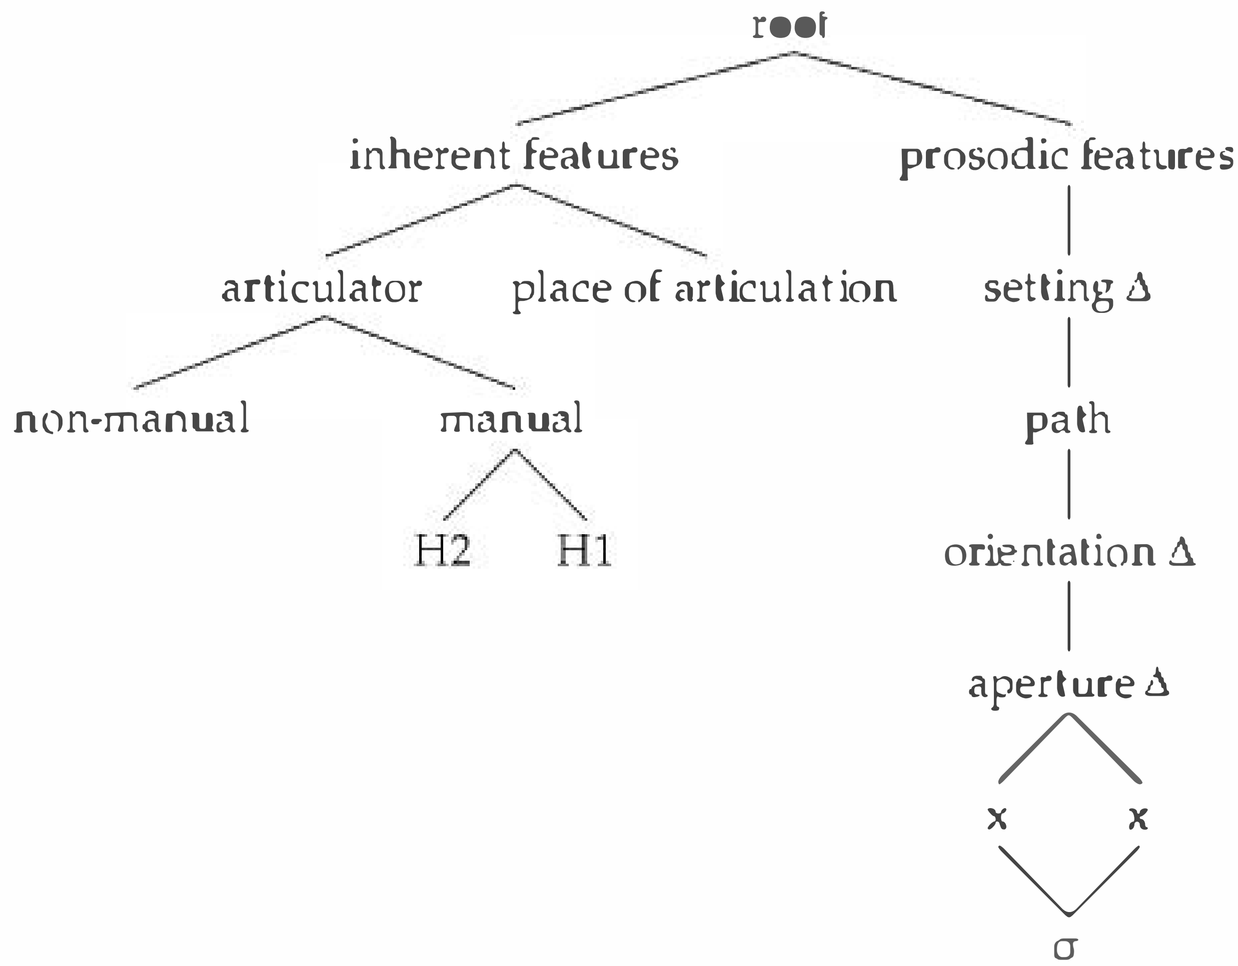
7.3 *Another perspective on reduplication: Templatic vs. prosodic*

Klima and Bellugi (1979) treat reduplication as part of a templatic approach to aspectual modification (CHAPTER 100: REDUPLICATION).[1] They refer to formational terms such as Planar locus (horizontal, vertical), Cyclicity (repetition), Direction (e.g. upward, downward), Geometric array (line, arc, circle, other arrangement), Quality (small, large), and Manner (continuous, hold, restrained). Thus, each morphological function (e.g. iterative, durative) involves a template composed of some of these formational features. But the choices of feature combinations in each template are not explained. Similarly, Sandler (CHAPTER 24: THE PHONOLOGY OF MOVEMENT IN SIGN LANGUAGE) argues for a templatic approach to reduplication, using additional M (movement) or L (location) segments to account for differences in movement type or final holding (what Klima and Bellugi refer to as "end marking").

Further discussion of reduplication with Klima and Bellugi led us to an interesting separation of function for spatial and temporal formational properties, with the spatial properties providing information about the arguments of the verb and the temporal/rhythmic properties providing information about aspect on the verb (Wilbur *et al.* 1983). We speculated that reduplication could be analyzed the same way as in spoken languages. It took over 20 years to work it out, but a standard Base-Copy reduplication approach can be applied to sign languages using the Prosodic Model (Wilbur 2005, 2009). In Brentari's model (8), the node dominating syllables and associated features is the root (CHAPTER 24: THE PHONOLOGY OF MOVEMENT IN SIGN LANGUAGE).

[1] It is important to distinguish repetition from reduplication. Here, repetition is viewed as prosodically driven, to fill the needs of a prosodic foot. Lexicalized repetition creates nouns from verbs, with only two formations of the lexically meaningful movement required. Reduplication is aspectually driven.

(8) *Brentari's Prosodic Model of syllable structure*



Whether one syllable or two in a root, the Base for reduplication is the root, and the entire Base is copied. A simple example with Base and Copies is illustrated in Figure 56.11; planar difference indicates argument differences.

There are, however, two modality differences between standard Base–Copy and what occurs in sign languages. First, multiple copies are common (Figure 56.11); indeed, a single copy implies "dual," so aspectual reduplication typically has two or more copies of the Base. A second difference is that for many aspectual reduplications the hand must return to its initial position in the Base before it can articulate the Copy, thus the sequence is Base–Return–Copy. Aspectual reduplication is a combinatorial system of Base event (verb root), followed by Return to initial position, which reflects the time between the end of the Base event and the onset of the repeated event in aspects involving iteration (Wilbur 2005, 2009). Different aspects determine the size of the Return (smaller than, equal to or greater than the Base) (Table 56.1). Whether the shape includes a stopping point or is smooth (circular, elliptical) is dependent entirely on whether the verb is telic (contains a stop) or atelic (cannot stop) (Wilbur 2008).

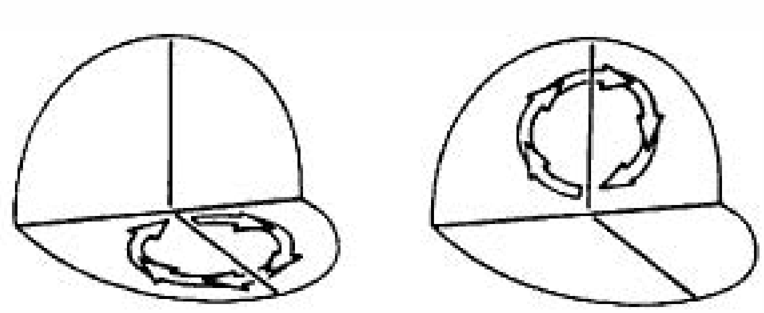


Figure 56.11 Base–Copy reduplication schemata for apportionative external and internal. By permission of Ursula Bellugi, The Salk Institute for Biological Studies

Table 56.1 Combinations of Return options and Base event type yield aspectual inflections

time between events	*telic event root*	*atelic event root*
[return = root]	habitual	durative
[return < root]	incessant	n/a
[return > root]	iterative	continuative

For telic events (Figure 56.12), when Return and Base are equal in size, there is the appearance of equal prominence on both (habitual); when the Return is smaller, there is a tendency for the Base to reduce as well (incessant). When the Return is larger than the Base, an arc is added (the morpheme EXTRA; Wilbur 2008). Thus, featurally, incessant aspect has [repeat] [return] [less than], habitual [repeat] [return] [equal] and iterative [repeat] [return] [greater than].

For atelic events (Figure 56.13), only two of the three options are possible, and the Base must be curved. Both of these requirements result from the absence of stops in the formation of atelic roots. Durative has [repeat] [return] [equal] and continuative has [repeat] [return] [greater than]. The atelic equivalent of the incessant, [repeat] [return] [less than], is not possible, because shortened movements would be perceptually equivalent either to stops, creating confusion with telics, or to trilled movement, which has a different interpretation (stative, not repeated). The difference between the modifications shown in Figures 56.12 and 56.13 is the Base root, which reflects the event structure in the semantics of the verb.

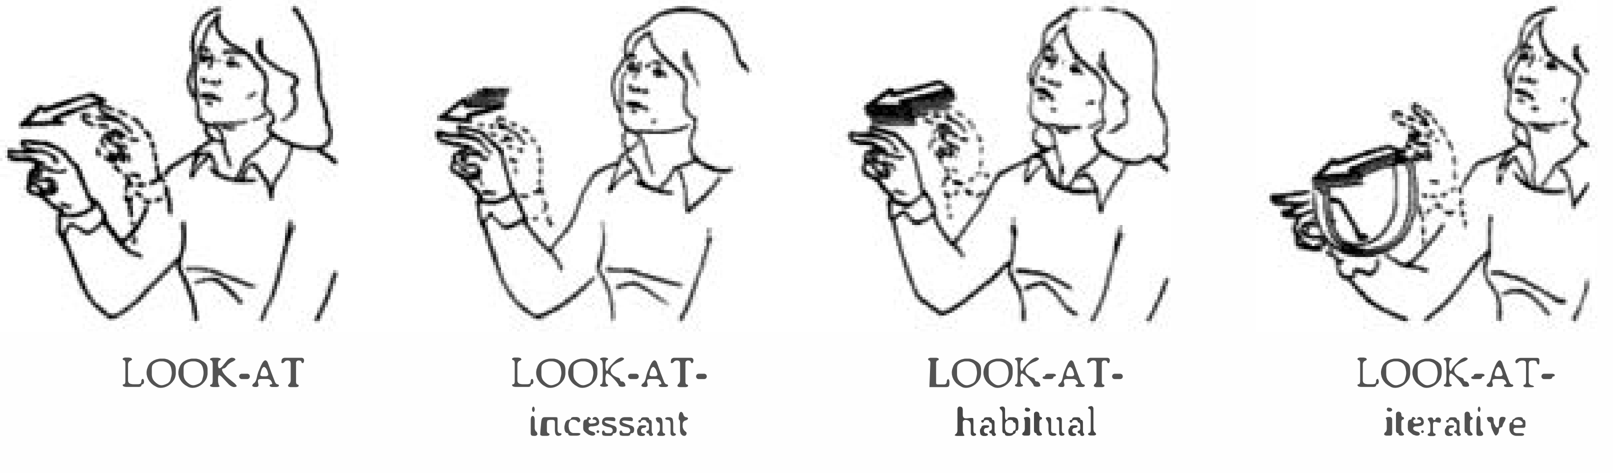

Figure 56.12 LOOK-AT and three inflections. By permission of Ursula Bellugi, The Salk Institute for Biological Studies

Figure 56.13 LOOK-stative and durative and continuative aspects. By permission of Ursula Bellugi, The Salk Institute for Biological Studies

These observations are not captured by a templatic approach to reduplication. Sandler's (1989, 2008) evidence for templatic analysis (for signs like BLOW-TOP, FAINT, and SNOOP) are all compatible with the generalization that aspectual reduplication copies the verb root. She argues that for the sign BLOW-TOP, which is a two-syllable compound created from HEAD and EXPLODE-OFF, EXPLODE-OFF is copied but not HEAD. Her explanation is that the rightmost M is copied in reduplication, whereas in lexicalized monosyllabic (single M) signs like FAINT (originally from MIND+DROP), the whole form is repeated. But in the alternative analysis presented here it is expected that EXPLODE-OFF will be copied. Similarly, Sandle cites SNOOP (from NOSE+STICK-IN) as an exception, with the syllable associated with STICK-IN reduplicating, even though the entire form is monosyllabic (single M). An explanation for this is that the initial movement *to the nose* for NOSE is purely epenthetic (as for MOTHER (Figure 56.3), and one of the two versions of PARENTS in §4.3). That is, SNOOP starts its STICK-IN movement at the nose but does not return there for subsequent repetitions. If so, it might be appropriate to consider the initial location at the nose to be something akin to a prefixal location adjoined/cliticized onto the beginning location of STICK-IN, resulting from the compound-to-lexical-item reduction process, leaving STICK-IN to be copied by reduplication with its original location, as shows up in subsequent repetitions.

This discussion highlights the kind of phonological level analysis that can be conducted with respect to syllables and their contents. Thus, factors other than phonology, such as verbal telicity and type of aspectual morphology, affect the final form of reduplicated signs (Wilbur 2005, 2009).

8 Conclusion

In this chapter, we started with two basic criteria for discussion of syllables in sign languages: linguistic meaningfulness and reliable measurement. To address the requirements of these criteria, we introduced the reader to relevant historical discussions of the status of syllables in sign languages. The key is that movement is the defining feature of a phonological syllable in sign languages. Then, we provided evidence that syllables in sign languages can be reliably measured. As for the criteria of linguistic meaningfulness, we reviewed several phenomena for which one has to make reference to the syllable for a reasonable account. Among those discussed were the phonologization of fingerspelled loan words, contact metathesis, handshape changes within and between signs, and some prosodic constraints.

We then turned to the debate concerning the formal representation of sign syllables. We reviewed the sequential and simultaneous models of syllable representation. Data presented – tapping, slips of the hand, and backwards signing – strongly favor the Prosodic Model proposed by Brentari (1998), resulting in a syllable model that is internally different from those that exist in speech. We then considered the implications of this conclusion, especially since it goes against expectations of similarity between signed and spoken languages. Issues of sonority, syllable weight, and Base–Copy reduplication indicate that the syllable performs similarly in sign language and spoken language phonologies despite the internal differences in organization.

To get to the point where we can use syllables for explaining other phenomena, we have needed a consistent and well-developed syllable model that makes empirically testable claims. This model has been tested in a variety of ways reviewed in this chapter, and there is more that has been omitted for reasons of space (variability of non-manual marking; judgments of well-formed syllables; Brentari and Wilbur 2008). The critical feature of the model is that it is a *prosodic* model, and the lowest level of the prosodic hierarchy is the syllable, for sign languages as well as spoken languages.

ACKNOWLEDGMENTS

The preparation of this chapter was funded in part by NIH-NIDCD: "Prosodic features of American Sign Language" (1993–98); NIH-NIDCD: "Modeling the nonmanuals of American Sign Language" (2004–10); NSF: "A basic grammar of Croatian Sign Language" (2004–10); NSF: "Syllables in American Sign Language" (1984–87). 57 Quantity-sensitivity

DRAGA ZEC

1 Introduction

Quantity-sensitivity is an important property of prosodic constituents, which are subclassified along this dimension as either light or heavy. In a typical hierarchical organization of prosodic units, as in (1) (Selkirk 1978, 1980; Nespor and Vogel 1986), each of the prosodic levels may be instantiated by constituents that vary in length, segment quality, or structural complexity (see CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE; CHAPTER 40: THE FOOT; CHAPTER 51: THE PHONOLOGICAL WORD; CHAPTER 84: CLITICS; CHAPTER 50: TONAL ALIGNMENT).

(1) *Prosodic hierarchy*

Prosodic phrase
Prosodic word
Foot
Syllable

This variation, in at least some of its aspects, introduces distinctions in quantity among constituents at the same level of the hierarchy, evidenced by distinctions in phonological behavior. While quantity-sensitivity is most clearly manifested at the level of the syllable, other prosodic levels exhibit this property as well. Quantity-sensitivity characterizes a wide range of phonological phenomena, including stress, tone, poetic meter, and various prosodic effects on morphosyntax. Moreover, quantity-sensitivity can be manifested either as a binary or as a scalar property. For these and other reasons to be addressed in this chapter, prosodic quantity needs to have its place in the formal representation of prosody, and is a central issue in any discussion of phonological representations.

The chapter is organized as follows: §2 addresses crucial aspects of weight-sensitivity in the syllable, providing a typology of weight patterns supported by a wide range of attested cases. §3 focuses on formal representations of the syllable and its weight, while §4 addresses the relevance of vowel length for quantity-sensitivity. §5 shows that weight distinctions could be binary in some languages, and multivalued in others. §6 documents inconsistencies in weight patterns, both with respect to phonological processes and phonological contexts. §7 addresses quantity-sensitivity in feet, focusing on binary patterns, and §8 focuses on scalar patterns of quantity. §9 touches upon quantity-sensitivity at the higher levels of the prosodic hierarchy, in prosodic words and prosodic phrases. §10 offers some remarks on markedness, and §11 concludes.

2 The syllable and quantity-sensitivity

Phonological quantity is primarily associated with the syllable. One of the traditional classifications of syllables is into those that are light and those that are heavy. This distinction is motivated on empirical grounds and is brought to relief by a number of quantity-sensitive phonological phenomena, including stress, tone, and poetic meter. We focus here only on those languages that do exhibit quantity-sensitivity at the syllable level, as this is not a universal prosodic property. In §2.1 we present a paradigm case of syllable weight, and then, in §2.2, turn to the typology of syllable-based quantity-sensitivity, supported by a wide range of phonological phenomena.

2.1 A paradigm case of quantity-sensitivity

Quantity-sensitivity has figured prominently in studies of classical languages and their prosody (Allen 1973). Latin provides a paradigm case of quantity-sensitivity, already known to the early grammarians such as Quintilian.

Latin stress (CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE) is quantity-sensitive, as illustrated in (2). If the penultimate syllable is heavy it is stressed, as in (2a), but if it is light the antepenultimate syllable is stressed, as in (2b).

(2) *Latin stress*

a. If the penultimate syllable is heavy, it is stressed.

for'tūna	'fortune (NOM SG)'
'gaudēns	'rejoicing (NOM SG)'
gau'dentem	'rejoicing (ACC SG)'

b. If the penultimate syllable is light, the antepenultimate is stressed.

'anima	'soul (NOM SG)'

Syllables that function as light are of the CV type, containing a short vowel, as the penultimate syllable in (2b). Syllables that function as heavy are more diverse, as shown in (2a). They are either of the CVV type, containing a long vowel or a diphthong, or of the CVC type, with a short vowel followed by a consonant. Significantly, syllables that are functionally equivalent may differ in their segmental content (CHAPTER 54: THE SKELETON). Within the set of heavy syllables, differences in segmental content are found not only across CVV and CVC syllables but also within the class of CVV syllables, which may contain either a long vowel or a diphthong. In this case, as in many others, onset consonants are excluded from the computation of weight (CHAPTER 55: ONSETS).

This same pattern of syllable weight also figures in Latin poetic meter. In one of the meters of Horace's *Odes*, known as the *First Asclepiad* (borrowed from

Greek), a line of verse contains a sequence of metrical positions that admit either heavy or light syllables (marked as – and ∪, respectively, with || marking the caesura), as in (3). In (3a), the first three metrical positions, all heavy, are filled with CVV syllables that contain either a diphthong or a long vowel, while in (3b) these same metrical positions are filled with CVC syllables. The light metrical positions, such as the next two, are filled in both lines with CV syllables. (The remaining metrical positions are filled in the same fashion, with the exception of the last vowel of *tollere* in (3b) which is elided, and therefore not scanned.)

(3) *Latin poetic meter: Horace,* First Asclepiad

a. – – – ∪∪ – || – ∪∪ – ∪ x
Maecēnās atavīs ēdite rēgibus
'O Maecenas, born from kingly ancestors!' (*Odes* 1.1.1)

b. – – – ∪ ∪ – || – ∪ ∪ – ∪ x
Certat tergeminīs tollere honoribus
'vies to lift [him] with triple magistracies.' (*Odes* 1.1.8)

Thus, in Latin, both stress and poetic meter are sensitive to distinctions in quantity, with weight characterized identically in the two phonological subsystems.

2.2 *Patterns of quantity-sensitivity*

The system of quantity in Latin exemplified in (2) and (3) was taken in much relevant work to be the standard mode of computing quantity, with broad empirical support. This is how syllable weight was characterized in Kuryłowicz (1948) and later in Newman (1972), among others. Newman (1972), in particular, identifies quantity-sensitivity in a number of languages, all exemplifying the pattern of quantity with light CV and heavy CVV and CVC syllables. In addition to Latin, the list includes Classical Greek, Finnish, Estonian, Classical Arabic, and Gothic, as well as three Chadic languages, Bolanci, Kanakuru, and Hausa. In fact, a number of researchers stated important generalizations about quantity-sensitivity solely in terms of the Latin pattern of weight (e.g. Kiparsky 1979, 1981; Halle and Vergnaud 1980; Clements and Keyser 1983).

The Latin pattern, however, is not the only empirically attested mode of computing quantity, as shown in Hyman's (1977) broad survey of stress systems and in much later work. In what follows we present the range of quantity patterns that have been empirically attested, and a typology of weight distinctions.

2.2.1 *Weight patterns: A typology*

McCarthy (1979) made the crucial theoretical statement that quantity-sensitivity can be instantiated in more than one way. In addition to the Latin weight pattern, with light CV and heavy CVV and CVC syllables as in (4a), henceforth type 1, there is a further weight pattern, one in which only CVV syllables are heavy and both CV and CVC syllables are light, as in (4b), henceforth type 2. A number of languages were identified to belong to this weight type: for example, Huasteco Mayan in Hyman (1977) and Yidin^y and Tiberian Hebrew in McCarthy (1979). Many more such cases figure in Hayes (1980, 1995) and Gordon (2006).

(4) *Possible weight patterns* (first approximation)

a. Type 1: heavy CVV, CVC *vs.* light CV
b. Type 2: heavy CVV *vs.* light CV, CVC

Thus the weight of CVC syllable is "parameterized": while in (4a) such syllables form a natural class with CVV, in (4b) they form a natural class with CV. This is crucially due to the status of the final consonant in a CVC syllable, which contributes to weight in (4a), but not in (4b) types of languages. McCarthy (1979) further identifies an important implicational relation: a language with heavy CVC syllables also has heavy CVV syllables. This supports the prediction about the following impossible weight pattern: no language can have heavy CVC but light CVV syllables.

But computation of quantity can be even more fine-grained than in (4), and in order to show this we invoke the sonority of segments. In particular, vowels are more sonorous than consonants, and within the class of consonants, sonorants (CHAPTER 8: SONORANTS) are more sonorous than obstruents. (For a general discussion of sonority, see CHAPTER 49: SONORITY.) In addition to the two weight systems in (4), one in which all consonants contribute to weight, and one in which no consonants contribute to weight, there is also a type 3 system, in which only some consonants contribute to weight (see Prince 1983; Zec 1988, 1995). In such split systems, the subset of consonants contributing to weight is generally sonorants. Such a case is exemplified by Kwakw'ala, to be discussed in §2.2.2, in which heavy syllables are CVV and CVR (sonorant), while light syllables are CV and CVO (obstruent). This yields the implicational relation that if CVO syllables are heavy, so are CVR syllables; and excludes the impossible system, with CVV and CVO syllables being heavy, and CV and CVR syllables being light (Zec 1995). Furthermore, while other splits in the hierarchy should in principle be possible, say, with liquids being weight-bearing to the exclusion of obstruents and nasals, such systems have not been attested. Only major splits within the sonority hierarchy appear to be exploited for distinctions in quantity, those in particular that correspond to splits imposed by the major class features (Chomsky and Halle 1968).

To summarize, a basic typology of weight patterns is given in (5). In type 1 languages, all segments contribute to weight, so that both CVV and CVC syllables are heavy; in type 2 languages only vowels are weight-bearing, which makes CVC syllables light; and in type 3 languages vowels and sonorant consonants are weight-bearing, to the exclusion of obstruents. The set of weight-bearing segments follows the sonority hierarchy: if a less sonorous segment contributes to weight, so does a more sonorous segment.

(5) *Typology of weight patterns*

	Heavy	*Light*
Type 1	CVV,CVC	CV
Type 2	CVV	CV, CVC
Type 3	CVV,CVR	CV, CVO

A special case of type 2 languages is those that lack CVC syllables. In a syllable inventory including only CV and CVV syllables, the former are light and the latter are heavy, as in Fijian (Hayes 1995; among others). Likewise, a special case of type 3 languages consists of those that lack CVO syllables, with an inventory that includes light CV and heavy CVV and CVR syllables, as in Tiv (Zec 1995); or Manam, in which the set of heavy syllables includes CVV and CVN (nasal), but excludes syllables closed with liquids (Lichtenberk 1983; Buckley 1998).

Crucially, the onset is excluded from the computation of weight: the number of segments in the onset does not affect the weight status of a syllable. This empirically grounded property of onsets will need to be captured in the representation of the syllable, an issue to be addressed in §3. But although broadly attested, this is not a universal property of onsets; see CHAPTER 55: ONSETS for cases of weight-sensitive onsets, which constitute counterexamples to this claim.

To conclude, it has been shown that there is a measure of language-specificity, with different modes of quantity computation employed in different languages. It has also been shown that there is an implicational relation across occurring weight patterns, or, more specifically, across the sets of heavy syllables in different languages, as in (6):

(6) *Implicational relations among heavy syllables*

a. If a language has heavy CVC syllables, it also has heavy CVV syllables.
b. If a language has heavy CVO syllables, it also has heavy CVR syllables.

2.2.2 *Weight patterns: Case studies*

The three patterns of quantity in (5) are documented below with two types of quantity-sensitive phonological phenomena: stress and tone. We begin with stress, which provides the most striking cases of quantity-sensitivity. It should be noted though that only some stress systems are quantity-sensitive. According to Gordon's (2006: 20–21) extensive survey, based on 408 languages, 310 languages have culminative accent systems. Out of those, 136 (43.9 percent) exhibit quantity-sensitivity, and 86 belong to one of the three weight systems we exemplify here.

Languages with quantity-sensitive stress show a clear preference for placing stress on heavy syllables (cf. Hyman 1977; Hayes 1980, 1995; Halle and Vergnaud 1987; Halle and Idsardi 1995). Simply stated, heavy syllables attract stress (Prince 1990). Moreover, languages with quantity-sensitive stress systems are of either type 1 or type 2, and rarely of type 3. The Latin stress pattern illustrated in §2.1, which belongs to type 1, is found in a number of languages. Out of 86 languages with quantity-sensitive stress in Gordon's survey, 42 languages are of type 1. It is found, for example, in Modern Classical Arabic (as described in Ryding 2005), where stress falls on the penultimate heavy syllable, CVV or CVC, otherwise on the antepenultimate syllable. Note, however, the pattern in Classical Arabic, where stress falls on the rightmost (non-final) heavy syllable, as in (7a), otherwise on the first syllable, as in (7b) (McCarthy 1979, and the references therein).[1]

[1] Final syllables have a special status, in at least two respects. Stress does not fall on final CVC syllables, but CVVC and CVCC syllables, which are only found word-finally, do bear stress. The special behavior of final elements is a more general issue, to be addressed in §6.2.

(7) *Type 1: Classical Arabic*

a.	ki'taabun	'book (NOM SG)'
	manaa'diilu	'kerchiefs (NOM)'
	ju'ʃaariku	'he participates'
	'mamlakatun	'kingdom (NOM SG)'
b.	'kataba	'he wrote'
	'balaħatun	'date (NOM SG)'

The type 1 weight pattern is also noted in English, although the overall stress system is rife with idiosyncrasies. A small portion of the English lexicon, the set of underived nouns, has a relatively regular stress pattern: stress falls on the heavy penult, either CVV as in *e'litist*, *ma'rina*, and *Ari'zona*, or CVC as in *a'genda*, *a'malgam*, and *co'nundrum*; otherwise on the antepenult, as in *'discipline*, *'labyrinth*, and *A'merica* (Hayes 1982). This stress pattern is again reminiscent of Latin. Many more type 1 stress systems are documented in Hayes (1995) and Gordon (2006).

Quantity-sensitive stress systems of type 2 are evidenced in a wide range of languages, just like type 1 (Hayes 1995; Gordon 2006; among others): 40 out of 86 quantity-sensitive stress systems in Gordon's survey. It is found, for example, in the Mongolian language Buriat (Poppe 1960; Walker 1996), illustrated in (8): stress falls on the initial syllable in words with no long vowels, as in (8a), and on the rightmost *non-final* heavy syllable in words with more than one long vowel or diphthong, as in (8b). If a word has only one CVV syllable, stress falls on that syllable even if it is final, as in (8c). Note that CVC syllables figure in the language, yet do not attract stress, for example, the third syllable in /ta'ruulagdaxa/, in (8b).

(8) *Type 2: Buriat*

a.	'xada	'mountain'
b.	mo'rʲooroo	'by means of his own horse'
	dalai'gaaraa	'by one's own sea'
	ta'ruulagdaxa	'to be adapted to'
c.	xa'daar	'through the mountain'

Another type 2 system is Huasteco Mayan (Larsen and Pike 1949; Hyman 1977; Hayes 1995: 296): stress falls on the rightmost CVV syllable, otherwise on the initial CV syllable. Again, CVC syllables pattern with CV rather than CVV syllables. And, in Aguacatec Mayan (McArthur and McArthur 1956; Hayes 1980, 1995), stress falls on a CVV syllable regardless of its position within a word, as in (9a); stress is final in words with no long vowels, as in (9b).[2]

(9) *Type 2: Aguacatec Mayan stress*

a. *Forms with* CVV *syllables*

ʔin'ta:	'my father'
'ʧi:bah	'meat'
'ʔe:q'um	'carrier'

[2] All examples are from McArthur and McArthur (1956), who list no cases of final CV syllables. Also, they claim that stress falls on the rightmost CVV syllable, yet no words with more than one CVV syllable are found in this source.

b. *Forms with no* CVV *syllables*
wu'qan 'my foot'
ʔal'k'om 'thief'
tpil'taʔ 'courthouse'

Quantity-sensitive stress systems are very rarely of type 3. In Gordon's (2006) survey, only four out of 86 languages are of type 3. Here we illustrate the distribution of stress in Kwakw'ala, in which CVV and CVR syllables pattern as heavy, while CV and CVO pattern as light (Boas 1947; also Zec 1988 and references therein). Stress falls on the leftmost heavy syllable, either CVV, in (10a), or CVR, in (10b). In words that contain only light syllables, CV or CVO, stress is final, as in (10c) and (d).

(10) *Type 3 language: Kwakw'ala*

a.	'qa:sa	'to walk'
	'n'a:la	'day'
	'ts'e:kwa	'bird'
	t'ə'li:dᶻu	'large board on which fish are cut'
b.	'm'ənsa	'to measure'
	'dəlxa	'damp'
	'dzəmbətəls	'to bury in hole in ground'
	mə'xənxənd	'to strike edge'
c.	nə'pa	'to throw a round thing'
	bə'ha	'to cut'
	m'əkʷə'la	'moon'
	ts'əxə'laə	'to be sick'
d.	ts'ət'xa	'to squirt'
	təʎ'ts'a	'to warm oneself'
	kʷ'əs'xa	'to splash'

The three weight patterns in (5) can be further exemplified with tonal phenomena, those provided by languages with lexical, i.e. contrastive tone, in simpler systems commonly High, or High and Low (CHAPTER 45: THE REPRESENTATION OF TONE). Quantity-sensitive tonal phenomena differ substantially from quantity-sensitive stress.[3] Crucial evidence for quantity-sensitivity comes from the so-called contour tones. If no more than one tone is sponsored by a light syllable and no more than two by a heavy one, we can say that multiple tones, standardly referred to as contour tones, may occur on heavy, but not on light, syllables. In other words, we focus on those languages in which a light syllable has one tone-bearing unit and a heavy syllable has two (see Zhang 2002 for different characterizations of

[3] It is not typical for tone to be attracted to a heavy syllable, although some cases have been interpreted in this light. Thus Hopi, as described in Jeanne (1982), has been interpreted as a quantity-sensitive stress system (Hayes 1995): stress occurs on initial heavy syllables, either CVV or CVC, otherwise on non-final peninitial syllables; stress is initial in all disyllables. However, because stress is realized as tonal prominence, this system has also been interpreted as a tonal system in which High tone is attracted to the initial heavy syllable, otherwise to the second syllable, if non-final (Yip 2002: 245). This stress-like behavior of tone, if indeed correctly interpreted, is truly atypical.

contour tones).[4] We further focus on those languages in which the mapping between tones and tone-bearing units is fairly straightforward: a tone-bearing unit may be associated with at most one tone. With this background, we turn to the evidence for the three weight patterns coming from the tonal domain.

We again rely on Gordon's (2006: 32–33) survey: out of 408 languages in his survey, 111 use contrastive tone and, of those, 61 use tone in a quantity-sensitive mode. Type 2 and type 3 weight patterns are widely exploited by weight-sensitive tonal phenomena, while type 1 is rarely associated with quantity-sensitive tone. Type 2 pattern is found in 28 languages (four without CVC syllables), and type 3 is found in 30 languages. In type 2 languages, contour tones occur on CVV syllables, but are absent from both CV and CVC syllables. In Navajo, contour tones occur only on CVV syllables as in (11a), while simple tones occur on all syllable types; (11b) exemplifies the absence of contour tones on CV and CVC syllables (Zhang 2002, based on Young and Morgan 1987).

(11) *Type 2: Navajo contour tone*

a.	sáànìì	'old woman'
	hákòónèèʔ	'let's go'
	tèíIʔá	'they extend'
b.	hááʔált'èʔ	'exhumation'
	pìkʰìn	'his house'

Another type 2 language is Ju|'hoansi, in which, as reported in Miller-Ockhuizen (1998; also Zhang 2002), contour tones are found only on long vowels and diphthongs, but not on CV syllables or syllables closed with nasals (the only type of closed syllable in the language).

Type 3 weight pattern is exemplified by a number of languages, including Nama (Khoisan), Lithuanian (Indo-European), and Tiv (Niger-Congo). Lithuanian has a pitch accent system, in which contour tones appear on heavy, but not on light, syllables. In particular, a Low High tonal contour, the so called circumflex accent, occurs on heavy syllables: CVV, as in /víinas/ 'wine', /zúikas/ 'rabbit', and CVR, as in /gársas/ 'sound', /bálsas/ 'voice', and /lánkas/ 'rainbow'. Syllables that pattern as light are CV and CVC, and those that pattern as heavy are CVV and CVR (Zec 1995 and references therein).

We now turn to the tonal evidence for the type 1 weight pattern. Contour tones are rare, and phonetically difficult to realize, on syllables closed with an obstruent. In his broad survey of quantity-sensitive tone, Gordon (2006) documents only three such cases: Hausa, Luganda, and Musey. Zhang (2002: 51) also lists Ngizim, and Yip (2002: 141–142) mentions the Nilo-Saharan language Kunama (Eritrea). Here we present evidence from Hausa, based on Gordon's (2006) experimental data. Hausa has three tones, two level tones, High and Low, and a contour High Low tone. As shown in (12), on the targeted initial syllables, the two level tones occur on all syllable types, while the contour tone occurs on CVV,

[4] Note, however, that tone languages vary as to what constitutes a tone-bearing unit. What we described here is one of several modes of selecting a tone-bearing unit. On tone and tone-bearing units, see CHAPTER 45: THE REPRESENTATION OF TONE.

CVR and CVO, but not on CV syllables. That is, the contour tone occurs on heavy, but not on light syllables.

(12) *Type 1: Hausa contour tone*

	L	H	HL
CV	fàsá:	sáfú:	–
CVV	mà:má:	rá:ná:	lâ:lá:
CVR	ràndá:	mándá:	mântá:
CVO	fàskí:	máskó:	râssá:

Of interest here is the fact that while sonorants, both vowels and consonants, are capable of phonetically realizing pitch, obstruents are not. As shown by Gordon (2006: 92), although the phonological weight of the CVO syllable provides the two tone-bearing units required for the realization of contour tone, the contour is phonetically realized on the vowel, which in this case has greater duration. No comparable increase in duration is evidenced in CVV and CVR syllables with contour tones. Thus, Hausa presents an interesting case of a mismatch between phonology and phonetics.

Other phonological phenomena that provide evidence for quantity-sensitivity include vowel shortening in closed syllables, to be addressed in §6, as well as compensatory lengthening (see CHAPTER 64: COMPENSATORY LENGTHENING) and poetic meter, which in §2.1 served as evidence for Latin. Onsets may on occasion exhibit quantity-sensitivity; for such cases, see CHAPTER 55: ONSETS and CHAPTER 47: INITIAL GEMINATES.

3 Representation of syllable quantity

The relevance of quantity-sensitivity, as well as its representation, was clearly recognized in early theoretical approaches to phonology. Both Jakobson (1931) and Trubetzkoy (1939) document weight distinctions among syllables, and cast them in terms of the unit of weight traditionally referred to as the mora: a light syllable contains one mora, and a heavy syllable contains two moras. Quantity-sensitivity was also recognized by Kuryłowicz (1948), who pursued the characterization of quantity in configurational terms, that is, in terms of a subconstituent of the syllable, the rhyme, whose structure is branching for heavy, and non-branching for light syllables. These two theoretical approaches to quantity-sensitivity, one in terms of constituency and the other in terms of arboreal configuration, emerged again in the 1970s and 80s, as competing representations of syllable weight, as well as the weight of other constituents in the prosodic hierarchy.

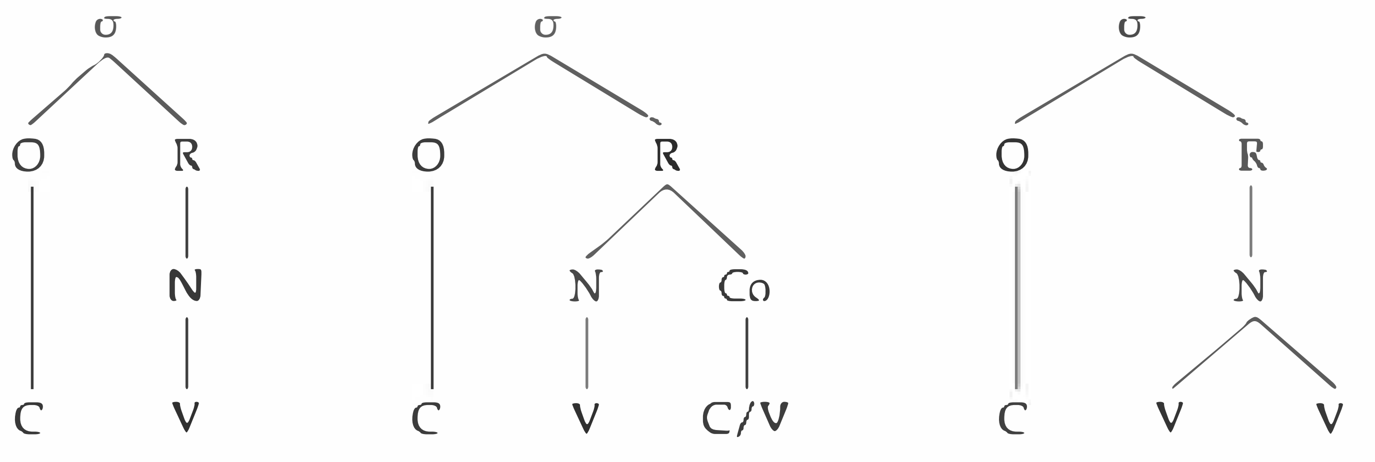
These two approaches both express an important intuition: that quantity formally corresponds to a binary structure. This will emerge as highly relevant in the representation of the syllable and its internal structure. This is also relevant for the representation of feet, as will be shown in §7.

The questions to be addressed in this section are: (i) how is weight computed from the representation of the syllable?; and (ii) how are different weight patterns represented? (For a general discussion of syllable structure and its representation, see CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE.)

3.1 Quantity represented in configurational terms

We begin with the configurational approach to syllable weight. In the representation in (13), the syllable branches into an onset and a rhyme, with the latter obligatorily dominating the nucleus and, optionally, the coda. The sub-syllabic constituent which is taken to be the domain of weight is the rhyme: if the rhyme branches, the syllable is heavy (13b); otherwise it is light (13a). An alternative assumption has been that a branching nucleus, as in (13c), has its role in the computation of quantity.

(13) a. *Light* b. *Heavy: Branching rhyme* c. *Heavy: Branching nucleus*



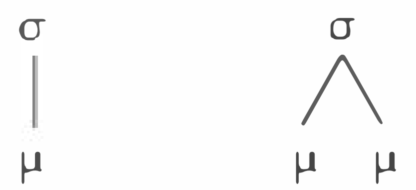
While this constituency was motivated on other grounds as well, capturing syllable quantity has been one of its important rationales. It was generally assumed that encoding weight distinctions is a crucial role of syllable structure. This representation was advocated, in this or somewhat modified form, by Kiparsky (1979, 1981), McCarthy (1979), Halle and Vergnaud (1980), Hayes (1980), Steriade (1982, 1988), and Levin (1985), among others. In all these approaches, the weight domain, provided by the rhyme subconstituent, crucially excludes the onset consonants, which do not participate in any of the weight patterns characterized in §2.2.

How does this representation capture the three weight patterns presented in (5)? In some proposals that primarily focus on type 2 languages (e.g. Halle and Vergnaud 1980), both CVV and CVC syllables are represented in terms of a branching rhyme, that is, as (13b). Capturing both type 1 and type 2 languages called for modifications. In one modification, CVV syllables are represented in terms of a branching nucleus, as in (13c), and CVC syllables in terms of a branching rhyme, as in (13b) (e.g. Hayes 1980). In another modification, different configurations are posited for type 1 and type 2 languages (e.g. McCarthy 1979). Type 3 language posed a special challenge: heavy CVR syllables in this language type were represented in terms of a branching nucleus (13c), with the weight-bearing sonorants residing in the nucleus together with vowels (Steriade 1990).

3.2 Quantity represented by constituency

Another way of capturing syllable weight is in terms of constituency. By positing the mora as a sub-syllabic constituent, syllable weight is represented in terms of the number of moras that the syllable dominates. A syllable with one mora is light, and a syllable with more than one mora is heavy.

(14) a. *Light* b. *Heavy*



While the mora as a unit of syllable weight goes back at least as far as the study of classical languages, it was introduced to theoretical phonology by Jakobson (1931) and Trubetzkoy (1939). Arguments for representing the mora as a sub-syllabic entity are primarily due to Hyman (1985), McCarthy and Prince (1986), Hayes (1989), and Zec (1988). Crucially, moras do not uniquely map to the level of segments. Moraic representations in (14) are thus sufficiently flexible to capture all three systems of syllable quantity. What needs to be stated is the set of segments that can be dominated by the second mora of the syllable: all segments, as in the type 1 weight pattern, only vowels, as in type 2, and vowels and sonorant consonants, as in type 3. How this is to be implemented varies with specific phonological models, which may rely either on rules or on constraints. Thus Hayes (1989) posits a weight-by-position rule, Zec (1988, 1995) posits language-specific sets of moraic segments that act as constraints on the second mora of a syllable, and Morén (1999) proposes optimality-theoretic constraints on moraic segments that parallel Prince and Smolensky's (1993) constraints on syllable nuclei.

4 Quantity-sensitivity and vowel length

Quantity-sensitivity is not a necessary property of the syllable. A number of languages, some listed in Hayes (1995), do not exhibit quantitative distinctions at the level of the syllable, for example, Bulgarian (Indo-European), Piro (Arawakan), Garawa (Karawic), and Modern Greek (Indo-European). Significantly, all these languages also lack vowel length (CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH). This strongly suggests that the basic weight contrast is in fact that between short and long vowels, and raises the question of possible implicational relations between syllable weight and vowel length, either phonemic or non-phonemic.

A strong claim on the relation of CVV and CVC syllables, proposed by Kuryłowicz (1948) and Newman (1972), among others, is that a language with heavy CVC syllables also has phonemic vowel length. While true in a number of specific cases, including Latin, Classical Arabic, and Fijian, this claim is too strong. A weaker claim is that the CVV syllable type is available in languages with heavy CVC syllables even if a language does not have phonemic vowel length (cf. Hayes 1989; Zec 1988, 1995). In such languages, vowel length could arise due to phonological processes such as compensatory lengthening, as in Ilokano (Hayes 1989), or iambic lengthening, as in Hixkaryana (Hayes 1995: 205 and the references therein). This claim rests crucially on a representation already available in a language (see §3), rather than on its phonemic distinctions.

5 Are weight distinctions binary or multivalued?

Cases of quantity-sensitivity presented thus far are characterized by two degrees of weight: a syllable is either light or heavy. The representations of syllable weight in §3 characterize quantity-sensitivity as a binary opposition, with two degrees of weight. However, a further question to be explored is whether there are cases of more than two degrees of weight, that is, whether quantity distinctions can be construed as scalar in nature.

Weight patterns with weight-bearing consonants, types 1 and 3, present an obvious point of departure. In a language with light CV and heavy CVV and CVC syllables, what is the status of CVVC and CVCC syllables? Are such syllable shapes allowed? And, if allowed, are they superheavy? That is, do they call for syllable structures that are either ternary branching or trimoraic? Likewise, what is the status of CVVR (and the less likely CVRR) syllables in type 3 languages?

Starting with type 1 languages, we find the following two cases. First, a language may have a syllable inventory that includes CVVC and CVCC syllables. In Hindi, such syllables give rise to three degrees of weight, as in (15a). Evidence for this ternary weight pattern comes from quantity-sensitivity in the stress system. Stress falls on a superheavy syllable if there is one, otherwise on a heavy syllable, otherwise on a light syllable (glossing over the complexities of this system, for details and examples, see §8). By contrast, Latin also has CVVC and CVCC syllables in addition to the standard type 1 inventory, yet exhibits only two degrees of weight, as in (15b). In this case, CVVC and CVCC syllables are functionally non-distinct from heavy syllables, CVV and CVC. This functional identity is supported by both stress and poetic meter.

(15) a. *Hindi*

light	CV
heavy	CVV,CVC
superheavy	CVVC, CVCC

b. *Latin*

light	CV
heavy	CVV, CVC, CVVC,CVCC

Newman (1972) claims that all weight distinctions are binary, pointing to languages like Latin. However, languages like Hindi clearly show that ternary weight distinctions are an attested reality.

Second, a language may have a restricted syllable inventory, with only CV, CVV, and CVC, excluding both CVVC and CVCC syllable shapes. Such languages impose binarity as an upper limit to syllable complexity both in terms of weight, or mora count, and in terms of the number of consonants that may occur at the right margin of the syllable. This situation is clearly illustrated by Turkish (Clements and Keyser 1983). The syllable inventory of Turkish, a type 1 language, includes light CV and heavy CVV and CVC syllables, and systematically lacks CVVC and CVCC syllables. If the prohibited syllable types arise by virtue of morpheme concatenation, they are eliminated by phonological processes. In (16a), the underlying long vowel is shortened in a closed syllable, (nominative and ablative), but not in the open syllable (accusative). And in (16b), the two post-vocalic consonants in the underlying form are split by an epenthetic vowel (CHAPTER 67: VOWEL EPENTHESIS), in order to avoid a CVCC syllable (nominative and ablative).

(16) *Turkish*

			accusative	*nominative*	*ablative*
a.	CVVC → CVC				
	/zamaːn-/	'time'	zamaːnɯ	zaman	zamandan
	/ispaːt-/	'proof'	ispaːtɯ	ispat	ispattan
b.	CVCC → CVCVC				
	/karn-/	'abdomen'	karnɯ	karɯn	karɯndan

Type 3 languages, or at least the known cases, do not provide evidence for ternary weight distinctions. Lithuanian, for example, has the following syllable shapes in its inventory, classified in terms of weight:

(17) *Lithuanian*

Light	CV, CVO, CVOO
Heavy	CVV, CVR, CVVO, CVRO

This weight pattern, as we saw in §2, is supported by the system of Lithuanian pitch accents (CHAPTER 42: PITCH ACCENT SYSTEMS): only heavy syllables, that is, CVV and CVR, can have contour tones. Lithuanian also provides evidence for strict binarity. This is evidenced by the process known as ablaut which applies in verbal morphology, with the effect of lengthening the root vowels in the preterite and infinitive, but not in the present form (Zec 1995). Vowel lengthening due to ablaut takes effect in all preterite forms: the root vowel occurs in an open syllable, due to the vowel-initial ending *-ee*, and is free to lengthen. In the infinitive forms, the root vowel is in a closed syllable, due to the consonant-initial ending *-ti*. Lengthening takes place in (18a), i.e. in roots that end in an obstruent, but not in roots that end in a sonorant (18b).

(18) *Lithuanian: Ablaut in verbal forms*

		root	*present*	*preterite*	*infinitive*	
a.	CVO	tup-	tupia	tuupee	tuupti	'perch'
		dreb-	drebia	dreebee	dreebti	'splash'
b.	CVR	vir-	viria	viiree	virti	'boil'
		mir-	miria	miiree	mirti	'die'

That is, ablaut may not create a superheavy CVVR syllable, and is therefore prevented from taking effect in the infinitives of the roots in (18b).

While type 2 languages may tolerate CVCC and CVVC syllables in their syllable inventories, such syllables do not form a natural class: the former has the weight of CV, and the latter has the weight of CVV syllables.

The extended syllable inventories we document in this section call for representations richer than those discussed in §3. This was directly addressed in moraic representations of the syllable and its weight: a constraint restricts the number of moras per syllable to no more than two; and this constraint can be violated in some languages, giving rise to trimoraic syllables, as in Hindi. The syllable inventory in Latin is accommodated by allowing some non-moraic consonants at the syllable's right margin (for a detailed discussion, see Sherer 1994).

6 Inconsistencies in weight patterns

The representations in §3, despite some conceptual differences, make the strong prediction that quantity distinctions in a language will be of the same type across the board, that is, in all relevant phonological processes, and in all contexts. However, a challenge to this strong position comes from many known cases of weight inconsistencies.

6.1 *Weight inconsistencies with respect to phonological process*

In §2.1 we saw that Latin belongs to the type 1 weight pattern both in its stress system and in the system of poetic meter. The phenomenon of compensatory lengthening (CHAPTER 64: COMPENSATORY LENGTHENING) conforms to this same weight pattern, as in /kasnus/ → [kaːnus]. While not uncommon, weight consistency across different phonological processes, as evidenced in Latin, is not the general case. Weight inconsistencies are encountered in a number of languages, as noted by Steriade (1990), as well as Hayes (1995) and Gordon (2006). One such case is Kiowa (Watkins 1984). As shown in (19), vowels are shortened in syllables closed by sonorants (19a), as well as those closed by obstruents (19b) and (19c), suggesting a type 1 weight system that obeys strict binarity.

(19) *Kiowa short vowels in closed syllables: Type 1*

a.	gúːlêː	'write-IMPERF-FUT'
	gûl	'write-IMP'
	gúltɔ̀ː	'write-FUT'
b.	cáːdɔ̀ː	'from the doorway'
	cát	'entrance, doorway'
	cátpé	'against the doorway'
c.	tʰɔ́ː	'beyond'
	tʰɔ́ːdèkʰìː	'next day'
	tʰɔ́p	'away beyond'

However, the distribution of contour tones, shown in (20), clearly points to a weight system of type 3. Contour tones occur on CVV syllables and syllables closed by a sonorant, as in (20a), but not on either CV syllables or syllables closed with an obstruent, as exemplified in (20b).

(20) *Kiowa contour tones: Type 3*

a.	páːlêː	'weak'
	sân	'child'
	kʰûl	'pull off'
b.	sàːné	'snake'
	sép	'rain'

Another case is Lhasa Tibetan (Gordon 2006, based on Dawson 1980), in which the stress system treats only CVV syllables as heavy, while the system of tone treats as heavy both CVV and CVR syllables (Gordon 2006 and references therein). In other words, Lhasa Tibetan is a type 2 language in its stress system, and a type 3 language in its tonal system. According to Steriade (1990), variability in weight is also found in Classical Greek, in which CVV syllables are heavy for the purposes of tone, yet all syllables are heavy for the purposes of stress distribution. Thus, stress falls on the penultimate syllable if the final syllable is heavy, either CVC(C) or CVV(C), otherwise it is antepenultimate. However, only CVV syllables can sustain tonal contours, either HL or LH.

Cases of weight variability in different phonological subsystems within a single language present an important challenge to formal representations, and call for fresh perspectives on the syllable and its quantity.

6.2 *Weight inconsistencies with respect to phonological context*

It has been noted in much work on stress that the weight of a syllable may be computed differently in word-internal and word-final positions. Thus in Classical Arabic, as shown in §2, stress falls on the rightmost CVV or CVC syllable, yet never on the final CVC. That is, CVC syllables are computed as heavy word-internally and as light word-finally. A further fact, not mentioned in §2, is that final CVCC syllables are always stressed, i.e. they are computed as heavy (CVCC do not occur word-internally). In other words, word-final consonants do not contribute to weight. Such cases of variable weight were subsumed in Hayes (1980) under the more general rubric of extrametricality (CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY), according to which certain phonological entities, segments as well as higher constituents, are "invisible" to phonological processes at word edges. There have been proposals, however, to treat contextual differences in weight as representational differences (Davis 1987; Kager 1989; Rice 1995; Rosenthall and van der Hulst 1999; see also CHAPTER 36: FINAL CONSONANTS). Under this view, the CVC sequence in Classical Arabic would be parsed as a heavy syllable word-internally, and as a light syllable word-finally.

It has been shown, however, that contextual weight differences are not restricted to word edges. Several cases of this type have been reported in Hayes (1994, 1995), among them Cahuilla and Eastern Ojibwa, as well as Central Alaskan and Pacific Yupik. In the Pacific Yupik dialect of Chugach, CVV syllables are heavy in all positions, while CVC syllables are heavy only initially, and light elsewhere. The distribution of stress in Chugach is fairly complex, and there can be more than one stress per word (for details, see Leer 1985; Kager 1993; Hayes 1995). We focus here on the evidence for the variable weight of CVC syllables. While initial CVV and CVC syllables are stressed, as in /'taːta'qa/ 'my father' and /'anciku'kut/ 'we'll go out', initial CV syllables are not, as in /mu'lu'kuːt/ 'if you take a long time'. But in medial position, CVC syllables pattern with CV rather than CVV syllables. Note that the second syllable in /'kal'maːnuq/ 'pocket', a CVV syllable, is stressed. Neither CV nor CVC syllables are stressed in this same environment, as in the forms /'anku'taχtu'a/ 'I'm going to go out' and /'atmaχ'ʧiqu'a/ 'I will backpack'.

Another relevant case is Goroa (Hayes 1980; Rosenthall and van der Hulst 1999, and references therein), in which stress falls on the leftmost CVV syllable, as in

(21a), or on the final CVC syllable, as in (21b); or on the penultimate syllable, as in (21c). Crucially, CVC syllables in positions other than final are not heavy: the second CVC syllable in /giram'bo:da/ does not win over the following CVV syllable, nor do the CVC syllables in /axe'mis/ and /idir'dana/ attract stress.

(21) *Gorоa stress: Variable weight of CVC syllables*

a. *Leftmost* CVV *stressed*

du:gnuno:	'thumb'
giram'bo:da	'snuff'
heni'nau	'young'

b. *Final* CVC *stressed*

a'dux	'heavy'
axe'mis	'hear'

c. *Penultimate syllable stressed*

oro'mila	'because'
am'rami	'ivory arm ring'
idir'dana	'sweet'

Contextually conditioned variation in syllable quantity affects CVC syllables, those that cross-linguistically could be either light or heavy. Thus the variability of the weight of CVC syllables found across languages has also been evidenced within individual languages. The phenomenon of contextually conditioned weight inconsistency of CVC syllables has been addressed, with a fair amount of success, in the Optimality Theory framework, most notably in Rosenthall and van der Hulst (1999).

7 Quantity-sensitivity of the foot

Syllables are grouped into feet, which belong to the next higher level of the prosodic constituency in (1) (see CHAPTER 40: THE FOOT; CHAPTER 41: THE REPRESENTATION OF WORD STRESS). Quantity-sensitivity of the syllable is directly reflected at the level of the foot, as noted in Hayes (1980, 1995), McCarthy and Prince (1986), and Prince (1990), among others. Feet play an important role in the characterization of stress and in prosodic morphology, and our examples will come from both domains.

As shown in a vast body of literature, feet tend to be binary. That is, feet are prosodic constituents resulting from grouping at most two constituents at the next lower level (Hayes 1995; McCarthy and Prince 1986; Prince 1990; among others). How this proceeds depends crucially on whether a language has a quantity-sensitive or a quantity-insensitive foot system (Hayes 1980). In quantity-insensitive systems, pairs of syllables are incorporated into feet regardless of their weight. Relevant for our discussion is foot formation in quantity-sensitive systems, in which syllable weight plays a crucial role. An important property of such systems is the commensurability of a heavy syllable with two lights. There are two types of quantity-sensitive feet, trochaic and iambic (CHAPTER 44: THE IAMBIC–TROCHAIC LAW).

In quantity-sensitive trochaic systems a foot corresponds to either one heavy syllable, as in (22a), or two light syllables, as in (22b); feet are left-headed, that is, have initial prominence, shown in (22b) by underlining.

(22) *Trochaic foot inventory*

a. σ_H
b. $\underline{\sigma_L}\ \sigma_L$

This receives a straightforward interpretation in moraic theory of syllable structure: a foot contains two moras, a condition met either by one heavy syllable, as in (22a), or by two lights, as in (22b). A heavy syllable has a dual status: it counts not only as a syllable but also as a foot. This foot inventory is active in the stress system of Fijian, a type 2 language (Hayes 1995, and references therein). In words with only a light syllable, pairs of syllables are incorporated into feet, computing from right to left, and foot-initial syllables are assigned stress. As a result, stress falls on every second syllable, computed from the right edge, as shown in (23). Parsing of syllables into feet obeys strict binarity, but is not necessarily exhaustive. In words with an odd number of syllables, as in (23c) and (23e), a syllable at the left edge is not footed. (The rightmost stressed syllable bears primary stress; others bear secondary stress.)

(23) *Fijian stress: Light syllables only*

a.	('lako)	'go'
b.	('talo)	'pour'
c.	βi ('naka)	'good'
d.	(ˌⁿdiko) ('nesi)	'deaconess'
e.	pe (ˌresi) ('teⁿdi)	'president'

(24) *Fijian stress: Light and heavy syllables*

a.	ki ('la:)	'know'
e.	(ˌᵐbe:) ('leti)	'belt'
c.	(ˌᵐbele) (ˌᵐbo:) ('tomu)	'bellbottoms'
d.	pa(ˌro:) ka ('ramu)	'program'
e.	(ˌmi:) (ˌsini) ('ᵑgani)	'machine-gun'

In words with both light and heavy syllables, each heavy syllable corresponds to a foot, and is stressed. Right-to-left footing is thus disrupted by heavy syllables, and has to work around them. In the disyllabic form with a heavy final syllable, in (24a), the initial syllable is left unfooted. And the form in (24d), which has five syllables, two light syllables, the first and the third, are left unfooted. All syllables are footed in the remaining forms in (24).

The inventory of feet in (22) captures the distribution of stress in a number of trochaic quantity-sensitive systems, including some of the cases presented in §2. In particular, stress in Latin follows the same pattern as in Fijian, with one notable difference: The final syllable is ignored for the purposes of stress (another case of so-called extrametricality, see §6.2). As a result, trisyllabic forms with only light syllables have initial stress, as in ('*ani*)*ma* 'soul (NOM SG)'. Likewise, final heavy syllables are not stressed: in ('*gau*)*dēns* 'rejoicing (NOM SG)' the penultimate heavy, but not the final heavy, is footed, and stressed (for a detailed analysis, see Mester 1994; Hayes 1995).

We also present a case of prosodic morphology that employs the foot inventory in (22). In the system of Japanese hypocoristic formation, as characterized in

Poser's (1990) detailed study, hypocoristics are formed by adding the suffix *-tjan* to proper names, either to their full or modified form. As shown by Poser, what is considered to be modification is really a case of template satisfaction. Crucially, the template corresponds to a trochaic foot: either to two light syllables or one heavy syllable. Japanese, a type 1 language, has light CV and heavy CVV and CVC syllables. As shown by the truncated versions of the proper name *Hanako*, the suffix is added to two light syllables, as in (25a) or one heavy, as in (25b) and (25c). The truncated form cannot be smaller than a foot, corresponding to a single light syllable, as in the ill-formed (25d). Nor can the truncated form be greater than a foot, corresponding to three light syllables, as shown by the ill-formed (26b). Proper names corresponding to a light syllable are converted to a heavy syllable, that is, to a foot; in (27a) this is accomplished by vowel lengthening. Note that (27b) is also available, as *-tjan* can be added to any proper name in its full form regardless of its size.

(25) *Hypocoristic forms for* Hanako

a. hanatjan
b. haatjan
c. hattjan
d. *hatjan

(26) *Hypocoristic forms for* Takatugu

a. takatjan
b. *takatutjan

(27) *Hypocoristic forms for* Ti

a. tiitjan
b. titjan

Thus, in trochaic prosodic morphology, just as in trochaic stress systems, a heavy syllable is functionally equivalent with two light syllables.

Quantity-sensitive iambic feet differ somewhat in shape from the trochaic set, as shown by the inventory in (28). Iambic feet are right-headed, indicated by the underlining.

(28) *Iambic foot inventory*

a. σ_H
b. $\sigma_L\ \underline{\sigma_L}$
c. $\sigma_L\ \underline{\sigma_H}$

In this case, as well, syllable quantity plays a central role: for a foot to be well-formed, it needs to contain syllables of the correct weight. The iambic system of quantitative feet captures the distribution of stress in Asheninca (Hayes 1995; Payne 1990). Asheninca has a type 2 weight system, with only CVV heavy syllables. The forms in (29a) contain only light syllables: binary right-headed feet are computed from right to left. The final syllable is regularly left unfooted, which yields initial stress in disyllables, as in /'haka/ 'here'. Crucial are the forms in (29b), which contain both light and heavy syllables, and can therefore exemplify all members of the foot inventory.

(29) *Asheninca stress system*

a.	(pa.'me).(na.'ko).(wen.'ta).ke.ro	'take care of her'
	(ha.'ma).(nan.'ta).(ke.'ne).ro	'he bought it for her'
	(no.'ko).(wa.'we).ta.ka	'I wanted (it) in vain'
	(no.'ton).(ka.'men).to	'my gun'
	(ka.'man).ta.ke	'he/she said'
b.	(no.'ma).(ko.'rjaa).('wai).(ta.'paa).ke	'I rested a while'
	(pi.'ɲaa).('paa).ke	'you saw on arrival'
	(i.'kjaa).('piin).ti	'he always enters'
	('poo).(ka.'na).ke.ro	'you threw it out'
	('paa).(ti.'ka).ke.ri	'you stepped on him'

Quantity-sensitive iambic feet also figure in prosodic morphology. In Ulwa, which has a type 1 weight system, the suffix /-ka/ is attached to the leftmost iambic foot, as in (30). It occurs at the right edge of a stem only when the entire stem corresponds exactly to a foot, as in (30a). In (30b), the only way for /-ka/ to be attached to an iambic foot is to occur stem-internally.

(30) *Ulwa construct state* (from McCarthy and Prince 1990: 228)

	base	*possessed*	
a.	al	al-ka	'man'
	bas	bas-ka	'hair'
	kii	kii-ka	'stone'
	sana	sana-ka	'deer'
	amak	amak-ka	'bee'
	sapaa	sapaa-ka	'forehead'
b.	suulu	suu-ka-lu	'dog'
	kuhbil	kuh-ka-bil	'knife'
	baskarna	bas-ka-karna	'comb'
	siwanak	siwa-ka-nak	'root'
	anaalaaka	anaa-ka-laaka	'chin'
	karasmak	karas-ka-mak	'knee'

Trochaic and iambic systems differ with regard to the role of quantity, as noted in Hayes (1985) and Prince (1990) as well as CHAPTER 44: THE IAMBIC–TROCHAIC LAW. The preferred type of trochaic disyllabic feet includes two light syllables, while iambic feet optimally correspond to a sequence of a light and heavy syllable. Thus, disyllabic trochaic feet are preferably even, while iambic feet are preferably of uneven quantity. Evidence for even trochaic quantity comes from the so-called trochaic shortening, which makes an uneven trochee even by vowel shortening, as exemplified by Fijian. The form in (31a), with an underlying long vowel, undergoes shortening when integrated into a disyllabic foot, as in (31b).

(31) *Fijian: Trochaic shortening*

a.	'ta:	'chop'
b.	'ta-ja	'chop-TRANS-3SG OBJ'

By contrast, uneven quantity is an important feature of iambic systems. A number of iambic stress systems are characterized by iambic lengthening, including

Menomini, Hixkaryana, and Kashaya (Hayes 1995). In Hixkaryana (Caribian), prominent CV syllables undergo vowel lengthening, as in (32a) and (32b), and thus become heavy. Note that prominent CVC syllables, which are already heavy, are not subject to lengthening, as in the second foot in (32c), and the initial syllables in (32a) and (32b).

(32) *Hixkaryana: Iambic lengthening*

a.	owtohona	('ow)(to'ho:)na	'to the village'
b.	tohkurʲehonahaʃaka	('toh)(ku'rʲe:)(ho'na:) (ha'ʃa:)ka	'finally in Tohkurye'
c.	nɨhananɨhno	(mɨ'ha:)(na'nɨh)no	'you taught him'

Generalizations about the quantity of trochaic and iambic groupings are stated in Hayes (1995) as the Iambic–Trochaic Law (see CHAPTER 44: THE IAMBIC–TROCHAIC LAW):

(33) *The Iambic–Trochaic Law*

a. Elements contrasting in intensity naturally form groupings with initial prominence.
b. Elements contrasting in duration naturally form groupings with final prominence.

8 Scalar quantity systems

While binary quantity systems are based primarily on grouping syllables into feet, scalar quantity systems are based on prominence, defined along some dimension (Prince and Smolensky 1993; Hayes 1995). A central prominence dimension is syllable weight, although other dimensions, such as tone and vowel height, have been evidenced as well.

We present two cases with syllable weight as the prominence dimension. One is Kashmiri, with examples given in (34) (Kenstowicz 1993; Rosenthall and van der Hulst 1999). In Kashmiri, CVV syllables are heavier than CVC, which in turn are heavier than CV. Thus, in words with only CV and CVV syllables, stress falls on the leftmost CVV, as in (34a). In words with only CV and CVC, stress falls on the leftmost CVC, as in (34b). In words with both CVC and CVV syllables, stress falls on the CVV syllable, as in (34c). Finally, with only CV syllables present, stress is initial, as in (34d). The final syllable is excluded from scansion. (None of the sources supply glosses for Kashmiri forms.)

(34) *Kashmiri stress:* CVV > CVC > CV

a.	mu'si:ba[illegible]	c.	am'ri:ka
	a'jo:gja ta:		mas'ra:wun
b.	ba'gandarladin	d.	'tsaripop
	juni'varsiti		'paharadari:

Languages in which stress is assigned on the basis of scalar syllable prominence may have several degrees of syllable weight. Thus Hindi (for the dialect described in Kelkar 1968) has three degrees of syllable weight: superheavy syllables CVVC and CVCC are more prominent than heavy syllables, CVV and CVC, which in turn are more prominent than CV syllables, as stated in (35).

(35) CVVC, CVCC > CVV, CVC > CV

Excluding the final syllable from scansion, stress is assigned to the heaviest available syllable, as in (36). In both forms stress falls on a CVVC syllable, which in (36b) wins over a CVV syllable, and in (36a) over both a CV and CVV syllable.

(36) a. 'ʃoːxʤabaːniː 'talkative'
b. 'reːzgaːriː 'small change'

If there is a tie, stress is assigned to the rightmost (non-final) syllable: to a CV syllable in (37a), and a CVV syllable in (37b) and (37c).

(37) a. sa'miti 'committee'
b. roː'zaːnaː 'daily'
c. kaː'riːgariː 'craftsmanship'

Interestingly, when the final syllable is the heaviest in the word, it is not excluded from scansion, as in (38):

(38) ki'dʰar 'which way'
ru'pia 'rupee'
as'baːb 'goods'

Quantity in Hindi is thus computed along a scale of syllable weight, with the superheavy syllable being most prominent, followed by the heavy syllable and then by the least prominent light syllable. This case is analyzed in precisely these terms in Hayes (1995) and Prince and Smolensky (1993), although in different frameworks: in rule-based metrical theory and in Optimality Theory, respectively.

An interesting mode of computing prominence is found in Pirahã, a Mura language of Brazil (Everett 1988; Hayes 1995). The Pirahã prominence scale combines syllable weight and onset quality (on onsets, see CHAPTER 55: ONSETS). While CVV syllables are more prominent than CV syllables, voiceless onsets are more prominent than voiced onsets, and presence of onset is more prominent than its absence, yielding the scale in (39).

(39) KVV > GVV > VV > KV > GV [K = voiceless, G = voiced]

Stress falls on one of the last three syllables of the word that is highest on this scale, as in (40a). In the event of ties, the rightmost syllable wins, as in (40b).

(40) *Pirahã prominence-based stress*

a.	'kaːgai	b.	ko'po
	ʔapa'baːsi		ʔaba'pa
	'ʔibogi		paohoa'hai

Further dimensions for computing prominence are in no obvious way related to patterns of syllable quantity we surveyed here. Yet, because of their scalar nature, they are highly reminiscent of quantity-based systems of prominence. One such dimension is vowel quality: given the sonority scale, stress falls on the most sonorous vowel. Prominence systems of this type have been analyzed in Kenstowicz (1997) and de Lacy (2004). In Mordwin, for example, non-high vowels are more prominent than high vowels (CHAPTER 21: VOWEL HEIGHT). In words with only non-high vowels, or with only high vowels, stress falls on the leftmost syllable. However, in words that contain both high and non-high vowels, stress falls on a non-high vowel, regardless of its position in the word. Another dimension is tonal prominence: syllables associated with High tones are more prominent than syllables associated with Low tones, and thus more likely to be associated with stress. Prominence systems of this type are described in Hayes (1995) and de Lacy (2002); for a somewhat different perspective, see Zec (2003). Of particular interest is the complex case of Nanti, a Kampa language of Peru: its stress system, which is of the iambic type, is also governed by several types of prominence, including syllable quantity and vowel quality (Crowhurst and Michael 2005).

9 Quantity-sensitivity at the higher levels of the prosodic hierarchy

When focusing on higher levels of the prosodic hierarchy, the prosodic word and the prosodic phrase, we are in fact dealing with morphosyntax/prosody interface. Quantity-sensitivity is a specifically prosodic phenomenon and is not known to play any role in other modules of the grammar. Any effects of quantity-sensitivity in either morphology or syntax are therefore to be attributed to prosody. We addressed the interfaces with morphology in §8, with two cases of affixes that select not only a morphological class, but also a prosodic type of the stem; both in this case select for the foot. Many more such cases are found in the literature (McCarthy and Prince 1986, 1990, 1995; among others).

The word level of the prosodic hierarchy is constituted by a grouping of feet (CHAPTER 41: THE REPRESENTATION OF WORD STRESS; CHAPTER 51: THE PHONOLOGICAL WORD). In practice, however, one foot is sufficient for a prosodic word to achieve the desired quantity, as documented by numerous cases of minimal word size. Moreover, in a number of languages, no minimal size beyond a single syllable is imposed on prosodic words. This is broadly documented in Hayes (1995) and Downing (2006), among others. In sum, the prosodic word provides no evidence for quantity-sensitivity of the sort found at the level of the syllable and the foot: its binary structure is not distinct from that of a foot. There are no known cases of a prosodic word minimally branching into two feet, yet this would be expected, based on the situation at the lower end of the prosodic hierarchy.

However, quantity-sensitivity has been evidenced at the higher end of the hierarchy, that is, at the level of the prosodic phrase. The distribution of a syntactic constituent should not be affected by its length or internal complexity. When such effects arise, they are generally attributed to prosody. We focus here on cases of branching in prosodic phrases, typical cases of apparent quantity-sensitivity of syntactic constituents. Cases of binary branching prosodic phrases were reported by Nespor and Vogel (1986), with evidence from Italian, French, and English. In Italian, for example, a prosodic phrase preferably contains more than one prosodic word, as shown by the following cases (Nespor and Vogel 1986):

(41) *Prosodic phrase formation in Italian*

a. *Av'rà trovato (il pescecane)*$_\varphi$
'He will have found the shark.'

b. *(I cari'bù nanni)*$_\varphi$ *sono estinti*
'Dwarf caribous are extinct.'

c. *Hanno dei (car'ibù)*$_\varphi$ *(molto piccoli)*$_\varphi$
'They have very small caribous.'

While complements that correspond to single prosodic words, as in (41a), form one-word prosodic phrases, multiple word complements, as in (41b) and (41c), correspond to branching prosodic phrases. The prosodic phrasing in (41c) further shows that complements with three prosodic words do not correspond to a single prosodic phrase, as branching prosodic phrases contain at most two prosodic words. By contrast, Serbo-Croatian sentence-initial topics have to include at least two prosodic words (Zec and Inkelas 1990), and thus exemplify obligatory branching in prosodic phrases. This line of research has been further continued by Ghini (1993), Selkirk (2000), and Sandalo and Truckenbrodt (2002), among others.

10 Remarks on markedness

It is important to note that the markedness (CHAPTER 4: MARKEDNESS) of light and heavy constituents is not identical across prosodic levels: heavy constituents are marked at the level of the syllable, while light constituents are marked at the level of the foot. This is directly encoded in Optimality Theory. Constraints listed in (42) assign marked status to heavy syllables: to CVV syllables, as in (42a), and to syllables with coda consonants, as in (42b) and (42c). While (42b) targets any coda consonant, (42c) targets any weight-bearing segment.

(42) a. NoLongVowel (Rosenthall 1994)
A vowel should not be long, i.e. linked to more than one mora.

b. NoCoda (Prince and Smolensky 1993)
Syllables must not have a coda.

c. *Mora[seg] (Morén 1999)
Do not associate a mora with a particular type of segment.

These constraints, which belong to the markedness family, penalize binary structures at the syllable level, thus favoring a simple CV syllable, which is light. Thus, light syllables emerge as the unmarked case: all languages have light syllables, and some may also have heavy syllables. Superheavy, i.e. trimoraic, syllables are, of course, also marked, and are penalized as such by a constraint against trimoraic syllables proposed by Sherer (1994).

By contrast, heavy feet are preferred over light ones. Binary constituents are highly desirable at the level of the foot, both in trochaic and iambic systems. Non-binary, or light, feet are permitted in some languages under very special conditions and banned in others. The unmarked condition for feet is thus to be binary, that is, heavy, either under moraic or syllabic analysis, and this is codified in Optimality Theory by a corresponding constraint:

(43) FootBinarity (McCarthy and Prince 1993)

Feet must be binary under a syllabic or moraic analysis.

At the higher prosodic levels, constituent size is largely determined by morphosyntax, as is the distribution of light and heavy constituents. However, where permitted by morphosyntax, heavy, i.e. branching, constituents are preferred over light ones (see §9).

11 Conclusion

Quantity-sensitivity is an important property of prosodic structure, evidenced at each of its levels. As we have seen, constituents at any level of the prosodic hierarchy can be classified into those that are light and those that are heavy. While quantity-sensitivity is typically associated with the syllable and the foot, all prosodic levels exhibit this property. Whether a syllable is light or heavy crucially depends on its segmental setup; quantity at the level of the foot relies on, and is largely characterized in terms of syllable quantity; quantity-sensitivity of the prosodic word is non-distinct from that of the foot; and quantity-sensitivity at the higher prosodic levels is heavily influenced by morphosyntax.

While characterization of quantity largely depends on level-specific criteria, a general property of heavy constituents is their greater size and complexity, and often their binary structure. It is interesting, however, that preference, or dispreference, for heavy constituents varies across prosodic levels. The unmarked condition for syllables is to be light while the unmarked condition for feet is to be heavy. The latter condition persists through the higher levels of the prosodic hierarchy. Thus, while light syllables are preferred over heavy ones, feet and prosodic words are preferably heavy. Heavy prosodic phrases are preferred as well, although in a very weak sense.

ACKNOWLEDGMENTS

I am most grateful to Adam Cooper, Michael Weiss, and Kimberly Will, to an anonymous referee, and to the editors, Marc van Oostendorp and Keren Rice, for their invaluable comments and suggestions, which have led to major improvements to this chapter.

Volume I: General Issues and Segmental Phonology
Volume II: Suprasegmental and Prosodic Phonology
Volume III: Phonological Processes
Volume IV: Phonological Interfaces
Volume V: Phonology across Languages

The Blackwell Companion to Phonology is a major reference work drawing together 124 new contributions from leading scholars in the field. Led by a team of renowned international scholars, the *Companion* represents a diverse range of approaches and methodologies to key phenomena in phonological research. In contrast to other handbooks and reference works currently available for phonology, these volumes focus on phenomena and case studies that highlight past and ongoing debates in the field. Interdisciplinary connections, such as those with the social and computational sciences, are covered, as well as statistical and experimental techniques. The *Companion* will be a touchstone for future phonological theorists, giving an overview of data and insights which any theory of phonology should be able to cover.

Simultaneously offering broad coverage and a high level of detail, *The Blackwell Companion to Phonology* is a landmark work available in both print and online editions that will be indispensable to students and researchers in the field for years to come.

86 Morpheme Structure Constraints

Geert Booij

1 Introduction

Morpheme structure constraints are constraints on the segmental make-up of the morphemes of a language. A textbook example of such a constraint is that *bnik* is an impossible morpheme of English, whereas *blik* is a possible English morpheme that happens not to exist. Hence, *bnik* is a systematic gap in the morpheme inventory of English, whereas *blik* is an accidental gap in this inventory. This can be taken to imply that there is a morpheme structure constraint that prevents English morphemes from beginning with a /b/ followed by a nasal consonant.

Halle (1959: 38) proposed to account for such distributional generalizations by means of morpheme structure rules, which define the class of possible morphemes of a language. Morpheme structure rules were conceived of as rules that fill in predictable specifications of the sound segments of a morpheme. For instance, in the case of English morphemes that begin with the consonant cluster *b*C, such as *brick*, it is predictable that the C must be a liquid, i.e. a non-nasal sonorant consonant. That is, the feature specifications [−nasal] and [+sonorant] of the second consonant of *brick* are predictable. They can therefore be omitted in the lexical phonological specification of the relevant morphemes. Morpheme structure rules fill in the blank cells of the lexical phonological matrix, and thus turn this underspecified matrix into a systematic phonological matrix, with all feature values of its segments specified. This is the underlying phonological form of a morpheme to which the phonological rules of a language apply. In sum, morpheme structure rules function as redundancy rules that specify predictable information, and at the same time they define the set of possible morphemes of a language.

Stanley (1967) proposed to replace Halle's notion "morpheme structure rule" by the notion "morpheme structure condition" (MSC). All morpheme structure conditions function as redundancy statements with respect to fully specified lexical phonological matrices, which form the input for the phonological rules (P-rules).

The notion "morpheme structure condition" as discussed above forms part of the theoretical machinery of classical generative phonology, but has been subject to debate. In this chapter this debate will be summarized. Before doing that, I will provide some examples of phonotactic properties of morphemes in §2. The problems raised by the concept of "morpheme structure condition" will then be discussed in §3–§5. These problems are the following:

(i) The redundancy problem: is there any need for a specific set of morpheme structure conditions, or can they be made to follow from other types of phonological rules or constraints? (§3 and §4)
(ii) The duplication problem: how can we avoid the same distributional generalization (for example the homorganicity of a nasal consonant and a following obstruent in consonant clusters) being expressed by both an MSC and a phonological rule (P-rule), and thus making the grammar unnecessarily complex? (§4)
(iii) The status of MSCs: are they absolute constraints, or statistical tendencies only? (§5)

The chapter will conclude with some observations on the expressive functions of morphemes with specific phonotactic properties (§6) and a summary of our findings on the status of MSCs (§7).

2 Morpheme structure conditions

The unequal distribution of phonemes across words and morphemes was an important topic of research in structuralist phonology, because distributional facts were interpreted as signaling the presence or absence of grammatical boundaries, as in the work of Trubetzkoy (Wiese 2001). For instance, in German the phoneme /j/ only occurs at the beginning of lexical morphemes (as in *jagen* 'to hunt' and its derivative *verjagen* 'to chase away'). Hence, the presence of the /j/ is a positive signal of a left-edge morpheme boundary (van Wijk 1939: 125). Such facts show that the phonological and grammatical dimensions of linguistic structure are not completely autonomous, but are related in a systematic fashion (Jakobson 1949). The relation between the distribution of phonemes and grammatical units such as morphemes and words is therefore an aspect of the interface between phonology and morphology. Jakobson (1949) drew attention to the fact that different grammatical units may have different phonotactic properties. For instance, he observed that of the 23 Czech consonants, only eight are found in inflectional suffixes. Jakobson also mentioned that only the following consonants appear in the inflectional suffixes of English: /z d n ŋ/.

Dutch exhibits a number of such asymmetries between lexical morphemes on the one hand and derivational and inflectional suffixes on the other (Booij 1995). For Dutch, the following generalizations hold:

(1) a. Suffixes may consist of consonants only (/s/, /t/ or a combination thereof).
b. Suffixes may begin with the vowel /ə/.
c. Suffixes may have /ə/ as their only vowel.

Lexical morphemes of Dutch, on the other hand, do not have the phonotactic possibilities listed in (1) for suffixes, and require the presence of at least one full vowel (that is, a vowel that is not /ə/; see CHAPTER 26: SCHWA), and cannot be schwa-initial. Dutch prefixes cannot begin with a schwa either, but can have the schwa as their only vowel, as is the case for the Dutch prefix *be-* /bə/. Thus, we can sometimes tell from the phonological make-up of a morpheme whether it is a lexical morpheme or an affix.

A famous type of morpheme structure constraint is the restricted distribution of consonants in Semitic roots (see CHAPTER 108: SEMITIC TEMPLATES). Most Semitic roots are triliteral, that is, they contain three consonants, the consonantal skeleton. These skeletons are intercalated with vowels, and these vowel patterns are the exponents of grammatical information. Greenberg (1950) observed that the first two consonants of a Semitic CCC skeleton cannot be identical, whereas the last two can. Furthermore, homorganic consonants, i.e. consonants with the same place of articulation, are excluded, unless they are identical, even if they are the last two consonants. This is exemplified by the following distributional patterns in Arabic:

(2)
(2)	*m-m-d	
	m-d-d	'to stretch'
	f-r-r	'to flee'
	*b-m-C	
	*C-b-m	
	*g-k-C	
	ʃ-k-k	'to split'
	*ʃ-k-g	

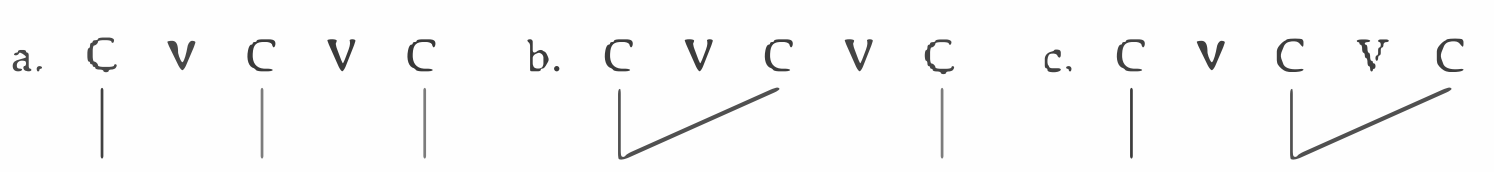
Similar facts are reported for Modern Hebrew in Bar-Lev (1978: 321): "well-formed roots contain only consonants from different places of articulation." For instance, the following patterns can be observed in existing Modern Hebrew roots (cf. also Berent *et al.* 2002):

(3)	labial – velar – dental	*bagad*	'to betray'
	velar – labial – dental	*gibor*	'hero'
	dental – velar – labial	*dégem*	'model'
	labial – dental – velar	*mélex*	'king'

Crucially, these constraints apply to morphemes only; hence they are tautomorphemic constraints. As McCarthy (1986: 209) observes, there is no Arabic root *tatak*, with two identical consonants, but there are inflected forms of verbs like *ta-takallam* 'you converse' in which the first *t* belongs to a prefix, and hence does not belong to the same morpheme as the second *t*. Thus the prohibition on identical consonants is not violated.

McCarthy (1986) proposes to analyze this constraint as following from the Obligatory Contour Principle (OCP), which states that identical elements on the melodic tier of a morpheme are not permitted (see CHAPTER 14: AUTOSEGMENTS). If the OCP applies to the lexical representations of Arabic roots, and assuming that all autosegmental spreading in Arabic is rightwards, it is predicted that, of the following three structures, only the third one is well-formed (McCarthy 1986: 209):

(4)



In (4a), the OCP is violated on the melodic tier, whereas in (4b) leftward spreading has taken place. Hence, if the V is /a/, the root **sasam* is excluded, and only the root *samam* is well-formed. In order to exclude sequences of homorganic but not identical consonants as well, the OCP must be interpreted here as OCP-Place. That is, assuming that there is a separate tier for Place specifications of sounds, OCP-Place forbids adjacent identical specifications on the Place tier, and this excludes adjacent homorganic consonants (including identical ones, which by definition have the same specification on the Place tier).

Phonotactic properties of morphemes may also reveal that they belong to a particular stratum of the lexicon of that language, and may differentiate between native and borrowed morphemes (see CHAPTER 95: LOANWORD PHONOLOGY). Itô and Mester (1995: 819) mention examples of constraints from several languages that are specific for native morphemes of those languages. Japanese is interesting in that its morphemes can be divided into four subclasses: Yamato (native), Sino-Japanese, Foreign and Mimetic. Each subclass is characterized by a set of constraints, some of which are valid for more than one subclass. For instance, Sino-Japanese roots consist of one syllable only, and Lyman's Law (morphemes contain at most one voiced obstruent) holds for Yamato morphemes only (Itô and Mester 1995).

Dutch words that begin with *pn-* in the spelling, such as *pneumatisch* 'pneumatic' and *pneumonie* 'pneumonia', betray their non-native origin: *pn-* is a well-formed word-initial consonant cluster in Greek, but not in Dutch. This suggests that morphemes with *pn-* do not belong to the set of possible native morphemes of Dutch, and the constraint *[pn- partially characterizes the set of native Dutch morphemes. In English this constraint applies to all morphemes, and hence the combination *pn-* is realized as /n/.

The range of phonotactic patterns found in morphemes may be smaller than those in words. English morphemes, for instance, never end in a cluster of voiced obstruents (there are no morphemes like **lovd* or **dubd*), whereas such clusters do occur in complex words like past tense forms of verbs (as in *loved* /vd/, and *dubbed* /bd/). Dutch morphemes are subject to the constraint that voiced obstruent clusters only occur in complex words: morpheme-internally we only find clusters like /pt/ and /st/, but in complex words we find clusters like /bd/ and /zd/, as in the past tense forms *eb-de* /ɛbdə/ 'receded' and *raas-de* /raːzdə/ 'raged'. The only exceptions to this Dutch MSC are a few loanwords like *labda* /labdaː/ 'lambda' and *budget* /[bœdʒɛt/ 'budget'. Hence, the occurrence of voiced obstruent clusters morpheme-internally makes the relevant Dutch morphemes recognizable as loans (Zonneveld 1983).

As observed by Shibatani (1973), MSCs may have a different status from phonological rules or constraints, in that loanwords are not necessarily adapted to the MSCs of a borrowing language, whereas the application of the phonological constraints cannot be suppressed. Hence, the Dutch loan *labda* keeps its voiced obstruent cluster, and is not pronounced as *la*[pt]*a*. Dressler (1985: 219–245) also provides examples from various languages of distributional patterns that are characteristic of morphemes.

In sum, there are distributional constraints that are characteristic of morphemes, but not of words in general. The question is whether and how they have to be accounted for by a specific type of constraint, the MSC.

3 The redundancy problem

As we saw above, in classical generative phonology constraints on the segmental composition of (lexical) morphemes are interpreted as lexical redundancy rules or morpheme structure constraints (MSCs) (Halle 1959, 1964; Stanley 1967; Chomsky and Halle 1968). For instance, in many languages, nasal consonants in morpheme-internal clusters share their place of articulation with a following consonant. This generalization can be expressed by omitting the place of articulation of the nasals in the lexical representation of the relevant morphemes. A lexical redundancy rule will then fill in the proper value for the feature [place], and thus derive fully specified underlying phonological representations to which the phonological rules of a language apply. Thus, in the phonological component of the grammar the set of rules that express static phonotactic generalizations is ordered to apply before the set of phonological rules that account for alternations. The two sets of rules (MSCs and phonological rules) together are considered to express all the phonotactic regularities of a language (Postal 1968: 214; see also CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION).

The role and importance of MSCs have been questioned for a number of reasons. In the first place, as pointed out by Hooper (1972), the role of the syllable as a domain of phonotactic generalizations cannot be ignored. The notion "syllable" does not play any formal role in the type of generative phonology codified in Chomsky and Halle (1968), but since then a wealth of evidence for the crucial role of the syllable (and larger prosodic units such as the foot and the prosodic word) in phonological analysis has been amassed (Nespor and Vogel 1986). Constraints on syllable structure are by definition constraints on how phonemes can combine into larger units. Hence, a lot of constraints on phoneme sequences are in fact syllable structure constraints (Hooper 1972). For example, the constraint that an English word cannot begin with a consonant cluster of the type nasal + obstruent follows from the universal principle of syllable structure that the sonority of consonants must decrease towards the edges of the syllable (see CHAPTER 49: SONORITY). Thus, sequences like **mpat* and **ntak* are impossible English morphemes. This means that morphemes must have a phonological composition that will lead to well-formed prosodic structures.

A second argument for the syllable as a phonotactic unit is that we cannot determine whether a particular segmental string is ill-formed without taking syllabification into account. For instance, the consonant sequence /bkm/ is always phonotactically ill-formed in English, because there is no possible division across two syllables that leads to a sequence of well-formed syllables. On the other hand, the consonant cluster /kn/, which does not appear word-initially in English words, can appear word-internally, as in *acne*, because this word can be syllabified as *ak.ne*, with two well-formed syllables (dots indicate syllable boundaries). That is, the following generalization holds:

(5) A (grammatical) word is phonotactically well-formed *iff* it can be parsed exhaustively into one or more well-formed prosodic constituents.

The class of well-formed syllables and higher prosodic constituents (foot, prosodic word) can be defined by the prosodification algorithm of each language, which is partially universal and partially language-specific. This algorithm groups the sounds of words into syllables, feet, and prosodic words (Rubach and Booij 1990). Alternatively, the grammar contains a set of ranked prosodic constraints that determine the optimal prosodification of a string of sounds, as in Optimality Theory (Kager 1999).

We might therefore claim that MSCs are superfluous because phonotactic restrictions on morphemes can be seen as the effects of phonological constraints on the output forms of words. For instance, English does not have a morpheme *abkmer*, since this morpheme cannot be prosodified exhaustively: the /k/ cannot be made part of the first or the second syllable. Similarly, the reason that a Dutch lexical morpheme requires the presence of at least one full vowel is that, otherwise, such a morpheme cannot yield a well-formed prosodic word. Dutch suffixes, on the other hand, can be vowelless or contain the vowel /ə/ only, as mentioned in (1), because they always combine with a lexical morpheme. That is, the phonotactic shape of Dutch suffixes has to do with their being dependent on a host morpheme to which they attach. We might therefore consider these suffix-specific phonotactic properties as something that need not be expressed separately, since it follows from the mapping of morphological structure onto prosodic structure.

Hooper (1972) offers a second argument against MSCs, that formulating phonotactic constraints with the morpheme as domain may also lead to spurious generalizations. For instance, Dutch lexical morphemes of Romance origin may end in obstruent clusters that are unpronounceable in isolation:

(6) *castr-eer* 'castrate'
celebr-eer 'celebrate'
emigr-eer 'emigrate'
penetr-eer 'penetrate'

One might conclude that Dutch morphemes can end in clusters of the type /Cr/, but this generalization does not reveal what is really at stake: those morphemes are only acceptable because they are bound roots, obligatorily followed by a vowel-initial suffix. Hence, these consonant clusters will form proper syllable onsets, as in *pe.ne.treer*. Similar observations can be found in Kenstowicz and Kisseberth (1977: 145) for Tunica, and they therefore concluded that in such cases it is the word rather than the morpheme that is the domain of phonotactic constraints. Nevertheless, the occurrence of such root-final consonant clusters is revealing in the sense that they betray the Romance origin of those roots: Germanic roots of Dutch never have this form because they can be used as words without further suffixation.

A third example of the role of prosody in the phonotactics of morphemes is that in many languages lexical morphemes are subject to prosodic minimality conditions. For instance, Dutch lexical morphemes are subject to the constraint that they consist of at least one heavy syllable (with either a long vowel or a short vowel followed by a consonant). That is, a lexical morpheme cannot consist of a light syllable only; bimoraicity is required. It is only in exclamations like *hè* /hɛ/ that the use of such light syllables with a short vowel is possible.

Prosodic conditions on morphemes create a problem for the classical MSCs: the syllable structure of a morpheme is not part of its lexical representations, but a derived property. Therefore, MSCs cannot refer to derived prosodic properties such as bimoraicity (McCarthy 1998). The only way to circumvent this problem is to phrase the constraint in terms of segment sequences: a lexical morpheme must contain either a long vowel, or a short vowel followed by at least once consonant. However, we then miss the generalization that it is a prosodic syllable weight condition that is involved. Once more, this suggests that the segmental composition of morphemes is governed by phonological output conditions. A similar problem occurs when we want to express the following generalization for Dutch: "In mono-morphemic forms we do not find sequences of schwa-headed syllables" (van Oostendorp 1995: 141). Again, this MSC refers to the derived property of syllable structure (cf. Downing 2006 for a cross-linguistic survey of prosodic minimality conditions).

In sum, we have to find a way in which prosodic constraints can account for at least part of the phonotactic constraints on morphemes.

3.1 Non-syllabic sequential constraints

Not all constraints on segmental sequencing can be reduced to syllable structure or prosodic minimality requirements. There are sequential constraints on consonant clusters that hold independently from the tautosyllabic or heterosyllabic status of these clusters. For instance, Yip (1991) proposes the following generalization for English (see also CHAPTER 12: CORONALS):

(7) *Consonant Cluster Condition*

In consonant clusters, consonants may have at most one other articulator feature than Coronal.

Thus, we find English clusters like /pt/ and /kt/ (*apt, act*), but not (tauto- or heterosyllabic) clusters like /kp/, /pk/, /km/, /mk/, /xm/, and /gm/ (loanwords like *drachma* and *stigma* are exceptions to this generalization). Note that the ill-formedness of such clusters does not follow from syllable structure constraints since they could be heterosyllabic. Yet they do not occur. If we come across such clusters in words (as in *zipcode* and *backpack*), we can conclude that these words must be compounds, consisting of more than one lexical morpheme.

An example of a sequential constraint that holds both for tautosyllabic and heterosyllabic sound sequences, observed for English by Davis (1991), and for Dutch by Booij (1995: 46), is that in the sequence sCVC the two Cs should not be identical, unless they are coronal. Here are some Dutch examples with labial and coronal consonants (such sequences of velar consonants do not occur for independent reasons):

(8)

CVC			sCVC		
poep	/pup/	'shit'	**spoep*	/spup/	
mam	/mam/	'mother'	**smam*	/smam/	
toet	/tut/	'face'	*stoet*	/stut/	'procession'

This constraint is also valid for heterosyllabic sequences: they are not acceptable when followed by a vowel, as shown by forms like **spupo* and **smama*.

The point that not all phonotactic constraints can be reduced to syllable structure constraints is particularly clear for word-edge constraints, which are discussed in the next subsection.

