Phonetically, final devoicing in particular has invited appeals to the aerodynamics of speech, according to which utterance or breath group-final edges are produced with reduced pulmonary pressure; others have attributed final devoicing to a phonological assimilation to the following silence (cf. Hock 1999 on both points). And for stops, in particular, it has been argued that modal voicing is difficult to maintain in general; see Gamkrelidze (1975), although Westbury and Keating (1986) advise that solid data on this point are limited.

While neutralization is typically categorical phonologically, the phonetic cues to laryngeal distinctions, including those in final position, have proven to be remarkably complex. With respect to the ostensibly simple issue of English "voicing," Lisker (1986) alone catalogues 16 distinct cues for stops in medial position, including glottal pulsing, consonant and vowel duration, and changes in fundamental frequency and in the first formant. Lisker notes, however, that the list is hardly exhaustive, and more recent work shows that still other factors, including amplitude, also play a role. The function of these cues varies of course by prosodic context, and while stressed word-initial position may be captured relatively straightforwardly by measurement of Voice Onset Time delay, final position proves particularly elusive. In fact, Rodgers *et al.* (2010) show that for a set of speakers from the American Upper Midwest, a different range of acoustic characteristics provides the best correlation for distinguishing word-final /t/ from /d/ in both frame sentences and running speech. These include RMS amplitude, rate of change of RMS amplitude, and, even more specifically, amplitude of individual harmonics and formants. In short, the full acoustic picture of final laryngeal distinctions is far from clear, even for a well-studied language like English.

We lay out in the next paragraphs some implications that this phonetic complexity carries for the phonology of final laryngeal neutralization. First, we argue that a successful account must pay attention to the role of multiple cues and trading relations in producing distinctions (§3.1). Second, we review briefly the possibility that final laryngeal distinctions undergo at most "incomplete neutralization," concluding that complete phonological neutralization is attested (§3.2). This leads to a third point reaching beyond phonetics, namely the range of other effects that come into play in neutralization (§3.3).

3.1 *Multiple cues*

While an extensive body of research shows that final neutralization can be complete (see below for references), the presence of multiple possible and actual phonetic cues to laryngeal distinctions raises questions about the mapping between the phonetics of such cues and phonological contrasts. (For one view on the topic, see Kingston *et al.* 2008.) Evidence from variation in American English points to the importance of "trading relations" among cues. Purnell *et al.* (2005a, 2005b) show that, over several generations of real- and apparent-time speech from eastern Wisconsin, speakers have systematically changed how they realize these contrasts finally, from exploiting actual glottal pulsing early on to later relying on duration of the preceding vowel.[5] A perception test showed that listeners who were speakers of other varieties of American English did not, in general, have difficulty interpreting either set of cues to laryngeal distinctions. That is, the phonetic realization of the distinction has changed over time in this region, but the phonological distinction, even for outsiders, has remained stable.

3.2 *Incomplete neutralization in production*

Although many cases of final laryngeal neutralization have been described as effecting complete merger, a long thread of work has argued that neutralization is sometimes not truly complete, often in the service of challenging the notion of phonological contrasts (e.g. Dinnsen and Charles-Luce 1984; Port and O'Dell 1985; Charles-Luce and Dinnsen 1987). Fourakis and Iverson (1984) attribute the incompleteness effect reported for German to a laboratory artifact introduced by awareness on the part of participants (who presumably also spoke English, a language with a final distinction) as to the purpose of the experimentation, thus resulting in partially hypercorrect pronunciations of finals with traces of their morphophonemically lenis properties rather than as fully neutralized fortis obstruents. But under conditions in which the real purpose of the experiment is concealed in the guise of a morphological exercise (strong verb conjugation) rather than presented as an (apparently intimidating) evaluation of pronunciation, participants neutralized German final obstruents completely. Jassem and Richter (1989) found that final neutralization under conditions such as these is also complete in Polish – *contra* Slowiaczek and Dinnsen (1985) – and Kim and Jongman (1996) report complete neutralization of final manner contrasts in Korean.

[5] In contrast to the productions of earlier generations, the youngest group of speakers appears to be developing final laryngeal neutralization. Evidence of devoicing in northwestern Indiana can be found in José (2009), with reference to a range of other studies. The pattern appears to be stable over time in that community.

3.3 *Incomplete neutralization in perception*

Studies seeking to establish perceptually incomplete neutralization ultimately face challenges beyond what listeners glean from the acoustic signal, which is not, it turns out, the only clue that listeners have to whether even nonce forms belong to one or another class (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). Ernestus and Baayen (2003: 6), for instance, hypothesize that "Speakers recognize that there is neutralization and base their choice for the underlying representation on the distribution of the underlying representations among existing morphemes, serving as exemplars." They show that the Dutch lexicon has clear asymmetries with regard to the phonotactics of final underlying voice (cf. also Ernestus and Baayen 2007 and other papers in van de Weijer and van der Torre 2007). The distribution of word-final labial stops in Dutch, for example, is heavily biased toward underlyingly voiceless, but labial fricatives are even more heavily biased toward voiced.[6] A production experiment showed that speakers treated novel forms in line with those patterns, leading Ernestus and Baayen (2003: 31) to conclude:

> First, our data show that the underlying [voice] specification of final obstruents in Dutch is predictable to a far greater extent than has generally been assumed. It is predictable not only for linguists having computerized statistical techniques at their disposal, but also for naive speakers, since they use this predictability in language production. Second, we see that the predictability is based on the similarity structure in the lexicon.

Moreover, it has proven challenging for even well-designed experiments to control for issues like orthography. Warner *et al.* (2004, 2006) report a set of very low-level acoustic differences between underlying voiced and voiceless obstruents in Dutch, but then later follow up with new experiments showing that "incomplete neutralization may be entirely caused by orthographic differences" (Warner *et al.* 2006: 292).[7] Indeed, Fourakis and Iverson (1984) noted that previous laboratory investigations of German final neutralization had found acoustic traces of lenis articulation in the orthographic *d* of *und* 'and' and the *g* of *weg* 'away'. Both of these forms represent non-alternating and therefore uncontroversially phonemically fortis stops in modern German that happen only for historical reasons to be spelled with the lenis graphemes *d* and *g* rather than fortis *t* and *k*, respectively.

Aside from extra-phonological influences such as these, studies of ordinary speech, including present-day Wisconsin English and many cases cited by Blevins and others, show that early stages in the historical development of final laryngeal neutralization are prone to being both variable and partial, parallel in some ways to patterns familiar from vocalic "near-mergers" (Di Paolo 1988; Labov 1994). Moreover, even complete neutralizations are often recoverable perceptually from the pragmatic context (morphological differences aside, German *Rat* 'advice' and

[6] This is perhaps surprising, given a heavy cross-linguistic bias for languages to have voiceless fricatives and no voiced ones (Maddieson 1984: 52ff.). That is, frequency in cross-linguistic inventories patterns quite differently from the lexical patterns found within Dutch.

[7] For a fuller range of evidence and discussion of the complex devoicing and other laryngeal phonology of Dutch, see van de Weijer and van der Torre (2007).

Rad 'wheel' are unlikely to be confusable even if they occur in the same discussion) or based on phonological gaps in lexical distribution. Thus, German morphophonemically fortis stops freely occur after lax vowels (*Ecke* 'corner', *Beck* 'brook'), but lenis stops rarely do (*Ebbe* 'ebb tide', *gib* 'give! (SG IMP)'),[8] and there are numerous underlying sequences of stem-final labial or velar lax stop preceded by tense vowel (*Lieb-* 'love'), but hardly any with underlying fortis stop in this context. These kinds of patterns allow Piroth and Janker (2004: 99–100) to observe that, "Due to lexical and morphological structure there are only very few minimal pairs of alternating paradigms with underlying voiceless vs. underlying voiced final obstruents." That is, the phonological contrast differentiates few homophones, so that there is little lexical competition in the sense of Blevins and Wedel (2009: esp. 169).

3.4 Summary

This section has surveyed some issues in the phonetics of final laryngeal distinctions, drawing especially on English, which maintains a distinction in almost all varieties and most contexts, and German, in which most varieties do not. First, we have argued here that phonetic cues to final laryngeal distinctions show remarkable complexity, and can change even as phonological contrasts remain stable in perception and production. Second, this informs the question of whether final neutralization is always complete or can be incomplete. At least when realized by feature deletion, it appears that complete phonological neutralization in ordinary speech is observable both acoustically and perceptually, but recovery of the neutralization is enhanced by considerations of pragmatics, skewed phonotactic distributions, spelling conventions, and lexical limitations on homophony.

4 The domains of final laryngeal neutralization and paths of change

Whether accomplished via feature removal or addition, final laryngeal neutralization is widely attested at all levels of the prosodic hierarchy, from utterance-final to phrase-final to word-final to syllable-coda position. In fact, the major route by which languages develop final laryngeal neutralization has been seen as running along that hierarchy, beginning with large units and moving downwards (e.g. Hock 1999; Blevins 2004, 2006).

For feature-removing neutralization, universal physical and acoustic motivations make voicing particularly challenging at the end of breath groups. By definition, at the end of breath groups pulmonary pressure reaches its minimum for that stretch of speech, but that can also be controlled and enhanced as part of speech. Lieberman (1967: 104) found that American English speakers lower subglottal air pressure during the last 150–200 msecs of sentences, with acoustic effects including falling fundamental frequency. Decreased pressure exacerbates the inherent difficulties of voicing stops in particular, with further biases by place of articulation, as noted above.

[8] In fact, speakers vary in having a tense and lax vowel in *gib*, and the standard reference work on standard pronunciation gives [giːp] for this form (Mangold 2005).

While neutralization at the end of longer stretches of speech is directly rooted in the physiology and physics of speech (pulmonary pressure and the aerodynamics of vocal fold vibration), movement down the prosodic hierarchy involves steadily broadening generalizations made by learners and speakers over generations, as argued by Iverson and Salmons (2009), Salmons (2010), and many others. Blevins (2006: 140–143) presents broad evidence from a wide range of families on historical paths of development of final laryngeal neutralization. "Early stages" of devoicing co-occur with prepausal or phrase-final position, and they may be variable, gradient, and sensitive to aerodynamic properties (like a preference for devoicing /g/), in addition to occurring only at the right edges of phrases (or presumably other longer stretches of speech). She posits an implicational hierarchy of such patterns, according to which languages may neutralize at the right edges of larger prosodic units and not at smaller ones, but never vice versa. For instance, numerous languages (Dhaasanac, Maltese, and some varieties of German) neutralize at the ends of words (and larger units), but not of syllables.[9] Of course the reverse pattern would be inherently odd structurally: word-final is coda position and phrase-final is word-final, for instance, so that coda neutralization should apply to higher levels. As observed above, the historical development of glottalization is reported to parallel this path over prosodic domains closely, as discussed above, but remains laryngeally non-neutralizing and often leads to the loss of final oral stops.

Overall, these patterns reflect the historical paths of development laid out in the theory of Evolutionary Phonology (Blevins 2004, 2006): laryngeal neutralization by means of feature addition, especially if accompanied by mandatory release, appears to function as an edge marker, arising via release of final stops in salient prosodic positions, whereas neutralization via feature loss appears driven by mandatory or facultative absence of release. Even if the motivation is different, edge marking shows distributions similar to those of neutralization by feature removal. For example, in the Tundra Nenets case discussed above, glottal reinforcement occurs with all consonants prepausally.

Some varieties of American English may be starting down this path today. As already noted above, young speakers of Upper Midwestern English show nascent word-final devoicing. Purnell *et al.* (2009) present evidence that may reflect an earlier stage of this process: 2008 Republican vice-presidential candidate Sarah Palin showed variable final neutralization, with a preference for phrase-final position; i.e. what looks like a slightly earlier stage of development than that found now in Wisconsin. Palin was raised in an Alaskan community settled overwhelmingly by 1930s emigrants from northern Wisconsin, Michigan, and Minnesota, and this colonial variety of Upper Midwestern English may preserve the earlier patterns.

9 Blevins's treatment does not involve detailed language histories, but see Mihm (2004) and Iverson and Salmons (2007) for the beginnings of a case study of German.

5 History and Universal Grammar in final laryngeal neutralization

In the preceding sections, we laid out two contrasting positions with regard to how to explain final laryngeal neutralization. Following the discussion in Kiparsky (2008), one position favors the view that grammatical structure constrains language change and the other favors the view that language change is the primary shaper of grammar. The former is the classic generative position, illustrated on this issue by the work of Kiparsky, and the latter is associated with various approaches, mostly recently Evolutionary Phonology, illustrated by the work of Blevins, both discussed above. Kiparsky (2008: 52) concludes that:

> The two programs can coexist without contradiction or circularity as long as we can make a principled separation between true universals, which constrain both synchronic grammars and language change, and typological generalizations, which are simply the results of typical paths of change.

We share that ecumenical spirit, and note that it can be difficult to find the seam between such true universals and typological generalizations. We have argued above that Kiparsky has proposed a "true universal" which does not ultimately hold up empirically. This suggests that Universal Grammar is leaner than has often been claimed, in line with many views emerging in the field today. The preceding sections aim to develop generalizations, some of which may prove to be "true universals," while others will clearly be "typological generalizations." In contrast to Kiparsky's approach, Blevins (2008: 107) concludes that "Within the phonological realm, there appear to be few, if any, substantive universals," with specific rejection of distinctive features as "substantive phonological universals," treating them instead as "emergent properties" (see also CHAPTER 17: DISTINCTIVE FEATURES). Full justification would go well beyond our assigned task here, but we are not prepared to abandon the core substance of phonology. Above, we have relied on abstract featural characterizations, but argued that they must be considered in the context of phonetic variability and an array of psycholinguistic factors. History, internal and external, shapes contrasts and features through that context.

6 Summary and conclusions

In the foregoing, we started from a synthetic survey of what is known at present about final devoicing and laryngeal neutralization generally. Along the way, we have identified a number of phonological patterns based on the currently available evidence. Assuming privative laryngeal contrasts, neutralization can occur toward either a marked or an unmarked feature configuration, that is, by feature removal or insertion. Another form of right-edge marking, glottalization, appears to occur in languages for which [constricted] is not contrastive, thus without triggering laryngeal neutralization. These points all bear on current phonological discussions, i.e. about featural representations, the role of prosody and history in synchronic phonology, and the nature of neutralization in "weak" positions. All of these discussions represent areas of potential progress.

While we have kept a focus on phonological theory, we have done so in the context of phonetics (especially perception), sound change, and prosody, all of which, we argue, are critical to a full understanding of final neutralization. Several conclusions follow, including these:

(i) *Featural characterization matters*: The deletion of [voice], or final devoicing *sensu stricto*, is pervasive although not ubiquitous cross-linguistically. Addition of [voice] is rare to the point that some doubt its existence. The addition of [spread], or final fortition, is well attested, if potentially less common than devoicing. Deletion of [spread] (often with other features) is relatively common. Laryngeal realism, we have suggested, provides a robust typological generalization that would be impossible on the traditional interpretation of phonemically lenis stops with [+voice], and of phonemically aspirated stops with [−voice].

(ii) *Phonetics, phonotactics, and other patterns matter*: Laryngeal distinctions are carried by a wide range of phonetic cues, even within a single variety or even speaker. Still, long-standing efforts to argue for "incomplete neutralization" in German or Dutch may reflect nothing about the acoustic signal, but much about the generalizations speakers/listeners are able to make based on their knowledge of phonotactics and lexical frequency. This is especially important because the phonetics of final laryngeal distinctions is particularly complex, a fact that has left open the possibility that some cue to the distinction may survive neutralization. Phonologically, however, evidence indicates that final neutralization in languages like Dutch and German is typically complete.

(iii) *Both structure and history matter*: Both the "design" of language and historical forces play significant roles in synchronic sound patterns. In the particular example at hand, some claims about the role of language design have proven to be overstated, but such refinements are the work of healthy science.

As noted in §2, numerous scholars have treated "final devoicing" and its relatives as particular forms of final weakening, synchronic or diachronic. Research to date on final laryngeal neutralization reveals widespread patterns of feature addition and fortition. As with laryngeal realism itself, we would suggest that final neutralizations can come about by either weakening – through feature loss – or strengthening – through feature addition, including glottal reinforcement where it is not contrastive in any of the languages surveyed.

This presentation raises a number of new questions, especially on the typological front. The data we are aware of suggest some striking and as yet unexplored patterns, like the tendency of [spread] to delete finally together with other laryngeal features (Sanskrit), while [voice] appears able to delete independently (Dhaasanac). The answers to questions about such patterns will doubtless sharpen our understanding of the subtle interactions between the human linguistic endowment and the historical patterns we are presented with as learners.

ACKNOWLEDGMENTS

We thank the editors for the invitation to contribute to this project and an anonymous reviewer for helpful comments. Pattie Epps, Beth Hume, José Hualde, Sadaf Munshi, Marc van Oostendorp, Tom Purnell, Eric Raimy, Blake Rodgers, and Alan Yu all provided helpful discussions on this topic and in some cases comments on earlier versions of this chapter. 70 Conspiracies

CHARLES W. KISSEBERTH

1 Conspiracies: The essential argument

The paper "On the functional unity of phonological rules" (Kisseberth 1970; henceforth FUPR) made what in essence is a very simple argument. It claimed that in the phonologies of the world's languages, it is often the case that there are phonological structures that are either barred or required, and that (from a standard generative phonology point of view) multiple rules may be involved in guaranteeing that these structures are avoided or achieved. This observation seems to be undeniably accurate. FUPR, however, went further and suggested that it was not sufficient to simply recognize this truth about the world's phonologies, but that somehow (a) these barred/required structures should be an explicit part of the phonological system of a given language, and (b) grammars that utilize multiple means to achieve/avoid a certain structure are not to be viewed as more complex than grammars that use fewer rules for the same end. As we shall discuss below, these claims are not consistent with the prevailing notion in generative phonology that all significant linguistic generalizations are expressible in terms of simplifications in the formal system of rules and representations. FUPR suggested that there was instead a *functional* aspect to phonological rules that eluded the formal approach of early generative phonology. It should be emphasized that the use of the term "functional" in FUPR is distinct from later usage where functional refers to the idea that (a) phonological phenomena are motivated by, i.e. grounded in, phonetic considerations (summarized in Boersma 1997 as the "minimization of articulatory effort and maximization of perceptual contrast"), as well as the idea that (b) notions such as contrast, paradigmatic considerations and frequency may shape the phonological grammar. FUPR emphasized the existence of avoided/ preferred structures, but not what factors make the structure in question good or bad nor what factors favor one repair over another.

The idea that phonological rules "conspire" to avoid/achieve a given phonological structure is one that had been suggested to me originally by Haj Ross and George Lakoff on the basis of their syntactic work (as well as that of David Perlmutter). A close reading of major pre-generative linguists (particularly Boas and Sapir) seemed to support this notion, as these linguists not infrequently linked a particular phonological phenomenon (e.g. so-called "inorganic" vowels) to some claimed limitation on phonological structure. It was, however, Morris Halle who wisely suggested to me that I take a close look at the Yawelmani dialect of Yokuts if I wished to push this line of thought.

Yawelmani has, over the decades, been a point of reference for almost every approach to the essential problems of phonology. Newman (1944) provided the initial detailed description of Yawelmani (as well as three other dialects of the Yokuts language). His description of the language was in the tradition of Sapir. Harris (1944) and Hockett (1967, 1973) looked at the Yawelmani data from the point of view of American structuralism, and Kuroda (1967) reworked Newman's analysis in terms of standard generative phonology. Later, Archangeli (1984 and subsequent work) applied the principles of underspecification and non-linear phonology to Yawelmani. In the optimality-theoretic literature, Yawelmani has been critical to the analysis of opacity (cf. Cole and Kisseberth 1995; McCarthy 2007).

FUPR examined a number of the essential aspects of Yawelmani phonology, but while not differing radically from Kuroda's analysis, drew a conclusion that was out of the mainstream. What follows is a detailed summary of FUPR's account of Yawelmani.

Yawelmani words, in their surface form, consist of a sequence of syllables of the shape CV, CVV, CVC (where **VV** = long vowel). Thus all words begin with a single consonant and they may end either in a vowel or a single consonant. Internal to the word, vowels do not occur in succession: there is at least one and at most two consonants located between vowels. Vowels may be long or short, but when a vowel stands in the environment __ CC or __ C#, it can only be short. These observations lead to the conclusion that Yawelmani bans syllables with complex margins (i.e. consonant clusters in either onset or coda position) as well as trimoraic syllables.

In the timeframe of FUPR, syllables played no role in generative phonology (see CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE). As a consequence, all of the statements about phonological structures and all the rules formulated referred only to sequences of consonants and vowels. The discussion below follows the presentation in FUPR, but also translates it into a syllable-based analysis.

Underlying representations in Yawelmani are shaped in part by the above limitations on surface structure (CHAPTER 1: UNDERLYING REPRESENTATIONS). There are no prefixes in Yawelmani, so stems always occupy word-initial position. All stems in Yawelmani have an initial consonant. Thus there is no need to have a rule to insert a consonant at the beginning of vowel-initial words. On the other hand, while no stem contains a sequence of three consonants, some stems do end in two consonants. When such stems are followed by a consonant-initial suffix, we have a situation where the ban on triconsonantal clusters (or complex margins) is endangered. An epenthetic vowel is introduced between the first two consonants in the three-consonant sequence (CHAPTER 67: VOWEL EPENTHESIS). This vowel epenthesis phenomenon is illustrated by the data in (1). (We have supplemented the data cited in FUPR for purposes of exposition.)

(1)	*Underlying form of stem*	*Stem + aorist* /hin/	
	ˀilk	ˀilik-hin	'sing'
	ˀutj	ˀutuj-hun	'fall'
	logw	logiw-hin	'pulverize'
	ˀajj	ˀajij-hin	'pole a boat'

The stems in (1) appear in their underlying form when followed by a vowel-initial suffix (e.g. [ʔilk-al] 'might sing', [logw-ol] 'might pulverize', [ʔajj-al] 'might pole a boat', etc.), but with an epenthetic [i] when followed by a consonant-initial suffix like the aorist /-hin/. If these stems appear in word-final position (e.g. in the imperative), then a vowel is also epenthesized between the two consonants that stand in word-final position (due to the fact that a word can only end in a single consonant, as a consequence of the ban on complex codas). Thus the stem /ʔilk/ will appear as [ʔilik] if not followed by a suffix. The epenthetic vowel in Yawelmani is the high front unround vowel [i], though this vowel will appear as [u] when preceded by a high round vowel (cf. [ʔutuj-hun]).

In FUPR, the rule in (2) is postulated for Yawelmani:

(2) *Vowel Epenthesis*

Ø → i / C __ C {#, C}

These epenthetic vowels are clearly a means to avoid complex syllable margins. But Vowel Epenthesis is not the sole method for avoiding complex margins in Yawelmani. Specifically, there are two morphologically restricted cases where one of the consonants is deleted. One case involves two suffixes that have an initial consonant cluster (in both cases, the first consonant in the cluster is a laryngeal), where the first of these consonants is deleted in position after a consonant-final stem. For example, the suffix /-hnil-/ elides its initial consonant after a consonant-final stem like /gitiin-/ 'to hold under the arm' (this morpheme sequence occurs in the noun 'armpit' and there is other morphology and irrelevant phonology involved in the final form of this noun, [giten-nel-a-w]). The available data are not sufficient to make it clear whether the two suffixes in question are at all productive. The rule given in (3), if ordered before Vowel Epenthesis, will correctly delete the initial consonant of /-hnil-/.

(3) C → Ø / C + __ C
(in fact, the only consonants that occur in the environment C + __ C are [ʔ h])

The second case of consonant deletion occurs as an aspect of the phonology of certain suffixes which trigger moraic reduction in a preceding stem (in Newman's terminology, these suffixes require the "zero" form of a stem). For instance, stems with three consonants (e.g. /halaal-/ 'lift up') are converted to the shape CVCC- (e.g. [hall-]) in front of a suffix such as /-hatin/. This suffix, in turn, will elide its initial consonant, due to the prohibition against three-consonant sequences (i.e. complex margins). Again, we are not aware of whether a suffix such as /-hatin/ is productive. The rule given in (4), if ordered before Vowel Epenthesis, will correctly delete the initial consonant of the specified suffixes.

(4) C → Ø / CC + __
(affects only suffixes such as /-hatin/ that trigger the so-called "zero stem")

It is clear that both of these restricted deletion rules are functionally related to the vowel epenthesis phenomenon: they guarantee that an input that potentially violates the ban on triliteral consonant clusters and word-final consonant clusters (i.e. complex syllable margins) will in fact obey this constraint on the surface (CHAPTER 68: DELETION). Of course, all the potential violations of the ban on complex margins could be avoided by the single phenomenon of Vowel Epenthesis. The consonant deletion processes in (3) and (4) are not necessary in order to secure an outcome where there are no complex margins. However, what the existence of conspiracies tells us is that (in a rule-based approach to phonology) languages do not always opt to use the fewest number of rules possible to avoid an offending phonological structure.

Rules (2)–(4) constitute only one part of the Yawelmani conspiracy against complex margins. There is evidence to motivate the postulation of a rule in Yawelmani that elides a short vowel (either /i/ or /a/) in the environment VC __ CV. This rule can explain both cases where vowels in verb suffixes are elided, and also aspects of the nominal case system. Specifically, it deletes what Newman referred to as the "protective" vowel /a/ in a structure like /k'iliij + a + ni/ 'cloud (INDIRECT OBJECTIVE)' but not in a structure like /puulm + a + ni/ 'husband (INDIRECT OBJECTIVE)'. In an example like /k'iliij + a + ni/, deletion of /a/ yields an output where there is only one consonant in onset position and one consonant in coda position. On the other hand, there is no deletion of /a/ in /puulm + a + ni/, due to the fact that such a deletion would yield an output with three consonants in a row: [lmn], a sequence that would require either a complex onset or a complex coda.

The rule in (5) achieves the correct result.

(5) $V \rightarrow \emptyset$ / VC __ CV

Rule (5) does not bear any *formal* similarity to either the vowel epenthesis rule in (2) or the consonant deletion rules in (3) and (4). However, despite this lack of formal similarity, there is an obvious functional similarity: (5) deletes a vowel *unless* to do so would create violations of the ban on complex margins. Deleting a vowel is of course the opposite of inserting one from a formal point of view, but both actions, along with consonant deletion, reveal the overarching principle that complex margins are not permitted in Yawelmani.

There is yet one more aspect to the Yawelmani complex margin conspiracy. Word-final verbal suffixes of the shape -CV elide their vowel when preceded by a vowel-final stem but not a consonant-final stem. In other words, the vowel of these suffixes will elide unless its elision would produce a violation of the ban on complex margins. Thus the imperative suffix /-k'a/ loses its vowel after the stem /taxaa-/ 'take', yielding [taxa-k'], but no elision takes place after the stem /xat-/ 'eat', yielding [xat-k'a] rather than *[xat-k'], with a complex coda. This second vowel deletion rule is formulated in (6):

(6) $V \rightarrow \emptyset$ / V + C __ #

There is of course some formal similarity between (5) and (6), since both are vowel deletion rules and only apply in the event a VC structure precedes. However, since (6) is restricted to word-final vowels that are part of a CV suffix, there is not identity even in terms of the preceding structure: i.e. VC __ in (5) but V + C in (6).