3.2 *Word edges*

The difference between syllable structure constraints and sequential constraints is stressed by Kristoffersen (2000: 46–48), in relation to the distribution of consonants at word edges. In Norwegian, the cluster *tl-* is a proper syllable onset. It occurs word-internally in words like *Be.tlem* 'Bethlehem' and *A.tle* (proper name). Yet Norwegian words never begin with this cluster. Kristoffersen also observed that, although Norwegian words never begin with *pn-*, a cluster that does not violate the Sonority Hierarchy Constraint on syllable structure, Norwegians have no difficulty in pronouncing loan words like *pneumatisk* 'pneumatic'. These observations imply that /tl-/ and /pn-/ are proper syllable onsets in Norwegian, and that the non-occurrence of initial /tl-/ and /pn-/ is not due to a syllable structure constraint, but to a constraint that holds for the left edge of Norwegian root morphemes or prosodic words. A similar example from Dutch is that lexical morphemes do not begin with *pj-*, *tj-*, or *kj-*; however, the diminutive suffix allomorphs *-pje*, *-tje*, *-kje* begin with these clusters, and hence these clusters do appear in word-internal syllable onsets, as in *riem-pje* 'belt-DIM' with the prosodic structure $((\text{rim})_\sigma(\text{pjə})_\sigma)_\omega$ (ω = prosodic word, σ = syllable). Therefore, the non-occurrence of these clusters cannot be attributed to a syllable structure constraint. The word-initial sequences /pj- tj- kj-/ do occur in borrowed proper names for male persons, such as *Pjotr*, *Tjeerd*, *Kjeld*, and they do not cause pronunciation problems for speakers of Dutch.

The edges of words may have special phonotactic properties, since they may either impose more restrictions than what syllable well-formedness requires, or allow for extra consonants compared to what is possible in syllables in general. The Norwegian examples above (no *tl-* or *pn-* at the beginning of a word) are a case in point. Other examples of more restricted phonotactics at word edges can be found in Booij (1983): in Huichol, for example, words cannot end in a consonant but syllables can (source: Bell 1976).

In Polish, extra consonants may be added in word-initial position that violate the universal Sonority Sequencing constraint (Rubach and Booij 1990: 434; see also CHAPTER 109: POLISH SYLLABLE STRUCTURE):

(9)
rwać 'tear'
rdza 'rust'
łgnąć 'stick'
mdły 'tasteless'
mnich 'monk'

In these words, a sonorant consonant is followed by a consonant of the same or higher degree of sonority, in violation of the Sonority Sequencing requirement that the sonority of consonants must increase towards the direction of the nucleus. The account that Rubach and Booij (1990) propose is that Polish prosodic words have an extra optional word-initial slot for an extrasyllabic consonant preceding the regular syllables, which is exempt from the requirements of the Sonority

Sequencing condition. This analysis implies that allowing for these marked consonant clusters is not to be seen as a property of lexical morphemes, but of the prosodic words that corresponds with such morphemes.

The special phonotactics of word edges is dealt with in Optimality Theory in the form of alignment constraints (McCarthy and Prince 1993). The basic idea of this approach, which makes crucial use of ranked output constraints in computing the phonetic form of words, is that there are alignment constraints that require the alignment of prosodic and grammatical boundaries. According to McCarthy and Prince (1993), the language Axininca Campa has word-initial onsetless syllables, whereas word-internally a vowel hiatus must always be filled by an epenthetic consonant. The relevant alignment constraint blocks the insertion of an epenthetic consonant in word-initial position. If epenthesis took place, there would be no alignment of the left edge of the prosodic word with the left edge of the (vowel-initial) morpheme. That is, the alignment constraint is ranked higher than the constraint that penalizes empty onsets. Note, however, that this analysis does not directly express that the left edges of Axininca Campa morphemes can begin with a vowel, even though syllables in this language normally begin with a consonant. The alignment mechanism allows for a difference in make-up between the edges of morphemes and syllables, but does not express it.

3.3 *Phonotactic differences between simplex and complex words*

As briefly mentioned at the end of §2, the range of phonotactic patterns in morphemes may be smaller than in complex words. Harris (1994) presents a number of observations on the phonotactic differences between simplex words and complex words in English. For instance, one will not find a heterosyllabic sequence /pt/, as in *laptop*, within a morpheme (except for loans like *helicopter*), even though a heterosyllabic cluster /pt/ would not violate the syllable structure constraints of English: a syllable can end in a /p/, and begin with a /t/. The same applies to the cluster /pw/: a proper name like *Sopwith*, which is historically a compound, is exceptional in this respect, and thus betrays its historical origin as a compound. Such opaque compounds tend to be adapted to the phonotactic patterns. The proper name *Greenwich* with the sequence /nw/ is now pronounced without the /w/, thus adapting to the phonotactic constraints for monomorphemic words (Harris 1994: 51).

The observation that certain consonant clusters only occur at morpheme boundaries is often used in linguistic analyses for assigning multi-morphemic status to words (see CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS). For instance, many words in the Amerindian language Athapaskan are considered to be compounds, even though the constituents do not occur as words by themselves, because they contain consonant clusters that are characteristic of morpheme boundaries (Rice 2009: 546).

Phonotactic differences between root morphemes and complex words have also been observed for vowel harmony (cf. §4 for a more detailed discussion of such facts for Turkish). The necessity of a separate morpheme structure condition on vowel combinations in roots is explicitly defended in the analysis of Hungarian vowel harmony in Vago (1976); see also CHAPTER 123: HUNGARIAN VOWEL HARMONY. Harvey and Baker (2005: 1459) observed that in the Australian language

Warlpiri, a language with vowel harmony with respect to the feature [round], the sequence [−round][+round] is not permitted for two consecutive vowels (with intermediate consonants) within roots, whereas the disharmonic sequence [+round] [−round] is. They account for this difference not by assuming an agreement constraint, but by proposing separate constraints for each type of disharmonic sequence. In addition, there is a constraint of root identity that requires the feature specifications for [round] to be preserved in the output. Thus they do not need to assume two rules of vowel harmony, a morpheme structure constraint and a phonological constraint that applies to complex words, and the duplication problem is avoided. Note, however, that this analysis requires reference to the root, a type of morpheme, as the domain of an identity constraint. That is, reference to morphemes in phonological constraints is still required.

Different phonotactics may also play a role in recognizing the lexical category of a word. In Dutch, there is a marked difference in phonological make-up between simplex nouns and simplex verbs. Verbs tend to consist of at most two syllables; if there is a second syllable, it will end in a schwa followed by a liquid. Nouns, on the other hand, allow for a larger variety of phonological structures, such as those consisting of three or more syllables, or ending in a full vowel. It appears that speakers of Dutch are able to categorize words as nouns or verbs on the basis of such phonotactic knowledge (Don and Erkelens 2006).

In sum, the distributional properties of segments within morphemes relate to the phonological rules or constraints of the relevant language, but not all morpheme-internal phonotactics can be reduced to these more general phonological regularities. In the words of Stanley (1967: 397): "The constraints holding within single morphemes are more restrictive than the constraints which characterize larger units."

4 The duplication problem

The problem that the assumption of both MSCs and P-rules seems to lead to unnecessary complications of the grammar was noted by Stanley (1967). For instance, Turkish has two general P-rules of vowel harmony that also predict the distribution of vowels within morphemes: all vowels agree in backness, and high vowels agree in roundness (see CHAPTER 118: TURKISH VOWEL HARMONY). As Zimmer (1969: 310) points out:

> The restrictions on vowel co-occurrence within almost all bases of Turkic origin are nearly the same as those just described for suffix vowels; thus for the "harmonic" part of the lexicon, there are two MSC's which replicate, to a great extent, the vowel-harmony rules that determine the selection of vowels in suffixes. There is, however, a large number of loanwords to which these vowel harmony MSC's do not apply, – e.g. /günah/ 'sin', /kalem/ 'pen', /sosis/ 'sausage', /viraž/ 'curve'.

In addition, there is an MSC that does not double as a P-rule, the Labial Consonant MSC (Zimmer 1969: 312):

(10) After /a/, a [+high] vowel agrees in labiality with a preceding [+labial] consonant.

An example of a morpheme that obeys MSC (10) is *karpuz* 'watermelon', in which the second vowel is round, even though the first vowel is non-round. This is an interesting MSC for the debate on the redundancy of MSCs, since it has no P-rule counterpart.

This duplication problem, already noted by Stanley (1967), is discussed by Anderson (1974: ch. 16). Anderson observes that many Turkish morphemes such as *kitap* 'book' are disharmonic, but do not block the application of vowel harmony rules once they have been suffixed. Anderson therefore concludes that we need both MSCs and P-rules for vowel harmony in Turkish, since they may be subject to different idiosyncrasies. In Anderson's view, the relation between MSCs and P-rules dealing with vowel harmony is a functional one, which need not and cannot be expressed formally by unifying them into one rule.

Shibatani (1973) proposes that such constraints should be considered to be both MSCs and Surface Phonetic Constraints (SPCs). A constraint can be marked as an MSC, a SPC, or both an MSC and a SPC. Clayton (1976) argues that constraints that hold for underlying forms of morphemes only are unmotivated, and do not reflect the speaker's knowledge of his/her language. Therefore, Clayton claims that Surface Phonetic constraints suffice.

The duplication problem is also considered by Kiparsky (1982: 167–170), in the framework of Lexical Phonology (see also Kaisse and Shaw 1985: 25; CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME). In this framework, phonological rules apply cyclically. Rules apply either in a structure-adding fashion or in a structure-changing one. Rules only apply in a structure-changing fashion in derived environments, i.e. in environments created by the previous application of a morphological or a phonological rule (see Booij 2000 for a survey of this theory). Kiparsky (1982) proposed that there are no Morpheme Structure Rules. The lexical representations of morphemes are underspecified; that is, predictable properties are omitted. On the first cycle, phonological rules specify these features; i.e. they fill in the blanks. If a word is complex, the same rule can apply in a structure-changing fashion on the next cycle, since the complex word is a derived environment. For instance, the Dutch rule that requires obstruents to have the same specification for the feature [voice] as an adjacent obstruent can be applied as a blank-filling rule to the underspecified feature matrix for /x/ in a word like *achter* /ɑxtər/ 'back', and it can be applied in a structure-changing fashion in a complex word like *as-bak* 'ash-tray' (underlying /ɑs-bɑk/; phonetic form [ɑzbɑk]). In English, the place of articulation of the nasal consonant in *damp* can be left unspecified, and filled in by the rule of Nasal Place assimilation, whereas the same rule will change the underlying coronal nasal /n/ into [m] in the derived word *compress* (underlyingly *con-press*).

Such an analysis can also deal with exceptions to MSCs. For instance, the Dutch word *imker* /ɪmkər/ 'bee-keeper', which is synchronically a simplex word, violates the constraint on homorganicity of nasal–obstruent clusters. In Kiparsky's proposal, this is no problem: the nasal consonant will be fully specified as being labial, and the rule that predicts the feature [velar] for a nasal followed by /k/ is blocked from applying because feature-changing applications of this rule are allowed in derived environments only.

In the case of Turkish vowel harmony, the same solution would apply. Disharmonic roots are fully specified, and therefore the P-rules of vowel harmony are blocked from applying to these morphemes, whereas they will apply in derived environments, to the vowels of the suffixes.

In short, in Kiparsky's proposal, the duplication problem is solved by abolishing the class of morpheme structure rules, and having P-rules apply in two different fashions. However, not all types of generalizations over the phonological shape of morphemes mentioned above can be expressed this way. This applies in particular to prosodic conditions on the shape of morphemes.

4.2 MSCs in Optimality Theory: Lexicon optimization and output–output faithfulness

Optimality Theory (OT) does not allow for constraints on the inputs of phonological evaluation. Output constraints are the only mechanisms for expressing phonotactic patterns. This idea of OT is referred to as the Richness of the Base hypothesis. For instance, there is no input constraint that forbids the morpheme **bnik* as a morpheme of English. The output constraints will penalize such a form, and evaluate this form in such a way that the optimal output form is not faithful to this form, but different, e.g. *blik*. Since forms such as *bnik* will never surface in English, it does not make sense to store an underlying form *bnik* for *blik*. This is the effect of lexicon optimization. Thus, the phonological output constraints of a language will be reflected by the input forms. This point of view is foreshadowed in Sommerstein (1974: 73), who argued that judgments about whether a sound sequence is a possible morpheme must be made on the basis of surface representations.

This idea is discussed in more detail in McCarthy (1998, 2002, 2005), and can be illustrated as follows. Suppose there is a language with the constraint that obstruents are voiceless at the end of a syllable, and with the suffix /-ən/ as plural ending for nouns, as in [hut] – [hutən] 'hat(s)'. Furthermore, this language has no alternations of the type [hut] – [hudən]. That is, morphemes that end in an obstruent will always end in a voiceless obstruent. Given the word [hut], the Richness of the Base hypothesis implies that we might assume the underlying form /hud/ for the singular form. The correct phonetic form [hut] will be computed anyway. However, in an optimal lexicon the underlying form to be chosen will be /hut/ because of lexicon optimization. This means that of the possible tableaux that select the right form, the most harmonic one will be selected, i.e. the one with the minimal number of violations of constraints. The assumption of the underlying form /hud/ will imply violation of the input–output (IO) faithfulness condition, unlike the underlying form /hut/. IO faithfulness requires the underlying form to be selected as the surface form, unless it is overruled by higher-ranked constraints. The optimal underlying form can be selected by comparison of tableaux, and the selection of the most harmonic one. Thus, lexicon optimization makes restrictions on input forms superfluous.

If there are no MSCs, the question arises of how to account for constraints that hold for morphemes only. One example of a distributional difference between morphemes and words concerns the distribution of nasals in Dutch. Within morphemes, nasal consonants are always homorganic with a following obstruent (with the exception of *imker*; cf. §4.1). Hence, we find *damp* /dɑmp/ 'damp', *tand* /tɑnt/ 'tooth' and *dank* /dɑŋk/ 'thanks', but no morphemes ending in */-mt -mk -ŋp -ŋt/. On the other hand, complex words such as the 3rd singular present forms of verbs always end in /-t/, preceded by all three types of nasals: *klim-t* 'climbs', *zon-t* 'sunbathes', *zing-t* /zɪŋt/ 'sings'. If we assume a markedness constraint NC (nasals are homorganic with a following consonant), this constraint must be blocked from changing a verb form like *klimt* into *klint*. McCarthy (1998) argued that this can be achieved by making use of output–output (OO) correspondence constraints. If we rank OO faithfulness conditions for the relation between a base word and its derivatives higher than the markedness constraint NC, a verb form like *klimt* cannot be changed to *klint*, because this would violate the requirement of correspondence of the stem of this inflected form with the verbal stem *klim*.

Nasal assimilation should not be blocked in all derived environments, however. In a prefixed word like *compress*, the prefix-final /n/ of *con-* does assimilate to the next /p/. This can be accounted for if we assume that the NC constraint is ranked higher than faithfulness to the underlying form of the prefix, /kɔn/. The more general observation is that affixes tend to adapt to roots rather than the other way around. Hence, in OT analyses it is often assumed that faithfulness constraints for affixes rank lower than those for roots (Alderete 2003). This implies that constraints have to be indexed for particular morphological categories such as root and affix. Therefore, we have to allow for reference to morphological domains in a system of phonological output constraints.

4.3 *Domains and strata*

Our conclusion so far is that, even when we do not allow for constraints on underlying forms of morphemes, it should be possible to index a phonological output constraint for a particular morphological domain such as the lexical morpheme. This will make it possible to specify distributional constraints that hold for lexical morphemes only. For instance, the Dutch constraint that lexical morphemes and prefixes cannot begin with /Cj/, whereas suffixes can, is expressible by indexing this constraint for the relevant morphological domains.

As observed in §3, particular phonotactic properties may only hold for certain strata of the lexicon. This is discussed in detail for Japanese by Itô and Mester (1995, 1999, 2001), who argue that "phonological generalizations can be covert by being lexically partial: they hold within a subdomain of the lexical space, but are violated in peripheral areas occupied e.g. by loanwords or onomatopeia" (Itô and Mester 2001: 274). For instance, in Japanese the palatalization constraint that changes /t/ into /ts/ before /i/ (this constraint also excludes tautomorphemic /ti/ sequences) does not affect loanwords like English *tea* and *party*. Therefore, Itô and Mester defend the idea of stratum-specific (ranking of) faithfulness constraints.

A Dutch example of a stratum-specific constraint was mentioned in §2: in native Dutch morphemes morpheme-internal obstruent clusters are always voiceless, but this constraint does not hold for non-native morphemes such as *labda* /lɑbdaː/ 'lambda', or the brand name *Mazda* /mɑzdaː/. Such non-native morphemes preserve their foreign pronunciation. The word *labda*, for instance, will not be changed to [lɑptaː], and Dutch speakers will recognize it as a loan due to this phonological property. Another example is the word-initial cluster *sk-*, which does not occur in Dutch native words, but only in loans from English, e.g. *scan* and *Skype*.

A similar distinction between native and non-native morphemes can be observed for languages with vowel harmony: non-native lexical morphemes may be disharmonic, and this is not changed through application of the vowel harmony constraints. For instance, the Hungarian noun *soför* 'chauffeur' is disharmonic (the first vowel is back, the second one is front), and remains so, even though it selects its suffix vowels in accordance with the frontness/backness vowel harmony constraint.

In sum, phonological constraints may have to be indexed for particular morphological categories or for lexical strata.

5 Absolute constraints or tendencies?

A final important point of debate concerning MSCs is whether they are absolute constraints or just statistical tendencies. Zimmer (1969) investigated the psychological reality of the Labial Consonant MSC of Turkish (10) mentioned above. Recall that this constraint holds for morphemes only, and is not supported by the two P-rules of vowel harmony. Zimmer made up lists of pairs of nonsense words, and asked subjects, Turkish students in California, to determine which word of such a pair sounds more like a word that might actually occur in Turkish. In the case of word pairs where the P-rules of vowel harmony played a role, the results were as expected, with a strong preference for the word in accordance with the vowel harmony constraints. For the pairs that involved the Labial Consonant MSC, on the other hand, there was hardly any difference in number between expected responses (the words in accordance with the MSC) and unexpected responses. Zimmer (1969: 320) therefore concluded that an MSC that is not supported by a P-rule might not be internalized by native speakers of Turkish.

5.1 OCP-Place

The psychological reality of OCP-Place, discussed in §2, which excludes identical adjacent place specifications, has been investigated for speakers of Jordanian Arabic (Frisch and Zawaydeh 2001; Frisch *et al.* 2004). It appears that "Jordanian Arabic speakers do recognize systematic gaps that are violations of OCP-Place as different from accidental gaps involving unrelated consonant pairs" (Frisch and Zawaydeh 2001: 99), even though there are violations of OCP-Place. Frisch *et al.* (2004) argue that OCP-Place is not an absolute, universal constraint. They consider the constraint as reflecting the generalizations that Arabic speakers make on the basis of their lexicon. OCP-Place is claimed to be a gradient constraint, since there are quite a number of words that violate it, but in different degrees. "Forms that violate the constraint to a lesser degree are more frequent than forms that violate the constraint to a greater degree" (Frisch *et al.* 2004: 182). Frisch *et al.* also point out that the co-occurrence of homorganic consonants that are non-adjacent (occurring in the first and third positions) is less restricted than the co-occurrence of adjacent homorganic consonants. In other words, the OCP-Place constraint is a gradient, but psychologically real constraint: "the native speaker knows an abstract but gradient OCP Place constraint ('Roots with repeated homorganic consonants are unusual') based on generalizations over the statistical patterns found in the lexicon" (Frisch *et al.* 2004: 216).

Frisch *et al.* also looked at the effect of OCP-Place on the borrowing of Italian verbs in Maltese, a variety of Arabic with many loans from Italian. The number of Italian verbs whose consonant pattern conforms to OCP-Place is significantly higher than that of the Italian verbs that violate OCP-Place (but these latter verbs may also be borrowed, and adapted to Maltese). This again supports the psychological reality of such a constraint, without it being categorical.

These findings suggest that OCP-Place is a gradient constraint that aims at avoidance of similarity: the more similar adjacent consonants are, the more they are avoided. Speakers are able to make phonotactic generalizations about lexical morphemes, but the corresponding constraints need not be categorical.

Statistical tendencies for the composition of various morphological categories such as the root and the stem have been observed by Wiese (2001): 94% of all German roots begin with a consonant, and 96% of all German roots end in a consonant. In OT, this can be expressed by alignment constraints that require the left and right edges of a root to coincide with the feature [+cons]. For those roots that violate the constraint, IO faithfulness will preserve the vowel at the edges. Note in particular that the tendency to have consonants at the end of roots does not follow from a syllable constraint, since the universally most unmarked syllable is the open syllable. Thus, this type of distribution may function as a boundary signal.

5.2 *Constraints on underlying forms*

Dutch exhibits intriguing constraints on sequences of vowels followed by fricatives. The basic generalization is that a vowel is short before /f s/, whereas it is long before /v z/. Let us call this the VZ constraint. Due to the effect of Final Devoicing, the constraint that obstruents are voiceless at the end of a syllable, this constraint can only be observed directly if the fricative is not morpheme-final. The following morphemes illustrate this constraint:

(11)	*short vowel*			*long vowel*			*excluded*
	effen	/ɛfən/	'even'	*even*	/e:vən/	'even'	/ɛvən, e:fən/
	dissel	/dɪsəl/	'pole'	*vezel*	/ve:zəl/	'fiber'	/ɛzəl, e:səl/

This constraint is violated by a few loanwords like *mazzel* /mɑzəl/ 'good luck' and *puzzel* /pœzəl/ 'puzzle', and by the native morpheme *oefen-* /u:fən/ 'to exercise'. This shows that this constraint is not an absolute condition on pronounceability, but a statistical generalization about morphemes.

This VZ constraint seems to apply to intervocalic sequences only, since we do find long vowels followed by /f s/ at the end of morphemes, as in the singular forms of the following nouns:

(12)	*graaf*	[ɣra:f]	'earl (SG)'	*grav-en*	[ɣra:vən]	(PL)
	kaas	[ka:s]	'cheese (SG)'	*kaz-en*	[ka:zən]	(PL)

However, we can interpret this constraint as also applying to morpheme-final sequences if we assume the constraint to hold for the underlying forms of morphemes. Morphemes like *graaf* and *kaas* end in a voiced fricative underlyingly, as shown by their plural forms, and hence the underlying forms of these morphemes are /ɣra:v/ and /ka:z/, respectively. There are a few exceptions, such as the non-native word *graaf* 'graph' with the plural form *graf-en* [ɣraːfən]. In the case of /s/ *vs.* /z/, the number of exceptions is much higher, since there are a number of verbs like *eis-en* [ɛisən] 'require (INF)' and *ruis-en* [rœysən] 'rustle (INF)', in which the diphthong, which counts as a long vowel, is followed by [s]. Speakers of Dutch may thus recognize a plural form as *grafen* as being non-native, whereas the phonetic form of its singular form *graaf* [ɣraːf] does not betray this stratal property.

If we allow for phonotactic constraints on underlying forms that cannot be observed from their corresponding surface forms, this enables us to make generalizations about the kind of alternations we may find in a language (Booij 1999). This topic is also broached in Ernestus and Baayen (2003). They raise the question to what extent the occurrence of alternations between morpheme-final voiceless and morpheme-final voiced obstruents in Dutch morphemes is predictable. There appear to be clear regularities. For instance, if a Dutch morpheme ends in a long vowel plus a labial stop, that stop is always an underlying /p/; that is, we do not find the alternation [p – b] for such morphemes. In the case of the fricatives discussed above, we saw that the length of the preceding vowel is a strong predictor of whether the final obstruent is underlyingly voiced or voiceless, although stronger for /f v/ than for /s z/. The question is whether language users possess this kind of knowledge. Ernestus and Baayen (2003) tested this by asking subjects to make past tense forms for nonsense words. If the underlying form of the verbal root morpheme ends in a voiceless obstruent, the past tense suffix *-te* /tə/ will be chosen, and *-de* /də/ otherwise. It appeared that language users do make use of the phonotactic tendencies involved: there is a strong correlation between the proportion of *-te*/*-de* choices for nonsense morphemes and the proportion for existing morphemes with a similar phonotactic make-up. Ernestus and Baayen (2003) therefore concluded that the speaker chooses an underlying representation for a nonsense morpheme that makes it resemble similar morphemes in the lexicon. As was the case for the Arabic roots discussed in §5.1, such phonotactic generalizations concerning morphemes may be statistical rather than absolute in nature. Moreover, they may pertain to underlying forms, where properties are present that may not be accessible in surface form.

This kind of knowledge about the type of alternations that occur in a language may also be formalized without restricting such MSCs to underlying forms. Consider the singular/plural pairs of nouns in Dutch with a stem-final obstruent such as *hoed* [hut] – *hoed-en* [hudən] 'hat (SG, PL)'. The voice specification of the stem-final obstruent of the morpheme *hoed* can only be determined on the basis of the plural form. The plural form is the most informative form of the paradigm (Albright 2005, 2008), and we may assume that it is stored in lexical memory. The relation between the two forms can be specified by a schema of the following type:

(13) $[x]_{SG} \leftrightarrow [x - \text{ən}]_{PL}$

(The symbol ↔ indicates the correlation between the two forms; *x* is a variable for a string of segments.) The plural form is the only reliable form for the computation of the underlying form, that is, the form on the basis of which new derived words and inflected forms can be computed. For instance, if we were to coin the adjective *hoed-ig* [hudəx] 'hat-like', the stem has to end in a /d/, since the phonetic form [hutəx] is wrong. That is, an underlying form is not necessarily a lexically stored representation, but may be computed when necessary for a morphological operation. In the case of Dutch verbs, we need to compute the underlying form of the verbal stem for the choice of the proper form of the past tense suffix (*-te* or *-de*).

Recall now the generalization for Dutch verbal stems that after a long vowel (VV) there is never a *p/b* alternation: if a singular form ends in [VVp], its plural form will never end in [VVbən]. This generalization also holds for nouns, and this can be expressed by the following subschema of (13) (*y* is a variable for segmental strings):

(14) $[y\ \text{VVp}]_{\text{SG}} \leftrightarrow [y\ \text{VVp-ən}]_{\text{PL}}$

In the case of the Dutch s/z alternations discussed above, we might assume subschemas like the following for nouns:

(15) a. $[y\ \text{VVs}]_{\text{SG}} \leftrightarrow [y\ \text{VVz-ən}]_{\text{PL}}$ (as in *kaas* – *kazen* 'cheese (SG, PL)')
b. $[y\ \text{Vs}]_{\text{SG}} \leftrightarrow [y\ \text{Vs-ən}]_{\text{PL}}$ (as in *kas* – *kassen* 'greenhouse (SG, PL)')

If such schemas do not apply to all words, that is, if they are statistical generalizations only, they can be given a weight that indicates their probability.

The generalizations expressed in (15) apply almost exceptionlessly to nouns, and are confirmed by irregular pairs of singular and plural nouns with vowel length alternation. Vowel Lengthening is no longer a regular rule of Dutch, but an idiosyncratic alternation, a relic of Prokosch's Law that applied to Early Germanic, illustrated here for the noun *glas*:

(16) glas [ɣlɑs] 'glass (SG)' glaz-en [ɣlaːzən] 'glass (PL)'

The correspondence between the length of the vowel and the [voice] specification given in (15) is maintained in these irregular pairs by the combination of vowel length alternation and choice of obstruent: the forms *[ɣlɑzən] and *[ɣlaːsən] are both ill-formed.

In sum: whether there is an alternation between a voiced and a voiceless stem-final obstruent for Dutch lexical morphemes can only be determined with 100 percent certainty on the basis of inflected forms such as plurals. Yet, segmental composition of the lexical morpheme may give a clue, in some cases with almost 100 percent reliability. This type of knowledge may be modeled by constraints on the underlying forms of lexical morphemes, or by alternation schemas of the type proposed in (14) and (15).

6 The expressive value of phonotactics

A final phenomenon to be discussed is that particular sound sequences may have a specific semantic or pragmatic value. Sound symbolism is the usual term for such phenomena (see Hinton *et al.* 1994 for a number of detailed studies). In particular, there are phonaesthemes, recurring sounds or sound sequences, with a particular value. For instance, Marchand (1969: 397) argued that "/ɪ/ is suggestive of the subjective, emotionally small and is therefore frequent with diminutive and pet suffixes," and Bauer (1996) also found a cross-linguistic tendency for the use of this vowel in diminutive suffixes (see also Nichols 1971 for consonant sound symbolism in diminutives). According to Marchand (1969), the word-initial sequence *fl-* in words like *flick, flip, flap, flash* is expressive of brisk, quick movement, and Marchand provides many examples of such phonaesthemes. Such sound combinations are not to be considered as morphemes by themselves; yet they have a particular value. Hence, one may claim that phonotactic properties of morphemes can have an expressive role.

Japanese has a class of mimetic morphemes, which are sound-imitating or manner-symbolic roots. These morphemes have to be minimally bimoraic, and usually they appear in reduplicated or some other bipodic form (Mester and Itô 1989: 268):

(17) *poko-poko* 'up and down movement'
noro-noro 'slow movement'
paku-paku 'munching'
pata-pata 'palpitating'

In her study of the expressive value of lexical patterns, Klamer (2002) observed that the violation of general phonotactic constraints in specific classes of lexical items may have an expressive value. That is, a marked semantic value correlates with a marked phonotactic structure. An example from Dutch is the class of monosyllabic words of the type /lVl/, that is, words with the same consonant /l/ in onset and coda. Such words violate the phonotactic constraint or tendency of Dutch that the liquid consonants /l r/ in a syllable should be different. Words with this kind of phonotactics may have marked interpretations, as the following examples from Klamer (2002: 273) illustrate:

(18) *lal* (V) 'jabber, babble, slur one's words'
lel (N) 'earlobe, clout, whopper'
lil (V) 'quiver'
lol (N) 'fun, lark, trick'
lul (N) 'prick, jerk'
lul (V) 'talk nonsense'

Morphemes in which the vowel of /lVl/ is long do not occur at all.

In sum, the expressive value of phonotactic patterns within morphemes may be considered from a different angle: the violation of a constraint may have expressive value.

7 Conclusions

There is no doubt that there are distributional generalizations concerning the phonological make-up of morphemes that need to be expressed somehow in a proper phonological theory. The main theoretical issues are to what extent they can be made to follow from phonological generalizations that also hold for larger units than morphemes, and whether they are absolute constraints, or gradient constraints that express statistical tendencies. MSCs may also reveal different layers of the lexicon. Thus this chapter provides a range of data, observations, and considerations that can be used as a testing ground for the adequacy of theoretical phonological models.

ACKNOWLEDGMENTS

I would like to thank Paulo Chagas de Souza, Moira Yip, two anonymous reviewers, and the editors for their constructive comments and advice on an earlier draft of this chapter. In writing the final version, I also profited from taking part in a phonology seminar on phonotactic learning taught by Adam Albright at MIT and Harvard in the Spring semester of 2010.

58 The Emergence of the Unmarked

Michael Becker
Kathryn Flack Potts

1 Introduction

The term "The Emergence of the Unmarked" (TETU), originally coined by McCarthy and Prince (1994), refers to situations where some marked structure is generally allowed in a language, but banned in particular contexts; the complementary unmarked structure thus "emerges." In Nuu-chah-nulth (Wakashan, referred to by McCarthy and Prince by its former name, Nootka), for example, syllables can generally have codas; reduplicants, however, are exceptional in that codas are banned. This results in words like [ʧ̓i-ʧ̓im.s'iːħ] 'hunting bear' and [waː-waːs.ʧ̓iɬ] 'naming where', in which unmarked (codaless) syllables emerge in reduplicants despite the presence of marked codas in bases.

TETU effects came to prominence in phonological theory with the advent of Optimality Theory (OT; Prince and Smolensky 1993). In OT terms, these effects typically follow from rankings like (1), where a markedness constraint M is dominated by a faithfulness constraint F1, which blocks M's activity in some, though crucially not all, contexts. M is free to become active in contexts where F1 isn't relevant; here, M can motivate violation of still lower-ranked faithfulness constraints (F2).

(1) F1 >> M >> F2

The Nuu-chah-nulth pattern described above results from a ranking of this type, as shown in (2) and (3). The markedness constraint NoCoda is dominated by the anti-deletion constraint IO-Max; this ranking protects underlying codas from deletion, eliminating the unmarked, codaless candidate (2b). Since reduplicants are assumed not to stand in correspondence with inputs, however (chapter 100: reduplication), high-ranking IO-Max is irrelevant in their evaluation.[1] Because NoCoda dominates BR-Max, the emergence of unmarked CV syllables is permitted

[1] Correspondence between input and output candidates is evaluated by input–output (IO) faithfulness constraints. Reduplicants stand in correspondence relationships with the output forms of their bases, and are evaluated by base-reduplicant (BR) faithfulness constraints (McCarthy and Prince 1999). Faithfulness constraints in this chapter assess IO correspondence, unless otherwise noted.

in reduplicants. Concretely, candidates (3a) and (3b) are identical, except that the reduplicant in (3b) contains a copy of the coda of the root-initial syllable, while the reduplicant in (3a) doesn't. Because NoCoda dominates BR-Max, the additional NoCoda violation in (3b) rules out this candidate in favor of the less marked (3a).

(2)

/ʧims-ʼiːh/	IO-Max	NoCoda	BR-Max

☞ a. ʧi.ʧim.sʼiːħ		**	****
b. ʧim.ʧim.sʼiːħ		***!	***

Increasing attention to TETU effects was a natural result of inquiry into Optimality Theory. As McCarthy and Prince note, TETU is a direct result of two fundamental properties of OT. First, OT is a theory of ranked, violable constraints. Constraints are frequently active in a language even if they are not always satisfied; this is at the heart of TETU effects, which occur when a markedness constraint is dominated but still active. They observe that this "sharply differentiates OT from approaches to linguistic structure and interlinguistic variation based on parameters, rules, or other devices that see linguistic principles in globally all-or-nothing terms" (1994: 363–364).[2]

Second, distinctions between marked and unmarked structures are fundamental to OT, allowing the existence and emergence of unmarkedness to be formally defined. As McCarthy and Prince explain, "OT (Prince and Smolensky 1993) offers an approach to linguistic theory that aims to combine an empirically adequate theory of markedness with a precise formal sense of what it means to be 'unmarked'" (1994: 333). At the heart of OT are two basic constraint types: those demanding identity, typically between inputs and outputs (faithfulness), and those penalizing particular output structures (markedness) (chapter 63: markedness and faithfulness constraints; see also chapter 4: markedness). Marked structures are defined as exactly those structures which violate a markedness constraint.[3] "Emergence" can be defined with similar precision, again by reference to basic properties of OT: an unmarked structure can be said to emerge in a language if the markedness constraint violated by that structure is dominated by some (typically faithfulness) constraint which blocks its activity in some, but not all, contexts in that language.

§2 elaborates on this basic understanding of TETU as "activity despite domination," surveying three types of cases in which a dominating constraint is inactive in a particular evaluation, allowing a lower-ranked markedness constraint

[2] This view is elaborated in McCarthy (2002: 129–134), where it is noted that theories with ordered rules can mimic some TETU effects with the application of default rules.

[3] More precisely, structures which violate some markedness constraint M1 are marked with respect to M1; if these structures do not violate some other markedness constraint M2, no conflict arises in saying that they are also unmarked with respect to M2. In OT, markedness is multidimensional, assessed by each markedness constraint individually.

to emerge. §3 then describes gradient TETU effects found in languages where the emergent markedness constraint is never categorically active. Finally, §4 compares true TETU effects with situations where faithfulness, rather than markedness, constraints are active despite domination and thus emergent.

2 TETU typology

The typical TETU ranking is F1 >> M >> F2, with M emerging in evaluations where F1 is not decisive. This section will discuss three subclasses of TETU rankings, following from three different contexts in which high-ranking F1 may be rendered inactive. §2.1 looks at output segments and structures which have no input correspondents and so are invisible to IO-faithfulness constraints; these include reduplicants, epenthetic segments, and syllable boundaries. §2.2 considers evaluations in which multiple candidates tie on a particular high-ranking constraint, and §2.3 surveys faithfulness constraints which evaluate only some positions or aspects of outputs while ignoring others. In each of these situations, a high-ranking constraint is inactive and a dominated markedness constraint becomes active, choosing the winning output.

2.1 *Output segments and structures without input correspondents*

TETU is commonly observed in output structures which lack input correspondents and thus cannot be evaluated by IO-faithfulness. Recall the Nuu-chah-nulth ranking in (2) and (3), of the form IO-F >> M >> BR-F. Because reduplicants have no input correspondents in this theory, they cannot be evaluated by IO-faithfulness, allowing the effects of M (NoCoda in Nuu-chah-nulth) to emerge. This section describes similar TETU patterns found in two other structures which are present in outputs but not inputs: epenthetic segments and syllable boundaries.

2.1.1 *Epenthesis*

Kager (1999) observes that markedness constraints which are generally freely violated in a language often determine the quality of epenthetic segments (CHAPTER 67: VOWEL EPENTHESIS). These segments are typically featurally unmarked; epenthetic vowels like [i], [ɨ], and [ə], and consonants like [ʔ], [h], and glides, are cross-linguistically common, while marked segments like [f] and [æ] are rarely epenthesized.[4] This is due to TETU rankings like IO-Ident >> M, where M is a featural markedness constraint. When a constraint demanding identity between input and output features outranks markedness (here, IO-Ident >> M), the latter has little power to ban marked features in the language as a whole. While the presence of an epenthetic segment violates the anti-epenthesis constraint Dep, its lack of an input correspondent means that it is invisible to high-ranked IO-Ident; thus, epenthetic segments are subject to markedness constraints which require them to have unmarked feature values.

[4] See Vaux (2002, 2008) for a survey of epenthetic segments and a diachronic perspective. See also Steriade (2001, 2009) for the view that epenthetic segments are chosen by faithfulness constraints minimizing the perceptual distance between representations with and without the epenthetic segment.

2.1.2 *Syllable structure*

Not every aspect of linguistic outputs is evaluated by faithfulness constraints; some output properties, like prosodic structure above the mora level, are generally taken to be governed by markedness constraints only (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE). In a language like Timugon Murut (Austronesian), where DEP >> ONSET as in (4) and (5) (McCarthy and Prince 1994), the dominated markedness constraint ONSET emerges to make decisions in cases where DEP cannot distinguish between candidates. DEP's high ranking results in a language where epenthesis never occurs in order to avoid onsetless syllables, thus allowing words like [ambi'luo] 'soul' in (4). DEP (and similarly MAX, IDENT, etc.) cannot, however, distinguish between the candidates in (5), which differ only in syllabification. Because faithfulness constraints cannot see these differences, the decision is handed down to the emergent markedness constraint ONSET.

(4)

/ambi'luo/	DEP	ONSET
☞ a. am.bi.'lu.o		**
b. ʔam.bi.'lu.ʔo	**!	

(5)

/ambi'luo/	DEP	ONSET
☞ a. am.bi.'lu.o		**
b. am.bil.'u.o		***!

Cross-linguistically, the markedness constraint ONSET commonly triggers epenthesis, deletion, and other changes to prevent onsetless syllables. But its effects can also emerge even in languages like Timugon Murut, where ONSET is crucially dominated and so cannot require all syllables to have onsets; here, ONSET nonetheless requires syllabification of available consonants as onsets rather than codas. This contrasts with a parameter-based view of phonology, where onsetless syllables are present only when the ONSET parameter is "off," and thus cannot affect syllabification in any way.

2.2 *Output candidates not distinguished by dominating constraints*

Unmarkedness can also emerge when multiple output candidates are evaluated identically by all constraints dominating the emergent markedness constraint. This section discusses allomorph selection, which has been traditionally analyzed as a TETU effect of this sort within OT, as well as a similar example from the syntax–phonology interface.

2.2.1 *Allomorphy*

Mascaró (2004) observes that when a morpheme has multiple underlying forms, Gen supplies candidates that vary in the forms they correspond to (CHAPTER 99: PHONOLOGICALLY CONDITIONED ALLOMORPH SELECTION). In cases like English *a/an*, where the indefinite article has two lexically listed allomorphs, some members of the candidate set stand in correspondence with underlying *a*, while others stand in correspondence with underlying *an*. For this reason, the two output candidates shown in (6), *a wug* and **an wug*, tie on all high-ranked IO-faithfulness constraints. While the ranking of faithfulness constraints (here, simply FAITH) above NOCODA generally permits codas throughout English, NOCODA nevertheless emerges as decisive here, ruling out **an wug* in this unique case where multiple possible outputs are equally faithful to their respective inputs.[5]

(6)

{*a, an*} /wʌg/	FAITH	NOCODA
☞ a. ə.wʌg		*
b. ən.wʌg		**!

A more complex TETU analysis of lexically specific allomorph selection is offered in Becker's (2009) discussion of the Turkish aorist (Lees 1961; Napikoğlu and Ketrez 2006). The aorist suffix has two allomorphs: /-Ir/, with a high vowel, is used after all polysyllabic roots; /-Er/, with a non-high vowel, is used after all monosyllabic obstruent-final roots (the backness and height of these vowels are determined by vowel harmony; CHAPTER 118: TURKISH VOWEL HARMONY). Monosyllabic sonorant-final roots allow lexical exceptions: some take /-Ir/, while others take /-Er/.

(7)

shape of stem	*affix*					
polysyllabic	-Ir	[gere'k-ir]	'need'	[ʧali'ʃ-ir]	'work'
obstruent-final monosyllabic	-Er	[sa't-ar]	'sell'	[œ'p-er]	'kiss'
{r l n}-final monosyllabic	-Ir	[ka'l-ir]	'stay'	[gœ'r-yr]	'see'
	-Er	[da'l-ar]	'dive'	[œ'r-er]	'knit'

Turkish vowels are typically faithful to their underlying height specification, both in roots and in affixes; for example, the affix /-E/ (DATIVE) (e.g. [je're] 'to the place') contrasts with the affix /-I/ (3SG POSS) (e.g. [je'ri] 'his/her place'). This indicates that IDENT[high] outranks both of the markedness constraints in (8). When two allomorphs are available to choose from, however, as in these aorist examples, IDENT[high] is satisfied regardless of the choice of allomorph; the markedness constraints can thus emerge as decisive. (9) illustrates how *'σ/high consistently selects the /-Er/ allomorph in monosyllabic obstruent-final roots.

(8) a. *'σ/high
No stressed high vowels.
b. *RER
No non-high vowels between sonorants.

(9)

/sat-{-Er, -Ir}/	IDENT[high]	*'σ/high	*RER
☞ a. sa't-ar			
b. sa't-ir		*!	

[5] The ranking FAITH >> ONSET similarly chooses [ən.ʌg] over *[ə.ʌg].

The situation is more complex in the monosyllabic sonorant-final roots, which don't behave uniformly. Some of these occur with /-Er/, violating *RER, as shown in (10), while others occur with /-Ir/, violating *'σ/high, as in (11). Becker argues that sonorant-final monosyllabic roots are linked to lexically specified constraint rankings: for /-Er/-selecting roots like /dal/, *'σ/high >> *RER, while the opposite ranking holds for /-Ir/-selecting roots like /kal/. The overall pattern is one where each markedness constraint is emergent for a particular class of roots. See Becker (2009) for further details of the analysis, including the treatment of polysyllables and mechanisms for learning both affix URs and lexically specific rankings.

(10)

/dal-{-Er, -Ir}/	Ident[high]	*'σ/high	*RER
☞ a. da'l-ar			*
b. da'l-ɨr		*!	

(11)

/kal-{-Er, -Ir}/	Ident[high]	*RER	*'σ/high
a. ka'l-ar		*!	
☞ b. ka'l-ɨr			*

This TETU analysis of the Turkish aorist accounts for the fact that the lexically specific distribution of this affix is limited to sonorant-final roots. Since *RER is ranked below Ident[high], its effect can only be observed when a root contributes one sonorant and one of two lexically listed allomorphs (here, of the aorist affix) contributes the other. This contrasts with a diacritic-based approach to exceptionality; since such an approach isn't based on markedness constraints, it runs the risk of missing phonological restrictions on the distribution of exceptions. See Gouskova (2010) for further arguments in favor of a grammar-based approach to exceptionality (also chapter 106: exceptionality).

Rankings in each of these allomorphy examples take the form F >> M, where F cannot distinguish between candidates containing different allomorphs. Because multiple candidates are equally faithful, satisfying M does not require violating a lower-ranked F2, as is required in the prototypical TETU cases discussed in §1. The Turkish example shows that satisfying an emergent markedness constraint can also require violating a lower-ranked markedness constraint, in a ranking like F >> M1 >> M2. This occurs because markedness constraints can conflict with each other, as well as with faithfulness constraints. The following discussion of phonological phrasing and the syntax–phonology interface carries this observation further, demonstrating that markedness constraints can also emerge in contexts where a higher-ranked, conflicting markedness constraint is inactive.

2.2.2 *Phonological phrasing*

Because faithfulness constraints do not evaluate prosodic structure, analyses of phonological phrasing are generally based on rankings of conflicting markedness constraints. While most familiar TETU rankings involve domination by a conflicting faithfulness constraint, the dominating constraint may also be a second markedness constraint. That is, dominated M2 may also emerge in a ranking like (12).

(12) M1 >> M2

Truckenbrodt (1999) proposes an analysis of phonological phrasing based only on markedness constraints; in contexts where high-ranking markedness constraints are rendered inactive, lower-ranking markedness constraints emerge. In Chewa (Bantu, referred to by Truckenbrodt as Chicheŵa), a complex VP like $[V\ NP\ NP]_{VP}$ is produced as single phonological phrase, $(V\ NP\ NP)_{PhP}$, rather than $^*(V\ NP)_{PhP}$ $(NP)_{PhP}$, as in (13). The large phrase satisfies WRAP-XP, a constraint that penalizes any syntactic phrase whose elements are parsed into smaller phonological phrases. Other dominated markedness constraints express conflicting preferences for smaller phonological phrases: ALIGN-XP demands alignment of the right edge of each syntactic phrase with the right edge of a corresponding phonological phrase. The winner in (13) incurs a violation due to the first NP, which has no phrase break at its right edge.

The ranking WRAP-XP >> ALIGN-XP generally thwarts ALIGN-XP's desire for additional phonological phrases. ALIGN-XP's effects emerge, however, under focus. ALIGN-FOC requires focused verbs to fall at the end of phonological phrases; the ranking ALIGN-FOC >> WRAP-XP rules out candidate (14a). Candidates (14b) and (14c) both satisfy ALIGN-FOC, and both violate WRAP-XP, rendering WRAP-XP inactive as well in selecting the optimal output. Because these candidates tie on high-ranking constraints, we again see a TETU effect: ALIGN-XP emerges, selecting the unmarked candidate, (14c).

(13)

$/[V\ NP\ NP]_{VP}/$	ALIGN-FOC	WRAP-XP	ALIGN-XP
☞ a. $(V\ NP\ NP)_{PhP}$			*
b. $(V\ NP)_{PhP}\ (NP)_{PhP}$		*!	

(14)

$/[V_{FOC}\ NP\ NP]_{VP}/$	ALIGN-FOC	WRAP-XP	ALIGN-XP
a. $(V_{FOC}\ NP\ NP)_{PhP}$	*!		*
b. $(V_{FOC})_{PhP}\ (NP\ NP)_{PhP}$		*	*!
☞ c. $(V_{FOC})_{PhP}\ (NP)_{PhP}\ (NP)_{PhP}$		*	

Truckenbrodt notes that this analysis of Chewa is particularly interesting, due to the non-local nature of the TETU effect: the appearance of an (unmarked) prosodic break after the focused verb causes another break to appear after a subsequent non-focused noun phrase.

2.3 *Output segments not evaluated by specific faithfulness*

This final subsection discusses situations where general IO-faithfulness is low-ranked, and the emerging markedness constraint is instead dominated by a different type of faithfulness constraint. In other words, these are TETU rankings of the type Special-F >> M >> General-F. We discuss three kinds of faithfulness that can outrank general IO-faithfulness: positional faithfulness, which protects strong positions inside a candidate; output-output faithfulness, which protects the base in a morphologically complex form; and USELISTED, which protects correspondents of existing forms in a speaker's lexicon.

2.3.1 *Positional faithfulness*

Beckman (1999) examines patterns where contrasts are licensed only in strong positions like initial syllables, stressed syllables, and onsets. She analyzes these using positional faithfulness constraints, which assess correspondence only for segments in particular output positions (here, onsets).

Catalan (Romance) allows contrastive voicing in onsets, but bans voiced obstruents in codas (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). Beckman accounts for this with the ranking shown in (15)–(17). Underlyingly voiced coda obstruents are devoiced in surface forms, due to the ranking *VoiObs >> Ident[voice], as in (15). In onsets, however, underlying voicing surfaces faithfully, due to the high-ranking positional faithfulness constraint Ident[voice]/Onset, as in (16)–(17). Here the markedness constraint *VoiObs is dominated, yet active in non-onset contexts, making this a TETU effect.

(15)

/griz/ 'gray (MASC)'	Ident[voice]/Onset	*VoiObs	Ident[voice]
a. 'griz		**!	
☞ b. 'gris		*	*

(16)

/gos-a/ 'dog (FEM)'	Ident[voice]/Onset	*VoiObs	Ident[voice]
a. 'go.zə	*!	**	*
☞ b. 'go.sə		*	

(17)

/griz-a/ 'gray (FEM)'	Ident[voice]/Onset	*VoiObs	Ident[voice]
☞ a. 'gri.zə		**	
b. 'gri.sə	*!	*	*

In addition to protecting phonologically strong positions (initial syllable, stressed syllables, onsets), positional faithfulness may also protect morphologically strong contexts such as roots (McCarthy and Prince 1995) and nouns (Smith 1999, 2001; see also CHAPTER 102: CATEGORY-SPECIFIC EFFECTS). Smith notes that in Spanish, stress is lexically marked in nouns but predictable in verbs. She analyzes a range of such patterns using noun-specific faithfulness constraints (F/Noun) in the ranking schema F/Noun >> M >> F. Here, nouns may be faithful to lexically specified stress thanks to high-ranking F/Noun; in verbs, however, stress is instead governed by emergent markedness constraints.

The activity of markedness constraints in all of these rankings, despite their domination by a conflicting (here position-specific) faithfulness constraint, identifies these as TETU effects. There is a significant difference, however, between many positional faithfulness patterns and most other TETU patterns. In the TETU ranking schemata discussed in previous sections, general IO-faithfulness constraints dominate emergent markedness constraints. Here, though, markedness dominates (general, though not position-specific) IO-faithfulness. This results in different surface distributions of the emergent unmarked structures.

Typically, when IO-F >> M, marked structures are licensed in most contexts throughout the language; unmarkedness emerges in specific, less frequent contexts like reduplicants, epenthetic segments, or allomorphs. When TETU results from high-ranking positional faithfulness, however, the reversed ranking M >> IO-F can result in a language which is largely *unmarked*; in these languages, marked structures are restricted to the specific set of contexts protected by the positional faithfulness constraint. When this set of markedness licensing contexts is small, as for FAITH/σ1 or FAITH/'σ (faithfulness to word-initial and stressed syllables, respectively), unmarked structures are required in the majority of contexts: the set of positions in which markedness may occur is atypically smaller than those where unmarkedness is required.[6] This distributional pattern will be discussed further in §4.

2.3.2 *Output–output faithfulness*

Another family of constraints which evaluates only some outputs and so gives rise to TETU effects is output-output (OO) faithfulness (Benua 1997). OO-faithfulness constraints evaluate correspondence between the base of a morphologically complex word and that base's stand-alone surface form. Harris (1990) discusses examples of Aitken's Law in dialects of the Central Scottish Lowlands. Here, stressed vowels in roots have predictable length: when followed by any consonant other than /r v ð z/, vowels are short; otherwise, they are long. /ɪ ʌ/ are exceptions, remaining short in all positions. (See also CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH.) For example, stop-final *feed* has a short vowel, while the open syllable *key* has a long vowel. The past tense *keyed*, however, keeps the long vowel which is present in its base *key*, despite its final stop coda. This can be attributed to protection from high-ranking OO-FAITH, as described below (Benua 1997; McCarthy 2002).

Because OO-faithfulness constraints target only a subset of a language's output forms – those which are morphologically complex – they can give rise to TETU effects. A ranking like OO-F >> M >> IO-F operates much like the positional faithfulness TETU ranking discussed above. The markedness constraint *V:C] ("no long vowels in syllables closed by any consonant other than /r v ð z/") dominates IO-faithfulness; tableau (18) shows that this results in a language which is typically unmarked: long vowels are absent from closed syllables. Long vowels appear in open syllables, as in (19); because OO-IDENT(length) >> *V:C], long vowels also appear in closed syllables in morphologically complex forms derived from roots with long vowels, as in *keyed* [ki:d] (cf. *key* [ki:]) in (20).

(18)

/fi:d/	OO-ID(length)	V:C]	IO-ID(length)
☞ a. fid			*
b. fi:d		*!	

(19)

/ki:/	OO-ID(length)	V:C]	IO-ID(length)
a. ki			*!
☞ b. ki:			

[6] Positional faithfulness TETU rankings can also result in languages where, as is more typical of TETU, unmarkedness is the less frequent pattern; this occurs when the positional faithfulness constraint targets a broad set of positions, e.g. FAITH/Root.

(20)

/kiː-d/	OO-ID(length)	V:C]	IO-ID(length)
a. kid	*!		*
☞ b. kiːd		*	

Here, again, a markedness constraint is active in the language despite its domination by (here, OO) faithfulness. Similar TETU effects are possible in other theories that use faithfulness relations between members of a paradigm, such as McCarthy's (2005) Optimal Paradigms.

2.3.3 UseListed

Zuraw (2000) proposes an additional novel kind of faithfulness constraint, UseListed, which protects items that are listed in a speaker's lexicon. Listed items include all roots and all morphologically complex forms that a particular speaker has heard, with more frequent items assumed to be more strongly listed.

In producing a previously heard, morphologically complex form, the speaker has two options: they could use either the lexically listed forms of the root and affixes as inputs to the grammar, or they could instead use the single lexically listed complex form (again, as input to the grammar). Zuraw proposes that these two possible input structures compete in a single evaluation, with UseListed penalizing outputs derived from productive combinations of morphemes.

For novel roots and novel complex forms (i.e. novel combinations of roots and affixes, even if a speaker is familiar with each morpheme in other contexts), however, no lexical listing is available. Thus outputs based on any of these forms will violate UseListed equally. Markedness constraints ranked below UseListed can therefore emerge in evaluations of unfamiliar items, as in Hayes and Londe's (2006) analysis of Hungarian vowel harmony.

The Hungarian dative appears with a back vowel when the root's final syllable has a back vowel ([glykoːz-nɔk] 'glucose-DAT'), and it appears with a front vowel when the root's final syllable has a front rounded vowel ([ʃoføːr-nɛk] 'chauffeur-DAT') (CHAPTER 123: HUNGARIAN VOWEL HARMONY). When the root's final syllable has a front unrounded vowel, some items take a front suffix ([tsiːm-nɛk] 'address-DAT') and others take a back suffix ([hiːd-nɔk] 'bridge-DAT'). Taking a back suffix is especially likely when the final front unrounded vowel is preceded by a back vowel ([aːtseːl-nɔk] 'steel-DAT'). Here, the relevant markedness constraints will be Local[eː], which penalizes back vowels in the syllable immediately following an [eː], and Distal[back], which penalizes front vowels in any syllable following a back vowel.

Hungarian speakers agree on the dative forms of familiar (lexically listed) items such as [aːtseːl-nɔk]. UseListed is decisive in these cases, preferring the listed form over productive combinations of the root and the suffix, and thus rendering lower-ranked markedness constraints on vowel harmony inactive. The two candidates (21a) and (21b) are generated from the listed form [aːtseːl-nɔk], and thus satisfy UseListed (despite the unfaithful surface form of this input in (21b)). The second two candidates are generated productively by combining the root /aːtseːl/ with the dative suffix, and are thus ruled out by UseListed.

(21)

/aːtseːl-{nɛk, nɔk}/, *listed*: [aːtseːl-nɔk]	USE LISTED	IDENT [back]	LOCAL [eː]	DISTAL [back]
☞ a. /aːtseːl-nɔk/ → aːtseːl-nɔk			*	*
b. /aːtseːl-nɔk/ → aːtseːl-nɛk		*!		**
c. /aːtseːl-{nɛk, nɔk}/ → aːtseːl-nɔk	*!		*	*
d. /aːtseːl-{nɛk, nɔk}/ → aːtseːl-nɛk	*!			**

But when Hungarian speakers hear a novel root containing a back vowel followed by a front unrounded vowel, e.g. [haːdeːl], the suffix vowel in the dative forms can agree with either root vowel: some speakers prefer [haːdeːl-nɔk], as in (22a), while others prefer [haːdeːl-nɛk], as in (22b). Both candidates in (22) violate UseListed, since no lexical listing exists for this novel item, and thus the dative form must be derived productively by combining the root /haːdeːl/ with the dative suffix.

(22)

/haːdeːl-{nɛk, nɔk}/, *listed*: [ ]	USE LISTED	IDENT [back]	LOCAL [eː]	DISTAL [back]
☞ a. /haːdeːl-{nɛk, nɔk}/ → haːdeːl-nɔk	*		*	*
☞ b. /haːdeːl-{nɛk, nɔk}/ → haːdeːl-nɛk	*			**

Hayes and Londe argue that a particular speaker's actual output depends on a stochastic ranking between the two competing markedness constraints on vowel harmony, Local[eː] and Distal[back]. Crucially, as in the Turkish example in §2.2.1, one of these two low-ranked markedness constraints emerges; here, this occurs when dominating UseListed cannot distinguish between candidate outputs for a novel input.

3 Gradient TETU

The previous sections have surveyed various ways in which high-ranking constraints can be rendered irrelevant in particular evaluations, allowing lower-ranked markedness constraints to emerge. Of course, not all markedness constraints which are dominated in a particular language emerge; many are ranked too low to ever be active in choosing a winning surface form. Recent work suggests, however, that subtle TETU effects can be identified even for markedness constraints which never distinguish between grammatical and ungrammatical forms.

Consonants in Arabic roots are subject to various co-occurrence restrictions (chapter 86: morpheme structure constraints). Among grammatical consonant combinations, preferences for particular combinations are found: some are much more frequent than others in the lexicon, and novel words conforming to the more frequent patterns are judged as more well-formed in rating tasks (chapter 90: frequency effects). Coetzee and Pater's (2008) analysis of these preferences among grammatical forms casts them as gradient TETU effects, where markedness constraints which are never categorically obeyed nevertheless exert subtle preferences for unmarked forms (chapter 89: gradience and categoricality in

PHONOLOGICAL THEORY). Rankings giving rise to these gradient effects are illustrated in (23) and (24). Roots including both coronal stops and fricatives (e.g. /dasar/ 'to push', represented here as TS) and those containing coronal stops and sonorants (e.g. /dalaq/ 'to spill', represented here as TL) both surface faithfully in Arabic, although these combinations are underrepresented, i.e. they are attested less often than expected, given the overall frequency of each type of consonant. In the lexicon, however, TS roots are more severely underrepresented than TL roots, suggesting that TL roots are in some sense more easily tolerated. Coetzee and Pater argue that both combinations violate a constraint against roots with two coronals (*TT), while only the dispreferred TS roots violate an additional constraint against roots with two coronals of similar sonority (*TT[son]).

(23)

/TS/	IDENT(place)	*TT[son]	*TT
☞ a. TS		*	*
b. PS	*!		

(24)

/TL/	IDENT(place)	*TT[son]	*TT
☞ a. TL			*
b. PL	*!		

Here, no markedness constraint is ranked highly enough to ban TS or TL outputs. These consonant combinations are protected by faithfulness, and are thus attested and grammatical, but they are not judged by speakers to be quite as well formed as roots that lack OCP violations. TS's additional violation of *TT[son] contributes to its decreased acceptability relative to TL, as observed in the results of word-likeness tasks and similar psycholinguistic experiments. In other words, the markedness constraint *TT[son] is active in Arabic even though it is crucially dominated by IDENT(place). This activity is evidenced by the underattestation of actual TS roots and the decreased acceptability of novel TS roots, even though it doesn't force unfaithful mappings.

The incorporation of gradient generalizations into the grammar can also be used to identify relative rankings of undominated markedness constraints, i.e. the opposite of gradient TETU. If neither of two markedness constraints is ever crucially dominated by a conflicting constraint in some language, the relative ranking of these constraints cannot be determined from either categorical phonotactics or paradigmatic information. This approach, however, allows evidence for their relative ranking to come from gradient phonotactics and psycholinguistic data. Coetzee (2009) compares the grammaticality of English homorganic stops after [s], noting that coronals are attested, as in *state*, but labials and dorsals are not, as in **skake* or **spape* (see also Davis 1984, 1991; Frisch 1996; Frisch *et al.* 2004).

Coetzee's psycholinguistic experiments show that speakers rate **spape* as less acceptable than **skake*, and both are less acceptable than *state*. He uses this result to propose that while *sPVP and *sKVK are both undominated in English, the constraint penalizing *sPVP is more highly ranked than the constraint penalizing *sKVK. This view is also supported by the existence of words that come close to violating *sᴋVᴋ, such as *skag*, *skulk*, or *squeak*, compared with the non-existence of **spab*, **spulp*, or **spweep*.

4 The emergence of the faithful

As mentioned in §2.3.1, there is an important distinction between the formal definition of TETU and the most intuitive surface-oriented descriptions of these patterns. McCarthy and Prince (1994: 334) define TETU as follows:

> Even in languages where [some markedness constraint] C is crucially dominated and therefore violated, the effects of C can still be observed under conditions where the dominating constraint is not relevant. . . . this [is] "emergence of the unmarked."

The same passage describes the typical surface pattern that results from constraint activity despite domination:

> in the language as a whole, C may be roundly violated, but in a particular domain it is obeyed exactly. In that particular domain, the structure unmarked with respect to C emerges.

Patterns where high-ranking positional faithfulness constraints allow unmarkedness to emerge (e.g. Iᴅᴇɴᴛ[voice]/Oɴsᴇᴛ >> *VᴏɪOʙs >> Iᴅᴇɴᴛ[voice]) demonstrate that activity-despite-domination rankings can also give rise to a converse pattern: a markedness constraint may in fact be obeyed in the language as a whole, but violated in a particular domain. In these cases, the structure unmarked with respect to the markedness constraint emerges in the language as a whole, despite its ungrammaticality in a particular domain.

The lack of a necessary connection between a markedness constraint's activity despite domination and the relative rarity of the resulting unmarkedness is also illustrated in patterns following from the activity of positional markedness constraints. Like positional faithfulness constraints, these are versions of regularly attested markedness constraints which evaluate only structures in particular output positions, e.g. Oɴsᴇᴛ/σ1, a constraint that penalizes onsetlessness in the initial syllable only (ᴄʜᴀᴘᴛᴇʀ 55: ᴏɴsᴇᴛs).

An example of this pattern comes from Arapaho (Algonquian, Smith 2002: 127, from Salzman 1956: 53–54). In this language, onsetless syllables occur in non-initial syllables (e.g. the onsetless third syllable in [wo.ˈʔo.uː.soː] 'kitten'), as shown in (25). Word-initial vowels are, however, banned (e.g. *[o.toʔ]), as shown in (26). These patterns follow from the ranking Oɴsᴇᴛ/σ1 >> Dᴇᴘ >> Oɴsᴇᴛ, and are identical in character to the typical TETU surface pattern: marked structures are licensed in most of the language, but a small pocket of enforced unmarkedness is found in initial syllables. Many other languages of this type are discussed by Smith (2002) and Flack (2009).

(25)

/woˈʔouːsoː/	Oɴsᴇᴛ/σ1	Dᴇᴘ	Oɴsᴇᴛ
☞ a. wo.ˈʔo.uː.soː			*
b. wo.ˈʔo.ʔuː.soː		*!	

(26)

/oto?/	Onset/σ1	Dep	Onset
☞ a. ho.to?		*	
b. o.to?	*!		*

Despite the surface similarities between positional markedness patterns and classic TETU patterns, the formal structure of these rankings distinguishes them from TETU rankings. These follow the schematic form M1 >> F >> M2, rather than the TETU form F1 >> M >> F2. These patterns thus might be dubbed "The Emergence of the Faithful": F emerges (i.e. is active despite domination) in cases where dominating Onset/σ1 is inactive.

Albright (2004) discusses patterns of this sort, using the term "The Emergence of the Marked" to describe their surface pattern. In Lakota (Siouan), codas are banned in roots but licensed elsewhere (e.g. affixes, reduplicants, function words). This pattern results from the positional markedness ranking NoCoda-root >> F >> NoCoda; as Albright explains, this pattern is a "mirror image of the TETU configuration: here, greater faithfulness emerges outside roots, when a higher-ranked markedness constraint (NoCoda-root) is inapplicable" (2004: 7). Here, markedness "emerges" in distributionally rare root-external contexts. To be clear, the distributional sense of "emerge" used here is different from the formal sense used by McCarthy and Prince: formally, effects of the constraint which is dominated yet active emerges; distributionally, whichever pattern is not generally permitted (markedness *vs.* unmarkedness) "emerges" in specific, restricted contexts.

5 Conclusion

TETU is a property of theories with violable constraints, and sets these theories apart from those with parameters or inviolable constraints. In TETU rankings, a markedness constraint is shown to be dominated in a language, yet active in situations where the dominating constraints are irrelevant. Three types of such situations are surveyed in §2. Active-yet-dominated markedness constraints have also been used in the analysis of gradient patterns, as discussed in §3. Finally, patterns mirroring TETU which result from active-yet-dominated faithfulness constraints are discussed in §4.

TETU effects, which demonstrate the violability of OT constraints, set OT apart from theories with inviolable constraints, also known as parameters in Principles and Parameters Theory (Chomsky 1981, 1986). In Principles and Parameters Theory, the learner starts with parameters set to their default, or unmarked, position; parameters can be switched off given evidence from the ambient language. The NoCoda parameter, for instance, will remain on for a speaker of Hawaiian, as this language doesn't allow codas. However, speakers of English or Nuu-chah-nulth will switch the NoCoda parameter off, as codas are generally allowed in these languages. Once off, however, the NoCoda parameter can no longer be used to account for the contexts in which these two languages prefer codaless syllables (see §1 and §2.2.1 above), causing a loss of generality in the analysis of these languages (McCarthy 2002: 131–132).

Interest in TETU effects initially brought attention to a variety of cases where constraints were shown to be active even in languages where they were roundly violated, e.g. NoCoda in English. This lent support to the view that there is a single, universal constraint set for all languages, which in turn led to fruitful research on how language-specific rankings of these universal constraints could be learned (see e.g. Tesar 1995; Tesar and Smolensky 1998; and much work since).

Early work in OT typically assumed that this universal constraint set was innate; assumptions of both innateness and constraint universality have begun to lose favor in recent years with the advent of proposals that some or all constraints are induced by learners (Flack 2007; Hayes and Wilson 2008; Moreton 2010).

TETU effects were a major focus of interest in the early days of Optimality Theory, when the concept of violable constraints was new to the linguistic community. With the increased acceptance of violable constraints in theoretical work, cases of TETU no longer attract special attention, even as interest turns to other theories that incorporate violable constraints, including OT-CC (McCarthy 2007), Harmonic Grammar (Legendre *et al.* 1990; Pater 2009), and MaxEnt (Goldwater and Johnson 2003; Hayes and Wilson 2008).

59 Metathesis

Eugene Buckley

The term *metathesis* – Greek for 'transposition' – refers to a reordering of segments. This chapter outlines the range of phenomena that fall under this description, and theoretical perspectives on their insightful analysis. Other cross-linguistic surveys of this topic include Webb (1974), Ultan (1978), Hock (1985), Wanner (1989), Blevins and Garrett (1998, 2004), Becker (2000), and Hume (2001, 2004).

The term has traditionally been best known for the description of historical sound changes (CHAPTER 93: SOUND CHANGE), often described as sporadic. For example, Osthoff and Brugmann (1878: xiv, n. 1) cite metathesis, along with dissimilation (CHAPTER 60: DISSIMILATION), as lacking the "mechanical" character of regular sound change. Hock (1985), however, argues that diachronic metathesis is regular when it serves to enforce a structural constraint. For example, in early attestations of Persian, as well as in reconstructed forms, clusters of an obstruent or nasal plus a liquid can be found before a final vowel. Loss of that vowel leads to a final cluster with a rising sonority profile (CHAPTER 49: SONORITY; CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS); this configuration is repaired by metathesis of the two consonants, so that the more sonorous liquid is closer to the vowel. (The segments involved are underlined in (1).)

(1) *Persian liquid metathesis* (Hock 1985: 534)

suxra	>	surx	'red'
vafra	>	barf	'snow, ice'
asru	>	ars	'tear'
*namra	>	narm	'soft'

Although much of the literature discusses historical metathesis – where copious examples can be found – this chapter focuses on instances of metathesis that are active synchronically. By this I mean alternations in the ordering of segments that appear to be part of a speaker's productive grammatical knowledge, and therefore must be accounted for in theories of linguistic competence. There is of course an intimate connection between diachronic metathesis and the synchronic alternations that may persist in the grammar as a result, but I will take care to distinguish examples for which only diachronic change is well attested, and where the results of the change appear to be new underlying forms rather than a new phonological alternation. Similarly, although the emphasis is on phonologically defined patterns, some types of metathesis require reference to morphological context, even if the specific change is expressed in terms of phonological categories.

For most of the twentieth century, metathesis was described either in prose or, as formalisms became more sophisticated, as reorderings of indexed objects in a string. Chomsky and Halle (1968: 361) describe metathesis as "a perfectly common phonological process," and permit transformations that effect permutation. In their notation, /skt/ → [kst] metathesis in Faroese, shown below in (3), could be expressed as follows.

(2) *Metathesis as a transformation*

Structural description	s	k	t				
Structural change	1	2	3	→	2	1	3

The need for indexation distinguishes metathesis from most other processes, such as insertion (CHAPTER 67: VOWEL EPENTHESIS), deletion (CHAPTER 68: DELETION), and featural assimilation (CHAPTER 81: LOCAL ASSIMILATION). In those sorts of changes, whatever elements of the representation remain after the change maintain their relative ordering on their tier. A true featural equivalent to segmental metathesis would be a swap in feature values on the same tier (or at some non-root node), such as a change from LH to HL tone in a context where underspecification of the L with simple shift of H is not a plausible analysis. As noted in §1.4, there is limited evidence for tonal metathesis of this sort.

Following the most common modern usage, in this chapter I apply the term *metathesis* to permutations of segments regardless of intervening material. §1 deals with *local* metathesis, including the sequences CC, CV, and VV, followed by brief consideration of other types. §2 considers the *long-distance* metathesis of non-adjacent segments, as well as the displacement of a segment that is not exchanged with another. §3 considers the relation of metathesis to other phenomena with which it shares some formal properties, such as infixation.

1 Local metathesis

In local metathesis, two adjacent segments are swapped, without any necessary change in their features, although in some cases other processes may affect the outcome. These can be classified formally according to the segments involved in the reversal: two consonants, a consonant and a vowel (in either order), or two vowels.

1.1 CC metathesis

To organize this presentation, I group the processes according to the features of the segments involved. These include the special role of sibilants, place of articulation, and manner of articulation.

1.1.1 *Sibilants*

Sibilant consonants are often observed to reverse order with an adjacent stop consonant (Silva 1973; Hume 2001: 12–14; Seo and Hume 2001; Steriade 2001: 234f.; Blevins and Garrett 2004: 139f.; Hume and Seo 2004: 36–39). An example is found in Faroese, where /sk/ followed by /t/ is reversed (Lockwood 1955: 23f.).

(3) *Faroese metathesis of* /sk/ (Lockwood 1955: 24)

masculine	*neuter*	
fɛsk-ur	fɛks-t	'fresh'
rask-ur	raks-t	'energetic'
dansk-ur	daŋks-t	'Danish'

As noted above, metathesis has typically been considered a sporadic or irregular process, unlike phenomena such as assimilation that can often be described in very general and regular terms (see Hume 2001: 1f. for representative quotations). But the Faroese reversal illustrates that a process of metathesis can be fully regular while also quite restricted in scope, simply because the necessary configuration does not often arise. Thus the neuter noun suffix /t/ provides the environment for reversal of stem-final /sk/; but a similar environment in verbs also triggers the changes, as can be seen in /ʊʏŋks-ti/ 'wish (PAST SG)' compared to the present singular /uʏnsk-ir/ with the underlying ordering thanks to the following vowel (Hume 1999: 294).

It was traditionally claimed that metathesis yields sequences that are in some way better formed than the input ordering, usually in the sense of "ease of articulation" or satisfying a language's phonotactic constraints (Wechssler 1900: 497; Grammont 1933: 239; Ultan 1978: 390). More recent work has placed greater emphasis on the role of perception (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY), and on historical explanations for how metathesis arises (CHAPTER 93: SOUND CHANGE). Faroese can be seen as *auditory metathesis* – the temporal decoupling of the noise of a fricative, especially a sibilant, from the surrounding signal, which can lead to a sibilant and an adjacent stop being reinterpreted as occurring in the opposite of the original order (Blevins and Garrett 2004: 120). A segment often moves to a position in which it is more easily perceptible, especially due to the formant transitions in an adjacent vowel (Hume 1999: 295f.; Seo and Hume 2001: 215–217). Thus Faroese metathesis places the stop /k/ in a more perceptible position, adjacent to the preceding vowel, while the sibilant remains perceptible without an adjacent vowel. This directionality suggests that confusibility in the ordering of the segments is not the sole factor, since symmetrical confusion predicts random reordering according to the two possible interpretations of an ambiguous auditory signal (Steriade 2001: 233–235); but see Blevins and Garrett (2004: 119f.) for a defense of the misperception account. The outcome in particular languages may depend on prosody, such as the location of stress, and phonetic detail, such as the release of final stops; such differences may explain the symmetrically opposite changes in Late West Saxon (/frosk/ → [froks] 'frog') and a certain variety of colloquial French (/fiks/ → [fisk] 'fixed') (Blevins and Garrett 2004: 139f.).

A transformational rule that reverses the order of segments does not make reference to the apparent motivations of the reordering, such as an improvement in markedness (CHAPTER 4: MARKEDNESS). But like other phonological processes, metathesis may operate in order to satisfy the phonotactic restrictions of a language. That is, just as the place assimilation in *anba* → *amba* satisfies a condition that nasal codas must agree in place with a following stop, so a metathesis such as *inma* → *imna* in (6) satisfies a condition on the sequencing of coronal and labial consonants. Recent approaches have attempted to capture this insight and to treat metathesis more on a par with other processes.

In the surface orientation of Optimality Theory (Prince and Smolensky 2004), the expected Faroese sequence [skt] can be penalized by a constraint against a stop that occurs between two other consonants (Hume 1999: 298), whether it is defined directly in terms of perceptibility or as a more abstract configuration. This pressure must dominate the correspondence constraint LINEARITY, which otherwise prevents reorderings of segments, and obviously plays a central role in the analysis of metathesis (Hume 1998: 149, 68f.; McCarthy and Prince 1995: 371f.; McCarthy 2000: 173). Metathesis occurs only when LINEARITY is ranked below faithfulness constraints such as MAX and DEP; these prevent deletion or insertion of material that otherwise might serve to remedy the surface constraint that metathesis addresses.

(4)

/raskt/	*STOP/C__C	MAX	DEP	LINEARITY
☞ a. raskt	*!			
b. rast		*!		
c. rask		*!		
d. raskit			*!	
e. rakst				*

Naturally, no violation of LINEARITY is required in a form such as [raskur], where the stop /k/ is adjacent to a vowel, and the sequence surfaces intact.

Another relatively restricted case of stop–sibilant metathesis is the Tiberian Hebrew *hitpa'el* verb form, where the /t/ of the prefix reverses with a stem-initial sibilant (Malone 1993: 52f.; Coetzee 1999: 106; see Malone 1971 for similar facts in other Semitic languages; see also CHAPTER 108: SEMITIC TEMPLATES). The examples in (5a) show the lack of metathesis with non-sibilants.

(5) *Tiberian Hebrew metathesis* (Coetzee 1999: 106)

a.	hit-pallel	→	hitpallel	'he prayed'
	hit-qaddeʃ	→	hitqaddeʃ	'he sanctified himself'
b.	hit-sappex	→	histappex	'he felt attached to'
	hit-ʃammer	→	hiʃtammer	'he protected himself'
	hit-śakker	→	hiśtakker	'he gave himself into service'
	hit-zakker	→	hizdakker	'he remembered'
	hit-sˤaddeq	→	hisˤtˤaddeq	'he considered himself righteous'

For Coetzee (1999: 122f.), the motivation for metathesis in exactly this context, when a /t/ would otherwise precede a sibilant, is that a [t] + sibilant sequence would be subject to reinterpretation as an affricate, a type of segment disfavored in Tiberian Hebrew. He proposes a constraint *t+SIBILANT against that sequence, again with relatively low-ranked LINEARITY. Hume (2004: 222f.), discussing the equivalent metathesis in Modern Hebrew, argues that the poor attestation of [t] + sibilant sequences in Hebrew sets the stage for a reinterpretation with the sibilant in first position: an ambiguous acoustic signal is likely to be interpreted sequentially according to the most commonly attested ordering of those segments, dependent not necessarily on universal principles, but on the lexicon and grammar of the language in question.

1.1.2 *Place of articulation*

Many instances of CC metathesis depend on place of articulation (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION), with certain orderings of place favored over others. Permutation of this type is found in a range of Malayo-Polynesian languages (Blevins and Garrett 2004: 136). In Cebuano, for instance, a coronal stop or nasal followed by a labial or velar consonant is reversed, optionally in some cases (Blust 1979: 110).[1] The consonants come to be adjacent as the result of vowel syncope after a vowel-initial suffix is added.

(6) *Cebuano metathesis of coronal + non-coronal clusters* (Blust 1979: 110)

stem	*suffixed form*	
lutuk	lukt-un	'put the finger in'
gitik	gitk-anun ~ gikt-anun	'ticklish'
atup	atp-an ~ apt-an	'roof'
inum	imn-a	'drink'

Stems such as /lakat/ 'walk' that already have the preferred ordering maintain it ([lakt-un]), showing that the process is not simply an across-the-board reversal in consonant clusters. In this case, the favored ordering places the coronal in second position.

The two changes in Cebuano – deletion of the vowel and reversal in the resulting cluster – were likely ordered historical events, and this history can be modeled easily by ordered synchronic rules. But the same facts are also consistent with simultaneous satisfaction of two surface constraints in OT. The candidates *[lutukun] and *[lutkun] both violate one of these constraints – by the lack of syncope, or the disfavored consonant ordering – whereas [luktun] satisfies both, and wins under low ranking of LINEARITY and MAX-V.

(7)

/lutuk-un/	*VCVCV	*TK	LINEARITY	MAX-V
a. lutukun	*!			
b. lutkun		*!		*
☞ c. luktun			*	*

A phonetic explanation for this type of reordering is *co-articulatory metathesis*, which results from the overlap in adjacent consonant gestures (Blevins and Garrett 2004:

[1] Similar patterns are found in a number of other Philippine languages (Blust 1971: 85f.; 1979: 104f.; Crowhurst 1998: 597), including Tagalog, where, however, it is poorly attested and classified with irregular verbs (Schachter and Otanes 1972: 375–380).

136–138); for example, overlapping coronal (T) and non-coronal closures (K) are perceived as the non-coronal, which leads to reversals such as TK → KT in Cebuano (6). A general preference for apicals to follow non-apicals has been cited with regard to metathesis in other languages such as Greek, which may be related to the tendency for coronal codas to assimilate to following non-coronals (Bailey 1970: 348). One abstract phonological approach formalizes the licensing properties of different places of articulation (Rubin 2001: 194–199); unmarked Coronal is a *natural head* and licenses the place features of a preceding non-coronal, favoring KT over TK. See also Blust (1979: 102f.) and Winters (2001) on the general preference for coronals to occur second in a cluster.

Some reorderings have considerably more complex origins. In the Kondh branch of Dravidian, sequences of a velar /k g/ plus a labial /p b/ are reversed. The Pengo examples below illustrate two allomorphs /-pa/ and /-ba/ of the intensive-frequentative or plural action suffix, both of which also occur in contexts without metathesis as seen in (8a). For similar Kui examples, see Hume (2001: 8).

(8) *Pengo velar + labial metathesis* (Burrow and Bhattacharya 1970: 82f., 201)

a.	gru:t-pa-	→	gru:t-pa-	'fell'
	huz-ba-	→	huz-ba-	'roast'
b.	ḍrik-pa-	→	ḍripka-	'break'
	ku:k-pa-	→	ku:pka-	'call'
	ṛa:k-ba-	→	ṛa:bga-	'sacrifice'
	tog-ba-	→	tobga-	'be split'

According to Garrett and Blevins (2009: 538ff.), this metathesis pattern arose by re-analysis of complex allomorphy deep in the history of Dravidian. Briefly, causative /p/ could replace the last consonant of the stem, as in Kolami [melg-] 'grow (INTR)' and derived [mel-p-] 'rear'. This was interpreted as a rule deleting the velar before the labial, which was extended to other labial-initial suffixes, including the plural action containing [-p-]. This would yield an alternation between simple */ku:k-/ 'call' and plural action */ku:k-p/→ *[ku:-p-]. But there is another basic allomorph of the plural action suffix containing /-k-/; if this were added to the existing plural action in order to make the exponence of that category clearer, the result is the pair *[ku:k-] and *[ku:-p-k-], which then gives the appearance of metathesis of the suffixal /p/ and the stem-final /k/.

Whatever the historical origin of Pengo metathesis, it became part of the grammar thanks to learners treating it as an active synchronic process. The constraint encoding the Pengo alternation must penalize a velar + labial sequence; call it *KP. In addition to MAX and DEP, it is especially relevant here to include the constraint IDENT to prevent changes to the features targeted by the phonotactic constraint.

(9)

/togba/	*KP	MAX	DEP	IDENT	LINEARITY
a. togba	*!				
b. toba		*!			
c. togiba			*!		
d. tomba				*!	
☞ e. tobga					*

Perceptual factors may contribute to such re-analyses. Placing the labial first in the cluster, at least in related Kui, puts it in the stressed syllable, which may enhance its perceptibility; the weak bursts of labial stops reduce the benefit of being located in the onset (Hume 1999: 296). Experimental evidence indicates that labial place is more perceptible in codas than is velar, and that velars benefit more in perceptibility from being in the onset than do labials (Winters 2001: 238–241). This means that the ordering PK is overall more likely to be heard correctly than KP. Emphasizing historical origin, however, Blevins and Garrett (2004: 136) consider the perceptually based prediction to be PK → KP, as attested in other languages such as Mokilese /apkas/ → [akpas] 'now', and claim that the Dravidian pattern favoring PK could arise only by such means as re-analysis of a morphological pattern.

Segments undergoing metathesis may originate in different morphemes, as in Pengo, but may also occur inside a single morpheme. Across a morpheme boundary, the offending cluster is created by concatenation; within a morpheme, the context for metathesis may be created directly by a syncope rule that brings the consonants into contact (as in Cebuano (6)), or a triggering context introduced by concatenation but affecting two consonants that are underlyingly adjacent (as in Faroese (3)).

1.1.3 *Manner of articulation*

Classes of consonants defined by manner, such as liquids or sonorants (see CHAPTER 13: THE STRICTURE FEATURES), are often targeted specifically by metathesis. (One might also include here the sibilants discussed in §1.1.1.) Metathesis involving the class of liquids is found in a number of languages (Blevins and Garrett 2004: 128f.); a historical example from Persian was cited in (1). In Rendille (Cushitic, Kenya), an /r/ and a preceding obstruent or nasal reverse in order after they become adjacent upon deletion of the intervening vowel (Sim 1981: 7, 9f.; Hume 1998: 178; Blevins and Garrett 2004: 129).

(10) *Rendille metathesis of /r/ in clusters* (Sim 1981: 7, 9)

feminine	*masculine*	
údur-te	úrd-e	's/he slept'
ágar-te	árg-e	's/he saw'
hámar-te	hárm-e	's/he shivered'

In the framework of Blevins and Garrett (2004: 121–125), this *perceptual metathesis* arises when the cues for a sequence of sounds are perceived by the listener as reordered relative to the speaker's intention, which is possible when some feature is realized over a relatively long duration and therefore contains ambiguity of analysis. This is true for consonant clusters as well as vowel–consonant sequences (see §1.2). Besides liquids (CHAPTER 30: THE REPRESENTATION OF RHOTICS; CHAPTER 31: LATERAL CONSONANTS), other segment types with elongated cues include pharyngeals (CHAPTER 25: PHARYNGEALS), secondary labialization (CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION), palatalization (CHAPTER 71: PALATALIZATION), and glottalization or aspiration (Blevins and Garrett 2004: 123). Hume (2004: 220–227) argues similarly that ambiguity or indeterminacy in the auditory signal sets the stage for a reinterpretation of linear order, but places a special emphasis on the role of the specific attested sequences in the language, as discussed for Hebrew above.

In Kambata (East Cushitic, Ethiopia), a suffix-initial nasal transposes with a preceding obstruent, and is also subject to place assimilation in this position, as illustrated by [ŋk] and [mb] resulting from an /n/-initial suffix (Hudson 1980: 105); similarly the related language Sidamo (Vennemann 1988: 55) and several other East Cushitic languages (Garrett and Blevins 2009: 532f.).

(11) *Kambata metathesis of obstruent + nasal clusters* (Hudson 1980: 105)

it-ne:mmi	→	inte:mmi	'we have eaten'
t'u:d-na:mmi	→	t'u:nda:mmi	'we will see'
oros-na:mmi	→	oronsa:mmi	'we will take'
sok-ne:mmi	→	soŋke:mmi	'we have sent'
hab-no:mmi	→	hambo:mmi	'we forgot'

This metathesis is part of a conspiracy (CHAPTER 70: CONSPIRACIES) of changes (including complete assimilation and vowel epenthesis) that avoid ill-formed consonant clusters, in this case obstruent + sonorant; see Hume (1999: 300–302) for a perceptual-optimization account. In a novel strategy that anticipates Optimality Theory, Hudson (1980: 109) proposes that affixation generates two outputs with alternate orderings of juxtaposed consonants (such as [itne:mmi], [inte:mmi]), where the choice between the outputs is made according to conditions on phonotactics. This technique would not, however, generalize to examples such as Faroese and Cebuano, in which the relevant consonants are not juxtaposed across a morpheme boundary.

The obstruent + nasal reversal in East Cushitic has been cited as an example of a metathesis that does not result from a conventional source such as a misperception of the ordering of the cues (Garrett and Blevins 2009: 532–537). Rather, it appears to reflect the pressure of other consonant interactions; I illustrate with the facts of Kambata, but follow the argument of Garrett and Blevins, who use data from related Bayso. In some clusters that occur at stem boundaries, we find regressive assimilation, as in /rn/ → [nn] and /mt/ → [nt]; but in others, there is apparent progressive assimilation to create a geminate, as in /bt/ → [bb].

(12) *Kambata assimilation in clusters* (Hudson 1980: 105)

a.	im-to:ʔi	→	into:ʔi	'she dug'
	ful-na:mmi	→	funna:mmi	'we will go out'
	kam-no:mmi	→	kanno:mmi	'we forbade'
	mar-ni	→	manni	'we, going'
b.	ub-to:ʔi	→	ubbo:ʔi	'she fell'
	dag-tonti	→	daggonti	'you knew'
	t'u:d-tenti	→	t'u:ddenti	'you have seen'
	oros-ta:nti	→	orossa:nti	'you will go'

If the learner seeks to generalize to a single process of regressive assimilation, then an intermediate step of metathesis is necessary to create the right outcome: /bt/ → tb → [bb]. Extending this to instances of obstruent + nasal, such as /bn/

→ nb → [mb], also has the effect of preserving the features of the root-final consonant and yielding a nasal + obstruent sequence of the sort that is common in other concatenations. Interestingly, whereas Kambata assimilation and metathesis apply to all places of articulation, in Bayso both are restricted to coronals, which reinforces the connection; this correlation is found across the East Cushitic languages (Garrett and Blevins 2009: 536f.). From the perspective of synchronic phonology, an unavoidable conclusion is that metathesis processes are available to the learner, whether the pattern results from a misperception of the phonetic signal or a generalization of an existing pattern.

1.2 CV metathesis

Ordering reversals of a consonant and vowel involve many of the same principles of explanation and analysis as CC reversals – for example, the historical reinterpretation of an ambiguous signal, and a synchronic constraint that dominates LINEARITY. From the examples in the literature, however, synchronic CV metathesis appears to be strongly associated with specific morphological contexts, and the reordering may be the main exponence of a grammatical category, something that is not typical of CC metathesis. But before considering such cases, we examine a few more strictly phonological examples.

1.2.1 *Phonological reorderings*

A well-known case that has been treated as metathesis is Cayuga (Iroquoian), in which a laryngeal consonant /h ˀ/ transposes with a preceding vowel when it occurs in an odd-numbered, non-final syllable (Foster 1982: 69f.; Blevins and Garrett 1998: 509–512). The necessary prosodic context can be analyzed as the weak branch of an iambic foot (Hayes 1995: 222f.; see also CHAPTER 44: THE IAMBIC–TROCHAIC LAW).

(13) *Cayuga laryngeal metathesis* (Foster 1982: 69f.)

kahwistaˀeks	→	kʰḁ'wisdˀaes	'it strikes, chimes'
koˀnikõhaˀ	→	gˀo̥'nikhwaˀ	'her mind'
akekahaˀ	→	a'gekhaaˀ	'my eye'
ahanohaeˀ	→	a'hanhwaeˀ	'he washed it'

To some degree, however, it is uncertain whether this process is truly a reversal of segment order or instead a spreading of features across the vowel, resulting in overlap rather than reordering (Foster 1982: 70). Somewhat similar metathesis of vowel + /h/ occurs in Cherokee when a stop consonant precedes the vowel; the result is that the laryngeal is realized as aspiration on the stop (Flemming 1996; Blevins and Garrett 1998: 520f.).

In the framework of Blevins and Garrett (1998: 509f., 2004: 121–125), Cayuga and Cherokee show the results of *perceptual metathesis*. Just as with the CC metathesis involving liquids and other segment types, the spread of laryngealization or devoicing through the vowel leads to the possibility of reinterpretation. Diachronic instances of the same phenomenon include liquid metathesis in Slavic, as in *orbota 'work' > Polish /robota/; and reordering of /r/ with schwa in Le Havre French, such as [bərbi] 'ewe' compared to standard [brəbi] (Blevins and Garrett

1998: 513, 16f.). The Slavic example is somewhat unusual, in that it involves an initial sequence undergoing metathesis; reordering is cross-linguistically disfavored for root-initial segments, since a disruption in that position interferes with effective word recognition more than metathesis of other segments (Hume and Mielke 2001).

A clearer example of synchronic CV metathesis is found in the Austronesian language Leti, discussed in detail by Hume (1998) and Blevins and Garrett (1998: 541–547). Alternating stem forms in Leti are phonologically conditioned according to the following context; in particular, morpheme-final VC reverses to CV to avoid an illicit consonant cluster within a phrase.

(14) *Leti* VC *metathesis* (Hume 1998: 153)

a.	ukar lavan	→	ukarlavan	'thumb, big toe'
b.	ukar ppalu	→	ukrappallu	'index finger'
	ukar muani	→	ukramwani	'middle finger'

There is, additionally, the same reversal in phrase-final position, so that 'finger' appears as [ukra]; here, rather than serving general phonotactics, the metathesized form appears to mark the word as phrase-final (Bonthuis 2001: 37f.).

Because metathesis in Leti affects all consonant types – compare /ulit/ → [ulti] 'skin', /mɛtam/ → [mɛtma] 'black' – it cannot be attributed to the elongated phonetic realization of a class such as laryngeals, and is not perceptual metathesis. Instead, Blevins and Garrett (1998: 539–547) identify it as *pseudo-metathesis*. By this they mean an alternation in ordering that did not arise historically as a direct reinterpretation of segment order. In the case of Leti, two main steps are posited, with evidence from other patterns within Leti and in related languages. First, an epenthetic vowel was inserted after final consonants, /ulit/ → [ulitə̟]. Although the inserted vowel was not a copy of the preceding vowel, it nevertheless would have been subject to co-articulatory effects of the more palatal or labial quality of a preceding /i/ or /u/, as in [ulitə̟]. Second, syncope of medial vowels led to loss of that schwa preceding another word beginning CV ([ulitə̟] → [ulit]), but loss of the original medial vowel in other contexts ([ulitə̟] > [ultə̟]); here, however, the vowel quality of the deleted vowel is preserved in the final schwa due to the co-articulation ([ultə̟] > [ulti]). Words containing the low vowel, such as /ukar/, do not show palatal or labial co-articulation, but result from the fact that schwa more generally became /a/ in the history of Leti (thus /ukarə/ > /ukrə/ > /ukra/). From the point of view of synchronic phonology, the crucial point is that alternations such as [ulit] ~ [ulti] were successfully integrated into the grammar as learners re-analyzed the historical patterns.

1.2.2 *Morphological context*

As noted above, CV metathesis often appears to occur in the presence of a particular morphological trigger, even if the reordering that occurs can be defined phonologically. A famous example, also from Austronesian, is found in Rotuman. In this language, words appear in two different "phases," called complete and incomplete (Churchward 1940). The incomplete form is derived from the complete by a variety of means, but the default strategy is metathesis of the final CV to VC, often forming a short diphthong with the preceding vowel.

(15) *Metathesis in Rotuman phase alternations* (Churchward 1940: 14)

complete	*incomplete*	
ho.sa	hoas	'flower'
i.ʔa	iaʔ	'fish'
pu.re	puer	'to rule, decide'
ti.ko	tiok	'flesh'
se.se.va	se.seav	'erroneous'

The process applies to loanwords as well, such as /pe.pa/ → [peap] 'paper'. Consistent with many other languages, Rotuman short diphthongs must consist of two vowels with rising sonority (i.e. movement from a higher to a lower vowel). Where this condition is not met, the incomplete phase is realized in other ways: by dropping a final vowel, as in /to.ki.ri/ → [to.kir] 'to roll'; by fusing two vowels brought together by metathesis, as in /mo.se/ → [møs] 'to sleep'; or by directly changing a vowel sequence to a long diphthong, as in /ke.u/ → [keu] 'to push'.

Blevins and Garrett (1998: 527–529) categorize the Rotuman alternation as *compensatory metathesis*. Historically, this entails an anticipation or perseveration of vowel features across an intervening consonant toward the stressed vowel, leading to "extreme vowel-to-vowel coarticulation." In Rotuman there would have been anticipation of the final vowel in the direction of the preceding stressed syllable, followed by loss of the final vowel, essentially /hosa/ > /hoasa/ > /hoas/. In some vowel sequences, further changes occurred, such as /mose/ > /moese/ > /moes/ > /møs/. Metathesis of similar origin is also pervasive in the related language Kwara'ae, where final CV changes in most communicative contexts to VC to mark phrasal boundaries (Sohn 1980: 311f.); the details of Kwara'ae vowel realization lend particular support to the proposed historical origin as compensatory metathesis (Blevins and Garrett 1998: 530f.).

The phases of Rotuman were originally described by Churchward in complex syntactic and semantic terms, but some recent work has argued that their specific realization depends on prosody, and therefore that they are basically phonologically determined rather than triggered by a morphological or other grammatical context (Hale and Kissock 1998: 120–123). For example, it has been proposed that the desired outcome achieved by metathesis as well as the other processes is a word-final heavy syllable (Blevins and Garrett 1998: 531–534; McCarthy 2000: 159, 73f.). From this point of view, the reversal in order is just one way of satisfying the heavy-syllable constraint; there is no specific rule demanding metathesis. This analysis relies on the claim of Hale and Kissock (1998) that the complete phase occurs before monomoraic morphemes such as /-me/ 'hither' in [hoʔa-me] 'to bring', and the incomplete before bimoraic morphemes such as transitive /-kia/ in [hoaʔ-kia] 'to take (TRANS)'. The essential idea is that right-aligned prosodic structure in [ho(ʔa-me)] requires the stem-final CV syllable to be grouped with the CV suffix in a proper bimoraic foot, and the pressure for a stem-final heavy syllable is thwarted. But in [(hoaʔ)-(kia)], the stem and the suffix are footed independently, and the stem undergoes metathesis to ensure a stem-final heavy syllable. The same result is predicted in the absence of a suffix.

Kurisu (2001: 187) cites, in addition to certain exceptional suffixes, minimal pairs from Churchward (1940: 15) showing that the two phases can occur in an identical phonological context, such as complete [ʔepa la hoaʔ] 'the mats will be taken' and incomplete [ʔeap la hoaʔ] 'some mats will be taken'. This overlap indicates that the phase changes must in some way be triggered by the presence of a morphosyntactic category, the Incomplete Phase. For Kurisu, the high-ranked constraint REALIZEMORPHEME forces the incomplete to be phonologically distinct from the complete phase (CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE); the relative ranking of phonological constraints, including LINEARITY, determines exactly how the base form is modified. The metathesis outcome is favored by the constraint ranking, although particular configurations (such as vowel sequences with falling sonority) lead to other outcomes, including fusion of the vowel features. Notably, in this more morphologically oriented approach, there is still no specific morphological demand for metathesis; rather, the drive for distinctness of word forms interacts with phonological constraints to produce metathesis, among other results.

The examples presented so far involve underlying CV changing to VC, especially stem-finally. The converse change at the left edge, where initial VC changes to CV, is attested in some Northern Paman languages such as Ngkot̪, following the historical loss of initial consonants (Hale 1976: 17f., 23–28; Blevins and Garrett 1998: 537f., 2004: 135f.).

(16) *Ngkot̪ initial VC metathesis* (Hale 1976: 23–28)

*nʲipul-	>	*ipul-	>	pjul-	'you (NON-SG)'
*nˡiːna-	>	*ina-	>	n̪ja-	'to sit'
*kulan-	>	*ulan-	>	lwan-	'possum'
*puŋa-	>	*uŋa-	>	ŋwa-	'son'
*ŋali-	>	*ali-	>	laj-	'we (DUAL INCL)'
*kami-	>	*ami-	>	maj-	'mother's mother'

Unlike in Rotuman and a number of other Austronesian languages, however, this metathesis appears to be diachronic only.

A somewhat similar pattern is found synchronically for a number of verbs in the Nilo-Saharan language Fur (Jakobi 1990: 57f., 64–74; Hume and Mielke 2001: 141f.). These verbs, when preceded by a monoconsonantal person-marking prefix, undergo reversal of the initial CV.

(17) *Fur CV metathesis under prefixation* (Jakobi 1990: 57f., 64–74)

k-ba-	→	kab-	'we drink'
k-teer-	→	keter-	'we forge'
k-lat-	→	kald-	'we beat, hit'

Some alternations are quite irregular, such as /li-/ → [al-] 'wash' and /tii-/ → [ei-] 'catch', so that a plausible alternative is that the allomorphs are lexically listed. This account would also address the formal problems in alternations such as /bul-/ → [ulb-] (→ [ulm-]) 'find', which involve two apparent metatheses (Hume 2001: 18f.); see §2.3 below. Even if the allomorphs are listed, however, metathesis was a crucial historical source.

1.2.3 *Metathesis in templates*

Languages with *templatic morphology* express certain inflectional or derivational categories by changes to the syllable structure of the stem (see CHAPTER 105: TIER SEGREGATION; CHAPTER 108: SEMITIC TEMPLATES). If a particular paradigm includes different orderings of C and V elements, then the result is a form of metathesis. Templatically created metathesis generally does not derive from general phonological properties of a language, but rather from potentially arbitrary exponence of a morphological category. For example, a relatively productive metathesis applies to derived Classical Arabic nominal stems two syllables in length; initial /Ca/ is reversed to [aC] and a glottal stop onset is inserted (McCarthy and Prince 1990: 213f., 279f.). Examples include /kabar/ → [ʔakbar] 'greater, greatest' and /dʒanib-at/ → [ʔadʒnib-at] 'wings'; compare the underived forms [kabiːr] 'great' and [dʒanaːb-at] 'wing', without metathesis. The change cannot be treated as a general phonological process, because it is limited to certain morphological categories, and does not occur in verbs such as /katab/ 'he wrote' (*[ʔaktab]).

In Mutsun, a Costanoan language of northern California, templatic alternations include the reversal of a stem-final sequence of vowel and consonant; the primary stem is consonant-final and the derived stem is vowel-final (Okrand 1979: 126f.). The choice between alternate verb stem forms depends on what suffix is added; in other cases (18b) the primary stem is a noun, and the derived stem is a verb with related meaning. The derived stem has the uniform shape CVCCV, despite considerable variation in the primary stem shape.

(18) *Mutsun stem alternations* (Okrand 1979: 126f.)

	primary	*derived*	
a.	pasik-	paski-	'to visit'
	litʃːej-	litʃʼje-	'to stand'
	matːal-	matla-	'to be face down'
b.	lulːup-	lulpu-	'flute / to play the flute'
	toːher-	tohre-	'a cough / to cough'
	laːlak-	lalka-	'goose / to get geese'
	posoːl-	poslo-	'posole (stew) / to make posole'

Okrand observes that while the vowel-final derived stem is the form used with all suffixes that would create an illicit consonant cluster if added to the primary stem ([litʃʼje-hte] 'standing', *[litʃːej-hte]), it also occurs with some suffixes that would be phonotactically well-formed with a preceding consonant ([matla-nu] 'put (someone) face down', alongside [mattal-pu] 'put oneself face down'). Therefore, this morphologically defined reordering does not merely repair phonological violations, even if it sometimes conspires to avoid phonotactically problematic concatenations. It has been pointed out that for similar alternations in related Sierra Miwok, a representation with V/C segregation makes a specific metathesis rule unnecessary (Smith 1985: 366f.; Goldsmith 1990: 91; Stonham 1994: 157f.); more on this below.

In Tunisian Arabic, a stem-internal alternation is a cleaner example of metathesis than what we find in Classical Arabic (Kilani-Schoch and Dressler 1986; Becker 2000: 579f.). Historical changes to vowels within stems have led to minimal differences defined by ordering, such as Classical Arabic /malak-a, milk-u/ > Tunisian /mlək, məlk/; this pattern is now productive in relating triliteral surface forms.

(19) *Tunisian Arabic stem alternations* (Kilani-Schoch and Dressler 1986: 62, 65f.)

mlək	'he possessed'	məlk	'property'
fhəm	'he understood'	fəhm	'understanding'
ħrəm	'he forbade'	ħarm	'prohibition'
kfɔr	'he blasphemed'	kɔfr	'blasphemy'

A similar alternation is found in Alsea (Buckley 2007). In this coastal Oregon language, stems generally show at least two forms; the full stem contains a root vowel, while the short stem lacks it. For stems with a medial sonorant consonant, an additional distinction is found: the full stem occurs in two varieties, light and heavy, according to whether the root vowel follows or precedes the sonorant. The stem choice depends on the presence of particular suffixes as well as an aspectual distinction.

(20) *Alsea stems with a medial sonorant* (Buckley 2007: 8f.)

light (CV)	*heavy* (VC)	*short* (no V)	
stlak-	stalk-	stlk-	'slide'
twih-	tiwh-	twh-	'pour'
tmus-	tums-	tms-	'close'

In the analysis of Buckley (2007: 15–18), the light stem is the underlying form; the short stem is created by deletion of the root vowel, and the heavy stem results from VC metathesis. Since only sonorants undergo this potential reordering, they alone are treated as weight-bearing in the coda, and therefore only in that case can metathesis yield satisfaction of the heavy template requirement. The same approach might be applied to Tunisian Arabic, with the difference that all consonant classes are moraic, and therefore metathesis applies to stems regardless of the medial consonant. The larger point is that the requirement for a heavy syllable is morphologically determined, but the effect is generated phonologically.

Similar is the stem alternation found in Klallam and other Straits Salish languages, in two forms called the actual and non-actual aspect (Thompson and Thompson 1969: 215–217; Demers 1974: 17f.; Montler 1989: 96f.).

(21) *Klallam stem alternations* (Thompson and Thompson 1969: 216)

non-actual	*actual*	
ʧ'kʷu-	ṭ'ukʷ-	'shoot'
ɬq'i-	qiq'-	'restrain'
ɹ̣q'ɔ-	ɹ̣ɔq'-	'swallow'
mtəqʷ-	mətqʷ-	'put in water'

Anderson (2005: 9–11) argues that synchronically, Klallam and similar languages require a processual rule of metathesis to express this morphological category. Montler (1989: 93), however, expresses this effect for Saanich as a CVCC template that causes metathesis in a form such as /ˈsχət/ 'push it' → [ˈsəχt] 'pushing it'. In roots where the CVCC template cannot be satisfied by metathesis, other strategies are available, such as glottal stop insertion after the vowel in /ˈweqəs/ 'yawn' → [ˈweˀqəs] or reduplication to achieve this templatic result, as in /ˈqen'/ 'steal' → [ˈqeqn'] (→ [ˈqeqən'] by epenthesis). The same additional strategies occur in Klallam as well. In a prosodic version of the template approach, Stonham (1994: 173f.) proposes insertion of a mora in Klallam and Saanich that forces CCV to surface as CVC, a heavy syllable, and also causes the related effects of coda insertion and reduplication. The templatic and moraic approaches treat metathesis as one possible means of satisfying the morphologically determined, but phonologically expressed, restriction on shape. As with Rotuman, metathesis is one change among several, and not necessarily the direct goal of the morphological category.

In a more strictly phonological approach for closely related Lummi, Demers (1974: 16) proposes a rule that deletes unstressed schwa between obstruents. In this view, the actual and non-actual forms are both based on a CəCə root, but have different stress placement. Schwa deletion yields apparent metathesis in pairs with the surface shapes seen in/ˈCəCə/ → [ˈCəC] and /CəˈCə/ → [ˈCCə]. Although the synchronic evidence for exactly this derivation is missing in Klallam, the Lummi pattern suggests the likely diachronic origin of metathesis as a reinterpretation of vowel deletion. Such a historical origin can explain why these templatic changes normally involve reorderings of consonants and vowels, but not of consonants. For example, suppose that (similar to Lummi) the Alsea stem 'to close' that alternates between [tmus] and [tums] derives from original *tumus, with deletion of the unstressed vowel in forms with distinct stress patterns due to different suffixation: *ˈtumus-a > /ˈtums-a/ 'door' and *tuˈmus-χ > /ˈtmus-χ/ 'is closed' (Buckley 2007: 22f.). The alternate forms that preserve different vowels are subject to reinterpretation as a stem with a single underlying vowel that is reordered with the adjacent consonant in different suffixal contexts; but vowel deletion by itself will not result in the reordering of consonants. Given the frequency of vowel harmony and syncope, patterns like this can be expected to arise rather often.

Despite the crucial role of morphological context in conditioning these reorderings, phonological techniques can often be used to generate the necessary effects. One important tool has been the segregation of vowels and consonants onto different tiers (see CHAPTER 105: TIER SEGREGATION), so that they have no underlying ordering and no actual metathesis occurs in the derivation (McCarthy 1989: 5, 22f.). The advent of Optimality Theory, with its emphasis on output constraints rather than restricted input representations, makes V/C segregation "superfluous" (McCarthy 2000: 180f.). Even in an approach that does not treat the consonantal root as a morpheme listed independent of any vowels, derivational and inflectional morphemes often consist of vowels that overwrite the underlying vowels of the stem (Ussishkin 2005). Apparent VC metathesis among surface forms is merely the result of different overwriting patterns, as when the elements /h i i/ are imposed on Modern Hebrew /gadal/ 'grow' to form [h-igdil] 'enlarge'. Constraints on the realization of affixal material in the stem lead to particular overwriting patterns, but the vowels of the affixes still have no underlying ordering relation to the consonants of the input word.

It is less clear how a vowel-overwriting approach for Semitic can extend to language families such as Miwok-Costanoan and Yokuts, where the vowels and consonants can be reordered, but the vowels do not have the status of separate morphemes (McCarthy 1989: 74, 78). Thus in Mutsun, the verb 'to visit' is lexically specified with not only the consonants /psk/ but also the vowels /ai/, combined in different ways, including [paski-] and [pasik-] (18). The overwriting operation would have to be available for subparts of one lexical entry, rather than independent morphemes, in order to account for languages like Mutsun.

1.3 VV metathesis

Although CV and CC metathesis are robustly attested, there is weak evidence for VV metathesis. Webb (1974: 8) states that "[e]ven as a sporadic change metathesis of vowels appears to be quite uncommon." Kiparsky and O'Neil (1976: 531, n. 7) believe "there are few if any rules that metathesize contiguous syllabic segments in any language." McCarthy (2000: 176) observes that the few synchronic analyses that posit VV reversals "involve very abstract analyses, in which the underlying representations and/or the consequences of metathesis are by no means apparent." The rarity of such reversals may be related to the much longer typical duration of vowel gestures compared to consonants, so that a considerable temporal shift would be required for re-analysis of the ordering of two vowels (Steriade 1990: 390f.; McCarthy 2000: 176).

A classic example is VV reversal in Kasem, to which Chomsky and Halle (1968: 361) first applied the transformational rule format for metathesis. In particular, the vowel sequence /ia/ is reversed to [ai] when followed by the plural suffix /i/; but the first /i/ deletes and then the remaining vowels coalesce, as in /pia-i/, which surfaces as [pe] 'sheep (PL)'. Needless to say, on first inspection /piai/ → [pe] is not an obvious example of metathesis. Phelps (1975: 303f., 10f., 25, 1979: 56f.) argues against the Chomsky and Halle VV metathesis rule, but in favor of an entirely different CV metathesis, in derivations such as /boa:l-u/ → [bola:-u] (→ [bolo] 'valley'). This derivation is again complex, although with different assumptions about underlying forms. Both of Phelps's general conclusions regarding Kasem metathesis – CV is transposed but not VV – are endorsed, in a more modern framework, by Haas (1988: 241–253, 45f.); see also Burton (1989: 29f.) for an analysis of vowel coalescence without an intermediate reordering.

Similar re-analyses have been proposed for other languages with apparent VV metathesis. Keyser (1975: 404) posits a rule for Old English that reverses vowels in order to feed a vowel elision rule, as in /lufa-i/ → lufia → [lufa] 'love!'; Kiparsky and O'Neil (1976: 535f.) argue that a revised formulation of vowel elision makes metathesis unnecessary. A rule of VV metathesis has been claimed to play "a central role" in Latvian phonology; it reverses the order of elements in the diphthongs /ai au æi æu/, although under restricted conditions (Halle and Zeps 1966: 108). In a more recent treatment of Latvian vowels, although not focusing on metathesis, Anderson and Durand (1988: 34, n. 7) reject some of the synchronic abstractness assumed by Halle and Zeps; instead they assume raising of a monophthongal vowel that then undergoes breaking to form a diphthong, where no metathesis is required.

A few diachronic examples of VV metathesis can be cited, especially if we include vowel/glide reversals in this category, since the same set of segmental features may serve as a glide or vowel before and after the metathesis (Ultan 1978: 375f.). Two examples from Portuguese are /genukulum/ > /geoʎo/ > /ʒoeʎo/ 'knee' and /dehonestaːre/ > /deostar/ > /doestar/ 'to insult' (Williams 1962: 111); these reversals may have occurred "on the analogy of the more familiar sequence *oe*" (Ultan 1978: 376).

1.4 Other types of metathesis

Permutations involving something larger than a segment may fall under broader definitions of metathesis (Ultan 1978: 370). These include syllable reversals in language games or *ludlings*, such as Chasu /i.ku.mi/ → [i.mi.ku] 'ten' (Bagemihl 1995: 704). Metathesis has also been proposed for elements such as *location* in sign language phonology (Sandler 1993: 246).

Hyman and Leben (2000: 590) state that there are "sporadic reports of tonal metathesis in the literature"; some examples include Bamileke-Dschang (Pulleyblank 1986: 41, 50), Mixtec (Goldsmith 1990: 25), and Dangme (Holscher *et al.* 1992: 126). These processes typically involve the movement of a floating tone, originating at the edge of a word or other domain, past a single linked tone. But – like VV metathesis in §1.3 – they are also embedded in complex derivations, and depend on multiple assumptions about how the pieces of the analysis fit together. Under other assumptions, metathesis may not be required. For example, Pulleyblank (1986: 41) proposes that in Bamileke-Dschang a floating L tone moves leftward across a H, and remains floating to represent downstep; Hyman (1985: 71, 73), on the other hand, links the L directly to the H on a second tonal tier as a direct representation of a downstepped H. In essence, the new rule is a merger rather than a reordering, similar to Zoque palatalization in §3 below.

It should be kept in mind that "metathesis" of syllabicity, as in French /oj/ > /wɛ/ > modern /wa/ and Proto-Slavic *ew > /ju/ (Ultan 1978: 376), does not involve transposition of segmental features but rather a shift in affiliation relative to the head of the syllable. Thus in French /oj/ > /wɛ/, the round vocoid continues to precede the front vocoid; in Slavic *ew > /ju/, the round element is second, but remains there. The same observation can be made for English /iw/ > /ju/, found in words such as *few* (Jespersen 1949: 101), which is quite similar to the Proto-Slavic change. None of these represents segmental metathesis.

2 Non-local effects

Often grouped with local metathesis is the exchange of segments that are not adjacent, called *long-distance* or *non-contiguous* metathesis (Ultan 1978: 380–383). In fact, *metathesis* or its equivalent in another language has been used, especially by earlier writers, specifically for such long-distance effects (Blevins and Garrett 1998: 525). Grammont (1933: 239ff., 339ff.) devotes separate chapters to long-distance *métathèse* and local *interversion*, a terminology found more recently, for example, in Pierret (1994: 61); but Wechssler (1900: 496) already uses *Metathese* for both local and long-distance transpositions. As noted at the beginning of this chapter, metathesis here refers to either type of reordering.

2.1 *Diachronic*

A famous diachronic example of transposition over intervening segments is the Spanish metathesis of *r . . . l* > *l . . . r*, observable in a few modern words (Ultan 1978: 381; Penny 2002: 36).

(22) *Spanish liquid metathesis* (Penny 2002: 36)

Latin		*Spanish*	
mi:ra:kulum	>	milagro	'miracle'
peri:kulum	>	peligro	'danger'
parabola	>	palabra	'word'

These pronunciations were probably influenced by the greater frequency of consonant + *r* in the lexicon; various sound changes had eliminated many inherited instances of consonant + *l* (Ultan 1978: 391; Penny 2002: 70–72); the change can also be viewed as two steps, first the change of /l/ to /r/ in a cluster, and then the well-attested dissimilation of identical liquids (Wanner 1989: 444f.).

Comparison of cognate words in the Yuman family of the American Southwest reveals a variety of historical metathesis processes, including root consonants in Walapai /'pil/ 'burns' ~ Cocopa /'lip/ 'flames up', or Havasupai /ka'to/ ~ Walapai /ta'ko/ 'chin' (Langdon 1976). There are also variant forms within languages, such as Ipai Diegueño /maxa'tun/ ~ /xama'tun/ 'knee'. These alternations are widespread, but remain lexically specific. Swapping of the consonants in largely CVC roots is also common in the Salish family, as seen in apparent cognate pairs such as Shuswap /xʷej/ ~ Twana /jəxʷ/ 'disappear', and Klallam /ts'əq'ʷ/ ~ Upper Chehalis /q'ʷəts'/ 'dirty' (Noonan 1997: 482). The pervasiveness of this pattern in Salish is unusual, and is possibly best explained by historical processes of reduplication and consonant deletion rather than direct metathesis (Hume and Mielke 2001: 143, n. 4; Noonan 1997: 513).

Prunet (2006: 57–61) discusses examples of consonant metathesis within Semitic roots. These are said to be particularly common in the Hebrew lexicon, as in synonymous variants such as [keveś] ~ [keśev] 'lamb' and related meanings such as [ʔa:raz] 'tie packages' ~ [ʔa:zar] 'bind, girdle' (Horowitz 1960: 228–234). More dramatic examples of non-contiguous consonant metatheses are found in language games in Bedouin Hijazi and Moroccan Arabic, in which the root consonants are scrambled (Prunet *et al.* 2000: 623f.); in Hijazi, /kattab/ 'caused to write' can be realized as [battak], [takkab], [kabbat], [tabbak], and [bakkat]. Although this radical permutation is not part of the basic grammar, such language games show an impressive computational capacity for synchronically active metathesis (Bagemihl 1995: 703f.; Anderson 2005: 11f.).

2.2 *Synchronic*

Typological surveys have claimed that permutation of non-adjacent segments does not occur as a regular synchronic process (Webb 1974: 5; Wanner 1989: 445; Hume and Mielke 2001: 145f.). Certainly, the permutation of non-adjacent segments is common in speech errors, such as classic Spoonerisms, but such errors also involve strings of segments such as complex onsets and rhymes (Fromkin 1971: 31f.).

(23) *Metathesis in speech errors* (Fromkin 1971: 31f.)

intended		*error*	
kip ə teɪp	→	tip ə keɪp	'keep a tape'
fɑr mɔr	→	mɑr fɔr	'far more'
peɪ skeɪl	→	skeɪ peɪl	'pay scale'
swɛrə drajɪŋ	→	drɛrə swajɪŋ	'sweater drying'
hip ɔv ʤʌŋk	→	hʌŋk ɔv ʤip	'heap of junk'

These form part of a larger phenomenon of anticipation, perseveration, deletion, and so forth. Speech errors may, however, be a source of sporadic metathesis in historical change (Wanner 1989: 445). The outputs of speech errors, like more systematic metathesis, overwhelmingly respect the existing phonotactics of the language (Wells 1951: 26; Fromkin 1971: 40–42; Dell 1995: 200); but transposition of adjacent consonants, so common in regular metathesis, is "exceptionally rare" as a speech error, such as *whipser* for *whisper* (Berg 1987: 9). Elements that transpose by error usually occupy parallel syllable positions, which is not the case for adjacent consonants; instead, as discussed above, metathesis of such segments normally arises historically by misperception rather than production or planning errors.

An interesting comparison is an optional metathesis reported for a few words in Turkana (Dimmendaal 1983: 48f.; Hume and Mielke 2001: 139f.; Hume 2004: 218). Here two consonants with the same value of [sonorant] that serve as onsets to successive syllables, and are adjacent to identical vowels, are optionally transposed in fast speech.

(24) *Turkana onset metathesis* (Dimmendaal 1983: 48f.)

preferred	*alternate*	
ŋa-kɛ̀mɛ̀r-a	ŋa-kɛ̀rɛ̀m-a	'mole'
ŋi-kwaŋɔ̀rɔmɔk-à	ŋi-kwaŋɔ̀mɔrɔk-à	'a kind of tree'
ɛ-sɪkɪn-aˋ	ɛ-kɪsɪn-aˋ	'breast'

These alternations have the appearance of a common speech error that has become somewhat conventionalized. In particular, it has been widely observed that exchange (and other) errors are more likely when the sounds in question are found in similar phonological environments, so that for example *left hemisphere* → *heft lemisphere*, where the initial consonants are both followed by /ɛ/, is more likely than the parallel error in *right hemisphere*, where the vowels are different (MacKay 1970: 325–328; Dell 1984: 222).

Morphologically restricted metathesis (§1.2.2) can apply synchronically to surface non-adjacent segments. For example, Akkadian has a /t/ infixed in reciprocal verbs; it surfaces there in most cases, exemplified by [pitrus-] (25a), which motivates the stem-internal position as basic. But this stop is transposed to word-initial position when the root has an initial coronal obstruent as in (25b) (Caldwell *et al.* 1977: 118; McCarthy 1981: 381; Buccellati 1996: 233f.; Huehnergard 2005: 390, 531, 611).

(25) *Akkadian long-distance metathesis* (Caldwell *et al.* 1977; Huehnergard 2005)

	root	*infinitive*	*reciprocal*		
a.	/prs/	paraːs-	pitrus-		'divide'
	/rkb/	rakaːb-	ritkub-		'mount, ride'
	/kmr/	kamaːr-	kitmur-		'heap up'
b.	/sˤbt/	sˤabaːt-	tisˤbut-	*sˤitbut-	'seize'
	/snq/	sanaːq-	tisnuq-	*sitnuq-	'be near'
	/zkr/	zakaːr-	tizkur-	*zitkur-	'declare'
	/dkʃ/	dakaːʃ-	tidkuʃ-	*ditkuʃ-	'swell'

The same metathesis occurs in iterative stems: [pitarrus-] but [tisˤabbut-] (*[sˤitabbut-]). In the analysis of Łubowicz (2009), Akkadian metathesis serves to move the /t/ outside the stem domain, where it would cause a violation of the Obligatory Contour Principle (OCP) penalizing two tier-adjacent coronal consonants; thus [tizkur] does not violate this constraint, whereas *[zitkur] would, because the /t/ is located within the stem. This approach gives a relatively prominent role to phonology (the OCP constraint on coronals) while maintaining a crucial morphological component, due to the role of the stem domain.

2.3 *Displacement*

A related phenomenon, which is also called metathesis by many authors (Grammont 1933: 339; Ultan 1978: 372), involves the shift or *displacement* of a segment over more than one intervening segment. A famous example comes from the Occitan dialect of Bagnères-de-Luchon in southwestern France (Grammont 1905–6: 74, 85, 1933: 341; Blevins and Garrett 1998: 526). Among other processes, a liquid following a stop shifts leftward to form a cluster in the preceding syllable.

(26) *Bagnères-de-Luchon long-distance shift of liquids* (Grammont 1905–6: 74, 85, 1933: 341)

*ˈkabra	>	ˈkrabo	'goat'
*ˈbespras	>	ˈbrespes	'vespers'
*ˈpawpro	>	ˈprawbe	'poor'
*ˈtendro	>	ˈtrende	'tender'
*ˈkambra	>	ˈkrambo	'room'
*kumˈpra	>	krumˈpa	'to buy'
*eˈspingla	>	eˈsplingo	'pin'

A shift like this is formally identical to metathesis when just one segment is skipped. However, with intervening material that includes non-constituent strings such as /esp/, it must be movement of /r/ rather than exchange. A similar shift of /r/ to the initial syllable is attested in South Italian Greek (Rohlfs 1930; Blevins and Garrett 2004: 130f., 34f.).

If it is to be classified with long-distance metathesis, displacement might be expected to be absent from synchronic grammars. But synchronically active long-distance displacement is attested at least for laryngeal and pharyngeal features (Blevins and Garrett 2004: 132–134; see also CHAPTER 25: PHARYNGEALS). For example, in the Interior Salish language Colville (Nxilxcín), the pharyngeal consonant of a root is displaced to a stressed suffix, where it lowers the adjacent vowel to [a] (Mattina 1979).

(27) *Colville pharyngeal displacement* (Mattina 1979: 17f.)

ˈq’ʷˤaj	→	ˈq’ʷˤaj	‘black’
ˈq’ʷˤaj-ˈ**us**	→	q’ʷəjˈˤas	‘black man’
ˈq’ʷˤaj-ˈ**lstˣu**t	→	q’ʷəjlstˣˈˤat	‘his clothes are dirty’

Both pharyngealization and laryngealization can be seen as suprasegmental features in Salish (Mattina 1979: 19f.). Displacement of these features appears to reflect the spread of features over multiple syllables that may then be localized to a salient position (Blevins and Garrett 2004: 122f.). Such displacement resembles the *mobility* of a tone that shifts from the morpheme with which it is underlyingly affiliated to some phonologically defined position such as the penultimate syllable (Yip 2002: 65f., 89f., 132). A reasonable synchronic analysis is a [pharyngeal] feature affiliated with the root, which is attracted to the stressed syllable and possibly realized there as a segment. By the same token, the displacement of /r/ to the initial syllable in South Italian Greek reflects the salience and perceptual prominence of such syllables due to their location in the word (Blevins and Garrett 2004: 134); in Luchonnais, both stress and initial position favor the first syllable.

Patterns of this sort have similar historical origins to simple exchanges of segments – in particular, phonetic cues that are relatively long in the temporal dimension and therefore subject to re-analysis, as discussed above for perceptual metathesis. But since they are displacements rather than exchanges, they are not formally equivalent to true metathesis as the exchange of positions. In particular, if local metathesis is seen as a minimal displacement (across a single segment), then long-distance metathesis would have to involve two simultaneous displacements, one leftward and one rightward, as in /abXcdYef/ → [abYcdXef]. This extra formal complexity may account for the rarity of synchronic non-local metathesis, which seems to be restricted to limited examples such as the optional reversal in Turkana (24) and the morphologically defined environment in Akkadian (25).

An ordering alternation in the form of two suffixes is reported for several Costanoan languages, including Mutsun (Okrand 1979; Hume 1998: 170f., 1999: 300f., 2004: 223f.). Both suffixes have the shape CCV after a vowel-final stem, and CVC after a consonant-final stem, which makes phonotactic sense insofar as a three-consonant cluster at the stem boundary would be ill-formed.

(28) *Mutsun suffix alternations* (Okrand 1979: 127f., n. 17)

CCV		CVC	
pire-tka	‘on the ground’	ʔurkan-tak	‘in the mortar’
rukka-kma	‘houses’	wimmah-mak	‘wings’

Although the locative [tka] ~ [tak] can be treated as local metathesis, in the plural [kma] ~ [mak], the [k] appears to move across two other segments. If Linearity is gradiently violable, with one violation for each segment over which another is displaced, the minimal change (one ordering reversal) is generally optimal (Hume 1998: 168–171, 2001: 17–19). Gradient violation does still permit Mutsun /mak/ → [kma] when other constraints force multiple violations of

LINEARITY, and the alternation can be seen as part of the synchronic grammar; but such cases seem to be quite rare and limited in scope. In the more recent version of OT that incorporates candidate chains (OT-CC), changes to the representation occur by minimal steps, and non-contiguous metathesis is subject to the requirement that each change in linear order increase well-formedness (McCarthy 2007: 87f.). In a suffix alternation requiring the synchronic derivation /mak/ → mka → [kma], the first step might be motivated by a preference for sonorant codas, but that change does not appear to be motivated more generally in Mutsun; in fact, Hume (1998: 170f.) specifically gives the constraint *m]$_{coda}$. It might therefore be that the architecture of OT-CC forces the Mutsun alternation to be treated as listed allomorphy (CHAPTER 99: PHONOLOGICALLY CONDITIONED ALLOMORPH SELECTION).

3 Related processes

In some cases, a pattern that was originally considered to be metathesis was later seen as non-metathesis – and occasionally vice versa. A good example is the Zoque 3rd person singular prefix /j-/, which never surfaces as a strict prefix, but has been described as permuting with the stem-initial consonant, as in /j-pata/ → [pʲata] 'his mat' (Wonderly 1951: 117f.; Dell 1973: 110). Sagey (1986: 105–111) argues that the glide /j/ actually merges featurally with the following consonant to produce a palatalized segment (CHAPTER 71: PALATALIZATION), which may be realized with an offglide, as implied by transcriptions such as [pʲ]. This position is supported by the independent need for a non-metathesis source of palatalized segments found at compound boundaries; cases such as /kuj-tʌm/ → [kujtʲʌm] 'avocado' show that the glide spreads, rather than reversing in order. A similar pattern is found in several languages of Nigeria and Cameroon. Prefixes that can be reconstructed as the high vowels *i and *u are realized as a glide – or a secondary articulation on the consonant – after the stem-initial consonant, as in Noni /k-w-en/ 'firewood' from the base /ken/ (Blevins and Garrett 1998: 514–516). See also the cases in Webb (1974: 12f.).

Another phenomenon that has a certain affinity to metathesis is *infixation*, since it likewise requires a reordering from the expected position. In particular, "infixation and metathesis commonly show the potential mobility of full segments" rather than just subsegments such as features or nodes (Zoll 2001: 51). The closest analogy can be found in the infixation of a single consonant across one other consonant, as in the active neutral infix /-m-/ of Atayal /t-m-apeh/ 'beckon' (Egerod 1965: 265f.); this is formally similar to the metathesis of adjacent consonants. But infixation encompasses a broader set of phenomena that can include multiple segments in the item that undergoes reordering, as well as multiple segments in the span over which the infix is displaced; both are illustrated by the Tagalog actor focus /-um-/ that (optionally) moves over complex onsets in borrowed words such as /gr-um-adwet/ ~ /g-um-radwet/ 'graduate' (Orgun and Sprouse 1999: 204). On the other hand, Halle (2001) argues that the apparent Tagalog infixes appearing as /-um-/ and /-in-/ are actually CV underlyingly, with non-local metathesis of the two leftmost onsets, as /mu-tawag/ → [tu-mawag]. Theoretical and empirical problems with this approach are discussed by Klein (2005: 989–991), who advocates an infixation analysis within Optimality Theory.

Another phenomenon that might be seen as involving either metathesis or infixation (or even other possibilities) is *imbrication* in Bantu languages such as Cibemba (Hyman 1995). In this process, the perfective suffix /-il/ combines with a polysyllabic stem, such that the /l/ of the suffix disappears and the /i/ combines with the rightmost vowel in the stem according to the usual coalescence rules of the language, as in /sákat-il-e/ → [sákeete] 'seize'. The striking fact is that the suffixal vowel appears to skip over the stem-final consonant; in principle, this could be handled a variety of ways, including either CV metathesis, /sákat-il-e/ → sákaitle → [sákeete]; or infixation of the suffix inside the final consonant, /sáka-il-t-/ → sákailt-e → [sákeete]. These approaches assume subsequent simplification of the consonant cluster, as well as vowel coalescence. Hyman (1995: 11–16) argues in favor of infixation, which he relates to the positioning of the perfective (and the applicative) before the passive and causative suffixes.

Diachronically, metathesis is the origin of some instances of infixation (Ultan 1975: 178f.; Yu 2007: 139–148). Another point of comparison is found in Horwood (2002: 170, 2004: 11), who uses Linearity to control the displacement of prefixes and suffixes to infixed positions. A crucial difference is that infixation of this sort (that is, excluding infixation tied to prosodically prominent constituents) is inherently edge-oriented; the infixed material remains as close to the left or right edge of the stem as possible, subject to the phonotactic constraints or other pressures that force deviation from simple prefixation or suffixation (McCarthy and Prince 1993; Prince and Smolensky 2004: 40–43; Yu 2007: 67–71). Metathesis, on the other hand, often occurs at stem edges as the result of morpheme concatenation, but in principle can occur anywhere in a word – recall the stem-medial cases in Cebuano and Rendille (§1.1). In addition, the infix has the status of a morpheme, which may happen to consist of a single segment; but in metathesis the single-segment status is fundamental, and not necessarily correlated with a particular morpheme.

It can be noted finally that metathesis as a phenomenon is important evidence in favor of the category *segment*, however it may be formalized (chapter 54: the skeleton). Whether one considers the category of segment to be innate in the language faculty or something that emerges from the coordination of phonological gestures (Bybee 2001: 85f.), it is impossible to describe reorderings coherently in terms of disparate features or phonetic cues: the essential property of metathesis is that it moves all features associated with a segment, and the cues that instantiate these features are affected as a group. Indeed, the features may be implemented by rather different cues in the new position. For example, the Alsea alternation [stlak] ~ [stalk] affects just two of the five segments in this root. Even if /la/ were to be described as a core syllable, which is then reversed in some sense, the notion of "reversal" makes covert reference to the segments within the CV syllable. Otherwise there must be a claim that the prevocalic /l/ has the same phonetic realization as when it occurs in the coda, and that the release of the /t/ into the /a/ is no different from that into the /l/ in the nonmetathesized form. The need to refer to discrete segments even to characterize metathesis, and even more so to provide a theoretical analysis, presents particularly good evidence against suggestions that segments have no psychological reality, and are a mere artifact of an alphabetic writing system (Ladefoged 2005: 191; Silverman 2006: 6, 203).

60 Dissimilation

Patrik Bye

1 Introduction

Dissimilation prototypically refers to a situation in which a segment becomes less similar to a nearby segment with respect to a given feature. As a synchronic alternation, it can be exemplified by liquid dissimilation in Georgian, where the ethnonym-forming suffix {-uri} becomes [uli] when an /r/ precedes it anywhere within the word (Fallon 1993; Odden 1994). The resulting pattern of alternation is shown in (1).

(1) *Georgian r-dissimilation*

a.	p'olon-uri	'Polish'
	somχ-uri	'Armenian'
b.	sur-uli	'Assyrian'
	p'rusi-uli	'Prussian'
c.	avst'ral-uri	'Australian'
	kartl-uri	'Kartvelian'

In (1a), the suffix surfaces in its basic (non-dissimilated) form. The forms in (1b) illustrate the result of unbounded dissimilation within the word. In the word meaning 'Prussian' it takes place despite the presence of the intervening consonant. If a lateral /l/ intervenes between the two rhotics, however, dissimilation does not apply. This is shown in (1c).

A very similar example of liquid dissimilation comes from Latin (e.g. Kent 1936, 1945; Steriade 1987), where the alternation is reversed. The adjectival suffix *-ālis*, as in *nāvālis* 'naval', dissimilates to *-āris* whenever another /l/ precedes it in the word, e.g. *lūnāris* 'lunar'. Dissimilation is similarly blocked whenever /r/ intervenes between the trigger and the target, e.g. *flōrālis* 'floral', **flōrāris*.

As a diachronic change, dissimilation is most often sporadic, applying to random lexical items (Posner 1961). The historical development of Latin and the Romance languages furnish several examples of sporadic liquid dissimilation, e.g. Latin *arbor* > Spanish *arbol* 'tree', *peregrīnus* > Late Latin *pelegrīnus* 'pilgrim'. Regular synchronic alternations involving dissimilatory processes are far more rare and, as a result, dissimilation has been afforded somewhat less systematic attention than other more common segmental patterns like assimilation. Nevertheless, the study of dissimilation phenomena offers a valuable source of insights into the fundamental questions phonologists ask. These questions include (a) the nature of rules and representations, and the relation between the two, (b) the division of labor between the grammar and the lexicon, and (c) whether phonological patterns reflect possibly innate cognitive biases or extralinguistic factors operating during acquisition.

The organization of the remainder of this chapter is as follows. §2 sets out the major parameters of dissimilation, explaining which features participate, along with restrictions on the interaction of context and focus determined by locality and domain of application. §3 addresses the contribution that the study of dissimilation phenomena has made to phonological theory, assessing how it has shaped our understanding of both representations and rules. §4 provides an overview of the motivations for dissimilatory patterns proposed in the literature. Conclusions and questions for future research are given in §5.

2 Dissimilatory patterns and their parameters

2.1 *Participating features*

Suzuki (1998) presents a comprehensive survey of cross-linguistic dissimilatory patterns. His survey includes 39 dissimilatory alternations. Table 60.1 provides a somewhat revised summary with a total of 46 alternations, adducing a few additional cases not covered in Suzuki's original survey, and suppressing cases that on closer inspection turn out not to be true dissimilation.[1] The second column of the table specifies the locality condition on the process (for illustration

[1] For example, Suzuki's cases 54–57 are grouped under "polarity", but on closer inspection they appear to have little in common. The reasons for reclassifying or not including these cases here are, briefly, as follows. In Russian *jakan'e* (54) a pre-tonic non-high vowel reduces to [i] or [a], depending on the quality of the following stressed vowel. The high or low quality of the reduced vowel gives the impression of maximizing the contrast in vowel height, e.g. /sʲeˈmʲju/ → [sʲaˈmʲju] 'seven (INST)', but /dʲiˈsʲatka/ → /dʲiˈsʲatka/ 'tenfold'. Crosswhite (1999: 79–83), however, argues that the dissimilatory effect is only epiphenomenal, and actually has nothing to do with dissimilation or enhancement of vowel height contrast. Based on work by Alderete (1995), she argues that what is at issue is actually a difference in foot structure. Syllables with prominent nuclei may constitute feet on their own. In [dʲi(ˈsʲa$_{\mu\mu}$t)ka], the stressed syllable forms a foot on its own, whereas in [(sʲaˈmʲju)] the pre-tonic syllable must also be incorporated because the stressed nucleus is not sufficiently prominent. The choice of raising or lowering thus comes to depend on whether the focus is parsed into a foot or not. Dinka (55) represents a morphological exchange rule, which is highly controversial in linguistic theory. See Wolf (2007) for an alternative analysis of exchange rules in terms of featural affix allomorphs. Huamelultec Chontal (56) appears to be a case of [spread glottis] dissimilation, not polarity. Margi (57) represents a case of allomorphy. Also not included is Thurneysen's Law in Gothic, which recent research by Woodhouse (1998) shows to be a case of analogical relexicalization rather than a phonological rule. Suzuki also includes Finnish consonant gradation (Keyser and Kiparsky 1984; Alderete 1997), but it is excluded here, since it is neither synchronically properly phonological nor obviously a dissimilation rule. One language cited as evincing low vowel dissimilation is the Chadic language Kera (Ebert 1974; Kenstowicz and Kisseberth 1979), where /a/ is claimed to dissimilate to [ə] preceding another /a/. Recent work by Pearce (2008), however, shows that the effect is due to reduction in unstressed syllables.

Table 60.1 Dissimilatory alternations (Rt = root adjacency; σ = syllable adjacency; unbounded (within the word); P = progressive; R = regressive)

Feature	*Locality*	*Example*
labial	Rt	Tashlhiyt Berber (P: Elmedlaoui 1985, 1995; Jebbour 1985; Boukous 1987; Larsi 1991; Odden 1994)
	σ	Cantonese (P: Yip 1982, 1988), Palauan (R: Josephs 1975, 1990; Finer 1986)
	unbounded	Akkadian (R: Soden 1969; McCarthy 1979; Yip 1988; Hume 1992; Odden 1994), Tashlhiyt Berber (2xR; see references above), Palauan (R; see references above)
coronal	Rt	Dakota (R: Shaw 1976, 1985)
lateral	unbounded	Kuman (R: Trefry 1969; Walsh Dickey 1997), Latin (P: Kent 1936, 1945; Posner 1961; Johnson 1973; Steriade 1987, 1995; Odden 1994; Walsh Dickey 1997), Yidiɲ (R: Dixon 1977; Steriade 1995; Walsh Dickey 1997), Yimas (P: Foley 1991; Odden 1994; Walsh Dickey 1997)
rhotic	Rt	Ainu (R: Maddieson 1984; Shibatani 1990)
	unbounded	Georgian (P: Fallon 1993; Odden 1994), Modern Greek (R: Newton 1971; Walsh Dickey 1997), Sundanese (R: Cohn 1992; Holton 1995), Yindjibarndi (P: Wordick 1982)
voice	σ	Bantu (R: Bennett 1967; Davy & Nurse 1982; Odden 1994; Lombardi 1995), Japanese (Itô & Mester 1986; Alderete 1997)
spread glottis	σ	Ancient Greek (R: Grassmann 1863), Huamelultec Chontal (P: Waterhouse 1949, 1962; Kenstowicz & Kisseberth 1979), Inari Saami (P: Itkonen 1986–91)
constricted glottis	σ	Seri (R: Marlett & Stemberger 1983; Yip 1988), Cuzco Quechua (R: Parker 1997)
nasal	Rt	Chukchi (R: Odden 1987)
NC	σ	Gooniyandi (P: McGregor 1990; Odden 1994; Evans 1995)
	unbounded	Gunindji (P: McConvell 1988; Odden 1994; Evans 1995), Yindjibarndi (P: Wordick 1982; Odden 1994)
continuant	Rt	Modern Greek (P: Kaisse 1988), Northern Greek (R: Newton 1971), Tsou (P: Szakos 1994), (P: Quintero 2004), North Central Spanish (R: González 2008)
high	σ	Guere (R: Paradis & Prunet 1989)
	Rt	Arusa (R: Levergood 1987), Wintu (Pitkin 1984)
low	σ	Marshallese (R: Bender 1968, 1969; Kenstowicz & Kisseberth 1977), Woleaian (R: Sohn 1975; Sohn & Tawerilmang 1976; Poser 1982)
length	σ	Gidabal (P: Geytenbeek & Geytenbeek 1971), Latin (R: Leumann 1977; Sihler 1995), Oromo (P: Gragg 1976; Lloret 1988; Alderete 1997), Slovak (P: Kenstowicz & Kisseberth 1977, 1979; Rubach 1993)
H	Rt	Bantu (P: Goldsmith 1984; Odden 1994)
	σ	Bantu (P: Goldsmith 1984; Odden 1994)
	unbounded	Arusa (P: Levergood 1987; Odden 1994)
L	unbounded	Peñoles Mixtec (P: Daly 1993; Odden 1994)

of dissimilations with different locality conditions, see §2.2). Also indicated is the direction of dissimilation and, in case the language has more than one, the number of dissimilative patterns. The numbers of progressive and regressive dissimilations are more or less evenly split, with 21 and 24 cases respectively.

Major class features such as [consonantal], [sonorant], and [approximant] do not appear to participate in dissimilation. The existence of some of these features is indeed contested in the literature. While there is something of a consensus that [sonorant] is necessary,[2] Hume and Odden (1996) propose that [consonantal] may be dispensed with. There is also a widespread assumption that the feature [approximant] is not contrastive in language, although see Levi (2008) for evidence to the contrary.

Beyond the major class features, all classes of feature may be involved in dissimilation, including place of articulation, laryngeal state, manner (continuancy, liquid, nasality), vowel height, and suprasegmental properties such as length and tone. We shall illustrate some of these in this section; other alternations that raise particular theoretical issues will be illustrated in the relevant sections. Thus, see §3 for examples of nasal dissimilation, and §4.3 for continuant dissimilation.

Of the place of articulation features, only [labial] dissimilation is common. Labial dissimilation is illustrated in (2) with data from Tashlhiyt Berber (Odden 1994). The labial nasal /m/ in a prefix dissimilates to [n] if the stem contains a labial consonant anywhere within it.

(2) *Labial dissimilation in Tashlhiyt Berber*

a.	las	'shear'	am-las	'shearer'
	agur	'remain'	am-agur	'abandoned'
b.	ˤrmi	'be tired'	an-ˤrmi	'tired person'
	bur	'remain celibate'	an-bur	'bachelor'
	ˤazum	'fast'	an-ˤazum	'faster'

Dissimilation of [coronal] is only attested in a single case, Dakota (Shaw 1976, 1985). Underlying coronal non-continuants /t ʧ n d/ are all neutralized to [k] (or, with regressive voicing assimilation, [g]) before another coronal consonant. The examples in (3) are from Shaw (1985: 184); see also Shaw (1976: 337).

(3) *Coronal dissimilation in Dakota reduplication*

a.	/ʧek/	ʧek-ˈʧeka	'stagger'
	/ʧap/	ʧap-ˈʧapa	'trot'
	/tʼĩs/	tʼĩs-ˈtĩza	'draw tight'
	/khuʃ/	khuʃ-ˈkhuʒa	'lazy'
b.	/sut/	suk-ˈsuta	'strong'
	/ʒat/	ʒag-ˈʒata	'curved'
	/tʰeʧ/	tʰek-ˈtʰeʧa	'be new'
	/ʧʰeʧ/	ʧʰek-ˈʧʰeʧʼa	'to look like'
	/nin/	nig-ˈnina	'very'

2 This consensus naturally does not extend to those representational theories like Government Phonology, where the elements of representation must have autonomous interpretations (see especially Kaye *et al.* 1985). Obviously, [sonorant] has no phonetic interpretation independent of the place and manner features with which it is associated.

There are apparently no attested examples of dissimilation involving the feature [dorsal].

Alternations involving laterals and rhotics are relatively common. We shall provide examples of liquid dissimilation in §2.2 in connection with the discussion of locality parameters.

Several Australian languages show dissimilation of prenasalized stops or nasal + stop clusters (NC). In Gurindji (Pama-Nyungan, Northern Territory; McConvell 1988; Odden 1994), this process is unbounded, e.g. /lutcu-ŋka/ 'ridge', /pinka-ŋka/ → [pinka-ka] 'river-LOC', /kankula-mpa/ → [kankula-pa] 'high ground-LOC'.

Several languages have restrictions on consecutive heavy nuclei that do not appear reducible to prosodic structure. In Slovak, for example, a long nucleus becomes short following a long nucleus, according to a rule known as the Rhythmic Law (Rubach 1993: 172–175). Thus, the suffixes {-aː} (FEM SG) and {-eːmu} (DAT SG) shorten their first vowel following a long vowel, e.g. [ma'l-a] 'small-FEM SG' *vs.* ['mlːkv-a] 'silent-FEM SG'; [ma'l-emu] 'small-MASC DAT SG' *vs.* ['mlːkv-emu] 'silent-MASC DAT SG'. The alternation is apparently unrelated to stress (Rubach 1993: 41–42). At least in Western Slovak, the main stress falls on the initial syllable of the word, and sources report a binary stress pattern, some with the possibility of ternary alternation. The Rhythmic Law nevertheless applies in odd-numbered syllables, where we would expect resumption of secondary stress on a binary alternating pattern. This is shown by derivations with the agentive suffix {-niːk} and the diminutive {-ik}, e.g. [hutniːk] 'steelworker' *vs.* [ʧaluːnik] 'wallpaperer', [xlebiːk] 'bread' *vs.* ['ʤbaːnik] 'pot'.

Several languages of Vanuatu have productive Low Vowel Dissimilation (Lynch 2003). In Maskelynes (Malayo-Polynesian), the nominalizer prefix is realized as [nə-] when the following vowel is low /e a o/, and [na-] following a high vowel /i ə u/.

(4)	a.	na-vis	'banana'
		na-xəmar	'men's house'
		na-xut	'louse'
	b.	nə-matu	'right (hand)'
		nə-gor	'green coconut'

Dissimilation is occasionally also used to refer to the deletion of one of a pair of similar neighboring sounds. Hall (2009), for example, describes this phenomenon with reference to /r/ in American English, in principle giving alternations like [fɑɻm] *farm* *vs.* [fɑmɚ] *farmer*, and [istən] *eastern* *vs.* [istənɚ] *easterner*.

All the cases we have looked at so far involve the elimination of sequences of similar sounds. Preventive dissimilation is when the creation of new sequences of similar sounds is blocked. One example is provided by Inari Saami (Itkonen 1986–91), which has a morphologically conditioned process of consonant gradation. An overlong obstruent in the "strong" grade generally alternates with the corresponding singleton in the "weak" grade, as shown in (5). In each of the examples below, the strong grade form on the left represents the nominative singular, the weak grade form on the right the accusative-genitive singular. Examples have been adapted from Finno-Ugric transcription into IPA, according to the conventions set out in Bye *et al.* (2009) ([ʌ] is a somewhat low central vowel; [ʌ̆] is "ultrashort").

(5) *Inari Saami consonant gradation (obstruents)*

tsuop:pʰă	tsuopʰʌ	'meat of fish'
fat:tă	faatʌ	'yard'
ɲeʃ:ʃi	ɲeeʃi	'mud, slush'

Under normal circumstances, the overlong aspirated velar stop /k:kʰ/ alternates with /h/, as shown in (6). This may be taken to reflect a general process that debuccalizes /kʰ/, leaving bare [h].

(6) *Inari Saami consonant gradation: Debuccalization of aspirated velar stop*

kak:kʰu	kaahu, *kaakʰu	'unleavened rye-bread'
ʧok:kʰi	ʧohii, *ʧokʰii	'peak, summit'
kal:kkʰă	kaalhʌ, *kaalkʰʌ	'chalk'

However, there is one situation where debuccalization to [h] fails to take place. As (7) shows, this is when the onset of the preceding syllable is also /h/.

(7) *Inari Saami consonant gradation: Debuccalization blocked*

hik:kʰi	hiikʰi, *hiihi	'hay-basket'
hak:kʰă	haakʰʌ, *haahʌ	'canon'
hul:kkʰă	huulkʰʌ, *huulhʌ	'knife-sheath'

2.2 Locality and domains

Dissimilation may be associated with one of three locality conditions listed in (8). This parameter was first addressed in detail by Odden (1994). Suzuki's (1998) survey largely confirms this picture.

(8) *Locality conditions*

a. Root adjacency
b. Syllable adjacency
c. Unbounded

Liquid dissimilation may be used to exemplify all three locality conditions. Ainu, a language isolate of Japan, illustrates the root-adjacency condition (Shibatani 1990: 13). Given an underlying cluster /rr/, the first /r/ dissimilates to [n], as shown in (9).

(9) *Ainu* r-*dissimilation*

kukor kur	'my husband'	kukon rusuj	'I want to have (something)'
kor mat	'his wife'	kon rametok	'his bravery'

Yimas (Foley 1991: 54), a Sepik-Ramu language of Papua New Guinea, illustrates liquid dissimilation operating under syllable adjacency. An /r/ dissimilates to [t] if there is an /r/ in the immediately preceding syllable. The examples in (10) show variation in the shape of the inchoative suffix {-ara} (1991: 290).

(10) *Yimas ɾ-dissimilation*

tuak-ara-	'break open'
kamprak-ara-	'snap'
apr-ata-	'open, spread'

Dissimilation may also be unbounded within the word, as we have already seen in the Georgian example in (1) with which we opened this chapter.

3 Dissimilation in the grammar

One of the fundamental issues in generative phonology has always been whether linguistically significant generalizations should be assigned to particular designated levels of representation, such as the underlying or surface level, or to the rules that map one representation onto another (McCarthy 2007; Bye, forthcoming). In earlier approaches in the style of *SPE* (Chomsky and Halle 1968), dissimilations were described in terms of feature-changing rules of the general form shown in (11).

(11) $X \rightarrow [-F] \; / \; \_\_ \; [+F]$

Rules of this kind were criticized because the pairing of structural change and environment was arbitrary. Because of this, they were unable to distinguish between natural assimilations like (12a) and arbitrary rules like (12b) (example from Odden 1987).

(12) a. [+consonantal] → [+voice] / __ [+voice]
b. [+consonantal] → [+voice] / __ [+continuant]

Concerns about the generative power of feature-changing rules thus motivated the development in the mid-1970s and 1980s of non-linear approaches to phonological representation (Goldsmith 1976) that permitted greater elegance and simplicity in the statement of natural rules. Assimilation rules were remodeled as feature-filling spreading (see CHAPTER 81: LOCAL ASSIMILATION and CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS). In non-linear terms, dissimilation is simply the deletion or delinking of a feature and, in accounts that retain a view of features as binary, independently motivated insertion of a default value (Odden 1987, 1994; CHAPTER 27: THE ORGANIZATION OF FEATURES). For example, Chukchi has a process changing underlying /ŋ/ to [ɣ] before another nasal, shown in (13).

(13)

taraŋ-ək	'build a dwelling'	nə-taraɣ-mori	'we built a dwelling'
inawrəŋ-ək	'to give as a gift'	inawrəɣ-nin	'he gave it'
pitˀiŋ	'cold'	pitˀiɣ-ŋinqij	'boy with a cold'

Odden (1987: 242) provides an analysis of this alternation as delinking of [+nasal] before another [+nasal], as shown in (14). Subsequently, redundancy rules fill in the feature [−nasal] by default.

```
(14)          denasalization              default
    inawrəŋ-ən    →   inawrəK-ən     →   inawrəɣ-ən
          |   |                 |                |   |
      [+N][+N]               [+N]            [−N][+N]
```

Accompanying the development of non-linear representations was a return to the idea that at least certain phonological generalizations are best stated as constraints on surface forms. This conception made it feasible to explain how it was possible that certain rules seemed to share the same functional teleology (the "conspiracy" problem; see Kisseberth 1970 and CHAPTER 70: CONSPIRACIES). Such constraints could trigger the application of repairs, such as the deletion of the first of the two [+nasal] features, or block the application of rules that would otherwise apply (see examples of preventive dissimilation in §2). The first such constraint on output representations was the Obligatory Contour Principle (Leben 1973; Goldsmith 1976; McCarthy 1979, 1981, 1986, 1988; Odden 1988; Yip 1988, 1989), one formulation of which is provided in (15).

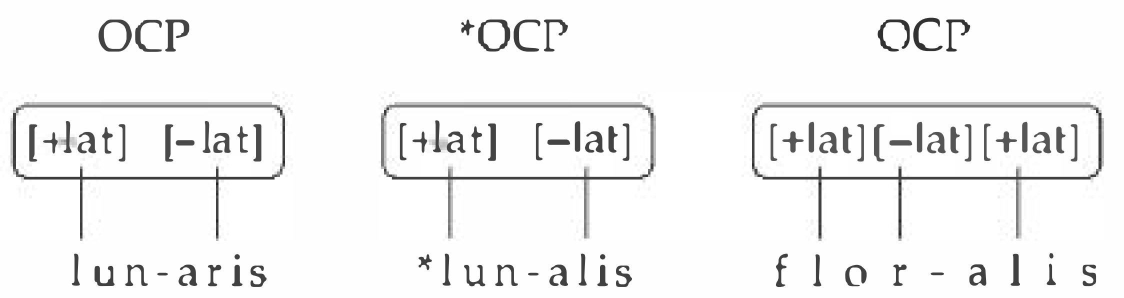
(15) *Obligatory Contour Principle (OCP)* (McCarthy 1986, 1988)

At the melodic level, adjacent identical elements are prohibited.

The OCP was originally used in accounting for tonal phenomena, especially adjacency of high tones, but it was subsequently extended to include other features. The OCP specifies a negative output target, and dissimilation only represents one strategy for satisfying it. Other repair strategies include merger of adjacent identical nodes, blocking of syncope (McCarthy 1986), and the insertion of epenthetic segments (Yip 1988). The OCP was incorporated into work couched in the framework of Optimality Theory (OT: McCarthy and Prince 1993; Prince and Smolensky 1993), where it became a violable constraint. Alderete (1997) and Itô and Mester (2003) propose that the OCP may represent a local self-conjunction of more primitive markedness constraints (Smolensky 1995, 1997). $\text{OCP}_{[F]}$ is violated precisely when *[F] is violated more than once within some local domain.

Another major theoretical concern during the 1980s especially was locality conditions on the application of rules, and dissimilation played a major part in this debate. The autosegmentalization of representations into tiers permitted the elimination of many kinds of apparent long-distance effects. Sounds that are non-adjacent on the level of the segmental root may nevertheless dissimilate, provided that the relevant features are adjacent on the same autosegmental tier. Steriade (1987) argues that the Latin facts mentioned at the beginning of this chapter may be accounted for by a version of the OCP with jurisdiction over the [lateral] tier, over which interactions between tier-adjacent liquids may be described. The diagrams in (16) show how the liquids in the words *lūnāris* and *flōrālis* are projected onto separate tier-specifying values of [lateral]. This allows us to explain the ungrammaticality of the counterfactual form **lūnālis* as a result of the two occurrences of [+lateral] being adjacent on the [lateral] tier, in violation of $\text{OCP}_{[\text{lateral}]}$. In *flōrālis*, on the other hand, there is an intervening [−lateral] between the two occurrences of [+lateral], so the OCP is not violated.

(16) *Lateral dissimilation*



Even with the possibility of factoring the representation into tiers, though, there is still an empirical residue that poses a problem for a strict interpretation of locality. In some theories, vocalic place (V-Place) and consonantal place (C-Place) are represented on separate planes (Clements 1991; Clements and Hume 1995; Morén 2003; see also CHAPTER 19: VOWEL PLACE and CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION). This organization implies that non-adjacent consonants and vowels should not display any interaction, but this expectation is not borne out. Akkadian (Soden 1969: 64ff.), for example, has a nominalizer prefix |ma-| that dissimilates to [na-] if followed by a labial consonant in the stem, e.g. /ma-šʔal-t-u/ 'question' but /ma-rkab-t/ → [na-rkab-t] 'chariot'. If a labial vowel or glide intervenes between the trigger and the target, however, dissimilation is blocked, e.g. /ma-wmii-t-um/ → *[ma-amii-t-um] 'oath'. Odden (1994: 319) argues for an additional adjacency parameter, transplanar locality, to cover these cases, but it is unclear how this is to be formalized.

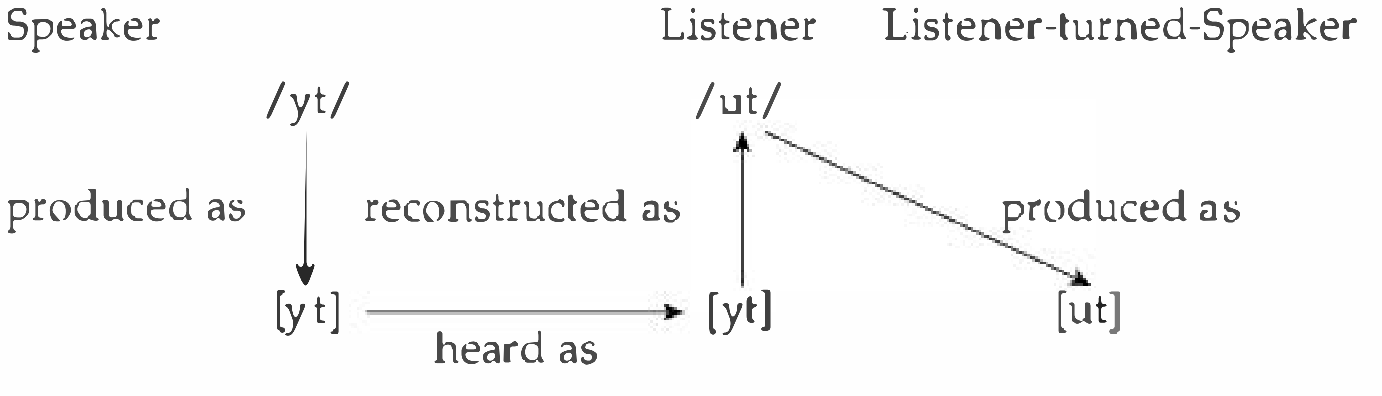
4 Motivations for dissimilation

There are a number of theories of what causes dissimilation. The purpose of this section is to review the major proposals as well as some others of more limited applicability. Our point of departure will be Ohala's Co-articulation-Hypercorrection Theory (CHT; Ohala 1981, 1993, 2003), which is presented in §4.1. According to the CHT, dissimilation results when the listener reverses a perceived co-articulation. The central prediction of the CHT is that dissimilation should only occur with features that have cues that are significantly extended in time. Other theories assume a processing motivation. Frisch *et al.* (2004) argue that similarity avoidance effects are due to the difficulties associated with processing the sequencing of similar segments. This bias is reflected in the statistical structure of the lexicon and is described in §4.2. Following on from this, §4.3 considers the possibility that dissimilation in manner between pairs of adjacent fricatives or stops may be understood in terms of the enhancement of place cues. In §4.4 we look at dissimilation-like phenomena in certain kinds of reduplication ("echo" reduplication) and language games, which exploit non-identity for aesthetic, ludic, or secret purposes.

4.1 Dissimilation as listener reversal of co-articulation

The phonetic realization of certain features may extend over long temporal domains. Long-domain features are interesting because they create an ambiguity for the listener faced with the task of reconstructing the feature's place in phonological structure. This ambiguity creates conditions favorable to reanalysis, which – in the case of temporally extended features – may take one of three forms: assimilation, metathesis, or dissimilation (Blevins 2004). In dissimilation, when one instance of a distinctive feature occurs within the phonetic domain of another instance of the same distinctive feature, there is an ambiguity as to whether the phonetic effects should be ascribed to the first or second instance of the feature, or both. In a series of highly influential publications, Ohala (1981, 1993, 2003) argues that dissimilation as a sound change is the result of reversal by the listener of perceived co-articulation (see CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). The driving force of the change on this view is the overzealous application of reconstructive rules, with the result that long-domain effects that are actually intended by the speaker become reversed. This is known as hypercorrection. The mechanism of Ohala's Co-articulation-Hypercorrection Theory is schematized in (17).

(17) *Dissimilation as sound change by the listener* (after Ohala 1981: 187)



In this example, the speaker intends to say [yt], which is also the form that the listener actually hears. However, the listener is in possession of tacit phonetic knowledge that coronal consonants raise the value of F2 on neighboring vowels. Drawing on this knowledge, he concludes that the intended quality of the vowel has been distorted due to its proximity to the coronal consonant. The perceived distortion is then eliminated by reconstructing the intended form as /ut/: the /y/ dissimilates.

There are three important entailments of the CHT. The first follows from the assumption that dissimilation involves co-articulation. Segments are only expected to dissimilate to the extent that they entail overlapping articulations. Many dissimilations involve segments that are not phonologically adjacent on the level of the segmental root node. A well-known example is Grassmann's Law in Indo-European (Grassmann 1863). In Ancient Greek, which provides one instantiate of the sound law, there cannot be more than one aspirated stop in a pair of adjacent syllables (Smyth 1956 [1920]: 31). Thus, earlier /t^hrik^h-os/ 'hair (GEN SG)' became [trik^{h}os] τρίχος (cf. [t^hriks] θρίξ (NOM SG)). Grassmann's Law apparently represents an interaction between two non-adjacent consonants. Once we take into account the co-articulatory effect of the aspiration on the following vowel, the apparent action-at-a-distance effect evaporates because the aspiration overlaps phonetically with the dissimilation target. Following release of the stop closure, aspiration persists into the following vowel for 60 msecs or so, presenting the listener with an ambiguity as to whether the aspiration represents post-aspiration of the first stop or pre-aspiration of the second. Segments that are outside of each other's co-articulatory range are not expected to dissimilate according to the CHT.

The second consequence of the CHT is that dissimilation cannot take the form of a quantitative change within the same category. Dissimilation should always be limited to phonologically contrastive features (cf. Grammont 1895; Kiparsky 2003). This follows directly from the assumption that what listeners are doing, when they hypercorrect, is reconstructing what they believe is the intended form, which must be a distinctive segment of the language. Assimilative changes, on the other hand, may give rise to novel structures or segments.

The third consequence of the CHT is that it should not matter which direction the perceived distortion is resolved in. The CHT is neutral with respect to whether the dissimilation is progressive or regressive. In (17), an equally valid outcome would have been dissimilation of the consonant, e.g. to /yk/.

The empirical substance of Ohala's proposal consists of the following predictions.

(18) *Ohala's predictions*

a. The likelihood that a given consonantal feature participates in dissimilation depends on whether the associated perceptual cues have a short or long domain.
b. The domain of dissimilation should be linked to the temporal extension of the perceptual cues.
c. Features whose cues are localized on the segment should not show dissimilatory behavior.

On this basis, an up-to-date list of the features shown to have temporal extension, and therefore likely to dissimilate according to the CHT, is shown in Table 60.2, adapted from a corresponding table in a paper on the evolution of metathesis by Blevins and Garrett (2004: 123). Examples are incorporated from the surrounding discussion in their text.

Features not likely to dissimilate according to the CHT are fricative, affricate, stop, and voice. The phonetic cues for each of these segment types are localized on the segment itself. For example, stops are cued by high amplitude bursts on release of the closure. These bursts are very short, of the order of 5 msecs to 10 msecs. The temporal extent of voicing and fricative noise is limited by the extent of the segment's articulation phase. Examples of continuancy and voicing dissimilation nevertheless exist. Examples of continuancy dissimilation are discussed in §4.3, along with a possible phonetic motivation. When Ohala (1981) initially framed his CHT, the existence of liquid dissimilation appeared to present a problem, since at that time no work had been done on temporally extended cues for liquids. Far from being occasional, liquids are, after labials, the most likely to dissimilate. Moreover, they show pronounced action-at-a-distance, as the Georgian example at the beginning of this chapter shows. This is surprising if it is all down to the formant transitions onto neighboring vowels. Starting with Kelly and Local (1986) and Kelly (1989), however, much research has shown that liquids have temporally extended acoustic-perceptual cues. Tunley (1999) demonstrated experimentally that /l/ causes raising in F2 and F3 on neighboring high vowels, while /r/ results in lowering. These effects are moreover observable up to five syllables away from the lateral segment itself (Hawkins and Smith 2001; see also CHAPTER 30: THE REPRESENTATION OF RHOTICS). West (1999b) found that when the liquid and its phonetic context were masked with white noise, speakers were nonetheless able

Table 60.2 Temporally extended features. References to acoustic properties are from Ladefoged (1993; L), Ladefoged *et al.* (1988; LMJ) and Ladefoged and Maddieson (1996; LM)

Feature	*Acoustic property*	*Examples*
rounding	lowering of all formants (LM 356–358)	French, English (Benguerel & Cowan 1974; Lubker & Gay 1982)
velarization	lowered F2 (LM 361–362)	Arabic (Ghazali 1977; Card 1983)
pharyngealization	lowered F3, raised F1 (LM 307)	Interior Salish (Bessell 1998a, 1998b)
palatalization	raised F2 (LM 364)	Catalan (Recasens 1984, 1987), English (Hawkins & Slater 1994), Japanese (Magen 1984), Marshallese (Choi 1992), Russian (Keating 1988), Bantu (Manuel 1987)
retroflection	lowered F3, F4, clustering of F2, F3, F4 (E 203, LM 28)	Gooniyandi (McGregor 1990), Gujarati (Dave 1977), Hindi (Stevens & Blumstein 1975), Malayalam (Dart 1991), Tiwi (Anderson & Maddieson 1994)
laryngealization	more energy in F1, F2, more jitter (LMJ)	Cayuga (Dougherty 1993)
aspiration	more energy in F0, more noise (LMJ)	Cayuga (Dougherty 1993)
nasalization	spectral zero, nasal anti-resonance (LM 116)	English (Cohn 1990)
jaw lowering	raised F1	English (Amerman *et al.* 1970)
rhoticity	lowered F3 (LM 244, 313)	
laterality	lateral formants (LM: 193–197), raised/lowered F2/F3	English (Kelly & Local 1986; Kelly 1989; Tunley 1999; West 1999a, 1999b, 2000; Hawkins & Smith 2001)

to reconstruct the intended liquid from the resonances in vowels up to three syllable nuclei away. These recent findings on the phonetics of liquids thus square well with the prediction that the phonological domain of the dissimilating feature should mirror the temporal extension of the corresponding cues.

Ohala does not consider dissimilation between vowels. Öhman (1966) showed that vowels may co-articulate across intervening consonants. Dissimilation of vowels across syllables is thus consistent with Ohala's broader claims. Interestingly, though, all of the known examples of vowel dissimilation involve vowel height (CHAPTER 21: VOWEL HEIGHT). Vowel height dissimilation is certainly consistent with the experimental finding that lowering of the jaw co-articulates (Amerman *et al.* 1970), but the existence of co-articulation is apparently not a sufficient predictor of dissimilation. Indeed there is a striking complementarity of phonological patterning between vowel height, on the one hand, and vowel color (roundness and backness), on the other. To date, no examples of dissimilation involving the labial or front–back dimensions have come to light. Conversely, systems of vowel harmony in which backness or rounding (or both) are active are richly attested in the literature, but the feature [low] is not frequent in vowel harmony (see Krause 1979 for a possible example from Chukchee). Further discussion of this problem may be found in Alderete and Frisch (2007).

There is also still a residue of dissimilatory patterns for which the CHT does not seem to offer an explanation, including NC, long vowel, continuancy (see §4.3 below), and voicing. In the next section we will consider an alternative theory of the origins of dissimilation that does not seem to make any prediction about which features participate.

4.2 Similarity avoidance in the lexicon

Several recent studies have examined statistical asymmetries in the lexicon, pointing to a preference for phonetic dissimilarity between neighboring consonants in roots (see also CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS). Berkley (2000) studied English monosyllabic words and found evidence of gradient similarity avoidance effects. Focusing on words of the shape C_1VC_2, she found that there are significantly fewer such words containing homorganic consonants than would be expected if consonants combined randomly, i.e. had the same probability of occurring as two independent events. Under- or overrepresentation is the ratio of observed to expected frequency (see CHAPTER 90: FREQUENCY EFFECTS). A pair is underrepresented if the observed-to-expected (or O/E) ratio is less than 1, overrepresented if greater than 1. Words in which C_1 and C_2 are homorganic – such as *mop*, *lull*, and *king* – are underrepresented in the English lexicon. For CVVC words with a long vowel intervening between C_1 and C_2, the homorganic similarity avoidance effect is also present but weaker. These results, adapted from Berkley (2000), are shown in Table 60.3. Shaded cells indicate underrepresented combinations.

Frisch *et al.* (2004) studied similarity avoidance in the lexicon of Arabic triradical verb roots. They found a very strong effect for adjacent pairs of consonants

Table 60.3 Similarity avoidance in English monosyllabic roots

			Labial p b f v m w	Cor obs t d θ ð s z ʃ ʒ ʧ ʤ	Cor son n l r j	Dorso-guttural k g h ŋ w
CVC	Labial	p b f v m w	0.52	1.15	1.33	0.85
	Cor obs	t d θ ð s z ʃ ʒ ʧ ʤ		0.73	1.03	1.09
	Cor son	n l r j			0.59	1.21
	Dorso-guttural	k g h ŋ w				0.72
CVVC	Labial	p b f v m w	0.61	1.11	1.11	1.14
	Cor obs	t d θ ð s z ʃ ʒ ʧ ʤ		0.75	1.17	1.03
	Cor son	n l r j			0.70	1.01
	Dorso-guttural	k g h ŋ w				0.71

(C_1 and C_2, C_2 and C_3), tending to categorical, as shown in Table 60.4. For non-adjacent C_1 and C_3 the effect was still strong, although somewhat weaker. Under both adjacency and non-adjacency the similarity avoidance effect is far stronger than the one observed by Berkley for English. Gray cells are homorganic in terms of major class (Labial, Coronal obstruent, Dorsal, Guttural, Coronal sonorant). They also found that the avoidance was stronger the more similar the consonant. Within the major class of coronals, for example, an adjacent pair of coronals was significantly more frequent if they had different values for [continuant].

Frisch *et al.* argue that when observed co-occurrence deviates from expected co-occurrence, the learner posits a gradient phonological constraint, which they dub the gradient Obligatory Contour Principle that encodes the generalization "roots with repeated homorganic consonants are unusual." Statistical generalizations like these form the basis of metalinguistic judgments of relative acceptability of novel words ("word-likeness"), influencing which words are actually used, and the phonological forms of novel and borrowed words (cf. Frisch 2004: 346).

For Frisch *et al.*, the gradient OCP represents a statistical generalization over a static lexicon; it does not encode tacit phonetic knowledge directly. Despite this, Frisch *et al.* do propose a functional explanation for the distributional asymmetries in the lexicon. Repetition of similar consonants is difficult to process (Frisch 2004). This finds the beginnings of an explanation in neural network models that encode linearization of segments. Nodes in the network must be excited and inhibited so as to fire in the right sequence. If there is a sequence of similar segments, the periods of excitation and inhibition may overlap, whether or not there is a corresponding overlap in the acoustic signal. Given two segments, C_1 and C_2, in linear sequence that activate the same distinctive feature node, if the node encoding C_1 is still firing when C_2 is perceived, this may result in simultaneous

Table 60.4 Similarity avoidance in Arabic verb roots

			Labial	Cor obs		Dorsal	Guttural		Cor son

	Cor son	l r n							0.67

perception of C_1 and C_2. The resulting blend of the two percepts may result in the same kind of ambiguity that results from co-articulation in the CHT, and is presumably consistent with the same re-analytic strategies. An alternative source of dissimilation in processing may be a refractory period during which the node must be reset in order to detect a second stimulus of the same type. Unlike the CHT and the blending scenario we have just sketched, the refractory period would seem to predict asymmetries in the direction of the resulting pattern. If C_2 occurs within this refractory period of a node that has just fired for C_1, the relevant feature will be perceived on C_1 but may not be perceived on C_2. The effective result is progressive dissimilation.

This processing bias may further help explain the pronounced difference in the strength of the effect in English and Arabic. Arabic has non-concatenative morphology and psychologically real abstract consonant roots like /ktb/ 'write'. In phonological analysis, this has motivated analyses in which consonants and vowels occupy separate tiers in the representation. Roots are vulnerable to speech errors involving misordering of radical consonants.

These functional mechanisms and their implications for linguistic patterning provide much fertile ground for further research. First, a greater range of languages must be studied to determine to what extent root co-occurrence constraints have a gradient character or not. Suzuki (1998) presents 16 examples of root co-occurrence restriction, which are summarized in Table 60.5, along with a couple of additional cases.

A second challenge concerns the difference between similarity and identity. Arabic shows avoidance of identical radicals. In English, however, segmental identity provides an escape hatch to the OCP. CVC roots where both C_1 and C_2 are labial are generally dispreferred, but not if C_1 and C_2 are identical. For example, selecting /p/ for C_1 and C_2 and permuting the possible nuclei, almost every cell of the paradigm corresponds to an actually occurring word of English: *pip, pep, pap, pop, pup, peep, poop, parp, pipe, Pape, pope*. See Idsardi and Raimy (2008) for a relevant proposal that segmental identity may be represented in a data structure they call a "linked list."

Finally, the similarity avoidance approach raises anew the question of which features are expected to participate in dissimilation. Are certain features associated with longer periods of excitation in perception than others? And if that turns out to be so, is there a systematic correlation between the length of a feature's temporal domain in the speech signal and the duration of excitation? To date, place and laryngeal features (MacEachern 1997) have been studied. These studies must therefore be extended to short-domain features, such as stops, fricatives, and voicing.

4.3 *Dissimilation and cue robustness*

Manner dissimilation is predicted not to occur by the CHT. Despite this, a small number of languages display dissimilation of pairs of adjacent stops or fricatives. For example, Osage (Quintero 2004), a Siouan language spoken in Oklahoma, has a rule dissimilating /ð/ to [t] following /s/, e.g. /ʃkɔ̃ʃða/ → [ʃkɔ̃ʃta] 'you want'. Tsou (Szakos 1994), an Austronesian language of Taiwan, has a rule that hardens /h/ to [k] following /s/, giving alternations such as [s-in-uhnu] 'send someone to do something (ACTOR VOICE)' ~ [skuna] (PATIENT VOICE), [s-in-ohpici] 'pinch

Table 60.5 Root co-occurrence restrictions

Feature	*Case*
place	Amharic (Bender & Fulass 1978), Arabic (Greenberg 1950; McCarthy 1979, 1981; Mester 1986; Yip 1989; Padgett 1991; Pierrehumbert 1993; Frisch *et al.* 2004), Cambodian (Yip 1989), French (Plénat 1996), Hawai'ian (McKay 1970), Hebrew (Koskinen 1964), Javanese (Uhlenbeck 1949; Mester 1986; Padgett 1991), Russian (Padgett 1991), Serbian (McKay 1970), Yucatec Mayan (Yip 1989; Lombardi 1991)
labial	Cantonese (Yip 1982, 1988), Ponapean (Rehg & Sohl 1981; Goodman 1995), Yao (Purnell 1965; Ohala 1981), Zulu (Doke 1926)
coronal	Akan (Welmers 1946; McCarthy & Prince 1995)
pharyngeal	Moses-Columbia Salish (Czaykowska-Higgins 1993)
liquid	Javanese (Uhlenbeck 1949; Mester 1986)
rhotic	American English (Hall 2009)
voice	Japanese (Itô & Mester 1986, 2003; Steriade 1987, 1995; Ishihara 1991; Archangeli & Pulleyblank 1994; Alderete 1997; Pater 1999), Bakairi (Gussenhoven & Jacobs 2005)
spread glottis	Sanskrit (Grassmann 1863; Langendoen 1966; Anderson 1970; Phelps & Brame 1973; Sag 1974, 1976; Phelps 1975; Schindler 1976; Borowsky & Mester 1983; Kaye & Lowenstamm 1985; Lombardi 1991)
high	Ngbaka (Thomas 1963; Chomsky & Halle 1968; Mester 1986)
back	Ainu (Itô 1984; Mester 1986; Archangeli & Pulleyblank 1994), Tzeltzal (Slocum 1948; Itô 1984)
length	Japanese

(ACTOR VOICE)' ~ [skopica] (PATIENT VOICE). Non-sibilant fricatives such as [θ x] have diffuse spectra. Harris (1958) shows that the F2 transition is required for reliable identification of the fricative. In a cluster of fricatives, one of the transitions, C–V or V–C, is missing. Dissimilating one of the fricatives to the corresponding stop has the effect of sharpening the F2 transition and adding a stop release burst, rendering the place of articulation more easily identifiable.[3] In Chontal (Waterhouse 1949, 1962; Kenstowicz and Kisseberth 1979), a Hokan language of Mexico, the imperative suffix is {-laʔ} after voiceless segments, and {-ɬaʔ} after voiced ones, e.g. [fuʃ-lʲaʔ] 'blow it!', [panx-laʔ] 'sit down!', [ko-ɬaʔ] 'say it!', [kan-ɬaʔ] 'leave it!'. The pattern seems to involve deleting the second [spread glottis] feature in a

[3] One of the apparent cases of continuant assimilation mentioned by Ohala as a potential counterexample to the CHT may in fact turn out to be best understood as an instance of it. Dyen (1972) shows that Proto-Austronesian */s . . . s . . ./ was dissimilated across an intervening vowel in Ngaju-Dayak to /t . . . s . . ./. The evidence, however, only consists of the two words PA *sisik > ND [tisik] 'fish-scale' and PA *susu > ND [tuso] 'breast'. It is perhaps relevant that the vowel immediately following the initial *s is a high vowel. High vowels are known to increase the degree of post-aspiration of a preceding voiceless stop and affrication of a preceding /t/. The initial sibilant may thus have been interpreted as the co-articulatory affrication of an intended /t/.

cluster of voiceless fricatives – assuming the claim of Vaux (1998) that voiceless fricatives are universally [spread glottis] – allowing the lateral to be more clearly identified as such.

Dissimilation between two stops is far more rare, but González (2008) supplies an example from North-Central Spanish, which shows dissimilation of coda /k/ to [θ] (and other realizations) before another stop (generally /t/, e.g. [doθ.'tor] 'doctor'. González also proposes an explanation in terms of cue robustness, noting that the cues for the first stop are not as salient before another stop as before other segments, due to weaker, or absent, stop release burst and formant transitions. Similar considerations have been argued to condition metathesis in other languages, e.g. Faroese, where final /skt/ metathesizes to [kst] (Hume and Seo 2004; see CHAPTER 59: METATHESIS).

4.4 The dissimilation game

In a different vein, people also apply tacit knowledge of similarity to a variety of ludic and poetic ends. Indeed, the term "dissimilation" entered the field in the 19th century from rhetoric, where it had been in use to describe the variation in style required for good public speaking (cf. Brugmann 1909). The criterion of a perfect rhyme in English, such as *pet – bet*, is not only that the material following the onset of each stressed syllable is identical, but that the onset of each stressed syllable is different. In considering rhyme in English, we do not appear to count features; we are merely interested in contrastive segments. The pair *pet – bet* is thus as good a rhyme as the pair *pet – set*. The same requirement of non-identity turns up in echo reduplication (Alderete *et al.* 1999; Nevins 2005; CHAPTER 100: REDUPLICATION), where the base is reduplicated with an onset determined by convention (fixed segmentism). In Hindi, this kind of reduplication gives a meaning 'X and the like' (Singh 1969; Nevins 2005). The fixed segment is /v/ unless the base also begins with a /v/, in which case the echo reduplicant begins with /ʃ/. Examples from Nevins (2005: 280) are shown in (19).[4]

(19) *Hindi echo reduplication with fixed segmentism*

paanii-vaani	'water and the like'
aam-vaam	'mangoes and the like'
tras-vras	'grief and the like'
yaar-vaar	'friends and the like'
vakil-ʃakil, *vakil-vakil	'lawyers and the like'

Similar facts are observed in English *shm-* reduplication, e.g. *potato–shmotato*, but *shmaltz-shpaltz* (Nevins and Vaux 2003), Kannada (Lidz 2001), and Javanese (Yip 1995). Yip (1995, 1998) proposes that these are due to a constraint against the repetition of identical elements, *REPEAT, ultimately due to Menn and MacWhinney (1984). Similar facts also turn up in secret languages. In the Kunshan secret language Mo-pa (Yip 1982: 652ff.), a base of the shape $C_1V_1(C_2)$ is mapped to a template C_1[o]-GV_1C_2, where G is a consonant whose value for the feature

[4] The forms in (19) represent Nevins's own fieldwork. The original source on Hindi echo words is Singh (1969).

[continuant] is the opposite of that of C_1. Examples, not glossed in the source, are given in (20).

(20) *Kunshan secret language Mo-pa*

təw	tʊ ləw
k'ɛ	k'o ɦe
d'oŋ	d'o loŋ
tsa	tso za
vã	vo pã
sja	so tsja
nɔw	no tɔw
ɲən	ɲa tɕan

Oral stops are replaced by voiced continuants, while nasals and continuants are replaced by the corresponding voiceless unaspirated stop. This continuant dissimilation is covered neither by the CHT nor cue robustness; the reason for the alternation seems to be purely ludic.

5 Conclusions

There are a number of theories of the origin of dissimilation, and dissimilation may apparently have one of several motivations. According to the Co-articulation-Hypercorrection Theory (Ohala 1981, 1993, 2003), dissimilation results when the listener reverses a perceived co-articulation. The central prediction of the CHT is that dissimilation should only occur with features that have elongated cues. Other theories assume a functional motivation. Frisch *et al.* (2004) argue that similarity avoidance effects are due to the difficulties associated with processing the sequencing of similar segments. This bias is reflected in the statistical structure of the lexicon in many languages. However, the predictions of processing-based accounts with respect to the observed featural asymmetries are not yet clear. It was suggested here that manner dissimilation in pairs of adjacent fricatives or stops is best understood as maximizing cues for place of articulation, while dissimilatory phenomena in language games fulfill an aesthetic role. Future research will hopefully extend the empirical base for the study of dissimilation phenomena, and determine more precisely what the division of labor and synergies between the factors discussed here should be.

ACKNOWLEDGMENTS

I would like to thank Beth Hume, Marc van Oostendorp, and two anonymous reviewers for helpful feedback on this chapter.

61 Hiatus Resolution

Roderic F. Casali

1 Overview of hiatus resolution

The term *vowel hiatus* is commonly used to refer to a sequence of adjacent vowels belonging to separate syllables, as in the following Hawaiian examples from Senturia (1998: 26). (Periods indicate syllable boundaries.)

(1) [ko.a.na] 'space'
 [Ii.le.a] (name of a shell)
 [ku.a] 'back'
 [hu.e.lo] 'tail'
 [hu.i.na] 'sum'
 [ko.e.na] 'remainder'

In some languages, vowel hiatus is permitted quite freely. Other languages place much stricter limits on the contexts in which heterosyllabic vowel sequences can occur, while some disallow them entirely. Languages that do not permit vowel hiatus may employ any of several processes that eliminate it in cases where it would otherwise arise (e.g. where an underlying vowel-final morpheme directly precedes a vowel-initial morpheme).

One of the most common forms of hiatus resolution involves the elision of one of the two vowels. (See CHAPTER 68: DELETION.) Vowel elision is illustrated below with examples from Yoruba, adapted from Pulleyblank (1988).

(2) /bu ata/ → [ba.ta] 'pour ground pepper'
 /gẹ́ olú/ → [gó.lú] 'cut mushrooms'
 /ta epo/ → [te.po] 'sell palm oil'
 /kɔ́ ɛ̀kɔ́/ → [kɛ́.kɔ̌] 'learn'
 /ra ɔwɔ̀/ → [rɔ.wɔ̀] 'buy a broom'

In all of these examples, it is the first of the two adjacent vowels (V_1) that deletes. Though this is the more common pattern cross-linguistically, cases in which the second vowel (V_2) deletes are also attested (and indeed, some instances of V_2 deletion are found in Yoruba itself).

In another very common hiatus resolution process, *glide formation*, V_1 is converted to a semivowel (see also CHAPTER 15: GLIDES). One well-known case, illustrated in (3), is Ganda (Tucker 1962; Katamba 1985; Clements 1986).[1]

(3)	/mu-iko/	→	[mwiː.ko]	'trowel'	cf. [mu-leːnzi]	'boy'
	/li-ato/	→	[ljaː.to]	'boats'	cf. [li-ggwa]	'thorn'
	/mu-ezi/	→	[mweː.zi]	'moon'		
	/mu-ogezi/	→	[mwoː.ge.zi]	'talker'		
	/mi-ezi/	→	[mjeː.zi]	'moons'		
	/mu-ana/	→	[mwaː.na]	'child'		

In general (we will look at an exception in §2.4 below), glide formation in Ganda applies only where V_1 is high. Non-high V_1's are elided before another vowel, with compensatory lengthening of V_2 (e.g. /ka-oto/ 'small fireplace' > [koːto]).

A third common pattern, *coalescence*, involves the merger of V_1 and V_2 to form a third vowel that combines features of both. This is illustrated in the Attic Greek examples below (de Haas 1988: 126). In these examples, various underlying sequences that combine a non-high [–ATR] vowel /a ɛ ɔ/ with a mid [+ATR] vowel /e o/ are realized phonetically as a long mid [–ATR] vowel that retains the backness and roundness of the original [+ATR] vowel.

(4)	/gene-a/	→	[gé.nɛː]	(/ea/ > [ɛː])	'race (NOM ACC PL)'
	/tiːma-omen/	→	[tiː.mɔ̂ː.men]	(/ao/ > [ɔː])	'honor (1PL PRES IND)'
	/ajdo-a/	→	[aj.dɔ̂ː]	(/oa/ > [ɔː])	'shame (ACC SG)'
	/dɛːlo-ɛːte/	→	[dɛ.lɔ̂ː.te]	(/oɛː/ > [ɔː])	'manifest (2PL PRES SUBJ)'
	/zdɛː-omen/	→	[zdɔ̂ː.men]	(/ɛːo/ > [ɔː])	'live (1PL PRES SUBJ)'

Note that for the pairs /a o/ and /ɛː o/, coalescence in Attic Greek is symmetric; the phonetic result is the same for both orders of input vowels.[2] Other languages with symmetric coalescence include Quebec French, Korean, Rotuman, Old Portuguese, and Classical Sanskrit (all discussed in de Haas 1988), and Afar (Bliese 1981). Symmetric coalescence is relatively uncommon, however. Much more frequently, coalescence applies only when the vowels occur in one of the two possible orders (see §2.3 below).

Other languages avoid hiatus by retaining both vowels but syllabifying them into the nucleus of a single syllable, a process generally known as *diphthong formation* or *diphthongization*. This occurs in Ngiti, as illustrated in the following examples, adapted from Kutsch Lojenga (1994: 90–91).

(5)	/abvo àji/	→	[a.bvoà.ji]	'widow'
	/tìtɔ̀ akpà/	→	[tì.tɔ̀a.kpà]	'liar'
	/opi àji/	→	[o.pìà.ji]	'Lendu woman'
	/ìndɽì akpà/	→	[ìn.dɽla.kpà]	'male goat'
	/fà ɔ́ɲò/	→	[fàɔ́.ɲò]	'our food'
	/fʊ̀kʊ́ oɓi/	→	[fʊ̀.kʊ́ó.ɓi]	'your (PL) knives'

[1] It is also common to find cases in which the second of two vowels becomes non-syllabic, e.g. /gene-i/ 'race (DAT SG)' > [ge.nej] in Attic Greek (de Haas 1988: 126). Generally, such cases are potentially analyzable as diphthong formation. See Senturia (1998: 12–15) for examples and related discussion.

[2] This is not the case in Attic for the pair /a e/: /a+e/ yields [ɛː], while /e+a/ yields [ea].

Kutsch Lojenga states that "both vowels must be realised as a short complex vowel nucleus on one V timing slot." She further notes (personal communication) that the first vowel in each sequence is shorter in duration than the second vowel, though not to the point where any auditory distinctions among vowels in V_1 position are neutralized. This argues against an analysis (i.e. glide formation) in which V_1 is syllabified as a consonantal onset.

Other languages that exhibit diphthong formation include Haitian Creole (Picard 2003), Indonesian (Rosenthall 1997), Attic Greek (Senturia 1998 and references therein), Obolo (Faraclas 1982), Bakossi (Hedinger and Hedinger 1977), Eastern Ojibwa (Howard 1973), Margi (Tranel 1992), and Larike (Rosenthall 1997).

Finally, an obvious means of eliminating vowel hiatus is to epenthesize a consonant between the two vowels. One language in which this occurs is Washo, as illustrated in the examples below, adapted from Midtlyng (2005); in each example a semivowel [j] is inserted between the initial vowel of a suffix and the final vowel of a preceding morpheme.

(6)	a.	'laːdu-a 'my hand-LOC'	→	['laː.du.ja]	'in my hand'
	b.	le'guʔu-iʔ '(1SG OBJ) mother's mother-ATTRIB-AG'	→	[le.'gu.ʔu.ji]	'my daughter's child'
	c.	'lemts'iha-i 'I cause to awake-IMP'	→	['lém.ts'i.ha.ji]	'I am waking him up'
	d.	'lemlu-'eːs-i 'I eat-NEG-IMP'	→	['lém.lu.'jeː.si]	'I am not eating'

Though these hiatus resolution strategies have been presented independently using data from different languages, it is common to find two or more different strategies at work in the same language (see §2.5).

It is also common to find that languages tolerate hiatus in some contexts but not others. A number of factors are capable of blocking or influencing hiatus resolution, including the nature of the prosodic or morphosyntactic boundary at which hiatus arises (Kaisse 1977; Baltazani 2006), prominence factors such as stress (Senturia 1998), vowel length and tone (Casali 1998: 73), minimal word length or weight conditions, the lexical or functional status of particular morphemes, rate of speech, and sensitivity to particular lexical items. Hiatus resolution also sometimes shows *derived environment effects* (see CHAPTER 88: DERIVED ENVIRONMENT EFFECTS), in which hiatus is tolerated in vowel sequences internal to a morpheme, but is eliminated in cases where two vowels come together across a morpheme boundary. Finally, morphemes consisting of just a single vowel are sometimes resistant to loss through elision, presumably due to the loss of semantic content that could result (Casali 1997).

Hiatus resolution can also arise in cases where *three* (or more) underlying vowels occur in sequence. Such cases are considerably less common, and it is difficult to make many strong generalizations about the resolution of $/V_1V_2V_3/$ sequences. Attested outcomes include gliding of V_2 (e.g. Eastern Ojibwa [Howard 1973]; Ganda [Clements 1986: 75]), and elision of both V_1 and V_2 (Baka [Parker 1985]).

The remainder of this paper is organized as follows. In §2, I describe some major respects in which hiatus resolution processes vary across languages. §3 discusses the treatment of hiatus resolution within various theoretical models and some associated challenges and issues. The paper concludes with a brief summary in §4.

2 Typological variation

Hiatus resolution patterns show considerable variation across languages, and any survey of this variation in a work of the present paper's scope will necessarily be selective.[3] Here we will look at certain aspects of variation involving consonant epenthesis (§2.1), vowel elision (§2.2), coalescence (§2.3), and glide formation (§2.4), as well as the co-occurrence of multiple processes within a single language (§2.5).

2.1 *Consonant epenthesis*

A question that naturally arises in looking at hiatus resolution by consonant epenthesis is *which* consonants can function epenthetically as hiatus interrupters. Three possibilities seem reasonably well attested:

(i) A semivowel, usually one that is homorganic with (i.e. shares the same frontness or roundness as) V_1 or V_2.
(ii) A glottal stop ([ʔ]) or fricative ([h]).
(iii) A coronal consonant, generally [t] or a rhotic.

By far the most common pattern (Picard 2003; Uffmann 2007) is the first one. This is sometimes explained (see for example Uffmann 2007) by assuming that homorganic glide epenthesis is in some sense different from (and less costly than) epenthesis of an entirely new segment, since the glide might be interpreted as a prolongation of phonological content that is already present. However, there are also languages – e.g. Ait Seghrouchen Berber (Senturia 1998), Galacian (Picard 2003), and Washo (Midtlyng 2005) – that consistently epenthesize [j], regardless of the featural content of adjacent vowels, and at least one language, Chamicuro (Parker 1989; de Lacy 2006), with consistent [w]-epenthesis.

An example of a language with glottal stop epenthesis is Malay (Ahmad 2001). The examples below show insertion of a glottal stop between a CV prefix and vowel-initial root:

(7)	/di-ubah/	→	[diʔubah]	'to change (PASS)'
	/sə-indah/	→	[səʔindah]	'to be as beautiful as'
	/sə-elok/	→	[səʔeloʔ]	'to be as pretty as'
	/di-olah/	→	[diʔolah]	'to beguile (PASS)'
	/di-aŋkat/	→	[diʔaŋkat]	'to lift (PASS)'

Other languages that epenthesize [ʔ] in at least some hiatus contexts include Ilokano, Selayarese, Tunica, and Indonesian (see Lombardi 2002 and references therein).

[3] One topic that is not treated, for reasons of space, is the typology of diphthong formation. See Schane (1987), Sohn (1987), Rosenthall (1994), and Senturia (1998) for some discussion.

A well-known case of epenthesis of a coronal consonant in hiatus contexts is Axininca Campa (Payne 1981; Lombardi 2002; Baković 2003), illustrated in the examples below (Payne 1981):

(8)	/i-N-koma-i/	→	[iŋkomati]	'he will paddle'
	/i-N-koma-aa-i/	→	[iŋkomataati]	'he will paddle again'

These examples show an epenthetic [t] interrupting vowel hiatus in suffixal contexts; hiatus in prefixal contexts is resolved in Axininca Campa by eliding one of the vowels instead.

The problem of predicting the range of possible epenthetic consonants has received significant attention in recent theoretical work. This is discussed further in §3.3.3 below.