We have now discussed the *rules* in Yawelmani that implement the ban on complex margins: (2)–(6). These rules, however, do not tell the entire story. In the standard generative phonology that prevailed at the time FUPR was written, it was proposed that *morpheme structure conditions* (CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS) served to restrict the shapes of morphemes in underlying representation. In Yawelmani, there are no morphemes that contain a sequence of three successive consonants. In other words, structures are avoided inside a morpheme if they could only be syllabified by creating a complex margin.

This aspect of conspiracies was developed at greater length in Kenstowicz and Kisseberth (1977), under the rubric of the "duplication problem." Specifically, it was noted that in theories where there are both "morpheme structure conditions" and also phonological rules, it is often necessary to repeat the same generalization both as a morpheme structure condition and also as a feature-changing rule. For example, underlying representations of morphemes may disallow a NC sequence where the nasal and the consonant are not of the same point of articulation, but a rule may still be required that converts a morpheme-final nasal to be homorganic with a consonant in initial position in the next morpheme (CHAPTER 81: LOCAL ASSIMILATION). As long as there is a morpheme structure component of the phonology that is distinct from the rules that account for alternations in the shapes of morphemes, then there will be conspiracies whereby structures that are banned in the underlying representations of morphemes will trigger morphophonemic alternations as well.

To summarize: in Yawelmani, a morpheme structure ban on trisyllabic consonant sequences prevents morphemes from having offensive segmental material to begin with. A rule of vowel epenthesis, as well as two minor rules of consonant deletion, prevents violations from occurring at the juncture of morphemes. Two vowel deletion phenomena are constrained in a fashion to prevent the creation of complex margins.

But having pointed out this conspiracy, what are we to make of it? FUPR suggested that although there is no way in which a *formal* unity can be found for these various rules, nevertheless the ban on triliteral and word-final consonant clusters (i.e. the ban on complex margins) should be part of the phonological grammar of Yawelmani. However, in standard generative phonology, a phonology is a set of representations and a set of ordered rules that derive a surface form from an input form. A ban on complex margins cannot be part of the phonology unless it participates in the derivation of surface forms from input forms; otherwise it is simply a useless appendage that has no basis for existence in a formal system. In an attempt to find some way to make the ban on complex margins a part of the phonology, FUPR suggested that bans of this sort might function as *derivational constraints*.

The idea of a derivational constraint is this. Suppose that we formulate rule (5) as (7):

(7) A word-medial (short) vowel elides.

Say that the application of this rule fails if its immediate output would violate the ban on triliteral or word-final consonant clusters (i.e. complex margins). This derivational constraint would allow a word-medial vowel to delete only if deletion does not produce an illicit structure. Of course, this notion of derivational constraint would radically alter the way in which rules apply, but it would mean that a constraint like the ban on complex margins in Yawelmani would have an actual role to play in derivations.

The notion of derivational constraints, however, is only a very partial account of the Yawelmani complex margin conspiracy. It is not evident how the ban on complex margins would play any role in the derivation of words where offending structures arise across morpheme boundaries. Because the notion of a derivational constraint did not solve the conspiracy problem, it did not play a significant role in phonology until considerably later.

2 Conspiracies: An historical overview

In order to fully understand the argument made in FUPR, one must begin with perhaps the central concern of early generative phonology: specifically, the question of how a language learner deduces the correct grammar from the data to which the language learner is exposed. The rough answer to this question that was advanced was that the learner adopts the "simplest" grammar. Simplicity, at least in terms of phonology, was taken to be determined by reference to the counting (particularly) of feature specifications both in rules and in lexical representations. A critical part of this enterprise was to design grammars so that the phonological patterns most commonly found in languages could be expressed in a simple fashion, while patterns that were never found in languages could be expressed only under great duress. An essential element of this enterprise was the building of a system of notation that would allow what the linguist understood to be the "same" or "related" phenomena to be subsumed under a single rule (a rule that while covering the observed data would often go beyond those data to make predictions about data the learner may not have encountered). (See Chomsky and Halle 1968 (*SPE*) for an extended discussion of this point of view. These ideas can be found throughout the entire early generative phonology literature.)

What FUPR showed was that in synchronic grammars one could find cases where obviously related phenomena could not be given a unitary treatment from the point of view of any available formal notation because they were related not in terms of their actions (insertions, deletions, feature changes, etc.), but rather the structural configurations that they either avoided or strove to achieve. As long as phonology was viewed as a theory of rules which married phonological actions to specific phonological contexts, a solution to the problem of conspiracies was impossible. The one partial solution suggested – derivational constraints – was a tentative step in the direction of separating the action (vowel deletion, in the Yawelmani case) from the context in which it occurs. It was, of course, not until the development of Optimality Theory (cf. Prince and Smolensky 1993) that a total solution emerged.

Although the FUPR paper itself focused on conspiracies in the synchronic grammars of specific languages, the paper developed out of my (ultimately unsuccessful) attempt to extend the ideas of "Chapter Nine" of Chomsky and Halle (1968) by developing a notion of "universal rules." What Chapter Nine attempted to do was to make it formally simpler for a grammar to conform to what is "natural" than for it to go against what is most natural. In terms of phonological representations, it did this by creating a system where an unmarked feature value was cost-free, while a marked feature value rendered the representation a more costly one. The consequence was that whenever possible, an underlying representation would contain an unmarked value rather than a marked value (since generative phonology claimed that the least costly grammar was always chosen over the more costly grammar if both grammars yielded the correct outputs). Chapter Nine went further, however, and attempted to extend the idea of making unmarked specifications cost-free when formulating phonological rules. However, it found only a very restricted way of achieving this goal. In particular, it proposed that if a phonological rule specifies a particular structural change, then markedness principles come into play to add other changes that follow naturally. For instance, Yawelmani has a vowel harmony rule whereby a vowel becomes round when preceded by a round vowel of the same height. This vowel harmony rule affects the vowel /i/ when it stands after the vowel /u/. However, when /i/ rounds, it also becomes back and surfaces as [u]. Chapter Nine suggested that in a case such as this, the vowel harmony rule simply specifies that a vowel acquires the feature [+round] and then markedness principles will automatically add the feature [+back].

In Chapter Nine, the only way that markedness considerations could play a role in "simplifying" the grammar was through this device of "linking" a natural structural change (e.g. the backing of a round vowel) to a language-specific rule (e.g. vowel harmony). As such, Chapter Nine had a proposal only for the case where a secondary structural change is natural given some primary structural change. It did not have an explanation for why the same primary changes occur under similar conditions in language after language (e.g. nasal assimilation, epenthesis of onsets, lenition).

In an earlier version of Kisseberth (1969), I attempted to develop (but later abandoned) the idea that grammars contain a set of universal rules (cost-free, so to speak). This proposal was motivated by the recognition that no matter how much tinkering one did with the system of notation, it would always be possible to state very simple rules that have linguistically implausible consequences. As a consequence, generative phonology's attempt to make more natural rules "easy" to formulate and less natural rules more difficult seemed fundamentally flawed.

The principal difficulties that the search for universal rules faced at the end of the 1960s included:

(i) In a given language, a very natural phonological process accrues a significant number of language-specific restrictions that reduce the generality of the rule needed to account for the phenomenon; it was unclear how to separate the essence of a rule from all the baggage required to properly delimit its scope of application.
(ii) *The conspiracy problem.* Specifically, there are multiple distinct actions (insertions, deletions, feature changes, sequencing changes) that are triggered by essentially the same context. Since a given language may utilize several rules to avoid/achieve a certain structural configuration, the scope of application of each rule must be delimited, obscuring the universal nature of the rule.
(iii) If "universal" means "in every language," why are there languages where these (proposed) universal rules are not in fact implemented in all cases or indeed at all?

Optimality Theory (Prince and Smolensky 1993 and a myriad of subsequent references), of course, ultimately provided a solution to these problems by (a) separating the actions themselves from the "rules" (now expressed as constraints),

(b) allowing constraints to interact with one so that different actions are favored in certain situations over other actions, and (c) postulating a type of constraint (faithfulness) that could suppress the effects of other constraints by outranking them.

As the preceding discussion indicates, FUPR developed out of the problem of developing a notion "universal rule." It could not succeed in solving the problem of conspiracies, since it assumed the existence of (learned) rules. Between FUPR and the optimality-theoretic solution to conspiracies and universal rules, there were many significant phonological developments. Most of these developments have some bearing on the conspiracy problem. Perhaps it will be useful to begin with an observation in McCarthy (1993: 169):

> The idea that constraints on well-formedness play a role in determining phonological alternations, which dates back at least to Kisseberth's (1970) pioneering work, has by now achieved almost universal acceptance. A tacit assumption of this program, largely unquestioned even in recent research, is the notion that valid constraints must state true generalizations about surface structure or some other level of phonological representation. Anything different would seem antithetical to the very idea of a well-formedness constraint.

McCarthy goes on to reject the point of view that the constraints that grammars conspire to enforce are necessarily true surface generalization. But it is important to understand the way in which the idea of conspiracies evolved and McCarthy here identifies a principal theme.

It is true that in the Yawelmani case the ban on complex onsets/codas is (largely) satisfied by the surface representations of the language. FUPR did not claim, however, that this was necessarily the case, but rather allowed for the possibility that a relevant constraint might be true of only a certain stage of the derivation. This conclusion was a necessary one, because FUPR did not propose to abandon the notion that phonological systems are systems where principles interact in a possibly complex way such that some principles may not be true of the surface but only of some other level of the representation. From that point of view, it could very easily be the case that a certain configuration is favored or disfavored through much of a derivation, only to have late, low-level rules derive surface forms where the principle in question is violated. It was well known, for instance, that commonly assumed laws of syllabification in English may be violated in fast speech. In other languages, violations may result from processes operative in careful speech as well.

Although FUPR was careful not to suggest that the phonological targets of conspiracies were surface targets, the discussion that evolved over the subsequent years generally emphasized the surface nature of the constraints that rules conspired to serve (e.g. Haiman 1972; Shibatani 1973; Sommerstein 1974). This emphasis is extremely significant, since it had the consequence that the essential point of FUPR was lost as phonological thinking veered in new directions. The question raised by Kiparsky (1968), "How abstract is phonology?" led several influential phonologists to move in various interrelated directions. On the one hand, "Natural Generative Phonology" (cf. Vennemann 1971, 1974; Hooper 1973, 1979) attempted to limit phonology to surface-true generalizations. On the other hand, the "Natural Phonology" of Stampe (1973) attempted to re-focus phonology away from the alternations observed in the shapes of morphemes (alternations which were often of restricted scope, were non-productive, and had exceptions, and which Stampe considered to be arbitrary and learned) towards processes that were "automatic," "exceptionless," and "innate," which could be observed in a variety of domains such as language acquisition, fast speech, unguarded speech, drunken speech, language games, etc. Both Natural Generative Phonology and Stampe's Natural Phonology did not survive, for a quite simple reason: both approaches essentially removed the many examples of very regular, productive morphophonemic processes from the scope of phonology, since they were usually not surface-true generalizations due to exceptions or interactions with independent phenomena, etc. However, Stampe's Natural Phonology did have a lasting impact, in that it eventually led to the so-called "Lexical Phonology" approach, which made a significant attempt to distinguish among principles that obtained in the lexicon and principles with a wider scope of application that were not dependent on the particulars of morphological structure (cf. Kiparsky 1982, 1985; Mohanan 1986, 1995). To this day this remains a critical issue in working out a comprehensive theory of phonology (CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME).

The debate with regard to the "abstractness" of phonology (i.e. the extent to which surface forms may differ from their underlying sources and what sorts of evidence are required in order to postulate a divergence between surface and underlying structure) had considerable implications for the concerns of FUPR, as well as the ultimately related notion of universal rules. If phonology has little abstractness, and if most of the rules that had been proposed during the early years of generative phonology were not really rules of phonology at all, then perhaps arguments such as the one presented in FUPR are irrelevant. If the various rules that we claimed conspire to avoid complex margins in Yawelmani are not in fact real rules of the language, then the argument in FUPR is no argument at all. And if the only phonological rules are ones that are directly represented by overt surface forms, then explaining how a phonological system is learned no longer seems so challenging, and appeal to universal considerations is less necessary.

The abstractness controversies of the early 1970s, however, were never really resolved, but instead phonologists turned to a new approach to phonological analysis and universals, namely an approach that emphasized the development of phonological representations from which outputs could be predicted with a minimal appeal to rules and rule interaction. The motto of phonology became "if the representations are right, then the rules will follow" (McCarthy 1988: 84). For our purposes, we will refer to this as *representational phonology* (cf. Goldsmith 1976, 1990; Clements and Goldsmith 1984; Clements 1985; and many other references). Although representational phonology had very considerable successes (e.g. the autosegmental approach provided substantial insights into the complicated tonal phenomena of Bantu languages and the vowel harmony patterns of a variety of languages; CHAPTER 114: BANTU TONE; CHAPTER 45: THE REPRESENTATION OF TONE; CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY), it became apparent from several of its most significant contributions that an adequate account of phonological patterns requires appeal not just to representations and rules, but also to constraints. The introduction of constraints can be found in such papers as Itô's (1989) theory of epenthesis, the extensive literature on the

Obligatory Contour Principle or concepts such as word-minimality in the work on prosodic morphology (cf. McCarthy 1979, 1981; McCarthy and Prince 1986).

The return to a role for constraints in phonological thinking naturally also triggered a return to relevance of the notion of conspiracies and constraints on derivations. Papers such as Myers (1991) on the notion of "persistent rules," the Theory of Constraints and Repairs developed in Paradis (1988), and ultimately Optimality Theory all found the issue identified in FUPR to be a significant one that needed to be addressed in phonological theory. We shall discuss the optimality-theoretic analysis of the conspiracy phenomena later, but at this point we would like to turn to specific examples of conspiracies.

3 Conspiracies in various domains of phonological research

The argument in FUPR is limited to a single synchronic phonological system, but the notion is relevant to most, if not all of the domains of phonological exploration: universals, variation, and dialectology (CHAPTER 92: VARIABILITY), language change (CHAPTER 93: SOUND CHANGE), acquisition (CHAPTER 101: THE INTERPRETATION OF PHONOLOGICAL PATTERNS IN FIRST LANGUAGE ACQUISITION), loanword phonology (CHAPTER 95: LOANWORD PHONOLOGY), etc. Space limitations do not permit an extensive discussion of all the domains where the notion of conspiracies is relevant, but we present some brief discussion of several domains: synchronic grammars, universal rules, phonological acquisition, and loanword phonology.

3.1 Conspiracies in synchronic grammars

We have already discussed at length the conspiracy in Yawelmani that revolves around the avoidance of complex syllable margins. There is a great variety of other examples of conspiracies that have been discussed over the past few decades. Here we will illustrate just two: hiatus avoidance conspiracies and conspiracies banning sequences of a nasal consonant followed by a voiceless obstruent.

Many languages do not allow onsetless syllables, particularly in word-medial position (cf. Casali 1997; CHAPTER 61: HIATUS RESOLUTION; CHAPTER 55: ONSETS for discussion). Traditionally, such languages are said to avoid hiatus (a succession of two vowels with no intervening consonant). There are, of course, several ways in which a VV sequence (hiatus) may be avoided. The first or the second vowel may be deleted. The first or the second vowel may undergo glide formation. A consonant may be inserted between the vowels. While some languages may choose to avoid hiatus by invoking a single anti-hiatus action, it is not at all uncommon to find a language invoking multiple actions according to the specific VV sequence.

Chicano Spanish provides a relevant example (cf. Hutchinson 1974; Reyes 1976; Baković 2007). Consider the data in (8), taken from Baković (2007). We have used orthographic representation for the input and retained that representation for the output, except that we put the surface form resulting from the hiatus avoidance rules inside brackets to highlight how the hiatus is dealt with.

(8)	a.	*tu uniforme*	*t*[u]*niforme*	'your uniform'	
		lo odio	*l*[o]*dio*	'hate (1SG him/it)'	
		era así	*er*[a]*sí*	'it was like that'	
		se escapó	*s*[e]*scapó*	'escaped (3SG)'	
		mi hijo	*m*[i]*jo*	'my son'	(*h* is silent)
	b.	*paga Evita*	*pag*[e]*vita*	'Evita pays'	
		la iglesia	*l*[i]*glesia*	'the church'	
		casa humilde	*cas*[u]*milde*	'humble home'	(*h* is silent)
		niña orgullosa	*niñ*[o]*rgullosa*	'proud girl'	
	c.	*mi obra*	*m*[jo]*bra*	'my deed'	
		mi ultima	*m*[ju]*ltima*	'my last one (FEM)'	
		mi hebra	*m*[je]*bra*	'my thread'	
		mi arbol	*m*[ja]*rbol*	'my tree'	
		tu epoca	*t*[we]*poca*	'your time'	
		tu alma	*t*[wa]*lma*	'your soul'	
		tu hijo	*t*[wi]*jo*	'your son'	(*h* is silent)
		su Homero	*s*[wo]*mero*	'your Homer'	(*h* is silent)
	d.	*me urge*	*m*[ju]*rge*	'it is urgent to me'	
		pague ocho	*pagu*[jo]*cho*	'that s/he pay eight'	
		porque aveces	*porqu*[ja]*veces*	'because sometimes'	
		como Eva	*com*[we]*va*	'like Eva'	
		tengo hipo	*teng*[wi]*po*	'I have the hiccups'	(*h* is silent)
		lo habla	*l*[wa]*bla*	'speaks it'	(*h* is silent)
	e.	*como uvitas*	*com*[u]*vitas*	'like grapes (DIM)'	
		se hinca	*s*[i]*nca*	'kneels'	(*h* is silent)

The data in (8) show that when two vowels are juxtaposed in Chicano Spanish, these VV sequences are not resolved in a single way. (7a) shows that when two identical vowels are adjacent to one another, the sequence is reduced to a single vowel. Thus in *tu uniforme*, a single [u] vowel is found. It is of course not readily apparent whether one or the other vowel is deleted or whether one should just say the two vowels coalesce.

(8b) demonstrates that a word-final low vowel *a* deletes before any vowel. Thus in *paga Evita*, the *a* at the end of the verb is absent in pronunciation. But the first vowel of the VV does not always delete. (8c) shows that if the first vowel is high, then it becomes the corresponding glide, whatever the second vowel might be. Thus *mi obra* yields [mjo] and *tu epoca* yields [twe]. On the other hand, if the first vowel is mid, the results are a bit more complex. (8d) shows that if the second vowel differs from the first with respect to either [±low] or [±back], then the initial vowel glides: *me urge* surfaces with [mju], *como Eva* results in [mwe] and *lo habla* (the *h* of the orthography is silent) becomes [lwa]. However, if the vowel that follows the mid vowel differs from it only with respect to the feature [±high], then there is no glide formation. Rather, as shown in (8e), the two vowels coalesce in a form identical to the second vowel: *como uvitas* results in [mu]. What this example from Chicano Spanish illustrates is that although a single strategy might avoid hiatus, languages may choose multiple means (for example vowel coalescence, vowel deletion, glide formation) to eliminate the problematic structures.

Combinations of a nasal consonant and a following voiceless consonant are disfavored in many languages (cf. Hayes and Stivers 2000 for discussion of the phonetic preference for voiced consonants following nasals; see also CHAPTER 8: SONORANTS). There are different ways in which these ill-formed consonant sequences could be avoided. The most common "repairs" are voicing the post-nasal consonant or deleting this consonant (while assimilating the nasal to the same point of articulation), or devoicing the nasal or even deleting it all together.

Pater (1999) points out that in various languages, nasal–voiceless stop sequences are avoided by the application of more than one rule (even though a single rule in principle could resolve the problem). For example, in Kwanyama, a Bantu language discussed in Steinbergs (1985), there is evidence to support a ban on nasal–voiceless consonant sequences. One piece of evidence for the ban is the absence of such sequences in morpheme-internal position. It is also the case that the sounds [k] and [g] are in complementary distribution. [k] occurs word-initially and intervocalically, and [g] appears only after nasals. This distributional pattern supports the proposition that there is a principle that voices a consonant after a nasal. Such a proposal is also supported by the treatment of English loanwords, as shown in (9) below.

(9) *Post-nasal voicing in Kwanyama loanwords*

[sitamba]	'stamp'
[pelenda]	'print'
[oinga]	'ink'

In these borrowings, English nasal–voiceless stop sequences are replaced by nasal–voiced stop sequences.

But voicing of the stop is not the only repair found in Kwanyama. A root-initial voiceless stop located after a nasal prefix requires assimilation of the nasal, but then elides from the representation.

(10) *Root-initial nasal substitution in Kwanyama*

/eːN + pati/	[eːmati]	'ribs'
/oN + pote/	[omote]	'good-for-nothing'
/oN + tana/	[onana]	'calf'

In two other Bantu languages, Umbundu and Luyana, the same ban on nasal–voiceless consonants can be found. In these languages we again find two different repairs. A nasal that comes to stand in front of a voiceless fricative elides, while a nasal in front of a stop will assimilate the stop's point of articulation, but the stop itself elides. Schadeberg (1982) illustrates from Umbundu that /N + tuma/ surfaces as [numa] 'I send', while /N + seva/ surfaces as [seva] 'I cook'. Givón (1970) shows that in Luyana /N + tabi/ surfaces as [nabi] 'prince', while /N + supa/ surfaces as [supa] 'soup'.

While Kwanyama, Umbundu, and Luyana use two distinct strategies to avoid a nasal–voiceless consonant sequence, other languages may opt for a uniform repair. According to Pater, in Indonesian a nasal assimilates the point of articulation of both a voiceless fricative and a voiceless stop, with the oral stop then eliding. In other languages, like Kelantan Malay, Venda, Swahili, and Maore, nasals delete before voiceless stops and fricatives alike. Although uniform avoidance strategies are possible, many languages are like Kwanyama, Umbundu, and

Luyana in that they opt for a (perhaps only superficially) more complex pattern of avoidance.

3.2 *Phonological conspiracies and universal grammar*

As mentioned earlier, the FUPR paper arose out of an attempt to make some sense out of the notion that there might be "universal" rules. The problem that confronted the researcher during the generative phonology period was that while one could easily find phenomena that seemed to reflect some universal principle, the rule-based descriptions were rarely uniform across languages in their details. Furthermore, just as in the case of conspiracies in synchronic grammars, sometimes formally unrelated rules in different languages could be involved in achieving the same outcome.

Let us take an example from Bantu tonal systems (CHAPTER 45: THE REPRESENTATION OF TONE; CHAPTER 114: BANTU TONE). Early on in the research on these systems, it was recognized that a *sequence* of H tones is not preferred in these languages. Meeussen (1963) observed that in Tonga, for example, a succession of two H tones is converted to HL. In Leben (1973) and Goldsmith (1976), this ban on successive H tones was seen as a natural consequence of the approach to phonology that came to be known as autosegmental phonology. Specifically, autosegmental models typically represent surface sequences of a feature value (e.g. H tone) as a single multiply linked autosegment. As a consequence, to the extent that this representation is maximized, sequences of the same autosegment will be unexpected. The proposed constraint against successive identical autosegments became known as the Obligatory Contour Principle (OCP). Although some support for the idea that the OCP constrains all features emerged in the phonological literature, there is no question that its tonal instantiation is by far the most robust evidence for the principle.

The notion of a ban on successive H tones depends on the ability to distinguish between *true* and apparent sequences of H tones. This distinction is captured in autosegmental phonology as follows. A true H tone is one located on the tonal tier, regardless of whether it is associated with one or more than one tone-bearing unit. Successive H-toned moras are not sequences of H tones if they are all linked to a single H tone on the tonal tier.

There are a number of ways in which the *HH principle can be manifested in a language. But before looking at these manifestations, two quite separates matters must be mentioned, both of which dramatically expand the diversity of the manifestations of the OCP. First of all, in the analysis of Bantu languages, it has sometimes been argued that phonologically there is just a contrast between H tone and the absence of tone. However, even in analyses that utilize inputs that lack L tones, rules have been proposed that derive L tones that then contrast with toneless moras. Consequently, we have some analyses where a H tone that violates the OCP may be simply deleted, and other analyses where it is changed to L. Formally, the rules are quite distinct, but in both versions the ban on successive H tones is satisfied. A second complication has to do with what it means for two H tones to be adjacent and thus in violation of the *HH ban. In some languages, adjacency of H tones on the tonal tier is the defining characteristic; in other languages, what is significant is that the H tones may not be associated with successive syllables; in yet other languages, what is critical is that the H tones not be linked to successive moras. Because of these differences in adjacency, there will be considerable variation from language to language with respect to which representations actually violate the ban on HH in those languages.

Let us now look at some of the different ways in which the *HH ban is implemented in different languages. One implementation has to do with the very nature of the underlying representations found in a given language (CHAPTER 1: UNDERLYING REPRESENTATIONS). For example, Cassimjee (1992) shows that in Venda (a Bantu language spoken in South Africa and adjacent parts of Zimbabwe) noun stems, there may be sequences of H-toned moras, but in every case there is evidence that these sequences consist of a single H tone on the tonal tier associated with multiple successive moras. There are no morphemes with successive true H tones. In other words, underlying representations are structured so as to avoid violations of the OCP. The evidence that these H-toned sequences are a single H tone comes from a morphophonemic phenomenon known as Meeussen's Rule (Goldsmith 1984), whereby a H tone that is immediately preceded by a H tone is changed to L. For example, a noun such as /góŋ´óŋ´ó/ 'bumblebee' will, when preceded by a verb ending in a H tone, change first of all to the intermediate form: */gòŋ´òŋ´ò/, due to Meeussen's Rule: i.e. all three syllables become L-toned (indicating that all three syllables started off linked to a single H tone that then changed to L). Subsequently, the preceding H tone spreads onto the first syllable forming a contour tone: */gô/. Falling tones in Venda, however, are only permitted on bimoraic vowels and bimoraic vowels occur only in the penultimate syllable of an Intonational Phrase. As a consequence, /gô/ surfaces simply as a H-toned syllable: [góŋ´òŋ´ò]. If /góŋ´óŋ´ó/ were analyzed as having a sequence of three H tones rather than having a single H-tone multiply linked, we would have to explain why Meeussen's Rule does not affect the underlying representation of this word (see Cassimjee 1992 for more detailed discussion).