2.2 *Vowel elision*

A natural question that arises in connection with vowel elision is *which* of two adjacent vowels elides. Cross-linguistically, elision of V_1 is far more common than elision of V_2 (Bergman 1968; Lamontagne and Rosenthall 1996; Casali 1997, 1998). Interestingly, it turns out that the contexts in which V_2 elision is well attested are not random. Clear cases of V_2 elision are largely confined to two contexts: (i) the boundary between a lexical (content) word and a following function word, and (ii) stem–suffix boundaries.[4]

Examples of the former type, from Etsako (Elimelech 1976), are shown in (9). Note that the latter also display V_1 elision of the final vowel of a *preceding* function word, suggesting rather strongly that it is lexical or non-lexical status, and not simple linear order, that is relevant in this case (see also CHAPTER 104: ROOT–AFFIX ASYMMETRIES).

(9)	/ɔna	aru	ɔli/	→	[ɔnaruli]	'that louse'
	the	louse	that			
	/ɔna	eɣi	ɔna/	→	[ɔneɣina]	'this tortoise'
	the	tortoise	this			

Examples of the latter type, adapted from Okpe (Pulleyblank 1986), are shown in (10).

(10)	/è-sé-ó/	→	[èsé]	'to fall'
	INF-fall-INF			
	/ɛ̀-dɛ́-ɔ́/	→	[ɛ̀dɛ́]	'to buy'
	INF-buy-INF			

Compare these forms with the additional Okpe words in (11), where the final V suffix is retained following an underlying high vowel, which undergoes glide formation.

[4] In addition to the more common cases in which the elided vowel is one that occupies a particular position, there are also cases (see Casali 1996, 1998; Causley 1999b) in which the vowel targeted depends on the featural makeup of the two vowels.

(11) /è-tí-ó/ → [ètjó] 'to pull'
INF-pull-INF
/ɛ̀-sú-ɔ́/ → [ɛ̀swɔ́] 'to sing'
INF-sing-INF

At other kinds of morphosyntactic boundaries, such as that between a prefix and following root or between two content words, elision regularly targets V_1. The cross-linguistically well-attested possibilities are summarized below. (See Casali 1997 for more discussion.)

(12) *Vowel elision and morphosyntactic position*

Context	*Robustly attested possibilities*
Between two content words	V_1 elision
Content word before function word	V_1 elision or V_2 elision
Prefix + root	V_1 elision
Root + suffix	V_1 elision or V_2 elision

2.3 *Coalescence*

As noted previously, symmetric coalescence, as in the Attic Greek data in (4), is relatively rare. By far the most common form of coalescence is a directionally asymmetric pattern, termed *height coalescence* in Casali (1998) (see also Lamontagne and Rosenthall 1996; Parkinson 1996), in which a non-high V_1 and a high V_2 coalesce to form a non-high vowel otherwise identical to V_2, e.g. /a+i/ > [e], /a+u/ > [o], as in the Xhosa examples below (Aoki 1974).

(13) /wa-inkosi/ → [wenkosi] 'of the chiefs'
/wa-umfazi/ → [womfazi] 'of the woman'

The reverse sequences /i+a/ and /u+a/ are not subject to coalescence in Xhosa, but are resolved instead by vowel elision and glide formation, respectively (see §2.5 below).

Languages in which the feature [ATR] is contrastive sometimes show a slightly more elaborate form of asymmetric height coalescence, in which the [ATR] value of a non-high V_1 is preserved in some cases as well. Such languages divide into two types: those in which [−ATR] is systematically preserved (e.g. /a+i/ > [ɛ], /ɛ+o/ > [ɔ]), and those in which [+ATR] is preserved (e.g. /a+i/ > [e], /o+ɪ/ > [e]). Languages of the former type include Owon Afa (Awobuluyi 1972) and Anufo (Adjekum *et al.* 1993). Languages of the latter type include several North Guang languages and Southern Sotho (Casali 1998, 2003 and references therein).[5]

Though asymmetric height coalescence most commonly applies to sequences in which V_1 is lower than V_2, cases of "reverse height coalescence" also exist in which a higher V_1 followed by a lower V_2 yields a lowered version of V_1 (e.g. /i+a/ > [e], /u+a/ > [o]), while the opposite sequences do not trigger coalescence. This occurs in Foodo (Kwa; Ghana; Plunkett 1991: 68), as shown below. (The initial

[5] The particular [ATR] value that is preserved under height coalescence shows a strong correlation with a language's vowel inventory structure; see Casali (1998, 2003) and Causley (1999a) for discussion.

and final /a/'s are noun class affixes. The tonal changes are due to independent processes discussed in Plunkett.)

(14)	a.	/i+a/	>	[eː]	/á-bì-á/	→	[ábêː]	'seeds'	cf. [dí-bí-lì]	'seed'
	b.	/ʊ+a/	>	[ɔː]	/á-sʊ́-á/	→	[ǎsɔ́ː]	'ears'	cf. [kʊ̀-sʊ́]	'ear'
	c.	/u+a/	>	[oː]	/á-jù-á/	→	[ájǒː]	'millet'	cf. [dú-jú-Ii]	'millet'

Sequences in which V_2 is high and V_1 is non-high do not undergo coalescence; compare the /ʊ+a/ sequence in (14b) with the /a+ʊ/ sequence in /kʊ̀-tá-ʊ́/ 'bow', which is retained in the surface form, [kʊ̀táʊ̀].

Other languages with reverse height coalescence patterns include Tem (Tchagbale 1976; de Craene 1986), Chagga (Nurse and Philippson 1977; Saloné 1980), Ewe (Westermann 1930), Bakossi (Hedinger and Hedinger 1977), and Nkengo (Hulstaert 1970). Interestingly, such patterns seem to occur predominantly at root–suffix boundaries, a restriction that partly parallels some limitations on the distribution of V_2 elision (§2.2).

A further coalescence pattern that should presumably be expected to occur is one in which front unrounded and back rounded vowels coalesce to form a front rounded vowel, e.g. /i+u/ > [y], /e+o/ > [ø], etc. Patterns of this type appear to be considerably less common than height coalescence. Two possible cases, Rotuman and Korean, are discussed in de Haas (1988) (see also Sohn 1987; Rice 1995; Causley 1999a). Coalescence of /e+o/ to [ø] is also described in Obolo (Faraclas 1982).

2.4 *Glide formation*

In Ganda (cf. (3) above) and quite a few other languages, both front and back V_1's are subject to glide formation. It is also quite common, however, to find that only back round vowels glide and that front V_1's trigger a different resolution strategy, most commonly elision. This is the case for example in Xhosa (see §2.5 below) and Chumburung (Snider 1985). Though they are seemingly less common, there are also languages (e.g. Polish; Rubach 2000) in which only front vowels glide.

A second point of variation involves the height of V_1. Generally, if a language has glide formation at all, high V_1's will undergo the process (Rosenthall 1994, 1997; Casali 1995). In some languages (e.g. Ebira; Adive 1989), *only* high V_1's glide. In quite a large number of other languages, however, mid V_1's also glide.[6] One such case, Chicano Spanish, is illustrated in the examples below (from Baković 2007, with phonemic forms substituted for orthographic ones):

(15)	a.	/mi ultima/	→	[mjultima]	'my last one (FEM)'
		/mi obra/	→	[mjoβra]	'my deed'
		/tu epoka/	→	[twepoka]	'your time'
		/tu alma/	→	[twalma]	'your soul'
	b.	/me urxe/	→	[mjurxe]	'it is urgent to me'
		/porke a beses/	→	[porkjaβeses]	'because sometimes'
		/komo eba/	→	[komweβa]	'like Eva'
		/lo abla/	→	[lwaβla]	'speaks it'

[6] In rare cases, e.g. Aghem (Hyman 1979), languages may glide the low vowel /a/ as well.

Further variation exists as well. In some languages, glide formation does not apply to sequences in which V_1 and V_2 share the same frontness and roundness. In Gichode (Casali 1998: 168–169), for example, glide formation of a round vowel occurs only before non-round vowels, e.g. /u+i/ > [wi] but /ʊ+o/ > [o] (*[wo]). (Contrast this with realization of /u+o/ as [wo] in Ganda, as in (3) above.) Glide formation is also blocked in some languages (e.g. Ganda; Clements 1986) following certain consonants.[7] Typically, both sorts of restrictions can be attributed to constraints that are effective quite generally in the language (e.g. languages that fail to glide /u/ or /o/ before a round vowel typically lack [Cw] before round vowels in general).

Finally, some languages impose less stringent restrictions on glide formation when V_1 occurs in absolute word-initial position. In Ganda, for example, only high V_1's generally glide in word-internal /CV_1-V_2/sequences. Word-initially, however, mid and even low V_1's undergo glide formation (in this case without compensatory lengthening), as in the examples below (Clements 1986: 75, n. 1):[8]

(16)	/o-a-gula/	→	[wagula]	'you (SG) bought'
	/a-a-gula/	→	[jagula]	'he/she bought'
	/e-a-laba/	→	[jalaba]	'it (cl. 9) saw'

Rather similar patterns are reported in Nyarwanda (Kimenyi 1979).

Notwithstanding the considerable variation that exists in its patterning, there is one very significant respect in which the behavior of glide formation is surprisingly regular across languages. Quite consistently, (non-word-initial) sequences in which V_1 and V_2 are identical regularly fail to undergo glide formation. We can illustrate this restriction with additional examples from Ganda (Clements 1986):

(17)	/mi-iko/	→	[miːko]	*[mjiːko]	'trowels'
	/lu-uji/	→	[luːji]	*[lwuːji]	'side'

Moreover, sequences such as /o+u/ and /e+i/, in which V_1 and V_2 are both front or both round and V_1 is *lower* than V_2, rarely if ever trigger glide formation, but are resolved instead by vowel elision or coalescence (Casali 1995, 1998: 172, n. 5).

Exceptions to these generalizations clearly arise in absolute word-initial position in some languages, as in the Ganda example in (16) above. I am not aware of any languages that consistently violate these restrictions word-internally, however.

2.5 *Multiple hiatus resolution strategies in the same language*

It is quite common to find two or more different hiatus resolution processes at work in the same language. In some such cases, different processes are operative

7 In some languages, glide formation following certain consonants triggers further changes, e.g. /siV/ and /ziV/ are realized as [ʃV] and [ʒV] respectively in Ebira (Adive 1989).

8 Intervocalic gliding of non-high vowels also occurs in some three-vowel sequences discussed by Clements, as in /te-a-a-gula/ 'he/she didn't buy', realized as [tejagula].

in different morphosyntactic contexts. In Axininca Campa (Baković 2003) and Washo (Midtlyng 2005), for example, hiatus is resolved by vowel elision at a prefix–stem boundary but by epenthesis at a stem–suffix boundary. In Lugisu (Brown 1970), a sequence /a+i/ is resolved by coalescence (to [e]) across a word boundary, but by eliding /a/ word-internally.

There are also many cases, however, in which multiple strategies apply in exactly the same morphosyntactic context, targeting different vowel sequences. Especially common are cases (see Casali 1998: 83–84) in which vowel elision occurs along with glide formation, coalescence, or both. Languages with both vowel elision and glide formation (but not coalescence) include Ganda, Etsako (Elimelech 1976), Igede (Bergman 1968), and Chicano Spanish (Baković 2007). Languages with coalescence and vowel elision (but not glide formation) include Afar (Bliese 1981) and Owon Afa (Awobuluyi 1972). Particularly intricate patterns are found in a considerable number of languages (32 cases are listed in Casali 1998: 83–84) that manifest all three processes. One such language is Xhosa (McLaren 1955; Aoki 1974), whose hiatus resolution alternations conform to the following generalizations:

(18) *Hiatus resolution in Xhosa*

a. Where V_1 is non-high and V_2 is high, the outcome is a [−high] version of V_2.
b. A round V_1 undergoes glide formation before a following non-round vowel.[9]
c. Elsewhere, V_1 elision applies.

The overall pattern corresponding to these generalizations is shown below in Table 61.1, where coalescent realizations are underlined and those involving glide formation are italicized. Note that in the case of the input /o+i/, *both* coalescence and glide formation apply.

Table 61.1 Glide formation, coalescence, and vowel elision (in Xhosa)

				V_2		
		i	e	a	o	u
	i	i	e	a	o	u
	e	$\underline{e}$	e	a	o	$\underline{o}$
V_1	a	$\underline{e}$	e	a	o	$\underline{o}$
	o	$\underline{\textit{we}}$	*we*	*wa*	o	$\underline{o}$
	u	*wi*	*we*	*wa*	o	u

[9] Aoki's description implies that glide formation should apply before round vowels as well, e.g. /u+o/ > [wo], but he gives no examples of such realizations. In contrast, McLaren's data and explicit statements (1955: 10) strongly suggest that gliding of /u/, /o/ occurs only before non-round vowels. I follow McLaren's account here.

Examples illustrating some of these realizations in Xhosa (Aoki 1974) are shown below:

(19)	/esisu-ini/[10]	→	[esiswini]	'stomach (LOC)'
	/ni-oʤa/	→	[noʤa]	'you roast'
	/ndi-akha/	→	[ndakha]	'I build'
	/ni-enza/	→	[nenza]	'you make'
	/wa-ejele/	→	[wejele]	'he fell in'
	/aɓa-oni/	→	[aɓoni]	'wrong doers'
	/aɓa-akhi/	→	[aɓakhi]	'builders'
	/wa-inkosi/	→	[wenkosi]	'of the chiefs'
	/wa-umfazi/	→	[womfazi]	'of the woman'
	/esilo-ini/	→	[esilweni]	'animal'

The descriptive summary of the Xhosa patterns in (18) illustrates something that is quite typical of languages that combine vowel elision with glide formation and/or coalescence, which is that it is generally possible to regard vowel elision as a kind of default process. That is, the simplest way of describing the relevant generalizations is often to specify the conditions under which glide formation and/or coalescence apply, with a statement that vowel elision applies elsewhere.

All three processes – vowel elision, glide formation, and coalescence – can occur either with or without compensatory lengthening, depending on the language (see CHAPTER 64: COMPENSATORY LENGTHENING). Typically, if compensatory lengthening applies with one process it will apply with the others as well. Thus, Ganda shows compensatory lengthening with both vowel elision and glide formation, while Xhosa does not show compensatory lengthening with either of these, nor with coalescence. It also appears generally true that languages (e.g. Ganda) with contrastive vowel length manifest compensatory lengthening while those with no phonemic length do not, but it remains to be seen how universal this correlation is.

3 Theoretical treatments and issues

3.1 *Early generative phonology*

Many analyses of hiatus resolution patterns in particular languages (e.g. Brown 1970; Aoki 1974; Phelps 1975, 1979; Elimelech 1976; Halle 1978; Shaw 1980; Snider 1985) were carried out within early generative phonological frameworks conforming roughly to the model proposed in Chomsky and Halle (1968) or its offshoots. In such models, hiatus resolution processes are due to the operation of language-specific phonological rules. To account for the Xhosa hiatus resolution patterns in (19), for example, Aoki (1974: 239) posits three ordered rules of Vowel Lowering, Glide Formation, and Vowel Deletion, which (with minor notational adjustments) are essentially those in (20):

[10] Aoki (1974: 238) displays the underlying forms of the first and last forms in (19) as /isisu-ini/ and /isilo-ini/, respectively, but describes the lowering of the word-initial vowel form /i/ to [e] as a morphosyntactic replacement, suggesting that initial /e/ is present underlyingly.

(20) a. *Vowel Lowering*

$$V \rightarrow [-\text{high}] \; / \begin{bmatrix} V \\ -\text{high} \end{bmatrix} \_\_$$

b. *Glide Formation*

$$\begin{bmatrix} V \\ +\text{round} \end{bmatrix} \rightarrow [-\text{vocalic}] \; / \; \_\_ \; V$$

c. *Vowel Deletion*

$$V \rightarrow \varnothing \; / \; \_\_ \; V$$

Derivations illustrating the operation of these rules are shown below (Aoki 1974: 40):[11]

(21)			
Underlying Form	/wa-umfazi/	/esisu-ini/	/esilo-ini/
Vowel Lowering	wa-omfazi	—	esilo-eni
Glide Formation	—	esisw-ini	esilw-eni
Vowel Deletion	w-omfazi	—	—
Output	[womfazi]	[esiswini]	[esilweni]

The formal apparatus of early generative phonology frequently offered multiple possibilities for analyzing a given pattern. For example, in contrast to Aoki's analysis of Xhosa coalescence using separate vowel lowering and elision rules, other researchers (e.g. Phelps 1975, 1979; Halle 1978) treated very similar patterns in other languages using a type of rule, known as a *transformational* rule, which is capable of simultaneously affecting (and, in the case of coalescence, merging the features of) two different segments. Perhaps not surprisingly, much of the literature on hiatus resolution patterns of this period focused on issues of rule formulation and the related question of when the rules for two potentially related processes might appropriately be collapsed into a single rule. Aoki's paper, which provides extensive arguments against a transformational rule analysis of coalescence (on the grounds that it is arbitrary and unrevealing and that it leads to an unnecessary increase in the complexity and power of the theory), is itself an interesting case in point. Other relevant work includes Brown (1970), Harms (1973), Hyman (1973), Shaw (1980), Snider (1985), and an extended debate (Chomsky and Halle 1968; Phelps 1975, 1979; Halle 1978) over some particularly intricate patterns in Kasem.

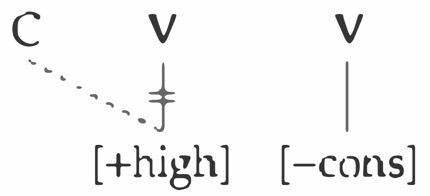
3.2 *Autosegmental and non-linear generative phonology*

The late 1970s and 1980s saw the development of alternative and greatly elaborated *autosegmental* or *non-linear* conceptions of phonological structure in which some or all phonological features are assumed to occur on separate structural tiers (see CHAPTER 14: AUTOSEGMENTS). A number of studies of hiatus resolution phenomena (e.g. Katamba 1985; Clements 1986; Pulleyblank 1986, 1988; Sohn 1987; de Haas 1988; Snider 1989) were carried out using such models. We will look at one representative (and influential) case in some detail, Clements' (1986) treatment

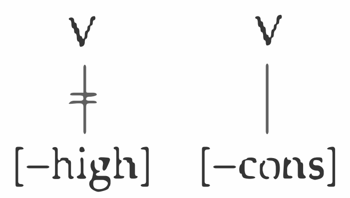
[11] The derivations in (21) differ slightly from those shown in Aoki due to an apparent typo in his derivation of [esiswini] and a minor (and irrelevant) difference in choice of underlying forms (see note 10).

of glide formation and elision in Ganda (see (3) above). Clements' analysis employs the rules in (22).[12]

(22) a. *Glide Formation*

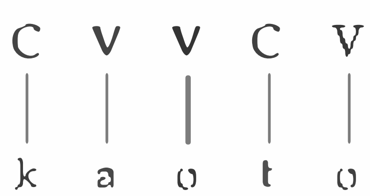


b. *Non-high Vowel Deletion*

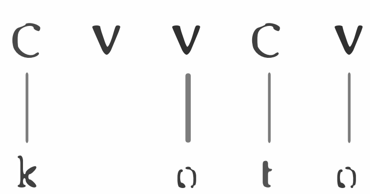


An appealing feature of Clements' analysis is that it provides a very straightforward account of the compensatory lengthening that accompanies both elision and glide formation in Ganda. Both rules in (22) have the effect of delinking a V element from its associated vowel features. This is illustrated below for the case of vowel elision. (23a) shows the underlying form corresponding to /ka-oto/ ([ko:to]) 'small fireplace' within Clements' model, while (23b) shows the representation that results when this form is subjected to rule (22b) (Non-high Vowel Deletion), which delinks /a/ from its associated V element, in conjunction with a further (universal) convention that is assumed to delete unassociated segments (in this case the delinked /a/).

(23) a.

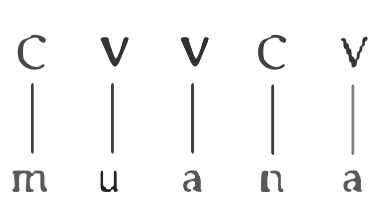


b.

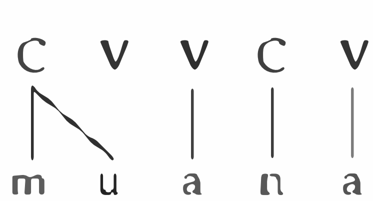


The parallel forms in (24) illustrate the application of the Glide Formation rule (22a). (24a) shows the underlying form of /mu-ana/ ([mwa:na]) 'child', and (24b) shows the result of applying Glide Formation to this form.

(24) a.



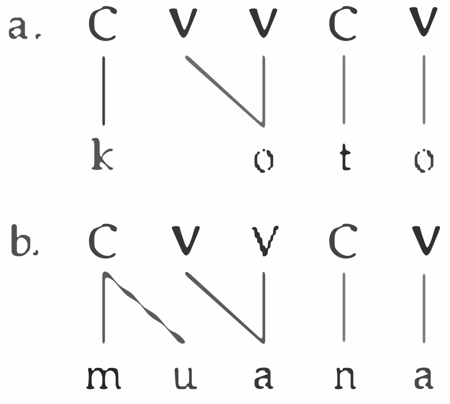
b.



[12] Glide Formation as formulated in (22a) does not account for the cases where non-high vowels glide word-initially in (16). Clements proposes an additional rule to account for these, which we will not treat here.

Following the application of these rules, the forms in (23b) and (24b) both contain an unassociated V element. Clements assumes that there is a universal *Linking Convention* that has the effect of automatically reassociating such an unassociated V element to an accessible vowel segment (subject to a general prohibition on crossing of association lines). Applied to the representations in (23b) and (24b), this convention yields the representations in (25a) and (b), respectively.

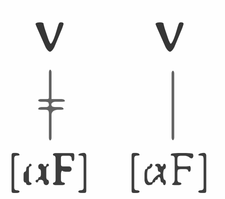
(25)



In these surface representations, V_2 emerges as a long vowel, since it is linked to two V elements (see CHAPTER 54: THE SKELETON). This account encodes quite directly the intuition that compensatory lengthening involves the transfer of duration from one segment to another.

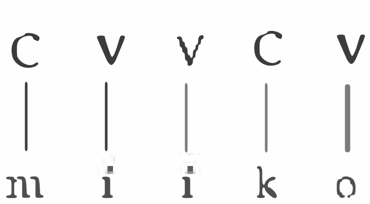
There is a further wrinkle to the analysis. As noted in §2.4 above, glide formation does not apply in Ganda to the sequences /i+i/ and /u+u/, in which V_1 and V_2 are identical. To prevent the Glide Formation rule (22a) from applying to these sequences, Clements posits an additional rule of Twin Vowel Deletion that is ordered before Glide Formation and functions to remove sequences of identical high vowels as possible inputs to the latter:

(26) *Twin Vowel Deletion*



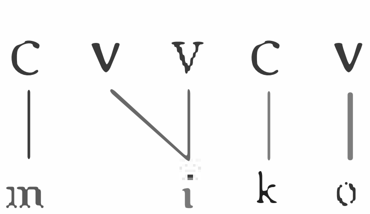
This rule is applicable to words like /mi-iko/ [miːko] 'trowels', whose underlying form is shown in (27):

(27)



Application of Twin Vowel Deletion, along with the universal convention requiring deletion of unassociated segments and the Linking Convention that accomplishes reassociation of a free V element, will convert this to (28).

(28)



Since the form in (28) does not meet the structural description for Glide Formation to apply, the analysis correctly predicts [mi:ko] and not *[mji:ko] as the surface form. While the analysis derives the correct forms, however, the need to posit the language-specific rule (26) implies that immunity of sequences of identical vowels from glide formation is an idiosyncratic characteristic of the language. As noted in §2.4, such sequences appear to be regularly exempt from glide formation in other languages as well, suggesting that something more universal than a language-specific rule (26) is at work. (Potentially, this presents an interesting challenge not only for autosegmental models like Clements' but for other approaches as well.)

A strong interest of many autosegmental theories is the specification of phonological features. Much research has been done in particular on the possibility of accounting for certain phonological patterns based on the assumption that only one value of a feature is phonologically specified (see CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION). Underspecification models of this type have potential implications for the analysis of vowel coalescence. One of the analytical questions that arises in connection with coalescence is what determines which features of the two merged vowels are preserved in the output. An interesting general answer to this question, pursued in a study by de Haas (1988) (see also Sohn 1987 and Snider 1989), is that the underlyingly specified features from both vowels are preserved in the output. Preservation of all specified features of both vowels under coalescence would presumably be impossible in cases where the two vowels have opposite values of some feature, since this would lead to a surface vowel simultaneously specified as both [+F] and [−F] for some feature [F]. Following previous work in radical underspecification theory, de Haas assumes that only one value of each feature is underlyingly specified. Consider in this regard the symmetric coalescence of /o/ and /a/ to [ɔ] in Attic Greek, as in the relevant forms in (4) above, repeated here as (29).

(29)	/tiːma-omen/	→	[tiː.mɔ̂ː.men]	(/ao/ > [ɔː])	'honor (1PL PRES IND)'
	/ajdo-a/	→	[aj.dɔ̂ː]	(/oa/ > [ɔː])	'shame (ACC SG)'

In de Haas's underspecification analysis, /a/ is specified only as [+low] and [+back] at the point where coalescence applies, while /o/ is specified only as [+round]. Combining all three feature values yields a [+low], [+back], [+round] vowel, which in de Haas's analysis is equivalent to [ɔ].

Many autosegmental treatments of hiatus resolution processes were also concerned with the relationship between hiatus resolution and syllable structure and attempted to establish a formal connection between the two. In the model of de Haas (1988), for example, (symmetric) coalescence is contingent on prior resyllabification of two adjacent vowels into a single syllable. Other autosegmental analyses that attempted to connect hiatus resolution to syllabification include Katamba (1985), Pulleyblank (1986), Walli-Sagey (1986), Schane (1987), and Sohn (1987).

3.3 *Optimality Theory*

Analyses of hiatus resolution patterns within Optimality Theory (OT) date from the early years of the paradigm and include, among other studies, Rosenthall (1994, 1997), Casali (1995, 1997, 1998), Orie and Pulleyblank (1998), Senturia (1998), Causley (1999a, 1999b), and Baković (2003, 2007). Though they differ somewhat in detail, most such analyses share the following general components:

(i) Some constraint (which must be highly ranked) that militates against heterosyllabic adjacent vowel sequences. There is some controversy (discussed below) over the exact identity of this constraint. For now, we will simply label it "NoHiatus."

(ii) Constraints that are violated by various hiatus resolution possibilities. Generally, vowel elision is assumed to violate a constraint Max, which requires underlying segments to be represented in surface forms. Epenthesis is assumed to violate a constraint Dep against insertion of material (as well as relevant markedness constraints against the features of the inserted consonant – see below). Diphthong formation violates a constraint NoDiph against diphthongs. Glide formation violates, minimally, a markedness constraint, here labeled *CC, against consonant + glide sequences.[13] Coalescence violates a constraint Uniformity, which prohibits merger of two underlyingly distinct segments into a single segment in the output.

Given these assumptions, hiatus resolution is forced whenever NoHiatus is ranked sufficiently high. At a rough first approximation, the particular form of hiatus resolution that occurs is determined by the constraint that is ranked lowest. For example, epenthesis is predicted to occur if the constraint Dep is outranked by the remaining constraints, as illustrated in (30), using a hypothetical input /ku abo/.

(30)

/ku abo/	NoHiatus	Max	NoDiph	*CC	Uniformity	Dep
a. .ku.a.bo.	*!					
b. .kua.bo.			*!			
c. .ka.bo.		*!				
d. .kwa.bo.				*!		
e. .ko.bo.					*!	
☞ f. .ku.ʔa.bo.						*

The simplified analysis sketched above would need to be significantly elaborated to account for the intricate patterns and interactions found in many languages.[14] It does, however, illustrate one important general feature of OT analyses, which is that all phonological processes occur in response to some markedness constraint(s). In this case, the primary markedness constraint is the constraint labeled 'NoHiatus' in (30). One of the issues that has been debated is the exact nature of this constraint. In what follows, we will look briefly at this question and several other important issues that arise within OT approaches to hiatus resolution.

13 Under some analyses (e.g. Baković 2007), gliding of [−high] vowels will also incur violations of a constraint Ident[high], which prohibits changes to the feature [high], since the resulting semivowel [w]/[j] is assumed to be [+high].

14 For some proposed constraints relevant to compensatory lengthening which are not considered in this simplified analysis, see Rosenthall (1997).

3.3.1 *What drives hiatus resolution?*

Many descriptions and analyses of vowel hiatus resolution processes (e.g. Brown 1970; Mtenje 1980; Shaw 1980; Katamba 1985; Pulleyblank 1986; Walli-Sagey 1986; Sohn 1987; de Haas 1988; Wiltshire 1992; Balogné Bérces 2006) have suggested that such processes are motivated by factors related to canonical syllable structure, and in particular the need to avoid onsetless syllables (see CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE and CHAPTER 55: ONSETS). In OT, this notion has often been formalized by high ranking of a constraint ONSET that requires syllables to have onsets, thus disallowing heterosyllabic V.V sequences which would arise in contexts where hiatus is maintained.

An alternative view is that hiatus resolution derives from an avoidance of vowel sequences, and not a requirement that all syllables have onsets. Such a view is made plausible by the observation that vowel hiatus seemingly involves unique phonetic difficulties not found with word-initial onsetless syllables. At least two kinds of difficulty have been cited. First, mutual co-articulatory interaction in a sequence of adjacent vowels tends to perturb the quality of each vowel, potentially making accurate identification of vowel qualities more difficult (Borroff 2003). A different explanation is proposed by de Haas (1988), who sees the problem as a kind of "sonority clash" or "bad syllable contact" (see CHAPTER 49: SONORITY and CHAPTER 21: VOWEL HEIGHT). The adjacent heterosyllabic vowels have (roughly) equal sonority, whereas the preferred transition between syllables should involve a sonority trough. Under the widespread assumption that constraints exist in response to particular phonetic challenges, these considerations lend support to the view that there should be some phonological constraint that specifically excludes hiatus.

Several studies have raised novel arguments that hiatus resolution cannot always be attributed to ONSET. Orie and Pulleyblank (1998) argue that attributing hiatus resolution to ONSET in Yoruba misses important generalizations about the conditions that govern the distribution of different hiatus resolution strategies across different contexts. They adopt instead a constraint NOHIATUS, which is violated by vowels in hiatus but not by onsetless syllables in general. Borroff (2003, 2007) presents data from a number of languages in which the same hiatus resolution patterns found with clear /VV/ sequences apply to /VʔV/ sequences as well. In Chickasaw (Borroff 2007: 57, citing Ulrich 1993), for example, /VV/ hiatus is resolved by glide epenthesis, as shown in (31a). Interestingly, the same process applies to /VʔV/, as in (31b).

(31)	a.	/tof-to-a/	→	[toftowa]	'to spit more than once'
	b.	/boʔ-a/	→	[boʔw-a]	'to be beaten'

On the assumption that an intervocalic [ʔ] should suffice to satisfy ONSET, the fact that the same glide epenthesis process applies even when an intervocalic [ʔ] is present argues that something other than ONSET is responsible for hiatus resolution in this case. Borroff (2003) argues for a constraint VCV-COORD, motivated with reference to phonetic facts involving the sequencing of vowel gestures, which in essence requires that a consonantal target appear between two different vowels.[15]

[15] More precisely, the label VCV-COORD is a shorthand for a conjoined alignment constraint (see CHAPTER 62: CONSTRAINT CONJUNCTION) ALIGN(V_1, release, C_1, target) & ALIGN(C_1, release, V_2, target), which is described in prose as a requirement to "align the release of the first vowel in a sequence of vowels with the achievement of the target of a consonant, and align the release of that same consonant with the achievement of the target of the second vowel of a sequence" (Borroff 2003: 11).

Though the constraint is equivalent for most purposes to NoHiatus, it is (in contrast to Onset) crucially not satisfied by an intervocalic glottal stop, which lacks an (oral) gestural target. An alternative analysis (Borroff 2007) is to assume that a prevocalic glottal stop does not in fact satisfy Onset. In either case, patterns such as these raise interesting challenges for familiar assumptions about hiatus resolution and its motivations.

3.3.2 *Directionality in vowel elision*

Any analysis of vowel elision in hiatus contexts must account for the choice of vowel, V_1 or V_2, that is elided. In rule-based models, the deleted vowel is typically specified directly in the form of the elision rule. For example, both the linear deletion rule (20c) and the autosegmental deletion rule (22b) given above stipulate deletion of the *first* of two adjacent vowels. In contrast, an account within Optimality Theory must assume that elision of V_1 or V_2 in a given context will violate different constraints, whose relative ranking determines which outcome occurs. The problem then becomes to identify the relevant constraints. The possible rankings of these constraints should also suffice to generate the V_1 or V_2 elision cases that are attested cross-linguistically, without predicting patterns that are unattested. Arguably, the relevant generalizations to be accounted for are at least approximately as summarized in (12) above.

A possible account of these generalizations is outlined in Casali (1997). The explanation assumes that at a prefix–root juncture or a boundary between two content words, V_2 is protected by a constraint MaxMI or MaxWI, demanding, respectively, preservation of morpheme- and word-initial vowels. In addition, the analysis continues to assume a generic Max constraint that is violated by deletion of a segment in *any* context. The analysis also assumes a constraint MaxLex requiring preservation of segments in roots and in content words. Crucially, there are no analogous Max constraints that specifically target word- or morpheme-*final* position, or affixes or function words.

A consequence of these assumptions is that in some contexts the constraint violations incurred by elision of V_1 will be a subset of those incurred by V_2 elision. At a prefix–root boundary, for example, elision of V_2 violates MaxMI (since V_2 is the root-initial segment), MaxLex, and (ordinary) Max, while elision of V_1 violates only the latter (assuming we are dealing with a minimally CV prefix, so that V_1 is not morpheme-initial).[16] Since the constraint violations incurred by V_1 elision in this context are a subset of those arising with V_2 elision, eliding V_2 in this context should, all else being equal, be more costly than eliding V_1. Thus, only V_1 elision is ordinarily expected in this context. This is illustrated below, using a hypothetical CV prefix and VCV root. Note that there is no ranking of the constraints under which the second candidate, with V_2 elision, is optimal.

(32)

/CV$_1$-V$_2$CV/	MaxMI	MaxLex	Max
☞ a. CV$_2$CV			*
b. CV$_1$CV	*!	*	*

[16] The full analysis in Casali (1997) actually predicts that V_2 elision should be possible at prefix–root boundaries in the special case of a V prefix, since V_1 is protected by MaxWI and an additional constraint MaxMS requiring preservation of monosegmental morphemes. We will ignore these complications here.

Similarly, only V_1 elision is predicted when underlying vowels abut at the boundary between two content words. In this case, both V_1 elision and V_2 elision violate MAXLEX and general MAX; the two possibilities thus tie on these constraints. However, since V_2 elision violates MAXWI while V_1 elision does not, the former outcome is less optimal. This is illustrated below for a sequence of two hypothetical VCV content words.

(33)

/VCV₁ V₂CV/	MAXWI	MAXLEX	MAX
☞ a. VC V₂CV		*	*
b. VCV₁ CV	*!	*	*

In other contexts, elision of either vowel is predicted to be possible. For example, at a root-suffix boundary V_2 elision violates MAXMI but not MAXLEX. Thus, V_2 elision is possible if MAXLEX outranks MAXMI, as shown below using a hypothetical VCV root and VC suffix:

(34)

/VCV₁-V₂C/	MAXLEX	MAXMI	MAX
a. VCV₂C	*!		*
☞ b. VCV₁C		*	*

V_1 elision, which violates MAXLEX but not MAXMI, is predicted under the opposite ranking:

(35)

/VCV₁-V₂C/	MAXMI	MAXLEX	MAX
☞ a. VCV₂C		*	*
b. VCV₁C	*!		*

For roughly analogous reasons, both V_1 elision and V_2 elision are predicted possibilities at the boundary between a content word and a following function word; in this context V_1 elision violates MAXLEX but not MAXWI, while V_2 elision violates only the latter.

Note that this model encodes no general context-independent preference for elision of V_1; the overall statistical predominance of V_1 elision noted above arises indirectly from the fact that V_1 elision is predicted in a wider range of contexts. An alternative interpretation of the observed typology might suppose that there is a general context-independent preference for preservation of V_2, expressible as some constraint(s), and that this can be overridden in cases where V_1 occurs in a prominent position (and hence falls under the protection of some positional faithfulness constraint). The view that hiatus patterns reveal a general context-independent preference for preservation of V_2 is expressed by Lamontagne and Rosenthall (1996) (see also Alderete 2003), who refer to this effect as the *persistence of* V_2.

Finding evidence to distinguish the two accounts is not easy. There is one context, however, in which the two views potentially make different predictions: where underlying vowels come together morpheme-internally, for example due to the optional deletion of an intervening consonant. While the Casali (1997) model offers no clear predictions in such cases, a model assuming general persistence of V_2 should predict, all else being equal, that V_1 must elide. A number of languages do show vowel elision in such cases, and in at least some of them, this prediction is not borne out. Yoruba (Orie and Pulleyblank 1998; Pulleyblank 1998) and Igbo (Emenanjo 1972) both elide V_2, not V_1, in such cases. Though it might be premature to rule out the possible influence of other factors in these cases, these patterns at least appear to challenge the Persistence of V_2 view, especially since both languages normally show V_1 elision in other contexts (which could be attributed to constraints favoring preservation of initial segments).

3.3.3 *Epenthetic consonants and markedness*

As noted in §2.1 above, only certain consonants are widely observed to function epenthetically as hiatus interrupters. An adequate phonological theory should explain why this is so. Within OT, the problem of explaining the range of possible epenthetic consonants is closely tied to the question of *markedness* (see CHAPTER 4: MARKEDNESS; CHAPTER 12: CORONALS; CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION). Since epenthetic consonants, by definition, are not present underlyingly, their featural content is not affected by faithfulness constraints requiring preservation of phonological material. Consequently, the epenthetic consonant used to resolve hiatus in a given language should be the consonant that is optimal with respect to relevant markedness constraints alone, as these are ranked in the language. The predicted typological range of possible epenthetic consonants should thus follow from the set of universal markedness constraints posited, together with any restrictions (assumed in some models) on their possible rankings.

We can illustrate the basic principles at issue with reference to markedness constraints on place of articulation (POA), which have received much attention in the recent literature. OT models have generally assumed markedness constraints targeting each major POA feature, e.g. the constraints *Lab, *Cor, *Dors, and *Glot, which ban, respectively, labial, coronal, dorsal (e.g. velar), and glottal consonants. All else being equal, the particular epenthetic consonant employed in a language is predicted to have the POA of whichever POA constraint is ranked lowest, e.g. a glottal consonant is expected if *Glot is lowest-ranked.

In a theory in which the possible ranking of these POA constraints varies freely across languages, we should expect that any POA could function epenthetically in some language. However, some phonologists have assumed that certain places of articulation are universally more marked than others. For example, de Lacy (2006) assumes the fixed scale in (36), where ">" means "is more marked than."

(36) dorsal > labial > coronal > glottal

It would be straightforward enough to translate this scale into a universally fixed ranking (i.e. one which is stipulated to hold in all languages as part of Universal Grammar) of POA constraints, as in (37).

(37) *Dors >> *Lab >> *Cor >> *Glot

Fixed rankings of this sort, with some disagreement over details, have played a role in a number of OT analyses (see for example Lombardi 2002). In place of such a fixed hierarchy, however, de Lacy (2006: 2) adopts a different technical implementation of the same general idea, specifically the set of freely rankable POA markedness constraints in (38):

(38) a. *[Dors] Assign a violation for each [dorsal] feature.
b. *[Dors,Lab] Assign a violation for each [dorsal] and each [labial] feature.
c. *[Dors,Lab,Cor] Assign a violation for each [dorsal], each [labial], and each [coronal] feature.
d. *[Dors,Lab,Cor,Glot] Assign a violation for each [dorsal], each [labial], each [coronal], and each [glottal] feature.

In this system, a consonant at a POA further to the left on the scale in (36) will always incur worse violations of these POA constraints than one further to the right. This is because the violations incurred by a POA further to the left are necessarily a superset of those incurred by a POA further to the right, regardless of how these constraints are ranked, as shown below (de Lacy 2006: 50):

(39)

	*{Dors}	*{Dors,Lab}	*{Dors,Lab,Cor}	*{Dors,Lab,Cor,Glot}
k	*	*	*	*
p		*	*	*
t			*	*
ʔ				*

(Crucially, there are no further POA constraints, e.g. *{Cor} or *{Cor,Glot}, targeting other individual places or place combinations.)

If a fixed place markedness hierarchy of this sort were the whole story, we would predict that epenthetic consonants would always be glottals, since an epenthetic glottal consonant is always least costly according to this constraint system. This prediction is too restrictive, as it does not account for various other possibilities (e.g. coronals or a homorganic semivowel) that are reported to exist (see §2.1 above).

De Lacy's solution assumes that there are additional markedness scales that refer to dimensions other than place, and that these interact with the place markedness hierarchy to produce the observed range of typological possibilities. For example, the possibility of epenthesizing a coronal stop [t], as in Axininca Campa, follows from the assumption of an additional set of markedness constraints (this time related not to place but to manner of articulation) against high-sonority consonants in onsets, along with the further (and controversial – see Lombardi 2002; Uffman 2007) assumption that glottal consonants [ʔ] and [h] are higher in sonority than all non-glottal consonants (see chapter 49: sonority). These assumptions motivate a constraint *__ Δ_σ/Glot prohibiting glottals in syllable margins (onsets or codas). In languages in which *__ Δ_σ/Glot is ranked above the relevant POA markedness constraints, glottals will be excluded as epenthetic hiatus interrupters, despite their (universal) optimality with respect to POA alone. With glottals ruled out, the predicted outcome (all else being equal) should be the POA that fares second best according to the constraint system (see (39)). This is coronal.[17] The predicted outcome is illustrated in (40), using a hypothetical input /ai/.

[17] See Lombardi (2002) for a similar proposal.

(40)

/ai/	*__ Δ_σ/ GLOTTAL	*{DORS}	*{DORS,LAB}	*{DORS,LAB, COR}	*{DORS,LAB, COR,GLOT}
a. aki		*	*	*	*
b. api			*	*	*
☞ c. ati				*	*
d. aʔi	*				*

Epenthetic homorganic semivowels (e.g. [w] following /u/, [j] following /i/) are predicted in de Lacy's theory in cases where further markedness constraints requiring consonants (including epenthetic ones) to agree in their place and manner features with adjacent vowels are highly ranked. Additional markedness constraints generate a few further predicted possibilities in languages in which they are highly ranked. In all, the model predicts the following restricted range of epenthetic consonants in hiatus contexts: [ʔ t h ɹ r w j]. De Lacy claims that this set corresponds to the attested range of possibilities.

While de Lacy's theory provides a detailed, plausible, and comprehensive OT account of consonant epenthesis, it is unlikely to be the last word on the subject. The topic of markedness (both with respect to epenthesis and other areas) has been an extremely complex and controversial one. Among other things, some phonologists (see Hume 2003; Rice 2007; CHAPTER 12: CORONALS; CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION) have questioned the claim that glottal (or any other) place of articulation is universally unmarked, arguing that either dorsal or labial (as well as coronal) can also function as the unmarked place in some languages. If this is correct, it would suggest the possibility of epenthetic consonants such as [p] or [k] as well. It remains, perhaps, to be seen whether such cases exist. De Lacy discusses several reported cases, but argues that they are better analyzed in other terms (for example because putative epenthetic consonants in some such cases can be treated as present underlyingly).

At present, a clear understanding of the typology of consonant epenthesis is arguably somewhat clouded by lack of clear consensus on relevant empirical generalizations. Considerable disagreement exists over the interpretation of patterns in some individual languages, a famous example being the question of whether the "intrusive r" phenomenon found in some English dialects (e.g. the pronunciation of *saw it* as [sɔɹɪt] in some Eastern Massachusetts dialects, including my own) constitutes epenthesis (see de Lacy 2006, Lombardi 2002, and Uffman 2007 for discussion of this and other cases). Certain cross-linguistic generalizations have also been disputed. For example, while glottal stop is widely regarded as a frequent choice of hiatus interrupter, Uffmann (2007) proposes that glottal stops are not typically inserted primarily to avoid hiatus, but are generally used (German is cited as one example) to provide an onset in prosodically strong positions, e.g. word-initially or before a stressed vowel, where they function to create a maximized sonority contrast with the following vowel. (This account crucially assumes that glottal stops are the *lowest* sonority consonants, which is exactly the opposite of what de Lacy assumes.) Undoubtedly, there will be further debate over some of the relevant empirical generalizations, as well as their appropriate theoretical treatment.

3.4 *The problem of gradience*

An important distinction in most phonological theories is the distinction between *categorical* and *gradient* processes (see CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). A categorical change involves a clear "either-or" shift in the presence of one or more segments or their features, as in a case where an underlying segment is removed completely (elision) or undergoes changes in the binary values of one or more features. Frequently, however, languages manifest gradient processes that involve changes in the *degree* of some feature, e.g. a phonemically oral vowel is slightly nasalized next to a nasal consonant but remains less nasal than phonemic nasal vowels in the same language. In hiatus contexts, a possible gradient change might involve the "near elision" of one of the adjacent vowels, e.g. a case where an underlying /V_1 V_2/ sequence is realized phonetically as V_2 (perhaps with lengthening) preceded by a short and variable remnant of V_1.

Hiatus resolution processes have most often been described and analyzed in terms that suggest categorical changes. However, two recent instrumental studies, Baltazani (2006) and Zsiga (1993, 1997), have shown that hiatus resolution patterns (glide formation and/or vowel elision) that had previously been described as categorical in two languages, Modern Greek and Igbo, respectively, actually involve gradient and highly variable timing adjustments. For reasons of space, we will consider only the Igbo case here.

Sequences of adjacent vowels arise very commonly in Igbo in cases where a word ending in a vowel precedes a word beginning in a vowel, as in the phrases shown below (from Zsiga 1997; the diacritics mark [–ATR] vowels).

(41) /a̙sa̙to̙ a̙to̙/ 'three sevens'
/o̙ti̙ o̙zo̙/ 'another grub'
/ezi a̙to̙/ 'three loans'
/ede a̙to̙/ 'three coco-yams'

Three Igbo subjects in Zsiga's (1993) study each produced six repetitions of each of these and various similar phrases in which one of the eight Igbo vowels occurs word-finally before one of the words [a̙to̙] 'three' or [o̙zo̙] 'another'. (In all, each of the eight vowels was used in two utterances.)

Vowel formant measurements of the digitized recordings showed extreme variation, even for the same utterance produced by the same speaker, in the realization of the underlying vowel sequences. These ranged from tokens showing essentially no deletion or assimilation (i.e. in which both vowels clearly surface) to those showing complete loss of V_1 (i.e. with the output consisting entirely of a lengthened version of V_2). If all the observed outcomes were of one of these two types, this might suggest a categorical but optional rule eliding V_1 with compensatory lengthening of V_2 (or a rule of total assimilation of V_1 to V_2). Importantly, however, the results show a range of intermediate realizations as well, in which formant values near the beginning of the vocalic span show a quality intermediate between V_1 and V_2. This intermediate quality varies across repetitions of the same utterance from one that is more similar to V_1 to one that is more similar to V_2. Zsiga argues that such findings are not easily reconcilable with an analysis that treats hiatus resolution as optional but categorical, and that the process is better understood as an adjustment in the relative timing of V_1 and V_2. More specifically, achievement of the target articulatory gestures for V_2 varies from relatively late (allowing for a more or less normal manifestation of a preceding V_1) to relatively early (resulting in partially assimilated tokens) to virtually at the release of the preceding consonant (in which case V_1 is essentially gone). Seen from this perspective, superficial instances of categorical deletion in some of the tokens are better regarded as simply the extreme endpoint of a process that applies along a continuum.

Though specific proposals vary, it has been widely assumed that the familiar kinds of phonological rules and/or constraints standardly used in the analysis of categorical processes are not appropriate to the treatment of gradient sound changes. Zsiga analyzes gradient hiatus resolution in Igbo using the framework of articulatory phonology (Browman and Goldstein 1990), a model that is well suited to handling variable adjustments in the relative timing of gestures.

In addition to highlighting the importance of (and need for additional) explicit theoretical treatments of gradient changes in hiatus contexts, these studies raise an important empirical issue as well. Hiatus resolution in both Igbo and Modern Greek had been described in some previous studies as categorical. This raises the possibility (see Zsiga 1997: 265) that other hiatus resolution processes that have been described as categorical in the literature might turn out to be gradient upon closer examination. Studies such as Baltazani's and Zsiga's underscore the need for careful attention to the possibility of gradience in the context of descriptive phonological fieldwork.

4 Summary

Hiatus resolution patterns are extremely varied. This chapter has provided a brief and necessarily selective look at some of the variation that occurs in the behavior of particular hiatus resolution processes and in their co-occurrence and interaction.

The range of explanatory models that have arisen in connection with hiatus resolution phenomena is also very broad. We have looked at a sample of theoretical proposals from several time periods, including early generative treatments, autosegmental analyses, and several OT models. The central research questions have varied somewhat from model to model. Whereas rule formalism and related issues were a central concern in early generative analyses, autosegmental analyses used more elaborated phonological representations to suggest new solutions to problems such as compensatory lengthening, the featural output of coalescence, and the role of syllable structure in hiatus resolution. Issues that have arisen within OT include the primary markedness constraint that triggers hiatus resolution, the constraint rankings that determine which of two adjacent vowels elides, and the problem of accounting for the range of consonants that can function epenthetically as hiatus interrupters. Finally, we have looked briefly at an issue, gradient hiatus-related processes, which poses potentially important theoretical and empirical challenges for any approach.

ACKNOWLEDGMENTS

I am grateful to Beth Hume, Marc van Oostendorp, Keith Snider, and two reviewers for their valuable comments and suggestions on an earlier version of this paper, and to Sudharsan Seshadri Nagarajan for assistance with relevant library research.

62 Constraint Conjunction

Megan J. Crowhurst

> . . . conjunctive interaction is from a formal point of view entirely natural in OT; indeed, in an important sense, its *absence* would be *unnatural*. By this I mean simply that without conjunction, basic OT typologies are not strongly harmonically complete, but with conjunction, they are. (Smolensky 2006: 139)

Interactions among constraints in early Optimality Theory (Prince and Smolensky 1993) were limited to a mode of strict domination, represented by the connective ">>." However, researchers soon noted that a theory of constraint interaction relying on strict domination did not adequately account for certain well-known sound behaviors, prompting arguments in favor of additional modes of interaction. Three main proposals for combining simple constraints into more complex ones using connectives other than ">>" were advanced: local conjunction, an analog of Boolean conjunction, and material implication.

1 Classical Optimality Theory

Optimality Theory (OT) made its debut in linguistics through the work of Prince and Smolensky (1993), who adapted a constraint-based model with a long history in other fields (including evolutionary biology, the information sciences, and economics) for the formal analysis of sound phenomena in language. In Prince and Smolensky's model, input states are mapped to output states through a procedure in which a set of potential analyses of the input (output candidates) is passed through a filter consisting of an evaluator, Eval, and a hierarchy of constraints restricting properties of the output. The constraints are members of Universal Grammar, and the priorities assigned to them vary by language. OT constraints are soft constraints – any constraint can be violated, but only under pressure from a constraint with higher priority. The predicted output is the candidate that survives the filter. This candidate is *optimal* in that it represents the input–output mapping that best satisfies the hierarchy by minimizing violations of higher-ranking constraints at the expense of lower-ranking ones.

According to the doctrine of strict domination, if two constraints A and B interact, then constraint A outranks B (or vice versa) in the hierarchy, notated as

A >> B (or B >> A). An interaction A >> B is exposed when the requirements of A and B are incompatible, and there is an input whose properties are such that no viable candidate satisfies both constraints. In such cases, the higher-ranking constraint A is easy to identify because its effect is evident, while B's effect is obscured. (Constraint B may, however, take effect when A is not at stake.) The following tableau illustrates the evaluation of a mini-set of two candidates, each violating either A or B and not the other. Being higher-ranked, A acts on the candidate set first: the candidate which best satisfies A is kept, and the less successful candidate (in regard to constraint A) is rejected. In this simple example, the candidate that fares best on A is the optimal candidate. Were the rankings of A and B reversed, candidate 2 would be the winner instead.

(1) *Constraint A >> Constraint B*

Input	Constraint A	Constraint B
☞ a. output candidate 1		*
b. output candidate 2	*!	

Given that OT is a theory of constraint interaction, an important issue naturally concerns the ways in which constraints might interact. As noted, for Prince and Smolensky and much subsequent work, only strict domination was sanctioned as a mode of constraint interaction.[1] Over time, various researchers have challenged this doctrine in considering what other relationships might hold among constraints. Some researchers have proposed a relation of *non-dominance*, in which neither constraint A nor B dominates the other (Crowhurst 2001). Under non-dominance, violations of A and B together are evaluated cumulatively. Others have argued that constraints can exist in a free ranking relationship to account for optional sound phenomena (e.g. Reynolds 1994; Prince 2001; Itô and Mester 2003a; Jacobs 2004). This chapter reviews proposals that have addressed the question "Can simple constraints combine with one other, and if so, how?" Or, "What connectives other than '>>,' if any, define relationships that can hold among constraints?"

2 Local conjunction: Rejecting the "worst of the worst"

The first proposal for combining constraints beyond the standard mode of strict domination, introduced in Smolensky (1993, 1995, 1997) and subsequently worked out in a series of presentations culminating in Smolensky (2006), was that elemental OT constraints can be *locally conjoined* to form a more complex constraint that is violated only if both of its members are violated in a specified domain. Other influential discussions of the details and applications of local conjunction appeared in a series of papers by Itô and Mester (e.g. 1996, 1998, 2003a), culminating in Itô and Mester (2003b). Smolensky's definition of local conjunction appears in (2) (Smolensky 2006: 43).

[1] Discussion here is limited to proposals advanced in the core OT phonological literature. Combinatorial devices have been used uncontroversially in probabilistic models of OT.

(2) *Local conjunction within a domain D*

*A $\&_D$ *B is violated if and only if a violation of *A and a (distinct) violation of *B both occur within a single domain of type D.

In evaluating local conjunctions, EVAL returns a mark "*" only when both conjuncts are violated, (3a). Some authors have observed (e.g. Hewitt and Crowhurst 1996) that local conjunction is in fact analogous to logical disjunction: "*" is equivalent to False (F), and the absence of a mark is equivalent to True (T). This can be seen by comparing (3a) with the truth table for logical disjunction.

(3) a. *Evaluation of a local conjunction*

	C_1	$C_1\&_DC_2$	C_2
Cand1			
Cand2	*		
Cand3			*
Cand4	*	*!	*

b. *Logical disjunction*

	C_1	$C_1 \vee C_2$	C_2
Cand1	T	T	T
Cand2	F	T	T
Cand3	T	T	F
Cand4	F	F	F

Itô and Mester (2003b: 24) and Smolensky (2006) assume that "&" is a combinatorial operation made available by UG to individual languages, which may *activate* "&" to derive complex constraints on a language-specific basis. On this view, all of the constraints specified in Con_{UG}, the universal set, plus any language-specific local conjunctions, are mapped onto a larger, language-specific constraint set, Con_G. So, ">>" determines strictly hierarchical rankings, while "&" combines constraints into "superconstraints," which can then be inserted into hierarchies defined by ">>."[2] The role of the "&" operator in grammars is formally defined by Itô and Mester (2003b: 25) as in (4).

(4) *Role of local conjunction in grammars*

A grammar G can expand the basic constraint set Con inherited from Universal Grammar to a superset $\text{Con}_G = \text{Con} \cup \{C_1\&C_2\}$, for $C_1, C_2 \in \text{Con}$. Expansion is potentially recursive, so that Con_G can in turn be extended to a superset Con_G' by adding $C_3\&C_4$ to Con_G, for $C_3, C_4 \in \text{Con}_G$, and so on.

2 But see Itô and Mester (1998) and Baković (2000) for a slightly different view.

The main goal of local conjunction is to derive empirical generalizations about markedness from irreducible principles. Constraint conjunction and other proposals for combining constraints have been criticized on the grounds that they greatly increase the expressive power of the formal architecture of OT by exponentially expanding the constraint set. However, the insights, the improvements in precision, and to some extent the economies achieved with local conjunction have often been impressive.

2.1 Coda conditions

The earliest works to employ local conjunction (e.g. Itô and Mester 1996; Spaelti 1997; Smolensky 2006) noted that the mechanism could be used to advantage in analyzing coda conditions, constraints which impose strict conditions on syllable codas rather than penalizing them outright (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE; CHAPTER 53: SYLLABLE CONTACT). Coda conditions have often been captured by the schema CODACOND[α], where α denotes restricted features. A common requirement is for obstruents in coda positions to be voiceless, other factors being equal (e.g. German, Turkish, Russian; see CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). The coda condition for voicing appears in (5).

(5) CODACOND[voi]

$$\left. \begin{array}{c} *\text{C} \\ | \\ \begin{bmatrix} -\text{son} \\ +\text{voice} \end{bmatrix} \end{array} \right]_\sigma$$

(One * for any voiced obstruent syllabified exclusively as a syllable coda.)

Early work promoting local conjunction noted that coda conditions can be treated as local conjunctions of two well-established constraints, NOCODA in (6a) on the one hand, and a markedness constraint such as (6b) on the other, to yield (6c), with the segment as the local domain of evaluation (Smolensky 1993, 2006; Itô and Mester 2003b; see also Morris 2002).

(6) a. NOCODA
Syllables do not have codas. (One * per syllable with a coda.)

b. *VOIOBST
*[−sonorant, +voice]. (One * for any voiced obstruent.)

c. NOCODA $\&_{SEG}$ *VOIOBST
(One * for any segment which is in a syllable coda *and* which is a voiced obstruent.)

Local conjunctions such as (6c) capture the intuition that constraints expressing coda conditions are really more restrictive versions of NOCODA. A standard assumption has been that a local conjunction is ranked above its conjuncts, and this is consistent with the understanding that the effects of special constraints are visible only when some constraint intervenes between the special constraint and a related, less highly ranked general constraint. In the case under discussion, restrictions on codas are visible in a grammar only when the following are true: (i) Max$_{IO}$(Seg) outranks both instantiations of NoCoda – the unconjoined version and the local conjunction in (6c) – so that the effects of the conjunction are not obscured by deletion; and (ii) Ident$_{IO}$[voi] ranks above the unconjoined constraint *VoiObst, allowing a surface obstruent voicing contrast, but below (6c), so that only voiceless obstruents will occur in coda position, unless higher-ranking constraints demand otherwise (as in cases of regressive voice assimilation). A tableau making this point is given in (7) (adapted from Itô and Mester 2003b: 27–28).

(7)

liːb	Max$_{IO}$(Seg)	NoCoda &$_{SEG}$ *VoiObst	Ident$_{IO}$[voi]	*VoiObst	NoCoda
☞ a. liːp			*		*
b. liːb		*!		b	*
c. liː	*!				

liːbə	Max$_{IO}$(Seg)	NoCoda &$_{SEG}$ *VoiObst	Ident$_{IO}$[voi]	*VoiObst	NoCoda
☞ a. liːbə				b	
b. liːpə			*!		

Three advantages to the reformulation of (5) as (6c) are immediately apparent. First, locally conjoining *VoiObst with NoCoda avoids the redundancy that occurs when *VoiObst is stated twice, once as the general feature co-occurrence constraint in (6b), and once again, embedded in the coda condition, (5). Second, restating a given CodaCond constraint as the local conjunction of NoCoda with a standard markedness constraint explains why we have restrictions on coda consonants, but no constraints that express similar restrictions on onsets (Itô and Mester 2003b: 29). In a grammar that allows conjunction, nothing prevents the local conjunction of Onset and a markedness constraint like *VoiObst, but as tableau (8) shows, a conjunction like Onset &$_{SEG}$ *VoiObst could never be violated: if Onset is violated, then there is no onset consonant to check against *VoiObst. Conversely, if *VoiObst is violated by a consonant in onset position, then Onset is clearly not violated.

(8)

bit	Onset &$_{SEG}$ *VoiObst	*VoiObst	Onset
a. bit	*!	b	
☞ b. pit			
c. it			*!

This latter result of local conjunction weighs strongly in its favor: given that *VoiObst encodes a standard generalization about markedness, and given that coda conditions stated in traditional terms following the model of (5) are common, it is notable that no evidence has been found for mirror image constraints imposing comparable restrictions on segments in onset position. The traditional approach has been to assume that a formal asymmetry matches the empirical one – that is, that there are no Onset conditions, or constraints imposing CodaCond-like requirements on segments in onset position. As we have just seen, the local conjunction approach requires no formal asymmetry: local conjunctions like Onset $\&_{SEG}$ *VoiObst might exist, but as they can never be active in selecting surface candidates, they will never be rankable, and their existence is moot.

2.2 *Universal markedness hierarchies*

Local conjunction has also been used successfully in explaining the fact that universal markedness hierarchies are preserved in multiple domains. Much work establishes the place harmony scale in (9a) (chapter 22: consonantal place of articulation). In OT grammars, this scale is expressed by the hierarchy in (9b). The subscript "UG" indicates that this ranking is "fixed," or specified in universal grammar, and does not vary across languages.

(9) a. Coronal > Labial, Dorsal
    b. *Lab, *Dors $>>_{UG}$ *Cor

The place markedness hierarchy in (9) is known to be preserved in different domains, and Smolensky (1993, 2006) advances a detailed argument as to why this might be so: given that (9b) is fixed in UG, any hierarchy in which the constraints in (9b) are locally conjoined with other constraints will be similarly fixed. To continue with the example of coda conditions, various authors, including Smolensky (1993, 2006), Zoll (1998), and Itô and Mester (2003b), have observed that locally conjoining the markedness constraints in (9b) with NoCoda produces the hierarchy in (10), which favors coronals over labials and dorsals in syllable codas.

(10) NoCoda $\&_{SEG}$ *Lab, NoCoda $\&_{SEG}$ *Dors $>>_{UG}$ NoCoda $\&_{SEG}$ *Cor

Smolensky (2006) uses the same reasoning to explain the commonly observed proliferation of segmental contrasts among coronal consonants in many segmental inventories, relative to the labial and dorsal classes (chapter 12: coronals). As an example, consider the consonant inventory of Tohono O'odham (Uto-Aztecan) in (11).

(11) *Tohono O'odham consonants*

	coronal				
labial	dental	retroflex	palato-alveolar	velar	glottal
p b	t̪ d̪	ɖ	ʧ ʤ	k g	ʔ
	s̪	ʂ			h
m	n̪		ɲ	ŋ	
w		ɭ	j		

The coronal class dominates the inventory: 11 of the 19 consonants are coronals. Note also that the coronals are represented by three places and three manners of articulation (stops, fricative, and affricates) in the obstruent class, whereas the labials and velars are represented only by stops. To abbreviate Smolensky's point, if a single-feature markedness constraint like *[+cont] (specified for fricatives and affricates; see CHAPTER 28: THE REPRESENTATION OF FRICATIVES; CHAPTER 16: AFFRICATES) can be locally conjoined with the fixed hierarchy in (9b), yielding (12), then a grammar that interposes a constraint IDENT$_{IO}$[Place] above *COR &$_{SEG}$ *[+cont] produces an inventory that has [+continuant] coronals, but no continuant obstruents at other places of articulation.

(12) *LAB &$_{SEG}$ *[+cont], *DORS &$_{SEG}$ *[+cont] >>$_{UG}$ *COR &$_{SEG}$ *[+cont]

2.3 *Feature harmonies*

Local conjunction has also been used to account for patterns of vowel and consonant harmony by locally conjoining markedness constraints to form *feature domains* (see also CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 72: CONSONANT HARMONY IN CHILD LANGUAGE; CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY). In Smolensky (2006), any contiguous sequence of segments which share one or more phonological features forms a feature domain, and any feature domain is a possible instantiation of the domain of a conjunction. An abbreviated version of Smolensky's (2006: 64) definition of a feature domain is given in (13).

(13) *Definition of feature domain* ("φ" stands for any feature)

A maximal contiguous span of φ-bearers with a common value [±φ] is a [±φ] feature domain D[±φ]. (Thus, by definition, contiguous domains of the same φ value are impossible.)

Smolensky's use of the feature domain in OT builds on earlier work (e.g. Kirchner 1993; Smolensky 1993; Cole and Kisseberth 1994; Cassimjee and Kisseberth 1998), but the insight that feature domains can be analyzed in terms of local conjunctions of constraints is due to Smolensky. Examples of Smolensky's (2006) use of feature domains as restrictors on local conjunction are seen in his treatments of vowel harmony and restrictions on consonant clusters.

Smolensky (2006) provides an extended discussion of vowel harmony, with special attention given to a pattern of source-conditioned [ATR] harmony found in Lango (Nilotic: Okello 1975; Bavin Woock and Noonan 1979; Noonan 1992; Archangeli and Pulleyblank 1994). The Lango facts are complex; for our purposes, a fragment of Smolensky's account will serve to make the point. Lango has the [+ATR] vowels [i e ə o u] and the [−ATR] vowels [ɪ ɛ a ɔ ʊ] (Noonan 1992). The examples in (14) show a root with a [−ATR] mid vowel /ɛ/ combining with a suffix containing a [+ATR] high vowel, /u/ or /i/. (Tone is omitted in these examples.) In (14a), we see that /ɛ/ assimilates [+ATR] when the suffix vowel is /i/, but not when it is /u/, as in (14b).

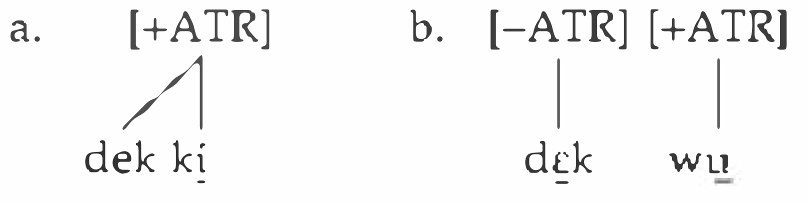
(14) *Lango* [ATR] *harmony*

a. *Regressive* [+ATR] *harmony*
/dɛk +Ci/ dek.ki 'your (SG) stew'

b. *No harmony*
/dɛk + wu/ dɛk.wu 'your (PL) stew'

In autosegmental terms, [+ATR] spreads regressively from /i/ to /ɛ/ in [dek.ki], forming a [+ATR] feature domain whose head is the source vowel [i̲], as shown in (15a). (Smolensky marks heads of feature domains with a superscript "o"; we will adopt the convention of underlining heads of feature domains.) The form [dɛk.wu], where no assimilation has applied, has both a [−ATR] and a [+ATR] feature domain.

(15)



According to Archangeli and Pulleyblank's (1994) autosegmental analysis of Lango, [+ATR] spreads regressively from a [+high] source vowel to a target vowel if one of the following is true: (i) the source vowel is [+front] and the target is any vowel in either an open or closed syllable; (ii) the source vowel is not [+front], source and target vowels are both [+high], and the target is in either an open or closed syllable; or (iii) the source vowel is not [+front], and the target is not [+high], and the target is in an open syllable. [+ATR] spread in (14a) meets condition (i), but (14b) meets none of the conditions for harmony.

Following Archangeli and Pulleyblank (1994), Smolensky's analysis (2006) of Lango draws on the insight that ATR harmony is conditioned by the markedness of segments that combine [−ATR] and [+ATR] with other features. Well-established markedness constraints are shown in (16).[3]

(16) a. [ATR] *and backness*

*[+ATR, −front]	(Avoid [+ATR] back vowels.)
*[−ATR, +front]	(Avoid [−ATR] front vowels.)

b. [ATR] *and height*

*[+ATR, −high]	(Avoid [+ATR] mid and low vowels.)
*[−ATR, +high]	(Avoid [−ATR] high vowels.)

c.

$*V_{[+A]}C]_{\sigma}$	(No [+ATR] vowels in closed syllables.)

Returning to the examples in (14), note that in [dek.ki], in which underlying /ɛ/ harmonizes with /i/, the outcome optimizes the constraint *[−ATR, +front], which prefers [e], but at the cost of violating *[+ATR, −high], which prefers [ɛ]. In [dɛk.wu], however, we see the opposite pattern of constraint satisfaction: [ɛ] in the output optimizes *[+ATR, −high] but violates *[−ATR, +front]. The critical difference is in the source vowel. Archangeli and Pulleyblank's intuition, which Smolensky seeks to capture, is that less marked segments make better domain heads, and that when possible, better domain heads propagate their features through harmony. To the constraints in (16), then, Smolensky's account adds *Hd[+ATR] and *Hd[−ATR], which penalize a segment for being the head of a [+ATR] or [−ATR] domain, respectively.

[3] The constraints in (16) and similar constraints, were proposed as elements of the "grounded phonology" framework developed in Archangeli and Pulleyblank (1994).

(17) a. Hd-L[−ATR]
A [−ATR] domain must be left-headed.
(No regressive [−ATR] spread.)

b. (*[−ATR, +front] & *Hd[ATR]) $\&_{D[ATR]}$ F[ATR]
No [+front] head of an unfaithful [−ATR] domain.
(No [−ATR] spread from a [+front] vowel.)

c. *[−ATR, +high]
Vowels do not combine the features [−ATR] and [+high].
(One * for either of [ɪ ʊ].)

d. (*[+ATR, −front] & Hd-L[ATR]) $\&_{D[ATR]}$ (*[+ATR, −high] & $^*V_{[+ATR]}C]_\sigma$ & F[ATR])
A [+ATR] domain with a [−front] head that is not leftmost must be faithful at a [−high] vowel at a closed syllable.
(No regressive [+ATR] spread from a [−front] source onto a [−high] vowel in a closed syllable.)

The constraints in (17b) and (17d) are complex and require further explanation. The embedded local conjunction (*[−ATR, +front] & *Hd[ATR]) penalizes a vowel which is both the head of an ATR domain and has the features *[−ATR, +front]. According to this restriction, the lax vowels [ɪ ɛ] cannot head an ATR domain. The syllable [dɛk] in [dɛk.wu] violates this requirement. Smolensky uses the expression F[ATR] in the "macro" local conjunction more or less as the more standard Ident[ATR] would be used, to require the segments in an ATR domain to be faithful to the value for [ATR] they came with. Conjoining (*[−ATR, +front] & *Hd[ATR]) and F[ATR], taking an ATR domain as the locus of violation, has the effect of minimizing ATR domains headed by [−ATR, +front] vowels. That is, the macro-conjunction prevents [−ATR] spread from a front vowel, and this is why /dɛk + wu/ surfaces as [dɛk.wu] and not [dɛk.wʊ].

By itself, the first embedded local conjunction in (17d), (*[+ATR, −front] & Hd-L[ATR]), would penalize a [+ATR] domain whose head, a [−front] vowel [u], [ə] or [o], is not leftmost within the domain.[4] The second embedded local conjunction, (*[+ATR, −high] & $^*V_{[+ATR]}C]_\sigma$ & F[ATR]), penalizes an unfaithful [+ATR] domain which contains a closed syllable whose vowel is [−high]. The macro-conjunction formed by locally conjoining the two smaller local conjunctions with an ATR domain as the locus of violation means just this: for a [+ATR] domain whose head is on the right and is one of the vowels [u ə o] to pass the macro-conjunction, there cannot be further to the left a closed syllable with a [−high] vowel, which is unfaithful through assimilation to the head. This is why regressive [+ATR] spread does not apply in /dɛk + wu/, so that on the surface we find [dɛk.wu] and not [dek.wu].

Tableau (18) shows why /dɛk + wu/ surfaces as [dɛk.wu] and not [dɛk.wʊ] or [dek.wu] (i.e. why we have neither regressive [+ATR] harmony nor progressive [−ATR] harmony in this case, under Smolensky's analysis).

[4] For example, a [+ATR] domains such as *e . . . u* would be penalized. Three types of ATR domain are permitted by the local conjunction (*[+ATR, −front] & Hd-L[ATR]). If the head is one of the set [i e ɪ ɛ a ɔ ʊ] (i.e. anything other than [u ə o]), then the head is rightmost or leftmost in the ATR domain. The head can be one of the set [u ə o] if it is domain-initial.

(18) *Lango: No regressive* [+ATR] *harmony*

/dɛk+wu/	(17d)	HD-L[−ATR]	(17b)	*[−ATR,hi]	AGREE[ATR]
a. dek.wu̲	*!				
☞ b. dɛ̲k.wu̲					*
c. dɛ̲k.wʊ			*!	*	

Tableau (19) shows how the analysis works for [dek.ki̲] (from /dɛk + Ci/). In this case, progressive [−ATR] is blocked just as for [dɛ̲k.wu̲], and for the same reason. However, in [dek.ki̲], regressive [+ATR] harmony is not blocked, because in this case, neither the head (a front vowel this time) nor the target of assimilation (the vowel /ɛ/, in an open, not closed syllable) violates the macro-conjunction in (17d).

(19) *Lango: Regressive* [+ATR] *harmony*

/dɛk+Ci/	(17d)	HD-L[−ATR]	(17b)	*[−ATR,hi]	AGREE[ATR]
☞ a. dek.ki̲					
b. dɛ̲k.ki̲					*!
c. dɛ̲k.kɪ			*!	*	

The brief discussion offered here falls short of representing the very complicated pattern of [ATR] harmony found in Lango, or of Smolensky's (2006) minutely detailed account of the same. The goal here has been to illustrate a proposal for combining constraints that are already complex into a macro-constraint. More detailed discussions of the Lango pattern can be found in Noonan (1992), Archangeli and Pulleyblank (1994), and Smolensky (2006).

Another very common type of restriction can be seen in conditions on consonant clusters: in languages that permit consonant clusters at all, coronals tend to combine with other consonants much more permissively than do labials and dorsals (CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS). For example, English allows coronals to cluster with other coronals, with labials, and with dorsal consonants, as shown in (20a). However, with the exception of a few loans (e.g. *Akbar*, *Afghan*) and clusters formed across compound boundaries (e.g. [[*cup*][*cake*]], [[*black*][*bird*]]), labials and dorsals do not cluster with either labials or dorsals, so that (with the regular exception of homorganic nasal + obstruent sequences), clusters such as those in (20b) are generally disallowed.

(20) a.

Cor with Cor	Cor with Lab	Cor with Dors

b.	Lab with Lab	Dors with Dors	Dors with Lab
	*pb, *bp	*kg, *gk	*kp, *pk, *gb, *bg
	*pm, *bm		*km, *gm
	*pf, *bv, *fp, etc.		*kf, *fk, *gv, *vg, etc.

The asymmetric distribution of place in consonant clusters is another effect of the place hierarchy in (9). Smolensky (2006) shows that these effects can be accounted for by locally conjoining the constraints in (9b) with one another to produce a cluster place markedness hierarchy like that in (21) ((21) expands Smolensky's hierarchy to include dorsals)

(21) *Place markedness hierarchy for two-consonant clusters*

$$\left\{\begin{matrix} {}^{*}[\text{Lab}]\&_{CL}{}^{*}[\text{Lab}] \\ {}^{*}[\text{Dors}]\&_{CL}{}^{*}[\text{Lab}] \\ {}^{*}[\text{Dors}]\&_{CL}{}^{*}[\text{Dor}] \end{matrix}\right\} \gg_{UG} \left\{\begin{matrix} {}^{*}[\text{Lab}]\&_{CL}{}^{*}[\text{Cor}] \\ {}^{*}[\text{Dors}]\&_{CL}{}^{*}[\text{Cor}] \end{matrix}\right\} \gg_{UG} {}^{*}[\text{Cor}]\&_{CL}{}^{*}[\text{Cor}]$$

In his analysis of phonotactic conditions on consonant sequences, Smolensky (2006) identifies the domain of local conjunction as a consonant cluster, CL. However, a consonant cluster per se is not a unit of phonological structure. Although Smolensky doesn't discuss consonant clusters in this light, any sequence of segments whose members share features can be thought of as instantiating feature domains. An obstruent cluster, for example, would instantiate the D[±φ] formed by the feature [–sonorant], and a nasal-stop cluster would correspond to the feature domain [–continuant].

2.4 *Counterfeeding effects*

One of the more striking advantages claimed for local conjunction is its usefulness in accounting for counterfeeding effects. Moreton and Smolensky (2002) show, refining a proposal in Kirchner (1996), that local conjunction can account for synchronic chain shifts of the type A → B, B → C.[5] In Western Basque, for example, when two identical vowels are juxtaposed, the low vowel /a/ raises to [e] before [a], and /e/ raises to [i] before [e], as shown in (22) (Kirchner 1996; Moreton and Smolensky 2002; Kawahara 2003).

(22)	a.	/a/ → [e] / __ V (violates Ident[low])			
		alaba bat	'daughter (INDEF)'	alabea	'daughter (DEF)'
		neska bat	'girl (INDEF)'	neskea	'girl (DEF)'
	b.	/e/ → [i] / __ V (violates Ident[high])			
		seme bat	'son (INDEF)'	semie	'son (DEF)'
		ate bat	'door (INDEF)'	atie	'door (DEF)'

The Kirchner and the Moreton and Smolensky account goes as follows: if the unmarked vowel is [i], then we'd expect both /a/ and /e/ to raise to [i] in the shifting environment, other factors being equal. However, each vowel moves only one step up, so that /a/ changes its value for the feature [low], and /e/ changes

5 See also Beckman (2003) and Smolensky (2006: §5).

its value for [high]. Neither adjustment results in a change of both features. This effect can be accounted for if a conjunction of the constraints Ident[low] and Ident[high] is ranked above a set of markedness constraints (presumably including at least one OCP constraint) that promote raising in a hiatus; call this set HR. Thus, either of the Ident constraints can be violated on its own, when they are ranked below HR, but no shift violating both constraints within a segment (the relevant domain) can occur. The tableaux in (23), adapted from Moreton and Smolensky (2002), illustrate the analysis for two identical sequences of vowels, /aa/ in /alaba-a/ and /ee/ in /seme-e/.

(23)

/alaba-a/	Ident[low] $\&_{SEG}$ Ident[high]	HR	Ident[low]	Ident[high]
☞ a. alabea			*	
b. alabaa		*		
c. alabia	*!			*

/seme-e/	Ident[low] $\&_{SEG}$ Ident[high]	HR	Ident[low]	Ident[high]
☞ a. semie				*
b. semee		*!		

In the tableaux for [alabea] and [semie], we see that the sequences /aa/ and /ee/ are ruled out by the markedness constraints (the HR set). For /alabaa/, an output [alabia], with raising to [i], is rejected by the local conjunction – the output is the candidate that violates only one of the Ident constraints (in this case Ident[high]). In the case of /semee/, [semie] with a high vowel is possible because raising in this case violates only Ident[high] and not Ident[low]. Violating only one of the Ident constraints, [semie], does not violate the local conjunction.

2.5 *The conjunction of markedness and faithfulness constraints*

So far, we have discussed the local conjunction of markedness constraints, and the conjunction of faithfulness constraints (chapter 63: markedness and faithfulness constraints). Baković (2000) and Łubowicz (2002, 2005) argue for a special role for the conjunction of markedness with faithfulness constraints (M&F conjunction). Baković (2000) shows that M&F conjunction can be used to resolve what he calls the "majority rules" problem in the analysis of voicing assimilation in obstruent clusters. In cross-syllabic obstruent clusters, voicing assimilation is generally controlled by the obstruent in onset position. In Dutch, for example, the medial clusters /kd/ *zakdoek* 'handkerchief' and /dk/ in *bloedkoraal* 'red coral' surface as [gd] and [tk], respectively (Kager 1999).[6] However, patterns of assimilation

[6] The pattern reported here for Dutch is very common. A seemingly odd characteristic of the dialect Kager describes that voiced fricatives in onset position are always devoiced (e.g. /zv/ in *kaasvorm* 'cheese mould' surfaces as [sf]), and this requirement compels the surface voicelessness of any preceding obstruent.

in word-final obstruent clusters are not influenced by requirements on syllable onsets. Consider a language in which an obstruent voicing contrast is preserved in word-final position, which has word-final clusters of two obstruents such as /bt#/ and /pd#/, and in which the markedness constraint AGREE[voice] (obstruent clusters must agree in voicing) dominates the faithfulness constraint IDENT[voice]. In such a case, where all candidates passing AGREE[voice] fail the faithfulness constraint, the candidate containing the voiceless cluster is selected by *VOIOBST. Where the input provides a two-consonant cluster which already satisfies the agreement constraint, for example /pt/ or /bd/, input voicing is generally preserved, showing that IDENT[voice] dominates *VOIOBST (as long as no "spoiler" constraint intervenes).

(24)

/pd/	AGREE[voice]	IDENT[voice]	*VOIOBST
a. pd	*!		*
b. bd		*	*!*
☞ c. pt		*	

/bt/	AGREE[voice]	IDENT[voice]	*VOIOBST
a. bt	*!		*
b. bd		*	*!*
☞ c. pt		*	

This analysis predicts a different outcome for clusters of more than two obstruents. Tableau (25) shows that in such cases the ranking IDENT[voice] >> *VOIOBST predicts that cluster voicing will be determined by the majority. This yields the typologically supported outcome for clusters like /skd/, in which two of three obstruents are voiceless at input (e.g. English *basked*). Unfortunately, it also predicts rare (if at all attested) outcomes like /zgt/ → [zgd] when two of three obstruents are voiced at input.

(25)

/zgt/	AGREE[voice]	IDENT[voice]	*VOIOBST
a. zgt	*!		**
☞ b. zgd		*	***
c. skt		**!	

/skd/	AGREE[voice]	IDENT[voice]	*VOIOBST
a. skd	*!		*
b. zgd		**!	***
☞ c. skt		*	

Baković shows that the "majority rules" problem is avoided if the constraints IDENT[voice] and *VOIOBST can be locally conjoined, assuming the segment as the domain of the conjunction. In (26) we see that on this analysis, of the two clusters that survive AGREE[voice], [zgd] and [skt], the fully voiced cluster [zkd] is rejected even though it is more faithful, because it violates the conjunction IDENT[voice] $\&_{SEG}$ *VOIOBST (which is ranked above both of its conjuncts).

(26)

/zgt/	AGREE[voice]	IDENT[voice] $\&_{SEG}$*VOIOBST	IDENT[voice]	*VOIOBST
a. zgd		*!	*	***
b. zgt	*!			**
c. zkt	*!	*	*	*
☞ d. skt			**	

Baković's larger point is that the presence of marked segments (in this case voiced obstruents) on the surface is one thing, but the presence of *unfaithful* marked segments is another. In cases of assimilation in mixed clusters, the presence of unfaithful marked segments can be compelled by high-ranking faithfulness constraints (e.g. assimilation to a voiced onset in cross-syllabic clusters). However, when such pressures are absent, *assimilation to the unmarked* is the pattern attested across languages. In Baković's example, an analysis that admits the local conjunction IDENT[voice] $\&_{SEG}$ *VOIOBST guarantees the typologically supported outcome, whereas an analysis that relies exclusively on the unconjoined constraints admits the (unsupported) *assimiliation to the marked* alternative.

Łubowicz (2002, 2005) argues that M&F conjunctions are necessary to account for derived environment effects (CHAPTER 88: DERIVED ENVIRONMENT EFFECTS), using palatalization in Polish (CHAPTER 121: SLAVIC PALATALIZATION) as an example. Other works using local conjunction to account for derived environment effects include Downing (2001) and Itô and Mester (2003a).

2.6 *Local self-conjunction*

As a special case of local conjunction, some researchers have argued that markedness constraints can be "self-conjoined," and that self-conjunction offers new insights into cases of dissimilation that have often been attributed to the OCP (e.g. Fukazawa 1999, 2001; Itô and Mester 1998, 2003b; Alderete 2004; Smolensky 2006). As Itô and Mester (2003b: 29) put it:

> the "Obligatory Contour Principle" is by itself neither a constraint nor a formal universal in phonological theory. The culprit in OCP-type dissimilations is not the adjacency of identical feature specifications on a tier, but the multiple presence of a marked type of structure within some domain.

Self-conjunction is intended to capture the intuition that in dissimilation, one violation of a markedness constraint is tolerated, but a double violation crosses what Itô and Mester aptly call a *markedness threshold*, and is categorically rejected.

As an example, let us consider the role of obstruent voicing in Japanese. In the lexical classes comprised by native Japanese and Sino-Japanese forms, voiced obstruents cannot co-occur within a morpheme (CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS), but neither voiceless obstruents nor voiced sonorants are subject to voicing restrictions (Itô and Mester 1998, 2003b). Thus, morphemes such as those in (27a) and (27b) are typical of Japanese (Itô and Mester 2003b: 34–35). However, native Japanese and Sino-Japanese morphemes containing more than one voiced obstruent (e.g. *[kabazi]) are not.

(27)	a.	kusa	'grass'	kataki	'enemy'
		tako	'octopus'	hotoke	'Buddha'
		sato	'village'	tatami	'straw mat'
	b.	kaze	'wind'	kasegi	'earning'
		geta	'clogs'	kagami	'mirror'
		hada	'skin'	-bakari	'only'

The obstruent voicing contrast in Japanese requires the constraint ranking IDENT_{IO} >> *VOIOBST. The fact that multiple occurrences of voiced obstruents within a morpheme is prohibited is accounted for by self-conjoining the constraint *VOIOBST, with the morpheme as the domain. The conjunction $\text{*VOIOBST}^2_{\text{MORPH}}$ (=*VOIOBST $\&_{\text{MORPH}}$ *VOIOBST) is ranked above IDENT_{IO}. Tableau (28) shows how a set of candidates based on the form *kaze* and the hypothetical input /gaze/ are evaluated under these rankings.

(28)

/kaze/	$\text{*VOIOBST}^2_{\text{MORPH}}$	IDENT_{IO}(Seg)	*VOIOBST
☞ a. kaze			z
b. kase		*!	
c. gase		*!*	g
d. gaze	*!	*	g z

/gaze/	$\text{*VOIOBST}^2_{\text{MORPH}}$	IDENT_{IO}(Seg)	*VOIOBST
☞ a. kaze		*	z
b. kase		**!	
☞ c. gase		*	g
d. gaze	*!		g z

Self-conjunction can account not only for passive restrictions on the occurrence of similar structures within a domain, but also cases in which the existence of alternations makes the dissimilation more obvious. A well-known example is Lyman's Law, which blocks the effect of Rendaku, a phenomenon seen in Japanese lexical compounds. Rendaku assigns the feature [+voice] to a voiceless obstruent appearing as the initial consonant of the second member of a compound. The feature [+voice] is treated as a special morpheme in this case, and as such, its presence in the output is required by the constraint RealizeMorph, defined in (29) (Walker 2000; chapter 103: phonological sensitivity to morphological structure).

(29) RealizeMorph

Every morpheme has a phonological exponent in the output. (One * for any null morpheme.)

The Rendaku effect requires RealizeMorph to be ranked more highly than Ident_{IO}(Seg). Tableau (30) is adapted from Itô and Mester (2003b: 37) (constraint names have been changed to match the names used here). The examples used in tableaux (31) and (30) are /ori + kami/ → [origami] 'paper folding' and /kami + kaze/ → [kamikaze] 'divine wind'.

(30)

/ori+R+kami/	RealizeMorph	Ident_{IO}(Seg)	*VoiObst
☞ a. origami		*	g
b. orikami	*!		

The Lyman's Law effect occurs because the self-conjunction $\text{*VoiObst}^2_{\text{Morph}}$ dominates RealizeMorph, neutralizing its effect.

(31)

/kami+R+kaze/	$\text{*VoiObst}^2_{\text{Morph}}$	Realize Morph	Ident_{IO}(Seg)	*VoiObst
☞ a. kamikaze		*		z
b. kamigaze	*(gaze)!		*	g z

Beyond the examples discussed in §2 local conjunction and its special variant, self-conjunction have been used in the analysis of a diverse set of phenomena. Local conjunction has been used in analyses of sonority distance restrictions on syllable structures (Baertsch 1998; Baertsch and Davis 2003; Smolensky 2006), the sonority hierarchy (Smolensky 2006), tone sandhi in Mandarin Chinese (Lin 2000), glide formation in German (Hall 2004, 2007), and accentual phenomena (Alderete 1999). Finally, Levelt *et al.* (1999) and Levelt and van de Vijver (1998) propose that local conjunction plays a role in children's acquisition of the constraint hierarchy of the language they are learning.

3 Other modes of constraint combination

Other proposals for deriving complex constraints from simpler ones using connectives other than "&" have included constraint analogs of Boolean conjunction and two versions of material implication.

3.1 *The "best of the best"*

Hewitt and Crowhurst (1996) and Crowhurst and Hewitt (1997) argue that in addition to local conjunction and self-conjunction, a proper account of some phonological patterns is best achieved using complex constraints derived using a connective, "$\wedge$," with the semantics of Boolean conjunction. Crowhurst and Hewitt call this mode of interaction simply "constraint conjunction." Here, we will call it b-conjunction, to distinguish it from local conjunction. In contrast to local conjunction, which bans the "worst of the worst," b-conjunction insists on the "best of the best." See the definitions and tables in (32) and (33).

(32) a. *Boolean conjunction*
The conjunction $A \wedge B$ is true iff proposition A is true *and* proposition B is true.

b. *B-conjunction*
A candidate Cand passes a b-conjunction $A \wedge B$ iff Cand passes constraint A *and* Cand passes constraint B.

(33) a. *Boolean conjunction*

A	$A \wedge B$	B
T	T	T
F	T	T
T	T	F
F	F	F

b. *Evaluation of a B-conjunction*

	C_1	$C_1 \wedge C_2$	C_2
Cand1			
Cand2	*	*!	
Cand3		*!	*
Cand4	*	*!	*

Crowhurst and Hewitt restrict b-conjunction to constraints that share what they call a *focus* (or *fulcrum* in Hewitt and Crowhurst 1996) which identifies the locus of violation for each of the conjuncts.

(34) *Focus (of a constraint)$_{def}$*

a. Every constraint has a unique focus.
b. A constraint's focus is identified by the universally quantified argument.

Crowhurst and Hewitt's use of b-conjunction is exemplified by their analysis of alignment effects in the stress system of Diyari (Pama-Nyungan; Austin 1981). In Diyari, any morpheme of two or more syllables has initial stress, and secondary stress falls on the penult in morphemes longer than three syllables, as shown in

(35a). The cases of special interest are polymorphemic words containing monosyllabic suffixes, exemplified in (35b). Monosyllabic suffixes are never stressed. Moreover, no syllable preceding *any* morpheme is ever stressed (cf. [ˈpulʲudu-ɳi-ˌmaʈa], [ˈmaɖa-ɭa-ɳi]). Thus, although they have the same number of syllables, the forms [ˈmaɖa-ɭa-ɳi] and [ˈkaɲa-ˌwaɽa] are assigned stress quite differently: the bisyllabic suffix [-ˈwaɽa-] has stress, but the sequence of suffixes [-ɭa-ɳi-] does not.[7]

(35)	a.	ˈkaɲa	(ˈka.ɲa)	'man'
		ˈpinadu	(ˈpi.na)du	'old man'

The lynchpin of Crowhurst and Hewitt's account of Diyari is the conjunction in (36c) of the two alignment constraints in (36a) and (36b). The individual constraints require an edge (left or right) of a morpheme to be aligned with the same edge of a foot. In conjunction, they require each edge of a morpheme to be aligned with the same edge of a foot.

(36) a. MORPHEMEFT-LEFT (MFL)
ALIGN-L(Morpheme, Ft)
(One * for any morpheme whose left edge does not coincide with the left edge of some foot.)

b. MORPHEMEFT-RIGHT (MFR)
ALIGN-R(Morpheme, Ft)
(One * for any morpheme whose right edge does not coincide with the right edge of some foot.)

c. MFL $\wedge^{\text{MORPH}}$ MFR
(One * per morpheme which fails MFL, MFR, or both.)

Crowhurst and Hewitt treat Diyari as a language that avoids foot structure when possible. They rank the standard constraint PARSE-σ below *STRUC(Ft), which assigns a penalty for each foot in the output. The conjunction in (36c) outranks *STRUC(Ft), resulting in a foot at each edge of morphemes whose syllable count makes this possible. FTMIN(σ) prevents the assignment of monosyllabic feet. Tableau (37) shows how the correct outputs (ˈwinta)ra(ˌnaja) and (ˈta.ji)-(ˌja.ti)(ˌma.ji) are selected under the rankings FTMIN >> MFL $\wedge^{\text{MORPH}}$ MFR >> *STRUC(Ft). (In the following tableaux, violations of the individual conjuncts that are promoted to

[7] Note that the underived pentasyllabic form [ˈwintaraˌnaja] has initial and penultimate (not antepenultimate) stress. Hewitt and Crowhurst (1996) use this example (from Austin 1981) to show that stress in Diyari is not assigned from left to right, as many theoretical accounts of Diyari have assumed (e.g. Poser 1989; Crowhurst 1994; Kager 1994). Rather, Diyari assigns a trochaic foot at both edges of a morpheme when it can.

violations of the conjunction are shown in parentheses. Violations of the alignment constraints are shown with a superscript corresponding to the initial phoneme of the morpheme that incurred the penalty.)

(37)

/taji-jatimaji/	FtMin	MFL	$\wedge^{MORPH}$	MFR	*Struc(Ft)
☞ a. ('ta.ji)-(ˌja.ti)(ˌma.ji)					***
b. ('ta.ji)-ja.ti(ˌma.ji)		(*^{i})	*^{i}!		**
c. ('ta.ji)-(ˌja.ti).ma.ji			*^{i}!	(*^{i})	**
d. ('ta.ji)-ja.ti.ma.ji		(*^{i})	*^{i}!	(*^{i})	*

/wintaranaja/	FtMin	MFL	$\wedge^{MORPH}$	MFR	*Struc(Ft)
☞ a. ('winta)ra(ˌnaja)					**
b. ('win.ta)ra.na.ja		(*^{w})	*^{w}!		**
c. win.ta.ra(ˌna.ja)			*^{w}!	(*^{w})	*

The crucial cases are those that contain monosyllabic affixes. In ['ɲan.ɖa-na-ˌma.ʈa], the monosyllabic suffix [-na-] is not footed, but the two bisyllabic morphemes are aligned at each edge with a foot. The especially interesting case is ['ma.ɖa-ɭa-ɳi], which has adjacent monosyllabic suffixes. The candidate ('ma.ɖa)-(ˌɭa)-(ˌɳi), which satisfies the alignment constraints, is ruled out by FtMin. If the constraints MFL and MFR were not conjoined but were evaluated independently, then of the remaining two, the optimal candidate should be ('ma.ɖa)-(ˌɭa-ɳi), which minimizes violations of MFL and MFR. However, the optimal candidate is in fact ('ma.ɖa)-ɭa-ɳi, in which neither of the suffixes is aligned with foot structure. When MFL and MFR are b-conjoined, however, a morpheme aligned at only one edge is no better than a morpheme aligned at both edges, so that ('ma.ɖa)-(ˌɭa-ɳi) and ('ma.ɖa)-ɭa-ɳi both fail the conjunction MFL $\wedge^{MORPH}$ MFR. In this case, *Struc(Ft) decides for the candidate ('ma.ɖa)-ɭa-ɳi, in which the monosyllabic suffixes are unfooted. The analysis of ['ma.ɖa-ɭa-ɳi] under b-conjunction is shown in (38).

(38)

/maɖa-ɭa-ɳi/	FtMin	MFL	$\wedge^{MORPH}$	MFR	*Struc(Ft)
☞ a. ('ma.ɖa)-ɭa-ɳi		(*^{ɭ} *^{ɳ})	*^{ɭ} *^{ɳ}	(*^{ɭ} *^{ɳ})	*
b. ('ma.ɖa)-(ˌɭa-ɳi)		(*^{ɳ})	*^{ɭ} *^{ɳ}	(*^{ɭ})	*
c. ('ma.ɖa)-(ˌɭa)-(ˌɳi)	*!*				***

The analysis just presented for ['ma.ɖa-ɭa-ɳi] predicts that trisyllabic roots should not be aligned with foot structure, yet, like all other root morphemes, they have initial stress. Crowhurst and Hewitt's analysis attributes the presence of initial stress to the constraint MainStress-L in (39), which insists that the head of the prosodic word stand exactly at the left edge of the prosodic word. Ranking MainStress-L above the conjunction MFL $\wedge^{MORPH}$ MFR compels the presence of an initial foot, even though that foot is poorly aligned with the root morpheme in the output.

(39) MainStress-L (MSL)
Align(PrWd, L; Head(PrWd), L)
(Every PrWd is left aligned with the stressed syllable in its head foot; one * per misaligned PrWd.)