Even if underlying representations are configured to avoid violations of the OCP (as in Venda), it still may happen that the juxtaposition of morphemes yields potential HH sequences. One very common reaction to this threat is the deletion/lowering of the rightmost of these adjacent H tones as shown above for Venda. Rules that target the rightmost H in a HH sequence are said to be instantiations of "Meeussen's Rule" (cf. Goldsmith 1984). In Venda it is necessary for Meeussen's Rule to change H to L in order to obtain the right results. In the Ikorovere dialect of Emakhuwa (spoken in southern Tanzania), Meeussen's Rule simply deletes the H tone. For example, an underlying form like /k-a-ho̲-ka̲viha/ 'I helped' (underlining indicates the location of input H tones) has a H-toned tense-aspect morpheme /ho/ followed by a stem /kaviha/, which has a H tone (predictably) associated with its first vowel. This morpheme sequence violates the OCP ban *HH. The second of these H tones deletes, but subsequently the first H tone doubles onto the second by a general High Tone Doubling rule that applies in a wide variety of circumstances in the language: [k-a-hó̲-ká̲viha]. Of course, one might ask: how do we know that the H tone on the stem-initial /ka/ has deleted if in fact this mora is pronounced on a H tone? The answer is simple. If the underlying H tone on /ka/ had not deleted, then it would have triggered doubling onto the next mora, resulting in the ill-formed *[k-a-hó̲-ká̲viha]. Notice that it is clear that the H tone on /ka/ is deleted and not the H tone on the preceding morpheme /ho/. If we had deleted the H tone from /ho/, then we would predict the incorrect output *[k-a-ho̲-ká̲víha], since the second H tone would double to its right. (See Kenstowicz and Kisseberth 1979 for a more extended discussion of Emakhuwa tone, albeit in a pre-autosegmental framework.)

Although deletion of the rightmost H is particularly common in Bantu, other responses to violations of the *HH constraint can be found. In some cases it is the leftmost of the two H tones that deletes or changes to L. For instance, in the Bantu language Rimi (Yukawa 1989), underlying H tones shift systematically one vowel to the right. Thus [u-t<u>e</u>ghéja] 'to understand' has a H-toned verb stem, where the H tone is underlying on the stem-initial vowel (underlined) but surfaces on the syllable [ghe]. In an example like [u-v<u>a</u>-ríghitja] 'to speak to them', the verb stem is toneless but the object prefix /va/ bears an underlying H tone that shifts onto the first syllable of the verb stem. When a H-toned object prefix precedes a H-toned verb stem, as in [u-v<u>a</u>-t<u>e</u>ghéya], we see that the object prefix loses its H tone and the syllable [te] retains its H tone, although this H tone does shift to the next vowel. Rimi thus differs from languages like Venda and Emakhuwa in that a violation of the OCP is repaired by deleting the leftmost H rather than the rightmost H.

In yet other cases, the two adjacent H tones are merged into a single H tone that is still linked to all of the moras that the original H tones were linked to. We can refer to this as H-tone fusion. The evidence for H-tone fusion is sometimes a bit indirect. The Bantu language Shambaa (Odden 1982) provides an interesting example, however, since in addition to the need for H-tone fusion, it also illustrates an entirely different means of avoiding *HH violations.

In Shambaa, whenever a sequence of H tones would be created (either within a word or across words), a downstep is inserted between the H tones. For example, the second H tone in each of the following examples is downstepped relative to the first (downstep is indicated by the downward arrow and an underlying H tone is indicated by underlining; the data also illustrate H tone spreading, but we do not discuss this aspect of the data): [at<u>é</u>-k↓<u>ó</u>má] 'he killed', [ang<u>é</u>-↓j<u>á</u>] 'he should have cooked', [<u>á</u>zak<u>ó</u>má nj↓<u>ó</u>ká] 'he killed a snake', and [n<u>í</u> k↓<u>ú</u>i] 'it is a dog'. These data suggest clearly that a sequence H!H does not count as a violation of *HH. It should be noted that while in some languages downstep may derive from a so-called "floating" L tone, this is not the case in Shambaa. We do not address here the issue of how downstep is represented, nor whether it is represented in the phonology or only in the phonetics.

The insertion of a downstep between successive H tones in Shambaa is a very general phenomenon, but there are some cases where successive input H tones are *not* separated by a downstep. For instance, there is no downstep between a H-toned object prefix and a H-toned verb stem: /ku-w<u>á</u>-k<u>ó</u>má/ 'to kill them'. Odden explains the failure of a downstep to be inserted at this juncture by proposing that the H tone of the object prefix and the H tone of the verb stem fuse into a single multiply linked H tone. As a consequence, there is a single H tone and insertion of downstep cannot occur (since downstep is used only between H tones).

In all the preceding examples, we have dealt with situations where an input would violate *HH and formally different rules operate to alter the representation so that it no longer has a H H sequence. The OCP ban *HH is manifested in other ways in the grammars of the world's languages. Recall from our discussion of Yawelmani how the ban on complex margins may serve to restrict the application of vowel deletion rules. The same thing can be observed in tonal systems: the ban on *HH may restrict the application of other tone rules. The most commonly observed phenomenon where *HH plays a restrictive role on another tonological process is in H-tone spreading. The precise formulation of H-tone spreading differs from language to language (at least in a rule-based model of phonology), but one overarching pattern is that spreading may be prevented from going onto a mora that itself is adjacent to a H-toned mora. It should be observed that in some languages, it is not spreading but shifting (i.e. spreading of a H followed by a delinking from all but the last mora in the spreading structure) that is blocked.

For example, in Isixhosa (cf. Cassimjee and Kisseberth 1998) the H tone on the subject prefix /bá-/ shifts to the following toneless syllable in [ba-yá-lwa] but is unable to do so in [bá-ya-bóna] due to the fact that the prefix /ya/ is followed in this case by a H-toned syllable. (As in our earlier examples, a mora that bears an underlying H tone is underlined.) Sometimes the adjacency of the H tones may be obfuscated. In Isixhosa the H on /bá-/ does not shift in [bá-ya-bonísa], even though at first glance it does not seem that the /ya/ is adjacent to a H-toned syllable. The problem in this example is that there is a H tone on the syllable /bó/ in the input, but in the output this H tone has shifted to the following syllable. What we observe here is the much discussed problem of phonological opacity: the H-toned nature of /bo/ serves to block spreading onto the syllable in front of it, even though in fact /bo/ is toneless on the surface.

The preceding discussion shows that if we look at *HH (an instantiation of the OCP) across a diverse set of languages, we find that it is entirely parallel to the constraint against complex margins in the synchronic grammar of Yawelmani. There is a "functional" unity that unites all these diverse ways of avoiding HH sequences: they are working towards the same end, representations that lack HH sequences. Any theory (such as generative phonology) that sees rules as devices that marry a structural change to a structural description will fail to express the universal principle *HH.

3.3 *Phonological conspiracies in phonological acquisition*

Much of the work on the child's acquisition of the phonology of a language assumes that the child accurately perceives (for the most part) the data to which s/he is exposed, but that various markedness principles (e.g. preferences for open syllables, preferences for oral over nasal vowels, preferences for stops over fricatives) restrict the child's attempt to produce an output faithful to that perception (CHAPTER 101: THE INTERPRETATION OF PHONOLOGICAL PATTERNS IN FIRST LANGUAGE ACQUISITION). As early as the extremely important work of Smith (1973), it was recognized that the notion of conspiracies is as relevant to child phonology as it is to adult phonologies. Smith proposed various rules to account for the fact that the child Amahl simplified consonant clusters in adult speech, but just as in Yawelmani, the unity found in the child's output was not reflected in the diversity of the rules that achieved this unity. Smith recognized this as a failing of his rule-based, derivational approach. Naturally, constraint-based approaches such as OT have gained currency in the field of phonological acquisition, at least in part because of their ability to capture conspiracies better in child language acquisition. It should be clear from the discussion throughout this chapter that "conspiracies" are first and foremost attempts to achieve an unmarked structure or avoid a marked structure. Since markedness principles serve to shape the child's outputs, it follows that we will expect conspiracies to be manifested.

Space considerations limit us to a single instance of a conspiracy in phonological acquisition. Pater (2002) and Pater and Barlow (2003) discuss the ban on fricatives, *FRICATIVE, which can be observed in the data on phonological acquisition (see also CHAPTER 28: THE REPRESENTATION OF FRICATIVES). The common repair of this constraint is for a fricative to be converted to the corresponding stop. Pater discusses a child LP65, aged 3:8 with a phonological delay, who in acquiring English lacked fricatives entirely from her output. However, adult English forms were repaired in two different ways: the deletion of the fricative or the stopping of the fricative. The choice of the repair was dependent on the adult input. If the fricative was part of a cluster, it was deleted. If it was not part of a cluster, it was converted to the corresponding stop. Thus *sneeze* became [ni:d], *three* became [wi], *drive* became [waɪb]. Two different repairs secure the absence of fricatives, one of the many examples of conspiracy in the acquisition literature.

3.4 Conspiracies in loanword phonology

When speakers of L1 adapt words from L2 for use in speaking their native language, some of these words may contain structures that violate a constraint operative in L1. If these words are fully nativized, then these structures will be altered so as to avoid violations of the constraint in question. If the notion of conspiracies is applicable to the phenomenon of loanword adaptation then we expect that there will be cases where a given constraint will be enforced by means of quite distinct adaptation strategies (see also CHAPTER 95: LOANWORD PHONOLOGY).

In the Australian Aboriginal language Gamilaraay, words must end either in a vowel or a coronal sonorant ([n j l rr]), according to McManus (2008). If Gamilaraay borrows an English word that ends in a consonant that is permitted word-finally, then that consonant will surface. Thus English *barrel* is realized as [baril], and *poison* as [baadjin]. When an English word ending in a labial or dorsal consonant is borrowed, an epenthetic vowel appears. This epenthetic vowel obviously functions to avoid a disallowed coda consonant. Some examples of epenthesis are given in (11).

(11)	baaybuu	'pipe'	nhaayba	'knife'
	dhuubuu	'soap'	yurraamu	'rum'
	milgin	'milk'	yurrugu	'rope'

However, when the English word ends in one of the coronal obstruents, which are not allowed in a word-final coda, an epenthetic vowel is *not* inserted; rather, the coronal is converted to a sonorant.

(12)	bulaang.giin ~ bulang.giin	'blanket'	burrgiyan	'pussy cat'
	marrgin	'musket'	yuruun ~ yurruun	'road'
	dhalbin	'tablet'		
	garaarr	'grass'	nhiigiliirr	'necklace'
	dhindirr	'tin dish'	maadjirr	'matches'
	yarrarr	'rice'	gabirr	'cabbage'

Gamilaraay employs both vowel epenthesis and the sonorization of a consonant to achieve an output where every output ends in a vowel or a sonorant coronal. Two formally distinct alterations yield an output that conforms to the same regularity.

4 The optimality-theoretic analysis of conspiracies

In the preceding section we provided some illustration of the relevance of the notion "conspiracy" in various domains of phonology. An examination of the phonological literature over the four decades since the publication of FUPR is rife with examples of the phenomenon. Although FUPR identified a facet of phonological structure that is no doubt of critical importance to the theory of phonology, it failed to offer a comprehensive solution to the problem that conspiracies pose. In addition, it failed to raise a significant question: *why* do conspiracies exist? Why do languages not employ a single device to achieve a preferred structure or to avoid a structure that is not preferred?

Optimality Theory provides the essential ingredients of both a comprehensive account of conspiracies and an explanation for why universal "rules" may not be reflected in the outputs of particular languages. By separating the constraints from the actions that repair potential violations of these constraints, it allows a constraint to both trigger some actions while preventing others. Thus *ComplexMargins can both trigger the appearance of an epenthetic vowel and block the elision of a vowel if elision would violate *ComplexMargins. OT is not a theory of actions, but rather a theory of how constraint interactions account for the pattern of observed actions. At the same time, the existence of highly ranked faithfulness constraints may prevent a constraint violation from being repaired at all in some languages.

Optimality Theory also explains why conspiracies occur, and can perhaps even be expected. Given a constraint such as *ComplexMargins, there are several different repairs that might avoid complex margins. However, each of these actions necessarily violates some other constraint (at the same time that they avoid a violation of *ComplexMargins). The constraints that the repair violates may be a faithfulness constraint, a markedness constraint, or some sort of morphological constraint. Since these other constraints have a particular ranking, this ranking will determine which repair to *ComplexMargins is optimal in a given situation.

Almost any optimality-theoretic description of a language will offer clear evidence that it has provided an insightful account of conspiracies. There is, however, a significant problem with the OT analysis of conspiracies. Specifically, for any constraint C, there are many logical "actions" that might repair a representation so that C is not violated. OT seems to claim that any of these actions could occur in some language. But is this in fact true? Various linguists have suggested that it is not true that all "repairs" for the violation of a constraint are in fact possible. This has been labeled the "Too Many Solutions" problem (cf. Steriade 2001, 2009). For example, Steriade considers the constraint that disfavors voiced obstruents at the end of a word. She notes that there are a considerable variety of phonological actions that might result in outputs that do not violate this constraint. Taking an input with a final /b/ as an example, the following repairs could avoid a violation of the constraint: (a) the devoicing of the /b/ to [p], (b) the nasalization of the /b/ to [m], (c) the lenition of /b/ to [w], (d) deletion of the /b/, (e) the insertion of an epenthetic vowel after /b/, and (f) the metathesis of the /b/ with a preceding consonant that does not violate the constraint, etc. Steriade argues, however, that in fact it is only devoicing that is utilized to repair violations of the ban on word-final voiced obstruent.