B-conjunction is also useful in stating templatic constraints on the size of reduplicants (chapter 100: reduplication). A constraint like Red=Ft, for example, can be stated as in (40a). However, note that this statement informally assumes the interpretation provided by b-conjunction: any reduplicant must be both left aligned and right aligned with the same foot. Under b-conjunction, the templatic effect is achieved by b-conjoining the constraints in (40b) and (40c), with the foot as the focus of the conjunction. Under this analysis, any foot will be evaluated against the conjunction. Any foot not co-extensive with Red will fail the conjunction, although it might be required by higher-ranking constraints on metrical structure. However, the constraint will be satisfied by reduplicated forms in which Red and a foot are co-extensive.

(40) a. Red=Ft
The reduplicant string is co-extensive with a foot (e.g. Downing 2000: 3).
b. FootRed-L
Align-L(Ft, $Affix_{RED}$)
One * for any reduplicant that is not left aligned with a foot.
c. FootRed-R
Align-R (Foot, $Affix_{RED}$)
One * for any reduplicant that is not right aligned with a foot.
d. FootRed-L $\wedge^{FOOT}$ FootRed-R

The connective "$\wedge$" is also used by Downing (1998, 2000) to account for exceptional alignment behavior found with onsetless syllables (e.g. as stress and tone bearers) and prosodic restrictions on reduplication in Kinande.

3.2 *Implication*

A different form of constraint combination, most closely related to material implication in logic, was proposed by Crowhurst and Hewitt (1997) as a way of analyzing effects of conflicting directionality (Kiparsky 1973; Zoll 1997) in the assignment of stress. As an example, Dongolese Nubian (Armbruster 1960) assigns a single stress, which surfaces on the rightmost of heavy syllable, if there are any (where only vowel length is relevant for syllable weight). Examples are shown in (41a). However, when only light syllables are present, as in (41b), stress falls on the initial syllable.

(41) a. *Heavy syllables*

'bɛɛ.kat.tɪ	'to be killed'
do.'goo.gɪr	'raise it'
tɛ.lɛ.'graaf.kɪ	'a telegram'
tɪn.tɪ.'nɛɛŋ.kɛ.gɪd	'their maternal aunt'
maa.'suu.ra	'tube, pipe'
maa.'lɛɛʃ	'it doesn't matter'
sɛ.rɛɛ.gɪr.ʃug.lɛɛ.rɛ.'daag	'be in the situation of having worked well'

b. *Light syllables*

'bu.run	'it is a girl'
'ta.ra.ga	'page, leaf'
'mu.go.san	'tell to leave'
'ʤɪ.ɲɪ.ran	'tell him (her) to go and wait'

Crowhurst and Hewitt's analysis of Dongolese uses the constraints in (42). The pattern found in words containing heavy syllables seems to require that the constraint HEAVYHEAD in (42a) be ranked above HEADS-R in (42b), which must in turn be ranked above HEADS-L, (42c).

(42) a. HEAVYHEAD
The head syllable of a foot is bimoraic.
(One * for any stressed light syllable.)

b. HEADS-R
ALIGN-R(Head(Ft), PrWd)
(One * per syllable coming between any stressed syllable and the right edge of the dominating PrWd.)

c. HEADS-L
ALIGN-L(Head(Ft), PrWd)
(One * per syllable coming between any stressed syllable and the left edge of the dominating PrWd.)

The problem is that the ranking required for the heavy syllable cases doesn't account for stress in forms containing only light syllables: these seem to require that the alignment constraints be ranked in the reverse order, HEADS-L >> HEADS-R.

The insight Crowhurst and Hewitt (1997) seek to capture is that in a language like Dongolese, heavy syllable stress and any conditions imposed on heavy syllables under stress (in this case, HEADS-R) take priority. HEADS-L becomes relevant only when no heavy syllables are present. Crowhurst and Hewitt propose that HEAVYHEAD and HEADS-R combine in a complex constraint that takes the form of an implication, in which the satisfaction of one requirement is unilaterally dependent on the satisfaction of another. Under their interpretation of material implication, whether a candidate passes A > B depends primarily on the candidate's success on constraint A, and secondarily on its success on constraint B. Crowhurst and Hewitt's definition of implication appears in (43).[8]

(43) *Implication* (Crowhurst and Hewitt 1997)

If Cand passes A, then Cand is evaluated with respect to B:
 If Cand passes B, then Cand passes A > B;
 If Cand fails B, then Cand fails A > B.
If Cand fails A, then Cand fails A > B and Cand's success on B is irrelevant.

As in the case of conjunction, Crowhurst and Hewitt propose that only constraints which share an argument may combine to form implications. Crowhurst

[8] Note that Crowhurst and Hewitt's use of implication does not have the semantics of classical material implication in Boolean logic.

and Hewitt's account of Dongolese ranks the implication HEAVYHEAD $>^{HEAD(FT)}$ HEADS-R above HEADS-L. Tableau (44) shows how their analysis works in forms like ['mu.go.san], which contain only light syllables. All viable candidates violate HEAVYHEAD (constraint A), and this translates to one violation each against the implication HEAVYHEAD $>^{HEAD(FT)}$ HEADS-R. (HEADS-R cells have been shaded to indicate that, per Crowhurst and Hewitt's definition, this constraint has no effect on the outcome.) So it is that in forms containing only light syllables, HEADS-L selects the initially stressed candidate.

(44)

/mugosan/	HEAVYHEAD $>^{HEAD(FT)}$		HEADS-R	HEADS-L
☞ a. ('mu.go)san	(*)	*	(**)	
b. mu('go.san)	(*)	*	(*)	*!
c. mu.go('san)	(*)	*		*!*

Tableau (45) shows how the analysis selects the correct result in forms containing long vowels, [maa.'suu.ra].

(45)

/maasuura/	HEAVYHEAD $>^{HEAD(FT)}$		HEADS-R	HEADS-L
☞ a. maa('suu)ra			(*)	*
b. ('maa)suu.ra		*!	(**)	
c. (ˌmaa)('suu)ra		*!	(***)	*
d. maa.suu('ra)	(*)	*!		

In response to Crowhurst and Hewitt, Balari *et al.* (2000) argue essentially that Crowhurst and Hewitt's interpretation of implication should not be allowed. These authors maintain that if complex constraints are to be derived using logical connectives, they should be connectives with classical Boolean semantics. Like Crowhurst and Hewitt, Balari *et al.*'s analysis of Dongolese uses HEADS-L and HEADS-R, but they replace HEAVYHEAD with a constraint LIGHTHEAD in (46a), which requires stress to fall on a *monomoraic* syllable, and they propose the (classically evaluated) implication in (46b).[9] The tableaux for ['mu.go.san] and [maa.'suu.ra] under BVM's analysis appear in (47).[10]

(46) a. LIGHTHEAD
The head σ of a foot is monomoraic.

b. LIGHTHEAD → HEADS-L
The implication is violated only if LIGHTHEAD is satisfied and HEADS-L is not.

[9] Balari *et al.* use the symbol "→" in the same way as ">" in Boolean logic. Balari *et al.*'s take on conflicting directionality is very close to that of Zoll (1997). Zoll proposes the constraint below to account for stress in Selkup. Note that Zoll's constraint is an unacknowledged complex constraint, which, when unpacked, has the semantics of Balari *et al.*'s implicational constraint.

(i) ALIGN-L('σμ, PWd): A light stressed syllable should be word-initial.

[10] Balari *et al.* differ from CH in assuming that HEADS-L and HEADS-R restricts the foot, not just the stressed syllable. (47) is taken from their work and therefore reflects this difference.

(47)

/mugosan/	LightHead	→	Heads-L	Heads-R
☞ a. ('mu.go)san				*
b. mu('go.san)		*!	(*)	
c. mu.go('san)		*!	(**)	

/maasuura/	LightHead	→	Heads-L	Heads-R
☞ a. maa('suu)ra	(*)		(*)	*
b. ('maa)suu.ra	(*)			**!
c. (ˌmaa)('suu)ra	(*)		(*)	**!*
d. maa.suu('ra)		*!	(**)	

In the end, it turns out that neither version of implication is strictly necessary to account for standard effects of conflicting directionality in stress. Conflicting directionality in stress, as in Dongolese, can be analyzed using the local conjunction of the constraints *Pk$_{\text{FT}}$/σμ and InitialStress in (48a) and (48b) (taking the domain of the conjunction to be the prosodic word).

(48) a. *Pk$_{\text{FT}}$/σμ
Avoid stress on monomoraic syllables.

b. InitialStress
Align-L(Head(PrWd), PrWd)
The head of the PrWd, syllable with main stress, occurs initially in its prosodic word.

c. *Pk$_{\text{FT}}$/σμ &$_{\text{PRWD}}$ InitialStress

Tableau (49) shows that the hierarchy *Pk$_{\text{FT}}$/σμ &$_{\text{PRWD}}$ InitialStress >> *Pk$_{\text{FT}}$/σμ >> Heads-R correctly accounts for Dongolese.

(49)

/mugosan/	*Pk$_{\text{FT}}$/σμ&$_{\text{PRWD}}$InitialStress	*Pk$_{\text{FT}}$/σμ	Heads-R
☞ a. ('mu.go)san		*	**
b. mu('go.san)	*!	*	*
c. mu.go('san)	*!	*	

/maasuura/	*Pk$_{\text{FT}}$/σμ&$_{\text{PRWD}}$InitialStress	*Pk$_{\text{FT}}$/σμ	Heads-R
☞ a. maa('suu)ra			*
b. ('maa)suu.ra			**!
c. maa.suu('ra)	*!	*	

In addition to Balari *et al.*, other arguments in favor of constraints derived using a connective with the semantics of Boolean material implication are presented in Archangeli *et al.* (1998) and Łubowicz (2005).

4 Different perspectives on the domain of conjunction

One distinguishing feature of work using various forms of conjunction has been researchers' different assumptions concerning what can constitute D, the domain of a conjunction. As the definition in (3) makes clear, Itô and Mester's (2003b) view is that D must be instantiated by a member of the set of phonological or morphological constituents. Smolensky's use of D is similar, but perhaps more inclusive in his use of the feature domain – a "maximal contiguous span of φ-bearers with a common value [±φ]" (see again (13)). We can say that for both Itô and Mester as well as Smolensky, the domain of a local conjunction is identified with a designated node in the phonological or morphological structure, and all material associated with this node (the association possibly being mediated by other intervening nodes). One difference between these authors seems to be that for Smolensky, but perhaps not Itô and Mester (2003b), any phonological feature can be the node that determines a domain.

A different perspective on D is found in Hewitt and Crowhurst (1996), Crowhurst and Hewitt (1997), Downing (1998, 2000), Baković (2000), and Łubowicz (2002, 2005), all of whom argue in one way or another that constraints can be conjoined only when they have the same locus of violation. As noted earlier, Hewitt and Crowhurst (1996), Crowhurst and Hewitt (1997), and Downing (1998, 2000) argue that b-conjunction should be limited to constraints that share an argument, which serves as the locus of violation of the conjoined constraint. In Crowhurst and Hewitt's analysis of Diyari reviewed earlier, for example, the locus of violation of the constraints MorphemeFt-L (MFL) and MorphemeFt-R (MFR) is the morpheme, and the conjunction of these constraints produces a complex constraint, MFL $\wedge^{MORPH}$ MFR, which has the same locus of violation.

An extended formal discussion of the *locus of violation* as a principled restriction on the domain of local conjunctions of markedness and faithfulness constraints is developed in Łubowicz (2005). Her definitions of restricted local conjunction and of the locus for local conjunction are shown in (50).

(50) a. *Restricted local conjunction*
$C = C_1 \& C_2$ is violated iff $LOC_{C1} \cap LOC_{C2} \neq Ø$.
b. *Locus for local conjunction*
The locus for local conjunction is the intersection of the sets LOC_{C1} and LOC_{C2}.

Formally, (50a) states that the loci of violation for the conjuncts of a local conjunction must intersect and that this intersection may not be null; (50b) states that the locus of violation for the local conjunction is the intersection of sets defined in (50a).

In a similar vein, Baković (2000) proposes that two constraints can be conjoined only if they are *co-relevant*, meaning that the definition of each conjunct specifies a particular feature also mentioned by the other conjunct. The co-relevance restriction plays an important role in Baković's use of M&F (markedness and faithfulness) conjunctions to account for "assimilation to the unmarked" phenomena, as discussed earlier. In his words, "the net effect of a co-relevant local conjunction of markedness and faithfulness is to specifically prohibit the unfaithful introduction of a marked segment" (Baković 2000: 7). Baković notes that the co-relevance restriction (or Łubowicz's more precisely defined restriction based on locus of violation) provides an answer to Itô and Mester (1998), who take the position that M&F conjunctions should not be allowed because they lead to undesirable results. Positioning the conjunction NoCoda & Ident[voice] above the fragment *[+voice] >> Ident[voice], for example, would falsely predict a language in which obstruents are voiced only in syllable codas. Baković notes that conjuncts used to illustrate Itô and Mester's point are not co-relevant, and in fact uses the example to reinforce his claim that *only* co-relevant constraints are conjoinable.

5 Taming the beast: Curbing the expressive power of constraint conjunction

Proposals for combining simpler constraints into more complex ones using connectives other than ">>" have not been universally welcomed (see for example Orgun and Sprouse 1999; Parker 2001; Idsardi 2006; Iverson and Salmons 2007; Zhang 2007). The issue of restricting the power of a formal theory that permits the derivation of complex constraints from simpler ones has generated concern, and inspired various proposals aimed at restrictiveness. The position of some scholars that restrictions on conjunction should be encoded in restrictions on the domain of conjunction was discussed in the last section. Other ways in which the issue of restrictiveness has played into arguments for and against constraint conjunction are reviewed below.

5.1 *Chain shifts: An argument against material implication*

Wolf (2007) calls for restricting the set of connectives that can be used to combine constraints. He asserts that local conjunction and strict domination exhaust the ways in which constraints may interact. In particular, he argues that complex constraints with the semantics of material implication must *not* be allowed, because admitting such constraints would have the consequence of allowing OT to model synchronic circular chain shifts. A circular chain shift takes the form A → B → A (where B can be expanded to accommodate additional links in the chain), in which a phoneme /A/ shifts to sound [B], and phoneme /B/, also present in the language, shifts to [A] (see also CHAPTER 73: CHAIN SHIFTS). The existence of a circular chain shift in which all links occur synchronically would present a problem for the OT doctrine of *harmonic ascent* (Prince and Smolensky 1993; McCarthy 2002). This is because a change A → B could only occur if B is less marked than A (and this would require a particular set of markedness constraints to outrank a particular set of faithfulness ones). But then, if B is less marked than A, there would be no reason for the change B → A (and the ranking that accounted for A → B could not account for the second change). Moreton (1999) provides a formal proof showing that an OT grammar that admits only faithfulness and markedness constraints is incapable of modeling circular chain shifts. As it turns out, there are no convincing synchronic examples of a circular chain shift conditioned by purely phonological factors, although there do appear to be examples triggered by morphological conditions (Anderson and Brown 1973). Diachronic examples of phonologically conditioned circular chain shifts are quite common (e.g. the flip-flop /i/ → /i/ → /ɨ/ in Siriono: Crowhurst 2000; the Germanic *Kreislauf*: Iverson and Salmons 2008), but these might be best handled by an analysis that assumes changes in constraint rankings at various stages of a language's development, along the lines proposed in Holt (2003).

5.2 *Other proposals for promoting restrictiveness*

Several other proposals aimed at promoting restrictiveness should be mentioned.

Some researchers have proposed restrictions (beyond the locus of violation) on the kinds of constraints that can combine. As noted earlier, Itô and Mester (1998) argued against the conjunction of markedness with faithfulness constraints. Fukazawa and Miglio (1998) proposed that conjunction should be limited to constraints within the same family, which would have much the same effect. These proposals have been countered by persuasive demonstrations of the benefits of conjoining faithfulness and markedness constraints (see §2.5).

A commonly accepted restriction has been to allow only complex constraints whose parts are independently necessary constraints. To do otherwise would permit unnatural results. Smolensky (2006) provides the example of a rule spreading [+ATR] from a [−high] vowel (e.g. [o . . . e] → [ɔ . . . ɛ]). This pattern is exactly what we don't find in ATR harmony, because [−ATR] non-high vowels are marked, and only unmarked feature bearers propagate their features (Archangeli and Pulleyblank 1994). Smolensky (2006) notes that ranking the conjunction *[+ATR, +hi] & HD-L[+ATR] above F[ATR] (the constraint requiring a feature domain to be faithful) could produce this result. However, the conjunction *[+ATR, +hi] & HD-L[+ATR] could simply never exist; one of its conjuncts *[+ATR, +hi] is not a member of Con, since from a markedness perspective, [+ATR] favors high vowels.

However pernicious, conjunctive relations of this type have in fact been proposed in the literature, sometimes to account for very real phenomena. An example would be the implication in (46b), used by Balari *et al.* (2000) to account for directional stress effects. Their constraint LightHead, which *demands* that stressed syllables be light, has no independent motivation – it is in fact an *anti*-harmonic constraint (since stress on light syllables is less harmonic than stress on heavy syllables). If LightHead is not a plausible candidate for membership in Con, then it would seem reasonable to conclude that Balari *et al.*'s conjunction LightHead → Heads-L is not an admissible complex constraint. Another example would be the constraint *Lapse in (51), employed by Elenbaas and Kager (1999: 282), who are proponents of the view that only independently motivated constraints may be combined.

(51) *Lapse

Every weak beat must be adjacent to a strong beat or the word edge.

Elenbaas and Kager note the disjunction in the requirement imposed by (51), but they point out that one of the disjuncts has no justification as a constraint in its own right. The first requirement, "every weak beat must be adjacent to a strong beat," is a cross-linguistically common restriction. However, Elenbaas and Kager note that there is no clear and independent motivation for the second requirement, that "every weak beat must be adjacent to the word edge." For this reason, they conclude that *Lapse should not be treated as a complex constraint. However, whether acknowledged or not, *Lapse is a form of disjunction (local conjunction), and a proper definition of the constraint would have to take account (more on this below). *Lapse is more problematic than the previous example, because the need for *Lapse is well established: as we showed in the last section, the Balari *et al.* implication is unnecessary; alternatives are readily available.

6 Concluding remarks

Proponents of allowing devices for combining constraints have argued that they further the goal of deriving empirical generalizations about markedness from irreducible principles (Itô and Mester 2003b; Smolensky 2006) and (a related point) that they promote greater precision and formal explicitness. Resistance to accepting complex constraints has been due largely to the observation that despite the advantages claimed, devices for combining constraints greatly increase the expressive power of the formal architecture, especially in regard to the constraint inventory Con. On the other hand, Itô and Mester (2003b: 22) note that in fact, the use of connectives keeps in check the proliferation of inexplicit constraints that duplicate aspects of others without a formal account of their components and the relations among them. (That is, since the need for the constraints in (6a) and (6b) is uncontroversial, and if we can combine them as in (4c), then we don't need the coda condition in (5).)

In closing, I will put forward a consideration that may seem provocative, but which ought to be taken seriously. Smolensky (2006) points out that the statement normally given for a constraint such as (51) (of which there are many examples in the literature) may pass as a translation of the definition of a constraint into English (or pseudo-formal language blended with English), but it is not a proper definition of that constraint (i.e. stated in the precise language of formal logic). A precise definition of (51) in formal language must necessarily take account of the disjunction it contains; it cannot do otherwise. Whether complex constraints *should* be allowed is a non-issue. In fact, they *have been* used without controversy from the inception of OT, camouflaged as informal descriptions that have been accepted as definitions of constraints. The issue that deserves consideration is whether the position that complex constraints should be excluded can be maintained in light of its implications – most seriously, the implication that an enormous number of generally accepted constraints ought to be expelled from Con, or at least rethought. On the issue of overgeneration, we may perhaps leave the last word, for now, to Itô and Mester:

> The broadly defined outline of local conjunction theory . . . admits a huge number of conjoined constraints, only a small subset of which will turn out to play a role in grammar, and many of which are unwanted. In our view, the task of distinguishing between "reasonable," "plausible," "expected" conjunctions and "unreasonable," "implausible," "unexpected" conjunctions cannot be relegated to the syntax of conjunction, which simply provides a system for expressing derived constraints. The distinction is an issue of phonological substance and phonetic groundedness, not one of formalization (Itô and Mester 2003b: 24).

ACKNOWLEDGMENTS

The author appreciates useful comments received from the editors, Marc van Oostendorp and Keren Rice, and from Scott Myers, Joe Salmons, and two anonyomous reviewers. Their input has helped to make this a better chapter.

63 Markedness and Faithfulness Constraints

PAUL DE LACY

1 Introduction

Objects and mechanisms called "constraints" have featured in many theories of the phonological and syntactic modules. However, the explicit bifurcation into "markedness and faithfulness" constraints is specifically found in Optimality Theory (OT; Prince and Smolensky 1993) and its developments (especially McCarthy and Prince 1999), as well as in theories based on OT (Stochastic OT: Boersma and Hayes 2001; Targeted Constraint Theory: Wilson 2001; OT with Candidate Chains: McCarthy 2007; Stratal OT: Bermúdez-Otero, forthcoming; Kiparsky, forthcoming). So this chapter focuses on the things called "constraints" in OT (specifically the "classical OT" of Prince and Smolensky 1993 and McCarthy and Prince 1999). In particular, it focuses on OT constraints in the phonological module; there are also OT theories of the syntactic module and OT theories of morphology – they will not be discussed here.

This chapter's aim is to examine the basic syntax and semantics of constraints. On the syntax side: What is the form of constraints? What is the "constraint construction language"? On the semantics side: How are constraints "interpreted" – i.e. how are constraints used to assess a candidate's violation marks?

This chapter focuses on the basics of constraints, so it does not aspire to identify every constraint theory or list every constraint and constraint generator (§4.2) that has been proposed; for that, see the ongoing *ConCat* project.[1]

An OT constraint is commonly treated as a function that takes a candidate and returns "violation marks" (see Prince and Smolensky 1993). Violation marks are discrete elements; they are usually written as a string of asterisks with one asterisk per unique element (but violation marks in their formal implementation are not necessarily a string). For example, a constraint *DORSAL returns one violation mark for each instance of the representational element [dorsal] in an output representation (constraint names are usually written in small capitals). So for a candidate that includes an output representation [pakak], *DORSAL returns **, because there are two [dorsal] features in the form (one for each [k]). "Candidates" are sets of

[1] Available at http://concat.wiki.xs4all.nl.

forms including at least an output and input representation, but probably many other related representations as well as relations between them (§3.3; Prince and Smolensky 1993).

Constraints fit into the overall phonological system thus (following Prince and Smolensky 2004). An input is drawn from the lexicon; the input consists of phonological material with morphological and syntactic annotation/structure. A generation mechanism (GEN) produces many (perhaps an infinite number of) candidates. One or more candidates is selected from the array; the selection process (EVAL) involves constraints generating violation marks for candidates and an algorithm that uses the violation marks and other factors to determine the winning candidate(s). EVAL refers to "ranking" – a total order on constraints. Ranking does not influence how violation marks are calculated; however, ranking is crucial in discovering the winning candidate. The phonetic module then takes (one of) the winner(s) and realizes it (i.e. converts it into articulatory movements that produce speech sound).

In short, constraints are just one part of many mechanisms that work together to determine the winning output representation. Constraints do not determine winners on their own.

The term "markedness and faithfulness" as applied to constraints was coined in Prince and Smolensky (1993: §1.4). "Markedness constraints" return violation marks based solely on the form of the output representation. *Dorsal above is a markedness constraint. Unfortunately, the term "markedness" can cause confusion because it seems to imply an inherent connection to theories of markedness (see CHAPTER 4: MARKEDNESS). However, theories of markedness are expressed in OT via both markedness and faithfulness constraints (e.g. de Lacy 2006). The term "output constraint" is therefore less confusing than "markedness constraint," and I will use it here. However, the phrase "markedness constraint" is in such widespread use that I fear "output constraint" will never catch on, in spite of my efforts in this chapter (to add to the confusion there are constraints called "output–output constraints," which are actually faithfulness constraints; see §3.3).

As originally used, "faithfulness constraints" are those that return violation marks based on comparison of the output representation with the input (Prince and Smolensky 1993: §1.2; though strictly speaking the output *includes* the input, as discussed in §3.1). Later work, especially McCarthy and Prince (1999), broadens the term to include any constraint that assigned violations by comparing any pair of inter- or intra-representational forms (e.g. the base of reduplication and the reduplicant (McCarthy and Prince 1999); the derivational base and the output (Benua 1997); a designated form and the output (McCarthy 1999)). The majority of work in OT now uses McCarthy and Prince's Correspondence Theory, so in these cases it is accurate to refer to "correspondence constraints" – i.e. those that use correspondence relations in their calculation of violation marks. However, non-correspondence faithfulness constraints exist in some versions of OT (e.g. containment theories –§3.1), so "faithfulness constraints" is still a usefully broad term.

This chapter focuses on a few important issues about constraints. §2 discusses constraint form in output constraints: What are constraints made of, and how do they return violation marks? §3 deals with faithfulness and correspondence constraints. §4 discusses the source of constraints – whether they are innate and how/whether they relate to external sources.

1.1 "Constraint" in other theories

The term "constraint" is used in many different ways in many different theories. In some rule-based theories there are objects called "constraints" or "filters" that – if their conditions are met – doom the derivation or block rules from applying. If an input I undergoes a series of rules to create a representation φ and there is a filter *φ, the derivation is doomed (i.e. input I has no corresponding output). See Chomsky and Lasnik (1977) for early examples in syntax, and Itô (1986) for conditions on syllable structure. The filter/condition concept does not have a direct analogue in OT – OT constraints assign violations; EVAL is the source of (relative) doom for candidates.

Occasionally, "constraint" is used to refer to the side-effects of conditions on representational primitives and to restrictions on the algorithm that generates output candidates (GEN). Obviously, output representations can only be constructed out of objects and relations that are available (i.e. prosodic nodes, features, planes, tiers; precedence, dominance). For example, there is no candidate in which a node can both precede and follow another node, because the phonological precedence relation is asymmetric (i.e. if *a* and *b* are on the same tier and *a* < *b* (i.e. *a* precedes *b*) and *b* < *a* then *a* = *b*) (see CHAPTER 34: PRECEDENCE RELATIONS IN PHONOLOGY for a discussion of precedence). One could informally call the asymmetry of phonological precedence a "constraint," but it is not an OT constraint.

2 Output constraints

A constraint takes a candidate and returns violation marks.[2] For example, the constraint *DORSAL returns one violation mark for [ka], two for [kax], and so on. A constraint's violation assignment can be described in informal terms: e.g. "*k returns a violation mark for each [dorsal] segment." This informal description is useful, but far from being a formal definition. A formal definition of a constraint must be couched in a Constraint Definition Language (CDL). A comprehensive CDL specifies representational primitives and relations and restrictions on their combination in constraints.

The same distinction can be made for rule-based theories like Chomsky and Halle (1968; *SPE*). Suppose we observe a rule R that takes an input representation /ak/ and converts it to the representation [aʔ]. R could be described as "change /k/ into a [ʔ] word-finally." However, R must be *defined* in terms of a Rule Definition Language (RDL); an RDL is the elements and relations that can be used to construct a rule and limits on their combination. Most of Chomsky and Halle (1968) is devoted to developing such an RDL; R is defined as /k/ → [ʔ] / __ [−seg, −FB, +WB] (the rightmost cluster of features is a word boundary).

[2] It is common to see comments like "constraints impose a partial order on the candidate set" (Samek-Lodovici and Prince 1999: 9), "this constraint dooms the candidate," and so on. These comments are meant as a quick way of describing the complex process of determining order among candidates; the process involves constraints, VR (§2.2), ranking, and EVAL's mechanisms; constraints are merely one part of the process of establishing the winning candidate.

Some work in OT uses informal descriptions to talk about constraints. Formal objects (representational elements like prosodic nodes, features, etc.) are often mentioned in the informal descriptions, but the constraints are nevertheless not defined in terms of an overarching CDL. There have been attempts to develop a comprehensive CDL (Eisner 1997; Potts and Pullum 2002), but most work has either focused on particular groups of constraints, or treated constraints as "black boxes."

To explain, it is possible to fruitfully investigate some (perhaps many) aspects of OT theories without knowing the precise definition of constraints, but only knowing which violation marks constraints assign in which situations. After all, the winning candidate is not directly determined by constraints, but by their violation marks. So, if the violation marks are known then the winner can be determined – the exact means by which the violation marks came to be assigned is often not crucial. For this reason I believe it is fair to say that there has been less focus on developing a CDL in OT theories than on developing RDLs in rule-based theories like Chomsky and Halle (1968).

Even so, there have been detailed proposals of CDLs for groups of OT constraints (see §4 below), and some proposals about aspects of the general CDL. In my own (joint) work, for example, Bye and de Lacy (2000) propose restrictions on how constraints can refer to constituent edges; de Lacy (2006) proposes that constraints cannot include both prosodic nodes and segmental features in their definitions.

An explicit CDL is both useful and ultimately essential to a complete optimality theory. A CDL can tell us which constraint formulations are valid, and thus set a bound on which constraints can and cannot exist.

The following subsections will discuss a CDL. There is a strong uniformity in constraint descriptions and definitions that suggests broad agreement about certain aspects of the CDL. For expository reasons, I will start with the CDL for output constraints. As a word of warning, due to space limitations I will discuss only a few CDLs, and focus on the basic components of just one. The CDL discussed below deals with a broad set of output constraints that I believe every phonologist would accept as possible constraints. I will not attempt to comprehensively discuss all extant CDLs or aspects of CDLs, but instead focus on basic CDL properties.

2.1 *Output constraints: Representation*

There is not a lot of explicit discussion about how constraints work in OT. It seems to me that the majority of work in OT treats constraints as functions from candidates to violation marks. Output constraints inspect the output representation in a candidate, and return a string of violation marks. So *Dorsal returns one violation for candidates with an output representation [ka], two for [kag], three for [gaxikan], and so on, leading to the description: "Assign one violation for each dorsal segment."

We are seeking a CDL in which *Dorsal can be formulated. One issue to address is the CDL's representational primitives. For example, *Dorsal might be cast in terms of a representational theory in which velar consonants are [+back, +high] (Chomsky and Halle 1968: 303), or one in which a Place node dominates a dorsal node which dominates [+back] and [+high] terminal nodes, or one in which an oral cavity node dominates a C-place node which dominates a dorsal terminal node (see Hall 2007 for an overview of feature theories). There are many extant representational theories, but for the purposes of this chapter I will adopt

Clements and Hume's model (there is no widespread consensus on which representational theory is correct, though; even less now than in 1995, I suspect; see also CHAPTER 27: THE ORGANIZATION OF FEATURES).

The CDL also must specify how representational elements can be combined in constraints. For example, a relatively lax CDL could allow several different versions of *DORSAL, as in (1). I use • for "root node" – the lowest node that dominates all segmental features. The symbol ↓ stands for the immediate dominance relation: a↓b means "a immediately dominates b" (i.e. a dominates b and there is no c such that a dominates c and c dominates b); a↓b↓c means "a immediately dominates b and b immediately dominates c." Dominance is an asymmetric transitive relation that holds between nodes on different autosegmental tiers. The descriptions are given in (1); the violation marks the constraint assigns are shown for [k], [kː] (assuming a one-root geminate theory), and [ŋk] (assuming obligatory feature sharing for adjacent elements; Schein and Steriade 1986).

(1) *DORSAL *versions*

Return a violation for ...	[k]	[kː]	[ŋk]
a. each distinct root node • s.t. •↓CPlace↓[dorsal]	*	*	**
b. each distinct [dorsal] feature	*	*	*
c. each distinct prosodic node *p* s.t. p↓•↓CPlace↓[dorsal]	*	**	**[3]

I do not know which of the constraints in (1) exist. Suppose it turns out that we need only (1a). The non-existence of (1b) and (1c) could be achieved by placing restrictions on the CDL such that all output constraints must refer to a root node in their definition and no constraint may mention both prosodic nodes and segmental features. Every extant theory of representation provides a CDL with a great deal of potentially expressive power. So, it is highly likely that any CDL theory will have to incorporate extensive limitations on permissible representations in constraints; it is probably too hopeful that all limits on constraints will be a side-effect of inherent limitations on representations (see §4).

The CDL must also specify how the representation is used to assess violation marks. For example, suppose a constraint mentions the structure [•↓CPlace↓[dorsal]]. How is this structure used to assess violation marks relative to some candidate? In the constraint description (1a), I assumed that the constraint searches the candidate's output representation and one violation mark is returned for each distinct structure that has the form [•↓CPlace↓[dorsal]]. However, could there be a constraint which returns one violation regardless of how many [•↓CPlace↓[dorsal]] structures there were? Such a constraint would return * for [ka], [kax], and [kaxga]. Let's turn to this issue now.

2.2 *Function or representation?*

I asserted without comment above that a constraint is a function: i.e. it takes a candidate as an input and returns violation marks. Conceiving of constraints as

[3] (1c) could return one violation if [ŋ] and [k] were both dominated by the same μ or σ node (e.g. as in [oiŋk]$_σ$).

independent functions opens up the possibility that different constraints could assign violation marks in very different ways.

For example, the ALIGN schema from McCarthy and Prince (1993) takes four arguments and assesses violation marks with respect to designated prosodic constituents. The violation marks from ALIGN(Ft, R; PrWd, R) are the sum of the number of syllables between the right edge of each foot and the right edge of the PrWd. So, the constraint returns nine violations for [(σσ)(σσ)(σσ)σ] (see McCarthy and Prince 1993: 15–16 for details; to understand this constraint see especially 1993: 10 and definitions 14–16). It is clear that the way in which this ALIGN constraint assesses violation marks is quite different from the way in which violations of *DORSAL are assessed (cf. McCarthy 2003).

If constraints are self-contained algorithms that return violation marks and the CDL is sufficiently powerful, we might see pairs of constraints that refer to the same representational structure but differ in how they calculate violation marks. For example, there could be a pair of constraints *∀DORSAL and *∃DORSAL, where *∀DORSAL returned as many violation marks as there are [dorsal] features in an output representation, but *∃DORSAL returned only one violation mark regardless of how many [dorsal] features there are in a form, as long as there is at least one (see Wolf 2007a for relevant discussion). The two constraints refer to the same structure – [•↓CPlace↓[dorsal]] – and differ only in terms of how that structure is used to assess violation marks from a candidate. A pair of constraints like this – i.e. that refer to the same representational structure but differ only in their quantification – would be strong evidence that each constraint is an independent algorithm that assigns violations (or at least that there are several groups of constraints that differ in how they assign violations).

However, my impression is that the constraints-as-functions approach is too powerful. The output constraints that have been proposed in phonological literature are often very similar: they essentially have the form *R, where R is a representation; one violation mark is assigned for each distinct occurrence of R in a candidate's output representation. *DORSAL is an example of such a constraint. The apparent uniformity in how constraints assess violations suggests that it is worthwhile considering an alternative theory of constraints in which constraints are not functions but solely representations.

In such an approach, there would be a single algorithm, Violation Assigner (VR). VR takes as its input an output constraint and a candidate and returns violation marks. VR works the same way for all constraints, thus imposing uniformity in how violation marks are assigned. So the constraint *DORSAL is really a representation [•↓CPlace↓[dorsal]]; *DORSAL itself does not assess violation marks.

There are many ways to formulate a VR algorithm that does the job described above. For example, one could take the set of all sub-representations of a candidate's output representation and compare each member of the set to a constraint representation; the number of violation marks returned for a particular constraint would be the number of subsets that were equivalent to the constraint's representation. I will instead discuss a somewhat more efficient algorithm that does a similar job.[4]

[4] See www.pauldelacy.net/VR for software which allows the user to see the VR below in action and try out various constraints and representations.

(2) *Violation Assigner (VR): Outline*

Inputs:
- a constraint C;
- a candidate that includes an output representation R;

Output:
- a set of violation marks (a set of unique identifiers) indexed to C and the candidate.

a. Take a node c in C.
b. For each node r in R:
If r is the same type and value as c,
then check whether r is connected to a structure equivalent to C.
– if it is, return a violation mark, and continue to the next r.
c. Add no other violation marks to the result.

For example, take a constraint *[+voice], which consists of one [voice] node with a value "+." Each node in the candidate's output representation is checked. If a node is a [voice] node and has the value "+," a violation mark is added to the result.

The VR might seem straightforward, but it has interesting complexities, particularly in the procedure that checks whether a node is "connected to a structure equivalent to [the constraint] C."

Take a more complex constraint – one that involves two nodes: e.g. $*\sigma_{\mu\mu}$, "Don't have bimoraic syllables." $*\sigma_{\mu\mu}$ has three nodes (σ, μ_1, μ_2) and three relations ($\sigma^{\downarrow}\mu_1$, $\sigma^{\downarrow}\mu_2$, $\mu_1 < \mu_2$). A node is selected from the constraint (it doesn't matter which one) – let's say σ in this case. The output representation is searched for σ nodes. When one is found, the next step is to check whether σ is connected to a structure equivalent to the constraint. The implementation of this checking procedure is that σ is checked to see if it is in any of the *relations* mentioned by the constraint: i.e. does the particular σ in the representation dominate two different μ nodes? If it does, then the μ nodes that are dominated by σ are checked to see whether their relations have equivalents in the constraint. After nodes and relations are found in the output representation that are equivalent to those in the constraint, a violation mark is returned.

The procedure that checks whether *n* is connected to a structure equivalent to C means that constraints cannot be unconnected. For example, suppose that there is a constraint $*\mu_1, \mu_2$ which is violated if a word contains two (not necessarily adjacent) moras; these moras are unconnected in this constraint – there is no precedence relation between them, nor is there a node that dominates them both. VR can evaluate such a constraint, but the constraint will never return any violation marks. VR checks *relations* between nodes: i.e. VR will search for a μ_1 node, and then check its relations. Since μ_1 has no connection to μ_2 via either precedence or dominance, VR will never find any structure in any R that is equivalent to the structure described by the constraint.

So the VR algorithm itself, through how it compares the constraint's structure to structures in the output representation, imposes a weak connectedness requirement on constraints. For a constraint C ever to return a violation mark, every node in C must be connected to every other node. Nodes *x* and *y* are "connected" here if it is possible to trace a direct route through precedence and dominance relations from *x* to *y*.[5]

The connectedness requirement that results from VR is *weak*, because a much stronger requirement could be imagined and implemented: i.e. in a constraint, every pair of nodes on the same tier must be in a precedence relation, and every pair of nodes on different tiers must be in a dominance relation. The difference between weak and strong connectedness can be seen in a less connected version of $*\sigma_{\mu\mu}$: one where $\sigma^{\downarrow}\mu_1$ and $\sigma^{\downarrow}\mu_2$, but there is no precedence relation between μ_1 and μ_2. Such a constraint would not be evaluated by a VR that imposes strong connectedness because it has two nodes on the same tier (μ_1, μ_2) that are not in a precedence relation. However, it is perfectly acceptable in the weak-connectedness VR described above, because every node is connected to every other node.

Weak connectedness allows constraints of the form $*[x \ldots x]_D$, where there are two nodes of type x within a particular domain D (e.g. Suzuki 1998; see also the discussion of local conjunction in §4.2).

The connectedness side-effect of VR is desirable – as far as I am aware, no one has proposed constraints that have completely unconnected elements.

The larger point here is that the nature of the algorithm that assigns violation marks is crucial in any theory of constraints. The algorithm not only determines how violation marks are assigned, but whether particular constraints will ever assign violation marks (i.e. it effectively puts restrictions on constraint form just as VR means that constraints must contain connected representations).

If constraints are representations and there is a single VR, there should be broad uniformity in the way that violation marks are assigned. For example, the constraint [$\bullet^{\downarrow}$CPlace$^{\downarrow}$[dorsal]] will assign violations for each occurrence of its representation in the candidate's output representation. In contrast, there is no way to formulate a constraint like *∃dorsal: if the constraint consists of the representation [$\bullet^{\downarrow}$CPlace$^{\downarrow}$[dorsal]], then the VR will return a violation for *each* occurrence of [$\bullet^{\downarrow}$CPlace$^{\downarrow}$[dorsal]]; it cannot be limited to assigning one violation regardless of the number of occurrences of [$\bullet^{\downarrow}$CPlace$^{\downarrow}$[dorsal]].

So the VR theory means that output constraints should all assign violations in fundamentally the same way, while the constraints-as-functions theory allows for significant differences. It is even possible that there is a middle ground: there could be several violation assignment algorithms, with VR being just one of them. With several VRs, we would expect to see uniformity in how violations are assigned, but only within particular groups of constraints.

Which view is correct? How much uniformity in violation mark assignment is there?

2.3 *Regularities and irregularities in violation assignment*

There is a great deal of regularity in the way that violation marks are assessed in output constraints. In fact, there is so much regularity that I am sure there would be no confusion among phonologists about how a constraint like *ʃr works (even though I concocted it just now): it would return a violation mark for each

[5] Let us define a transitive symmetric relation ⊕: $x \oplus y$ if $x < y$ or $x^{\downarrow}y$. Nodes x and y are connected if $x \oplus y$. For example, in the constraint $*\{\sigma^{\downarrow}\mu_1, \sigma^{\downarrow}\mu_2\}$, μ_1 and μ_2 are connected because $\sigma \oplus \mu_1$ and $\sigma \oplus \mu_2$, so $\mu_1 \oplus \sigma$ (by symmetry) and $\mu_1 \oplus \mu_2$. There is no need for a direct implementation of ⊕ in VR; connectedness follows as a side-effect of the procedure that matches the constraint to the representation.

[ʃ] immediately followed by [ɾ] in the output representation. There is an implicit "quantificational" regularity here: one violation mark is returned for *each* distinct [ʃɾ] (i.e. [ʃɾaʃɾi] returns two violations), not for just having some [ʃɾ] (where [ʃɾaʃɾi] would return just one violation).

As mentioned above, such "quantification" regularity is expressed straightforwardly in VR. The process of iterating through every node in the representation means that a violation will be returned *each time* a node is found that is part of a representation that matches the constraint's.

There are other widespread similarities in constraints. Many output constraints refer to tier-contiguous representations. For example, a constraint like *ŋk refers to *adjacent* root nodes; *ŋk returns one violation for [aŋko], but [aŋok] gets none (i.e. *ŋk is ŋ < k, where "<" is used here to mean "immediately precedes"). I have not yet seen a constraint *ŋ . . . % . . . k proposed which is violated whenever [ŋ] and [k] appear in the same output in any order (i.e. one violation for each of [aŋko], [aŋok], [a kŋo], [akoŋ], etc.) (the "%" notation is from Bach 1968).

The particular implementation of VR discussed above has intra-tier contiguity as a side-effect of the way that the algorithm works. When a node is encountered in the output representation, the node's relations (i.e. precedence and dominance) are checked against the constraint's. If the node is in a precedence or dominance relation with some other node, that other node's relations are then checked, and so on. This method of checking means that only nodes that are connected in the representation will be examined. So, for a constraint *ŋ . . . % . . . k, a node [ŋ] might be found in the representation, but [ŋ] does not precede any other node, so [k] will never be found by the VR procedure, and the constraint's representation will never be matched. (See CHAPTER 34: PRECEDENCE RELATIONS IN PHONOLOGY for more discussion of precedence.)

Some authors have proposed constraints with weakly contiguous representations to deal with processes like long-distance assimilation and dissimilation (e.g. Suzuki 1998; see also CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS). These constraints refer to segmental nodes that are not in a precedence relation, but are related by dominance (i.e. with the form $*[x \ldots \% \ldots y]_D$, where x and y are nodes dominated by constituent D. Such constraints always require or ban identical elements (not non-identical ones, as above), leading some recent work to recast such processes as involving local correspondence relations (e.g. Rose and Walker 2004) or to restrict the domain of such constraints so that the representations they refer to are mostly always tier-contiguous (e.g. Łubowicz 2005). Such a move might mean that VR should implement a strong contiguity requirement, where within a constraint every node on a particular tier is in a precedence relation with every other node on that tier.

There is a widely accepted constraint type that does not always easily fit with VR: "positive" constraints. A positive constraint penalizes a representation for *lacking* a particular property, while negative constraints like *DORSAL return violations for *having* a particular structure. A well-known constraint that is often positively formulated is ONSET: "Syllables must have onsets."[6] Another example is PLACE→DORSAL: "Every Place node must dominate a [dorsal] node." Because positive constraints do not mention a representation but rather the *lack* of a

[6] See other definitions of this constraint, including negative ones, at *Concat* http://concat.wiki.xs4all.nl/index.php?title=Onset.

representation, they cannot be fed into the VR. That is to say, PLACE→DORSAL does not mention the representation [•↓Cplace↓[dorsal]]. Instead, it requires that for every root node • there must be some member of the set of all sub-representations of a candidate that includes • and has the structure [•↓Cplace↓[dorsal]]. It is not hard to formulate a VR algorithm that can handle positive constraints (VR^{POS}), but such an algorithm is different from the one that handles negative constraints (VR^{NEG}).

Are both VR^{NEG} and VR^{POS} necessary? Many positively formulated constraints can be reformulated negatively, and many negative ones can be reformulated positively. However, the success of reformulation depends entirely on the particular CDL used. For example, within fairly standard representational theories it is not possible to reformulate *DORSAL as a positive constraint or even a set of positive constraints without resulting in the "pile-up problem" (de Lacy 2002: 90ff., 2006: chapter 2). Similarly, the success of reformulating positive constraints as negative ones depends on the CDL's representational primitives and restrictions. For example, can ONSET be reformulated as *[$_\sigma$V "Return a violation mark for each vowel at the left edge of a syllable" (Kager 1999)? Yes, but *only* if the CDL allows reference to syllable edges in this way and the VR can process it. Whether such boundary reference is possible depends entirely on the CDL and VR.

There are a variety of popular positive constraints that seem to defy easy negative reformulation; e.g. FTBIN: "Assign a violation for each Foot node that does not dominate exactly two moras or two syllables" (after McCarthy and Prince 1986; Prince and Smolensky 1993; see also CHAPTER 40: THE FOOT). Elías Ulloa (2006) proposes breaking the constraint down into constraints that put upper and lower bounds on moraic content. A constraint against more than two sub-foot elements is straightforward using VR: *{$Ft_i \Downarrow x_a$, $Ft_i \Downarrow x_b$, $Ft_i \Downarrow x_c$}, where x_a, x_b, x_c are all distinct prosodic nodes (i.e. μ or σ) and ⇓ here is *dominance*, not *immediate dominance* (↓). A constraint against having *fewer* than two sub-foot daughter nodes is more difficult: How do we penalize a monomoraic/monosyllabic foot structure using a representation ($Ft \Downarrow x$) and the VR, without also penalizing larger structures? Perhaps the VR could be tweaked, making it seek out complete constituents in evaluating constraints. Or it might be possible to capitalize on boundaries, banning a sub-foot prosodic node that is both a left and right foot boundary (e.g. *$[_{Ft}x]_{Ft}$), depending on how boundary reference is permitted in the CDL.

The literature is full of examples of positively and negatively formulated constraints. If there is a single VR, a big challenge is to figure out how to recast the positive constraints into negative ones (or vice versa, depending on one's VR), or alternatively identify sets of negative constraints that take over the effect of the positive ones.

The VR has other interesting side-effects, such as its inability to deal with ALIGN-type constraints and "gradient" constraints generally (McCarthy 2003).

Which option is right? Is there a single VR algorithm and output constraints are really representations? Or is every constraint its own violation mark calculation algorithm, opening the possibility that constraints could assign violation marks in wildly different fashions? The fact that there is such widespread similarity in how constraints work makes me hope for the former option. However, there is no doubt that recasting every extant output constraint in VR-friendly terms is extremely challenging. It is also quite possible that there are several VR-like algorithms, and that constraints are indexed for which violation calculation algorithm they undergo.

The issues become more complicated when we consider the other major set of constraints – correspondence constraints.

3 Faithfulness constraints

Output constraints refer to the output representation in candidates when violation marks are calculated. However, if only output constraints exist, each grammar would produce the same output, regardless of what the input is. So, constraints are needed to regulate inter- and intra-representational relations. For example, there must be constraints that keep outputs from being altered relative to the input form (see McCarthy 2007 for discussion). There is after all a significant difference between [ʔaki] and [ki] in terms of how they relate to the input /aki/. How are constraints used to decide which one of these competitors wins? In more common parlance, how do constraints regulate the *faithfulness* of the output to the input?

3.1 *Containment and correspondence*

Prince and Smolensky (1993) proposed a theory – Containment – that expresses differences in the output relative to the input in terms of output symbols. In the process of generating output representations from an input, a segment can be marked as unparsed (e.g. <k>), which means that it will not be phonetically realized. A segment can also be epenthesized – added to the output – and marked as such (e.g. $\underline{k}$).[7]

Containment Theory provides a straightforward way to ban deletion and epenthesis. Constraints against deletion are simply output constraints that ban unparsed segments: *<•> bans deletion of root nodes, and *$\underline{\bullet}$ bans epenthesis. Such constraints fit straightforwardly into the VR algorithm.

However, McCarthy and Prince (1999) argue for a very different approach. Their proposal – Correspondence Theory (CT) – is now the most widely used theory of inter- and intra-representational identity.

CT proposes a relation – "correspondence" – that holds between root nodes (at least; see §3.2). For example, the root node /k/ in the input /aki/ can be in a correspondence relation with the root node [k] in the output [ʔaki]. However, in the process of making output candidates from an input, GEN has a free hand in generating correspondence relations. So, there will also be a candidate consisting of the input /aki/ and an output [ʔaki], where /k/ corresponds to [ʔ]. Correspondence relations are often written with subscript numerals when it is not obvious which elements correspond (e.g. /$a_1k_2i_3$/: [ʔ$a_1k_2i_3$] *vs.* [ʔ$_2a_1k_2i_3$]).

With a free assignment of correspondence relations, there are many candidates consisting of the input /aki/ and output [ʔaki], where the only difference is correspondence. However, due to the way correspondence constraints work, the vast majority of such candidates will never win under any ranking.

Constraints that regulate the correspondence relations between input and output root nodes are responsible for keeping outputs looking like inputs. For

[7] Prince and Smolensky adopted the theory that epenthetic segments are empty prosodic positions. However, this proposal is no longer widely accepted; I have updated the description of Containment Theory accordingly.

example, IO-MAX returns a violation for each input root node that is not in a correspondence relation with some output root node. So, candidates consist of (at least) an input representation, an output representation, and the correspondence relations that hold between them.

Correspondence was a new concept in phonological theory. In *SPE* and its rule-based successors, input–output faithfulness is an epiphenomenon of rule non-application; an output form is perfectly faithful to its input if no rules apply to it. The more rules that apply, the more likely the output is to become less faithful (though not necessarily: later rules could undo the effect of preceding rules). However, at any point in the derivation of a rule-based theory, except for the first rule application, the original input is *not accessible;* the only accessible representation at any point for a rule theory is the current one (i.e. the input to the rule). In contrast, for every candidate in CT, the input representation is always directly accessible via correspondence: constraints regulate how the output candidate fares relative to the input via correspondence relations.

McCarthy and Prince (1993) proposed a framework of correspondence constraints that has remained substantially unchanged in most subsequent work (see §3.3); see their Appendix A for detailed formulations. I discuss a select few here.

IO-MAX returns a violation mark for every input root node that has no output correspondent. So, IO-MAX returns a violation for /p$_1$a$_2$n$_3$/ → [p$_1$a$_2$], because /n/ has no output correspondent; it returns no violation for /p$_1$a$_2$n$_3$/ → [p$_1$ã$_{2,3}$], because /n/ corresponds to [ã]. Notice that correspondence is not a function; an output segment can correspond to more than one input segment, and vice versa.

IO-DEP returns a violation for every output root node that has no input correspondent; IO-DEP is violated by epenthesis: one violation for /i$_1$/ → [ʔi$_1$], but none for /i$_1$/ → [j$_1$i$_1$].

IO-IDENT[F] regulates feature change; it returns a violation for each input root node whose output correspondent does not have the same value for feature F. There are probably individual IO-IDENT[F] constraints for every feature, and possibly for groups of features too. For example, IO-IDENT[continuant] is violated once in /k$_1$a/ → [x$_1$a].

Other correspondence constraints regulate multiple correspondence: UNIFORMITY (preventing coalescence), INTEGRITY (preventing breaking/diphthongization/split), CONTIGUITY, LINEARITY (preservation of precedence and adjacency), and ANCHOR (preservation of edge proximity).

A caveat is in order here. It is common in informal discussion to say that a constraint *does* some particular task: "MAX bans deletion"; "DEP militates against epenthesis," "UNIFORMITY eschews coalescence," and so on. It is dangerous to take such statements too seriously. MAX does not ban deletion; it simply returns violations if an input root node has no output correspondent. In fact, MAX has effects that do not fit easily into the traditional concept of "deletion." For example, in the mapping /p$_1$a$_2$i$_3$/ → [p$_1$e$_{2,3}$], there has not been any violation of MAX, though a standard *SPE* account would say that there has been deletion relative to the input (/pai/ → [pei] → [pe]). In the mapping /k$_1$a$_2$/ → [ʔa$_2$], it looks as if /k/ has changed into [ʔ], rather than being deleted, yet there is a violation of MAX (in an *SPE*-type analysis there *is* a step with deletion: /ka/ → [a] → [ʔa]). See Gouskova (2007) for detailed discussion of this point in relation to DEP.

Correspondence constraints essentially encourage identity – i.e. preservation of a particular input property in the output, or vice versa. IO-Max and IO-Dep require identity of the number of root nodes; IO-Ident[F] requires identity of feature values, and the other constraints preserve precedence and position.

McCarthy and Prince's correspondence constraints have a simplicity and symmetry that is surprising compared to the complexities of output constraints. For example, IO-Dep is actually IO-Max with an output-oriented focus (i.e. IO-Dep is just "OI-Max"). There also may be constraints of the OI-Ident[F] form; they differ from IO-Ident[F] constraints in terms of coalescence and breaking (see Pater 1999).

3.2 *Constraint Definition Languages for correspondence*

There are many ways to conceive of a CDL for correspondence constraints. Regardless of the CDL, though, it seems challenging to conceive of how the VR algorithm discussed in §2.2 could process correspondence constraints straightforwardly; correspondence constraints demand identity in a way that is not inherent to VR. It is therefore possible that each faithfulness constraint is its own function. However, there is such an overwhelming regularity in terms of how they behave that it is very tempting to assume that there is one algorithm that calculates violations for correspondence constraints, even if it is different from VR.

There is therefore a temptation to set up a separate violation mark calculation algorithm just for correspondence constraints (C-VR). However, it is also possible to combine containment and correspondence so that correspondence constraints are expressed in terms that the VR can process, and regulation of identity follows from the VR. In fact, this is essentially how Prince and Smolensky's Containment Theory works. Here I will discuss an updated version as an example.

For IO-Max, suppose that there is a computable function K over correspondence that is included in each candidate. For every root node in the input, K returns the output root node it corresponds to. If the root node does not correspond to any output root node, K returns a unique phonetically uninterpreted element ψ that is designated as belonging to the output (ψ is unconnected to the output representation, though).[8] Much like the other containment theories, then, IO-Max is $*\psi^{\bullet}$, effectively incurring a violation for each output ψ returned by K. IO-Dep is $*\psi^{I}$.[9] More complex constraints like IO-Max[vowel], which preserve segments that are vowels in the input, can be expressed as $*\{\bullet_i K \psi^{O}, \bullet_i^{I}[+vocalic]\}$.

IO-Ident[F] poses a greater challenge in such a quasi-containment implementation. However, the containment approach essentially replaces identity requirements with a ban on dissimilarity, and this method can be capitalized on for Ident. Let us define a relation G, such that if a root node α dominates feature F, then any α-corresponding β (including α itself, assuming that correspondence is reflexive) is in the relation βGF. The structure in (3) shows two corresponding root nodes α and β. It provides their G relations.

[8] There is a strong similarity in this approach to McCarthy's and Wolf's (2005) "string-based" correspondence, where the input string /x/ is deleted if /x/ corresponds to an empty string ε (correspondence is between strings not root nodes in this view). Here, correspondence is still between root nodes, with an additional uninterpretable root node ψ thrown in.

[9] See www.pauldelacy.net/VR for a partial implementation of this approach.

(3) *Input* *Output*

α_1	β_1
|	|
[−voice]	[+voice]
αG[−voice], αG[+voice]	βG[−voice], βG[+voice]

The constraint IO-IDENT[voice] can then be expressed as $*\{\bullet^{i}G[-\text{voice}], \bullet^{i}G[+\text{voice}]\}$ – i.e. a ban on an input segment having different instances of the same feature with different values. The virtue of this approach is that interrepresentational identity here is recast as avoidance of dissimilarity, which is what many output constraints strive to do (e.g. assimilation constraints; de Lacy 2002: chapter 7; Baković 2007).

However, there have been proposals that support the idea that correspondence constraints are independent functions (or at least that there are several FVRs). Alderete (2001) and Struijke (2000) propose that there are correspondence constraints that differ only in terms of how they assess violations in relation to quantification.

Struijke (2000) argues that there are counterparts to correspondence constraints that differ solely in terms of "quantification." So, while IO-IDENT[nasal] returns a violation for each pair of corresponding input–output segments that have different values for [nasal], IO-∃IDENT[nasal] returns a violation for each input segment for which there is *some* output that has a different value for [nasal]. The difference is seen when an input segment corresponds to more than one output segment. For example, if /ã$_1$/ splits to become [a$_1$n$_1$], IO-IDENT[nasal] returns one violation, because there is an IO pair that disagrees in [nasal]: </ã/, [a]>. However, IO-∃IDENT[nasal] does not return any violations, because for every input segment (i.e. /ã/) there is *some* pair that preserves the [nasal] value (i.e. </ã/, [n]>).

Alderete (2001) argues that at least some faithfulness constraints have "anti-faithfulness" counterparts. For example, OO-IDENT[voice] returns a violation for each corresponding segment that has different values of [voice] (for the OO-part, see §3.3). However, ¬OO-IDENT[voice] returns a violation if there is no pair of correspondents that disagrees on [voice] values. The constraints differ in terms of how they assess violations rather than the representations they refer to.

If Struijke's (2000) and Alderete's (2001) proposals are correct, they pose a serious challenge to an approach that seeks to find a single F-VR algorithm. Their proposals mean that there are sets of constraints that differ only in terms of the procedure of violation mark assignment, not in the representation and relations they refer to.

3.3 *Developments in correspondence constraints*

The theory of correspondence constraints has been reduced, altered, and extended since McCarthy and Prince (1993).

For example, Keer (1999) argues that UNIFORMITY does not exist, with the effect that coalescence is obligatory in certain situations. Similarly, a number of authors have argued that DEP does not exist (e.g. Bernhardt and Stemberger 1998). They observe that output constraints do a similar job to IO-DEP; output constraints (usually) prefer less representational structure over more, and so does IO-Dep. However, Gouskova (2007) argues that the effects of IO-Dep can be distinguished from structural constraints.

Most work has focused on extending correspondence to new nodes (§3.3.1) and dimensions (§3.3.2).

3.3.1 Loci of correspondence

McCarthy and Prince (1993: 14) proposed that correspondence holds between segments. I have adopted a particular theory of representation (autosegmental theory) in this chapter that does not provide an easy way to define "segment"; in this theory, the most natural understanding of McCarthy and Prince's proposal is to say that correspondence holds between "root nodes." McCarthy and Prince also suggest that correspondence could hold between other nodes: tonal nodes, prosodic nodes, and terminal and non-terminal feature nodes.

Myers (1997) develops this idea for tonal nodes. For example, IO-Max-T requires that every input tone node correspond to some output tone node. The most significant effect of the proposal is that tones can survive even when their segmental sponsors are deleted. See Yip (2007) for an introduction to tone constraints; also CHAPTER 45: THE REPRESENTATION OF TONE.

McCarthy (2000) argues for a variety of constraints that require (at least some) prosodic nodes to be in correspondence. Since (most) prosodic structure is apparently absent in inputs, evidence for correspondence between syllables and feet comes from identity across other forms (e.g. base–reduplicant, base–derivative; see §3.3.2).

A widely discussed extension has been feature correspondence. Lombardi (2001) argues that feature-to-feature correspondence is essential in explaining differences between how place features and voice features differ in their behavior.

However, coalescence can be achieved without feature correspondence (e.g. Pater 1999; de Lacy 2002: chapter 8), and a general concern with Max-feature approaches is the lack of observed feature autonomy. In several theories, features do not seem to have the same kind of independence as tones: while tones can survive if their sponsors are deleted, there may not be similar effects for features (featural morphemes are special cases, however; see Wolf 2007b: §2.2 and CHAPTER 82: FEATURAL AFFIXES for discussion).

3.3.2 Dimensions of correspondence

The discussion above has focused on correspondence between inputs and outputs. However, there have been many proposals that extend the reach of correspondence. The proposals fall into two categories: intra-representational correspondence and inter-representational correspondence.

McCarthy and Prince (1999) propose that intra-representational correspondence is found in reduplication (see also CHAPTER 100: REDUPLICATION). A reduplicant morpheme has no input content, but its output segments can correspond to certain other output segments (the reduplicant's "base"). For example, one of the reduplicated forms of Māori [paɾau] 'baffled' is [paɾapaɾau]. The reduplicated segments correspond to other output segments thus: [$p_1a_2ɾ_3a_4p_1a_2ɾ_3a_4u_5$].

McCarthy and Prince (1993) argue that constraints on Base–Reduplicant (BR) correspondence have the same form as constraints on IO correspondence. BR-Max requires every base element to have some correspondent in the reduplicant (violated once in [p$_1$a$_2$ɾ$_3$a$_4$p$_1$a$_2$ɾ$_3$a$_4$u$_5$]), BR-Dep requires every reduplicant segment to have a correspondent in the base, and BR-Ident[F] regulates featural identity between base and reduplicant.

What is surprising about the extension of correspondence to the Base–Reduplicant dimension is that there is essentially one formal mechanism that accounts for both the input–output relation and reduplication. Other theories of reduplication conceive of the phenomenon as involving templates or a type of long-distance assimilation, perhaps through autosegmental spreading (see e.g. McCarthy and Prince 1986). Urbanczyk (2007) gives an overview of BR correspondence and reduplication.

Other intra-representational correspondence relations have been proposed. Kitto and de Lacy (1999) argue that epenthetic segments can correspond to other output segments, resulting in "copy epenthesis": e.g. Winnebago [boːpũnũs] 'hit at random' (Miner 1992). The reason for proposing correspondence here is "overapplication": nasal vowels only occur after nasal consonants in Winnebago, except when epenthetic vowels copy a post-nasal vowel, as above. Such "overapplication" is expected with correspondence, since featural identity of corresponding elements can trump phonotactic restrictions; and is also found in reduplication and other types of correspondence (see Urbanczyk 2007 for discussion of under- and overapplication in reduplication; and Benua 1997 for output–output correspondence).

Hansson (2001) and Rose and Walker (2004) go further in arguing that any output segment can correspond to another output segment. The effect is seen in long-distance agreement. For example, in Chumash sibilants agree in anteriority within a word: /s-ilakʃ/ → [ʃilakʃ] 'it is soft'; cf. [s-ixut] 'it burns'.

There have been many proposals for inter-representational correspondence, too. Benua (1997) proposes that segments in the output representation can correspond to segments in the "trans-derivational base" of that output. The trans-derivational base of a word is basically the word minus its structurally outermost affix. So, the base of *original* [[origin]al] is *origin*. *Original* itself is the base of *originality*, and *origin* is also the base of *originate*.

OO-correspondence can be used to explain why some morphologically complex words do not follow expected phonological patterns, but instead remain similar to their base. For example, in my idiolect (and in many other English-based idiolects) the head foot avoids final syllables in nouns, but otherwise is drawn to the right edge of a PrWd: [əd('məsə)bu] *admissible*, [ədməsə('bələ)ri] *admissibility* ([ə] can be stressed in my dialect, and /l/ → [u] outside onsets). However, with some affixes the foot does not get drawn rightward as expected: [əd('məsə)bunəs] *admissibleness*, *[ədmə('səbu)nəs]. When *ness* appears in a word, it subjects the candidate to an OO-faithfulness requirement that has the effect of forcing the correspondent of the base's head syllable to also be a head. So *[ədmə('səbu)nəs] loses to [əd('məsə)bunəs] because the corresponding head syllable in the base [əd('məsə)bu] is [mə], not [sə].

Further work on interword relationships has argued that candidates should consist of entire output paradigms of related word forms. See McCarthy (2005) for references and discussion.

Yet other work has proposed correspondence relations between the output representation and another output representation that is identified by a special selection mechanism, with the aim being to account for phonological opacity.

4 Possible and impossible constraints

Even after defining the CDL's representational elements, relations, and algorithm(s) assigning violation marks, there remains the question of which constraints actually exist.

I wish I could list all the phonological constraints that exist in the human brain here. Unfortunately, there is no agreed-upon list. Many constraints have been proposed, and many algorithms too. Given the rapid changes in phonological theories and variety of constraint proposals, it is more useful to discuss general intrinsic and extrinsic restrictions on theories of constraints.

Every CDL imposes intrinsic limits on possible constraints. The nature of the elements and relations by which constraints are defined means that some imaginable constraints could not occur. For example, suppose the CDL has no disjunction operator. A constraint that assigns a violation to a segment if it is either [+voice] or [labial] is then not possible – it is impossible to formulate using the CDL's syntax. Similarly, the VR itself may impose "restrictions" on constraints in the sense that certain constraints might be well formed in the CDL, but not assign violation marks. In the VR discussed above, constraints that had unconnected representational elements would not assign violation marks; so, while such unconnected constraints could exist, they are effectively inert and will never be observed to have an effect on selecting a winning candidate. Other cases were discussed in §1.1 and §2.2.

It is also possible (even likely) that there are extrinsic limits on constraints. An extrinsic limit is a restriction on particular types of constraint even though the constraint would have a well-formed syntactic structure in the CDL. For example, suppose there was a CDL that made it possible to define a constraint that banned syllable onsets, yet such a constraint did not exist: an extrinsic limit would have to be responsible. The alternative is to suppose that there are almost no significant extrinsic limits: the set of constraints includes every constraint definable using the CDL (up to a certain level of complexity). The issue of extrinsic limits is a very difficult one. The first issue addressed below is methodological: how can we tell whether there are extrinsic limits on constraints (§4.1)? §4.2 discusses where those extrinsic limits come from.

4.1 Evidence for extrinsic restrictions

The majority of OT theories and subtheories do propose many extrinsic restrictions on constraints, specified by the CDL (cf. discussion in Blevins 2004). The evidence comes from restrictions and requirements that cannot be attributed to non-cognitive mechanisms.

To explain, suppose we never observe a particular phonological property in any human language, like an epenthetic [k] (e.g. /iti/ never surfaces as [<u>k</u>iti] in any grammar). It is possible that the lack of [k]-epenthesis is due to constraints. For [k] to be epenthetic, there has to be a (set of) output constraint(s) that returns violation marks for every segment except [k]. Without such a constraint, epenthetic [k] won't occur (see e.g. de Lacy 2006: ch. 3).

However, there are potentially non-CDL reasons why epenthetic [k] is never observed. Some other part of the phonological component could be responsible (see §4.2). There is also luck – e.g. war, pestilence, or plague – which may have accidentally wiped out all speakers of languages with epenthetic [k]. After all, every theory of phonology predicts many tens of thousands of distinct phonological systems, and only a few thousand have existed and will ever exist.

For epenthetic [k] to be observed, it must also be learnable. Actuation of a phonological change comes about through learner misperception or misarticulation. So if epenthetic [k] cannot come about through such a situation, it won't be observed. Even if a sound change can be actuated easily, it will quickly disappear if it cannot be transmitted effectively. In this particular case, though, there is evidence that learners could misperceive vowel hiatus as involving a [k] (Kingston and de Lacy 2006).

So, suppose a phonological situation P never occurs. Suppose further that the lack of P cannot be ascribed to non-constraint grammatical processes or extra-phonological mechanisms. In such a case, phonological extrinsic restrictions on constraints are responsible for the lack of P. For epenthetic [k], it is easy to come up with a set of constraints that penalize everything except [k] (e.g. *Labial, *Coronal, *Glottal), so the CDL must not permit this set of constraints (or at least, this set of constraints with free ranking).

There are several other methods of determining that a particular phonological situation is due to constraints. See Kingston and de Lacy (2006: §3.3) and references cited for discussion.

4.2 Origins and universality of constraints

If there are restrictions on possible constraints, where do those restrictions come from? There are fundamentally two different proposals: (a) innateness and (b) constraint-construction mechanisms that refer to phonology-external structures.

The innateness view is that constraints are hard-wired into the brain (i.e. part of our genetic make-up). The "hard-wired" view comes in two versions. One is that each constraint is specified independently. In this version, only those constraints that are hard-wired into the brain exist, so extrinsic limits on constraints boil down to genetics. The other version is that there are hard-wired algorithms that automatically generate constraints – "constraint generators" (sometimes called "schemas"). For example, there would be an "Ident[F]" constraint generator that produces constraints with the form D-Ident[F] where D is a pair of dimensions (input–output, base–reduplicant, etc.), and F is a subsegmental node. The generator is "complete" in that it would generate constraints for every D and every F (Green 1993). The constraint-construction algorithms determine which constraints exist.

The alternative is to propose mechanisms that are derived from phonology-external mechanisms, or at least can take phonology-external factors into account. A growing body of work argues that there are many algorithms that take phonetic factors like ease of articulation and perceptual distinctiveness into account in evaluating which phonological constraints to generate. In this view, limits on constraints are a combination of the inherent limits of the constraint-construction algorithm *and* the restrictions imposed by the phonology-external factors that those algorithms refer to.

For example, Hayes (1995) discusses phonological constraints on voiced stops. Phonetic voicing in stops is hard to maintain; the further back the stop is, the more difficult it is to maintain voicing during the closure phase: it is harder to maintain voicing during the closure phase of [g] than for [d], and it is harder for [d] than for [b]. Suppose there is a constraint generator that produces constraints on voicing in stops. It could imaginably generate many constraints, e.g. *g, *d, *b, *g/d, *g/b, *d/b, *g/d/b (where *x/y means "Return a violation for any segment that is x or y"). However, if the mechanism referred to articulation in a way that reflected voicing difficulty, the constraints would be winnowed down to *g, *g/d, *g/d/b. Hayes (1995) further observes that the CDL's intrinsic representational restrictions could impose further limits on the possible constraints: *g/d, for example, is not definable in some feature theories, as there is no feature that [g] and [d] share to the exclusion of [b]; with such representational theories, the only constraints generated by the mechanism would be *g and *g/d/b (i.e. *[+voice, −continuant, −nasal]).

To summarize, the majority of work in OT adopts the idea that there are constraint generators. However, there is ongoing disagreement over whether constraint generators can refer to phonology-external factors like ease of articulation and perceptual difficulty. Gordon (2007) provides discussion and references; see also CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY.

A related issue is constraint universality. A constraint is "universal" if it exists in every grammar. A constraint can exist in every grammar because it is hard-wired into CON (the set of constraints), or because it is produced by a constraint generator (see §4.2) that produces the same constraints in the same way for every grammar. A "language-specific" constraint is one that exists in only some languages; it must be learned. For specific discussions of constraint universality, see Green (1993), Prince and Smolensky (1993), and McCarthy (2002: §1.2.1, §3.1.5.2).

There is an important nuance to constraint universality/language specificity. It is possible that constraints are not universal, but rather *constraint generators* are. For example, ALIGN is a constraint generator that exists in every grammar. However, if ALIGN is allowed to take individual morphemes (or morphs) as arguments, it could produce language-specific constraints like ALIGN($[um]_{Af}$, L; Stem, L), "The affix *um* occurs stem-initially, is a prefix" for Tagalog, and ALIGN($[ka]_{Af}$, L; Ft′, R), "The affix *ka* follows, is a suffix to, the head foot" for Ulwa (McCarthy and Prince 1993). So, while ALIGN($[um]_{Af}$, L; Stem, L) does not exist in every language, the constraint generator that created it does. The point could be extended to other constraint generators, and even those that refer to phonology-external factors. If a constraint generator refers to an articulatory or acoustic factor that varies among speakers, it could be that the same constraint generator will produce speaker-specific constraints.

5 Summary

This chapter has left a vast number of issues about constraints untouched and only barely skimmed over a few others. However, a few points about constraints emerge. A formal theory of constraint form – a "Constraint Definition Language" – provides valuable insight into which constraints can and cannot exist. There is fairly widespread (if tacit) agreement on many aspects of such a CDL, but also many disagreements about both fundamental issues and the details. Constraints are only one part of a complex system that determines phonological winners;

constraints themselves do not determine winners, and no constraint or set of constraints has any predictive power on its own. Only when the entire collection of constraints, GEN, EVAL, and the phonetic module interface are examined together can anything be asserted about the predictive power or restrictive nature of the theory.

ACKNOWLEDGMENT

My thanks to Marc van Oostendorp, Keren Rice, Matt Wolf, and an anonymous reviewer for their extensive comments.

64 Compensatory Lengthening

Randall Gess

1 Types of compensatory lengthening

Compensatory lengthening is the lengthening of one segment, referred to here as the "target," in compensation for the loss or reduction of another, referred to here as the "trigger" (see also CHAPTER 37: GEMINATES and CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH). The segments are usually in close proximity to one another – either adjacent or in adjacent syllables. Theoretically, a consonant can be lengthened in compensation for the loss or reduction of another consonant or vowel, and a vowel can be lengthened in compensation for the loss or reduction of another vowel or consonant. In fact, an argument can be made that all types of compensatory lengthening exist, although as Table 64.1 indicates, some types are far more common than others. There is also a problem in the classification of some types as compensatory lengthening proper rather than as instantiations of other processes, such as total assimilation (2A, B) or rhythmic lengthening (1D).

In Table 64.1, Row 1 lists cases in which the target for lengthening is a vowel, and Row 2 lists cases in which the target for lengthening is a consonant. Column A lists cases in which the trigger for lengthening (the reduced or deleted segment) is a reduced consonant following the target, Column B those in which the trigger is a reduced consonant preceding the target, Column C those in which the trigger is

Table 64.1 Types of compensatory lengthening

		Trigger			
		A / __ C	B / C __	C / __ (X)V	D / V(X) __
Target	1: V	numerous	limited	numerous	limited
	2: C	limited	numerous	isolated	limited

a reduced vowel following the target, and Column D those in which the trigger is a reduced vowel preceding the target.

Examples representative of each cell in Table 64.1 are provided in the following brief sections.

1.1 *Type 1A* (Target V; Trigger / __ C)

(1) *Old French* (Gess 1998, 1999)

a.	*blasmer*	[blazmer]	>	[blaːmer]	'to blame'
b.	*angle*	[ãnglə]	>	[ãːglə]	'angel'
c.	*large*	[lardʒə]	>	[laːdʒə]	'wide'

The type of compensatory lengthening in (1) is common. Kavitskaya (2002: App. 1) lists 58 languages in which it is manifested. Other cases not mentioned by Kavitskaya can be found in Gordon (1999) and Beltzung (2008).

More exotic types of compensatory lengthening triggered by a following consonant are ones in which the trigger is an intervocalic consonant, or in which the target and trigger are separated by an intervening consonant, i.e. in which the triggering consonant is the second of a sequence of two intervocalic consonants (e.g. Ancient Greek *odwos > East Ionic /oːdos/ (Wetzels 1986: 310). Hayes (1989) refers to this type of compensatory lengthening as a "double flop," a term which has gained currency in the literature (see Beltzung 2008 for an extensive discussion of "exotic" types of compensatory vowel lengthening triggered by consonant loss).

1.2 *Type 1B* (Target V; Trigger / C __)

(2) *Samothraki Greek* (Katsanis 1996, as reported in Topintzi 2006; see also CHAPTER 55: ONSETS)

a.	'rafts	>	'aːfts	'tailor (MASC)'
b.	'ruxa	>	'uːxa	'clothes'
c.	'rema	>	'eːma	'stream'
d.	'protos	>	'poːtus	'first'
e.	'vrisi	>	'viːs'	'tap'
f.	me'trun	>	mi'tuːn	'they count'
g.	'extra	>	'extaː	'hostility'

The type of lengthening shown in (2) is rare and somewhat controversial (see Beltzung 2008 for an overview), as it is predicted not to occur by the framework of Moraic Phonology developed in Hayes (1989). In Samothraki Greek this process is limited to rhotics in word-initial or post-consonantal position – it does not occur when the segment is in intervocalic position or in a coda position (there is no deletion of syllable-final /r/ in Samothraki Greek). According to Beltzung (2008), the segments implicated in this type of compensatory lengthening are rhotics, pharyngeals, and laryngeals.

1.3 *Type 1C* (Target V; Trigger / __ CV)

(3) *Hungarian* (Kálmán 1972, as reported in Kavitskaya 2002)

a.	*wizi	>	viːz	'water'
b.	*tyzy	>	tyːz	'fire'
c.	*utu	>	uːt	'road'
d.	*ludu	>	luːd	'goose'
e.	*neʒi	>	neːʒ	'four'
f.	*modoru	>	modoːr	'bird'
g.	*teheni	>	teheːn	'cow'

Cases like the one illustrated here are relatively common, but appear to be more phonologically restricted and less widespread than the type shown in §1.1. Kavitskaya (2002: App. 2) lists 21 languages (neglecting to include Yapese (Jensen 1977), where it appears to be a synchronic process) in which this process occurs or has occurred, whereas she lists 58 languages (App. 1) in which the CVC type of compensatory lengthening shown in §1.1 is manifested. As indicated in Table 64.1, this type of compensatory lengthening does not always involve an intervening consonant (e.g. Old French [fiː] < [fiə]; Pope 1952: 205).

1.4 *Type 1D* (Target V, Trigger / VC __)

According to Hayes (1989: 284), this type of compensatory lengthening "appears not to exist." However, a process in Macuxi may prove problematic for this claim. In a section entitled "Compensatory length," Carson (1981: 50) states that "[w]hen a short vowel is suppressed, the vowel that immediately precedes a stop consonant in its vicinity is lengthened." Representative data are shown in (4).

(4) *Macuxi* (Carson 1981)

kasa'pan	→	ksaa'pan	'sand'
kusupa'ra	→	'ksuu'pra	'machete'
'wakiri'pe	→	'wakrii'pe	'agreeable'
'miki-'rɨ	→	'miɨ'kri	'he'

It appears in all the examples but the last one that the lengthened vowel is the one that follows the deleted one. However, the absence of otherwise expected *['mɨ'krɨɨ] in the last example may be attributed to what Pessoa (2006: 78, 2009: 117), citing Abbott (1991), refers to as the absence of "silaba alongada fonológica na última posiçao," since final syllables are already rhythmically lengthened.

According to Kavitskaya (2002: 149), lengthening in Macuxi (as described in Kager 1997) is not a case of compensatory lengthening, and "should be attributed to the properties of iambic systems" since it "happens regardless of syncope" (see also CHAPTER 44: THE IAMBIC–TROCHAIC LAW). She cites the following examples from Kager (1997: 466–467).

(5) *More examples from Macuxi*

/piripi/	(ˌpriː).('piː)	'spindle'
/waimujami/	(ˌwai).(mjaː).('miː)	'rats'

The first example is taken by Kager (1997) from Hawkins (1950: 89), and the second from Abbott (1991: 147). In both examples, the final syllable of the form in question is apparently lengthened, and there is no vowel syncope to point to as a trigger. However, with respect to the first form, no lengthening in any position is indicated by Hawkins (1950), who says nothing more about final vowels than that "[t]he last vowel in each stress contour in the basic form of any utterance is always retained," and he transcribes the form as 'pripí', with the acute accent marking "the end point of contours" (Hawkins 1950: 89).

It may be that length is present and not noted by Hawkins, but if so, it is just as easily described as phrase-final lengthening that is independent of iambic (foot-level) lengthening. According to Abbott (1991: 145), "[t]he final CV in a phonological phrase (i.e. a phrase bounded by a pause) is always long and stressed." Abbott describes rhythmically derived length on even-numbered V or CV syllables, counting from the left, as well as on final syllables. Again, though, Hawkins (1950) says nothing about lengthening in any context, and does not indicate it in any transcriptions. Nevertheless, Kager (1997) introduces foot-level lengthening systematically in forms taken from both authors, as well as syncope in forms where Abbott indicates none. Hawkins (1950) does discuss "stress contours" in which the contour consists of "a stretch of speech marked by loud stress on the last vowel," and he notes that "[w]hen more than one word occurs in a stress contour, the last vowel in each non-final word in the contour is retained." However, retention of a vowel is a far cry from lengthening.

Carson (1981) does not indicate final lengthening either. Kager (1997) chooses to ignore the data from Carson (1981), cited above, noting that she posits "lexical tone rather than stress," and that her data must be "based on a different dialect than those studied by Hawkins and Abbott" (1997: 466). In fact Carson describes lexical pitch accent (1981: 42–45), which may be "disturbed" at the phrasal level (1981: 46). If Carson is correct, that the variety she documented manifests pitch accent, then the lengthening she describes cannot appropriately be attributed to iambic lengthening.

Two points arise from the preceding discussion. First, it is not clear that rhythmic lengthening, independent of vowel reduction or deletion, does occur in the Macuxi variety described by Abbott (1991) (and Hawkins 1950, if lengthening other than in final syllables even occurs in the variety he describes). Second, the lengthening described by Carson (1981) cannot be dismissed on the grounds suggested by Kavitskaya (2002).

An important question arises with respect to the first point in the preceding paragraph: If rhythmic lengthening is always tied to vowel reduction or deletion, can it properly be considered compensatory lengthening? Kavitskaya's point is that it is not – that it is better in this case to consider it a property of iambic systems, together with rhythmic vowel deletion. It is unclear, however, why a foot-based process that can be described as CVCV > CvCV: (where "v" represents a reduced vowel) should be treated any differently than one that can be described as CVCV > CV:Cv, i.e. the fairly common type of compensatory lengthening described in (3) (1C in Table 64.1), that is uncontroversially labeled as such.

Two other types of compensatory lengthening can result from a triggering vowel preceding the target vowel, in these cases with no intervening consonant. The first of these is compensatory lengthening through glide formation (typically from high vowels), a relatively common synchronic process in Bantu languages (e.g. Ganda

/li+ato/ 'boat' → [ljaato]; Clements 1986: 47). The other type of process is also attested in Ganda, involving the deletion of non-high vowels in prevocalic position (e.g. /ka+oto/ 'fireplace (DIM)' → [kooto]; Clements 1986: 49).

1.5 *Type 2A* (Target C; Trigger / __ C)

(6) *Semitic* (Lipiński 2001: 195)

*usˤtabbit	>	usˤsˤabbit	'he imprisoned'	(Assyro-Babylonian)
*atˤtarad	>	atˤtˤarad	'I sent'	(Assyro-Babylonian)
*itˤtalaba	>	itˤtˤalaba	'he sought'	(Arabic)
*ʔətzəkkar	>	ʔəzzəkkar	'I remember'	(Ge'ez)
*jilkədenhu:	>	jilkədennu:	'he shall capture him'	(Hebrew)
*gəmaːlathu:	>	gəmaːlattu:	'she weaned him'	(Hebrew)
*wɛsfi	>	wɛssi	'awl'	(Gurage)
*nisf	>	nəsˤsˤ	'half'	(Colloquial Arabic)

This type of compensatory lengthening appears to be relatively uncommon, and like the type described in the following section, it is not formally distinguishable from total assimilation.

1.6 *Type 2B* (Target C; Trigger / C __)

(7) *Bengali* (Hayes and Lahiri 1991: 81)

bɔrʃa	~	bɔʃʃa	'rainy season'
bɔrdi	~	bɔddi	'elder sister'
bʰorti	~	bʰotti	'full'
kortʃʰe	~	ko-tʃʰe	'do-3PRES'
kor-lo	~	kol-lo	'do-3FUT'

Although this type of compensatory lengthening is quite common, unlike the type illustrated in (6), it shares with that process the lack of any formal distinctiveness from total assimilation.

1.7 *Type 2C* (Target C; Trigger / __ V)

(8) *Bulgarian* (Shishkov 2002)

'balite	>	'bal'ːte	'the bales'
er'genite	>	er'gen'ːte	'the bachelors'
ku'ʃarite	>	ku'ʃar'ːte	'the (sheep) pens'
'belezite	>	'belesːte	'the scars'
'babinata	>	'babinːta	'the grandmother's (things)'
ven'tʃiloto	>	ven'tʃilːtu	'the wedding'
ameri'kancite	>	amerː'kancite	'the Americans'
done'sa	>	donː'se	'bring (3SG)'

Cases such as the one illustrated in (8), in which a consonant is lengthened before a following reduced vowel, appear to be isolated. It is noteworthy that the consonants involved in the Bulgarian process are of relatively high sonority – only sonorants and /z/, although there is at least one attested case of synchronic compensatory lengthening in this category in which sonority does not appear to be relevant (compensatory lengthening resulting from glide formation, as in Ilokano /'luto+en/ → /lutt'w-en/ 'cook-GOAL FOCUS'; Hayes 1989: 269).

1.8 *Type 2D* (Target C; Trigger / V __)

(9) *Ganda* (adapted from Clements 1986: 62–63)

/li + kubo/ > [kkubo]
/li + tabi/ > [ttabi]
/li+ daala/ > [ddaala]

According to Clements (1986: 6), the synchronic rule deriving geminates from a CV prefix is "a restructuring of the historical situation, in which a phonetically motivated rule is replaced by a morphologically conditioned one." Clements assumes the geminates to have arisen historically from earlier *Vį sequences (į represents an upper high front vowel), "with the process giving rise to consonant gemination [being] one in which the articulation of a consonant is anticipated on a preceding postvocalic *į" (1986: 65). They are now associated with a certain class of nominal prefixes.

2 Approaches to compensatory lengthening

Most documented cases of compensatory lengthening, at least those formally distinguishable from total assimilation of adjacent consonants, involve the compensatory lengthening of vowels. Furthermore, the most common types of compensatory lengthening of vowels involve those in which the trigger follows, rather than precedes, the target – i.e. the types of cases illustrated in §1.1 and §1.3. These two types of compensatory lengthening are commonly referred to as CVC and CVCV compensatory lengthening, respectively. In this section, I focus on these most common types and, since synchronic cases of compensatory lengthening are derived from historical ones, I focus on the diachronic instantiation of the processes.

I first summarize three general approaches to compensatory lengthening, all of which have in common an implicit assumption that the phenomenon is speaker-controlled. A fourth section outlines an alternative approach put forth in Kavitskaya's (2002) quite comprehensive treatment of compensatory lengthening, which may be considered somewhat radical in proposing a strictly listener-oriented account of the process. The relevance of the various approaches to synchronic cases of compensatory lengthening, as well as to the other types illustrated in §1, is discussed in §4.

The first three approaches to be examined in this section fall into two categories, as described by Kavitskaya (2002): one that treats compensatory lengthening as a type of conservation and one that does not. The first category is the most common, and assumes that compensatory lengthening is fundamentally teleological in that its goal is to preserve length present in the input in the output string. Being the most common category, it comprises two of the three approaches: a phonetic conservation approach and a phonological conservation approach. The third approach, in a category of its own, is the non-conservation approach, which denies the existence of any intrinsic connection between the loss of a segment and the lengthening of another.

2.1 *Phonetic conservation approach*

In a phonetic conservation approach, compensatory lengthening is viewed as a goal-oriented process functioning to preserve some or all of the physical duration of lost segmental material.

Timberlake (1983) discusses a case in Slavic in which a number of modern dialects have long or tense vowels in syllables that preceded a weak jer in Late Common Slavic (see also CHAPTER 122: SLAVIC YERS). This is a case of CVCV compensatory lengthening (Timberlake does not discuss CVC cases). According to Timberlake, a long reflex of a vowel in a syllable before a Late Common Slavic weak jer "is in some way a result of the phonetic weakening and the eventual phonemic loss of the following jer vowel" (1983: 293). He suggests that:

> Late Common Slavic was subject to a constraint on the preservation of word timing, such that phonetic reduction in one syllable (containing the "weak" jer) was compensated for by increased phonetic duration in the preceding, "strong" syllable.

In Timberlake's model, compensatory lengthening takes place phonologically through re-analysis. Re-analysis depends upon both the phonemic elimination of jers and the surpassing of a "critical duration" on the part of the phonetically lengthened preceding vowel. If, when jers are "eliminated phonemically, either by identification with another vowel or by identification with null" (1983: 299), phonetically lengthened vowels are sufficiently lengthened, the latter are re-analyzed as phonemically long (or tense). Timberlake sets the critical duration for re-analysis arbitrarily at anything beyond 1.5 times "full duration (nearly or exactly 1.0 morae. [. . .] numerical values for duration [. . .] are intended to be highly approximate)" (1983: 298).

Timberlake's model is an additive one, "in which the duration of vowels is adjusted by adding or subtracting increments of duration depending on various factors." The various factors at play in Late Common Slavic were the consonant intervening between the jer and the lengthened preceding vowel; the position of the CVCə sequence in the word (final or internal); and the accent of the lengthened vowel.

The phonetic process of compensatory lengthening is described by Timberlake (1983: 298) as in (10).

(10) *Compensatory lengthening as a phonetic process*

$$/CVCə/ > [CV^{1.0+\alpha}Cə^{-\alpha}]$$

The formula in (10) states that for any reduction of value α in the phonetic length of a jer, a preceding vowel is realized at full duration (1.0) plus α.

In order to model the gradual nature of phonetic lengthening, Timberlake breaks the process down into discrete stages, arbitrarily shown in 0.2 increments, as illustrated in (11), from Timberlake (1983: 298).

(11) *Jer reduction and compensatory lengthening*

a. /CVCə/ > [CV$^{1.2}$Cə$^{-0.2}$] {$\alpha = 0.2$}
b. /CVCə/ > [CV$^{1.4}$Cə$^{-0.4}$] {$\alpha = 0.4$}
c. /CVCə/ > [CV$^{1.6}$Cə$^{-0.6}$] {$\alpha = 0.6$}
d. /CVCə/ > [CV$^{1.8}$Cə$^{-0.8}$] {$\alpha = 0.8$}

Finally, as indicated above, Timberlake assumes re-analysis at anything beyond 1.5 times full duration. Regarding the cut-off, Timberlake (1983: 299) explains:

> When reduced jers were eliminated phonemically, the phonetic phase of CL was necessarily interrupted, and the lengthened variant of a vowel in strong position had to be identified as phonemically long (tense) or short (lax).

This view of re-analysis is illustrated schematically in (12).

(12) *Phonemic analysis*

a. [CV$^{1.2}$Cə$^{-0.2}$] ⇒ /CVC/ {$\alpha = 0.2$}
b. [CV$^{1.4}$Cə$^{-0.4}$] ⇒ /CVC/ {$\alpha = 0.4$}
c. [CV$^{1.6}$Cə$^{-0.6}$] ⇒ /CV:C/ {$\alpha = 0.6$}
d. [CV$^{1.8}$Cə$^{-0.8}$] ⇒ /CV:C/ {$\alpha = 0.8$}

Timberlake's account of CVCV compensatory lengthening can be straightforwardly extended to CVC compensatory lengthening. A demonstration of this is provided in Gess (forthcoming).

Explicit criticisms of phonetic conservation approaches to compensatory lengthening are minimal. The most obvious thing to point out here is the limited relevance of this approach to synchronic cases of compensatory lengthening. That is, while the approach may be useful in showing how compensatory lengthening may arise historically, it is not well suited for modeling the processes in synchronic grammars unless the process at hand is, or at least could be, a change in progress (i.e. it is a gradient, post-lexical process). Another problem with the phonetic conservation approach, pointed out by Gess (forthcoming), is that its extension to CVC cases of compensatory lengthening, while straightforward in a mechanical sense, seems to entail at least implicitly the problematic assumption that moras associated with consonants are equivalent in duration to those associated with vowels. This problem could be overcome by making assumptions regarding the formalisms used more explicit.

2.2 *Phonological conservation approach*

In a phonological conservation approach, compensatory lengthening is viewed as a goal-oriented process functioning to preserve some aspect of the phonological representation (a suprasegmental unit) associated with the loss of segmental material. In fact, compensatory lengthening phenomena crucially informed the debate as to the best way to characterize the prosodic tier (or timing tier) assumed in autosegmental phonology, i.e. in terms of C- and V-slots, X-slots, or moras (McCarthy 1979; Clements and Keyser 1983; Hyman 1984, 1985; Levin 1985; Lowenstamm and Kaye 1986; McCarthy and Prince 1986; Hayes 1989; Beltzung 2008 (especially Chapter 3); see also CHAPTER 54: THE SKELETON).

In order to explain constraints on compensatory lengthening (e.g. that triggers in CVC cases are only coda consonants and not onset consonants [an assumption later proven problematic; Topintzi 2006; Beltzung 2008], and even more specifically that coda consonants are triggers only when they contribute to syllable weight in the language in question), Hayes (1989), in probably the most influential single article on compensatory lengthening, suggests that lengthening only occurs when deletion results in an empty prosodic position and that only a prosodic frame defined in terms of moras yields the correct typological results. (Hayes 1989: 260–261 also provides a simple and straightforward demonstration of the inability of a linear approach to account for compensatory lengthening.)

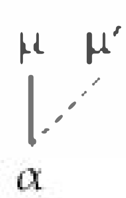
Hayes (1989) accounts for CVC compensatory lengthening as illustrated in (13), with Latin [kasnus] > [kaːnus] 'dog'.

(13) *Compensatory lengthening in* CVC *sequences* (Hayes 1989: 262)

a. */s/-deletion*

$$s \rightarrow \varnothing \ / \ \_\_ \begin{bmatrix} +\text{son} \\ +\text{ant} \end{bmatrix}$$ (segmental tier only)

b. *Compensatory lengthening*



where μ' is a segmentally unaffiliated mora

c. 
A theory assuming a prosodic frame defined in terms of X-slots can account for the example above, but not for the fact that in the same language (Latin), /s/-deletion does not trigger lengthening when it is word-initial, as in *snurus* > *nurus* (the same problem holds for the type of compensatory lengthening illustrated in §1.2). In a segmental theory based on X-slots, any deleted segment should trigger lengthening, whereas in a moraic theory only those segments that are mora bearing will do so.

The moraic theory of compensatory lengthening accounts for CVCV cases as illustrated in (14) with Middle English [talə] > [taːl] 'tale' (see Minkova 1982 for an in-depth discussion of this case).

(14) *Compensatory lengthening in* CVCV *sequences* (Hayes 1989: 268–269)

a. 
Input

b. 
Schwa drop

c. 
Parasitic delinking

d. 
Compensatory lengthening

e. 
Resyllabification

= [taːl]

Parasitic delinking, illustrated in (14c), is a principle that eliminates ill-formed syllable structure, caused in this case by the loss of the vowel segment via schwa drop.

A very positive aspect of Hayes (1989) is that a wide range of cases of compensatory lengthening are discussed (although a potentially problematic empirical gap is discussed below). Besides the classic CVC and CVCV cases, Hayes (1989) treats the so-called "double flop" cases in which the deletion of a glide triggers compensatory lengthening of a vowel in a preceding syllable, as in Ancient Greek *odwos > /oːdos/ (1989: 265–266), and compensatory lengthening from glide formation, as in the Ilokano case mentioned earlier /ˈluto+en/ → /lutt'w-en/. He also mentions (without providing a formal treatment) "straightforward" cases like compensatory lengthening through progressive and regressive total assimilation of consonants, compensatory lengthening through prenasalization, and so-called "inverse compensatory lengthening," which involves the lengthening of a consonant triggered by the shortening or loss of a vowel (1989: 279–281).

Fox (2000) points out a number of what he sees as problems for Hayes's (1989) approach. The first is that the principle of parasitic delinking is "a radical measure which is not required in most other processes of Compensatory Lengthening." The second relates to the required linking of the vowel of the first syllable to the mora stranded by deletion of the second syllable. According to Fox (2000: 100–102), this is:

> unmotivated by the normal principles of the model, since, according to one view at least, the syllable would be perfectly well-formed without this linking; the final mora would be linked to the final consonant and is thus not left stranded.

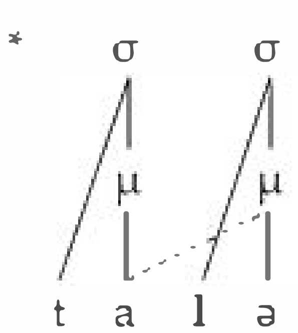
Finally, Fox (2000) suggests that Hayes's (1989) principle of mora conservation is inappropriate as a motivation for CVCV compensatory lengthening. This is because Hayes defines the mora as "the basic unit for syllable weight" (1989: 285) and syllable weight is not maintained in these cases. Rather, what is maintained is the length of the foot (2000: 101).

One might also argue that a problem for phonological conservation approaches generally is that they are ill equipped to deal with the gradual nature of diachronic compensatory lengthening. For example, the Middle English case discussed above did not take place as a discrete change in one fell swoop. According to Minkova (1982: 50):

> Before becoming identified with existing long vowels or developing into new ones, i.e. prior to the establishment of a phonological length contrast, the short vowels in the environment / __ C_1e# undergo phonetic lengthening. [. . .] In a situation where forms with and without the second syllabic element, the *-e*, are both available to the speaker, there will be a negative correlation between it and the first syllabic element. Phonetically, "the word as a whole has a certain duration that tends to remain relatively constant." (Lehiste 1970: 40)

One way to show intermediate length in moraic phonology is to have segments share a mora. In this case, a standard interpretation of the formalism prevents this because it would involve the crossing of association lines, as illustrated in (15).

(15) *Potential inadequacy of Hayes's mora conservation approach with respect to modeling gradual change:* CVCV *cases*



If one adopts a strict and unnuanced view of the ban on crossed association lines, since parasitic delinking (illustrated in (14c)) is triggered only when ill-formed syllable structure is present, the moraic account of compensatory lengthening is only able to succeed if the final vowel is entirely deleted and parasitic delinking applies. That is, the account is unable to account for the allophonic lengthening that must be assumed to precede phonemic lengthening. However, a more relaxed view might interpret the ban on crossed association lines as applying separately to distinct C and V tiers.

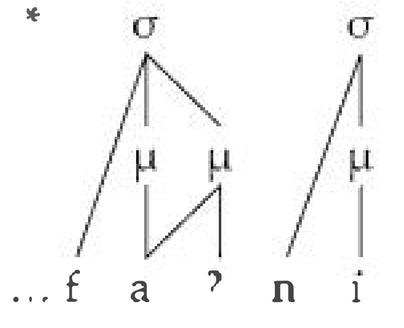
Gradual change might also be seen as a problem for the mora conservation approach in diachronic cases involving CVC compensatory lengthening. Hock (1986) mentions a case reported in Brockelman (1908) from Tunisian Arabic (with similar instances in Ge'ez and Tigrinya), in which a preconsonantal glottal stop is reduced (not deleted), with compensatory lengthening on the preceding vowel. The examples provided are shown in (16).

(16) *Compensatory lengthening triggered by segmental reduction in Tunisian Arabic* (Hock 1986: 444)

ʃeffaʔni > ʃeffaːˀni
smaʔtkum > smaːˀtkum

In autosegmental representation, the output of this process would be as illustrated in (17).

(17) *Potential inadequacy of Hayes's mora conservation approach with respect to modeling gradual change:* CVC *cases*



While the shared mora representation in (17) is adequate for representing an intermediate stage between a fully moraic glottal segment following the short vowel and a long vowel with no following glottal, one might argue that it cannot represent any more than a single such stage, whereas more stages might well be warranted. However, this potential criticism disregards the possibility of a single phonemic representation having different phonetic interpretations at different periods (or indeed across speakers at a single period).

We must also note (as have others) one apparent empirical weakness with the phonological conservation approach, as put forth in Hayes (1989). This involves cases in which compensatory lengthening is triggered by a prevocalic consonant that in normal circumstances would not be associated with a mora. Some such cases are discussed in Hock (1986), a paper cited by Hayes (1989), but without mention of these specific examples. Strangely, the cases are also problematic for Hock, although he does not treat them as such. Hock's interest in the cases is that they involve compensatory lengthening triggered not by deletion of a segment, but by its weakening only (as in the case illustrated in (17), but in intervocalic position). The first case is from Tyrone Irish (as discussed in Stockman and Wagner 1965), where:

> vowels are dialectally distinctively lengthened before the highly reduced glottal-fricative outcome of earlier voiceless fricatives (as well as before sonorant + consonant etc. and in "ordinary" CL environments, *but not in open syllables*). (Hock 1986: 443–444, emphasis added – RG)

The fact that Hock takes care to note that compensatory lengthening does not take place in open syllables suggests that the reduced segments in question might be ambisyllabic, but this is not made explicit anywhere, including in the original source. If it is the case that the segments in question are ambisyllabic, then an argument could be made that they are doubly linked – to a mora in the first syllable and to the onset of the second. The relevant data are shown in (18).

(18) *Compensatory lengthening triggered by segmental reduction in Tyrone Irish* (Hock 1986: 444)

srathar	[straːʰər]
tachas	[tɔːʰəs]

The second problematic case mentioned by Hock (1986) is from the Westphalian dialect of Soest, as reported in Holthausen (1886: 28–29). In this dialect, as illustrated in (19), compensatory lengthening occurs before highly reduced, voiced labial and velar fricatives, and before a deleted "secondary" (analogically reinserted) voiced alveolar stop.

(19) *Compensatory lengthening triggered by segmental reduction in Westphalian* (Hock 1986: 444)

*hege	'hedge'	>	(*)hiəgə	>	hiːəɣə	
*seven	'seven'	>	(*)siəv(e)n	>	siːəvn	
*snede	'slice'	>	(*)sniəde	>	sniːə	(*with* əə > ə)

Again, there is no suggestion that the consonants triggering compensatory lengthening in these cases were ambisyllabic, nor is there any reason to believe that they were. This case therefore represents an apparent problem for Hayes's (1989) mora conservation approach, aside from the issue of the gradient nature of the triggering segmental reduction. (The case also poses a problem for Hock 1986, which represents a mora conservation approach as well, although one not couched in an autosegmental framework.) As mentioned earlier, other cases of compensatory lengthening triggered by the loss of intervocalic consonants are discussed by Beltzung (2008: especially ch. 2).

Finally, the phonological conservation approach *à la* Hayes (1989), particularly in the case of CVC compensatory lengthening, has proven difficult to model in Optimality Theory (OT). The basic problem is that in order for lengthening to occur, consonants must be assigned weight before deletion happens, thus suggesting a serial analysis. Getting around this problem has necessitated the abandonment of some of the basic tenets of OT. For example, one could simply assume that consonants are moraic in the input (Sprouse 1997), but this requires a sidestepping of OT's principle of Richness of the Base, whereby output well-formedness is determined solely by constraints and their ranking, and not by restrictions on input. Other ways of handling the problem involve treatments designed to handle opacity more generally, such as stratal OT (Kiparsky 2000), which rejects strict serialism, Turbidity Theory (Goldrick 2001), Sympathy Theory (McCarthy 2003), or OT with candidate chains (McCarthy 2005; Shaw 2009), which require reference to what amounts to one or more intermediate representations.

2.3 *Non-conservation approach*

In an influential article, de Chene and Anderson (1979) take a novel approach to compensatory lengthening by rejecting the notion that such a process exists as "an independent mechanism of phonetic change" (1979: 505) (they discuss only cases of CVC compensatory lengthening). For them, putative cases of compensatory lengthening can be decomposed into two independent processes: weakening of the consonant in question to a glide, and subsequent monophthongization of the resulting vowel + glide sequence. De Chene and Anderson further contend that monophthongization will result in a long vowel only if the language in question has a pre-existing vowel length distinction. The latter claim is about a structure-preserving condition on compensatory lengthening and not about the process itself. Discussion of it is explored further in §3. For now, let us look in more detail at the first claim.

The proposal that cases labeled compensatory lengthening are in fact the result of two unrelated processes has generated much discussion. Gess (1998) points out that it has been challenged by numerous scholars, including Hock (1986), Poser (1986), Sezer (1986), and Gildea (1995). According to Gess (1998: 353), "[E]ach of these scholars provides a strong case against the view that compensatory lengthening is always decomposable into two distinct stages. The ensemble of their arguments renders this claim simply untenable." Without laboring the point, then, we simply illustrate de Chene and Anderson's hypothesis with one straightforward example. According to de Chene and Anderson (1979: 512):

> In Latin, compensatory lengthening involving loss of a dental spirant is limited in source to *Vz[C, +dent] sequences, where *z is the reconstructed allophone of *s before a voiced segment. Thus we have *ni-sd-o > *nīdus* 'nest' and *si-sd-ō > *sīdō* 'I sit down', both involving the zero grade of **sed* 'to sit' (cf. *sedeō* 'I sit').

De Chene and Anderson continue: "Our posited intermediate development involves the loss of occlusion in (preconsonantal) *[z], leading to the voiced glottal spirant [ɦ]" (1979: 512). In this type of analysis, de Chene and Anderson were not in fact alone. Jeffers and Lehiste (1979) propose the analysis in (20) for the remarkably similar change from Proto-Indo-European (PIE) *nisdo to Sanskrit /niːḍa-/.

(20) *Jeffers and Lehiste's analysis of* PIE *nisdo > *Sanskrit* /niːḍa-/ (as presented in Hock 1986: 435)

nisd-	
nizd-	voicing assimilation
nizḍ-	retroflexion
niẓḍ-	retroflex assimilation
nijḍ-	gliding
niːḍ-	contraction

In noting the similarity in analyses, Hock (1986: 435) points out that what distinguishes Jeffers and Lehiste's analysis from de Chene and Anderson's is the fact that the former is "not proposed as explanations for *all* cases traditionally labeled loss with compensatory lengthening, but only for a certain subset, however poorly that subset may be defined." (Note that Kavitskaya 2002: 38 incorrectly interprets this sentence as referring to de Chene and Anderson 1979, rather than to Jeffers and Lehiste 1979.)

Hock (1986: 435) continues by saying that he is:

> ready to concede that many instances of what has traditionally been called loss with compensatory lengthening may well be ambiguous, and can be analyzed either as weakening-cum-assimilation or as cases of loss-with-mora-retention. However, in light of the fact that there are [. . .] cases of loss with CL which cannot be explained in terms of weakening-cum-assimilation, any theory which recognizes only the latter process must be considered insufficient.

One of the examples provided by Hock that is not amenable to explanation under de Chene and Anderson's non-conservation approach is from Icelandic, and is provided in (21).

(21) *Compensatory lengthening in Icelandic* (Hock 1986: 442)

*liugan	'lie'	>	lju:ga
*keosan	'choose'	>	kjo:sa
(*)priar	'three-FEM'	>	prja:r
(*)se:an	'see'	>	sja:

In this case, which is similar to the Ganda case at the end of §1.4, although there is weakening to a glide, it involves a preceding vowel rather than a following consonant, and there is no monophthongization involved.

Hock's (1986: 435) reproach of de Chene and Anderson (1979) for proposing an alternative explanation of all cases traditionally called compensatory lengthening while neglecting to treat all types extends to other cases as well. For example, while de Chene and Anderson are aware of CVCV compensatory lengthening, they choose not to discuss it (1979: 506, n. 1).

2.4 *Kavitskaya (2002)*

Kavitskaya (2002) puts forth a model of compensatory lengthening that can be considered a radical departure from previous treatments, in that it assumes the process to be entirely listener-oriented (see CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). In this respect, her model is representative of the overall approach to phonological change espoused in Blevins (2004, 2006), Evolutionary Phonology. This is a model that rejects any explanations for historical phenomena that involve the synchronic phonologies of speakers (e.g. by assuming a role for phonological rules or markedness constraints) when there is an alternative, diachronic explanation available. This essentially removes the speaker from the story of phonological change, except as a source of variation from which potential changes may or may not take root through "innocent misperception" on the part of the listener. This variation is constrained by

> speaker-specific anatomical differences, and within the speech of a given speaker, due to phonetic transforms of speech dependent (at least) on: rate of speech; degree of physical effort involved; and the humanly physical impossibility of making exactly the same sound twice. (Blevins 2006: 125–126)

According to Kavitskaya's (2002) listener-oriented account of compensatory lengthening:

> diachronic CL through consonant loss [CVC > CV:] ultimately has its origin in the phonetic lengthening of vowels in the environment of neighboring consonants; the subsequent loss of a consonant conditioning such length causes the length to be re-analyzed as phonological. (Kavitskaya 2002: 8)

Further, according to Kavitskaya, with respect to diachronic compensatory lengthening through vowel loss [CVCV > CV:C]:

> Prior to the deletion of the final vowel, the longer vowel duration characteristic of open syllables is correctly parsed by listeners as a phonetic consequence of syllable structure in the first syllable of a CVCV sequence, and is discounted [. . .] Upon deletion of the final vowel, however, the duration of the vowel in the newly-closed syllable becomes inexplicable, since it is longer than is expected in the closed syllable. (Kavitskaya 2002: 9)

If Kavitskaya's arguments are right, then compensatory lengthening is not really compensatory in nature. For the process to be compensatory, the compensatory aspect would rely on a role for the speaker, as is assumed at least implicitly in all other models of compensatory lengthening.

In so far as Kavitskaya (2002) is representative of the Evolutionary Phonology framework proposed in Blevins (2004, 2006), it is susceptible to the general criticisms that have been leveled against that framework. Lindblom (2006) criticizes the Evolutionary Phonology framework for its reliance on so-called "extra-phonological" explanations over phonological accounts. According to Blevins (2006: 20), "principled extra-phonological explanations for sound patterns have priority over competing phonological explanations unless independent evidence demonstrates that a purely phonological account is warranted." Lindblom takes exception to this stance on the grounds that it highlights a "phonetics/phonology split" and traps the framework in "the conceptual prison of the form/substance distinction" (2006: 242).

As the title of his response to Blevins (2006) declares very loudly, Lindblom (2006) rejects the phonetics/phonology split. Lindblom admonishes us to:

> Deduce sound structure from language use. Anchor theory construction in the universal conditions under which all speech communication must take place. Start from "first principles" and not circularly from the data to be explained (cf. "markedness"). At the level of the individual user, model *phonological structure*, not as autonomous form, but as *an emergent organization of phonetic substance* acquired by each native speaker in the context of socially shared, ambient knowledge. At the population level, model this knowledge as a use- & user-dependent process that undergoes change along the historical time scale. Get rid of the distinction between "phonological" and "extraphonological." Here is a key step: *Make the "intrinsic content" an integral part of the theory from scratch*. Treat "intrinsic content" as the source that helps generate discrete structure and that constrains both synchronic and diachronic phonological patterning. (2006: 243)

In §4, we will explore how a rejection of the phonetics/phonology split might be helpful in accounting for the many types of compensatory lengthening as a unified phenomenon. We conclude this section by looking at an empirical challenge to Kavitskaya's listener-oriented approach – a synchronic case of compensatory lengthening that suggests an explanation in terms of speaker-controlled behavior.

McRobbie-Utasi (1999) provides evidence for a synchronic case of compensatory lengthening that is apparently speaker-controlled and that suggests the relevance of a principle of isochrony in a synchronic production grammar. In an acoustic analysis of quantity in Skolt Saami, McRobbie-Utasi shows a clear connection between the distribution of duration in V1, intervening C, and V2 sequences in disyllabic groups, and a phonological process realized as "an optional rule that either reduces word-final short vowels or deletes them" (1999: 111). Deletion of the final vowel is a feature of casual speech. The relevant optional rule is shown in (22).

(22) *Word-final vowel deletion in Skolt Saami* (McRobbie-Utasi 1999: 111)

V --> Ø / __ #

Vowel deletion rule
A word-final vowel is optionally deleted in Type 1–5 disyllabics.

It is important to note that in the V1, intervening C, and V2 sequences, the intervening C can be long and ambisyllabic (in four of the five types mentioned), or short and affiliated as the onset of the second syllable.

The principal relevant passage from McRobbie-Utasi (1999) is shown below, where the "stress-group locations" referred to are the V1 and following C in the relevant sequences. V2 constitutes a third "stress-group location." According to McRobbie-Utasi (1999: 114–115):

> From the [. . .] measurements an important tendency can be deduced: namely, that the presence or absence (or reduced duration) of the vowel in the second syllable has clear consequences for the distribution of duration in the first syllabic vowel and the consonant(s) following it. Thus, an increase in duration takes place as a result of compensatory lengthening. It will be recalled that second syllabic vowel durations were constant in all the structural types once they were realized as full vowels, with an average of 87 msec [. . .]; also, that durations signaling differences between the structural types and/or gradation types are manifested in the first syllabic vowel and the consonant(s) following it. The fact that the presence or absence of the second syllabic has a considerable effect on these durational distributions in the segments preceding has important implications. The durational changes noticeable in these two stress-group locations (i.e. first syllabic vowel and the consonant(s) following) must be recognized as exemplifying the phenomenon of compensatory lengthening. The absence or reduced status of the second syllabic vowel results in an increase of duration in both of the stress-group locations referred to above.

Compensatory lengthening in Skolt Saami, triggered by the reduction or deletion of a final vowel, affects both the preceding vowel and consonant in four of five types (those in which the consonant is long and ambisyllabic), and the lengthening that occurs does so in a way that precisely preserves the overall V/C ratio. In the remaining type, in which the consonant is short and syllabified as the onset of the second syllable, "reduced duration of the second syllabic vowel results in compensatory lengthening in the first syllabic *vowel* only. There is practically no durational increase in the consonant following this vowel" (McRobbie-Utasi 1999: 118).

It is difficult, although perhaps not impossible, to reconcile McRobbie-Utasi's (1999) findings with a listener-based approach. Although McRobbie-Utasi's study involved only two speakers of Skolt Saami, their behavior with respect to the 550 test words used (recorded three times by both speakers, for a total of 3079 usable tokens) was remarkably consistent. Nor do the types of sequences involved lend themselves readily to Kavitskaya's line of explanation for CVCV compensatory lengthening, since they do not involve (except for Type 3) phonetically lengthened vowels in open syllables. (As expected, V1 in Type 3 sequences is longer than in other types, both when V2 is fully realized and when it is not.) Nor has any reanalysis occurred (whatever that might look like given the sequences involved and their variety [five types]) since the trigger for compensatory lengthening is still synchronically recoverable. Rather, it appears that the speakers are guided directly or indirectly by a principle of isochrony with respect to the disyllabic group.

Other empirical problems for Kavitskaya's approach, from historical French (manifesting types 1A and 1C), are discussed in Gess (forthcoming).

3 A putative constraint on compensatory lengthening

This section briefly explores the second claim made by de Chene and Anderson (1979): that compensatory lengthening can only occur in a language with a pre-existing vowel length contrast – i.e. that it is strictly structure preserving (CHAPTER 76: STRUCTURE PRESERVATION: THE RESILIENCE OF DISTINCTIVE INFORMATION). This issue is discussed in detail in Gess (1998), which treats the very data from Old French on which de Chene and Anderson base their claim, thus adding a particularly severe blow to a claim already questioned in other work (for example, in Hock 1986, Hayes 1989, Morin 1994, and Lin 1997, as well as two further cases discussed more recently in Beltzung 2008: 20–21).

According to de Chene and Anderson (1979: 517), "a necessary condition for the development of contrastively long vowels through monophthongization is the independent existence of a length contrast in the language." With respect to historical French, de Chene and Anderson compare two distinct processes (in the ninth and sixteenth centuries) of monophthongization of the diphthong [aw]. At the earlier stage, the resulting monophthong [o] was short. However, at the later stage, the outcome was the long vowel [oː]. (Strangely, de Chene and Anderson (1979: 519) also suggest a sixteenth-century date for the loss of preconsonantal [l] – the same century in which they contend that monophthongization of the vowel + glide sequence resulting from its loss had occurred. However, Gess (1999) provides strong evidence for a much earlier date for the loss of syllable-final [l], after the latter part of the eleventh century – and many scholars assume a much earlier date still.)

The difference in outcomes in the monophthongization of derived [aw] was due, according to de Chene and Anderson, to the introduction of vowel length into the language via the loss of intervocalic consonants, in the late ninth and early tenth centuries (1979: 521). This introduction of vowel length also allowed for compensatory lengthening, according to de Chene and Anderson, following the loss (through an intermediate stage as a glide) of syllable-final [z], [s], and nasals.

Loss of the latter is incorrectly dated by de Chene and Anderson in the sixteenth century, while loss of the former, [z] and [s], is dated in the twelfth and thirteenth centuries. According to Gess (1999), loss of nasal consonants dates from the thirteenth century, and loss of [z] and [s] dates from the eleventh to the thirteenth centuries.

De Chene and Anderson (1979: 522) make the following claim with respect to the establishment of long vowels in Old French:

> There is a solid body of long vowels, however, that were established by 1100 through deletion of the consonant in original V_iCV_i sequences. In these cases, no leveling or assimilation being necessary, a long vowel is the automatic result of loss of the consonant.

They go on to provide a list of several words illustrating the relevant consonant loss and the resulting putative long vowels. However, Gess (1998) found each of the forms listed by de Chene and Anderson in twelfth- and thirteenth-century Old French poetry and, in each case, the forms are clearly treated as consisting of two syllables. Gess (1998: 358) "found many other examples of orthographic geminate vowels in 12th and 13th-century Old French poetry, all of which are treated as bisyllabic."

The fact that sequences of two vowels were still counted as bisyllabic in the thirteenth century, when the loss of [z] at the very least had occurred, with compensatory lengthening, shows that a pre-existing vowel length contrast in the language was not a prerequisite for compensatory lengthening to take place. Rather, Hayes's (1989) assumption is likely the right one, that a syllable weight distinction in the language in question is necessary and, crucially, sufficient for compensatory lengthening to take place. Gess (1998: 364) points out that from an optimality-theoretic perspective this would be a rather unsurprising consequence of the general principle of minimal violation, in this case of faithfulness to the input. While a given constraint ranking may allow for the erosion of segmental features, it may still protect prosodic structure.

4 Assessment and recent directions

§2 outlined various approaches to compensatory lengthening: a phonetic conservation approach, a phonological conservation approach, a non-conservation approach, and a listener-based approach. We saw that the non-conservation approach, proposed only in the context of CVC compensatory lengthening, is basically untenable, both because it fails to account for any other type of compensatory lengthening and because there are instances of CVC compensatory lengthening that appear not to be decomposable into the stages suggested by de Chene and Anderson (1979). This leaves us with two conservation approaches, both suggestive of a speaker-based process, and a listener-based approach.

We have noted problems with each of these approaches, which I will summarize briefly here. We have observed that the phonetic conservation approach proposed in Timberlake (1983) is most relevant to those instances of compensatory lengthening that are gradient in nature and that may be characterized as changes in progress. This approach seems ill suited for dealing with synchronic cases of compensatory lengthening that involve complete loss of the trigger. Without some refinement, the approach also has difficulty with CVC cases of compensatory lengthening given the assumption implicit in its formalism that moras associated with consonants are of equal duration to those associated with vowels.

With respect to synchrony/diachrony dichotomy, the phonological conservation approach suffers the opposite problem from the phonetic conservation approach. That is, while it can account for most, if not all, cases of synchronic compensatory lengthening, it is not ideally suited to account for compensatory lengthening as a gradual diachronic process or as a process that involves a trigger that is only reduced and not entirely lost. Other criticisms of the phonological conservation approach relate to formalisms (e.g. motivation for parasitic delinking in a rule-based approach and required mechanisms for dealing with opacity in an OT approach) and empirical weakness (its inability to account for compensatory lengthening involving non-moraic segments).

The listener-based approach is explicitly an historical approach. That is, it aims to account only for the diachronic development of compensatory lengthening and does not attempt to model synchronic instantiations of the process. For synchronic cases, it is compatible with (but also limited by) the formalisms required by the phonological conservation approach so long as the process involves a trigger that is synchronically recoverable (see Kavitskaya 2002: ch. 5). The principal problem with the listener-based approach is its inability to account for cases that do not lend themselves to re-analysis via misperception. One such case is the synchronic process in Skolt Saami, which involves a prevocalic VC complex as the target, with lengthening affecting the complex as a whole, and with VC ratios precisely maintained. Also problematic for the listener-based approach is left-to-right CVCV compensatory lengthening (1D), which is why it is so important for Kavitskaya to dismiss such cases as instances of non-compensatory, rhythmic lengthening. Further research is necessary to shed light on this particular issue.

The listener-based approach will also have difficulty accounting for left-to-right compensatory lengthening processes in which both target and trigger are consonants (2A). Note that this difficulty will obtain for an Evolutionary Phonology inspired approach whether one labels the process as compensatory lengthening or as total assimilation since the second consonant in such sequences will normally be perceptually stronger. Further challenges for the listener-based approach come from the compensatory lengthening of consonants triggered by either a following vowel (2C) or a preceding one (2D). Whether the approach can be developed sufficiently to meet these challenges will be interesting to see.

It may be worthwhile for future work to explore the compatibility of the different approaches to compensatory lengthening. Note, for example, that a phonetically based speaker-oriented analysis neither denies a role for the listener, nor necessarily discounts phonological (e.g. moraic) structure. Timberlake (1983), for example, makes clear reference to the mora as the "full duration" of a vowel. Hock (1986: 432), who does not cite Timberlake (1983), also points out that "at least some traditional historical linguists have offered a phonetic explanation of CL in terms of the concept 'mora'." Note that mora-based phonological approaches do not necessarily deny a gradual, phonetic aspect either, at least those prior to autosegmentalist accounts. Minkova (1982) provides a clear phonological account of compensatory lengthening in Middle English, based on syllables and rhythmic units (metrical feet) "described [. . .] with reference to their phonological/moric composition" (1982: 48), but is careful to "complete the picture by adding some considerations of purely phonetic nature" (1982: 50). Minkova also touts as an advantage of her revised environment for Middle English Open Syllable Lengthening the fact that "it is the only way in which the shift from allophonic to phonemic length of the stressed vowel can be accounted for" (1982: 51).

Hock (1986: 434) cites the "striking extent" to which historical evidence coincides with "fine-phonetic" experimental data. Indeed, Hock goes even further (1986: 445), citing the apparent fact "that CL may set in *before* the complete loss of a segment, simply as the result of TC [temporary compensation] for the *reduction* of the segment" (emphasis in the original). An important consequence of this is that:

> the situation just described requires an important modification of the notion "mora": Rather than referring to a temporal unit measureable in terms of segment length, it must – at least for CL – be permitted to refer to time spans which are fractions of ordinary segment length. (Hock 1986: 445)

This view of the "mora" is entirely in keeping with an analysis along the lines of the one proposed in Timberlake (1983). It is also in keeping with the spirit of Lindblom's (2006) view of phonological structure as non-autonomous and emergent from phonetic substance, at least if we assume both that the mora is an abstract temporal unit *and* that reference is permitted to time spans that may be fractions thereof.

A rejection of the phonetics/phonology split with respect to the mora may be the only way to achieve real explanatory adequacy with respect to compensatory lengthening. It allows us to explain the gradual nature of compensatory lengthening – a clearly phonetic aspect of the process. On the phonological side, it also accounts for the fact that CVC compensatory lengthening tends to occur mostly in languages with moraic consonants and for the fact that the process in general functions to preserve moraic structure. In conceptual terms, it is the phonological status of the mora, as an abstract unit of weight functioning in the grammar, that provides the motivation for preserving it when an associated segment is subject to gradual reduction and eventual elimination. On the other hand, it is the physical timing associated with moraic elements that guides the actual articulatory implementation of reduction with concomitant compensatory lengthening, a process that is gradual (and variable) in nature. Since all segments have physical timing associated with them, the only (unsurprising) assumption we have to make is that preservation of timing associated with weight-bearing units is generally privileged over the preservation of timing associated with units that do not bear weight.

Recent work by Topintzi (2006) and Beltzung (2008) demonstrates the continuing relevance of compensatory lengthening for phonological theorizing. It has directly tackled the problems that compensatory lengthening poses for OT and manages to maintain the basic tenets of the framework. Both pieces of work must be categorized as phonological conservation approaches, both seek to expand the empirical coverage of previous approaches (notably to account for non-moraic consonant triggers of compensatory vowel lengthening), and, interestingly, both demonstrate the need for formal appeal to the preservation of segment positions in addition to moras. Both appear compatible, therefore, with a rejection of the phonetics/phonology split as described above (whether or not the authors themselves agree with such a rejection). Both also appear compatible with a potential complementary, phonetically based OT approach that might focus on the functional motivation for and phonetic implementation of non-categorical reduction with concomitant lengthening, as it has for assimilation (Jun 1995) and lenition (Kirchner 1998, 2004; Gess 2003, 2004, 2009) (again, whether or not the authors themselves agree with such a move, which is not part of the OT orthodoxy). It seems safe to conclude that compensatory lengthening will continue to be a topic of some interest in the phonological community.

65 Consonant Mutation

Janet Grijzenhout

1 Introduction

The phenomenon of "consonant mutation" occurs in a wide array of unrelated languages and comprises changes that are also known as "consonant weakening" (or *lenition*), "consonant strengthening" (or *fortition*), and "nasalization." In this chapter, "consonant mutation" will be defined as a change in one phonetic property of a consonant that affects its degree of sonority and that does not depend on the position of the consonant within a prosodic domain (i.e. neutralization and enhancement phenomena are excluded), nor on the position immediately adjacent to a segment with which it forms a natural class (i.e. progressive and regressive voicing and place assimilations are not regarded as instances of "consonant mutations"). More specifically, the term "consonant mutation" refers to a class of processes by which a consonant turns into a segment with a different degree of voicing, continuancy, or nasality that is not due to neutralization or assimilation to a neighboring segment of the same natural class.[1]

Some types of consonant mutation can be described as alternations that take place in a particular phonological environment; for instance, an oral stop may turn into a fricative between a sonorant consonant and a vowel. Other types of consonant mutation take place in a certain morphological or lexical context; for example, stem-initial oral stops are realized as continuants under certain morphosyntactic conditions, while continuants are deleted or realized as a laryngeal sound under the same conditions in Modern Irish (e.g. Ní Chiosáin 1991; CHAPTER 117: CELTIC MUTATIONS). The interesting aspect of consonant mutation in general is a diachronic one: what starts out as a purely phonological alternation induced by neighboring segments may gradually turn into a morphological alternation for which the phonological context is no longer transparent (CHAPTER 93: SOUND CHANGE). In the course of this chapter, we will encounter various examples of such developments.

[1] Note that changes in voicing, continuancy, or nasality make a consonant either more or less sonorant. Consonant mutation processes thus have in common that they alter a consonant's degree of sonority.

Typically, mutations are "scalar." In the languages of the world, we find consonant mutations where a consonant's degree of stricture decreases (e.g. in Archaic Irish and Finnish an underlying geminate stop is realized as a singleton stop, while an underlying singleton stop is realized as a continuant sound) or increases. Another example of a scalar mutation is one in which a consonant's degree of laryngeal specificity and/or nasality increases (e.g. in Old Irish, an aspirated voiceless stop is realized as an unaspirated one in the same context in which an unaspirated oral stop is realized as a prenasalized stop).

This chapter first discusses possible consonant alternations in more detail (§2). As examples of languages that have relatively many types of consonant mutations (i.e. spirantization, gemination, nasalization, and/or prenasalization), we discuss Southern Paiute (§3) and Fula (§4). Balto-Finnic, Sami, and some Australian languages show scalar mutations (§5). §6 points out the merits and drawbacks of some theoretical accounts of consonant mutation that exist in phonological literature. §7 summarizes the discussion.

2 Consonant alternations within prosodic and morphological domains

Consonants are highly adaptable elements that may change their properties for a variety of reasons. This section will focus on some phonological and morphological environments that may trigger a change in one phonetic property of a consonant. We start with consonant alternations that are characterized by the fact that a phonological opposition is neutralized in a certain prosodic environment, viz. final devoicing and debuccalization. We will also briefly consider consonant alternations that occur at the left edge of a prosodic domain. Next, five consonant alternations that are not triggered merely by a prosodic environment (i.e. that are independent of the position within a prosodic domain) and that fall under the rubric of "consonant mutation" are introduced: (a) stopping (Soninke), (b) obstruent voicing (Burmese), (c) spirantization or fricativization (Djapu; the first stage of Grimm's Law), (d) devoicing (the second stage of Grimm's Law), and (e) deaspiration (the third stage of Grimm's Law). Other types of consonant mutation that are frequently encountered in languages – both diachronically and synchronically – are gemination, degemination, and (pre)nasalization. The latter phenomena will be discussed in later sections.

Many consonant alternations are characterized by the fact that a phonological opposition is neutralized in a certain prosodic environment. In a variety of unrelated languages, e.g. Catalan, Czech, Dutch, German, Ojibwa, Polish, Russian, Turkish, and Wolof, we find that the opposition between voiced and voiceless obstruents is neutralized in one particular environment only, viz. at the end of a prosodic domain (usually the syllable; see Brockhaus 1995 and CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). In other languages, place of articulation contrasts are neutralized at the end of a prosodic domain – usually the syllable coda – and this phenomenon is known as "debuccalization" (CHAPTER 80: MERGERS AND NEUTRALIZATION). In some generative frameworks, alternations at the end of a prosodic domain are described as processes where consonants "lose" their underlying marked specification for laryngeal features or place of articulation features.[2] Conversely, in other positions of the word, consonants may become reinforced phonetically, e.g. by initial aspiration (which is seen as a form of enhancement, for instance, by Keyser and Stevens 2006: 42ff.). Consonant alternations that involve neutralization of an opposition in a particular prosodic context (e.g. the contrast between voiced and voiceless obstruents in Dutch and German is neutralized at the end of a prosodic domain), or that involve adding a feature to enhance an opposition in a particular prosodic domain (e.g. the contrast between voiced and voiceless stops is enhanced by adding aspiration for the voiceless plosives at the left word edge in English) do not fall under the category of "consonant mutations" as understood here.

In the examples in (1), stem-final consonants optionally change their laryngeal properties to become more similar to the neighboring consonants within a phonological phrase (e.g. Berendsen 1983 for Dutch) and in (2) the consonant /n/ changes its place of articulation to the same place of articulation as the following obstruent (CHAPTER 81: LOCAL ASSIMILATION).

(1) *Regressive laryngeal assimilation in obstruents*

a. *Dutch*

zeep + doos	→	*zee*[bd]*oos*	soap + box	'soap-box'
kas + boek	→	*ka*[zb]*oek*	cash + book	'cash-book'
zak + doek	→	*za*[gd]*oek*	pocket + cloth	'handkerchief'

b. *Hungarian*

zseb + kendo	→	*zse*[pk]*endõ*	pocket + cloth	'handkerchief'

(2) *Regressive place assimilation of* n- *(marker of noun classes* 9 *and* 10*) in Kisukuma* (data from Batibo 2000: 169)

n + buli	→	mbuli	'goat'
n + dama	→	ndama	'calf'
n + guzu	→	ŋguzu	'strength, energy'

Cases where consonants change a laryngeal or place feature under the influence of an adjacent consonant within a certain prosodic domain are most commonly referred to as "assimilations" rather than "mutations," and these processes are relatively easy to describe in theoretical frameworks, e.g. in autosegmental theory as spreading of laryngeal or place features or in Optimality Theory (OT) as phenomena that are the result of ranking AGREE[feature] and *[αfeature] constraints higher than the corresponding IDENT[feature] constraint (e.g. Lombardi 1996). The reason for assimilation is not to increase or decrease the degree of sonority of a segment, but rather to become "more similar" with respect to laryngeal or place properties to an immediately adjacent obstruent (in the Dutch or Hungarian examples) or a stop (in Kisukuma).

[2] Note that the assumption about laryngeal neutralization being a case of "weakening" in the sense that the consonant "loses" an underlying feature is highly controversial, as can be seen, for example, by the German terminology *Auslautverhärtung* ("final hardening") for syllable-final devoicing. Foley (1970), for instance, claims that a change from voiced to voiceless obstruent should be considered a case of strengthening ("fortition") rather than weakening ("lenition"). For further discussion on the issue of what exactly constitutes strengthening or weakening, I refer to CHAPTER 66: LENITION.

The set of data below illustrates a process whereby the oral stricture of initial consonants of nouns increases, i.e. voiceless fricatives or voiced continuants are realized as oral stops (3a), /l/ (3b), or nasal stops (3c) after nasal segments:[3]

(3) *Consonant alternations after nasals in Soninke*

a.	fare	'donkey'	n pare	'my donkey'
	si	'horse'	n ʧi	'my horse'
	xore	'charcoal'	n gore	'my charcoal'
b.	raqqe	'mouth'	n laqqe	'my mouth'
c.	wulle	'dog'	n ŋulle	'my dog'
	jaaxe	'eye'	n ɲaaxe	'my eye'

In the examples in (3), all continuant consonants are affected and the trigger of the change is always the same, i.e. a nasal element. Intuitively, we may formulate the consonant alternation as a process that increases a consonant's oral stricture after a nasal stop or nasalized vowel. Nevertheless, it is not easy to describe this process as one in which a single feature of the stem-initial consonant changes under the influence of a preceding nasal vowel or stop.[4] Furthermore, some nouns (especially names) "resist" change and do not participate in the consonant alternation process. Moreover, under some morphological conditions, the nasal trigger is absent, but the change takes place nonetheless, for instance in some imperative forms, e.g. /pagu/ 'fill up!' and /ʧi/ 'shave!' (cf. /si/ 'to shave'). According to Kendall and Bird (1982), the language is thus in a transitional stage in which the phonologically triggered process of consonant change has developed into a process that is no longer purely phonological; there are exceptions as well as overapplications, i.e. cases where the consonantal change takes place without an overt phonological trigger.

We next consider another type of consonant alternation where the phonological context determines the shape of a consonant: in Burmese, voiceless stops are voiced in intervocalic position (4a), (4b) or following a nasal (4c).

(4) *Intersonorant stop gradation in Burmese* (data from Campbell 1995: 98–102)

a.	θwa + pa	→	θwàba	'please go'
b.	θwa + tɔ + lu	→	θwàdɔ̀lu	'the man who is going'
c.	kauŋ + kauŋ	→	kauŋgauŋ	'to be good'

[3] Soninke is a Mende language spoken in West Africa. All Soninke data presented in this chapter are from Kendall and Bird (1982). The nasals in (3a) assimilate in place of articulation to the following segment. Kendall and Bird (1982: 1, 3) state that the same consonant alternation occurs both after nasal consonants and after nasalized vowels, e.g. /r/ in /ri/ 'to come' is realized as /l/ after a nasalized vowel in /nili/ 'I came'.

[4] In *SPE* (Chomsky and Halle 1968), we could formulate a rewrite rule [+continuant] → [–continuant] / [+nasal] __, with some additional rules to account for the fact that voiced continuants turn into a lateral or nasal stop. In autosegmental phonology, there is no single feature that nasal consonants and vowels have in common that could spread unto the following consonant. In OT, it is possible to formulate a constraint that bans continuant consonants after a nasal consonant or vowel (e.g. *[+nas][+cont, –voc]), but this constraint would be an ad hoc one and leaves open the possibility of other ad hoc constraints such as *[+strid][–cont] or *[+nas][lab], etc.

In the Australian language Djapu, stops are only realized as such in lexical words after obstruents and nasal stops. Thus the dative suffix /-ku/ appears as such in [buurut̪ʲ-ku] 'mosquito'; when preceded by a vowel or a liquid, however, the labial and velar stops become a labial-velar glide (e.g. [ŋajmil-wu] 'Ngaymil clan') and the dental stop becomes a palatal glide (Morphy 1983).

Cases where consonants change in an intersonorant environment are most often referred to as "gradations" or "mutations." When glides become fricatives, when underlying continuants becomes non-continuant segments (as in Soninke), or when singleton stops are geminated, the mutation is often referred to as "consonant hardening" or "fortition." If the mutated consonant increases its degree of sonority, this type of mutation is often referred to as "consonant weakening" or "lenition." The environment for gradation in Soninke can be characterized as "after a nasal"; gradation in Burmese is "in intervocalic position or between a nasal stop and a vowel," whereas the environment for gradation in Djapu is "in intervocalic position or between a liquid and a vowel." CHAPTER 66: LENITION provides more examples of intervocalic voicing and spirantization.

The interesting problem that consonant mutations pose for phonological theory is that they change the degree of sonority of a segment (CHAPTER 49: SONORITY) and that they are not easily accounted for by means of autosegmental processes such as spreading, inserting, or deleting a phonological feature or class of features within a natural phonological context (CHAPTER 14: AUTOSEGMENTS). Neither is it easy to account for them by means of well-formedness constraints that correctly predict surface forms in non-mutation contexts and the corresponding alternating forms in mutation contexts. Consider in this respect that a possible constraint that penalizes intersonorant voiceless stops could be *[+son][−son, −voice][+son] (i.e. no voiceless obstruent in between two sonorants). This constraint would be violated in a potential output [θwàpa]. If the markedness constraint in question is ranked higher than the faithfulness constraint IDENT[voice] – which, presumably would be the case in Burmese – the output [θwàba] would win. Now consider the fact that the winning candidate in Burmese would be a form that is disallowed in Spanish (see e.g. Harris 1969). Whereas Spanish allows intervocalic voiceless stops – suggesting that *[+son][−son, −voice][+son] is low-ranked – it does not have output forms with intervocalic voiced stops (resembling the winning candidates for Burmese). In an optimality-theoretical framework, we could again propose a constraint, e.g. *[+son][−son, −cont, +voice][+son] (i.e. no voiced stop between two sonorants), which would have to be ranked higher than a faithfulness constraint, e.g. IDENT[−son, −cont] to generate the correct output for Spanish. Apart from the fact that there is an ad hoc flavor to the OT accounts suggested immediately above, a further complicating factor is the fact that some languages exhibit both consonant alternations in their grammars. In Northern Corsican, for example, voiceless stops become voiced where voiced stops spirantize. Moreover, we find exactly the same consonant alternations in contexts that cannot be described in a straightforward way as being "inter-sonorant." Rather, as will be shown in subsequent sections, the same consonant alternations as described here appear in different morphological contexts or are lexicalized in various unrelated languages.

The cases presented so far all reflect synchronic processes. The interest in consonant mutations, however, first arose with respect to diachronic changes such as the first consonant shift in West Germanic (also known as Grimm's Law) and early Celtic consonant mutations (Pedersen 1897; Thurneysen 1898).[5]

Grimm's Law is often formulated as follows: the Indo-European stops /p t k kʷ/ spirantized and became fricatives, the unaspirated stops /b d g gʷ/ became voiceless aspirated stops, and so-called "breathy voiced" stops /bʰ dʰ gʰ gʷʰ/ were replaced by voiced unaspirated stops (CHAPTER 73: CHAIN SHIFTS). Iverson and Salmons's (1995) account of the first shift in Grimm's Law runs as follows. The voiceless aspirated stops became voiceless fricatives when aspiration was audible (i.e. only when the stop was released, so that stops following /s/, geminates and stop–stop clusters did not undergo the shift). The unaspirated stops – in which voicing was optional – had a "stronger and longer" closure phase, which made them unlikely candidates for fricativization. Thus, the outcome of the first shift in Grimm's Law is a system in which we find fricatives (specified for [stiff vocal folds]), unaspirated stops (unspecified for laryngeal features), and voiced aspirated stops (specified for [slack vocal folds, spread glottis]). The second stage of Grimm's Law is the process whereby the contrast between stops unmarked for laryngeal features (/b d g gʷ/) and stops marked as "slack with aspiration" (/bʰ dʰ gʰ gʷʰ/) is increased by introducing [stiff vocal folds] (which is available already in the fricative series) for the unmarked stops. In the system where [stiff vocal folds] stops contrast with [slack vocal folds] ones, there is no need to maintain the aspiration contrast and hence the feature [spread glottis] for breathy voiced stops gradually loses its place in the stop system. The three subsequent mutations may thus be characterized as follows: (a) fricativization of voiceless stops (/p t k kʷ/ → /f θ x xʷ/), (b) fortition or devoicing of lax stops (/b d g gʷ/ → /p t k kʷ/), and (c) deaspiration of aspirated lax stops (/bʰ dʰ gʰ gʷʰ/ → /b d g gʷ/).

This section has introduced five consonant alternations that affect the degree of sonority and that fall under the rubric of "mutations": stopping, obstruent voicing, spirantization or fricativization, devoicing, and deaspiration. Other mutations that are frequently encountered in languages – both diachronically and synchronically – are gemination, degemination, and (pre)nasalization. In the following sections we will discuss informative examples of synchronic consonant mutations. We start with Southern Paiute, a language that exhibits spirantization, gemination, and nasalization.

3 Southern Paiute consonant mutations

Sapir (1930) describes the Shoshonean dialect Kaibab Paiute, as it was spoken in southwestern Utah and northwestern Arizona during the 1910s. In this dialect, consonants can appear in one form when in suffix-initial position after a consonant or in word-initial position, and in various alternating forms when – by the process of derivation or compounding – they are immediately preceded by a vowel. The particular process that a suffix undergoes is dependent on the lexical item it is attached to and is not phonologically predictable in any obvious way.

[5] For a discussion on the history and present-day exponents of Celtic consonant mutations the reader is referred to CHAPTER 117: CELTIC MUTATIONS.

(5) *Southern Paiute consonant mutations* (Sapir 1930: 62)[6]

underlying	*spirantized*	*geminated*	*nasalized*
p	β	p:	mp
t	ɹ	t:	nt
k	ɣ	k:	ŋk
kʷ	ɣʷ	kʷ:	ŋkʷ
ts/ʧ	ts/ʧ	ts:/ʧ:	nts/nʧ
s/ʃ		s:/ʃ:	
m	ŋʷ	m:	m:
n		n:	n:

Under spirantization, oral stops change into voiced continuants, affricates do not change, and the labial nasal becomes a "back palatal" labialized nasal consonant (represented as /ŋʷ/ by Sapir). Harms (1966) attempts to describe Paiute spirantization as a regular phonological rule ([+consonantal, –vocalic, –strident] → [+continuant, +voice] / [–consonantal, +vocalic, +voice] __), but such a rule only accounts for part of the alternation, and leaves the change from labial nasal to dorsal labialized nasal unexplained. Before we turn to another analysis of Southern Paiute consonant mutations, we first introduce some examples.

To illustrate the effect of mutation, Sapir (1930: 63, 67) mentions the verbalizing suffix /-ka/ and the agentive suffix /-pi/, with their respective mutated initial consonants following adjectival (6a)–(6c) and nominal stems (6d)–(6e):

(6) *Consonant mutations affecting morpheme-initial /k/ and /p/ in Southern Paiute*

a.	aŋka	+	-ka	→	aŋkaɣa	'to be red'	*spirantization*
b.	kụʧa	+	-ka	→	kụʧak:a	'to be gray'	*gemination*
c.	paɨ	+	-ka	→	paɨŋka	'to be smooth'	*prenasalization*
d.	nɔ	+	-pi	→	nɔvi	'carrier'	*spirantization*
e.	taŋa	+	-pi	→	taŋampi	'kicker'	*prenasalization*

Note that the stem /aŋka/ 'red' triggers spirantization in a following suffix (6a), but is followed by a geminated consonant in compounds (7):

(7) *Consonant mutations affecting stem-initial /k/ and /p/ in Southern Paiute compounds*

aŋka	+	kani	→	aŋkak:anị	red + house	'red house'
aŋka	+	pajɨ	→	aŋkap:aji	red + fish	'trout'

As a possible explanation for the difference in the choice of consonant mutation between derivation and compounding in some nouns, Sapir (1930: 70) suggests that "the tendency to use geminated consonants in composition is probably due to the greater phonetic similarity thus brought about between a simplex and its compound."

[6] The consonants and the consonant alternations mentioned by Sapir (1930) are represented here by means of the corresponding IPA symbols. According to Sapir, spirantized consonants following voiced vowels are voiced, and those following voiceless vowels are voiceless. I present the voiced allophones only. The glides /w/ and /j/ and the nasal /ŋ/ do not occur in initial positions and are hence not affected by mutations. The glottal stop does not undergo mutations. The three blanks in (5) indicate that [s/ʃ] and [n] do not have a spirantized counterpart and that [s/ʃ] lacks a nasalized form.

McLaughlin (1984: 70–71) notes that prefixes are followed by one fixed mutation, i.e. all prefixes affect the initial consonant of a following stem, and Southern Paiute distinguishes "spirantizing," "geminating," and "nasalizing" prefixes. In compounds, noun stems may trigger one of three mutations, but in most cases nouns in compounds trigger gemination only. In verbal compounds, the verb of the second member has its initial consonant geminated in the majority of cases. To McLaughlin, these facts suggest that prefixes show the strongest reflection of an earlier stage in the language, viz. one in which a prefix-final phoneme triggered a change in the following consonant. The phoneme in question is lost, but the mutation that it triggered is still in effect. Nouns also show this effect, but are in a transient stage; nominal stems are cautiously on their way to induce one particular mutation only, i.e. gemination. Verbs have developed even further and generally geminate a following consonant.

To account for Southern Paiute consonant mutations, McLaughlin (1984) proposes that all prefixes, most noun stems, some adjectival stems, and a few verb stems end either in (a) a vowel, (b) an unspecified stop C, or (c) an unspecified nasal N.[7] The last two are reflexes of final stops and nasals that used to be present in earlier stages of the language. If a stem is preceded by a prefix or another stem ending in a vowel, its first consonant will undergo a rule of spirantization. A suffix or stem following an unspecified stop or nasal, however, will undergo a place assimilation rule (e.g. /taŋaN + pi/ → [taŋampi]). Finally, stems following an unspecified stop will also be subject to a lengthening rule, so that the result will be a geminate consonant. Another rule may subsequently degeminate the stop in question when it follows an unstressed vowel.

McLaughlin's analysis of spirantization thus involves a regular spirantization rule, which turns stops into voiced spirants in inter-sonorant position. The analysis of gemination and nasalization, on the other hand, depends on "ghost" elements, i.e. a final stop or nasal that never surfaces, but has a geminating or nasalizing effect if another consonant follows in the next morpheme (i.e. a suffix in the case of derivation and a stem in the case of compounding). These processes are thus lexical in the sense that in the lexicon, the morphemes in question (prefixes, most noun stems, and some adjectival stems) end either in a vowel or in an unspecified stop or nasal. The mutation triggered by verb stems is becoming more and more morphologized; i.e. morphological leveling is producing ever larger numbers of geminating verb stems.

Since oral stops become continuants under spirantization, we would perhaps expect the labial nasal stop to turn into a labial approximant [w] (CHAPTER 28: THE REPRESENTATION OF FRICATIVES), as is the case in Celtic (see CHAPTER 117: CELTIC MUTATIONS). The question arises why this is not the case. With respect to the quirky character of spirantized /m/, McCarthy and Prince (1995: 349ff.) make the following suggestion. They first observe that the segments [w] and [ŋʷ] are in complementary distribution: the former is found word initially and the latter occurs post-vocalically.[8] This distribution follows from the following

[7] For similar proposals to account for Celtic consonant mutation, see CHAPTER 117: CELTIC MUTATIONS.

[8] The only exception is the context of reduplication, where "w" surfaces between vowels due to an identity constraint that says that a base and a reduplicated form cannot have different values for the feature [nasal]. The fact that [ŋʷ] is not allowed to occur in word-initial positions (*]ŋʷ) rules out a candidate like hypothetical *[ŋʷa-ŋʷaxipija]. In *[wa-ŋʷaxipija] the constraint IDENT-BR[nasal] is violated and the candidate [wa-waxipija] is the winner even though it has a "w" after a vowel (i.e. the constraints mentioned in this footnote are ranked as follows: *]ŋʷ, IDENT-BR[nasal] >> *VwV).

ranking of constraints: *VwV >> *ŋʷ >> *w. Even though this ranking accounts for the fact that we are more likely to find [ŋʷ] rather than [w] in intervocalic position, it is not immediately clear why /m/ alternates with [ŋʷ] in the first place, i.e. why /m/ surfaces as a nasal with a "back palatal" place of articulation in a spirantization context. If spirantization means that oral or nasal stops are realized as continuants, and if there is an operation or constraint (*VwV) that prevents the nasal /m/ from being realized as the corresponding continuant [w], it is still not evident that /m/ undergoes a transformation whereby it turns into a labialized dorsal nasal stop. I will leave this issue for further research.

4 Fula consonant mutation

Fula (also known as Fulani, Fulbe, Fulfulde, Pular, Pulaar, and Peul) is spoken in West Africa; the majority of the speakers live in Nigeria (Campbell 1995: 178). In all dialects of Fula, initial consonants of verbal radicals and nominal, numeral and verbo-nominal stems can have different forms. In contrast to Southern Paiute – where stem-initial consonants change their form depending on the mutating requirements of the preceding prefix or stem – one cannot argue that in Fula a segment has a different surface form depending on a preceding vowel or a morpheme specified for a mutating feature. Arnott (1970) shows that in the Gombe dialect of Fula, stem-initial consonants surface as homorganic stops, continuants or prenasals, depending on the adjective or noun class.

(8) *Fula consonant mutations* (based on Arnott 1970: 42–43)[9]

stop	*spirant*	*prenasal*
p	f	p
b	w	mb
d	r	nd
ʃ[10]	s	ʃ
ɟ	j	ɲɟ
k	h	k
g	j/w[11]	ŋg

According to Arnott (1970), adjectives and nouns are marked as belonging to one of 25 possible classes. Class membership is indicated by a suffix[12] and a particular manner of articulation of the initial consonant of the stem: 11 classes are marked by a stem-initial voiceless or voiced stop, six classes are marked by

[9] The consonant alternations mentioned by Arnott are represented here by means of the corresponding IPA symbols. Note that the glottalized consonants /ɓ ɗ ƴ/, the nasals /m n ɲ ŋ/, and the coronal consonants /t c l/ are "invariable" and do not alternate.

[10] Note that this sound is a fricative, but in the mutation system it functions as a stop. In most analyses of Fula consonant mutations that can be found in the literature, this sound is usually transcribed as the palatal stop /c/, but this does not tally with Arnott's (1970) description of this sound.

[11] The palatal glide is found before the front vowels /i e/ and the labial-velar one before the back vowels /u o a/.

[12] Suffixes belong to certain grades, indicated as grades A, B, C, or D in Arnott (1970). In the phrase /gude daneeje/ 'white cloths', both the noun and the adjective belong to class 24 (i.e. one of the classes that are marked by an initial stop), but the noun /gude/ 'cloths' has a grade A suffix /-e/ and the adjective /daneeje/ 'white' has a grade B suffix /-je/.

an initial spirant and eight are marked by an initial voiceless oral stop or a prenasalized stop. The marker of noun class 1 (singular nouns referring to persons), for instance, is a suffix ending in the vowel /o/ and a stem-initial stop. The marker of noun class 2 (plural nouns referring to persons) is a spirant-initial stem consonant and the suffix /-ɓe/. The marker of class 7 is a suffix ending in the vowel /a/ and a stem-initial oral voiceless stop or prenasalized stop for consonants that alternate with a voiced stop in class 1:

(9) *Stem-initial consonant alternations in Fula nouns* (data from Arnott 1970: 98–99)

class 1	*class 2*	*class 7*	
pull-o	ful-ɓe	pul-a	'Fula'
beer-o	weer-ɓe	mbeer-a	'host'
dim-o	rim-ɓe	ndim-a	'free man'
ʃook-o	sook-ɓe	ʃook-a	'poor man'
ɟuul-ɗo	juul-ɓe	ɲɟuul-ŋga	'Moslim'
kor-ɗo	hor-ɓe	kor-ga	'female slave'
gim-ɗo	jim-ɓe	ŋgim-ŋga	'person'

In an autosegmental framework that assumes radical underspecification (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION), Wiswall (1989) proposes that Fula voiceless continuants are underlyingly specified for [−voice], but not for manner of articulation. The voiceless stops are specified for [−voice] as well, and all underlying oral stops have a specification for [−continuant]. Underlying non-alternating nasal stops have a specification for [+sonorant] and [+nasal]. Wiswall furthermore suggests that noun class markers in Fula have floating features that associate to the initial consonant of the stem (CHAPTER 82: FEATURAL AFFIXES); the stop classes have a floating [−continuant] feature (which is problematical for the sound /ʃ/), the prenasal classes have a floating [+nasal] feature (which presumably cannot dock onto sounds underlyingly specified as being [−voice]), but the spirant classes do not have a floating feature. After association of the floating features, redundancy rules (e.g. [−continuant] → [−sonorant]), and default rules (Ø → [+continuant]) fill in the unspecified feature values. Grijzenhout (1991) points out some problems relating to the rule ordering (CHAPTER 74: RULE ORDERING) that Wiswall has to assume, especially related to the account of prenasals, which would involve a late counterintuitive redundancy rule [+nasal] → [−sonorant].

For an alternative account of the data involving the theory of "charm and government," the reader is referred to work by Paradis (e.g. Paradis 1987a, 1987b, 1992). Elzinga (1996) provides an OT account of Fula consonant mutation, which makes use of alignment and parsing constraints on the mutating features [continuant] and [nasal]. He furthermore employs morpheme constraints, i.e. constraints that indicate the type of stem ("invariable," "partially variable," or "fully variable"). The morpheme constraints are placed in between the feature alignment and parsing constraints, so that invariable stems and suffixes are ranked higher in the hierarchy than the mutation constraints, partially variable stems and suffiixes are ranked below some mutation constraints and above others, and fully variable stems and suffiixes are ranked lower than the mutation constraints.

We now turn to cases of scalar mutations, i.e. mutations that cause a change from one underlying consonant to another consonant, which also mutates into a different one.

5 Balto-Finnic and Sami consonant gradation

Most languages belonging to the Balto-Finnic group (i.e. Finnish, Estonian, Votic, Ingrian, and Karelian; excluding Livonian and Veps), as well as northern and eastern dialects of the closely related Sami group, exhibit consonant gradations. It is striking that a similar phenomenon, by which long stops were shortened and short stops were turned into spirants, occurred in the history of Iwaidjan languages in Australia (e.g. Evans 1998). The phonological condition that generated consonant gradation in languages belonging to the Balto-Finnic group was originally the following: after a vowel or sonorant consonant in a stressed syllable, stops in the so-called "strong grade" that appeared in the onset of a syllable that was closed by certain inflectional or derivational endings were mutated such that they appeared in the corresponding "weak grade." Under this condition, underlying long (or "geminate") stops were reduced to short (or "singleton") stops and underlying short stops were replaced by voiced and fricated consonantal variants. Thus, in the Balto-Finnic languages, long /pː/ alternated with short /p/ while short /p/ alternated with /b/ or /v/, and long /tː/ alternated with short /t/ while short /t/ alternated with /d/ or /ð/. Similarly, in the history of Iwaidjan languages, long intervocalic stops were shortened and short intervocalic stops became approximants or liquids (e.g. /pː/ → /p/ → /w/ and /cː/ → /c/ → /j/).

Different varieties of Sami and Estonian now have a three-way opposition between the strongest grade or quantity, the strong grade, and the weak grade, but the phonemes involved in the alternations are somewhat different for each language or language variety. We most often find that in contexts where gradation applies in these languages, (a) "overlong stops" (usually written as <pp tt kk>, corresponding to the sounds /pːː tːː kːː/) are realized as "long stops," (b) "long stops" (orthographic <p t k>, corresponding to the geminates /pː tː kː/) are realized as "short" consonants, and (c) underlyingly "short stops" (i.e. those with the shortest closure duration, usually written as <b d g>, corresponding to unaspirated /p, t, k/) spirantize.

Consonant gradation is more or less regular in most dialects of Sami. In many Sami dialects, consonant gradation was extended to consonants that had not been subject to gradation in earlier stages of the language and now also affects sonorant consonants; see (10d). Gradation applies when an affix closes an unstressed syllable. Moreover, gradation still occurs in genitive forms – see (10c) and (10d) – even though the original inflectional ending [-n] has been lost in some variations of Sami, so that the final syllable is no longer closed:

(10) *Sami consonant gradation* (Gordon 1998; Campbell 2004: 322)[13]

	non-gradated		*gradated*	
a.	bapppa	'priest (NOM SG)'	bappast	(ELAT SG)
b.	loppe	'permission (NOM SG)'	lobest	(ELAT SG)
c.	jokkâ	'river (NOM SG)'	jogâ	(GEN SG)
d.	guolle	'fish (NOM SG)'	guole	(GEN SG)

[13] Recall that orthographic <b g> in examples (10b) and (10c) correspond to short unaspirated /p k/.

Interestingly, in some Sami languages, the original gradation process now also works in reverse; single consonants are geminated in open syllables:

(11) *Sami "reversed" consonant gradation; i.e. gemination* (cf. Uralic languages 2010)

	geminated			*gradated*	
a.	ʧuotte	*ʧuote	'hundred (NOM SG)'	ʧuoðe	'hundred (GEN SG)'
b.	borra		'eats'	borâın	'I eat'

Thus, by "reversed gradation," the contrast between two related forms is enhanced: instead of a short stop–fricative contrast, we now have a geminate–fricative contrast in (11a).

The examples below illustrate the phenomenon of consonant gradation for Modern Finnish (e.g. Karttunen 1970; Skousen 1972; Keyser and Kiparsky 1984; Vainikka 1988); geminate stops degeminate (12a) in the same environment in which the singleton stops lessen their degree of stricture and become continuants (12b),[14] assimilate to a preceding sonorant consonant with the same place features as the stop in question (12c), or are not realized (12d):[15]

(12) *Finnish consonant gradation in closed syllables*

	underlying form (nominative)	*gradation (genitive)*	
a.	*lappu*	*lapun*	'piece of paper'
	matto	*maton*	'rug'
	kukka	*kukan*	'flower'
b.	*tapa*	*tavan*	'custom'
	mato	*madon*	'worm'
c.	*rampa*	*ramman*	'lame'
	lintu	*linnun*	'bird'
d.	*poika*	*pojan*	'boy'
	selkä	*selän*	'back'

As is the case in some variations of Sami – see (10c), (10d), and (11a) above – the original genitive ending /-n/ has been lost in Estonian, but gradation still occurs in genitive forms:

(13) *Estonian consonant gradation in genitive nouns* (Harms 1962)

	nominative	*genitive*	
a.	*leib*	*leiva*	'bread'
b.	*madu*	*mao*	'snake'
c.	*lind*	*linnu*	'bird'
d.	*selg*	*selja*	'back'

[14] Finnish <v> represents an approximant; <d> is a dental sonorous element whose value varies from dialect to dialect; see e.g. Vainikka (1988). Here and in what follows, I abstract away from dialectal variation.

[15] Finnish <j> represents /j/; see e.g. Vainikka (1988).

We again witness how a phonologically triggered mutation gradually changes into a morphologically triggered mutation. The original consonantal morphological ending caused the syllable in question to become closed and thus provided the phonological environment for gradation to take place. When the consonantal ending disappeared in the course of history, gradation still took place. In present-day Estonian, consonant gradation is thus triggered by morphology rather than phonology.

The type of consonant gradation presented in this section is not unique to Balto-Finnic languages and varieties of Sami. Similar processes are found in some languages belonging to the Samoyedic branch of the Uralic language family (in particular Nganasan and Selkup; see CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE for examples and an OT account of consonant gradation in Nganasan).

6 Mutation and phonological representations

Our first examples of consonant mutation – i.e. stopping after nasal vowels and consonants in Soninke, inter-sonorant voicing in Burmese, and inter-sonorant spirantization in Djapu – have been accounted for in phonological literature as cases where one feature of a preceding segment (e.g. [–continuant] in the case of nasal stops, [+voice] in the case of vowels and sonorant consonants, and [+continuant] in the case of vowels) spreads to the target consonant.[16] The first drawback of such an analysis is the obvious fact that spreading of [±continuant] is hardly attested in obstruents (CHAPTER 13: THE STRICTURE FEATURES); cases where an oral stop induces a change in a preceding or following fricative (e.g. hypothetical /t + fare/ → [tpare]) are hardly – if ever – attested. Moreover, even though we find relatively many cases where vowels cause spirantization of stops, fricatives never cause spirantization of adjacent stops (see Wetzels 1991), and this makes the suggestion that intervocalic spirantization is analyzed best as a case of spreading the feature [+continuant] problematic (CHAPTER 28: THE REPRESENTATION OF FRICATIVES).

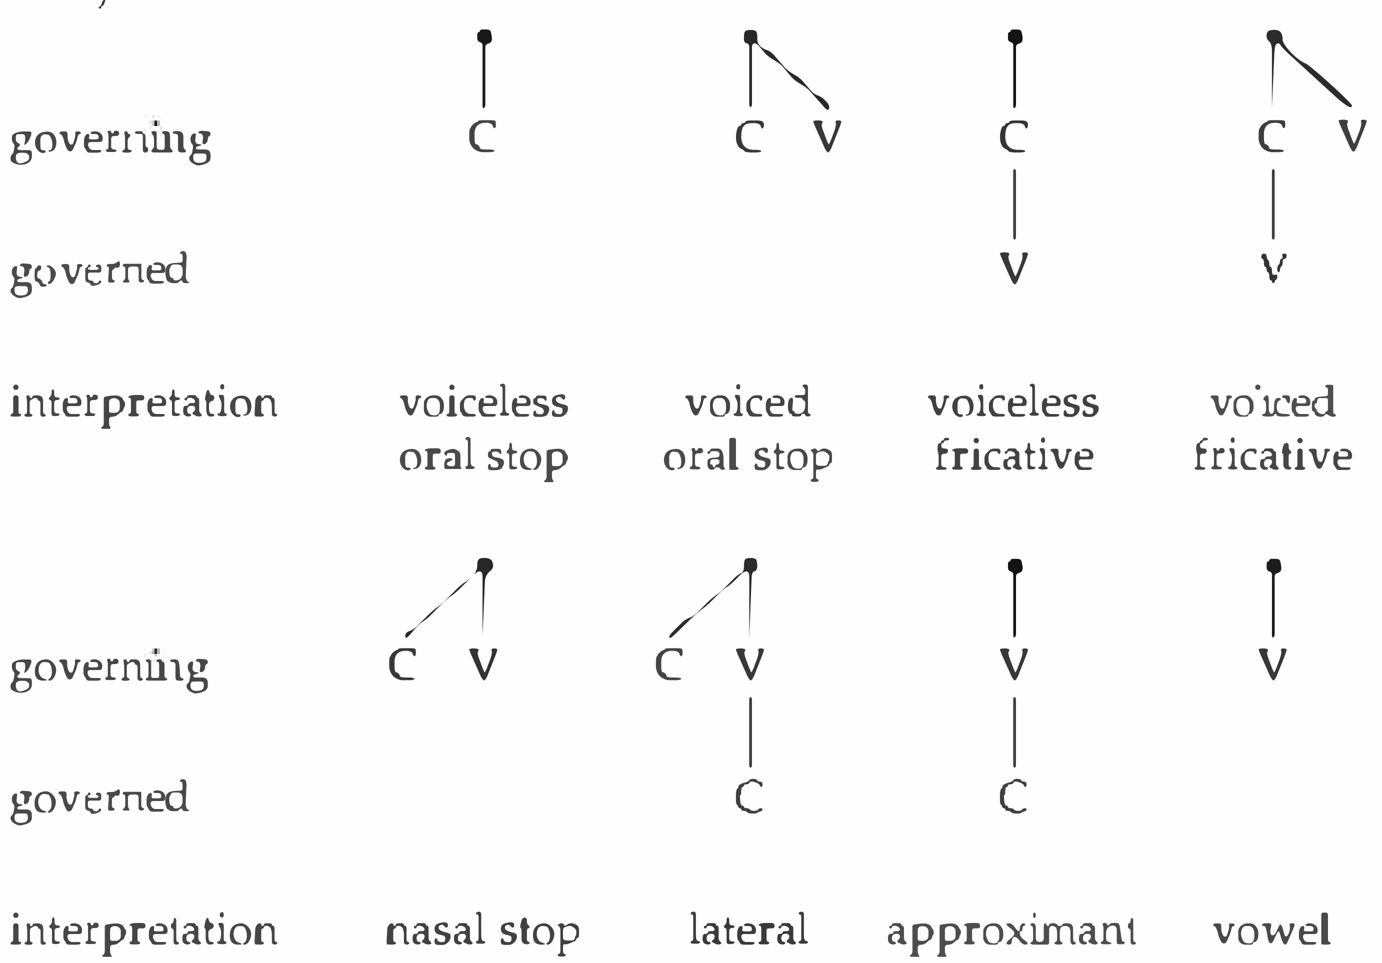
Furthermore, a spreading analysis is problematic for cases where there is no phonological segment that triggers the mutation. In those cases, e.g. Southern Paiute gemination, McLaughlin (1984) and others have suggested underlying underspecified segments that usually do not surface and only affect a following segment in mutation contexts, resulting in, for instance, a geminated consonant. Others, e.g. Wiswall (1989), propose "floating" features such as [+nasal] to account for initial prenasalization in, for instance, Fula (CHAPTER 82: FEATURAL AFFIXES). Mutation, then, is viewed as the change of one sound into another sound due to feature insertion; it is unpredictable which feature will cause a change under which circumstances in which language. The problem with this particular approach is the existence of the "scalar" mutations witnessed in Northern Corsican, Finnish, or Sami, for instance, which cannot be accounted for by means of insertion of a

[16] Thus, in these accounts, strengthening and weakening are treated as local processes where the target sound is adjacent to another sound that spreads one of its features to the target. Cf. Harris (1994), who proposes an account where an element expressing full closure or aperiodic energy (as for aspiration) spreads from one position to another in the case of strengthening, and where an element is delinked or deleted under lenition, so that the result is a "weaker" – i.e. less complex – segment.

single "floating" feature. Scalar mutations are changes in underlying consonants that result in more sonorant segments (e.g. voiceless stop → voiced stop → voiced continuant), or in segments with a higher degree of oral aperture (e.g. geminate stop → singleton stop → continuant consonant, with perhaps eventual segmental loss); feature-based analyses seem to be unable to capture this aspect.

Van der Hulst and Ewen (1991) suggest that the scalar nature of consonant mutation is most adequately accounted for by a framework in which sonority (CHAPTER 49: SONORITY) is expressed by C and V nodes that can either function as governing or governed nodes. In their system, the interpretation of a governing "C" is "some degree of oral closure that characterizes an obstruent" ([−sonorant]) and the interpretation of a governing "V" is "sonorant." The two elements "C" and "V" can also be adjoined to a governing element; an adjoined "C" is interpreted as "oral closure for sonorants" (in the case of nasal stops and laterals), and an adjoined "V" is interpreted as "periodic sound source" or "vocal cord vibration" (as expressed in feature-based frameworks by the feature [+voice]). An element "V" that is governed by an element "C" is interpreted as "continuous airflow" ([+continuant]):

(14) *C and V components in phonological representations* (van der Hulst and Ewen 1991)



Van der Hulst and Ewen (1991) further view the consonant mutations referred to as "inter-sonorant lenitions" as the result of imposing the element "V" from neighboring sonorant segments onto the consonant in question. Thus, in inter-sonorant positions, "V" can be added to the structure of a consonant either by adjunction – to give a voiced obstruent (/p/ → [b] and /f/ → [v]) – or by subjunction, to give a continuant (/p/ → [f] and /b/ → [v]). Within this theory, we might thus account for Northern Corsican consonant mutation as a process by which the element "V" is (a) adjoined to "C" segments that do not have an adjoined node and (b) subjoined to segments that involve "C" and an already adjoined "V" (thus, /p/ → [b], while /b/ → [β]).

Under this approach, another scalar mutation may involve a process by which the element "V" is adjoined to "C" segments that do not have an adjoined node and by which the element "V" is turned into the head element, so that the element "C" becomes the adjunct (thus, /p/ → [b], while /b/ → [m], as in e.g. Modern Irish initial nasalization).

The advantage of the approach suggested by van der Hulst and Ewen (1991) is clearly the fact that consonant mutations generally known as "lenitions" can be described as a more or less unified process involving an increase in the dominance of the element "V" (i.e. sonority). An account of stopping after nasals as observed in Soninke is less straightforward in this framework. Also, it is not immediately clear how the different mutations that do not have an overt phonetic trigger – such as the ones found in Southern Paiute or Fula – can be explained, and it is even less obvious how graded mutations in the Balto-Finnic and Sami languages would fit in this picture.

Another proposal for the representation sonority – especially sonority related to the degree of oral stricture – is formulated by Steriade (1993, 1994). Steriade defines slots to which laryngeal, place, and other features attach in terms of degrees of oral aperture. Released stops and affricates are viewed as sequences of a phase with complete oral closure (zero aperture, i.e. A_0) followed by a release phase (A_{fric} or A_{max}, also referred to as A_{rel} below).

(15) *The phonological representation of consonantal segments in Aperture Theory* (Steriade 1993, 1994)

oral stricture	A_0 A_{max}	A_0 A_{fric}	A_{fric}
place	[labial]	[labial]	[labial]
interpretation	labial oral released stop	labial affricate	labial fricative
nasality	[nasal]	[nasal]	
oral stricture	A_0 A_{max}	A_0 A_{max}	A_{max}
place	[labial]	[labial]	[labial]
interpretation	labial prenasal stop	labial nasal stop	labial approximant

Grijzenhout (1995, 1996) uses this framework to describe lenition as a form of loosening oral stricture and fortition as a procedure that increases oral stricture. The process by which a fricative is realized as a stop in Soninke can thus be described as one by which A_0 is inserted; the process by which a stop is realized as a fricative, e.g. in Spanish, involves deleting the A_0 slot from the representation:

(16) a. *Stopping (increase stricture) as insertion of* A_0

A_{rel} → A_0 A_{rel} (e.g. /f/ → [p] in Soninke)

b. *Spirantization (reduce stricture) as deletion of* A_0
$A_0\ A_{rel} \rightarrow A_{rel}$ (e.g. /b/ → [β] in Spanish)

Assuming that the articulation of long stops or geminates involves a long closure phase, long stops can be represented as elements with two A_0 nodes (17) (CHAPTER 37: GEMINATES). Southern Paiute gemination thus involves the same procedure as indicated above for Soninke stopping, i.e. insertion of A_0. Under consonant gradation, constriction loosens, which can be described as the loss of an A_0 slot (17b):

(17) a. *Gemination (increase stricture) as insertion of* A_0

short stop		*long stop*		
$A_0\ A_{rel}$	→	$A_0\ A_0\ A_{rel}$		
/p/	→	[pː]		Southern Paiute

b. *Consonant gradation (reduce stricture) as deletion of* A_0

long stop		*short stop*		*approximant*	
$A_0\ A_0\ A_{max}$	→	$A_0\ A_{max}$	→	A_{max}	
/pː/	→	[p]			Finnish
		/p/	→	[w]	

Other cases where single released stops are realized as fricatives also often involve a preceding vowel. Examples are Tigrinya and Biblical Hebrew post-vocalic spirantization; stops become more sonorant in the context of vowels, and the phonetic effect is that they are realized as fricatives. In Biblical Hebrew, post-vocalic singleton /p/ is realized as [f], /k/ is realized as [x], /t/ as [θ], /b/ as [v], /g/ as [ɣ], and /d/ as [ð] (Sampson 1973; Kenstowicz 1994: 53, 411, 417):[17]

(18) *Biblical Hebrew post-vocalic spirantization of single short stops*

/paːgaʃ/	[paːɣaʃ]	'meet (PERF)'
/ji-pgoːʃ/	[jifgoːʃ]	'meet (IMPERF)'
/kaːtab/	[kaːθav]	'write (PERF)'
/ji-ktob/	[jixtov]	'write (IMPERF)'
/gaːdal/	[gaːðal]	'become great (PERF)'

Note that in the same context, geminate stops are not affected, i.e. post-vocalic geminate stops do not alter:

(19) *Biblical Hebrew post-vocalic geminate stops*

/sappir/	[sapːir]	*[safpir]	'sapphire'
/gibboːr/	[gibːoːr]	*[givboːr]	'hero'
/giddeːl/	[gidːeːl]	*[giðdeːl]	'magnify (PERF)'

17 One reviewer asked why Biblical Hebrew and Tigrinya could not be accounted for as spread of [+continuant]. First, it is not obvious in current phonological theory that vowels are underlyingly specified for this feature. Second, fricatives – i.e. segments that are specified for the feature [+continuant] – do not trigger the spirantization process.

In Aperture Theory, we can capture the fact that vowels cause a change in oral stops and, at the same time, explain that a fricative does not cause a change in an oral or nasal stop (*/aspa/ → [asfa]; see Wetzels 1991). The change from released stop to fricative in the context of a preceding vowel involves decrease of constriction, which is expressed by deletion of an aperture node, as in (16b) and (20). After deletion of the aperture node for complete obstruction in the oral tract (i.e. A_0), the place feature is associated to the A_{rel} node and the result is a single fricative.

(20) *Post-vocalic spirantization as reduction of complete constriction in single stops (represented as deletion of an aperture node)*

a. A_0 A_{rel} | [labial] /p/

b. A_{rel} | [labial] /f/

Geminate stops do not undergo this process in Biblical Hebrew, due to the "uniformity condition" (Hayes 1986), which says that if a certain environment incurs a change in a feature or node of a particular segment – in this case a vowel that incurs omission of an aperture node of a following stop – every dominating slot linked to that feature (or node) must satisfy that environment. The second A0 slot dominating the place feature is not adjacent to a vowel, and deletion of the aperture node in (21) is therefore blocked.

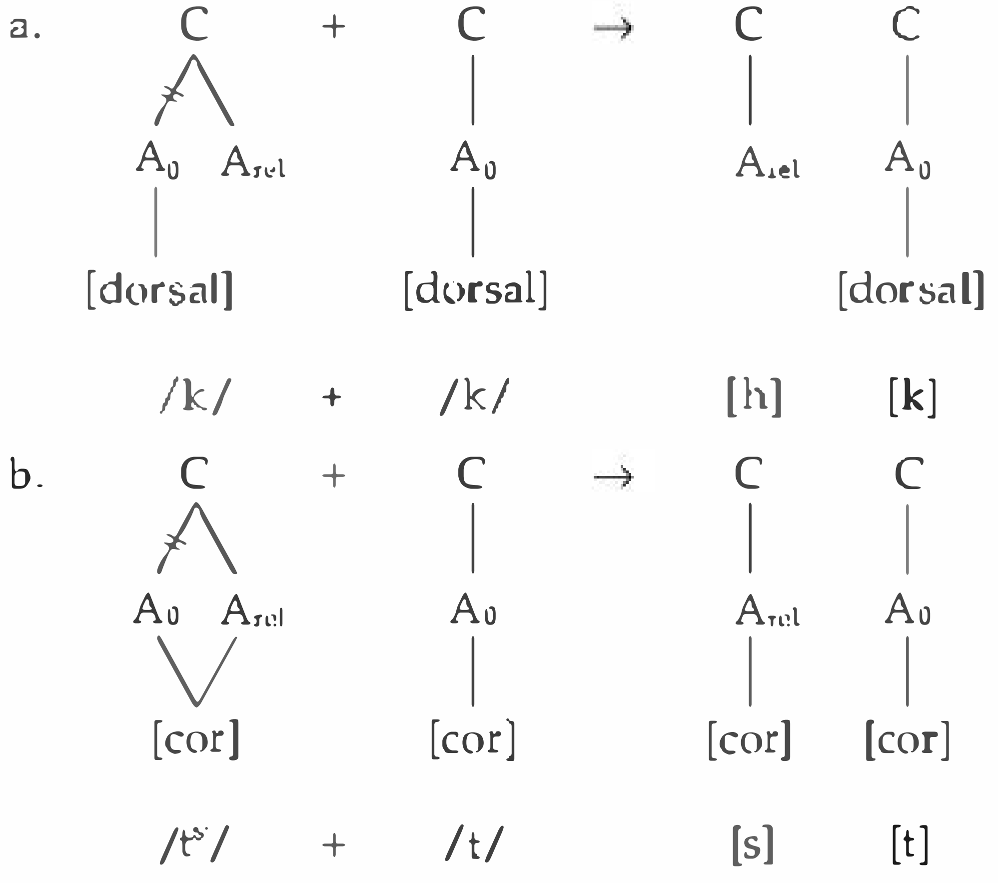
(21) *Geminate stop: Two aperture slots for closure sharing one place feature*

A_0 A_0 A_{rel} \/ [labial] /p:/

Note that the "uniformity condition" does not apply in the case of consonant gradation in Balto-Finnic languages and Sami, because the process of gradation is not triggered by a preceding vowel. In the languages discussed in §5, no vowel incurs gradation (or omission of an aperture node). Rather, the morphology determines whether or not gradation takes place, so that our account of this process is as shown in (17b) above.

Another case where Aperture Theory offers a more straightforward explanation than feature-based theories is Yukatec Maya degemination. In Yukatec Maya, a sequence of two homorganic stops is illicit. When two stops become adjacent due to a morphological process, the first one is realized as the placeless sound /h/ and the other retains its place of articulation (/k + k/ → [h k]; /t + t^j/ → [h t^j]). In cases where an affricate is immediately followed by an oral stop, it is realized as the corresponding fricative (/t^s + t/ → [s t]; /$t^ʃ$ + t/ → [ʃ t]); see McCarthy 1988; Lombardi 1990; Padgett 1991: 358–362. Under the assumption that this process involves delinking of the feature [–continuant], it is curious that oral stops do not retain their place of articulation when they are realized as a continuant, whereas affricates do. Under the proposal advocated here, this comes as no surprise. If a language disallows two adjacent stops, one of the aperture nodes for complete closure is deleted and in Yukatec Maya it is deleted together with the elements it dominates; i.e. when in oral stops the node for complete obstruction in the oral cavity (i.e. A_0) together with the node for the location of obstruction (i.e. the place feature) is deleted, an "empty" consonantal position remains that is phonetically realized as placeless /h/ (22a); conversely, when in affricates the A_0 node is deleted, a A_{rel}–Place association (which characterizes fricatives) remains (22b):

(22) *Delinking of one aperture node triggered by the OCP in Yukatec Maya*



In Aperture Theory, mutations that involve voicing or nasalization may be described as processes whereby the features [voice], [nasal], and/or Sonorant Voicing are attached to one of the aperture slots (Grijzenhout 1995, 1996). The framework of Aperture Theory encounters problems in accounting for the type of gradation that is attested in Northern Corsican, where voiceless stops alternate with voiced ones in the same context in which voiced stops alternate with continuants. Voiced stops have a shorter closure duration than voiceless ones, and the intuition behind lenition processes is thus that they reduce closure phases of stops (by degemination, voicing, reduction to incomplete closure, or even reduction to segment loss).

7 Summary and conclusion

This chapter discussed some cases of consonant mutation. By consonant mutation we understand here a change in a consonant that is not the result of neutralization (e.g. syllable-final obstruent devoicing) or assimilation (e.g. nasal place assimilation). Rather, consonant mutation is viewed as a process that increases or decreases the degree of sonority and/or the length and degree of oral stricture of a segment when there is: (i) a purely phonological context in which the mutation always takes place irrespective of speech style, e.g. inter-sonorant voicing in Burmese; intersonorant spirantization in Djapu and Spanish; or (ii) a "mixed" morphophonological environment, e.g. stopping in Soninke, where the mutation is sometimes brought on by a preceding nasal consonant or vowel, but may also have a morphological function, and consonant gradation in Estonian and Sami, where the consonant alternations sometimes take place in well-defined phonological contexts and sometimes in a context where the mutation has a grammatical function; or (iii) a morphosyntactic environment that induces mutation, e.g. word-initial spirantization in Southern Paiute and stem-initial spirantization in Fula.

Even though, from a historical perspective, consonant mutations may originally have had a phonological trigger (usually a preceding vowel or nasal), the fact that they also occur independently of a phonological environment is the first indication that an account that relies on the phonological contexts may be flawed. Moreover, accounts that regard mutations as phonological processes that involve spreading of a feature from a vowel or nasal onto the mutating consonant encounter problems when explaining why vowels and nasals spread these segmental features rather than fricatives and oral stops.

§6 discussed one theory that elegantly accounts for those mutations that involve increasing or decreasing sonority and one theory that provides an insightful account of mutations that involve increasing or decreasing oral stricture. Van der Hulst and Ewen (1991) propose to represent segments by means of C and V elements. In their view, sonority-increasing mutations involve adding a V element either as a governing node, an adjunct, or a governed node; sonority-decreasing mutations would presumably involve adding a C element or taking away a V element. §6 showed that this framework not only works for mutations that alter one class of segments into another class of segments (e.g. when voiceless stops become voiced, when stops become fricatives, or when voiced oral stops become nasal stops), but also for scalar mutations that induce a change in different classes of segments (e.g. when underlying voiceless stops become voiced while underlying voiced stops are nasalized or when underlying voiceless stops become voiced stops in the same environment where voiced stops are spirantized). This theory is less successful, however, in explaining other types of consonant gradations, for instance those where geminates become singletons in the same context where singletons spirantize (Balto-Finnic and Sami consonant gradation).

Steriade (1993, 1994) proposes using aperture nodes indicating the degree of oral stricture in phonological representations. This theory is useful in explaining processes where oral stricture increases (e.g. when continuants become stops or when the closure duration of short stops is extended) or decreases (e.g. when geminates degeminate where short stops spirantize). The downside of the theory is that it encounters difficulties in explaining scalar mutations of the type where underlying voiceless stops are voiced while underlying voiced stops are nasalized (e.g. Modern Irish initial nasalization), or when underlying voiceless stops are voiced in the same environment in which voiced stops are spirantized (e.g. Northern Corsican intervocalic consonant gradation).

§6 thus focused on two theories that are an improvement compared to feature-based accounts in the sense that they are able to explain scalar mutations that take place without an overt phonological trigger. However, the mutations that the one theory elegantly accounts for pose a puzzle for the other theory and vice versa. The problem for phonological theory thus remains the fact that there is as yet no unified account for the different types of consonant mutations that we can describe in layman's terms as changes that increase or decrease the level of sonority (a) expressed by laryngeal and nasal configurations, or (b) expressed by changes in oral aperture. Even though the description of consonant mutation is thus relatively simple, a phonological account is not.

ACKNOWLEDGMENTS

I would like to thank the editors for their invitation to contribute to the *Companion*. Thanks are also due to Colin Ewen, Harry van der Hulst, Glyne Piggott, Holly Winterton, and Wim Zonneveld for helpful discussions on the topic of consonant mutation. I also appreciate the comments of Bernhard Wälchli and two anonymous reviewers.

87 Neighborhood Effects

Adam Buchwald

1 Introduction

The organization of lexical knowledge at the phonological level has long been thought to incorporate some encoding of similarity neighborhoods: in the network structure of the lexicon, words that share phonological components are more closely connected to one another than words that are different. The notion of a "neighbor" as a similar word has provided tremendous insight into a variety of psycholinguistic phenomena related to spoken word recognition and spoken word production. The present chapter explores this notion of neighbor, focusing on the characterization of neighbors of a target word as the other words that are activated when that target is active. As we will see, this notion allows us to predict inhibitory or facilitatory effects depending on the task. These effects are well documented across tasks and participant populations. Following a brief description of the notion of the mental lexicon and competition in lexical access, we review research in spoken word recognition and production, and describe how the neighborhood construct (and similarity more generally) has been applied in phonologically based psycholinguistic research. We then examine how the notion of neighbor has been applied to domains such as language acquisition, language impairment, and other modalities of communication, including written language processing and audiovisual speech perception.

1.1 *Neighbors compete for lexical selection*

The term "mental lexicon" is typically used to refer to a network of words representing an individual's lexical knowledge (Oldfield 1966; Forster 1978). Accounts of lexical knowledge posit multiple types of lexical organization, notably including meaning-based organization and form-based organization. The notion of similarity among lexical items varies at these levels; at the level of meaning-based organization, neighbors share semantic features (e.g. *dog* and *cat* are semantic neighbors, sharing several semantic properties, such as "four-legged," "domesticated," and "animal," among others). With respect to form-based organization, neighbors are defined words that share phonological and phonetic detail, such as *cat* [kæt] and *cap* [kæp] (e.g. Luce and Pisoni 1998; see also Greenberg and Jenkins 1964 and

Landauer and Streeter 1973). The phonological neighbors of a word (e.g. *cat*) are the other words that share phonological structure (e.g. *cap, hat, kit*) and become activated when the word is activated in spoken word recognition and in word production. In short, these are the other words that are competing for lexical access. As all psycholinguistic accounts of lexical processing posit separate levels of meaning-based and form-based processing, the neighbors of a word at each of these levels are the other words competing for lexical selection (Dell *et al.* 1997; Vitevitch and Luce 1998, 1999; Levelt *et al.* 1999; Luce *et al.* 2000; Rapp and Goldrick 2000).

The first part of the chapter discusses how the fundamental description of neighbors as competitors in lexical selection processes affects spoken word recognition and spoken word production. We begin with a discussion of some of the seminal results in word recognition that have helped to shape our understanding of neighborhood effects, and explore how neighborhood effects relate to other lexical and sub-lexical properties. This is followed by a review of the spoken word production literature, including both lexical-level processing and phonetic differences that arise due to neighborhood structure.

2 Neighborhood effects in spoken word recognition

While there are many differences among accounts of spoken word recognition, there is widespread agreement that when a word is heard, recognition involves a selection process in which the listener accesses a lexical item among several competing alternatives (Morton 1969, 1979; Marslen-Wilson and Welsh 1978; Elman and McClelland 1986; Norris 1994; Luce and Pisoni 1998; Luce *et al.* 2000; Norris *et al.* 2000; see Jusczyk and Luce 2002 for a review). Luce and Pisoni (1998) formalize the Neighborhood Activation Model (NAM), in which it follows from the nature of lexical competition that *ceteris paribus* words with a lot of active neighbors (i.e. words in *dense* lexical neighborhoods) are harder to access than words with few active neighbors (i.e. in *sparse* lexical neighborhoods), as there is more competition during lexical selection (see also Luce *et al.* 2000 for a computational implementation of NAM). Because lexical selection is a competitive process, factors that strengthen a word's activation (e.g. high frequency) also help in recognizing that word. Therefore, high-frequency words from low-density neighborhoods are easier to access than low-frequency words from high-density neighborhoods (see also CHAPTER 90: FREQUENCY EFFECTS).

Luce and Pisoni (1998) examined the performance of participants on a variety of word recognition tasks with "easy" stimuli (high-frequency words from low-density neighborhoods) and "hard" stimuli (low-frequency words from high-density neighborhoods). The tasks they used included perceptual identification (written response to aural presentation), lexical decision, and word repetition. For each task, they reported that participants responded faster and/or more accurately to words from sparse phonological neighborhoods compared to words from dense phonological neighborhoods. The results indicated that the best predictor of performance was frequency-weighted neighborhood density, a measure indicating the frequency of a word compared to the total frequency of that word and its neighbors (also see Newman *et al.* 1997). These results are consistent with the claim that an increase in the number of neighbors leads to more competition in tasks that involve spoken word recognition and that more competition makes recognition slower and less accurate.

To determine whether these neighborhood properties affect online word recognition errors, Vitevitch (2002b) analyzed a corpus of spoken word recognition errors ("slips of the ear") and determined that words occurring in dense phonological neighborhoods were more prone to recognition errors than words in sparse neighborhoods. Taken together, these results suggest that the density of a word's phonological neighborhood is directly related to the strength of competition in word recognition; words from high-density neighborhoods have stronger, more active competitors, and recognition of these words is slower and more likely to engender spoken word recognition errors than words with low density neighborhoods (cf. Vitevitch and Rodríguez 2005).

Other studies have shown variance in neighborhood effects that are based on the *structure* of a neighborhood, even when the number of neighbors remains constant. Vitevitch (2002a) reported that subjects were slower to perform shadowing and lexical decision tasks for words with high onset density (i.e. a large proportion of neighbors sharing the initial phoneme) compared to words with lower onset density. Vitevitch (2007) reported on an auditory lexical decision task, a repetition task, and an AX (same–different) discrimination task using groups of words matched for neighborhood density but differing in neighborhood structure. In particular, Vitevitch used CVC words with different neighborhood *spread* – that is, the number of segment positions in the word that can be changed to form a new word. For example, *cat* has a spread of 3, as each segment can be changed to form a new word (e.g. *hat, kit, cap*), whereas *mob* has a spread of 2 (e.g. *lob, mop*, but there are no [mVb] words where V is not [ɑ]). Some stimulus words had neighbors that could be formed by substitutions of each segmental position, and others only had neighbors that could be formed from substituting one or two positions. Vitevitch (2007) found that participants were slower at responding to words with a spread of 3 than words with a spread of 2, even when the overall neighborhood size and frequency were controlled. The findings from these studies indicate that both the size and the structure of a lexical neighborhood affect spoken word recognition.

Magnuson *et al.* (2007) reported on the results from an eye-tracking study that provides more insight into the time course of lexical competition based on neighborhood properties. Magnuson *et al.* asked participants to perform an auditory word–picture matching recognition task. Participants heard instructions to click on a picture of an object which was in an array of four pictures. Rather than relying on accuracy or reaction time paradigms which infer the nature of cognitive processes from a single response, Magnuson *et al.* measured the participants' gaze toward different pictures in the array over time; thus, the eye-tracking paradigm allowed them to examine competition over the course of processing. Their findings indicated an early facilitatory effect of neighborhood density (revealed by participants looking toward the target), followed by a later inhibitory effect such as those more typically seen in word recognition studies (discussed above). Thus, by examining processing throughout the course of lexical access, Magnuson *et al.* were able to uncover a more nuanced characterization of competition effects in lexical access.

Thus far, we have discussed neighborhood density without providing a definition of a neighbor. The definition of a neighbor that is most commonly used in the word recognition literature is a word that differs from the target by a single segment deletion, addition, or substitution; in other words, words that differ from each other by an edit distance of 1. Thus, the neighbors of *cat* include *hat* (first segment substitution), *kit* (second segment substitution), *cap* (third segment substitution), *scat, cats* (insertions), and *at* (deletion), among others. This definition of neighbor has been used in large part because many of the seminal studies have focused on either CVC words or monosyllabic words more generally (Luce 1986; Luce and Pisoni 1998; Benkí 2003). For these words, there is a fair amount of variation in neighborhood density. However, when one looks over the entire lexicon rather than at a subset, more than half of the words in the lexicon are "hermits" by this definition; that is, they do not have any neighbors (Vitevitch 2008).

Buchwald *et al.* (2008) and Felty *et al.* (2008) attempt to examine this issue by inferring the most accurate definition of a neighbor from spoken word recognition errors. Felty *et al.* (2008) reported on a large database of spoken word recognition errors obtained by having participants identify words mixed with noise. Their 1428 stimulus words were designed to be representative of the English lexicon, including a range of syllable length, stress patterns, frequency, and familiarity. The words were randomly selected from a larger lexical database. The word recognition errors reported by the participants were taken to be a direct reflection of the words that were highly competitive with the target. They reported that, particularly for longer words, the responses typically differed from the target by an edit distance of greater than 1. Thus, while it remains likely that using words with a phoneme edit distance of 1 to define the lexical neighborhood can reasonably approximate neighborhood density effects in CVC words, it may not be the most appropriate definition of a lexical competitor.

2.1 *Phonotactic probability and lexical neighborhoods*

The nature of the competition effects we have been discussing focuses on the lexical selection process; that is, competition among lexical forms at a level of processing with word-level representations. However, it should be noted that the notion of lexical neighbor rests on some measure of sub-lexical phonetic similarity; for two words to be neighbors, they must share sub-lexical structure (e.g. *cat* and *hat* share [æt]). If a word has a lot of neighbors, then by definition there are many words that share its sub-lexical structure. Thus, it is worth asking whether having a lot of shared sub-lexical structure is directly related to the competition effect; that is, what is the role of *phonotactics*?

"Phonotactics" is the term used to refer to the sequential arrangements of segments in the words of a language (see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE). Consider the word *hang* [hæŋ], which is a perfectly well-formed word of English (i.e. it is phonotactically legal), with [h] in word-onset position and [ŋ] in the word-final coda position. However, a non-word such as *ngah* *[ŋæh] is not phonotactically legal, because it does not conform to the phonotactics of English, since English has phonotactic constraints both against [h] in coda and against [ŋ] in onset. The fact that languages have different phonemic inventories and that some languages restrict the segments in certain positions is a direct reflection of categorical phonotactic constraints (see CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS). In addition to these within-language constraints, it has been shown that participants can learn new phonotactic rules that do not exist in their language over the course of an experiment (Dell *et al.* 2000).

Of course, with respect to lexical selection, all lexical items in a language are phonotactically legal. Thus, many investigations in phonotactics have been more concerned with probabilistic phonotactics; that is, the likelihood that segments appear in specific syllabic positions, and the likelihood with which segments may co-occur (Jusczyk *et al.* 1994). Jusczyk *et al.* (1994) showed that 9-month-old infants prefer listening to phonotactic patterns that occur often in their native language to those that are attested, but occur less frequently.