The "Too Many Solutions" problem is a critical issue for Optimality Theory, since it calls into question the foundation of the theory – i.e. the separation of phonological actions from the constraints on structure that trigger these actions. It was the need to find an account of conspiracies that led to an abandonment of "rules" in favor of a set of constraints whose ranking determines the optimal action. So it is natural that a challenge to its analysis of conspiracies is at the same time a challenge to its very foundations.

There have been various attempts to solve the "Too Many Solutions" problem in OT: the "P-map" proposal in Steriade (2001, 2009), the "targeted constraints" in Wilson (2001), and the appeal to procedural markedness principles ("implicational constraint principle") in Blumenfeld (2006) are examples. It is beyond the scope of this chapter to explore the adequacy of these different attempted solutions, but there is no question that the issue is a central one in the exploration of OT approaches to phonology. Despite the challenges to the OT account of conspiracies, there is no doubt that much of the motivation for Optimality Theory resides in the advances that it made in explaining conspiracies, and these advances have been considerable indeed.

5 Conclusion

In this chapter we have explained the notion "conspiracy" in phonology and have illustrated its relevance to several domains of phonological investigation: synchronic grammars, phonological universals, the acquisition of phonology, and loanword adaptation. We have attempted to explain the historical background out of which the notion emerged, specifically the attempt to find what is universal in systems of phonological rules, and the reasons why an adequate solution was not available. We concluded with the observation that while Optimality Theory goes a long way towards providing an insightful account of conspiracies, it must still deal with the Too Many Solutions problem.

71 Palatalization

Alexei Kochetov

1 Introduction

The term "palatalization" denotes a phonological process by which consonants acquire secondary palatal articulation or shift their primary place to, or close to, the palatal region. This usually happens under the influence of an adjacent front vowel and/or a palatal glide (e.g. [ki] → [kʲi], [tja] → [tʃa]). As such, palatalization is a type of consonant–vowel interaction. The term may also refer to a phonemic contrast between consonants with secondary palatal articulation and their non-palatalized counterparts (e.g. [pʲa] *vs.* [pa]). The primary focus of this chapter will be on palatalization as a process, and particularly as a synchronic phonological process manifested in segmental alternations.

Palatalization has been typically viewed as a classic example of a "natural" phonological process – one that is widely attested across world languages and has a clear phonetic motivation, such as in consonant-to-vowel co-articulation (e.g. Hyman 1975; see also CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). However, many formal accounts of palatalization undertaken over the last 40 years have faced considerable challenges. These challenges partly stem from the fact that palatalization processes show a wide range of manifestations – across languages and within a given language. Many synchronic palatalization processes also exhibit complex phonological and morphological conditioning and pervasive opacity effects, reflecting complicated historical sound changes and paradigmatic restructuring. Given this, the difficulty faced by many theoretical approaches has been in providing an empirically adequate and uniform formal treatment of the phenomenon, capturing both cross-linguistic and language-particular generalizations. The goal of this chapter is to review some of the key formal accounts of palatalization, focusing particularly on the challenges posed by the phenomenon for generative theories of phonological representations.

The chapter is organized as follows. §2 presents some concrete examples of palatalization, followed by an overview of cross-linguistic patterns of the phenomenon. §3 examines how the feature system of the early generative phonology captures natural classes involved in palatalization. §4 focuses on two key approaches to palatalization within the feature geometry framework. §5 turns to treatments of palatalization within Optimality Theory, and §6 concludes with a review of some alternative proposals.

2 Background

2.1 *Some examples*

We will begin with some relatively well-known examples of palatalization. English has at least three kinds of alternations that fall under the general definition of palatalization processes. *Coronal palatalization* involves an alternation between alveolars [t d s z] and palato-alveolars [ʧ ʤ ʃ ʒ], as shown in (1). In these examples, the palato-alveolars occur before a palatal glide (in an unstressed syllable), while alveolars occur elsewhere. These alternations can be analyzed as a process – a change of alveolars to palato-alveolars in the context of [j] (Chomsky and Halle 1968; Borowsky 1986; among others).[1] The process is assimilatory in the sense that the consonants targeted by palatalization become more similar in place of articulation to the segment that triggers palatalization. Note that stops not only shift in place, but also undergo assimilation (becoming sibilant affricates). All the other features of the target consonants (e.g. continuancy, voicing, etc.) remain unchanged.

(1)	t – ʧ	*perpe*[t]*uity*	*perpe*[ʧ]*ual*
	d – ʤ	*resi*[d]*ue*	*resi*[ʤ]*ual*
	s – ʃ	*gra*[s]*e*	*gra*[ʃ]*ious*
	z – ʒ	*plea*[z]*e*	*plea*[ʒ]*ure*

The second process – *velar softening* – is exhibited by alternations between velar stops [k g] and coronal fricatives or affricates [s] and [ʤ], respectively. The coronal alternants are found before certain Latinate or Greek suffixes beginning with (mainly) front vowels; the velar alternants are found elsewhere (2). Given this, the alternations are usually analyzed as a palatalizing change of velars to coronals triggered by front vowels (Chomsky and Halle 1968; Borowsky 1986). Unlike coronal palatalization, this process is more complex, as it actually involves two non-identical changes – a shift of the voiced velar stop to the palato-alveolar affricate and a shift of the voiceless velar stop to the alveolar fricative. While the outputs of velar softening are not identical in terms of minor place of articulation and continuancy, they are both sibilant coronals.

(2)	a.	k – s	*medi*[k]*ation*	*medi*[s]*ine*
			criti[k]	*criti*[s]*ize*
	b.	g – ʤ	*analo*[g]	*analo*[ʤ]*y*
			pedago[g]*ue*	*pedago*[ʤ]*y*

The third process – *spirantization* – exhibits alternations between the alveolar stop [t] and the alveolar fricative [s] (or [ʃ] in conjunction with coronal palatalization). The latter segment occurs before suffixes with an unsyllabified /i/ (3), and this process is assumed to involve a change of stop to fricative before high front vowel (Borowsky 1986). As such, the process does not involve a change in place

[1] Similar, albeit optional and phonetically gradient, alternations are also exhibited across words, as in *go*[ʧ] *you*, *plea*[ʒ]*e yourself*, etc. (Zsiga 1993).

of articulation, but a change in continuancy and sibilancy (CHAPTER 28: THE REPRESENTATION OF FRICATIVES).

(3)	t – s	*secre*[t]	*secre*[s]*y*
		regen[t]	*regen*[s]*y*
		emergen[t]	*emergen*[s]*y*
		par[t]	*par*[ʃ]*ial*

The three palatalization processes manifested by the alternations in (1)–(3) differ in several respects. The targets of palatalization are anterior coronals (alveolars) in (1) and (3), and dorsals in (2). The outputs are posterior coronals (palato-alveolars) in (1) and (2b), and anterior coronals in (2a) and (3). The triggers are /j/ in (1), and high front vowels in (2) and (3). (The processes are also different in terms of their phonological or morphological conditioning: morpheme boundaries, particular suffixes, stress, etc.) What the processes have in common, however, is that they appear to be triggered by front vocoids and result in coronal segments, notably, all sibilants. As such, they are representative of the three general types of palatalization processes defined by Bhat (1978): "coronal raising" (1), "velar fronting" (2), and "spirantization," which may or may not be accompanied by change in place ((2) and (3) respectively), as discussed in the next section.

Another important type of palatalization, not exhibited by the English processes, is an addition of secondary palatal articulation, without a change in primary place or assibilation. As shown in (4a), Russian exhibits alternations between non-palatalized consonants of all places – labials, anterior coronals (dentals), and dorsals –and their palatalized counterparts (CHAPTER 121: SLAVIC PALATALIZATION). The palatalized segments in such alternations occur before front vowels (/e/ in (4a)), while non-palatalized consonants are unrestricted (Kenstowicz and Kisseberth 1979). These alternations can be straightforwardly analyzed as an assimilatory process involving a simple addition of secondary palatal articulation (the high front position of the tongue body) before front vowels. This process in Russian is fairly general, and is not restricted to particular morphological categories. Secondary palatalization may co-occur in a given language with "place-changing" palatalization. In Russian, non-palatalized dentals and velars also exhibit alternations with palato-alveolars, with the latter occurring before certain verbal suffixes (4b) (Lightner 1965; Kenstowicz and Kisseberth 1979). Note that the palatalizing suffixes may or may not begin with overt front vocoids, showing that place-changing palatalization in Russian is a more opaque, morphologically conditioned process. Note also that the relation between targets and outputs of palatalization in (4b) is less transparent than in (4a): for example, the same palato-alveolar output [ʧ] can result from two different target consonants, /t/ or /k/.

(4)	a.		*nom sg*	*dat sg*		
		$p – p^j$	trap-a	$trap^j$-e	'path'	
		$t – t^j$	s^jirat-a	$s^j irat^j$-e	'orphan'	
		$k – k^j$	sabak-a	$sabak^j$-e	'dog'	
	b.		*inf*	*3 pers sg*	*1 pers sg*	
		t – ʧ	$pr^j at$-at^j	pr^jaʧ-it	pr^jaʧ-u	'hide'
		k – ʧ	plak-at^j	plaʧ-it	plaʧ-u	'weep'

Palatalization in Russian produces outputs that are phonemic, since the language has palatalized consonants and posterior coronals whose occurrence is not conditioned by front vowels. The same can be said about the English palatalization processes. Allophonic palatalization is also quite common, however. In Nupe (5), for example, the velars have secondary palatal articulation before front vowels (5a), secondary labial articulation before round vowels (5b), and no secondary articulation before the back unrounded /a/ (5c). This pattern can be analyzed as an allophonic assimilatory process involving palatalization and labialization of phonemic plain velars before front and round vowels respectively (Sagey 1990; Archangeli and Pulleyblank 1994).

(5)	a.	/egi/	egʲi	'child'
		/ege/	egʲe	'beer'
	b.	/egũ/	egʷũ	'mud'
		/ego/	egʷo	'grass'
	c.	/ega/	ega	'stranger'

So far we have examined fairly representative examples of palatalization, those involving changes that are common across world languages. It is worth contrasting these examples with that from two Southern Bantu languages, Tswana and Swati, shown in (6). Here, labials alternate with (labialized) palato-alveolars in the context of the passive suffix /-wa/. Consonants of other places remain unaffected (cf. Tswana [ratʷa] /rat-wa/ 'love'; Swati [pʰegʷa] /pʰeg-wa/ 'cook'). These alternations are also considered to manifest palatalization (Halle 2005; Bateman 2007); however, the process is different from the cases above in several important respects. First, the targets are labial consonants to the exclusion of the other places, and the labials change their place of articulation, something that is usually restricted to coronals and dorsals. (Coronals, however, do undergo palatalization in other contexts.) Second, the trigger of the process, the suffix /-wa/, does not contain an overt or even an underlying front vocoid, but presumably develops it as a result of labial dissimilation (Kotzé and Zerbian 2008). Third, the process in Swati is not strictly local, as it can target labials occurring in non-adjacent syllables. All this makes palatalization in Tswana and Swati (and similar processes in other Southern Bantu languages) a relatively "unnatural" case in the typology of palatalization, as we will see below.

(6)		*non-passive*	*passive*		
a.	*Tswana*				
	p – ʧʷ	lɔpa	lɔːʧʷa	/lɔp-wa/	'request'
	pʰ – ʧʰʷ	tlʰʊpʰa	tlʰʊːʧʰʷa	/tlʰʊpʰ-wa/	'choose'
	b – ʤʷ	roba	rɔːʤʷa	/rob-wa/	'break'
b.	*Swati*				
	b – ʤ	hamb-	hanʤʷa	/hamb-wa/	'go'
	ɓ – ʧʼ	seɓenta	seʧʼentʷa	/seɓent-wa/	'work'
	pʰ – ʃ	sipʰula	siʃulʷa	/sipʰul-wa/	'uproot'

The examples from English, Russian, Nupe, Tswana, and Swati provide a snapshot of a vast range of variation found in palatalization processes both within and across languages. Of particular interest here are the variation and preferences in terms of featural composition of segmental classes involved in palatalization – its triggers, targets, and outputs. There are clearly many other theoretically important issues relevant to palatalization – including those of allophonic/phonemic status, morphological or lexical conditioning, locality, etc.; these, however, are beyond the scope of this chapter (on some of these topics, see CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION; CHAPTER 81: LOCAL ASSIMILATION; CHAPTER 88: DERIVED ENVIRONMENT EFFECTS; CHAPTER 121: SLAVIC PALATALIZATION).

2.2 *Typological patterns of palatalization*

To better understand the complexity of the phenomenon, it is useful to examine cross-linguistically more and less common patterns of palatalization. The following discussion is based on the author's survey of synchronic palatalization processes, with some reference to the earlier often-cited survey by Bhat (1978), and the more recent one by Bateman (2007).[2] (See also Chen 1973, Kochetov 2002, and Stadnik 2002 for surveys specific to certain geographic areas or phonological contrasts.)

The survey covers cases of palatalization as exhibited by segmental alternations (as opposed to phonotactic restrictions or historical changes) selected from theoretical phonological literature for the purposes of this chapter. Altogether, it contains data from 64 languages and dialects belonging to 17 language families and 25 genera. We will begin with observations about targets and outcomes of palatalization, and corresponding general types of palatalization processes. The focus will be on changes targeting labial, (anterior) coronal, and dorsal stops. Table 71.1 represents three general processes of palatalization: secondary palatalization

Table 71.1 Targets and outputs of palatalization (alternations only) and corresponding processes, and their relative frequency in world languages (based on numbers of language families and genera, given in square brackets; see the text for details)

Type	*Palatalization*		*labial*	*coronal*	*dorsal*
I	Secondary		$p \rightarrow p^j$ common [6, 9]	$t \rightarrow t^j$ common [6, 8]	$k \rightarrow k^j$ common [6, 7]
II	To a posterior coronal	a. to a non-sibilant	p → c rare [1, 1]	t → c common [7, 8]	k → c common [4, 6]
		b. to a sibilant	p → tʃ rare [1, 1]	t → tʃ common [9, 14]	k → tʃ common [4, 7]
III	To an anterior coronal	a. to a non-sibilant	p → t absent [0, 0]	n/a	k → t absent [0, 0]
		b. to a sibilant	p → ts rare [1, 1]	t → ts common [3, 6]	k → ts rare [2, 4]

[2] The latter two studies have certain limitations with respect to the goals of this chapter. Although quite extensive, Bhat's survey does not clearly distinguish between synchronic processes and historical sound changes, of which only the former are relevant here. Bateman's survey, while drawing on a genetically balanced language sample and focusing on synchronic processes, is restricted to only certain types of palatalization processes, leaving out, for example, place-changing palatalization of labials and changes resulting in anterior coronals. The latter types are important for our discussion, as these are the ones that have been most problematic for theoretical accounts.

(Type I), palatalization resulting in a posterior coronal (palato-alveolar or (alveolo-)palatal; Type II), and palatalization resulting in an anterior coronal (alveolar or dental; Type III). The Type II process can produce either non-sibilants or sibilants, resulting in two subtypes ((a), (b)). The same subdivision is given for the Type III process. Columns on the right schematically present typical (or expected) changes involved in each process, depending on the target consonant – labial, coronal, or dorsal. (To avoid cluttering the table, voiceless stops/ affricates stand here for segments regardless of their laryngeal specification, e.g. "ʧ" can include [ʧ˺], [ʧʼ], [ʧʰ], or [ʤ]; changes in continuancy are not noted, e.g. "k → ts" includes the changes to [ts] or [s].) To facilitate the comparison, each change is labeled as "common," "rare," or "absent," indicating its relative frequency in the sample, based on numbers of separate language families and genera (given in parentheses), rather than individual languages.[3] (See the online version of this chapter for examples of the processes.)

Note that the typology of processes in Table 71.1 is compatible with the typology of changes in Bhat (1978), whose terms are based on *SPE* (Chomsky and Halle 1968) feature terminology (see §3.1). Taking coronal targets as an example, Type I and Type IIa correspond to Bhat's process of alveolar "raising" without "spirantization" (i.e. [−high] → [+high] in *SPE* notation), Type IIb corresponds to "raising" accompanied by "spirantization" (i.e. [−high, −strident] → [+high, +strident]), and Type IIIb corresponds to "spirantization" without "raising" (i.e. [−strident] → [+strident]). Bhat's terms are not fully appropriate for our purposes, as they do not distinguish between secondary and place-changing palatalization, in addition to being tied to a specific feature framework. Place-changing processes (Types II and III) involving non-coronals have also been referred to as "coronalization" (Hume 1992; Flemming 2002).

What is interesting about the different types of palatalization shown in Table 71.1 is that certain targets and outputs (and the corresponding processes) are common, while others are rare or unattested. Overall, there is a tendency for place-changing palatalization to result in sibilants rather than non-sibilants. While both sibilants and non-sibilants are possible outputs for Type II palatalization, only sibilants are possible for Type III palatalization. Another important observation is that labials as targets of place-changing palatalization processes (Types II and III) are exceedingly rare, compared to coronals and dorsals. The only examples of labial place-changing palatalization (with stops as targets) in the sample are Southern Bantu languages (see (6)) and Moldova Romanian (e.g. [plop] 'poplar tree', [ploc] /plop-i/ (PLURAL); [drob] 'block (of salt)', [droɟ] /drob-i/ (PLURAL); Bateman 2007). Among the other two place categories, coronals as targets tend to occur overall more frequently than dorsals. Notably, the most common palatalization process is a change of alveolars to palato-alveolars (Type IIb), attested in nine language families and 14 genera. Further examination of the cases (Table 71.2) shows that in a given language, coronals and dorsals can be targeted

[3] As an example, Type IIb coronal palatalization in English (1) and Russian (4b) represents a single case of palatalization at the level of family (Indo-European), and two separate cases at the level of genus (Germanic and Slavic). This allows for an estimation of cross-linguistic frequency that is relatively conservative and less biased toward certain language families or genera. For expository reasons, "common" changes are defined as occurring in at least three or more families, and "rare" changes occur in one or two families. The study uses the language classification from Haspelmath *et al.* (2005).

Table 71.2 Targets of palatalization and their relative frequency in world languages

Target consonants	*Occurrence*
coronal only	common [13, 16]
dorsal only	common [4, 6]
labial only	absent [0, 0]
coronal and dorsal	common [3, 5]
coronal and labial	rare [1, 1]
dorsal and labial	absent [0, 0]
coronal, dorsal, and labial	common [6, 9]

by palatalization independently or together, while labials are targeted only when coronals (and dorsals) are targeted too (but see (6)). This suggests implicational relations among targets of palatalization, with place-changing palatalization of labials implying palatalization of coronals and dorsals (cf. Chen 1973; Foley 1977; Bhat 1978). The results of the survey are also indicative of a greater propensity of coronals to palatalization, compared to dorsals. This is consistent with some previous studies (cf. Bateman 2007), while in part contradicting those based on more limited language samples or mixed synchronic/diachronic data (Chen 1973; Foley 1977; see §3.2).

Turning to triggers of palatalization, Table 71.3 shows that these include front vocoids (vowels and glides) that differ in height and high vocoids that differ in backness. Non-high back vowels do not trigger palatalization. Among all the triggers, high front /i/ and /j/ are the most likely triggers, followed at a considerable distance by mid front vowels. Recall that these are the triggers in all examples shown above (leaving aside the more opaque Bantu cases). Examples of the rare types of palatalization triggered by front low vowels or high back vocoids include Slovak ([vnuːʧa] /vnuːk-æ/ 'grandson-DIM'; Hume 1992) and Lomongo ([konʤwá] /kond-wa/ 'cover with sand-PASS'; Kenstowicz and Kisseberth 1977). It is important to note that in a given language, low and mid front vowels

Table 71.3 Triggers of palatalization and their relative frequency in world languages

Trigger Backness	Height		*Occurrence*
front only	high only	i/j	common [17, 24]
front only	high and mid	i/j, e/ɛ	common [4, 5]
front only	high, mid, and low	i/j, e/ɛ, æ	rare [1, 1]
front only	mid/low	e/ɛ/æ	absent [0, 0]
front and back	high only	i/j, i/u/w	rare [1, 1]
back only	high only	i/ɯ/ɰ	absent [0, 0]
back	mid/low	ɑ/ə/o/ɔ	absent [0, 0]

apparently only trigger palatalization if high front vowels trigger it too.[4] Similarly, non-front high vocoids are triggers when front high vocoids are also triggers. These observations are indicative of implicational relations between vowel height/frontness and the ability to trigger palatalization (cf. Chen 1973; Foley 1977; Bateman 2007). Further, there are some interesting dependencies between triggers and targets. Coronals tend to be targeted by high vocoids, and especially by /j/, while dorsals are almost exclusively targeted by /i/ and other front vowels (see Bhat 1978: 52–56 for details).

In terms of directionality, palatalization processes can be regressive (right-to-left) or progressive (left-to-right). Both types are quite common, with regressive palatalization attested in eight families and sixteen genera, and progressive palatalization in nine families and nine genera (mainly in the Americas). Some languages show both types, although in different morphological/phonological contexts, as, for example, Chimalapa Zoque (7a) (Kenstowicz and Kisseberth 1977). The overwhelming majority of palatalization processes are local, triggered by immediately adjacent vocoids. In a few cases, however, palatalization can apply across a consonant, as in Barrow Inupiaq (7b) (Archangeli and Pulleyblank 1994), or across one or more syllables as in Harari (7c) (Rose 1997; cf. Swati in (6)).

2.3 *Summary*

Our examination of particular cases and cross-linguistic patterns of palatalization processes reveals a number of asymmetries involving targets, triggers, and outputs. Some of the key observations are restated in (8). First, certain places of articulation are better targets of palatalization than others (8a). Among the three places, the key difference is between coronals and dorsals on one hand and labials on the other. Another important difference is between coronals and non-coronals. Second, certain vowels/glides are better triggers of palatalization than others (8b). In particular, front vowels are considerably better triggers than non-front vowels, and among the former class, high vowels are the best triggers, and low vowels the worst. Third, there are important dependencies between the vowel height (and syllabicity) of triggers and the place of targets (8c). Fourth, outputs of palatalization are either palatalized consonants or coronals; among the latter, posterior coronals and/or sibilants are the preferred outputs (8d). In addition, all but a few cases of palatalization are local, triggered by immediately preceding or following vocoids.

[4] Bhat (1978) mentions some cases where mid front vowels palatalize velars to the exclusion of high front vowels. None of these cases, however, appears to involve alternations.

(8) *Main typological generalizations about palatalization*
(">" = "better than, more likely than")

a. *Target place asymmetry (place-changing palatalization)*
   i. coronal, dorsal > labial
   ii. coronal > dorsal, labial

b. *Trigger asymmetry*
   i. (high) front > high central/back
   ii. high front > mid front > low front

c. *Trigger–target dependencies*
   i. front vowels and dorsals
   ii. high vocoids (especially /j/) and coronals

d. *Output asymmetries*
   i. posterior > anterior
   ii. sibilant > non-sibilant

It should be noted that as a type of consonant–vowel interaction, palatalization is somewhat unique (see CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). Although other consonant-to-vowel assimilation processes commonly result in consonants with secondary vowel articulations (t → t^w / __ u), they hardly ever exhibit synchronic shifts in primary place of articulation (t → p or k / __ u) (cf. Ní Chiosáin and Padgett 1993). If such alternations are indeed observed, they appear to imply palatalization alternations, as in Ikalanga, where vowels (through gliding) trigger both place-changing velarization and palatalization (9) (Mathangwane 1996). In addition, unlike palatalization, hardly any other vowel–consonant interactions affect consonant manner features, in a way that, for example, produces sibilant affricates or fricatives from stops. Equally implausible are the processes that would produce the reverse effect of place-changing palatalization, for example, converting sibilant coronals to coronal or non-coronal stops (ʧ → t or k). All this underscores the seemingly unique place of palatalization in the typology of consonant–vowel interactions, and its highly asymmetric nature.

	semé	seɲáná	/seme-ana/	'basket'

What makes palatalization so special? Why are some patterns of palatalization cross-linguistically more common, while other patterns are rare or unattested? It has long been known that the naturalness of many palatalization processes has its roots in phonetics – articulation and perception. As Hyman (1975: 171) noted in his discussion of velar palatalization, gradient fronting of a [k] before [i] is a phonetic process that is universal, shared by all languages. The two articulatory gestures – the tongue body backing for [k] and the tongue body fronting for [i] – simply cannot be co-produced without this co-articulatory adjustment. In this sense, the process is automatic, part of the "universal phonetics" (although the degree of velar fronting can be language-particular). Further, fronted velars or palatals tend to be produced with greater frication at the release, which makes them acoustically more similar to palato-alveolar affricates. Given this acoustic similarity, the former are often auditorily confused with the latter (but not the reverse), resulting in common historical shifts of velars to palato-alveolars (Guion 1996). The change [k] → [ʧ] before [i] is therefore motivated by both articulation and perception. Similar articulatory, and possibly perceptual, reasons underlie the change of [t] → [ʧ] before [j] or [i] – presumably arising due to overlap of the tongue tip and tongue body gestures, producing a more retracted laminal constriction with a turbulent sibilant-like release (Zsiga 1993). In contrast, the articulation of [p] before [j] or [i] presents no articulatory difficulties, as the two gestures – the lips and the tongue body – are physically uncoupled and therefore can be freely co-produced. Despite some frication at the release, [pʲ] is still quite acoustically different from [ʧ] and is thus less likely to be confused with the former. This suggests that unlike dorsal and coronal palatalization, labial palatalization is phonetically much less plausible, and therefore phonologically less natural. Indeed, comparative historical evidence suggests that cases of labial palatalization have arisen through "telescoping" – a series of historical changes involving glide strengthening and cluster simplification (Hyman 1975; Bateman 2007). In fact, different stages of these developments are often reflected in closely related languages or dialects, as the case with Tswana and Moldova Romanian (10) (Udler 1976; Kotzé and Zerbian 2008). Finally, the lack of phonetic motivation can explain some of the asymmetries in triggers of palatalization (e.g. high front vocoids *vs.* low and back) and the unnaturalness of changes reverse to palatalization (e.g. [t̢ʃ] → [t] or [k]).

While the diachronic phonetic sources of palatalization have rarely been debated, most phonologists would agree that at least some of the common patterns and important asymmetries in palatalization in (9) (or any phonological process) require synchronic explanation (but see §6). Further, regardless of historical changes, it is commonly agreed that synchronic grammars should have ways of modeling palatalization alternations (as in English or Russian) or allophonic variation (as in Nupe). Yet the question of how to represent the process synchronically while capturing relevant significant generalizations has proven to be difficult, if not impossible. It is remarkable that almost 40 years after the first generative account of English velar palatalization in Chomsky and Halle (1968), Halle (2005: 23) concedes that "to this time there has been no proper account of palatalization that would relate it to the other properties of language, in particular, to the fact that it is found most commonly before front vowels." This is despite the fact that palatalization has received extensive treatment in early generative phonology, autosegmental phonology, and more recently Optimality Theory. The goal of this chapter is to review some of the influential theoretical treatments of palatalization as a synchronic process, while focusing particularly on distinctive features and feature geometry representations as ways of capturing the naturalness of common palatalization processes. As we will see, some of the problems encountered by formal models of palatalization can be attributed to the complexity of the phenomenon; other difficulties, however, seemingly stem from the reliance on a universally fixed, closed set of rigid, unidimensional representations. We will also examine other formal ways of capturing relevant generalizations using constraints and constraint hierarchies or more phonetically detailed representations in Optimality Theory, and conclude with a brief review of some recent alternative proposals that challenge traditional generative assumptions.