The concept of phonotactic probability is closely tied to that of neighborhood density; phonotactic sequences that have high probability will be shared by many words. Thus, words containing those sequences will be likely to belong to high-density neighborhoods. In a variety of tasks, including wordlikeness judgments and non-word repetition, English speakers have been shown to process non-words with high phonotactic probability faster and rate these non-words as more "English-like" compared to their low phonotactic probability counterparts (Vitevitch *et al.* 1997; Vitevitch *et al.* 1999; Frisch *et al.* 2000). This leads to an apparent contradiction: acoustic stimuli are processed faster and more accurately when they have high phonotactic probability but slower and less accurately when they are words from dense neighborhoods.

Vitevitch and Luce (1998, 1999) explored this apparent contradiction by contrasting words of high and low phonotactic probability (and neighborhood density) with non-words of high and low phonotactic probability. Vitevitch and Luce (1998) had participants perform a repetition task on these four stimulus types. Their results indicated that the competition effects of words from high-density neighborhoods slowed processing – even though those words had high phonotactic probability. In contrast, having a high phonotactic probability facilitated the processing of non-words. Thus, while words with a lot of competitors were processed less efficiently, the processing of non-words was facilitated when they had substantial lexical support for their segments and segmental sequences, indicating that the mechanism for non-word processing is sensitive to phonotactic probability. These results were interpreted as evidence for separate lexical and sub-lexical representations and processing systems. High phonotactic probability facilitates sub-lexical processing in production tasks whereas low neighborhood density facilitates lexical processing in perception tasks.

Bailey and Hahn (2001) raised the issue that the data of Vitevitch and Luce do not specifically show separate lexical effects (i.e. neighborhood density) and sub-lexical effects (i.e. phonotactic probability). To address this issue, Bailey and Hahn presented participants with a wordlikeness judgment task in which they directly contrasted phonotactic probability and neighborhood density for non-words. They reported that the best predictors of wordlikeness judgments incorporated lexical neighborhood influences, phonotactic probability, and the relationship between the two. One important innovation of Bailey and Hahn's work was to incorporate a measure of phonetic similarity that considered similarity among segments (e.g. that treated /k/ and /g/ as more similar than /k/ and /b/), thus using a more linguistically sophisticated notion of phonetic similarity among words. Pylkkänen *et al.* (2002; see also Pylkkänen and Marantz 2003) provided MEG (magneto-encephalography) support for the claim that lexical neighborhood effects and phonotactic probability effects are neurally distinct.

Storkel *et al.* (2006) further separated the effects of phonotactic probability and neighborhood density in a word-learning task. Participants had to learn novel words that varied orthogonally in phonotactic probability and neighborhood density. The results indicated that the participants were better at learning words from high-density neighborhoods than low-density neighborhoods, but worse at learning high-probability words than low-probability words. Storkel *et al.* argued that these findings revealed a facilitatory effect of neighborhood density in encoding and integrating novel lexical representations with previously stored lexical representations.

2.2 *Summary*

Neighborhood effects in word recognition may be described as effects of competition: words with a lot of phonetic neighbors that are strong competitors have a lot of competition for lexical access. Thus, having a large number of neighbors typically increases response latency in word recognition tasks. The precise properties of the neighbors and their relationship to the target can modulate these effects to some extent; in other words, some competitors are stronger than others. More recent work has begun to examine both the changes in lexical competition over the time course of word recognition and how different degrees of sub-phonemic similarity affect the strength of competitors in word recognition. The relationship between lexical competition resulting from neighborhood size and other phonological phenomena driven by similarity effects (e.g. gradient OCP constraint based on consonant similarity: Frisch *et al.* 2004; Coetzee and Pater 2008) remains relatively unexplored.

3 Neighborhood effects in spoken word production

As noted above, the neighbors of a target word are the other words that become activated when the target word is active. In the process of spoken word recognition, these other words compete for lexical selection and can make lexical access slower and more error prone. In spoken word production, however, the opposite pattern is seen; words from dense neighborhoods are produced faster and are less error prone than words from sparse neighborhoods.

In a variety of tasks examining speech production errors, Vitevitch and colleagues have reported that words from dense neighborhoods are produced faster and more accurately than words from sparse neighborhoods in English (Vitevitch 2002c; Vitevitch and Sommers 2003; Vitevitch *et al.* 2004). Vitevitch and Sommers (2003) performed a tip-of-the-tongue (TOT) elicitation task in which the lexical retrieval process is thought to stall before production of a word's form, even when the speaker may be able to access a variety of information about a word (meaning, gender, etc.). Vitevitch and Sommers reported that adults were significantly more likely to achieve a TOT state for words from sparse neighborhoods compared to words from dense neighborhoods. Similarly, Vitevitch (2002b) reported that speech errors were more likely for words from sparse neighborhoods compared to words from dense neighborhoods for two additional speech error-inducing tasks. These results are consistent with data from picture naming tasks as well (Vitevitch 2002c; Vitevitch *et al.* 2004), indicating that having a large number of similar words seems to facilitate the process of lexical retrieval in production.

Here we have another apparent contradiction: in spoken word recognition tasks, words from high-density phonological neighborhoods are recognized more slowly and less accurately, whereas in spoken word production tasks these words appear to be facilitated by their neighbors. The facilitatory effect of neighborhood density in speech production has been argued to follow in a straightforward fashion from interactive theories of speech production in which words are activated at a lexical level for lexical selection, and there is feedback from a "lower" sub-lexical level back up to this lexical level (Dell 1986, 1988; Dell *et al.* 1997; Rapp and Goldrick 2000; Dell and Gordon 2003; cf. Levelt *et al.* 1999, and see Vitevitch *et al.* 2004 for discussion). When a word is activated at the lexical level, it sends activation downstream to its phonemic constituents. Through the interactive process of feedback, the units representing the active phonemes send activation back up to the items at the lexical level that contain them. Thus when the unit(s) representing the word *cat* are activated on the lexical level, the units representing [k], [æ], and [t] on the sub-lexical level receive activation from this lexical unit. In a system with feedback, these sub-lexical units then send activation not only back up to *cat*, but also to the other words they are connected to (e.g. *cap*, *hat*, etc.), i.e. the neighbors of *cat*. This in turn provides more lexical support for the units representing those sounds, and thus makes the target word more likely to be produced than a semantic competitor which is not receiving additional activation from feedback. Thus, it is the interaction of lexical information and sub-lexical information that creates the facilitatory effect of high-density neighborhoods.

3.1 Phonetic effects of neighborhood density in speech production

In addition to examining speed and accuracy of production, researchers have looked at the effect of neighborhood density on a variety of phonetic and acoustic properties of speech production. One phenomenon that has been well documented is the expansion of the vowel space in the production of words from high-density neighborhoods compared to low-density neighborhoods (Munson and Solomon 2004; Wright 2004; Munson 2007). Each of these studies shows that vowels in words from dense neighborhoods are produced closer to the periphery of the vowel space, whereas vowels in words from sparse neighborhoods are produced closer to the center of the vowel space; in other words, the distinctiveness of the vowels in words from high-density neighborhoods is enhanced relative to vowels in words from low-density neighborhoods.

Vowel space expansion such as is documented in words from high-density neighborhoods is typical of what speakers do when they are producing "clear" speech (Bradlow 2002), and is also associated with more intelligible speakers (Bradlow *et al.* 1996). Thus, when speakers are producing words from dense phonological neighborhoods, they adopt the strategies used in clear speech, referred to as hyperarticulation in Lindblom's *Hyperspeech and Hypospeech* (H&H) theory (Lindblom 1990). Additionally, Scarborough (2004) found that vowels in low-frequency words from high-density neighborhoods exhibit more co-articulation (e.g. V-to-V co-articulation) than vowels in high-frequency words from low-density neighborhoods, which she argued (contra Lindblom 1990) is helpful to the process of lexical access for the listener.

In recent work, Baese-Berk and Goldrick (2009) address a specific type of neighborhood effect: the presence or absence of a specific minimal pair lexical item. They examined the productions of words beginning with a voiceless consonant that have a voiced consonant-initial cognate (e.g. *cod* ~ *god*) and compared them to voiceless-initial words without a voiced cognate (e.g. *cop* ~ **gop*). Their data revealed that participants produce more extreme voice onset times (VOT) when producing words with the minimal pair neighbor than when producing words without a minimal pair neighbor. As VOT is a key indicator of the voicing contrast (Lisker and Abramson 1964), the enhanced VOT in the presence of a minimal pair neighbor can be viewed as another type of hyper-articulation due to a lexical item being from a lexical neighborhood with a particular neighborhood structure.

As can be inferred from this limited review of phonetic consequences of neighborhood density and structure, there have been relatively few attempts to understand how lexical phonological properties such as neighborhood density can affect the acoustic details of speech production. Nevertheless, this remains a fruitful area of research for the future and will likely lead to further insights regarding the relationship between lexical representations in the lexicon and the processing systems that allow those representations to be articulated in speech production.

4 Lexical neighborhoods: Language acquisition and language impairment

4.1 *Language acquisition*

If the neighbors of a word are other phonetically similar words, then it stands to reason that, as we learn more words, the structure of our lexical neighborhoods will change. This issue of how lexical neighborhoods develop during language acquisition and how lexical neighborhoods affect children's language ability has been addressed in the literature in several ways. Many of the attempts to study this issue focus on analyses of children's phonological lexicons. In a straightforward analysis of age-appropriate lexicons, Charles-Luce and Luce (1990, 1995) reported that words in the vocabulary of younger children (5-year-olds) have fewer neighbors than the words in the vocabulary of older children (7-year-olds), which in turn have fewer neighbors than those words in the vocabulary of adults. In other words, as children learn more words, their lexical neighborhoods become denser. Charles-Luce and Luce argued that these findings indicate less need for detailed phonetic representations of words in younger children's lexicons, as there are fewer confusable words (cf. Dollaghan 1994).

One influential account of lexical acquisition holds that children's initial phonological representations are more holistic and only become more differentiated by encoding phonological and phonetic structure after their lexicons have grown (Walley 1993; CHAPTER 72: CONSONANT HARMONY IN CHILD LANGUAGE). Consistent with this account, Metsala (1997; see also Garlock *et al.* 2001) reported that during a word recognition task using the gating paradigm, children required less phonetic material to recognize words from sparse neighborhoods as they got older and their vocabularies increased. She argued that this reflects a more differentiated representation as children get older such that words can be recognized from their constituent parts rather than requiring the whole word for recognition.

Storkel (2004b) reported that children learn words from dense neighborhoods earlier than they learn words from sparse neighborhoods. Storkel (2002) argued that in the developing child's lexicon, words from dense neighborhoods have more detailed representations than words from sparse neighborhoods. Coady and Aslin (2003) reported that the early developing lexicon contains more words from high-density neighborhoods than the later lexicon, suggesting that infrequent sound patterns are learned later. Thus, they claimed that this is not consistent with an account of children's lexical representations in which they start impoverished and become more detailed later (as in Walley 1993).

In a direct comparison of neighborhood density effects in typically developing children, Munson *et al.* (2005) found that children at the age of 4;3 did not exhibit effects of neighborhood density on response time in a repetition task, but older children (7;2) did exhibit effects. However, children in both age groups showed an effect of phonotactic probability on onset-to-onset latency in non-word repetition. As with understanding spoken word processing in adults, the covariance of phonotactic probability and neighborhood density frequently makes effects of these properties quite difficult to disentangle (see Storkel 2004a, 2009 for discussion).

4.2 *Lexical neighborhoods and language impairment*

Effects of lexical neighborhood in language impairment have been studied in two broad populations: adults with acquired language impairment and children with developmental language impairment. While neighborhood effects have been reported in the language processing skills of each of these populations, there are differences that follow from differences in the populations.

With respect to adults with acquired language impairment (i.e. aphasia), Gordon (2002) reported that aphasic speakers produced words from high-density phonological neighborhoods more accurately in both spontaneous speech and in controlled picture-naming tasks, with a strong effect of neighborhood frequency in production as well. Goldrick *et al.* (2010) reported on analyses comparing the phonological errors of aphasic speakers with the intended target words. These analyses inferred neighborhood structure by using the word production errors as an index of the other active lexical competitors. They reported that responses and targets were more likely to share position-specific segmental information than is predicted by chance – in other words, neighbors that share the same segments in the same position within a word were more likely to be produced in error than neighbors of the same edit distance in which the segments did not share segmental position. They also reported an independent effect of sharing the first segment, in which responses sharing the first segment as the target were more likely to be selected than other possible words of the same edit distance from the target.

These effects seen in aphasic production errors presumably follow from the nature of the impairment. The individuals in these studies were adult speakers of the language with fully formed lexicons, and their later impairment had affected retrieval and production of words in production tasks. Thus, if the structure of the lexicon encodes similarity neighborhoods, it is unsurprising that these similarity neighborhoods would affect production errors. This contrasts with individuals with developmental language deficits (including phonological impairment as well as hearing impairment which may affect speech input), in which the impairment affects language processing alongside lexical development.

Newman and German (2002) examined the performance of 7- to 12-year-old typically developing children and children with word-finding difficulties on a series of repetition tasks. Their analyses revealed a number of interesting findings. First, children from both groups were more accurate at repeating words from sparse neighborhoods compared to words from dense neighborhoods, a result that likely reflects the facilitation that words from sparse neighborhoods receive from having fewer competitors for word recognition. Second, children in both groups were more accurate at repeating words from neighborhoods with high average neighborhood frequency. This result seemingly contrasts with the first finding, suggesting that word recognition in a neighborhood facilitates other recognition in that neighborhood. Here we have a facilitatory effect of having frequent neighbors, whereas the first finding was an inhibitory effect of competition. To address this apparent contradiction, Newman and German (2002) examined the number of neighbors that had a higher frequency than the target. Words with fewer neighbors of higher frequency were repeated more accurately than words with many neighbors of higher frequency. Thus, both groups of children were more accurate in repeating words from sparse neighborhoods with high-frequency neighbors. This suggests that the word recognition process for both groups was affected by the neighborhood size and structure, indicating that even children with word-finding difficulties appear to be sensitive to acoustic-phonetic similarity among words and organize their lexicons into lexical neighborhoods that are used in lexical processing tasks.

Another group of children who have been examined with respect to neighborhood effects are children with cochlear implants (CIs). The children that have been studied are typically born profoundly deaf and receive their CI – a neural prosthesis – early in life to provide auditory input from which spoken language abilities may be developed (Svirsky *et al.* 2000). Kirk *et al.* (1995) examined accuracy on word recognition tasks for children with CIs, and reported that they were more accurate at identifying "easy" words (high-frequency words from sparse neighborhoods) compared to "hard" words (low-frequency words from dense neighborhoods). Other work with adults with CIs and other hearing-impaired adults has reported similar effects, though sometimes diminished relative to healthy controls (CI: Collison *et al.* 2004; hearing-impaired: Dirks *et al.* 2001).

4.3 Summary

Research with typically developing children and individuals with language impairment demonstrates that the effects of lexical neighborhood are not limited to neurologically intact adults. There is evidence that these populations are also sensitive to acoustic-phonetic similarity and organize their lexical knowledge accordingly. Given the articulatory differences between words from high-density neighborhoods and words from low-density neighborhoods discussed in §3, it remains unexplored whether children acquiring language are able to exploit these differences in some way that facilitates the organization of lexical knowledge into acoustic-phonetically defined similarity neighborhoods.

5 Lexical neighborhood effects in orthographic processing and audiovisual perception

Thus far, we have discussed lexical neighborhood effects in the perception, acoustics, and articulation of spoken language. This work has largely focused on the storage and processing of acoustic-phonetic lexical knowledge. In this section, we briefly discuss findings indicating that lexical knowledge is stored in terms of lexical similarity neighborhoods in other modalities (e.g. orthography and visual speech) as well as in multimodal processing (e.g. audiovisual speech perception). These findings suggest that the effects of lexical organization on phonological processing are part of a broader class of effects from the organization of lexical knowledge.

5.1 *Orthographic similarity neighborhoods*

The literature on the effect of orthographic similarity neighborhoods on written language processing is extremely large, and much of it is outside the scope of the present chapter. We focus here on parallels between findings in orthography and the findings discussed in this chapter on phonological similarity neighborhoods. In a seminal paper on visual word recognition, Coltheart *et al.* (1977) defined a word's orthographic neighbors as those words that can be formed with one letter changed but letter positions remaining unchanged. This measure has become known as Coltheart's N (or just N, as used here), and has been used quite frequently in studies of visual word recognition (i.e. reading) as well as written language production (i.e. spelling).

Coltheart *et al.* reported that in a lexical decision task for visually presented words and non-words, participants were faster to respond to low N non-words than high N non-words. Coltheart *et al.* did not obtain the analogous finding for words. Later studies have been equivocal on the effect of N and neighborhood frequency for words in visual lexical decision tasks. It is common for studies to report a facilitatory effect of N (e.g. Andrews 1989, 1992; Sears *et al.* 1995) but an inhibitory effect of neighborhood frequency, or even a single high-frequency neighbor (e.g. Grainger *et al.* 1989; Grainger 1990; Grainger and Segui 1990; Carreiras *et al.* 1997). Recent attempts to disentangle this issue have shown that some neighbors appear to be stronger competitors than others (Davis and Taft 2005), and that rigid coding of letter position and word length may not be the best predictor of the make-up of orthographic similarity neighborhoods (see Grainger 2008 for a review, and Yarkoni *et al.* 2008 for a proposal).

In research on written language production, there have been relatively few studies, but the results have consistently shown a facilitatory effect of high-neighborhood density. For example, Roux and Bonin (2009) reported that healthy adults demonstrate faster and more accurate spelling of words from dense neighborhoods compared to words from sparse neighborhoods. Sage and Ellis (2006) reported on the spelling performance of BH, a brain-damaged individual with acquired dysgraphia. BH's impairment affected the working memory mechanism in written language production and she showed less impairment producing words from dense neighborhoods compared to words from sparse neighborhoods. The authors reported that there was a beneficial therapeutic effect for neighbors of trained words; if a word was trained, spelling accuracy on the neighbors of that word improved. Taken together, these studies suggest that orthographic similarity neighborhoods affect the cognitive processing involved in producing written language.

5.2 Similarity neighborhoods in visual and audiovisual speech processing

While researchers examining speech perception and spoken word recognition typically focus on the auditory modality, there has been longstanding evidence that shows that visual speech perception actively contributes to word recognition, even in normal hearing adults in clear listening conditions (Sumby and Pollack 1954; McGurk and MacDonald 1976). Over the past two decades, characterizations of speech perception and the sensory processing of speech signals have become more focused on the multimodal nature of speech (Massaro 1987, 1998; Summerfield 1987; Massaro and Cohen 1995; Massaro and Stork 1998; Calvert *et al.* 2004; Kim *et al.* 2004; Bernstein 2005; Rosenblum 2005). One line of work on this topic has explored the processing of linguistic information conveyed in visual speech, including the ability to identify words from visual-only speech signals (e.g. Auer and Bernstein 1997; Lachs *et al.* 2000; Auer 2002; Mattys *et al.* 2002).

Expanding on the notion of the perceptual equivalence class from Miller and Nicely (1955) (see also Shipman and Zue 1982 and Huttenlocher and Zue 1984), Auer and Bernstein (1997) developed the construct of lexical equivalence class (see also Lachs *et al.* 2000 and Mattys *et al.* 2002), which is an equivalence class for words that are indistinguishable from the visual speech stream (e.g. *pin* and *bin*, which differ only in voicing, a feature that is not detectable in visual speech). Mattys *et al.* (2002) and Auer (2002) showed that words with a large lexical equivalence class – the visual speech similarity neighborhood – were less recognizable than words with a small lexical equivalence class for both hearing and deaf observers. This is consistent with the notion of other words in the similarity neighborhood as competitors for word recognition, so words with few competitors are easier to recognize. Further, Tye-Murray *et al.* (2007) demonstrated that both auditory speech-based similarity neighborhoods and visual speech-based similarity neighborhoods are predictive of word recognition in audiovisual speech perception.

5.3 Summary

This section has explored the effects of similarity neighborhoods on other modalities of processing, including orthographic processing, visual speech processing, and audiovisual speech processing. In each of these domains, we have seen effects of similarity neighborhoods on task performance reflecting that the organization of lexical knowledge into neighborhoods of similar words is a general cognitive mechanism that is not specific to acoustic stimuli.

6 Conclusion and future directions

The research on form-based lexical similarity neighborhoods has been influential in revealing the nature of lexical processing as competition among lexical nodes.

This conception helps explain a variety of findings in spoken word recognition, as well as word recognition in other modalities. In language production, two distinct types of effect of lexical neighbors have been reported. First, there is a facilitatory effect of neighborhood size in tasks of lexical access in word production. This is likely due to feedback from a segmental level of processing to a lexical level – when words similar to the target are activated, they activate their constituent segments. These segments in turn send activation back up to the lexical nodes they are connected to, thus providing a facilitatory effect of density. Second, there are reported effects of neighborhood structure on the acoustic details of speech production. Many of the reported effects lead to hyperarticulation of words in dense neighborhoods (e.g. expanded vowel space; more extreme VOT), which presumably helps to keep these words distinct from their neighbors. Many of these effects of neighborhood are also seen in acquisition, in cases of language impairment, and in other modalities of form-based lexical processing.

One issue that arises in each domain we discussed is the relationship between lexical effects of neighborhood structure and sub-lexical effects of phonotactic probability. The widely held view on these related phenomena is that they exert their effects on different levels of processing, with a large neighborhood associated with slower and less accurate word recognition at a lexical processing level but high probability associated with faster and more accurate recognition at a sub-lexical processing level. While drawing the distinction between the two levels is parsimonious and fits with both behavioral and neural evidence, it is worth noting that phonotactic probability is an emergent property of the structure of the lexicon; that is, phonotactic probability is defined over the lexicon. Thus, these two properties that appear to generate opposite effects in word recognition come from different levels of generalization over the same representations, and each can be thought of as an effect of similarity. The relationship between these similarity-based effects and other similarity effects that have been explored in phonology (e.g. Frisch *et al.* 2004; Coetzee and Pater 2008) remains somewhat unexplored in the literature.

Another direction of future research, which builds on some recent work, involves generating a more detailed definition of similarity and of what it means to be the competitor of a target word. While many of the previous investigations into lexical similarity neighborhood effects have used relatively coarse-grained metrics for discussing similarity, a variety of more recent efforts have been made to generate a more phonetically driven notion of similarity (Bailey and Hahn 2001; Hahn and Bailey 2005; Albright 2006; Felty *et al.* 2008). One promising direction involves using graph theory to better understand the network structure of the mental lexicon (Vitevitch 2008; Gruenenfelder and Pisoni 2009). Future attempts to refine these metrics will hopefully provide a more precise, gradient measure of similarity which can better predict effects and perhaps be useful in designing treatment protocols that help people with acquired form-based lexical impairment (as in Sage and Ellis 2006).

Finally, it is critical to consider the possible role of lexical neighborhood density and neighborhood effects in phonological alternations. The notion that lexical frequency may play a role in phonological alternations has been advanced (e.g. Pierrehumbert 2001) with the argument that frequent words may be more likely to undergo sound change, but whether other lexical factors such as neighborhood density affect the likelihood of a word participating in alternations has received less attention. Hall (2005) reported that the incidence of Canadian Raising (i.e. where /aɪ/ → [ʌɪ] before voiceless obstruents, as in *write* → [rʌɪt]; cf. *ride* → [raɪd]) among English speakers was actually affected by the neighbors sharing the CV biphone, even though Canadian Raising is thought to be conditioned by whether the following consonant is voiced. However, whether lexical neighborhoods can be shown to predict the application of a phonological process (as lexical frequency has been shown to) remains largely unexplored.[1]

[1] With respect to a formal mechanism that could account for lexical neighborhood effects on phonological alternations, one prominent approach within Optimality Theory (Prince & Smolensky 1993) focuses on output–output faithfulness (Burzio 1994; Benua 1997) among morphemes and their related allomorphs. While this formal mechanism is typically applied to the different allomorphs of a single morpheme rather than to words from different morphological paradigms, it provides a blueprint of a formal mechanism that could be adapted to account for effects among similar words that are not from the same morphological paradigm. 66 Lenition

Naomi Gurevich

Lenition (German *Lenierung*, from Latin *lenire* 'weaken') is most commonly defined as "a 'relaxation' or 'weakening' of articulatory effort" (Hock 1991: 80). The term was coined by Thurneysen as one "used to describe a mutation of consonants which normally originated in a reduction of the energy employed in their articulation," and affects mostly consonants in intervocalic position (Thurneysen 1946: 74).

Below I present the processes that most commonly fall under the label of *lenition*, and make some observations that emerge from this list. The similarities between these processes and the way in which they pattern support the mostly uncontroversial view that lenition is indeed a group of similar phenomena. Kirchner writes that to his knowledge "no linguist has ever explicitly maintained the contrary view, that 'lenition' is merely an arbitrary collection of unrelated processes" (1998: 5). But while most acknowledge that the processes considered leniting are indeed related and form a coherent group, defining the exact criteria for group membership remains largely controversial and debates about the formalization, motivation, and even goal of lenition abound.

Three main approaches to lenition are presented here: formal, phonetic, and functional. The formal approach is the generative theory-based search to formalize synchronic rules of lenition processes. The phonetic approach seeks to determine what motivates the sound changes in question and what exactly constitutes "articulatory effort." The third, functional, take on lenition looks to matters of contrast maintenance, which exhibit an additional way in which lenitions pattern with great similarity, in its search for what constrains and sometimes triggers lenition phenomena.

1 Leniting processes

In this section I summarize the processes most commonly considered to fall under the cover term *lenition*. There is general agreement in the literature that all the processes listed below may be considered lenitions, but there is little agreement regarding the exact criteria required for membership in the lenition group.

In coining the term, Thurneysen suggests that leniting processes are characterized by some reduction in articulatory effort, but to date there has been no agreement on exactly what this entails. Among linguists there are intuitions regarding articulatory effort, some more accepted than others. Voicing, for example, has an explanation rooted in the laws of physics, specifically aerodynamics: intervocalically the vocal cords may continue to vibrate after the first vowel, through the consonant, and into the second vowel; but in final position – where final devoicing is encountered – aerodynamic conditions are not conducive to voicing (Westbury and Keating 1986). Other processes listed below have explanations that are more difficult to quantify, such as "some reduction in constriction degree or duration" (Kirchner 1998: 1).

Both open questions, criteria for group membership, and how to formalize effort reduction, are reiterated in the discussion of the formal and phonetic approaches to lenition (§3.1 and §3.2).

1.1 *Degemination*

Degemination is the shortening of a CC cluster, where both consonants are the same, to a singleton C (see also CHAPTER 37: GEMINATES). Two examples are diachronic degemination in Numic *kk > k / V __ V (Manaster Ramer 1993) and word-final degemination in Tiberian Hebrew.

(1) *Word-final degemination in Tiberian Hebrew* (Malone 1993: 73)

[qal] 'light (MASC)' [qallɔɔ] 'light (FEM)'

1.2 *Deaspiration*

Deaspiration is the loss or reduction of aspiration. For example, in the Pattani dialect of the Sino-Tibetan language Lahaul, aspiration of the bilabial voiceless stop is reduced in pre-accented syllables. In medial and final contexts, [p^h] is in free variation with [p].

(2) *Deaspiration in the Pattani dialect of Lahaul* (Sharma 1982: 48)

a. Reduction of aspiration
   i. aspiration in accented syllable p^{h}uka 'body'
   ii. reduced aspiration in pre-accented syllable p^{h}ukan 'four'

b. [p^h] ~ [p]
   i. ɖəgegp^{h}i ~ ɖəgegpi 'to tremble, shiver'
   ii. hjup^{h}ʧi ~ hjupʧi 'to open'

1.3 *Voicing*

Voicing involves a change from a voiceless sound to a voiced one and is a very common lenition process, second in prevalence only to spirantization (Gurevich 2004). Voicing usually affects whole series of sounds in the language where it applies. And although voicing can affect fricatives as in Sekani, a Na-Dene language spoken in Canada (3), where voiceless initials of noun and postposition stems voice when prefixed or preceded by a nominal possessor or object, it is much more common with stops, such as the intervocalic voicing in the Yanomam language Sanuma (4).

(3) /s ɬ ç x ʍ/ → [z l ʝ ɣ w] *in Sekani* (Hargus 1985: 270–271)

a.	xàs	'planning tool'	səɣàsè	'my planning tool'
b.	çən	'song'	səʝənè	'my song'
c.	xàz	'windfall roots'	tse ɣàz-e	'Old Friend Mt. (*roots* stem)'

(4) /p t ts k/ → [b d dz g] / V __ V *in Sanuma* (Borgman 1990: 220)

a.	ipa	[ipa] or [iba]	'my'
b.	hute	[hute] or [hude]	'heavy'
c.	hatsa	[hatsa] or [hadza]	'deer'
d.	ãka	[ãka] or [ãga]	'tongue'

1.4 *Spirantization*

Cross-linguistically, this is by far the most common lenition process. Spirantization involves the change of a stop to a fricative, most commonly in intervocalic position. This quite often affects whole series of sounds in a language's inventory, as for example in the Paya dialect of the Chibchan language Kuna (5), or in the Tümpisa dialect of the Uto-Aztecan language Shoshone (6).

(5) b d g → β ð ɣ / V __ V *following a stressed syllable in Paya Kuna* (Pike *et al.* 1986: 459)

a.	paβa	'father'
b.	peðe	'you'
c.	naɣa	'foot'

(6) p t c k kʷ → ɸ θ ç x xʷ / V __ [voiceless]V *in Tümpisa Shoshone* (Dayley 1989: xxviii–xxix)

a.	wisipin	[wiʃiɸi̥]	'thread'
b.	tapettsi	[taβetʧi̥]	'sun'
c.	citoohin	[ciðo:hi̥]	'push'
d.	petɨ$^{\text{-gem}}$	[peðɨ] ~ [peθɨ̥]	'daughter' (ends with a geminating segment)
e.	katɨ$^{\text{-gem}}$	[kaɾɨ] ~ [kaɾ̥ɨ̥]	'sit'
f.	miʔakwa	[mĩʔaɣʷa] ~ [mĩaɣʷa]	'go away!'

1.5 *Flapping*

Flapping is a process whereby a sound is replaced by a flap (usually either alveolar [ɾ] or retroflex [ɽ]; see CHAPTER 113: FLAPPING IN AMERICAN ENGLISH). Two examples are intervocalic flapping of the trill in the Sino-Tibetan language Kagate spoken in the village of Phedi (7) and final flapping of the retroflex stop in the Indo-European language Gujarati (8).

(7) *Flapping in Kagate:* /r/ → [ɾ] / V __ V (Hoehlig and Hari 1976: 19)

a.	/tari/	[târi]	'axe'
b.	/tihriŋ/	[tĭɾiŋ]	'today'
c.	/guhri/	[guɾi]	'cat'

(8) *Free variation of* [ɖ] *and* [ɽ] *in final position in Gujarati* (Cardona 1965: 24)

[ɟʰaɖ] ~ [ɟʰaɽ] 'tree'

Quite often the alveolar and retroflex stops undergo flapping as part of a more general spirantization process that affects other stops. For example, in the Calabar-Creek Town dialect of Efik (a Niger-Congo language) /b d k/ → [β ɾ ɣ] non-initially in a word stem and before a vowel: where /b/ and /k/ spirantize, the alveolar /d/ flaps (9). In the case of the retroflex, the [ɽ] appears to be the usual output of a process where the rest of the stop series spirantize. For example, in the Afro-Asiatic language of Somali, /b d ɖ g/ spirantize to [β ð ɽ ɣ] intervocalically, especially after a stressed syllable: where /b d g/ spirantize, the /ɖ/ flaps (10). In the case of the alveolar stops, however, there is a discernible pattern: spirantization of the stop series in languages whose inventories include a phonemic trill usually results in a /d/ → [ð] substitution, while in trill-less languages the alveolar stop flaps (/d/ → [ɾ]) where the rest of the stop series spirantizes. This happens with regularity in all 33 languages where alveolar stops are affected (Gurevich 2004).

(9) *Non-initial in a word stem and before a vowel in the Calabar-Creek Town dialect of Efik* (Dunstan 1969: 38)

a.	/b/	→	[β]	dwɔ̀β-èbà	'twelve'
b.	/d/	→	[ɾ]	íkɔ̥́ɾ-ẹ̀kpẹ̀nẹ̀	'name of a town'
c.	/k/	→	[ɣ]	úfɔ̥̀ɣ-údwà	'market store'

(10) *Spirantization of stops in Somali* (Armstrong 1964)

a.	'laba	['laβa]	'two'
b.	'badag	['baðag]	'goose'
c.	'tiɖi	['tiɽi]	'she said'
d.	'sagaal	['saɣaal]	'nine'

1.6 Debuccalization

Debuccalization is the loss of place of articulation, preserving only glottal constriction, resulting most commonly in either [h] or [ʔ] (see also CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION). For example, in the Cuisnahuat dialect of the Uto-Aztecan language Pipil, a syllable-final /w/ becomes [h] in word-final or preconsonantal position (11). In the Austronesian language Toba Batak, preconsonantal voiceless stops surface as glottal stops (12).

(11) *Debuccalization in the Cuisnahuat dialect of Pipil:* /w/ – /h/ (Campbell 1985: 34)

a.	kuwa	'to buy'	kuhki	'bought'
b.	puwa	'to count'	puhki	'counted'

(12) *Debuccalization in Toba Batak:* /p t k/ → [ʔ] / __ C (Hayes 1986: 341)

halak 'person' halaʔ batak 'Batak person'

1.7 Gliding

Gliding is the replacement of stops or spirants with a homorganic glide (see CHAPTER 15: GLIDES). For example, in the Djapu dialect of the Australian language Yolngu, [ḓ ɟ] ~ [j], [b g] ~ [w] in word-medial position following a vowel, liquid, or semivowel (13).

(13) *Gliding in the Djapu dialect of Yolngu* (Morphy 1983: 29)

a. minj'ci 'colour, paint' + ḓarpu-NG 'pierce'
minj'ci-jarpu-NG 'paint'
b. ɟarakaḻa'ju-N 'move in an uncontrolled way'
ɟarakaḻa'-jarakaḻaju-N 'keep moving in an uncontrolled way'
c. ḓaː 'mouth' + birka'ju-N 'try'
ḓaː-wirka'ju-N 'ask'
d. ḓawaḻ 'country' + gujaNi-∅ 'I think'
ḓawaḻ-wujaNi-∅ 'be born'

1.8 Loss

Loss is the deletion of a sound (most commonly a glide or a glottal) in certain contexts (see CHAPTER 68: DELETION), for example, the occasional loss of the intervocalic glottals [ʔ] and [h] in the Uto-Aztecan language Tümpisa Shoshone (14), where the presence and absence of these sounds is in free variation.

(14) *[ʔ h] ~ ∅ in Tümpisa Shoshone* (Dayley 1989: xxix)

a.	miʔakwa	[mĩʔaɣʷa] ~ [mĩaɣʷa]	'go away!'
b.	soʔoppɨtin	[soʔɔpːiɾɨ] ~ [sɔːpːiɾɨ]	'much, many'

1.9 Devoicing

Devoicing is the loss of voicing, usually in final positions (see CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). For example, the final devoicing of obstruents in Standard Bulgarian (15):

(15) *Final devoicing in Bulgarian* (Scatton 1984: 73)

a.	grad-ove	'cities'
b.	grat	'city'

2 Patterns of lenition

The examples in §1 touch on the cross-linguistic prevalence of some leniting phenomena, how common they are among the world's languages, and how widespread their effect may be within the languages where they apply. In this section I elaborate on a few other patterns that emerge from the list of leniting processes. The degree to which each theory of lenition discussed in the following section accounts for these patterns provides added perspective into the differing points of view.

The processes described above operate in two main contexts: syllable/word-finally and intervocalically. The bulk of the processes, those that apply in intervocalic context, line up in a discernible sequence: the products of degemination and deaspiration (/tt tʰ/ → [t]) are the sounds that undergo voicing (/t/ → [d]), resulting in the sound that most commonly undergoes spirantization, flapping, debuccalization, or gliding (/d/ → [ð ʔ/h ɾ j]), and glides and glottals are the sounds most commonly lost (/j ʔ h/ → Ø). This chain shift alignment of intervocalic lenition processes, where the output of some is the exact input of others, is illustrated in (16). In (17), the processes are listed in the order they could apply if they were to affect the same phoneme or its correspondent diachronically, although in some cases like spirantization and flapping or debuccalization and gliding, this order is arbitrary.

(16) *Hierarchy of input/output sounds in intervocalic lenition processes*

tt tʰ > t > d > (θ) ð ɾ > ʔ h j > Ø

(17) *The general order in which intervocalic lenition processes might apply*

Degemination	tt → t
Deaspiration	tʰ → t
Voicing	t → d
Spirantization	t d → (θ) ð
Flapping	t d → ɾ
Debuccalization	t → ʔ h
Gliding	t → j
Loss	ʔ h j → Ø

If the oft-cited observation that "a segment X is said to be weaker than a segment Y if Y goes through an X stage on its way to zero" (Venneman, cited in Hyman 1975: 165) is an accurate diagnostic of intervocalic consonant strength, then (16) lists consonants in order of their relative strength, from strongest to weakest (where [tt] is stronger than [t], which is stronger than [d], etc., to the weakest possible outcome of lenition, which is Ø). The resulting "weakening hierarchy" gives birth to the notion of lenition as gradation toward loss.

There are two ways in which the patterns illustrated in (16) and (17) manifest themselves in language data: as an outline of attested diachronic sound changes of the same phoneme or its correspondent, and as a list of synchronic sound substitutions that occur, often simultaneously, in any given language. Two examples of attested diachronic sound changes where some of the lenition processes listed in (17) sequentially affect the same phoneme are French, where intervocalic stops were voiced then spirantized before eventual gliding (not shown in the example) and deletion (18), and Latin, where there was a similar intervocalic voicing, spirantization/gliding, then loss (19).

(18) *French lenition:* t → d → ð → Ø (Jacobs 1994: 2)

fratrem > *[fradre] > [fraðre] > *frère* 'brother'

(19) *Latin lenition* (Hock 1991: 81)

pacatum > (*)*pagado* > Sp. [paɣaðo] > dialectal [paɣao] 'pacified, pleased'

Lenition processes that operate simultaneously in a given language may also exhibit the pattern in which the output of one process is the exact input of another, but in some cases these actually affect different phonemes. For example, in a given language there could be synchronic voicing of voiceless stops and spirantization of voiced ones. In such cases the chain-shift pattern of [t] → [d] and [d] → [ð] is maintained, but the phone [d] that is the output of voicing and the phonetically comparable [d] that undergoes spirantization do not represent the same phoneme. Two examples of such *phonemic overlap*, an intersection of phonemes where "a given sound [. . .] may belong to two or more different phonemes in the same dialect" (Bloch 1941: 93), are the interactions between intervocalic voicing and spirantization in Northern Corsican, and between debuccalization and loss in Nepali. In Northern Corsican, intervocalic voiceless stops are voiced (20), while existing voiced stops in the language are spirantized in the same context (21). The phonetic contrast between intervocalic voiceless and voiced stops shifts to spirantization and is maintained. In the Indo-European language Nepali there is intervocalic debuccalization of [ts^h] to [h] (Bandhu and Dahal 1971) and in the same context loss of the existing [h] in normal speech (22). So while the chain-shift pattern of [ts^h] → [h] and [h] → Ø is maintained, the output of the first process and the input of the second are not the same phoneme, and the previous contrast between the phonemes /ts^h/ and /h/ is preserved, and shifts to /h/ and Ø.

(20) [p t k] → [b d g] / V __ V *in Northern Corsican* (Dinnsen and Eckman 1977: 6)

a.	[peðe]	'foot'	[u beðe]	'the foot'
b.	[tengu]	'I have'	[u dengu]	'I have it'
c.	[kaza]	'house'	[a gaza]	'the house'

(21) [b d g] → [β ð ɣ] / V __ V *in Northern Corsican* (Dinnsen and Eckman 1977: 6)

a.	[bokka]	'mouth'	[a βokka]	'the mouth'
b.	[dente]	'tooth'	[u ðente]	'the tooth'
c.	[gola]	'throat'	[di ɣola]	'of throat'

(22) *Intervocalic loss of* /h/ *in Nepali* (Bandu and Dahal 1971: 26)

a.	/bəhiro/	[bəiro]	'deaf'
b.	/məhə/	[məə]	'honey'

The discussion of phonemic overlap brings up two additional features common to most lenition processes. First, Nepali intervocalic /h/-loss is reported to occur in *normal* speech. This added dimension to what we know about the context of many lenition processes is rather common cross-linguistically, and many leniting sound substitutions are reported mostly to occur in *relaxed*, *fast*, and *normal* speech (see CHAPTER 79: REDUCTION).

Second, the matter of contrast maintenance is raised (see CHAPTER 2: CONTRAST). In both the Northern Corsican and the Nepali examples the phonetic distinction between two phonemes is threatened by a leniting sound substitution (in Corsican the /p/:/b/, /t/:/d/, /k/:/g/ oppositions are threatened by the voicing of /p t k/, and in Nepali the /ts^h/:/h/ opposition is threatened with the debuccalization of /ts^h/ to [h]). In both cases, however, the distinctions are maintained by an additional leniting sound substitution in the same context (in Corsican the intervocalic spirantization of the existing voiced stops shifts the /p/:/b/, /t/:/d/, /k/:/g/ contrast to /b/:/β/, /d/:/ð/, /g/:/ɣ/, and in Nepali the loss of intervocalic /h/ shifts the /tsʰ/:/h/ contrast to /h/: Ø). As it turns out, lenition phenomena in general very rarely lead to neutralization, and almost never result in homophonic forms. A survey of 230 mostly leniting processes in 153 languages found that 92 percent avoid neutralization, while only 8 percent could potentially result in the kind of homophony that leads to the loss of lexical distinction that may interfere with communication (Gurevich 2004).

In summary, several ways in which lenition behaviors pattern together have been outlined in this section. These are listed in (23).

(23) *Patterns of lenitions*

a. The prevalence of certain processes (that is, how common some lenition processes are cross-linguistically and whether they affect a single sound or an entire series).
b. The fact that many lenition processes are reported to occur in *natural* or *fast* speech.
c. The gradation pattern of intervocalic lenition processes.
d. Phonemic overlap.
e. The strong tendency of lenition phenomena to avoid neutralization.

Current debates on lenition focus on formulating a unified description of all leniting processes, isolating what exactly motivates them and in some cases what constrains them. Exploring how and the degree to which each approach accounts for the patterns presented here sheds light on the foundation of each theory and its capacity to accommodate empirical data.

3 Theoretical approaches to lenition

There is somewhat of a general agreement among phonologists about the main processes that can be considered leniting, but formalizing this agreement has proved controversial. In this section, three main approaches to the question are explored. The formal approach (§3.1) seeks to define unified rules that would encode all vital information about lenition processes. These rules should form a model that can be used to determine unambiguously which processes are leniting, including all those that are and excluding all those that aren't. The phonetic approach (§3.2) seeks to isolate the underlying physical causes of all lenition processes. The third approach (§3.3) builds on the contrast-maintaining behavior of most lenition processes to identify the forces that may constrain the progress and outcome of such sound changes.

3.1 The formal approach

The formal approach to lenition is taken by generative grammarians. Its goal is to formalize a set of purely synchronic rules that would model all cases of lenition. Three notable formalizations of lenition under this approach are *feature spreading*, *sonority promotion*, and *simplification*. Additional formalizations exist, but they are mostly variations on these three models. All three models attempt to subsume the various sound changes that can be considered leniting, while excluding all other processes, under one formal expression. Success in this endeavor would result in a rule to be included in Universal Grammar (UG).

Lenition as autosegmental *feature spreading* (e.g. Jacobs and Wetzels 1988) involves the spreading of some feature of the surrounding sounds to the element undergoing lenition (see CHAPTER 81: LOCAL ASSIMILATION), for example the spreading of either the [+voiced] or [+continuant] feature of the vowels surrounding an intervocalic stop to that stop, causing it to either voice or spirantize. This formalization works well for voicing and spirantization, but not for the leniting process of debuccalization which, if anything, involves the delinking of features rather than the acquisition of new ones. Additional rules would be required to predict when a stop is voiced and when it is spirantized, since the surrounding vowels possess both features.

Lenition as *sonority promotion* (e.g. Hock 1991; Lavoie 1996) formalizes lenition rules as replacing a sound by a more sonorous version of itself in certain contexts. Sonority is determined based on the principle that "requires onsets to rise in sonority toward the nucleus and codas to fall in sonority from the nucleus" (Kenstowicz 1994: 254; see also CHAPTER 49: SONORITY). On the scale of sonority, stops are least sonorous, followed by fricatives, nasals, liquids, glides, and finally vowels, which are most sonorous. Lenition as sonority promotion is descriptively accurate for some of the leniting processes such as spirantization and gliding, but as a unified formalization of lenition it fails to include other processes commonly considered leniting such as deaspiration and degemination, neither of which has a more sonorous output than input.

A third formal view of lenition is one of *simplification*, where segmental complexity is measured by the number of features required to describe a consonant, and lenition is a process that simplifies this complexity by delinking some of the features. For example, deaspiration would involve the delinking of laryngeal features and debuccalization would delink place of articulation features. When this formalization is faced with a leniting sound change that does not appear to reduce the number of basic features of a given element, it turns to *markedness* for help: *markedness* is used as a measure of some degree of "naturalness," meant to make phonological features less abstract in terms of their intrinsic content (e.g. Chomsky and Halle 1968; Guitart 1976; McMahon 1994; Rice 1999). An element is considered *marked* by definition if it is less natural or more complex than another. In this way, every case that does not immediately conform to the view of lenition as simplification is solved, because within this approach the input of any lenition process, by definition, is more *marked* than the output, hence every lenition process is one of a move to the *unmarked*, or less complex state (see CHAPTER 4: MARKEDNESS).

Let us examine how the formal models presented here account for the patterns of lenition discussed in §2. Although there is not an explicit concern with the prevalence of some lenition processes over others (23a), the frequency of any element in comparison with another can be accommodated within generative theory as part of the UG principles of markedness: the less marked elements are expected to be more frequent. The view of lenition as gradation (23c) is relevant to both the *sonority promotion* and the *simplification* models: both formalize lenition as a move along a graded scale, either of sonority or of segmental complexity.

The sonority scale emulates to a large extent the lenition hierarchy mapped out in (16), and the case of loss especially provides compelling support for lenition as *simplification*. Due to its superlative nature, the output of loss is arbitrarily the least complex, least marked, and most natural segment, which, as the ultimate step in the gradation pattern, gives the impression that it is the goal. The remaining three patterns, fast speech (23b), phonemic overlap (23d), and contrast maintaining behavior of lenitions (23e), are not addressed.

The advent of Optimality Theory (Prince and Smolensky 1993) allows for the incorporation of elements of phonetic and functional detail into the formal grammatical expression of lenition patterns. Kirchner (1998), for example, incorporates notions of "articulatory ease" directly into his formal statement, in the form of so-called "lazy" constraints that are ranked with respect to (presumably "non-lazy") faithfulness constraints. Such a research program provides a very promising link to the phonetic and functional pressures that are demonstrably acting on patterns of lenition. We hold off our investigation of such approaches – despite their formal rigor – until the next section.

To summarize, the formal approach to lenition arises from the generative tradition. Its main goal is to find a unified formal rule that would subsume all the various processes that can be considered leniting. If such a rule is defined, it would be recognized as a linguistic universal, and the question of lenition would be solved. If a model is posited that does not apply to all processes generally considered leniting, then the offending processes are either amended (as in the case of the simplification model's use of *markedness*) or removed from the list of lenitions, using the argument that the model is sound, and if it is sound and does not include X, X must not be relevant. For example, degemination does not fit the view of lenition as "delinking of privative features" (a variation on the *simplification* model), so it is argued that this process should be excluded from the list of unambiguously agreed-on lenition phenomena (Szigetvári 2008).

3.2 The phonetic approach

The second approach is more in the spirit of how the term *lenition* came to be coined: an observation of how common certain processes are in certain environments and that there is some "reduction of articulatory energy" associated with these sound changes. Research in this direction is especially concerned with the physical motivation behind lenition, be it *articulatory effort reduction*, *prosody maintenance*, related to *acoustics* and *perception*, or possibly some combination of these factors.

Ohala (1981) notes that sound changes which are attested in diverse and unrelated languages are likely to have a phonetic origin. The degree to which lenition processes are common cross-linguistically suggests that they are motivated by what is common among speakers, i.e. biological factors which include the physical shape of the vocal organs, their movement, and their acoustic correlates. However, while it is widely assumed that lenition is conditioned by phonetic properties such as ease of production and perception (e.g. Flemming 1995; Jun 1995; Kirchner 1998; Steriade 2000), how exactly these properties should be described and measured is far from settled.

The concept of *effort minimization* precedes formal generative theories: Zipf, as early as 1935, suggests that the frequency of sounds depends on their degree of articulatory complexity. Rejection of this concept, based on the fact that effort is difficult to measure, was swift: Trubetzkoy (1939) argues that it is difficult to pinpoint the degree of complexity of sounds (e.g. which is more complex: tense vocal cords and relaxed mouth organs, or lax vocal cords and tense mouth organs?). Trubetzkoy's objection to describing sounds in terms of phonetic complexity leads to the introduction of *markedness* values and the eventual move toward formalizing phonology rules completely removed from phonetic information. But interest in characterizing lenition in terms of effort minimization has not waned.

Kirchner's (1998) phonetically based approach posits an effort minimization model of lenition where greater articulatory movement constitutes greater effort, and the push to reduce this effort results in the reduction of constriction degree or duration of an affected sound. Kirchner incorporates phonetic theory into a formal approach and models it within the framework of Optimality Theory (Prince and Smolensky 1993), where conflicting universal constraints are ranked with respect to each other. Articulatory effort minimization is therefore identified as a constraint (LAZY) that is ranked with respect to the counter-force constraints of *faithfulness* and *fortition*. Lenition is thus viewed as a force, encoded in universal grammar, to reduce articulatory effort by reducing articulatory movement and timing which results in falling short of articulatory targets.

Kingston argues that:

> the differences in effort between the lenited and unlenited pronunciations are so miniscule that they can hardly be what motivates a speaker to lenite. Both the differences in the distance the articulators travel (mere millimeters) and the time scales (at most tens of milliseconds) are much too small for effort to differ detectably between the two pronunciations. (Kingston 2008: 1)

He suggests that lenition's purpose is to *maintain prosodic structure*. He shows that lenition occurs most commonly inside prosodic constituents and argues that it is meant to communicate a continuing constituent, thereby reducing a sound's interruption of the stream of speech. Within this view, lenited pronunciation is the result of achieving a specific target that produces the desired acoustic consequences, such as greater intensity, rather than falling short of the desired target. Kingston also notes that "[l]enition is more likely in more frequent words than less frequent ones, because the listener needs less information to recognize more frequent words" (2008: 17); see also CHAPTER 90: FREQUENCY EFFECTS.

Acoustics and *perception* must also play some role in lenition, even if only as part of the natural interaction between speaker and hearer: "Speaker and hearer are interested in communicating and will pronounce words only as they have heard them (or think they have heard them) pronounced by others" (Ohala 1981: 197); see also CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY. Acoustic considerations may affect the perceived differences between certain sounds in certain contexts, which may facilitate or otherwise influence lenition phenomena. For example, acoustic theory suggests that prevocalic distinctions are more perceptible than preconsonantal ones (e.g. Silverman 1995; Ségéral and Scheer 1999; Steriade 1999). Since lenition processes are most frequent in intervocalic contexts, it is possible that lenition may proceed more easily in contexts where a sound is easier to perceive even when it is lenited. Kaplan (2008) suggests another angle: that in certain contexts the perceptual difference between a sound and its lenited counterpart plays a role in the prevalence of some lenition processes. She has had some success in showing that the perceptual difference between intervocalic voiced stops and spirants is smaller than between voiced and voiceless stops, which is somewhat consistent with the frequency of spirantization, although it is too soon to draw any broad conclusions based on such a limited study. The interaction between articulation and perception, speaker and hearer, also plays a role in the functional approach discussed in the following section.

Turning to the patterns listed in §2, by attributing the sound changes to physical properties common to all speakers, a unified approach to lenition that is based on phonetic considerations accounts for the similarities between, and to some extent the frequency of, cross-linguistic lenition processes (23a) and the fact that many leniting changes are reported to occur in *relaxed* or *fast* speech (23b). In fact, it is these empirical observations that suggest lenition phenomena may be phonetically driven in the first place. The view of lenition as gradation (23c), and especially the weakening hierarchy in (16), are central to effort-reduction theories. As with some formal models discussed above, the case of loss provides compelling support for the view of lenition as a graded move along a scale of effort minimization: loss is the ultimate step in lenition and it results in an element that unambiguously requires the least effort to articulate. Phonemic overlap (23d) is not addressed, but the strong tendency of lenition phenomena to avoid neutralization (23e) is inherent in Kingston's observation that lenition is more likely to affect more common words which rely less on acoustic cues to be recognized. Lenition is less likely to proceed unhindered and have widespread consequences if it obliterates meaning distinctions to the point where it interferes with communication (Gurevich 2004). This is also supported by the acoustic studies that suggest distinctions are more perceptible in prevocalic contexts, where most lenition phenomena occur. I return to this point in the following section.

3.3 *The functional approach*

The functional approach focuses on the effect that leniting sound substitutions have on contrasts in the languages where they apply, that is, the fact that lenition phenomena very rarely result in obliteration of contrast (neutralization). This is the goal of Gurevich (2004), who investigates 230 mostly leniting processes in 153 languages, and finds that 92 percent of these avoid neutralization. This approach is termed *functional* because the meaning distinction of words depends on the system of contrasts in a given language, and these distinctions affect communication, which is the primary *function* of language.

This approach to lenition is not independent of phonetically based motivation, and does not explicitly contradict any of the models presented in the previous section. It does, however, influence the extent to which physical properties can drive sound changes. If there is a physical "push" – whatever that push may be – to lenite, the degree to which this substitution may affect contrast in a given language may hinder the progress of the sound change. Lenition processes that threaten contrast may lead to loss of lexical distinctions which, in turn, could induce a significant amount of homophony that would result in confusion. And since confusing signals are less likely to be reproduced as listeners become speakers (Silverman 2006), the neutralizing sound substitutions, regardless of the physical "push" to invoke them, are less likely to become widespread.

Gurevich (2004) clearly shows that the progress and outcome of lenition processes are constrained by the functional considerations of contrast maintenance. The systems of contrast in languages appear to exert a gradual diachronic force over phonetic processes, affecting the progress and outcome of such processes depending on the degree to which they threaten contrast. Lenition processes that do not threaten contrast are far more likely to proceed unhindered, with the widespread consequences of affecting entire series of sounds in a language (this most commonly happens with voicing and spirantization). Changes that somewhat threaten contrast pattern according to the shapes of the phonemic inventory of a language. An example of this is the flapping that patterns with spirantization discussed in §1.5: in languages where the entire stop series is spirantized, the retroflex stop [ɖ] always results in a flap [ɽ], while the alveolar stop [d] results in a flap [ɾ] only in languages that do not have a phonemic trill; otherwise it spirantizes to [ð]. This suggests that flapping may be the preferred outcome of alveolar spirantization, as in the case of the retroflex stops, but is avoided when contrast is threatened. This threat comes in the form of a phonemic trill, a sound that is phonetically similar to a flap (the /r/:/ɾ/ contrast exists, but is rare; it is found in only three of the 153 languages investigated). Finally, changes that clearly threaten contrast, such as sound mergers and loss, often induce further changes that reshape phonological systems, thereby avoiding contrast obliteration: for example, cases of phonemic overlap discussed in §2 (e.g. in (20), where [p t k] → [b d g], and (21), where [b d g] → [β ð ɣ] intervocalically in Northern Corsican, which results in the avoidance of neutralization between the output of the voicing process and existing voiced stops in the language), or contrast shifts, where a sound may be deleted but its absence maintains contrast with Ø, an example of which is provided below in (24).

Phonetically conditioned sound changes that are found to be neutralizing (18 of the 230 processes, or 8 percent) are more common in preconsonantal positions where contrast is less perceptible and harder to maintain (see again Silverman 1995, Ségéral and Scheer 1999, and Steriade 1999). That is, the potential obliteration of contrast to the extent where it could interfere with lexical distinctions occurs more frequently in contexts where contrast is already less perceptible, in which case fewer words should depend exclusively on such contrasts for their distinctions. Hence the potential of these few neutralizing sound substitutions to hinder communication by inducing homophony is reduced, which further suggests that the relationship between leniting sound substitutions and contrast is not arbitrary.

Turning again to the patterns listed in §2, the cross-linguistic similarities of lenition processes are accounted for by relying on phonetically based motivation, and, in addition, the prevalence of certain processes, and possible wide-reaching consequences of affecting entire series of sounds within a language's inventory (23a), are accounted for directly by the degree to which these sound substitutions affect contrasts in a given language. That is, the less likely a sound substitution is to induce homophony, the more likely it is to proceed unhindered and have a widespread effect on the sound system of a language, as is in fact the case for both voicing and spirantization. Voicing, which comprises 39 cases of the 230 investigated, never results in neutralization and is not only common cross-linguistically, but is also most likely to affect whole series of sounds in the languages where it applies. Spirantization, of which there are 76 cases, is 95 percent non-neutralizing, is the most common cross-linguistic form of lenition, and is also likely to affect entire series of sounds.

The fact that lenitions commonly occur in *natural* or *fast* speech (23b) is not explicitly addressed within the functional approach, except as a natural consequence of its reliance on phonetic motivation as the force that drives most lenitions. The gradation pattern of intervocalic lenition processes (23c) has no implications for the functional approach. Interestingly, although the effect of contrast considerations on lenition is not related to the view of such processes as a trajectory of consonants toward their weakest state, the case of loss – which provides compelling support for the gradation view of several models discussed above – also plays a key role here. This final step in the view of lenition as erosion also has a superlative consequence for contrast: loss always results in phonetic neutralization because the elimination of a phoneme in some context always obliterates the phonetic distinction between that phoneme and Ø. But meaning distinctions are actually preserved in 71 percent of the cases of loss in the corpus of 230 processes. The most common ways in which contrast is maintained in such cases are phonemic overlap, like the examples in (20)–(22) above, and contrast shifts such as the one in Bulgarian (24), where nasals are lost between vowels and fricatives, followed by nasalization of the vowel. Here the /n/ is lost, but the nasalization of the preceding vowel maintains the distinction between /n/ and Ø.

(24) *Loss of nasal and nasalization of vowel in Bulgarian* (Scatton 1984: 57)

/onzi/ [õzi] 'that'

Phonemic overlap (23d) is central to the functional approach. It shows how leniting processes that threaten contrast may induce further changes, and suggests that some leniting changes may actually be, at least partially, triggered by contrast maintenance. Finally, the strong tendency of lenition to avoid neutralization (23e) is, of course, the basis of the functional approach, which posits that this tendency is what constrains the progress and outcome of lenitions. One could question the significance of a pattern that is so important to one approach but is not addressed by others. However, it is a pattern that is extremely prevalent and something that lenitions have more in common than almost any other characteristic. Its omission from all formal and most phonetically based models stems in part from the fact that this pattern had not previously been investigated, and in part from the general belief that, because contrasts are language specific, they have no place in universal grammar.

4 Conclusion

Leniting sound changes are common and exhibit similar cross-linguistic behaviors – this much we know. How to formalize this information in a unified model of lenition that all phonologists can agree on has so far eluded us. Depending on one's approach, such strong cross-linguistic similarities must be encoded in the UG and/or grounded in the physical properties of both speakers and hearers. Current debates range from the generative approach of how to encode lenition as purely phonological synchronic universal rules, to isolating the physical driving force that motivates these sound changes, to how the systems of contrasts in a given language play a role in constraining the progress and outcome of lenition processes.

The various models of lenition presented in this chapter have differing approaches to the questions of how to delimit the collection of processes that almost everyone agrees are related. Five general patterns of lenitions – all based to some extent on empirical data – are identified. The relative significance of each tendency depends on the theory one supports. Below is the summary of each pattern's role within the differing approaches to lenition.

(a) The *prevalence* of certain lenition processes as well as their overall cross-linguistic similarity: cross-linguistic frequency of certain lenitions is implicit in the *markedness* constraints of formal models, where the less marked element is more natural and therefore more frequent, and explicit in the phonetic approach's reliance on physical properties which are common to all speakers and hearers. The prevalence of some processes over others, as well as how widespread their consequence may be, is predicted by the contrast-maintenance considerations of the functional approach, where the less a process threatens contrast the more prevalent it is.

(b) The fact that many lenitions are reported to occur in *natural* or *fast* speech: this pattern is not addressed by the formal models but is inherent in the view of lenition as motivated by physical properties and therefore works with both the phonetic and the functional approaches.

(c) The *gradation pattern* of intervocalic lenition processes: this pattern emerges from the juxtaposition of diachronic lenition processes, and is critical to the sonority scale and simplification models of lenition under the formal approach, and to the view of lenition as consonant erosion within the effort-minimization model. This view of lenition is crucial to the characterization of lenitions as all part of one general process, a notion that is most advantageous to theories concerned with building a UG, whose hypothesized existence is directly tied to encoding rules in their most general and simple manner.

(d) The *phonemic overlap* pattern of some lenitions: this is a pattern that often emerges in languages where two synchronic lenition processes interact in the sense that the output of one is phonetically similar to the input of another. It is only addressed by the functional approach, which views such cases as an indication that the threat of contrast obliteration may trigger additional lenitions.

(e) The strong tendency of lenition phenomena to *avoid neutralization*: this recently identified tendency is the foundation on which the functional approach is built. Since this pattern is based on contrast considerations, which are language-specific, formal models do not address it in their search for universals.

67 Vowel Epenthesis

Nancy Hall

1 Introduction

The term "vowel epenthesis" can refer to any process in which a vowel is added to an utterance. Beyond this simple description, however, vowel epenthesis processes vary enormously in their characteristics, and many aspects of their typology are still not well understood. Accordingly, the empirical focus of this chapter is on the heterogeneity of vowel epenthesis processes.

This chapter is organized around several empirical questions, namely: What is the function or cause of vowel epenthesis (§2)? What determines the location (§3) and quality (§4) of an epenthetic vowel? Do epenthetic vowels differ phonetically or psycholinguistically from lexical vowels (§5)? What distinguishes an excrescent vowel (§6)? How does vowel epenthesis interact with other phonological processes (§7)? Finally, §8 reviews research on epenthetic vowels in loanwords, and revisits some of the previous questions to discuss how the answers may differ in the case of loanwords.

Throughout this chapter, epenthetic vowels are underlined for visual clarity.

2 What is the function/cause of vowel epenthesis?

In most cases, the function of vowel epenthesis is to repair an input that does not meet a language's structural requirements. In particular, vowel epenthesis allows the surfacing of consonants that underlyingly appear in phonotactically illegal contexts. For example, Lebanese Arabic epenthesizes vowels into many CC codas to break up undesirable coda clusters. Epenthesis is more or less obligatory in coda clusters of an obstruent followed by a sonorant, as in (1a), and optional in most other clusters as in (1b) (see Haddad 1984a for a detailed breakdown of coda types).

(1) *Epenthesis in Lebanese Arabic* (Abdul-Karim 1980: 32–33)

a.	/ʔism/	ʔisi̲m	'name'	b.	/kibʃ/	kibʃ ~ kibi̲ʃ	'ram'
	/ʔibn/	ʔibi̲n	'son'		/sabt/	sabt ~ sabi̲t	'Saturday'
	/ʃiɣl/	ʃiɣi̲l	'work'		/nafs/	nafs ~ nafi̲s	'self'

There is controversy over exactly how to analyze the phonotactic requirements that motivate epenthesis. Probably the most popular approach is to assume that epenthesis allows the syllabification of stray consonants (Itô 1989), but Broselow (1982) explores the idea that some epenthesis is simply triggered by particular sequences of consonants, irrespective of syllable structure requirements. Côté (2000) argues that epenthesis is motivated primarily by the need to make consonants perceptible, based on the Licensing by Cue approach of Steriade (1994). For example, one of the main cues that listeners rely on to identify place features of consonants is the formant transitions on neighboring vowels. Hence, a consonant that is not adjacent to a vowel is less easy to identify (see CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS).

In a case like Lebanese, it might be argued that claiming a structural motivation for vowel epenthesis is circular, given that this optional vowel epenthesis is the only evidence that such clusters are marked in this language. But in some languages, vowel epenthesis is only one of a "conspiracy" of processes removing a particular cluster type. In Welsh, for example, codas with rising sonority are repaired through deletion, as in (2a), lenition (2b), metathesis (2c), or vowel epenthesis (2d), while codas with falling sonority are left intact.

(2) *Welsh repair of obstruent–sonorant codas* (Awbery 1984)

a.	/fenestr/	→	feːnest	'window' (southern dialect)
b.	kevn	>	kɛwn	'back' (Pembrokeshire dialect)
c.	sɔvl	>	sɔlv	'stubble' (north-east dialect)
d.	/kevn/	→	keːve̱n	'back' (southern dialect)

The fact that all four processes target the same cluster type supports the idea that this cluster type is marked, and that vowel epenthesis is one of the repairs for the marked structure.

A second common reason for epenthesis is to bring a word up to a certain minimal size. Some languages require each lexical word to have a minimum of two moras or two syllables. Often, roots of smaller size are augmented with an epenthetic vowel, as shown in (3a) for Mono (Banda, spoken in Congo). The epenthetic vowels do not appear when the same roots appear in longer compounds, as in (3b).

(3) *Mono vowel epenthesis* (Olson 2003)

a.	/ʒī/	→	ī̱ʒī	'tooth'	
	/bè/	→	è̱bè	'liver'	
	/mà/	→	à̱mà	'mouth'	
	/ndà/	→	à̱ndà	'house'	
b.	/mà+ndà/	→	màndà	'door'	*à̱màà̱ndà

Metrical structure above the word level can also affect epenthesis. In Galician, vowels are optionally added at the end of an intonational phrase (Martínez-Gil 1997). This is illustrated in (4), where the word *pan* 'bread' can be pronounced with final [i] only if it directly precedes a prosodic break (a–c), not within an intonational phrase (d).

(4) *Epenthesis at intonational phrase boundaries in Galician* (Martínez-Gil 1997)

a. *Ela vai trael-o pan* (~ *pan*[i̲]).
'She's going to bring the bread.'
b. *O pan* (~ *pan*[i̲]), *fixo-no onte.*
'(As for) the bread, (s)he made it yesterday.'
c. *Dille que traia pan* (~ *pan*[i̲]), *non viño.*
'Tell him/her to bring bread, not wine.'
d. *Ela vai trae-lo pan* (**pan*[i̲]) *que comprou.*
'She's going to bring the bread that she bought.'

This epenthesis occurs only with words whose final syllable is stressed: words like ['bo] 'good' and [ka.'fɛ] 'coffee' have the variants ['bo.i̲] and [ka.'fɛ.i̲], but words with non-final stress like ['la.pis] 'pencil' cannot be pronounced *['la.pis.i̲]. Martínez-Gil proposes that the function of this epenthesis is to create a well-formed bimoraic trochee at the edge of each intonational phrase. A similar pattern occurs with optional [ə]-insertion in Parisian French (Fagyal 2000).

A different aspect of phrasal metrical structure affects epenthesis in Dutch. As shown in (5), Dutch has optional schwa epenthesis in coda clusters that consist of a liquid followed by a non-coronal consonant, as well as coda /rn/.

(5) *Dutch* [ə]-*epenthesis* (Booij 1995)

tʏlə̲p	~ tʏlp	'tulip'
hɛlə̲p	~ hɛlp	'help'
hɛrə̲fst	~ hɛrfst	'autumn'
kalə̲m	~ kalm	'quiet'

Kuijpers and van Donselaar (1997) find that speakers are more likely to insert the schwa if this will create a rhythmic alternation of stressed and unstressed vowels. Epenthesizing a schwa in /tʏlp/ changes the word from a single stressed syllable ('σ) to a stressed–unstressed sequence ('σσ) (see also CHAPTER 40: THE FOOT). This happens significantly more often when the first syllable of the following word is stressed than when it is unstressed, as shown in (6).

(6) *Effects of sentence rhythm on epenthesis in monosyllabic words*

context	[ə]-epenthesis	
σσ __ 'σ	50%	['tʏlp] and ['tʏlə̲p] equally preferred
'σσ __ σ	35%	['tʏlp] preferred over ['tʏlə̲p]

Metrical structure above the word level only has gradient effects on vowel epenthesis; there do not seem to be cases of obligatory vowel epenthesis for rhythmic purposes, aside from the minimal word requirement discussed above. Perhaps this is because phrase-level metrical structures themselves tend to show much optionality.

While most analyses of vowel epenthesis focus on structural motivations, there is a little research examining the effects of epenthesis on perception. Van Donselaar *et al.* (1999) bring evidence that vowel epenthesis in Dutch enhances the perceptibility of the consonants adjacent to the epenthetic vowel, particularly the preceding liquid. In lexical decision and phoneme identification tasks, subjects react faster to forms with epenthesis, like [tʏləp], than to forms without epenthesis, like [tʏlp], even though the form without epenthesis is more canonical and closer to the spelling. The authors suggest that speakers epenthesize the vowels to help the listener.

Finally, there are some cases where epenthetic vowels (or, at least, vowels widely described as epenthetic) have no apparent function in terms of phonotactics, metrics, or any other structural requirements. This is seen in Scots Gaelic, where epenthetic copy vowels historically arose in sonorant-obstruent coda clusters following short stressed vowels, as in (7). These vowels are widely analyzed as being still epenthetic today. As discussed further in §5, these vowels are phonetically marked by a special pitch and duration pattern, and they have a number of distinguishing phonological characteristics. Speakers are reported to consider these VRVC sequences monosyllabic, in contrast to other VRVC sequences.

(7) *Scots Gaelic* (Borgstrøm 1937, 1940; Oftedal 1956)

ʃalak	'hunting'
k^{h}ɛn^{yj}ɛ.p	'hemp'

Interestingly, there are many words where one of the consonants that originally triggered the epenthetic vowel has deleted historically, yet the epenthetic vowel has remained – and retained its unique phonetic and phonological characteristics. In the words in (8), the underlined vowel is one that sounds like an epenthetic vowel in terms of pitch and duration, yet synchronically, there is no consonant cluster present to trigger epenthesis. The epenthetic vowel now precedes a word boundary or another vowel, and hence plays no role in terms of improving phonotactics. In fact, it often creates a V.V sequence, which is cross-linguistically dispreferred.

(8) *Unpredictable vowel epenthesis in Scots Gaelic*

mara.i	*marbhaidh*	'will kill'
dɯr^{j}i	*duirgh*	'fishing lines'
ɛn^{yj}ɛ.i	*aithnichidh*	'will recognize'

There are many possible interpretations of such facts. One theory might be that the triggering consonants are present underlyingly and removed through a separate process; another theory is that vowels originally introduced through epenthesis have been reanalyzed as something else (see Hall 2003 for an argument that all "epenthetic" vowels in Scots Gaelic actually reflect a diphthong-like structure in which a vowel and sonorant are phonologically adjoined, and where their articulations overlap so that the same vowel is heard in two pieces). While cases like Scots Gaelic are unusual, they are a reminder that some vowel epenthesis patterns do not seem to have clear structural motivations.

3 What determines the location of an epenthetic vowel?

When vowel epenthesis is used to break up a consonant cluster, there is often more than one location where the vowel could be placed to produce a phonotactically acceptable output. For example, if a language has the syllable structure (C)V(C), hence disallowing CC clusters at the beginning of a word, an initial CCV could be broken up by putting a vowel before the consonants (VC.CV) or between the consonants (CV.CV). In a medial CCC cluster, the vowel could occur before the second or third consonant. The choice of epenthesis locations is language-specific. Arabic dialects, for example, systematically differ in this regard. As shown in (9), "onset" dialects like Egyptian syllabify the second consonant as an onset, meaning that the epenthetic vowel follows the second consonant, while "coda" dialects like Iraqi syllabify the second consonant as a coda, meaning that the epenthetic vowel follows the first consonant (Broselow 1992; Kiparsky 2003; Watson 2007).

(9) *Treatment of /CCC/ in Arabic dialects* (Itô 1989)

Cairene	/ˀul-t-l-u/	ˀul.ti.lu	'I said to him'
Iraqi	/gil-t-l-a/	gi.lit.la	'I said to him'

Temiar (Mon-Khmer, Malaysia) has a much-studied pattern of epenthetic vowel placement in long consonant clusters. Temiar allows only CV and CVC syllables. Given an onset of three or four consonants, Temiar inserts epenthetic vowels to form a string of open syllables terminated by a closed syllable. The epenthetic vowel is a schwa in open syllables; [e] in closed syllables.

(10) *Temiar syllabification* (Itô 1989)

/slɔg/	səlɔg	'sleep, marry (ACT PERF)'
/snlɔg/	senlɔg	'sleep, marry (ACT PERF NOMINALIZED)'
/snglɔg/	sənegl ɔg	'sleep, marry (ACT CONT NOMINALIZED)'

Itô (1989: 241) argues that these patterns of vowel placement can be explained if syllabification is directional. Abstracting away from certain theoretical details, the insight is that languages like Temiar and Iraqi compute maximal syllables starting from the end of the word, while languages like Egyptian compute maximal syllables from the beginning of the word. A stray consonant that could be syllabified more than one way becomes an onset of a following syllable in right-to-left languages, but the coda of a preceding syllable in left-to-right languages, and the placement of the epenthetic vowel varies accordingly.

(11) *Directionality in syllabification*

Left-to-right syllabification	Right-to-left syllabification	
Cairene	*Iraqi*	*Temiar*
/ˀultlu/	/giltla/	/snglɔg/
ˀul.	.la	.lɔg
ˀul.ti.	.lit.la	.neg.lɔg
ˀul.ti.lu	gi.lit.la	sə.neg.lɔg

While directional syllabification works well to explain epenthetic vowel placement in many languages, I will discuss in §8 some cases of loanword adaptation where directional syllabification cannot explain epenthetic vowel placement.

4 What determines the quality of an epenthetic vowel?

The quality of an epenthetic vowel may be determined in one of two ways: it is either a fixed, default quality (which may, of course, be subject to normal allophonic variation according to the language's phonology), or else the quality is determined by some part of the phonological context.

Lebanese Arabic is an example of a language with fixed-quality epenthetic vowels: the epenthetic vowel is always [i]. Different languages have different qualities for their epenthetic vowels, and some qualities are found more commonly than others. Epenthetic [i] and [ə] are especially frequent, but de Lacy (2006: 289) also lists examples of epenthetic [ɨ], [e], and [a]. It is rare for fixed-quality vowels to be [+round], but examples do occur in Quebec French (Martin 1998) and in the Austronesian languages Buol and Kambera (Rice 2008). (There are, of course, also many cases where a basically fixed-quality vowel becomes predictably rounded in some contexts through additional processes such as vowel harmony.)

In "copy vowel epenthesis," the epenthetic vowel must have the same quality as a nearby vowel. In Welsh, for example, final CC clusters are broken with a vowel that is a copy of the preceding vowel. The forms in the left column of (12) illustrate how the epenthetic vowel is absent when a suffix renders the CC cluster non-final.

(12) *Copy vowel epenthesis in Welsh* (Awbery 1984: 88)

gwadne	gwaːdan	'soles, sole'
kɛvne	keːven	'backs, back'
padri	puːdur	'to rot, rotten'
ɔχri	oːχor	'to side, side'

The direction of copying varies by language; both right-to-left and left-to-right copying are well attested.

In rare cases, the quality may relate to more than one nearby segment. In Scots Gaelic, the quality of the epenthetic vowel depends on both the preceding vowel and the preceding consonant. Sonorants in Scots Gaelic contrast for backness. When epenthesis occurs in a /VRC/ sequence where the vowel and sonorant disagree in backness, the epenthetic vowel shares the backness specification of the sonorant (Clements 1986; Ní Chiosáin 1995; Bosch and de Jong 1998; CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS).

(13) *Incomplete vowel copy in Scots Gaelic* (vowel transcription following Ní Chiosáin 1995)

fæɾak	'anger'
inɨxinɣʲa	'brain'
bulʲik	'bellows'
dɨlʲikʲ	'sorry'
mʌrʲev	'dead'

There has been controversy over whether the grammatical mechanisms that allow epenthetic vowels to copy other vowels' quality might be similar to the mechanisms involved in reduplication (where a morpheme copies its segmental content from other segments in the base word; CHAPTER 100: REDUPLICATION). Kitto and de Lacy (1999) argue for a unified theory of the two processes, in which segments in reduplicants and epenthesized segments both have a "correspondence" relation with another segment elsewhere in the word. Kawahara (2007), however, points out a couple of basic differences between these kinds of copying. First, epenthetic copy vowels always copy a vowel in an adjacent syllable, whereas reduplicants may skip adjacent syllables to copy more distant material. For example, in Nakanai (Oceanic; Johnston 1980), a vowel in a reduplicant copies the most sonorous vowel in the base, regardless of its location. Kawahara finds no cases of epenthetic vowels copying distant vowels in this manner. Secondly, copying in epenthetic vowels (especially in loanwords; see §8) is sometimes blocked when particular kinds of consonants intervene, but blocking effects like this are not found in reduplication, where copying can occur over any type of intervening segment. Kawahara proposes that long-distance, correspondence-based copying is available only for morphological operations like reduplication, and that copying of quality in epenthesis always reflects local feature spreading.

5 Do epenthetic vowels differ phonetically or psycholinguistically from lexical vowels?

5.1 *Phonetic characteristics of epenthetic vowels*

There is evidence that in some languages, epenthetic vowels differ articulatorily and acoustically from lexical vowels, and tests that probe speaker intuitions may also find differences. Since these phonetic or psycholinguistic differences may have implications for phonological questions, I will briefly review the evidence.

As shown in (1), Lebanese Arabic optionally inserts an epenthetic vowel in certain CCC or CC# clusters (/mitl/ → [mitil] 'like'). The epenthetic vowel is normally transcribed as [i], but Haddad (1984b: 61) impressionistically notes that "this representation is rather inadequate since an inserted vowel is more prone to suprasegmental features such as 'guttural' and 'emphatic' [pharyngealized] than an underlying vowel is." An acoustic phonetic study by Gouskova and Hall (2009) finds that for some speakers, epenthetic "[i]" is significantly shorter in duration than a lexical [i], and has a lower second formant value. The low F2 indicates that the articulation is relatively back, so that a more appropriate transcription might be [ɨ].

Sometimes the phonetic differences involved in vowel epenthesis are reported to extend over a longer string of the word. The Siouan language Hocank has epenthesis in certain CCV sequences, as in /kre/ → [kere] 'depart returning'. Although no instrumental study has been done, Susman (1943) and Miner (1979) agree that CVCV sequences resulting from epenthesis are audibly shorter in duration than lexical CVCV. The duration difference appears to involve not only the epenthetic vowel, but also the lexical vowel next to it.

Another kind of phonetic difference is reported in Scots Gaelic, where, as shown in (7), epenthesis occurs in certain CC sequences following a short stressed vowel (/tarv/ → [tarav] 'bull'). These epenthetic vowels are often *longer* than lexical vowels in the same position (Bosch and de Jong 1997). The pitch of the resulting

CVCV̲C sequence is distinctive: although a normal CVCVC disyllable has a rise and fall in pitch, Ladefoged *et al.* (1998) show that epenthetic CVCV̲C has only a pitch rise, confirming Oftedal's (1956) description. Speakers are reported to consider such sequences monosyllabic (Oftedal 1956: 29) or "nearly monosyllabic" (Borgstrøm 1940: 153).

Several studies couched in Articulatory Phonology have offered evidence that epenthetic schwa in English differs articulatorily from lexical schwa (see CHAPTER 26: SCHWA). Davidson and Stone (2003) present an ultrasound study of English speakers pronouncing pseudo-Slavic words that began with consonant clusters that are illegal in English, such as /zgomu/. Subjects frequently inserted an audible epenthetic schwa, producing [zə̲gomu]. However, when the articulation of schwa was compared to the lexical schwa of similar words like *succumb* [səkʌm], the tongue position differed significantly. Davidson and Stone suggest that the acoustic schwa does not correspond to a distinct articulatory gesture, but is essentially a transitional sound, the result of a low degree of overlap between the articulatory gestures comprising /z/ and /g/. Smorodinsky (2002) uses EMA to study the epenthetic schwas in English inflectional morphology, and reports differences (though not very robust ones) in tongue position between the epenthetic schwa in *cheate̲d* [ˈʧirə̲d] and the lexical schwa in *cheetah'd* [ˈʧirəd].

Gick and Wilson (2006) give a related analysis of the schwa that many English speakers insert between a high tense vowel and a liquid, as in *fire* (faɪr ~ faɪə̲r). They argue that the schwa sound is not an inserted phonological unit, but an incidental result of the tongue passing through a schwa-like configuration as it transitions between the opposing tongue root positions of the high front vowel and the liquid.

As of yet, few examples of epenthetic vowels have been instrumentally studied, so it is not clear whether epenthetic vowels differ phonetically from lexical vowels in every language. There are plenty of cases where epenthetic vowels are impressionistically described as being acoustically identical to lexical vowels (e.g. Mohawk; Michelson 1989: 40, 48). It is also unknown whether the vowels' phonetic nature correlates with any aspect of their phonological behavior (such as whether the vowel is obligatory or optional, or whether the vowel interacts opaquely with processes like stress assignment). This is likely a rich area for future research.

5.2 *Speaker intuitions about epenthetic vowels*

There are indications that speakers are not always conscious of epenthetic vowels in the same way as lexical vowels. One type of evidence comes from situations where speakers are asked to write their pronunciations phonetically. Pearce (2004: 19) asked speakers of Kera (East Chadic, spoken in Chad, with no tradition of writing) to choose between two possible spellings for acoustically CVCV̲CV words, where the middle vowel was analyzed as epenthetic. The speakers chose CVCCV spellings, suggesting that the middle vowel was not part of their conscious segmentation of the word. On the other hand, when I have asked Lebanese Arabic speakers to write colloquial pronunciations (which are not usually written, as orthography follows Classical Arabic), they do write in the epenthetic vowels. This suggests that speakers' consciousness of epenthetic vowels may differ from language to language.

Van Donselaar *et al.* (1999) argue that in Dutch, where vowel epenthesis is optional ([tʏlp] ~ [tʏlə̲p]), speakers treat the form without epenthesis as canonical. In an experiment, Dutch speakers were asked to perform different language-game-like reversals on monosyllables and disyllables: subjects were to reverse monosyllables segment by segment, changing [tap] to [pat], and reverse disyllables syllable by syllable, changing [hotel] to [tɛlho]. Over 90 percent of words with vowel epenthesis were treated like monosyllables, so that [tʏlə̲p] 'tulip' changed to [plʏt] rather than [lə̲ptʏ]. The authors suggest that speakers have a unitary representation for the forms with and without epenthesis. It might be objected, however, that the experiment is contaminated by orthographic differences between lexical schwa, which is written, and epenthetic schwa, which is not. Another objection, raised by a reviewer, is that [ləptʏ] is not a possible word in Dutch, due to its final lax vowel.

Speakers may be particularly likely to lack awareness of the kind of weak epenthetic vowels often called "excrescent" (discussed further in §6). For example, Harms (1976) reports that Finnish speakers are unaware of an epenthetic schwa that is easily perceived by some non-native speakers:

> [mɛləkein] (*melkein*) 'almost' has essentially the same vowel qualities ([ɛ, ə, ei]) and relative durations as the English verb *delegate* – [dɛləgeit]. From a descriptive phonetic point of view, the Finnish [epenthetic] schwa and the English reduced-vowel schwa represent very nearly identical classes of vowel sounds; i.e., they vary over a wide central area, with their range of variation conditioned by the preceding and following segments. But here the similarity ends. The schwa in the above Finnish forms is purely transitional in nature. Speakers perceive these forms as containing only two syllables, not three.

Few studies of vowel epenthesis have probed the intuitions of native speakers about the vowels, and it would be useful to have data from more languages on how speakers perceive epenthetic vowels, including how the vowels are written, treated in metrics, and treated in language games (see CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY).

6 What distinguishes an "excrescent" vowel?

A number of proposals distinguish a special class of epenthetic vowels often called "excrescent" (Levin 1987) or "intrusive" (Hall 2006). These terms are usually used for vowels that are noticeably phonetically weaker than other vowels. Typically, excrescent vowels are short in duration and centralized in quality. The excrescent vowel may have a quality not present in the language's lexical vowel system; for example, excrescent schwa may exist in a language that otherwise has no schwas. Excrescent vowels are systematically ignored by other phonological processes. The commonly expressed insight is that excrescent vowels are a kind of phonetic effect, likely a transition between consonant articulations.

A classic example of excrescent vowels is the short vowels that occur in consonant clusters in Piro (Arawakan), as shown in (14). Matteson and Pike (1958) note that these vowels differ from the short phonemic vowels of Piro (/i e o a ï/) in several ways. The excrescent vowels are subject to extensive free variation. Their quality can be highly variable, as in /hwï/ below, where the excrescent vowel has been recorded with five different qualities. Also, in some cases the presence of the excrescent vowel varies with "syllabification" of a consonant, as in /whene/ below. The vowels cannot bear any kind of stress, and they are of much shorter duration than lexical vowels. In terms of timing, the authors report that "in the rhythm of a phrase, a consonant plus the transition vocoid corresponds in timing to a single consonant rather than to a sequence of consonant plus vowel." The excrescent vowels fail to block a pattern of co-articulatory rounding that is blocked by other vowels. In Piro orthography, the excrescent vowels are not written.

(14) *Excrescent vowels in Piro* (Matteson and Pike 1958)

/kwalï/	k^{ə}walï ~ k^{ʊ}walï	'platform'
/tkatʃi/	t^{ɨ}katʃi	'sun'
/ʃjo/	ʃ^{i}jo	'bat'
/hwï/	h^{ɨ}wï ~ h^{u}wï ~ h^{ə}wï ~ h^{i}wï ~ h^{ɯ}wï	'O.K.'
/whene/	w̥hene ~ w^{ə}hene ~ w^{u}hene ~ w^{i}hene ~ w^{ɯ}hene	'child'

Based on the vowels' exceptional phonological and phonetic characteristics, the authors analyze them as "non-phonemic transitional vocoids." Vowels with similar characteristics occur in Finnish (Harms 1976), Sanskrit (Allen 1953: 173), South Hamburg German (Jannedy 1994), and other languages listed in Hall (2006).

Recently, a number of authors have formalized similar ideas about excrescent vowels in an Articulatory Phonology framework. Articulatory Phonology (Browman and Goldstein 1986, 1992) treats abstract articulatory gestures as primitives, and allows the grammar to regulate the timing of articulatory gestures with respect to one another. Vowel-like percepts can be created when two consonant gestures are phased to have a low degree of overlap with one another, leaving a period between the consonant constrictions where the vocal tract is relatively open (Browman and Goldstein 1992). See Gafos (2002) and Hall (2006) for arguments that excrescent vowels lack an independent gesture, and hence are not present as phonological units in the way that lexical vowels (and most epenthetic vowels) are.

7 How does vowel epenthesis interact with other processes?

One of the most interesting characteristics of epenthetic vowels is their tendency to interact opaquely with other phonological processes. It is common for phonological patterns to treat epenthetic vowels as if they were not present. This observation has many theoretical interpretations. Some argue that epenthetic vowels are representationally defective: Piggott (1995), for example, argues that some epenthetic vowels are weightless, lacking a mora. Other approaches handle opaque interactions through rule ordering, with the epenthetic vowels being inserted late in the derivation. Here, I will focus on the empirical issues to be explained, with examples of the kinds of interactions that have been reported.

7.1 Metrical patterns

Syllables whose nuclei are epenthetic vowels frequently fail to count as syllables in patterns such as stress assignment, minimal word requirements, and the conditioning of open syllable lengthening. This section gives an example of epenthesis interacting with each of these processes.

In Lebanese Arabic, a closed penult is stressed when it contains a lexical vowel, as in (15a), but not when it contains an epenthetic vowel, as in (15b) (see also CHAPTER 124: WORD STRESS IN ARABIC).

(15) *Stress–epenthesis interaction in Lebanese Arabic*

a.	/fihim-na/	fi.'him.na	'he understood us'
b.	/fihm-na/	'fi.hi̲m.na	'our understanding'

In words without a closed penult, stress normally falls on the final syllable if it is superheavy, i.e. CV:C or CVCC, as in (16a), and on the antepenult otherwise, as in (16b). Again, vowel epenthesis disrupts the pattern. If an epenthetic vowel is inserted into a final CC cluster, breaking up what would otherwise be a final superheavy syllable, stress is assigned to the penult, as in (16c). This is the only case in which a light penult can be stressed.

(16) *Lebanese Arabic* (Haddad 1984a)

a.	/nazzal-t/	naz.'zalt	'I brought down'
b.	/katab-it/	'ka.ta.bit	'she wrote'
c.	/katab-t/	ka.'ta.bi̲t	'I wrote'

For all of the patterns above, stress is simply assigned as if the epenthetic vowel were absent. The only exception to this generalization is an epenthetic vowel inserted in an underlying CCCC sequence. In this case alone, the epenthetic vowel is treated the same as a lexical vowel for stress. In (17), the epenthetic vowel falls in a closed penult, and is stressed, as is normal for a heavy penult (cf. (15a)).

(17) /katab-t-l-ha/ ka.tab.'ti̲l.ha 'I wrote to her'

Such patterns, where epenthetic vowels are visible to stress under some circumstances but invisible in others, also occur in Mohawk (Michelson 1989) and Selayarese (Broselow 1999).

In languages that require words to have a minimal size, epenthetic vowels may not count in determining this size. Mohawk, for example, requires each lexical word to contain two syllables, as in (18a). A verbal stem containing only one syllable is augmented with an epenthetic [i], as in (18b). Mohawk also inserts an epenthetic [e] after the first consonant of certain CC and CCC clusters. This [e] counts for metrical purposes if it is in a closed syllable, but not if it is in an open syllable. Hence, a two-syllable word containing an open epenthetic syllable, as in (18c), is augmented with epenthetic [i] as well. However, a two-syllable word containing epenthetic [e] in a closed syllable is not augmented, as seen in (18d).

(18) *Minimal word augmentation in Mohawk* (Michelson 1989)

a.	/k-hnˈuu-s/	ˈkhniː.nus	'I buy'
b.	/k-jʌ-s/	ˈi̲k.jʌs	'I put it'
c.	/s-riht/	ˈi̲.se̲.riht	'cook!'
d.	/s-rho-s/	ˈse̲r.hos	'you coat it with something'

This interaction highlights another interesting problem: the fact that there may be multiple vowel epenthesis processes in a single language, which differ in whether they are metrically "visible."

Epenthetic [e] in Mohawk also shows another type of metrical invisibility: it fails to trigger a rule by which stressed vowels lengthen in an open syllable. In (19a) we see this rule apply normally. In (19b), it appears that the stressed [i] is an open syllable, since the following epenthetic vowel has syllabified [r] as an onset; yet the stressed syllable fails to lengthen.

(19) *Stressed vowel lengthening in Mohawk*

a.	/wak-ashet-u/	wa.kas.ˈheː.tu	'I have counted it'
b.	/s-riht/	ˈi̲.se̲.riht	'cook!'

In sum, although epenthetic vowels are usually added in order to syllabify stray consonants, the syllables they form do not necessarily count as syllables for other aspects of the phonology.

7.2 *Segmental processes*

In some cases, epenthetic vowels fail to condition other segmental processes, such as deletion or allophonic variation, in the same way that lexical vowels condition them. In Dutch, for example, underlying /ən/ is optionally reduced to [ə], as in (20a). Yet when schwa epenthesis occurs before /n/, as in (20b), the epenthetic schwa does not condition deletion of the following [n]. Some speakers thus eliminate underlying /ən/, yet create surface [ən] through epenthesis.

(20) *Dutch* [n]-*deletion* (Booij 1995; Hall 2006)

a.	*regen*	/reɣən/	→	reɣən ~ reɣə		'rain'
	horen	/horən/	→	horən ~ horə		'to hear'
b.	*hoorn*	/horn/	→	horn ~ horə̲n	*horə̲	'horn'

Similarly, Herzallah (1990) describes a Palestinian Arabic dialect in which a pharyngealized [rˤ] loses its pharyngealization before lexical [i], but not before epenthetic [i] (CHAPTER 25: PHARYNGEALS).

Just as different epenthetic vowels within a single language may show different metrical behavior, they may also differ in whether they condition other segmental processes. For example, in Tiberian Hebrew, one kind of epenthetic vowel does condition spirantization in following stops, and another does not. Normally a stop becomes a fricative after vowels, as in (21a). One type of epenthetic vowel, which splits up final CC clusters in non-derived words, also causes spirantization. In (21b), we see /b/ spirantize to [β] following the epenthetic [e]. But another epenthetic vowel, which occurs in final clusters of a guttural and a following consonant, does not condition spirantization. In (21c), the /t/ following the epenthetic vowel is realized as [t] rather than [θ].

(21) *Tiberian Hebrew spirantization* (McCarthy 1979)

a.	/katab+t/	→	kaθaβt	'you (FEM SG) wrote'
b.	/kelb/	→	kele̱β	'dog'
c.	/ʃalaħ+t/	→	ʃalaħa̱t	'you (FEM SG) sent'

Thus, there is variation both within and between languages in how vowel epenthesis interacts with other processes.

8 How does epenthesis happen in loanwords?

Typological studies of vowel epenthesis frequently consider loanword data side by side with cases of epenthesis within languages, under the assumption that similar phonological mechanisms produce both (e.g. Broselow 1982; Kitto and de Lacy 1999; among many others). Since vowel epenthesis is particularly common in loanwords, loanword data have played a large role in theorizing on epenthesis, probably more than most other phenomena. However, I would like to argue that conflating loanword and native-language epenthesis is a serious methodological mistake. A growing body of evidence suggests that epenthesis in loanwords differs from epenthesis within languages in its formal characteristics, and may have different causes and functions. For this reason, facts about loanword epenthesis are reviewed here separately from within-language epenthesis, to highlight some likely empirical differences between the two kinds of epenthesis. I will also include some references to epenthesis in "interlanguage," which is the language produced by second language learners. While interlanguage and loanwords are not the same thing, they are related in the sense of both involving language contact, and many loanwords may arise historically from interlanguage forms (see also CHAPTER 95: LOANWORD PHONOLOGY).

8.1 Perceptual origin?

There is considerable debate over whether epenthesis in loanwords happens through perceptual errors by speakers of the borrowing language. Traditionally, it was assumed that a speaker of the borrowing language (likely a bilingual) would hear a foreign word, construct some reasonably accurate representation of the way the word was pronounced in the foreign language, and then alter that representation to fit the phonotactics of the borrower's native language. But Peperkamp and Dupoux (2002) argue that the borrower is likely to perceive the foreign word incorrectly, and that these perceptual errors are the main source of phonological alterations in loanwords (see also CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY and CHAPTER 95: LOANWORD PHONOLOGY for further discussion).

One piece of evidence for this view comes from Japanese, which inserts an epenthetic vowel to remove illegal codas in loanwords (only a nasal or the first half of a geminate can be a coda). The epenthetic vowel is [o] after [d] and [t], and [ɯ] elsewhere.

(22) *Japanese loanwords from English* (Itô and Mester 1995)

faito	'fight'
fesɯtibarɯ	'festival'
sɯfiŋkɯsɯ	'sphinx'

Dupoux *et al.* (1999) argue that Japanese speakers actually believe they hear this [ɯ] in the pronunciation of foreign CC clusters. In a perception experiment, Japanese and French listeners were asked to judge whether a middle vowel was present in nonsense words like [ebzo] and [ebɯzo]. For words like [ebzo], where no middle vowel was acoustically present, most Japanese listeners reported hearing a vowel, while most French listeners did not. Japanese listeners also had great difficulty in discriminating between tokens like [ebzo] and [ebɯzo] in an ABX discrimination test. Dupoux *et al.* point out that Japanese [ɯ] is frequently devoiced and shortened, and shows considerable allophonic variation. Knowing this may make listeners likely to fill in an illusory [ɯ] when they hear consonants with no vowel between them.

The idea that epenthesis in loanwords has a perceptual origin is controversial; see Rose and Demuth (2006), Smith (2006), and Uffmann (2007) for arguments that perceptual factors cannot account for all facets of loanword adaptation. Nevertheless, we will see below several additional arguments that perceptual factors play a special role in loanword vowel epenthesis.

8.2 *Function of vowel epenthesis*

For within-language phonology, epenthesis usually occurs to repair an input that does not meet the language's phonotactic or metrical requirements. In most cases, epenthesis in loanwords can be analyzed as having the same function, like the Japanese examples in (22). Yet surprisingly, there is at least one case where speakers add epenthetic vowels to loanwords that were phonotactically permissible in the borrowing language without the vowel. Korean (Kang 2003) frequently epenthesizes a final vowel after English loanwords ending in a stop, as in the examples below.

(23) *English loanwords in Korean* (Kang 2003: 223)

gag	→	kækɨ
pat	→	pʰætɨ
tube	→	tʰjupɨ

There is no phonotactic need to add vowels to these words. The consonants /k t p/ are among the acceptable codas of Korean, occurring in native words such as [kæk] 'guest', so epenthesis cannot be explained as a means of syllabifying stray consonants. Kang argues that the purpose of the vowel is to maximize perceptual similarity between the English word and the Korean word. English has more release of final stops than Korean does, and Kang claims that to Korean listeners, the release of a final stop of an English word sounds vocalic. She shows that final vowel insertion in loanwords from English is most common in precisely the environments where final stop release is most common in English, such as after voiced stops and when the preceding vowel is tense. Thus, epenthesis may be a means of preserving phonetic details of the source language, rather than a repair.

8.3 *Relation to native phonology*

The epenthetic vowel used in loanwords often differs from any vowel epenthesis process that exists in the native phonology, and epenthesis may be used in loanwords in contexts where other repairs would be used in the native phonology.

In Japanese, for example, consonant clusters that arise through morpheme concatenation in the native language are repaired through deletion of one of the consonants, as shown in (24). Yet consonant clusters in loanwords are repaired with vowel epenthesis, as in (22).

(24) *Deletion in Japanese native phonology* (McCawley 1968; Smith 2006)

non-past /-ɾɯ/		*causative* /-sase/		
/jom-ɾɯ/	jo.mɯ	/jom-sase/	jo.ma.se	'read'
/tob-ɾɯ/	to.bɯ	/tob-sase/	to.ba.se	'fly'

Karimi (1987) reports a similar case for Farsi: CCC clusters are subject to consonant deletion in the native phonology, but repaired through epenthesis in loanwords and interlanguage.

In general, vowel epenthesis seems to be a heavily favored repair type in loan adaptation, more than in native phonologies. Uffmann (2007) surveys case studies of loanword adaptation and concludes that consonant deletion is a marginal phenomenon, compared to epenthesis. Paradis and LaCharité (1997) invoke the "Preservation Principle," which states that segmental material is maximally preserved (see also CHAPTER 76: STRUCTURE PRESERVATION: THE RESILIENCE OF DISTINCTIVE INFORMATION). Hence, adding extra segments is less undesirable than deleting segments from the source word. It is possible that the prevalence of vowel epenthesis in loanwords is related to its prevalence in interlanguage. Jenkins (2000) observes, based on a corpus of conversations between non-native speakers of English, that more misunderstandings are caused by deletion of consonants than by addition of vowels. If bilinguals are aware of this fact and therefore favor vowel epenthesis in their interlanguage pronunciations, then any loanwords based on these interlanguage forms would also tend to favor vowel epenthesis.

8.4 *Quality*

As in native language phonology, epenthetic vowels in loanwords may have a default quality or copy their quality from nearby consonants or vowels. However, the patterns of vowel quality in loanwords are often strikingly complex in ways that are not common (and perhaps not attested at all) in native language epenthesis.

Consider the patterns of epenthetic vowel place in words borrowed from English or Afrikaans into the southern Bantu language Sotho, as described in Rose and Demuth (2006). This study examines only the front–back dimension of epenthetic vowel place. In word-initial CC clusters, the epenthetic vowel is back when it follows a labial (25a), and front when it follows a coronal (25b). When the initial

C is velar, the epenthetic vowel copies the place of the following vowel, as in (25c). In word-medial or word-final /CC/ clusters, usually the vowel copies its place from the preceding vowel, as in (25d). (A few further sub-patterns are ignored here. Only epenthetic vowels discussed in the text are underlined.)

(25) *Epenthesis in loanwords in Sotho* (Rose and Demuth 2006)

	source word	borrowed form	
a.	blɪk	bʊ̲leke	'tin can, dish'
b.	truwn	tɪ̲ronɪ	'throne'
c.	xʀɑːf	kʰɑ̲rɑfu	'spade'
d.	hibruw	hebe̲ru	'Hebrew'

Sotho also shows epenthesis for minimal word purposes within the native vocabulary, but in this case, the epenthetic vowel is always [ɪ], regardless of context. Sotho is not the only case where vowel epenthesis in loanwords follows such a complex pattern; Uffmann (2007) analyzes similarly complicated rules for epenthetic vowel quality in Shona, Sranan, Nyarwanda, and Samoan, each of which shows an interplay between copying the features of consonants, copying the features of vowels, and insertion of default features.

An informal survey of the literature gives the impression that such complex effects of phonological context on vowel quality are more or less confined to loanword epenthesis. Within languages, it is far more common to find epenthetic vowels of default quality, as in Arabic, or relatively simple kinds of copying, such as always copying in one direction, as in the Welsh pattern in (12). An extensive typological comparison of the formal qualities of vowel epenthesis in loanwords and non-loanwords would be a valuable contribution to understanding the difference between them.

Another important difference between loanword and native language epenthesis is that epenthesis in loanwords is often not fully predictable. As we saw in the Korean examples in (23), epenthesis in a given location may be optional, and in languages like Shona and Sotho, "rules" for epenthetic vowel quality in loanwords are not exceptionless. Uffmann (2007: 9–13) argues that loanword epenthesis needs to be studied by looking for statistical patterns in large corpora of loanwords, because incorrect generalizations are easily reached from impressionistic or limited data.

Both the complexity and unpredictability of some loanword epenthesis patterns may indicate that these patterns have not been internalized by speakers as true phonological "rules" – again, an argument for not considering them side by side with language-internal epenthesis.

8.5 Vowel placement

The problem of where to place an epenthetic vowel arises in loanword phonology in the same way as in native language phonology: initial CC clusters, or medial CCC clusters, can potentially be split in two ways.

In some cases, epenthesis location in loanwords or interlanguage appears to follow the same placement pattern as the borrowing language shows in its native epenthesis patterns. For example, we saw in (11) that Iraqi and Egyptian Arabic differ in how they break up word-medial CCC clusters in the native phonology: Iraqi puts the epenthetic vowel after the first consonant, and Egyptian after the second. These dialects differ in exactly the same way in how they epenthesize into CCC clusters in interlanguage phonology, as seen in (26). This pattern can be explained by the same mechanism, directionality of syllabification, that is commonly used to explain vowel placement in the native phonologies of these languages.

(26) *Iraqi* vs. *Egyptian epenthesis in* CCC *clusters* (Broselow 1987)

			Iraqi	Egyptian
native language	/kitab+t+l+V/	→	ki.ta.bit.la	ki.tab.ti.lu
interlanguage	*children*	→	*chilidren*	*childiren*

Yet in other cases the placement of the epenthetic vowel is not explainable as a transfer of native language epenthesis rules, and cannot be analyzed through directional syllabification alone. Fleischhacker (2001) presents a typological study of epenthesis in initial CC(C) clusters in loanwords and interlanguage, focusing on the question of whether the vowel precedes the cluster (VCC) or breaks up the cluster (CVC). She shows that in many languages, the placement of the vowel depends on what kind of consonants are in the cluster, as in the Egyptian Arabic examples in (27). In word-initial clusters consisting of a voiceless sibilant plus a stop, it is cross-linguistically more common to insert a vowel before the first consonant, as in (27a), while in word-initial clusters of an obstruent and sonorant, it is more common to place the vowel between the consonants, as in (27b).

(27) *Egyptian Arabic epenthesis in interlanguage* (Broselow 1987)

a.	*study*	→	istadi
	special	→	izbasjal
	ski	→	iski
b.	*sweater*	→	siwetar
	slide	→	silaid

Fleischhacker argues that the reason for this pattern is that epenthetic vowels are inserted where they will cause the least perceptual difference between the foreign word and the epenthesized adaptation (a theory which follows the P-map hypothesis of Steriade 2003). She presents an experiment in which English listeners were asked to judge auditory similarity between English words and modifications of those words with epenthetic vowels in different locations. Words beginning with sibilant–stop clusters, like *spar*, were judged more similar to versions with epenthesis before the cluster ([əspɑr]) than to versions with epenthesis within the cluster ([səpɑr]). Words beginning with obstruent–sonorant clusters, like *flit*, were judged more similar to versions with epenthesis within the cluster ([fəlɪt]) than to versions with epenthesis before the cluster ([əflɪt]). The results of the perception experiment thus match the cross-linguistic tendencies in epenthetic vowel placement, and add to the body of arguments that perceptual factors have a special role in loanword epenthesis.

9 Conclusion and suggested directions for future research

In the discussion above, I have tried to highlight some of the main empirical questions about vowel epenthesis, and to show that vowel epenthesis processes are greatly heterogeneous. A better understanding of vowel epenthesis will require work on two dimensions. One is detailed case studies of individual languages, in particular studies that combine the traditional, structural description of vowel epenthesis with attention to the acoustics, articulation, and perception of the epenthetic vowels, and also probe speaker intuitions about the vowels. Epenthetic vowels in Dutch are probably currently the best-studied in this regard, and it would be useful to have similar experiments done with epenthetic vowels in other languages. It would be interesting to examine whether the phonetic nature of an epenthetic vowel (for example, whether it is acoustically identical to a lexical vowel) correlates with any aspect of its phonological behavior (for example, whether it is visible to other phonological processes in the same way that lexical vowels are). The second area is typological work that looks for correlations between different characteristics of epenthetic vowels. Often, typological studies that focus on one variable, such as vowel quality, have lumped together vowel epenthesis processes that differ on other important parameters, such as whether the epenthesis occurs in native words or loanwords, whether the vowels are excrescent or not, whether they are morphologically conditioned, etc. However, it is possible that there may be relations between these variables. For example, it would be interesting to see more systematic comparisons of epenthesis in loanwords *vs.* native phonology, given the growing evidence that these processes may work differently.

68 Deletion

John Harris

1 Introduction

In language, we often come across situations where a morpheme shows up in two alternating phonological shapes, one of which contains a vowel or consonant segment that is missing from the other. For example, in Samoan the root meaning 'twist' has two alternants: [milos] and [milo]. The form ending in [s] is found before a vowel-initial suffix (as in [milos-ia] 'be twisted'), while the form lacking the [s] is found when the root falls at the end of a word.

In such situations, the two alternants usually stem from a single historical source, and we can attribute the alternation between segment and zero to the action of some sound change. The question then is whether or not the historical form contained the segment that alternates in the present-day forms. Either the segment was absent from the original form and has since been inserted in certain phonological contexts, or it was present and has since been deleted in certain contexts. Which of these scenarios is correct depends on whether the segment's occurrence is phonologically predictable or not.

In the case of Samoan, the [s] must have been part of the original form of the root meaning 'twist', because its presence is unpredictable. There is no regular sound change that could have inserted the consonant without also incorrectly inserting it in other morphemes. The unpredictability of the root-final consonant is confirmed by observing roots that show alternations with consonants other than [s], such as [oso] – [osof-ia] 'jump', [tau] – [taul-ia] 'cost'. The conclusion then is that Samoan has undergone a change that deleted consonants at the ends of words.

Whole-segment deletion is a pervasive phenomenon in the world's languages. Much of the terminology phonologists use to describe it – including the term *deletion* itself – dates from nineteenth-century philology. Although the terms were initially applied to historical deletion processes, they have subsequently been extended into synchronic phonology. This is largely due to a well-established tradition of assuming that when a sound change affects a grammar it can remain there as an active phonological process. According to this model of grammar, a synchronically live process allows regularly alternating forms to be derived from a single underlying form that strongly resembles the historical form (CHAPTER 93: SOUND CHANGE). In our Samoan example, this means that the form [milo] is derived from underlying /milos/ through the operation of a synchronic process that deletes a consonant when it is final in the word.

General terms used to describe whole-segment deletion include *elision, loss, drop,* and *truncation*. Although these terms continue to prove useful for descriptive purposes, they retain a strong flavor of the philological tradition within which they were conceived. There are at least two connotations that more recent research has shown should not be allowed to determine how we approach synchronic deletion. First, there is a procedural flavor to the terminology: deletion might suggest that a phonological form is derivationally altered by the irretrievable elimination of a sound. Second, there is an implication that what gets deleted is a phoneme-sized unit – an impression undoubtedly reinforced by the practice of using alphabetic transcription to present the relevant data. As we'll see, neither of these connotations accurately reflects how deletion is treated in modern phonological theory.

This chapter is laid out as follows. §2 catalogues the main types of vowel and consonant deletion, sticking as far as possible to theory-neutral descriptions. §3 discusses different approaches to how deletion effects are represented in phonological grammars. The next two sections examine the phonological conditions under which deletion occurs. §4 addresses the issue of what causes consonant deletion and reviews claims that it is driven by an imperative to simplify syllable structure. §5 focuses on vowel deletion and evaluates the assumption that it inevitably triggers resyllabification. The chapter concludes in §6 by considering an alternative to traditional derivational approaches to deletion.

2 Segmental deletion

2.1 *Consonant deletion*

The following forms expand the Samoan example we started with (data originally from Pratt 1911, cited in Bloomfield 1933):

(1) *Samoan*

	Simple	*Perfective*	
a.	olo	oloia	'rub'
	aŋa	aŋaia	'face'
	tau	tauia	'repay'
b.	api	apitia	'be lodged'
	sopo	sopoʔia	'go across'
	milo	milosia	'twist'
	oso	osofia	'jump'
	tau	taulia	'cost'
	asu	asuŋia	'smoke'
	ŋalo	ŋalomia	'forget'

The form of the perfective suffix, [-ia], is evident from the examples containing vowel-final roots in (1a). The examples in (1b) contain consonants that appear in the perfective but not in simple forms. Since the alternating consonants vary unpredictably from one word to another, we can conclude that each belongs to a root rather than the suffix. The phonological process responsible for the alternation can be summarized as follows: a consonant is deleted at the end of a word. The result is that root-final consonants are elided when word final but survive when prevocalic.

The effect of deletion in Samoan has been to bar any consonant from appearing word finally. In a more restricted version of the process, final deletion only targets consonants of a certain type. In Lardil, for example, the only type of consonant permitted finally is apical. Stem-final consonants, which show up before a suffix vowel, delete finally if not apical; compare (2a) with (2b) (Hale 1973).

(2) *Lardil*

	Bare noun	*Accusative*	
a.	pirŋen	pirŋen-in	'woman'
	kentapal	kentapal-in	'dugout'
b.	ŋalu	ŋaluk-in	'story'
	taŋku	taŋkuŋ-in	'oyster'
	murkuni	murkunim-an	'nullah'

Lardil illustrates another restricted form of final deletion, where the targeted consonant is preceded by another consonant. The effect of simplifying final consonant clusters in this way can be seen in (3), where the second of two stem-final consonants drops when word final. The process is fed by an independent process of final vowel deletion (on which more below) and itself feeds the deletion of final non-apical consonants exemplified in (2).

(3) *Lardil*

Input	*Output*	
/jukarpa/	jukar	'husband'
/wuluŋka/	wulun	'fruit'
/kantu-kantu/	kantukan	'red'

As the form [kantukan] in (3) attests, cluster simplification in Lardil affects any type of consonant, including apicals. In other languages, a more restricted version of this process shows sensitivity to the type of consonant involved. In Catalan, for example, final cluster simplification targets coronals but not other places; compare (4a) with (4b) (Mascaró 1983).

(4) *Catalan*

	Masculine	*Feminine*	
a.	əskerp	əskerpə	'shy'
	orp	orβə	'blind'
	ʎark	ʎarɣə	'long'
b.	al	altə	'tall'
	for	fortə	'strong'
	bɛr	bɛrðə	'green'
	san	santə	'saint'
	prufun	prufundə	'deep'
	blaŋ	blaŋkə	'white'

Cluster simplification can also target non-final consonants. Here, which member of a cluster drops varies in a way that is often attributed to differences in syllabification (on which more below). Pali illustrates the case where the second of two consonants deletes; as shown in (5), historical liquids (evident in the cognate Sanskrit forms) have been lost post-consonantally (Zec 1995).

(5)	*Sanskrit*	*Pali*	
	prati	paṭi	'against'
	traana	taana	'protection'
	kramati	kamati	'walks'

In syllabic terms, the deletion exemplified in (5) simplifies an onset cluster. The reverse situation, where it is the first of two non-final consonants that drops, is typically described as coda deletion. Consider the example of Diola Fogny, where the only permitted type of coda–onset cluster is a partial geminate consisting either of a nasal plus homorganic obstruent or of a liquid plus coronal obstruent (Sapir 1965; Itô 1986). As illustrated in (6a), this sequence can arise through morphological derivation, in which case it survives in output (with appropriate adjustments for homorganicity).

(6) *Diola Fogny*

	Input	*Output*	
a.	/ni-gam-gam/	nigaŋgam	'I judge'
	/ku-boɲ-boɲ/	kubomboɲ	'they sent'
	/na-tiiŋ-tiiŋ/	natiintiiŋ	'he cut through'
b.	/let-ku-jaw/	lekujaw	'they won't go'
	/ujuk-ja/	ujuja	'if you see'
	/kob-kob-en/	kokoben	'yearn'

If, however, the juxtaposition of two morphemes creates a consonant sequence other than a partial geminate, the first consonant is deleted. This is illustrated by the elision of the stops in the examples in (6b).

The deletion of one consonant before another is often accompanied by compensatory lengthening (see CHAPTER 64: COMPENSATORY LENGTHENING), where one segment lengthens to make up for the loss of a neighbor. The compensation can be undertaken by either the following consonant or the preceding vowel. The first scenario is illustrated by the development of earlier Romance to later Italian [nokte] > [notːe] 'night', the second by earlier to later English [nixt] > [niːt] ('night', subsequently diphthongized to [najt]).[1]

2.2 *Vowel deletion*

Vowel sequences lacking an intervening consonant are cross-linguistically dispreferred. Whenever morpheme concatenation threatens to create a hiatus configuration of this sort, languages can take various measures to resolve it

[1] Singleton consonants are sometimes observed to elide intervocalically, as in Turkish *inek* 'cow (NOM)' – *ineği* 'cow (POSS)'. In this environment, deletion is almost always the final stage of historical lenition (see below and CHAPTER 66: LENITION).

(CHAPTER 61: HIATUS RESOLUTION). One of the most favored of these is to delete one of the vowels, either the first, as in French (see (7a)), or the second, as in Karok (see (7b); Bright 1957).

(7)

		Input	*Output*	
	a.	*French*		
		/lə ami/	lami	'the friend (MASC)'
		/la ami/	lami	'the friend (FEM)'
	b.	*Karok*		
		/ni-axjar/	nixjar	'fill (1SG)'
		/ni-uksup/	nikʃup	'point (1SG)'
	c.	*Ganda*		
		/ba-ezi/	beːzi	'sweepers'
		/ba-ogezi/	boːgezi	'speakers'

As with consonant cluster simplification, vowel deletion under hiatus can, depending on the language, be accompanied by compensatory lengthening. We see this in the Luganda examples in (7c), where a stem-initial vowel lengthens to make up for the loss of a prefix vowel (Clements 1986).

Vowel deletion can also occur between consonants. Syncope, as this process is called, is typically sensitive to stress or to the vowel's position relative to a word's edge. The examples in (8) illustrate two forms of stress-sensitive syncope in English (syncope-prone vowels underlined).

(8) *English*

a. potato, parade, career
b. opera, factory, chocolate, reference, family, camera

Syncope in English, which is both lexically and phonetically variable, targets unstressed syllables in two environments (Bybee 2001): (a) a word-initial unfooted syllable (as in (8a)) and (b) between a stressed and an unstressed syllable where the consonant following the targeted vowel is a sonorant and more sonorous that the consonant preceding (as in (8b)). The effect of the second pattern is to contract a trisyllabic sequence into a bisyllabic trochaic foot.

One type of positionally conditioned syncope targets the middle syllable of a trisyllabic sequence located at either the left or the right edge of a word. The left-edge scenario is illustrated in (9a) by Tonkawa (Hoijer 1946), the right-edge one in (9b) by Tagalog (Kenstowicz and Kisseberth 1979).

(9)	a.	*Tonkawa*		
		Input	*Output*	
		/pit͡sena-n-oʔ/	pit͡snanoʔ	'he is cutting it'
		/we-pit͡sena-n-oʔ/	wep͡tsenanoʔ	'he is cutting them'
	b.	*Tagalog*		
		Bare root	*Patient*	
		bukas	buksin	'open'
		kapit	kaptin	'embrace'
		laman	lamnin	'fill'

In Tonkawa, it is the second vowel in a word that syncopates. As shown in (9a), this means that the first vowel of a root (here, the /i/ of input /picena/) shows up when it is also the first vowel in the word but is suppressed when the root is preceded by a prefix vowel. Meanwhile, the second root vowel (/e/ in /picena/) is suppressed when the root is unprefixed but shows up under prefixation. In Tagalog, the last vowel in a root shows up when it is also the last vowel in the word but is suppressed when a suffix vowel follows. A similar effect is seen in Turkish and Hindi.

Deletion can also target vowels at the absolute edges of words, usually when the affected syllable is unstressed or in some other way non-prominent. We have already seen a word-final example (apocope) in Lardil (see (3)). Less common is the word-initial equivalent (aphaeresis), as in colloquial English *'bout*, *'lectric*.

3 Modeling segmental deletion

3.1 *Linear-segmental analyses of deletion*

The first basic question a model of segmental deletion needs to provide an answer to is this: how is an alternant that retains a segment related to one that lacks it? The best-established approach to this question can be broadly defined as derivational: the alternants are derived from a single underlying form that contains the segment, which is then removed under certain phonological conditions by some mechanism that typically recapitulates historical deletion. For several generations, this basic assumption has remained largely unchallenged in mainstream phonological theory.

The derivational approach raises a second basic question: what impact does the deletion mechanism have on the representations it operates on? Over the years, there have been quite radical changes in how phonologists answer this question.

Interpreted derivationally, the term *deletion* might suggest a scenario where a segment disappears without trace. Certainly that is one of the readings implicit in the tradition of representing segments as phoneme-sized units strung together linear-fashion in phonological forms. The reading is reinforced by modeling the deletion mechanism as a rule that transforms an underlying or input form containing a given phoneme into a surface or output form that lacks it (for a textbook exposition of how deletion is treated in linear-derivational theory, see Kenstowicz and Kisseberth 1979). Combining these linear and derivational assumptions yields an analysis of Samoan along the lines of (10).

(10)	Input form	/milos/	'twist'	/milos-ia/	'twist (PASS)'
	Rule C → / __ #	↓		↓	
	Output form	[milo]		[milosia]	

This type of derivation can be described as destructive: the rule ("delete a word-final consonant") destroys information that is present in the input. A question that immediately arises is whether this information is recoverable. That is, can a language learner or listener reconstruct an underlying segment on the evidence of an output form from which it has been removed? In the example in (10), could a learner/listener retrieve the underlying /s/ in Samoan /milos/ on the basis of encountering surface [milo]? If the output form [milo] were the only available evidence, the answer would almost certainly have to be no.[2] On the face of it, no information is present in [milo] that would alert the learner/listener to the presence of /s/ in the adult talker's underlying form. In declarative theories of phonology, this lack of recoverability is enough to disqualify deletion as a derivational device (see e.g. Bird 1995; Scobbie *et al.* 1996).

For most phonologists, however, this definition of recoverability is too narrow. There is other evidence the learner/listener can potentially draw on to reconstruct an input segment that fails to appear in the output. In cases such as Samoan, the most obvious alternative source of evidence lies in the availability of alternants that preserve the deletion-prone segment in the output. According to a broader interpretation of recoverability, exposure to the [s] in a suffixed form such as [milosia] allows the learner to construct an underlying form /milos/, which can then be accessed whenever occurrences of the alternant without [s] are encountered. (For a summary of how this line of argumentation was deployed in earlier generative phonology, see again Kenstowicz and Kisseberth 1979.)

3.2 *Non-linear analyses of deletion*

Alternations are not the only source of evidence that can be exploited to recover deleted segments. A segment can sometimes leave its mark on output forms even in its absence. Historically, this situation can arise when a segment exerts some influence on a neighboring segment before being deleted. Crucially in such cases, deletion of the segment does not completely undo the effects of its influence.

By way of illustration, consider again the examples of hiatus-breaking vowel deletion exemplified by the three languages in (7). The situation in French (7a) and Karok (7b) is just as we would expect if deletion is viewed as targeting phonemes: one vowel vacates the representation, and the other segments simply shuffle up, leaving no evidence that the vowel was ever present in the input. In Ganda, on the other hand, deletion is accompanied by compensatory lengthening of the remaining vowel (7c). This suggests that, although the vowel-quality properties of the affected segment have been removed, its position within the word has been preserved. The deletion is thus only partial. A similar effect is witnessed in tonal stability, where a tone that is cut loose by the deletion of the vowel to which it is initially associated survives by attaching itself to a neighboring vowel (see CHAPTER 45: THE REPRESENTATION OF TONE).

Stable weight and tone effects of this type are just part of a large body of evidence indicating that it is wrong to think of segments as indissoluble phonemic units. Rather, they are composites of non-linearly linked properties, each of which can be independently targeted by phonological processes, including deletion. Embracing this insight opens up different perspectives on deletion than that offered

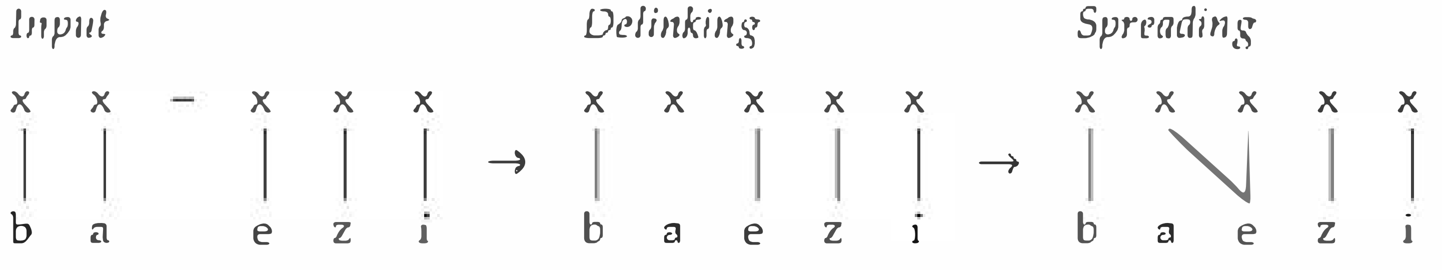
[2] The caveat "almost certainly" is necessary here in light of recent studies showing that a speaker's production of a given form can be influenced in phonetically fine-grained ways by the existence of another, morphologically related form (see, for example, Ernestus and Baayen 2007). If this were true of the Samoan case, it would mean for example that the [o]s of the output forms [milo] and [ŋalo] would be phonetically distinct; each would bear some phonetic trace of the deleted root-final consonant that appears in the alternant found in the passive forms [milos-ia] and [ŋalom-ia], respectively. As far as I know, this effect has never been reported for Samoan deletion.

by linear-phonemic theory. In particular, the representational technology of non-linear theory has a significant impact on how we conceive of the notion of segment in deletion processes.

In a non-linear representation, a sharp distinction is drawn between the feature content that specifies a segment's phonetic quality and the position the segment occupies in syllable structure (CHAPTER 14: AUTOSEGMENTS; CHAPTER 54: THE SKELETON). In principle, deletion could target either of these entities or both simultaneously. Simultaneous targeting, equivalent to the phonemic conception of deletion, is what is required for the type of situation illustrated by French in (7a) and Karok in (7b).

Compensatory lengthening, such as we see in Ganda in (7c), requires an operation that removes the targeted segment's feature content but leaves its syllabic position intact. The usual non-linear way of implementing this is along the lines of the derivation /ba-ezi/ → [beːzi] in (11) (from Clements 1986; see also Kavitskaya 2002; CHAPTER 64: COMPENSATORY LENGTHENING; and the papers in Wetzels and Sezer 1986). The x-slots represent positions in syllable structure (the syllabification details are not relevant at this point); the alphabetic symbols are shorthand for complexes of feature specifications; and the lines indicate associations between feature complexes on the one hand and syllabic positions on the other.

(11)



Deletion is implemented by an operation that delinks the feature complex specifying *a* from its syllabic position. Compensatory lengthening consists in the insertion of a new link between *e* and the position vacated by *a*.

Representing deletion as in (11) relies on the principle that a segment must be linked to a syllabic position in order to be phonetically expressed (Goldsmith's 1990 Linkage Condition). Based on this principle, regular alternations involving deletion can be modeled as the attachment *vs.* non-attachment of a segment to a position. There are two main ways in which this notion has been implemented. One is illustrated by the delinking step in (11): the alternating segment has an underlying association to a position but loses it under certain phonological conditions. The other approach is to assume that the segment lacks an underlying association but acquires one under the complementary set of conditions (for applications of this analysis to *liaison* consonants in French, see for example Encrevé 1988 and Charette 1991). Applied to our Samoan example, the latter analysis would posit an unassociated *s* at the end of /milos/. Before a vowel, this "floating" segment attaches to a position and thus surfaces (as in [milos-ia]); elsewhere it is left stranded and thus phonetically unrealized (as in [milo]).

3.3 *Stray erasure*

There is a consensus in the literature that unsyllabified or "stray" segments get erased and thus fail to be phonetically realized (McCarthy 1979; Steriade 1982;

Itô 1986). However, there is less than general agreement about where this erasure occurs – whether within the phonological grammar or in phonetics. These two views can be summarized as follows:

(12) a. *Phonological erasure*
Unsyllabified segments are absent from phonological output.
b. *Phonetic erasure (Containment)*
All input segments are present in phonological output; unsyllabified segments are phonetically erased.

The notion in (12b) that all input segments are "contained" in output, including those that remain unsyllabified, was adopted by early OT (McCarthy and Prince 1993; Prince and Smolensky 1993). Although the notion has since been abandoned in favor of phonology-internal erasure (12a) in most OT work since Correspondence Theory (McCarthy and Prince 1995), it continues to figure in some current output-oriented approaches (see for example van Oostendorp 2004, 2007).

The two principles in (12) are empirically distinguishable, at least if we limit ourselves to a consideration of the effect each can have on phonological output. On its own, phonological erasure makes the prediction that a deleted segment will leave no trace of itself in an output form. Containment, on the other hand, predicts that, since an unlinked segment is still present in output, it should be capable of influencing or even triggering processes that affect linked segments.

There is at least one type of evidence that, it is generally agreed, can be seen as conforming to the prediction made by Containment. It involves floating tones, which are tones that lack an association to a vowel, often as a result of their original host vowel being deleted (see CHAPTER 45: THE REPRESENTATION OF TONE). Where such a tone remains unassociated in output, it can usually be seen to influence the pitch of a following tone, either raising it (*upstep*, indicating a floating high) or lowering it (*downstep*, a floating low). This suggests an analysis under which tones can be delinked without being erased.

More controversial is the claim that similar evidence can be found to support the notion that non-tonal features or feature complexes can also be delinked without being phonologically erased. Most of the relevant evidence involves derivational opacity.

A derivation is said to be opaque if it produces forms showing the effects of processes applying in specific ways not predicted by regular phonological conditions: either a process fails to occur where it would be expected to (underapplication), or it occurs where it would not be expected to (overapplication). It is worth considering this issue in this chapter, since deletion processes figure very prominently in the literature on opacity. This is because of their inherent potential to eliminate segments that trigger other processes.

As an illustration of opacity, consider the case of fortition in Cypriot Greek (Newton 1972; Coutsougera 2002). The input to the process is a glide resulting from a general Greek process that desyllabifies *i* before a vowel, as in /psumi-u/ → [psumj-u] 'bread (GEN)' (cf. [psumi] 'bread (NOM)'). The basic fortition pattern in Cypriot Greek is illustrated in (13a) and (13b): the glide hardens to a velar stop after *r* and to a palatal stop after other oral consonants.

(13) *Cypriot Greek*

	Input	*Output*	
a.	/ʃeri-a/	ʃerka	'hands'
	/teri-azo/	terkazo	'I match'
b.	/mmati-a/	mmaθca	'eyes'
	/pulluði-a/	pulluθca	'little birds'
c.	/ðonði-a/	ðoɲca	'teeth'
	/vasti-ete/	vascete	'he is held'
d.	/xarti-a/	xarca	'papers'
	/karði-a/	karca	'heart'

As shown in (13b), the clusters produced by gliding and hardening are also subject to independent processes of spirantization and voice assimilation.

The opacity arises in forms that are affected by another independent process, illustrated in (13c), which simplifies input three-consonant clusters by deleting the medial segment, as in /vasti-ete/ → [vascete] (*[vastcete]). The opaque examples appear in (13d). They contain clusters where *r* is followed by a palatal stop rather than the velar variant that the regular conditions on hardening would lead us to expect (cf. (13a)). Looking at the input forms, we can see where the source of the opacity lies: *r* is separated from the gliding/hardening site by a consonant. The intervening consonant fails to appear in output as a result of being deleted by the cluster simplification process. Expressed in traditional serial-derivation terms, hardening must precede deletion (essentially following in the steps of historical sound changes). An ordered-rule derivation of [xarca], for example, runs something like this: /xarti-a/ → xartja → xartca → [xarca]. At the point in the derivation where hardening applies, the consonant adjacent to the target segment is not *r* but *t*, which determines that the hardened consonant is palatal in output.

There are two main output-oriented approaches to opacity involving deletion, distinguishable on the basis of whether they subscribe to the phonological or the phonetic version of stray erasure in (12).

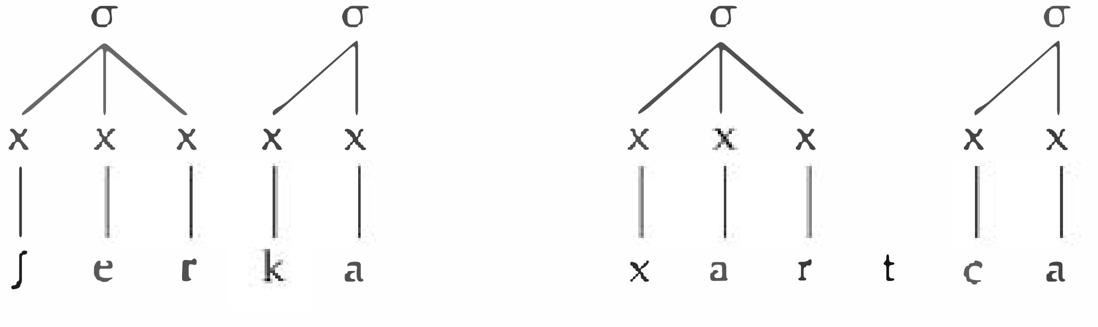
In the version of OT assuming phonological erasure, the basic approach to opacity is to allow the grammar to select a winning output candidate by cross-referring to a losing candidate that would figure as an intermediate form in an ordered-rule analysis. For example, in Cypriot Greek the attested output form [xarca] would be judged a more optimal output than *[xarka] on the grounds that it is the more similar of the two to non-surfacing *[xartca]. (For discussion of different approaches to how this cross-referencing can be achieved in OT, see McCarthy 2007.)

Containment approaches to deletion are equipped to treat opacity in a less obviously serial manner. Continuing with our Cypriot Greek example, consider the following analysis of [ʃerka] *vs.* [xarca].

(14) a. [ʃerka] 'hands' b. [xarca] 'papers'

input /ʃeri-a/ /xarti-a/

output



This analysis is of a type that was standard in early OT. It incorporates the widely held assumption that syllable structure is not present in lexical representation and is supplied by GEN, the mechanism that generates the set of candidate output forms.

In (14a), all of the input segments are parsed into syllable structure in output. The *k* of [ʃerka] is the hardened output of *i*, the velarity reflecting its adjacency to *r*.

In (14b), we see the effect of cluster simplification, driven by a high-ranked constraint banning complex codas (on which more later). The input *t* fails to be syllabified in output. In line with the Linkage Condition, a segment that is "underparsed" in this way is not phonetically realized. Nevertheless, in line with Containment, it remains in the output representation, where it can influence segments that fail to syllabify. In this example, *t* is in a position not only to trigger hardening but also to block *r* from causing the hardened output to be velar.

4 Conditions on consonant deletion

4.1 *Consonant deletion and syllabification*

What are the phonological conditions that favor whole-segment deletion? In answering this question, we need also to take into account processes of obstruent devoicing and consonant weakening, since these occur under similar conditions (see CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION and CHAPTER 66: LENITION). In fact, deletion figures prominently in what is perhaps the most reliable historical definition of phonological strength: segment A is weaker than segment B if A passes through a B stage on its way to deletion (Hyman 1975; Harris 1994).

There is a well-established tradition of approaching the question from the viewpoint of syllable structure. This is based on two main assumptions: certain syllabic positions are particularly favorable to deletion, and deletion changes the syllabification of the phonological forms it targets. These assumptions are themselves founded on a widely accepted model of syllabification that can be summarized as follows:

(15) *Standard syllabification model*

a. *Sonority*
Syllable nuclei always correspond to sonority peaks (typically vowels).

b. *Word edges*
i. A word-initial consonant forms a syllable onset.
ii. A word-final consonant forms a syllable coda.

These assumptions represent what can be considered the "standard" view of syllabification (see Vennemann 1972 and the literature summarized in Blevins 1995 and Zec 2007; see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE, and CHAPTER 55: ONSETS). However, it has increasingly been called into question, and this inevitably impacts on the validity of syllable-based analyses of deletion.

4.2 *Consonant deletion and syllabic markedness*

There are certain phonological contexts where consonants are especially vulnerable to deletion, particularly in clusters or at the end of a word. From the perspective of the standard model in (15), deleting a consonant in these contexts pushes syllable structure towards a less marked state. Removing a consonant from a cluster can open a previously closed syllable, simplify an onset, or reduce the size of a complex coda. Deleting a singleton consonant at the end of a word can be understood as having the same effect.

On the other hand, there are phonological contexts that are resistant to deletion. This is especially true of consonants at the beginning of a domain such as the word, stem, or foot, and to a lesser extent of word-internal prevocalic consonants. Here too we can detect a syllabic preference, in this case for syllables to contain at least one onset consonant.

There is a long tradition of interpreting these patterns to mean that consonant deletion is actively driven by a preference for less marked syllable structure. The tradition has been updated in OT by formulating the preferences in terms of markedness constraints (see CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS; also Prince and Smolensky 1993, Zec 2007, and the papers in Féry and van de Vijver 2003). In a given language, deletion can occur if any of these constraints outrank countervailing constraints that call for input consonants to be faithfully preserved in output. In what follows, this is the format I will employ to present the standard syllable-based approach to deletion, focusing on the following constraints:

(16) a. *Syllabic markedness constraints*
Codas
NoCoda
A syllable must be open.
NoComplexCoda
A coda must contain no more than one consonant.
Onsets
Onset
A syllable must have an onset consonant.
NoComplexOnset
An onset must contain no more than one consonant.

b. *Segmental faithfulness constraint*
MaxC
An input consonant must be preserved in output.

4.3 *Onset simplification*

(17) compares the grammars of two language types, one with complex onsets, the other without. As illustrated in (5), Sanskrit represents type (17a), while Pali represents (17b). The table shows two different output analyses of a schematic input form /CCV/, where CC potentially syllabifies as a complex onset. In grammar (17a), NoComplexOnset is outranked by MaxC, which allows the two input consonants to show up as an onset cluster. The reverse ranking in grammar (17b) forces onsets to be simplex: one input consonant takes up the only slot available in the onset, and the other drops (symbolized by C̲.)

(17) *Input* /CCV/

Language	*Output*	*Structure*	*Constraint ranking*
a	.CCV	Complex onset	MaxC >> NoComplexOns
b	.CC̲V	Simplex onset	NoComplexOns >> MaxC

A similar simplification effect is widely reported in first language acquisition. A child acquiring a language with complex onsets typically starts out by deleting the more sonorous of two onset consonants (as in *bring*, *blue*). The deletion evidently reflects a developmental stage where the only type of onset in the child's syllabic inventory is simplex. As is also typical of early phonology, the normally developing child nevertheless perceives the adult distinction between simple and complex onsets (as in *boo vs. blue*). This suggests that the liquid in consonant–liquid clusters is present in the child's lexical representations, but is phonologically erased in output as result of failing to find a berth in the child's simplified onset (see Bernhardt and Stemberger 1998 and the literature reviewed there).

4.4 Coda deletion

The syllable coda is widely regarded as the consonant deletion site *par excellence*. Under the standard syllabification view in (15), the coda subsumes consonants in three phonological contexts: (a) a word-final singleton consonant, (b) any member of a word-final cluster, and (c) the first member of a word-internal heterosyllabic cluster.

In an OT grammar, deletion of final singleton consonants (illustrated above by Samoan (1) and Lardil (2b)) results from MaxC being outranked by NoCoda. The reverse ranking defines languages that permit final consonants. This is shown in (18).

(18) *Input* /VC]/

Language	*Output*	*Structure*	*Constraint ranking*
a	VC.]	Final closed σ	MaxC >> NoCoda
b	V.<u>C</u>]	Final open σ	NoCoda >> MaxC

This basic treatment extends to consonant deletion in non-final codas, such as occurs in Diola Fogny (6).

As to the deletion of absolute word-final consonants in clusters (illustrated by Lardil in (3) and Catalan in (4)), the standard syllable-driven account is that it is motivated by a markedness imperative to reduce the complexity of codas. In OT terms, final cluster simplification occurs in languages of the type shown in (19b), where NoComplexCoda outranks MaxC (Prince and Smolensky 1993). The reverse ranking yields languages of type (19a), those with final clusters. The fact that words can be consonant final at all indicates that NoCoda is ranked relatively low in both of these grammars.

(19) *Input* /VCC]/

Language	*Output*	*Structure*	*Constraint ranking*
a	VCC.]	complex coda	MaxC >> NoComplexCoda, NoCoda
b	VC.<u>C</u>]	simplex coda	NoComplexCoda >> NoCoda, MaxC

Word-internal cluster simplification in Diola Fogny is selective in the type of coda it targets, deleting only those that do not form part of a partial geminate (see (6)). On their own, the syllabic markedness constraints in (16) are not enough to derive this selective behavior. What is required is an additional constraint that bans a coda from bearing or "licensing" certain feature specifications unless they are assimilated from a following onset. (The formulation of constraints of this type is based to a large extent on proposals by Itô 1986 and Goldsmith 1989.) With this constraint ranked high, a faithful output candidate such as *[u.juk.ja] is non-optimal, since the coda [k] bears its own place and manner specifications. Under these circumstances, the lower-ranked constraint NoCoda asserts itself, and the optimal candidate is the coda-less form [u.ju.ja] (an example of what in OT is called The Emergence of the Unmarked; see chapter 58: the emergence of the unmarked).

4.5 *Rethinking coda deletion*

According to the standard view in (15b.ii), a word-final consonant has the same syllabic status as a word-internal coda. This makes the strong prediction that whenever consonant deletion targets codas it should strike both of these positions simultaneously (chapter 36: final consonants).

There are certainly languages that bear this prediction out. In Lardil, for example, the set of non-apical singleton consonants that drop finally (as in (2b)) is largely the same as the set of consonants that are excluded from internal codas. In Samoan, the word-final deletion of root-final consonants shown in (1) coincides with an absence of internal closed syllables. Another example is provided by non-rhoticity in various languages, where historical *r* drops in exactly the combination of environments defined by the final-coda analysis. For example, in non-rhotic English, constricted *r* is suppressed both in an internal coda (as in *carnal*) and word finally (as in *car*).

Examples such as these represent some of the core evidence in favor of the assumption that consonants in internal codas and word-final positions are syllabified the same (again see Blevins 1995 for a summary of the relevant literature). However, alongside these examples we find deletion evidence that is difficult to square with the assumption. On the one hand are languages that preserve internal codas but either delete or lack word-final consonants; examples include Italian, colloquial Tamil, and Pali. On the other are languages that lack internal codas but have final consonants; examples include Kejaman (Strickland 1995), Yapese (Piggott 1999), and Central Sentani (Hartzler 1976).

Where historical final consonants can be reconstructed for the first of these syllabically "hybrid" types of language, they have either been deleted or survive as onsets followed by an epenthesized vowel. In Pali, for example, deletion has wiped out historically word-final consonants, which can be reconstructed on the basis of a comparison with cognate forms in Sanskrit (see (20a)) (Zec 1995). However, as shown in (20b), the process has not deleted internal codas, which survive as the first position of a partial or full geminate.

(20)		*Sanskrit*	*Pali*	
	a.	tatas	tato	'therefrom'
		punar	puno/puna	'again'
		pra:patat	papata	'hurled down'
	b.	danta	danta	'tamed'
		sapta	satta	'seven'
		karka	kakka	'precious stone'
		valka	vakka	'tree bark'
		kara	kaɳɳa	'ear'

It is true that internal codas in Pali have lost much of their historically contrastive feature content. However, the coda position itself has remained in place, picking up most or all of its feature interpretation from the following onset.

The existence of syllabically hybrid languages of the Pali type is inconsistent with the prediction that deletion will target internal codas and final consonants simultaneously. It could be further interpreted as undermining the assumption that final consonant deletion is motivated by syllabic structure independently of word structure. Does a final consonant delete because of its position in the syllable or because of its position within the word? Of course we could just say that a final consonant is a sub-type of coda, one that is particularly susceptible to deletion. But this is at best unparsimonious: it would be simpler just to say that deletion targets a consonant that is final in the word rather than having to say that it is final in both the word and the syllable.

In any event, the coda analysis faces additional problems, some of which become evident when we look more closely at consonant deletion in word-final clusters.

4.6 *Final cluster simplification*

According to the analysis outlined in §4.4, final cluster simplification results from the operation of the constraint NoComplexCoda in (16a). Two main objections have been leveled at this description. One has to do with the actual number of consonants permitted finally compared to internally, and the other with the phonotactics of final compared to internal clusters.

Cross-linguistically, there is a clear numerical asymmetry between final clusters and internal codas. Many languages, including English, which allow two or more consonants in final position only allow up to one consonant in an internal coda (Harris 1994; Duanmu 2008). It is hard to come up with clear examples of languages where the two positions exhibit equal complexity (still less languages where internal codas are actually more complex than final clusters).

Moreover, in languages showing the numerical mismatch between the two positions, it is noteworthy that the phonotactics of final clusters typically mimic those of initial or internal clusters containing onsets. Two basic patterns are attested in languages of this type. In one pattern, found in English, French, and Irish, for example, final clusters with a falling or level sonority profile (*mp, lt, pt*, etc.) share their phonotactics with internal coda–onset clusters (CHAPTER 53: SYLLABLE CONTACT). In the other – found in French, Polish, and Icelandic, for example – rising-sonority clusters (*pl, gl, dr*, etc.), share their phonotactics with internal or initial complex onsets (Harris 1994; Dell 1995; Harris and Gussmann 2002). In some languages, the two patterns overlap in three-consonant clusters; in French, for example, we find [rkl] both medially (as in [sɛrkle] 'circle (VB)') and finally (as in [sɛrkl] 'circle (N)').

If final clusters are treated as complex codas, the problem posed by cluster evidence from languages of this type is that the same set of phonotactic restrictions has to be assigned to two or even three different syllabic conditions. There have been two different responses to this problem, both of which challenge the claim that consonant deletion in final clusters is driven by some need to simplify complex codas. One persists with the notion that phonotactics are syllabically conditioned but proposes an alternative syllabification of final clusters to the standard one.

The other denies that cluster phonotactics are conditioned by syllable structure in the first place.

According to the first proposal, the simplest analysis of final clusters is to syllabify them in the same way as the internal clusters with which they show phonotactic parallels (Harris 1994; Dell 1995; Harris and Gussmann 2002). That is, final clusters of the non-rising sonority type (*mp*, *lt*, etc.) take the form coda plus onset, while those of the rising-sonority type (*pl*, *gr*, etc.) are complex onsets. While this captures the phonotactic parallels between final and internal clusters, it is questionable whether it provides a syllabic motivation for final cluster simplification. This is because there is a cross-linguistically strong preference for the second consonant to be targeted, regardless of whether the cluster is of the rising-sonority type or the non-rising (see the language surveys in Blevins 1995 and Côté 2004).

French provides us with an example of final deletion in rising-sonority clusters. In some varieties of the language the liquid is deleted in final clusters of this type, as in [pov<u>r</u>] 'poor', [minist<u>r</u>] 'minister' (Laks 1977; Côté 2004).

Deletion in final clusters of non-rising sonority is illustrated by the Catalan examples in (4). Feminine forms such as [askerpə] and [forta] show internal coda-onset clusters of falling sonority. The same clusters occurred historically in final position in masculine forms (Badia Margarit 1951). Of these final clusters, only those that are heterorganic survive into present-day Catalan, as in [əskerp] (see (4a)). The rest – those consisting of partial geminates – have been subject to simplification through deletion of the final consonant, as in /fort/ → [for] (see (4b)).

One conclusion that has been drawn from facts such as these is that the context for final cluster simplification is best stated in terms of word-finality without reference to syllable structure at all (as argued by Côté 2004, for example). A further reason for reaching this conclusion is the fact that the deletion that targets final clusters does not also automatically target the same clusters when they occur elsewhere in the word. For example, the dropping of the liquid in French final rising-sonority clusters does not also target initial and internal onsets. Final liquid deletion in French is thus not symptomatic of some more general simplification of complex onsets, such as has occurred in Pali for example (see (5)). By the same token, dropping the obstruent in Catalan final homorganic clusters, as in (4b), does not also target the same cluster when it occurs word internally.

Acknowledging that final cluster simplification might be best described without reference to syllable structure naturally raises the question of whether the same might be said of deletion in other phonological contexts. This line of argumentation has led some phonologists to claim that all patterns of consonant distribution should be expressed in a strictly linear fashion by referring exclusively to immediately adjacent segments and word boundaries (see e.g. Steriade 1999; Blevins 2003). At issue here is the fundamental question of why certain phonological positions promote deletion in the first place.

4.7 *What causes consonant deletion?*

What is it about consonants in word-final and pre-consonantal positions that makes them especially vulnerable to deletion? The answer is likely to be tied to the fact that these positions are also favorable sites for neutralization. Deletion is just one of a collection of process types that target consonants in these positions, and all of these processes tend to have the effect of neutralizing segmental contrasts. For example, these are the preferred contexts where we find that obstruent devoicing neutralizes laryngeal contrasts, debuccalization neutralizes place contrasts (e.g. /p t k / → [ʔ]), and vocalization neutralizes manner contrasts (e.g. /l r/ → [j]) (see CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). Deletion, too, can be seen as neutralizing, if it is understood as suspending the contrast between the presence and absence of a consonant, i.e. "merger with zero," as historical linguists put it (see Campbell 2004).

According to one proposal, the neutralizing tendency of certain positions can be attributed to the fact that they provide weaker auditory-perceptual cues to consonants than other positions (see e.g. Steriade 1999; Wright 2004). This point can be illustrated by comparing the cues projected by oral stops in different positions. The offset or release phase of a plosive provides more robust cues to its identity than does its approach phase (Bladon 1986; Ohala 1990). Moreover, the offset is most robustly cued when it is released onto a following vowel. Before another consonant or at the end of words, offset cues can be attenuated or suppressed altogether. In the first instance, they may be masked by the closure phase of the following consonant. In the second, since the end of a word often coincides with the end of an utterance, a final stop often offsets into silence.

Weakened cueing potential reduces the reliability with which listeners are able to detect consonant contrasts in particular positions, thereby increasing the likelihood that these contrasts will be eroded over time (see Ohala 1981, 1990). This would explain why preconsonantal and word-final positions are the most favorable sites for the neutralization of voice, place, and manner contrasts. Deletion, it can be argued, is an extreme manifestation of this overall effect (Côté 2004).

The question of whether consonant distribution and deletion are motivated by cueing potential or syllabic position continues to be debated. (For critiques of the "licensing-by-cue" approach, see for example Gerfen 2001 and Kochetov 2006.) It is not clear whether the two notions are in fact incompatible: the positions across which cueing potential is differentially distributed can in principle be stated in syllabic rather than linear terms.

On the face of it, neutralizing processes in general and deletion in particular seem to be communicatively dysfunctional, in that they suppress information that might otherwise be used to help keep words distinct from one another. However, the particular location of favored neutralizing positions within the word means that the impact of such processes on lexical distinctiveness is not as deleterious as it might otherwise have been. In lexical access, listeners rely much more heavily on phonological information at the beginning of words than towards the end (cf. Nooteboom 1981; Hawkins and Cutler 1988). It is no surprise, then, that of all phonological positions word-initial is the most resistant to deletion.

5 Conditions on vowel deletion

5.1 *Syllabification and vowel deletion*

If it is clear why there is a strong tradition of viewing consonant deletion as being driven by a pressure to simplify syllable structure, it is also easy to understand why no parallel tradition exists for vowel deletion. Deleting a vowel almost always increases syllabic markedness, at least according to the standard syllabification account. Apocope, illustrated by Lardil in (3), creates a final closed syllable (V.CV.] > VC.]). Syncope, illustrated by English in (8) and by Tonkawa and Tagalog in (9), creates a closed syllable and thus also a consonant cluster (V.CV.CV > VC.CV).

There is probably only one pattern of vowel deletion that can be straightforwardly viewed as reducing syllabic markedness: the type of hiatus-resolving elision seen in (7). The second vowel in a hiatus configuration occupies a syllable without an onset, a marked situation (acknowledged in OT by the ONSET constraint in (16a)).

Although apocope and syncope may not be syllabically motivated, they can generally be seen to be subject to other kinds of prosodic conditioning, specifically involving metrical or word structure or some combination of both. Moreover, the positions targeted by the two types of deletion can be broadly identified as prosodically weak or non-prominent. The processes are not always sensitive to stress, but when they are they typically target unstressed vowels. In stress-conditioned apocope, for example, the targeted vowel occurs either in the weak position of a foot or in an unfooted syllable. The emergence of word-final consonants in Catalan (see (4)) and certain other Romance languages is due to historical apocope of this type (Badía Margarit 1951; Lief 2006).

5.2 *Resyllabification?*

According to the sonority-driven model of syllabification in (15a), syncope and apocope necessarily have a much more profound impact on syllabification than consonant deletion: a vowel forms a local sonority peak and thus projects its own syllable nucleus, so removing it inevitably unleashes resyllabification. For example, by removing a final sonority peak, apocope forces a preceding consonant, originally an onset, into the coda of the preceding syllable.

This account of apocope predicts that the resyllabified consonant should take on the kind of coda-like behavior it did not exhibit when it was an onset. For example, it should now be able to trigger closed-syllable shortening in the preceding vowel. The prediction is not generally borne out. This is not surprising, since for stress purposes a final consonant typically behaves extrametrically: unlike an internal coda, it does not contribute to the weight of the syllable occupied by the preceding vowel (see Hayes 1995; CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY). Let us briefly consider two examples where developments accompanying apocope have not followed the path predicted by the final-coda analysis.

Modern English bears the marks of a limited form of historical closed syllable shortening, as a result of which certain consonants (very broadly speaking, non-coronals) can now appear in a word-internal coda only after a short vowel (see, for example, Myers 1987; Harris 1994). As the alternations in (21a) show, there is no parallel restriction when the corresponding consonants are word final.

(21) *English*

a. *perceptive* *perceive*
   reduction *reduce*

b. hɔpə > hɔːp > hoːp > howp *hope*
   bækə > bæːk > beːk > bejk *bake*

In Middle English, apocope of unstressed schwa was accompanied by lengthening of the stressed vowel in a preceding open syllable (Minkova 1991). If consonants rendered word final by apocope had resyllabified as codas, the non-coronals amongst them would have been expected either to prevent or to undo lengthening of a preceding vowel. As the examples in (21b) illustrate, that did not happen. Apocope in English thus failed to disturb the general Germanic pattern whereby a singleton word-final consonant, unlike an internal coda, has no influence on the length of a preceding vowel.

In Sesotho, final *i* has undergone apocope under certain quite specific phonological conditions. The effect of the change is evident in the locative suffix [-eŋ], which derives historically from [-eni] (the form still attested in some of Sesotho's Bantu sister languages) (Doke and Mofokeng 1957). There is clear evidence that apocope has not resulted in the nasal being resyllabified as a coda. One indication involves the widespread Bantu process that lengthens penultimate vowels in phrases of a certain type (with accompanying tonal effects not relevant here; see CHAPTER 114: BANTU TONE). The examples in (22a) illustrate this process in Sesotho (where vowel length is not lexically contrastive).

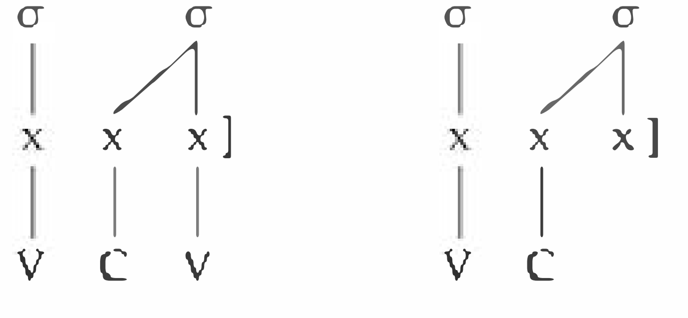
(22) *Sesotho*

a.	hase muːthu	'It's not a person'	
	kraː tla	'I am coming'	
b.	re teŋ lapeːŋ	'We are at home'	*laːpeŋ
	ba ile sedibeːŋ	'They have gone to the well'	*sediːbeŋ

If the final [ŋ] of the locative were a coda, penultimate lengthening would be predicted to target the vowel immediately preceding the suffix. However, as the forms in (22b) show, this is incorrect: the extra length falls instead on the suffix vowel itself. This suggests that the apocope that produced [-eŋ] has left the original bisyllabic structure of [-eni] undisturbed.

The more general conclusion we might draw from the evidence represented in (21) and (22) is that apocope has little or no impact on syllable structure. In fact it is just the sort of evidence that has led some phonologists to conclude that a word-final consonant is not a coda but the onset of a syllable with a phonetically unexpressed nucleus (see e.g. Giegerich 1985; Kaye 1990; Burzio 1994; Harris 1994; Piggott 1999; Harris and Gussmann 2002; Scheer 2004). According to this account, apocope only targets the feature content of a vowel while leaving its nuclear position untouched. This is schematized in (23) (where we abstract away from the issue of how the suppression of feature content is best represented).

(23) a. *Pre-apocope* b. *Post-apocope*



(A similar analysis has been applied word internally to syncope; see for example Charette's 1991 treatment of schwa in French.)

In (23), a consonant exposed to the right edge of a word by apocope remains syllabified as an onset. Since at no point does the consonant become a coda under this analysis, it is predicted not to trigger closed-syllable shortening. This is consistent with the scenario exemplified by English in (21). Similar reasoning would explain why penultimate lengthening in Sesotho targets the vowel immediately preceding word-final [ŋ] rather than the vowel before that, as shown in (22). The vowel before [ŋ] counts as the penultimate nucleus in the phrase, because there is another to its right, namely the final empty nucleus heading the syllable containing the nasal (as in [lapeːŋØ]).

Bearing on the question of whether apocope triggers resyllabification is the fact that the process is often reported to be phonetically continuous along the dimensions of duration and periodicity (see e.g. Silva 1994; Gordon 1998; Myers 2005). Similarly continuous effects are found with syncope; examples include Japanese (Beckman 1996), and the two types of syncope in English shown in (9) (Bybee 2001).

Phonetically continuous vowel deletion raises an awkward question for the standard model of syllabification: at what point do we decide that a fleeting vowel stops projecting a local sonority peak and causes a preceding consonant to resyllabify into a coda? This is particularly problematic where the gradience occurs within the speech of individual speakers. The sonority model suggests an implausible scenario in which a speaker's output flickers between one syllabification and the other. Under a stable-nucleus analysis, syllabification remains unaffected by vowel deletion, regardless of whether it is phonetically continuous or not. In the case of gradience, what varies is the manner in which the affected nucleus is phonetically expressed.

A further difference between the stable-nucleus and sonority-driven approaches to syllabification is that they offer empirically distinct perspectives on the relation between consonants flanking a syncope site. Under a sonority-driven analysis, the consonants start out as separate onsets but become syllabically adjacent after syncope. Newly formed clusters that happen to conform to existing phonotactic restrictions are wrongly predicted to be phonetically indistinguishable from clusters already existing outside the syncope context. In English, for example, the liquids in pairs such as *pa̲rade – prayed* and *po̲lite – plight* show differences in duration and voice onset time that listeners are able to utilize in word discrimination (Price 1980). One conclusion that might be drawn from this is that *p* and *r* are not phonotactically adjacent in *pa̲rade* in the way that they are in *prayed*. This is consistent with the view that, rather than triggering resyllabification, syncope of a vowel leaves the flanking consonants in phonotactically independent onsets separated by a stable but variably expressed nucleus.

6 Conclusion

Over the years, there has been a significant shift in the way phonologists model phonological processes in general and whole-segment deletion in particular. Previously, deletion processes were conceived of as rules that remove segments from linear strings of input phonemes. That view gave way to one according to which deletion rules selectively target elements within non-linear representations. Later, input-oriented rules were largely abandoned in favor of the notion that deletion results from the operation of output-oriented constraints.

For all the differences amongst the various approaches reviewed here, there remains an important shared assumption: that morphologically related forms showing a regular alternation between a segment and zero should be derived from a single lexical source. However, this idea too has been increasingly called into question.

Under the standard derivational analysis of deletion in Samoan, recall, the historical consonant-final form of an alternating root such as [milo] – [milos(-ia)] is preserved in a single underlying representation and is deleted in final position by a synchronic analogue of sound change (/milos/ → [milo]). The main argument in favor of this analysis is economy: speakers need memorize only one lexical form of each alternating root instead of two.

This reasoning was already being questioned as early as 1973 by Hale, citing evidence from Maori, a Polynesian relative of Samoan that shares the same historical deletion of word-final consonants. The evidence strongly suggests that speakers of present-day Maori have re-analyzed the original morphology of alternating forms by treating the formerly root-final consonant as now belonging to the suffix. This yields historical reparsings such as [awhit-ia] > [awhi-tia] 'embrace (PASS)' and [hopuk-ia] > [hopu-kia] 'catch (PASS)'. If this is correct – and it is corroborated by more recent evidence adduced by Eliasson (1990) – it indicates that the segment–zero alternation in this case is now a matter of allomorphy rather than regular phonology (CHAPTER 99: PHONOLOGICALLY CONDITIONED ALLOMORPH SELECTION): for each root, speakers simply memorize the appropriate consonant-initial suffix. (In fact, one of the re-analyzed suffix forms, *-tia*, has a much wider lexical distribution than the others and is the one now used by default in loanwords, neologisms, and code-switching; Eliasson 1990.) Similar historical restructurings involving consonant deletion have been reported for other languages (see e.g. the survey of the Sulawesi group of Western Malayo-Polynesian languages in Sneddon 1993).

Evidence from historical restructurings of this type presents an obvious challenge to any derivational treatment of segment deletion, be it formulated in terms of input-oriented rules or output-oriented constraints. In any case, the economy argument in favor of unique underlying forms is no longer as persuasive as it might have once seemed, since there are now known to be practically no limits on the storage capacity of lexical memory (Braine 1974; Landauer 1986).

Since Hale's (1973) paper, models of lexical storage and access have emerged that allow us to capture phonological connections between morphologically related forms without necessarily deriving them from a single lexical source. Part of the process of auditory word recognition involves a lexical search that leads to a specific neighborhood containing a number of forms with similar phonological characteristics (see the literature review in McQueen and Cutler 1997). Even if two alternants of the same morpheme are stored as separate lexical entries, they are thus likely to show up in the same search, depending on how phonologically similar they are to one another. In the Samoan deletion case, related forms such as *milo* and *milosia* can have separate addresses in the lexicon (which would account for their allomorphic behavior) and yet still be close neighbors and thus be accessed in unison. The fact that one form lacks a consonant that is present in the other is of course a source of dissimilarity. However, this is mitigated by the location of the dissimilarity – away from the initial portion of the forms that is known to provide the most valuable information in word recognition.

69 Final Devoicing and Final Laryngeal Neutralization

Gregory K. Iverson
Joseph C. Salmons

1 Introduction

In this chapter, we survey a set of phenomena that have traditionally been given the simple rubric "final devoicing." This name, however, clearly conflates a number of different phonological phenomena – deletion of other laryngeal features, even feature addition – and the relevant general pattern is better characterized as "final laryngeal neutralization." Widely attested across the languages of the world, final laryngeal neutralization represents a prototypical positional merger of phonological contrasts. Nonetheless, the attested patterns vary along several dimensions; they provide challenges to current phonological frameworks, on the one hand, and allow good testing grounds for them, on the other. In particular, the topic is highly relevant to the ongoing debates over the relationship between universal grammar and language change in shaping sound systems, such as Blevins (2004, 2006) *vs.* Kiparsky (2006, 2008) (see also CHAPTER 93: SOUND CHANGE).

In §2, after briefly reviewing some basic data, we provide a cross-linguistic survey of attested patterns in which (phonological) laryngeal features neutralize at right edges of prosodic constituents, while §3 introduces some aspects of the phonetics of final laryngeal neutralization with an eye toward what those aspects mean for the phonology of such processes. In §4, we then give an overview of the role of prosodic domains along which such patterns arise and generalize in sound change. In §5, we explore the major question in current phonology connected with this issue: the relationship between historical development and Universal Grammar. §6 summarizes and concludes.

We focus on laryngeal features, leaving aside broader neutralizations, such as loss of length distinctions in final position (e.g. Kümmel 2007: 133–136), although it is important to note that these are often connected (see Trubetzkoy 1977: 74). We also restrict discussion to processes affecting obstruents, although final vowel devoicing and other such phenomena are attested, as surveyed by Barnes (2002: ch. 3). Finally, we focus on "dynamic," alternation-supported neutralizations, leaving aside the "static" absence of contrasts, such as those in Thai and varieties of Quechua, in which laryngeal contrasts found in onsets (or word-initial position, etc.) are merely missing in codas (or word-final position, etc.), without morphophonemic alternation.

2 The phonological typology of final laryngeal neutralization

2.1 *Some basic data*

In many languages of the world, underlyingly voiced speech sounds do not show glottal pulsing at the ends of words, with the result that they are largely or often entirely indistinguishable from voiceless sounds. This occurs frequently with all obstruents, as in Catalan (Hualde 1992) or as illustrated here by nominal alternations from Polish (Rubach 1997: 553):

(1)

nom sg		*nom pl*		
klub	[p]	*klub-y*	[b]	'club'
majonez	[s]	*majonez-y*	[z]	'mayonnaise'
staw	[f]	*staw-y*	[v]	'pond'
kandelabr	[pr]	*kandelabr-y*	[br]	'lamp'

As the last example demonstrates, Polish shows a variety of wrinkles in devoicing. Phonologically, extrasyllabic consonants, /r/ in this case, do not block devoicing (see also CHAPTER 36: FINAL CONSONANTS). As Tieszen (1997) shows, Polish manifests complex regional and acoustic patterns, which include evidence for incomplete neutralization for at least some speakers.

Targets of this neutralization vary considerably across languages. Sometimes, not all obstruents alternate. In Turkish (Kopkallı 1993; Becker *et al.* 2008) most stops surface as voiceless finally (and with a degree of aspiration as well, per Vaux and Samuels 2005: 418), but may alternate with a voiced counterpart in suffixed word forms (data from Kopkallı 1993: 29; cf. also Nicolae and Nevins 2009; Feizollahi 2010):

(2) *Turkish final stop neutralization*

	nom sg	*acc sg*	
/kab/	[kap]	[kabɯ]	'container'
/kanad/	[kanat]	[kanadɯ]	'wing'

This pattern, however, does not extend to fricatives:

(3) *Turkish final fricative voicing alternation*

[af]	'pardon'	≠	[av]	'hunting'
[kas]	'muscle'	≠	[kaz]	'goose'

While our focus is on obstruent neutralizations, we note that, in other languages, final sonorants (CHAPTER 8: SONORANTS) may be subject to devoicing, as in Kaqchikel (Campbell 1998: 41):

(4) *Kaqchikel sonorant devoicing*

/kar/	[kar̥]	'fish'
/kow/	[koʋ̥v]	'hard'

We will not review the various technical approaches to laryngeal alternations among obstruents that have been offered in the past, such as Trubetzkoy's (1977: 71) analysis of German final neutralization in terms of archiphonemes, which treats the neutralized obstruents as identical neither with the underlying *Media* (lenis/voiced) nor *Tenuis* (fortis/voiceless). In modern work, these processes have been characterized as rules deleting the feature [voice] (or sometimes imposing [−voice]) or as constraints prohibiting that feature in final position, and that is our point of departure here as well.

But final laryngeal neutralization can also consist in the addition of a contrastive property, not just the loss of one exemplified in the cases involving removal of [voice] adduced above. In particular, the work of Vaux and Samuels (2005: 418–422) has shown that the addition of aspiration to stops in final position is cross-linguistically rather more common than has been appreciated. As they review for Kashmiri, contrasts between plain and aspirated final voiceless stops are merged in favor of the aspirated series, presumably via a rule that accrues the privative feature [spread glottis] (or [+spread glottis], in a binary system) to voiceless stops at the end of the word.[1]

(5) *Final aspiration in Kashmiri* (Vaux and Samuels 2005: 420, citing Syeed 1978)

	nom sg	*dat pl*	*agent pl*	
/wat/	[wat^h]	[watan]	[watau]	'way'
/kat^h/	[kat^h]	[kat^{h}an]	[kat^{h}au]	'story'

Similarly, in Klamath a three-way contrast among voiceless aspirated, ejective, and plain stops neutralizes to the aspirated series in word-final position. Such patterns clearly suggest feature addition.

(6) *Final aspiration in Klamath* (Vaux and Samuels 2005: 421, citing Blevins 1993)

/n'ep^h/	[n'ep^h]	'hand'	cf.	[n'ep^{h}eːʔa]	'puts on a glove'
/ntʃ'ek'/	[ntʃ'ek^h]	'in little bits'		[ntʃ'ek'aːni]	'small, little'
/nkak/	[nkak^h]	'turtle (sp.)'		[nkakam]	'turtle (ross)'

Vaux and Samuels take the existence of patterns such as these to justify the interpretation of aspiration as "unmarked" in languages that add this feature finally, attempting to salvage the widely subscribed view that neutralization in final position regularly entails merger to the unmarked member of a contrast (CHAPTER 2:

[1] Sadaf Munshi (personal communication) indicates that there are systematic exceptions to final aspiration in Kashmiri, apparently connected with patterns of historical apocope, e.g. [op] 'person who can't keep a secret'; [mot] 'madman'. She further points out (Munshi 2006: 58ff., personal communication) that, in Burushaski, the three-way voiced/aspirated/voiceless unaspirated contrast is regularly neutralized to voiceless unaspirated in final position, affecting stops, affricates, and fricatives, even in loanwords, whereas in Kashmiri final (aspirating) neutralization affects only stops.

CONTRAST; CHAPTER 4: MARKEDNESS), albeit now defined on a language-specific rather than universal basis. More generally, however, aspiration patterns such as Vaux and Samuels reveal have been simply disregarded, with final laryngeal neutralizations often all being treated without further differentiation as "final devoicing." The idea that such non-assimilatory neutralization involves feature loss rather than addition has been particularly strong: Lombardi (2001: 13, *passim*) starts from the position that "The laryngeal distinctions of voicing, aspiration, and glottalization are often neutralized to plain voiceless in coda position," exemplified by what she analyzes as the removal of [voice] in German codas. More recently, Kiparsky (2008: 46) uses the term "devoicing" to characterize the Korean process of final neutralization across three series – usually treated as lenis (laryngeally unmarked), aspirated, and tense. But the phonetic feature [voice] plays no phonological role in Korean on most views (cf. Avery and Idsardi 2001; Ahn and Iverson 2004), appearing only allophonically in the otherwise voiceless lenis series in intersonorant contexts because this is a position favorable to passive voicing. This aside, however, the characterization of final laryngeal neutralization generally as final devoicing has far-reaching implications for the nature of the phonological component in human grammar. Thus, Kiparsky (2006: 222) argues forcefully that "marked feature values are suppressed in 'weak' prosodic positions." On the question of how to formalize this, he writes:

> The right way to do it in my opinion is that constraints can single out marked feature values (but not unmarked feature values). From these, with certain additional assumptions, we can build a system of constraints that asymmetrically prohibit marked feature values in weak positions. In processual terms, it predicts the existence of coda devoicing (coda depalatalization, debuccalization, deaspiration, etc.) and excludes coda voicing (coda palatalization, buccalization, aspiration, etc.).

On this view, *ex nihilo* feature insertion or addition is impossible, prohibited by the "design of language." In the next section, however, we develop a typology of final neutralizations that includes a broad set of counterexamples to the claim that final neutralization invariably entails feature loss, or merger to the unmarked, but rather may involve motivated neutralization to marked feature values as conventionally (i.e. universally) construed.

2.2 *Overview*

We begin this section with an overview of laryngeal features, so as to provide a framework for discussing which ones participate in final neutralization and how. But it is clear at the outset that right edges of prosodic constituents are frequent loci of neutralization and reduction of many kinds. In this spirit, final laryngeal neutralization has often been regarded as a "subtype of final weakening" (Hock 1999: 19; Harris 2009; Honeybone, forthcoming), and thus related to lenition (CHAPTER 66: LENITION) and final consonant loss (CHAPTER 68: DELETION). Indeed, the view expressed just above (Kiparsky 2006) is that "weak positions" are actually governed by this directionality, so that final weakening in various forms is to be expected, but not final strengthening. We shall see, however, that a full typology of final laryngeal neutralization must also recognize the occurrence of final strengthening, or, as we shall refer to it, final fortition.

2.3 *Laryngeal features*

Now common in discussions of neutralization of "voicing" and other distinctions involving glottal states is the perspective known as "laryngeal realism" (cf. Iverson and Salmons 1995, 2003, 2006, 2007, 2009, the name taken from Honeybone 2005), which we will adopt here. On this view of laryngeal phonology, three privative features are considered to be sufficient to represent the known relevant contrasts in languages: [voice], [spread glottis] (henceforth [spread]), and [constricted glottis] ([constricted]) (see also CHAPTER 17: DISTINCTIVE FEATURES). In two-way systems, a "voice" language such as Spanish distinguishes marked voiced stops ([voice]) from unmarked voiceless unaspirated stops ([ ], using a blank space to indicate the absence of a phonological specification), whereas an "aspiration" language like English distinguishes marked aspirated or fortis stops ([spread]) from unmarked lenis (albeit often passively voiced) stops ([ ]). And a "glottalic" language like K'ekchi distinguishes marked ejectives ([constricted]) from unmarked, typically voiceless unaspirated stops ([ ]).

Combinations of these possibilities also exist to make up three-way contrasts, as in the aspirated–voiced–plain system of Thai ([spread], [voice], [ ]), the aspirated-ejective–plain system of Klamath ([spread], [constricted], [ ]) or the aspirated–implosive–plain system of Vietnamese ([spread], [constricted & voice], [ ]). Four-, five-, and even six-way systems are also attested, as laid out first by Ladefoged (1973) and charted under the present feature system by Iverson and Salmons (1995). For example, the four-way system of Hindi adds murmured (breathy or voiced aspirated) stops to the three types of distinctions found in Thai, via paradigmatic as well as syntagmatic combination of [voice] with [spread] ([voice], [spread], [voice & spread], [ ]). The thrust of this minimalist representation is thus to reconcile not only the phonetics but also the phonological, historical, and acquisitional behavior of speech sounds with their featural characterization.

Perhaps the most familiar neutralization of laryngeal contrasts among obstruents at the right edge of a prosodic constituent is the final neutralization process in German, documented comprehensively by Brockhaus (1995) and interpreted in the light of laryngeal realism by Iverson and Salmons (2007). Taking the realist perspective, German is an "aspiration language" in the sense described above, meaning that the laryngeal merger that takes place between fortis (aspirated) and lenis (passively voiced) obstruents syllable-finally is in fact final fortition (as implied by the descriptive German grammatical term, *Auslautverhärtung*), not final devoicing. (The domain varies regionally and stylistically between syllable-final and word-final.) In contrast to its sister Dutch, then, where final neutralization is devoicing (given that Dutch is a "voice language" in the sense described above), German neutralizes final laryngeal distinctions through feature addition rather than loss. The two types are illustrated below:

(7) a. *Final devoicing:* /d/ → [t] (Dutch)

d]$_\sigma$	Phonemic contrast:	/d/	/t/
ǂ		|	|
[voice]		[voice]	[ ]

b. *Final fortition:* /d̥/ → [tʰ] (German)

```
d̥ ]σ        Phonemic contrast:    /d̥/      /tʰ/
↑                                   |        |
[spread]                           [ ]    [spread]
```

In some languages, lack of required final release or other factors may make it difficult to distinguish between feature addition and feature removal, but the former pattern is securely and robustly attested.[2] For instance, in his treatment of Kashaya (Pomoan), Buckley (1994: 87–88) illustrates the rule of "Coda Aspiration" with respect to the palatal stop /c/:

(8) /s'uwac-i/ → s'uwaci 'dry it! (SG)'
/s'uwac-me-ʔ/ → s'uwacʰmeʔ 'dry it! (FORMAL)'

In this language, an underlyingly "plain" or laryngeally unmarked stop at the end of a word-internal syllable becomes "aspirated phonologically, and not simply subject to some rule of obligatory final release at the phonetic level" (Buckley 1994: 88). The aspiration rule also applies to word-final stops in loanwords, such as /'cajnikʰ/ 'teapot' (cf. Russian /ʧajnik/) and /ʃaki'taqʰ/ 'puffin' (cf. Alutiiq /ʃaki'ta-q/) (1994: 100).

Kashaya, in fact, shows a three-way contrast among plain, aspirated, and glottalic stops, but other processes besides coda aspiration contribute to the non-occurrence of plain finals. Thus, a suffix in a morphological category like the assertive (/=ʔ/) combines with a stem-final plain stop to yield a word-final glottalic (see Fallon 2002 on the notion of "fusion"):

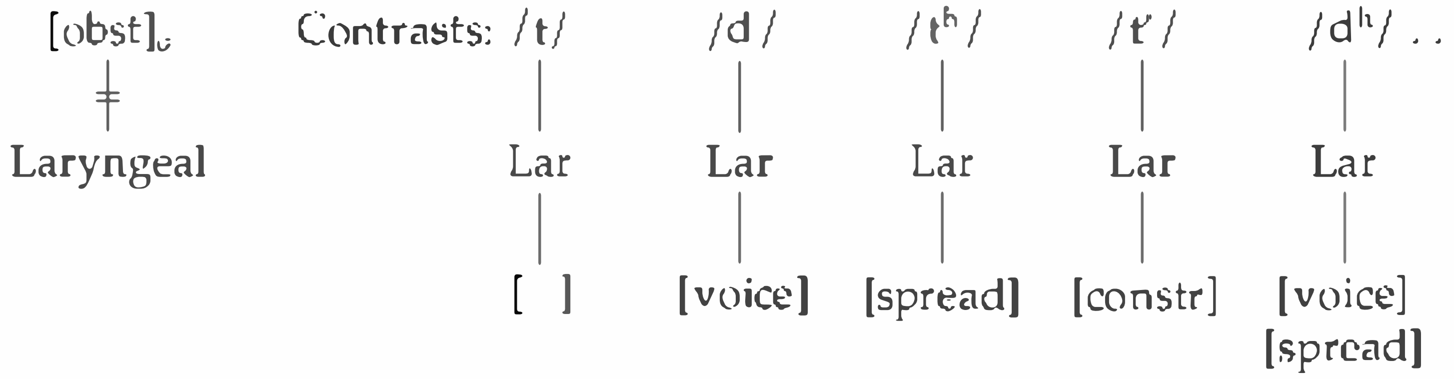
(9) /qahmat=ʔ/ [qahmát'] 'he's angry' cf. /qahmat/ [qahmáʔ] 'angry'

At the same time, non-verbs ending in a glottalic retain that ejective articulation (as in [hosiq'] 'screech owl'), whereas word-final plain stops in the native vocabulary, analyzed as laryngeally empty, debuccalize to glottal stop ([qahmáʔ] ← /qahmat/). In other words, the language aspirates plain stops in native word-internal codas (and word finally in loanwords), retains word-final phonemically aspirated and glottalic stops, but debuccalizes remaining word-final stops, with the result that final plain stops are phonetically absent.

As already noted above, a collection of similar cases, including Kashmiri and Klamath, has been adduced by Vaux and Samuels (2005). Ejectives and plain stops in Klamath neutralize to aspirates word finally (Blevins 1993), and Yu (2008, personal communication) reports the same pattern for Washo. In Kashaya, however, plain voiced stops do not undergo the neutralization to aspirates that affects the language's ejectives, just as in Kashmiri the phonemically voiced stops escape the final aspiration to which plain stops are subjected (Vaux and Samuels 2005: 419). The range of these phenomena suggests that final fortition, in addition to the expression in (7b), may be accompanied by the loss of all marked laryngeal content, not just the removal of [voice], as expressed in (7a):

[2] Throughout, we will see complex interaction between release features and laryngeal neutralization. Like Rice (2009: 316), we understand even release features to be phonologically relevant.

(10) *Final laryngeal delinking* (/d tʰ tʼ dʰ . . . / → [t])



The operation in (10) thus accounts for final devoicing, as in Dutch or Polish, but also for final deaspiration, as in Korean; and the effect of this generalized delinking for languages, which combines voicing with aspiration (e.g. Sanskrit) or other properties, is to neutralize all contrasting laryngeal manner types to the plain, voiceless unaspirated type. On this interpretation, then, final neutralization of the most common kind is effected by delinking of the Laryngeal node, with the consequence that the loss of any one of the contrasting laryngeal features in the system implies loss of all the others, too, if any (CHAPTER 27: THE ORGANIZATION OF FEATURES). This appears to be accurate, as final devoicing in more complex systems goes hand in hand with the removal of other contrastive laryngeal gestures as well.

Final fortition, on the other hand, consists in imposition of the feature [spread], as per (7b), but appears to affect only laryngeally unmarked obstruents. Thus, aspiration in Kashaya accrues to final plain (unmarked) stops, but not to final ejectives (marked as [constricted]), and aspiration in Kashmiri similarly accrues to final plain stops, but not to phonemically voiced ones. Final fortition, in sum, affects the class of laryngeally empty obstruent configurations as per the refinement of (7b) given in (11), attracting the feature [spread] to a final Laryngeal node that is otherwise empty, or unmarked. The situation in Klamath or Washo then falls into place as a combination of final laryngeal delinking (10) feeding into final fortition (11).

(11) *Final fortition* (/t d̥/ → [tʰ] (Kashmiri, Klamath, German)

As noted for Kashmiri above, neutralization to [spread] often leaves other, already laryngeally specified series untouched. For instance, Koyukon, Hupa, and Tlingit appear to aspirate unmarked stops finally, neutralizing with the [spread] series, but in each language the ejective series does not participate (Vaux and Samuels 2005: 418–441).

Final neutralization via the addition of other features appears to be far less common, according to the literature of which we are aware. Neutralization to a phonologically voiced member of an opposition may occur, but appears to be very rare, and controversial, as reviewed in recent discussion about the analysis of Lezgian (Yu 2004; Blevins 2006, drawing data from Haspelmath 1993). This Nakh-Daghestanian language possesses a four-way laryngeal distinction in onsets (voiceless, aspirated, voiced, ejective). In some monosyllabic noun classes, ejective and voiceless obstruents neutralize to voiced word-finally or after consonants, with suffixed forms showing the underlying obstruent and unsuffixed stems the neutralized realization (data from Yu 2004):

(12)	pab	pap-a	'wife'
	rug	ruk^{w}-adi	'dust'
	q'eb	q'ep'-ini	'cradle'
	t'ib	t^{h}jp'-er	'owl'

As Blevins (2004, 2006) emphasizes, there is no natural phonetic or aerodynamic reason to make stops voiced in final position, where modal voicing in obstruents is difficult to maintain as well as to perceive; accordingly, the regular occurrence of final voicing, although in principle learnable, is expectedly uncommon. In this instance, the phenomenon arose coincidentally as the product of separate but converging historical events. Specifically, the synchronic pattern in Lezgian is the result of "natural" sound changes involving old voiced obstruents in both medial and final position: the medials underwent gemination (and became voiceless) and subsequently degeminated, leaving the historically voiced word-finals to stand in alternation with now voiceless word-medial stem-finals.

Blevins (2004, 2006) suggests other candidates for synchronic final voicing, perhaps most clearly in Somali, where historically a neutralizing medial voicing process was followed by final vowel loss, thus creating a pattern of apparent final voicing. Kiparsky (2006: 225) reanalyzes Somali (and some other cases), however, as an aspiration language in our sense, rather than a voice language. That is, Somali final "voiced" stops are phonetically lenis and unaspirated, contrasting with aspirated stops marked by [spread]. This view appears to be consistent with available descriptions of Somali obstruent phonetics, most explicitly that of Orwin (1993), although the possibility remains open that some dialects of the language may employ [voice] rather than [spread].

Utterance-final position provides a potential universal starting point or trigger for anticipatory devoicing (to the following silence), whereas no such starting point exists to trigger utterance-final voicing. Phonologically, as a non-assimilatory addition of the feature [voice], final voicing is poorly motivated to begin with inasmuch as feature additions are almost always sourced in assimilation. On the other hand, in the structurally parallel case of final fortition as described above, non-assimilatory addition of [spread glottis] appears to serve a prosodic edge-marking function in association with the greater acoustic salience of fortis/aspirated over lenis/voiced consonants. This function is not compatible with final voicing, and would appear to be irrelevant, too, to the other laryngeal feature, which in principle could be added finally, [constricted glottis].

Thus, neutralization *per se* to glottalic consonants is not securely attested in the literature, although superimposition of a glottal stop on final voiceless oral stops is seemingly common. In the terminology of Michaud (2004: 120), three different kinds of glottal gestures (glottal stop, glottal constriction, and creaky voice/laryngealization):

> can be characterized phonetically as follows: (1) *Glottal stop* is a gesture of closure that has limited coarticulatory effects on the voice quality of the surrounding segments. (2) *Glottal constriction* (also referred to here as *glottal interrupt*) is a tense gesture of adduction of the vocal folds that extends over the whole of a syllable rhyme. (3) *Laryngealization* (i.e. lapse into *creaky voice*), resulting in irregular vocal fold vibration, is not tense in itself. *Glottalization* is used as a cover term for laryngealization and glottal constriction . . . .

Final neutralization directly via any of these three gestures is not known to us, nor are we familiar with final glottalization in the sense of Michaud's (2) and (3). At the same time, a familiar allophonic and optional instance of (1) is found in many varieties of English, e.g. in *bat* [b̥æt̚ˀ], perhaps as a prosodic right-edge marker appearing on fortis stops. This pattern of "glottal reinforcement" then sets the scene for the loss of supralaryngeal stops in some dialects, especially with /t/, e.g. *bat* [b̥æʔ], *bottle* [b̥aʔɫ̩].

Under the Dimensional Theory of feature representation advanced by Avery and Idsardi (2001, forthcoming), in fact, the gesture [constricted glottis] (which characterizes glottal closure, among other phenomena) is implemented via the dimension of Glottal Width, as a complement to the contrary gesture [spread glottis]. On this approach to feature organization, a relationship between these two contradictory gestures is thus predicted, so that an aspiration language such as English or German (with contrastive [spread glottis]) naturally gravitates toward implementation of its Glottal Width dimension in final position as either aspirated, when released (as in *bat* [b̥ætʰ]), or as glottalically closed, when unreleased (as in *bat* [b̥ætˀ]). As noted, many American speakers realize such codas simply as a glottal stop, with no supralaryngeal occlusion.

A striking illustration of the complementary relationship between aspiration and glottalization is found in McFarland's (2007) description of Filomeno Mata Totonac: "Glottal consonants [h] or [ʔ], or spread/constricted glottis features are required at certain domain edges in Filomeno Mata Totonac, and are disallowed domain-internally." The process is thus not neutralizing, as the language makes no laryngeal contrasts, but the differing manifestation of Glottal Width in domain-edge consonants is entirely predictable: glottalization in sonorants, aspiration in obstruents.

Thai – with its three-way laryngeal contrast of voiceless, voiced, and aspirated – shows a pattern of glottalization similar to English, albeit with a difference in frequency. As Esling *et al.* (2005: 388) describe it: "In English, unreleased final glottal reinforced oral stops [ˀp], [ˀt], and [ˀk] are optional allophonic variants, but in Thai they are the norm." Michaud (2004) reports that dialects of Chinese that retain Sino-Tibetan historical final stops (Fujian and Cantonese) typically accompany these with a glottal stop, too, and this co-articulation is taken as a step on the historical path toward loss of final oral stops altogether, first via debuccalization leaving only the glottal stop, as in modern Burmese and Min and Hakka Chinese, then loss of all trace (save tone) of the original stops, as in modern Mandarin.

Central to accounting for the attested patterns of featural addition in neutralization is doubtless the often-noted (e.g. Blevins 2004: 98–99, 2006: 138) tendency of languages not to require or allow final release of stops, thus partially or entirely obscuring distinctions carried by release features. One superficially exceptional-looking pattern underscores the role of release in such neutralizations: in Chong

(Mon-Khmer; Silverman 2006: 79–80), final stops are unreleased, but the language nonetheless maintains a distinction between root-final (= word-final, since the language has no suffixes) glottalized and non-glottalized stops. This is suggested by Silverman to correlate with the timing of glottalization: Chong has pre- rather than post-glottalization. That is, because of the timing of the gesture, the distinction between phonologically glottalized and non-glottalized stops is not dependent on final release.[3]

The literature contains a number of other similar instances from the languages of the world, where some set of final obstruents adds glottalization, without leading to neutralization; see Gurevich (2004: 137ff., 151ff.) on optional glottalization of final voiced stops in Lahaul (Pattani) and glottalization of voiceless stops before consonants or juncture in Maidu. In all these cases, glottal stop is present in the language, but the languages lack contrastive glottalization in the obstruent system. Similarly, the phoneme inventory of Dumi (Tibeto-Burman; van Driem 1993: 52–59) includes both /h/ and /ʔ/, the former restricted to onsets and the latter to codas. The language has three stop series: voiceless unaspirated, voiced, and breathy or murmured. The voiceless series appears finally unreleased with "simultaneous glottal stop," e.g. /leŋghok/ [lɛŋgɔʔk̚] 'throat'. The other two series do not appear in codas in native words, so that the effect of this glottalization is not neutralizing either. The related language Limbu (van Driem 1985: 7–16) shows similar patterns of glottalization of voiceless stops in codas without neutralization.

Debated as a possible case of final voicing (Blevins 2006; Kiparsky 2006), Tundra Nenets reinforces all consonants prepausally with a glottal stop (Salminen 1997: 31–32; see also Janhunen 1986: 81–83), which appears variably in word-internal codas as well.

Other less secure cases are closely parallel, like the glottalization reported for all three voiced stops (/b d g/) in syllable codas in Kamassian (an extinct South Samoyedic language), from Kümmel (2007: 187–188):

(13) b → ʔb ~ ʔ / __ #

As in all other languages we know to have final glottalization, this reinforcement is not contrastive in Kamassian. Like Chong, this involves pre- rather than post-glottalization and, like English, it appears to be connected with facultative loss of final stops for some speakers, as noted above for forms like [b̥æʔ] *bat*. Kümmel in fact suggests that loss of the original coda consonant may have triggered the glottalization. On the other hand, Barnes (2002: 210ff.) follows Hyman (1988) in arguing that "at least in many cases the epenthetic final glottal stop so common in the languages of the world is ultimately the phonologization of allophonic phrase-final creak." In any case, the occurrence of word- or phrase-final glottalic gestures does not itself lead directly to obstruent neutralization, as far as we can tell, but rather does so only indirectly through concomitant loss of oral gestures.

The full possible typology of final laryngeal neutralization, then, includes the patterns shown in (14).

[3] If correct, note that this suggests how phonetics can shape phonology: the gestural and timing patterns used to realize a feature (see Henton *et al.* 1992) appear to correlate with what does or does not happen phonologically, but see also Howe and Pulleyblank (2001).

(14) *Typology of possible final laryngeal neutralizations*

a. deletion of [voice] (Polish, Dutch, Catalan)
b. deletion of [spread] (Korean)
c. deletion of [constricted] (Hup, as discussed below)
d. deletion of [voice] and [spread] (Sanskrit, Burushaski)
e. deletion of [voice] and [constricted] (no clear cases)
f. insertion of [voice] (probably Lezgian, possibly Somali dialects)
g. insertion of [spread] (Kashmiri, Eastern Armenian, Kashaya, German)
h. insertion of [constricted] (final glottalization; no clear neutralizing cases)
i. insertion of [voice] and [spread] (final murmuring; no clear cases)
j. insertion of [voice] and [constricted] (final laryngealization; no clear neutralizing cases)

Of these types, deletion of [voice] (a) and insertion of [spread] (g) are widely and securely attested.[4] While Kiparsky (2008: 46) asserts that coda neutralizations in general "typically" go to unmarked values, he concludes that "the direction of voicing neutralization [is] universal" (2008: 53). As we have seen, however, at least in the particular instance of laryngeal neutralizations, the strong interpretation of this claim is simply false. Indeed, it is unclear to us whether (a) is even significantly more common among voice languages than (g) is among aspiration languages.

Neutralization via the deletion of other contrasting laryngeal features is exemplified in the deaspiration of (b) and the combination of deaspiration with devoicing in (d). Deglottalization via the deletion of [constricted], on the other hand, appears to be rare, but it is found in Hup (see below; on the view that laryngeal features are privative, thus ruling out the insertion of [−voice] or [−spread], see also CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION). And the devoicing in (a) need not necessarily lead to the loss of [constricted]: in Dhaasanac (Tosco 2001: 19–20; Blevins 2006: 143), for instance, word-final obstruents devoice but do not lose contrastive [constricted], so that the implosive series surfaces in final position as voiceless glottalized stops, [ˀp ˀt ˀk]. Fallon (2002) further shows that [constricted] often functions independently of other laryngeal features in other settings.

While the insertion specifically of [voice] (f) is perhaps only marginally instantiated, the deletion of [spread] (b) appears to be tied to the more general removal of all marked laryngeal features. Rather commonplace, however, are the opposites of these: the deletion of [voice] and the insertion of [spread]. Like deletion of [constricted] (c), insertion of contrastive [constricted] (h), (i) is not securely attested, although the literature on this question is more limited to date. Notable is that

[4] Indeed, the association between [voice] in our sense and devoicing is strong enough that van Rooy and Wissing (2001: 326) raise the possibility that phonemic [voice] might imply final devoicing. For [voice] languages that do not appear to have devoicing, like French and Ukrainian, they write that "the phonetics and phonology of these languages need careful investigation, as it appears from this paper that much of what appears to be variable from a phonological perspective can be explained from a phonetic perspective." While final devoicing in [voice] languages may be underreported, the widespread tendency for devoicing could also be the result of a strong historical bias toward deletion of [voice], which would find support in a variety of phonetic factors, many discussed below.

non-contrastive glottalization via insertion of [constricted], or laryngealization via insertion of simultaneous [constricted & voice], is a frequent optional process across a set of languages, whereas final murmuring via insertion of [voice & spread] is not known to us either as a neutralization or as an allophonic enhancement.

In complex laryngeal systems, with three-way or more contrasts, it appears often that not all series neutralize in a merger context. In the Amazonian language Hup, the glottalized series of stops (variably but non-contrastively voiced elsewhere) merges in final position with the plain voiceless series, although the neutralization is perhaps not always complete in nasal contexts (Epps 2008, personal communication). In the same environment, however, the language's phonemically voiced plain stops do not devoice (and so do not merge with voiceless and deglottalized finals), but rather post-nasalize, making them phonetically even more distinct from the other series. (Obstruent post-nasalization is an enhancement suggestive of "hypervoicing" in the sense of Henton *et al.* 1992.)

In summary, then, (a), (b), (d), and (g) are relatively well-attested neutralizations; (c), (e), and (f) seem reasonable, but are not widely attested; (h) is marginal (but learnable); and (i) and (j) appear to be unattested and are perhaps impossible, as we know of no solid cases of neutralization to compound features. Below, in §4, we consider the diachronic paths that may have given rise to some of these asymmetries.

3 How the phonetics of final neutralization informs the phonology