3 Palatalization in early generative phonology

3.1 *Distinctive features and marking conventions of* SPE

One possible way of capturing the naturalness of phonological processes is through stating natural classes of segments involved (as triggers, targets, and outputs), using distinctive features (CHAPTER 17: DISTINCTIVE FEATURES). The concept of natural classes encoded by a universal set of features has been an important part of generative phonology since Chomsky and Halle (1968; *SPE*). The distinctive features in *SPE* were exclusively articulatorily based (unlike the auditorily based features of Jakobson *et al.* 1952). One proposal that has important theoretical consequences for our discussion is the use of features [±high], [±back], and [±low] for both vowels and consonants. Among the latter, these features are used as "a natural manner to characterize subsidiary consonant articulations such as palatalization, velarization, and pharyngealization" (*SPE*: 305), which are defined as [−back, −low], [+back, −low], and [+back, +low], respectively. This proposal was intended to capture the fact that secondary articulations tend to occur before vowels of the same qualities, for example, palatalized consonants before front vowels (cf. Nupe (5)). The feature specification thus allowed one to state these restrictions as "an obvious case of regressive assimilation" (*SPE*: 308). In addition, the proposal captured a cross-linguistic observation that the three types of secondary articulations are mutually exclusive, since, for example, palatalized consonants cannot be simultaneously velarized or pharyngealized. These feature specifications also helped in the formulation of typical vowel raising and fronting changes in the environment of palatalized consonants as a simple case of assimilation. An example from Russian is shown in (11a), where underlying vowels /e/ and /a/ shift to [i] when occurring after a palatalized consonant in an unstressed syllable (Kenstowicz and Kisseberth 1979). An *SPE*-style rule capturing the process is stated in (11b).

(11)	a.	*1st plural*	*1st singular*	
		ˈpʲiʃim	pʲiˈʃu	'write'
		ˈmʲetʃim	mʲiˈtʃu	'throw'
		ˈvʲaʒim	vʲiˈʒu	'bind'
		ˈmaʃim	maˈʃu	'wave'
	b.	[+syll, −high] → [+high, −back] / [−syll, +high, −back] __		

Note that in this respect the *SPE* feature system is a step forward compared to Jakobson *et al.*'s (1952) system, where consonants with secondary articulations and corresponding vowels did not share the same feature values. For example, palatalized consonants were specified for [+sharp] (and [+grave] or [−grave]), while (high) front vowels were [−sharp] and [−grave].

The *SPE* specification for [+high, −back] was not limited to high front vowels and palatalized consonants, but also extended to palatals and postalveolars. This is important, because it naturally grouped together common triggers and outputs of palatalization processes (Types I and II). The feature system, however, treated palatals as non-coronals and grouped them with velars: both are [−coronal, −anterior, +high] and differ in [±back]. Notably, palatalized velars were not distinguished from palatals (both are [−coronal, −anterior, +high, −back]). These two specifications created certain problems. First, Type I (secondary) palatalization was represented as two different featural processes: a change from [−high] to [+high] (raising) for coronals and labials (which are [±coronal, +anterior, −high, −back]), and a change from [+back] to [−back] (fronting) for velars. This also predicted – partly incorrectly – that palatalization of velars should be triggered by front vowels only (regardless of height), while secondary palatalization of coronals and labials should be triggered by high vowels only (regardless of frontness/backness).

Another seemingly non-trivial problem is revealed by the treatment of place-changing palatalization processes (Types II and III). Consider the rules proposed to account for English coronal palatalization (12a) and velar softening (12b) (see (1) and (2)). As Chomsky and Halle note (*SPE*: 424), palatalization is an intrinsically assimilatory process. Nothing in the rules below, however, captures its assimilatory nature. In fact, specifications of triggers and outputs in each of the rules do not share a single feature.

(12) a.
$$\begin{bmatrix}\text{−son}\\ \text{+cor}\end{bmatrix} \rightarrow \begin{bmatrix}\text{−ant}\\ \text{−strid}\end{bmatrix} / \_\_ \begin{bmatrix}\text{−back}\\ \text{−voc}\\ \text{−cons}\end{bmatrix}\begin{bmatrix}\text{−cons}\\ \text{−stress}\end{bmatrix}$$

b.
$$\begin{bmatrix}\text{−cont}\\ \text{−ant}\\ \langle\text{−voice}\rangle\end{bmatrix} \rightarrow \begin{bmatrix}\text{+cor}\\ \text{+strid}\\ \langle\text{+ant}\rangle\end{bmatrix} / \_\_ \begin{bmatrix}\text{−back}\\ \text{−low}\\ \text{−cons}\end{bmatrix}$$

Acknowledging this and other problems arising from the excessively permissive rule notation mechanism as a "fundamental theoretical inadequacy" (*SPE*: 400), Chomsky and Halle propose to supplement rules and feature specification with a substantive component – a theory of markedness consisting of a list of "marking conventions." They illustrate the application of these conventions in rules representing historical palatalization processes in Slavic. The so-called "first velar palatalization" in Slavic (Type IIa; [k g x] → [ʧ ʤ ʃ]) can be stated as a "simple assimilation rule" (*SPE*: 400) by which velars ([−anterior]) acquire the [−back] value from following front vowels (13a). The change of stops to strident coronal affricates and fricatives ([+coronal, +delayed release, +strident]) is not an assimilatory effect, but is due to an application of relevant marking conventions (13b). According to these conventions, a postalveolar affricate [ʧ] is less marked than a palatal stop [c] or a palato-alveolar stop [ṯ], and therefore "when velar obstruents are fronted, it is simpler for them also to become strident palato-alveolars with delayed release" (*SPE*: 423). Thus, the unmarked value of the feature [coronal] ([ucoronal]) for [−back, −anterior] consonants is [+coronal], and the unmarked values for the other two features of posterior coronals are [+delayed release] and [+strident] (CHAPTER 12: CORONALS; CHAPTER 22: CONSONANTAL PLACE OF

ARTICULATION). Similar assimilation rules and marking conventions were proposed for the Slavic "second velar palatalization" and language-specific realizations of "dental palatalization" (Types IIa, IIb, and IIIb).

(13) a. [−ant] → [−back, +cor, +del rel, +strid] /__ [−cons, −back]
b. [*u*cor] → [+cor] / [__, −back, −ant]
[*u*del rel] → [+del rel] / [__, −ant, +cor]
[*u*strident] → [+strident] / [__, +del rel, +cor]

The combined use of rules and marking conventions made it possible to formulate palatalization as an assimilatory process. Yet it remains unclear when marking conventions should be invoked in general, and there are questions about the appropriateness of some of the conventions for particular cases of palatalization. For example, while it is true that postalveolar affricates are less marked (at least less cross-linguistically common) than palatal or postalveolar stops, the same is true, even more so, about the unmarked status of alveolar or labial stops (both [−anterior, −back]) – the segments that are never produced by palatalization. Further, the account views all place-changing palatalization processes as consisting of two consecutive stages – the fronting or secondary palatalization followed by simplification (e.g. [k] → [c] → [ʧ]; [t] → [tʲ] → [ʧ]). While these stages may correctly recapitulate the historical development of some palatalization processes (as in Slavic), it can be argued that they are simply unnecessary as statements of the synchronic rules of a language.

3.2 Naturalness and phonological rules

Questions about alternative ways of constraining the excessively powerful rule machinery of *SPE* were central to the theoretical debate in the late 1960s and the 1970s (see Hyman 1975 for a review). Why, for example, is the palatalization rule in (14a) cross-linguistically common and natural, while the exact reverse of it (14b) is highly unlikely and unnatural? From the point of view of computational simplicity, both rules are equally simple, involving the same number of features. The fact that the formal theory had no way of distinguishing between natural and unnatural rules was seen by some phonologists as highly problematic. In response to this, Schachter (1969) proposed to encode naturalness directly into phonological rules, introducing the feature specification *n*, marking feature values that are "natural" for a given process. Given this, the rule of velar palatalization can be rewritten as (14c), stating that the natural value of the feature [±back] before front vowels is [−back]. Features marked as natural are not counted by the rule simplicity metric, thus rendering the rule in (14c) less "costly" than the rule in (14b). Taking this idea further, Chen (1973) proposed to formalize the target place and trigger height asymmetries of palatalization (8a) and (8b.ii) as part of special meta-rules – language-specific rules supplemented with universal constraint statements. For example, his meta-rule in (14d) states that consonants become palatalized before front vowels ([1 back] = {i, e, æ}), however, with certain implicational relations: (i) if a consonant of a given point *m* along the backness scale undergoes palatalization, so does the consonant higher on the scale (i.e. [p] implies [t] and [k], and [t] implies [k]; cf. (8a), but see (8b)); (ii) if a consonant undergoes palatalization by a vowel of a given point *n* of the height scale, it also does so before any vowel higher on that scale (i.e. [æ] implies [e] and [i], and [e] implies [i]; cf. (8b.ii)).

In a related proposal, Foley (1977) formulated "synchronic truth statements" – implicational relations among triggers and targets of palatalization – and provided detailed calculations of relative probability of palatalization depending on the target place and trigger height (among other factors), as shown in (14e).

(14) a. C[+back] → [−back] / __ V[−back] (k → ʧ / __ [i, e, æ])
b. C[−back] → [+back] / __ V[+back] (ʧ → k /__ {u o a})
c. C[+back] → [*n*back] / __ V[−back]
d. C[αback] → palatalized / V[1back, βhigh]
language-universal constraints: $\alpha \geq m$, $\beta \geq n$, where
C backness scale: 1 [p], 2 [t], 3 [k]; V backness scale: 1 [i e æ], 2 [u o ɑ];
V height scale: 1 [æ], 2 [e], 3 [i]
e. Relative probability scale of palatalization
kj > ki, tj > ke, ti, pj > kæ, te, pi > tæ, pe > pæ

These proposals, despite some empirical inadequacies, are interesting as the first relatively systematic attempts to directly incorporate substantive factors into the formal computational mechanism. The use of phonetic naturalness as a formal phonological criterion, however, did not receive much support in mainstream generative phonology at the time, as it was difficult to reconcile with the fact that languages allow both natural and unnatural rules, seemingly without preference for the former. If naturalness considerations were part of the grammar, why would some languages maintain such phonetically implausible rules as labial palatalization (cf. Hyman 1975 on the Bantu rule [p] → [s] / __ [i])?

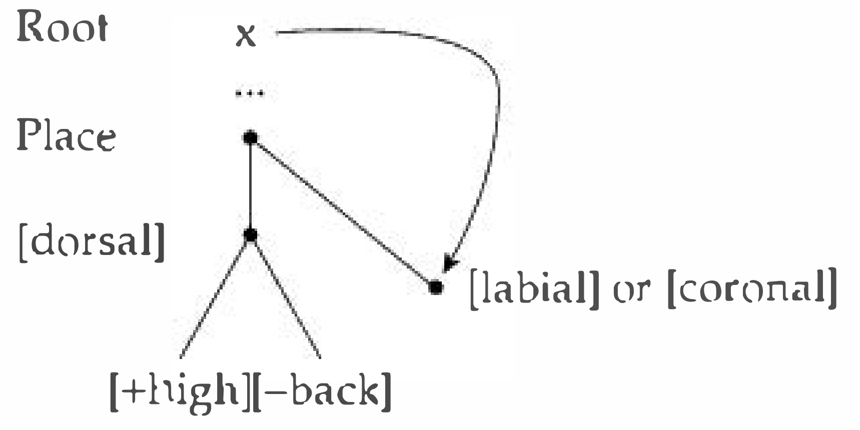
4 Feature geometry

New ways of constraining the application of phonological rules were brought by the framework of feature geometry (Clements 1985; Sagey 1986; among others; see also CHAPTER 27: THE ORGANIZATION OF FEATURES). More elaborate, geometrically organized autosegmental featural representations were expected to delimit the typology of phonological rules, distinguishing between possible, natural and impossible, unnatural processes. Within feature geometry, it is useful to distinguish two main approaches to palatalization. Both view palatalization as an assimilatory phenomenon, but differ in the feature specification of the main triggers of the process – front vocoids. The first approach treats front vocoids as [dorsal], essentially following the *SPE* tradition. The second approach specifies front vowels as [coronal], in an attempt to state some of the generalizations missed by the *SPE*-style featural accounts. Palatalization is thus modeled as either spreading [dorsal] or spreading [coronal].

4.1 *Palatalization as spreading* [dorsal]

One key proposal of this approach, initially developed in Sagey's dissertation (1986), is that vowels, glides, dorsal consonants, and secondary articulations like palatalization and velarization are characterized by the [dorsal] node with features [±high, ±back, ±low]. In contrast to *SPE*, labials and coronals are not specified for these features, but are characterized by [labial] and [coronal] nodes respectively. The feature [anterior] in the new approach is limited to coronals only, being specified under the [coronal] node. Palatalized consonants in this system are viewed as complex segments with temporally unordered primary [labial] or [coronal] nodes and the secondary [dorsal] node specified for [+high, −back] (with "designated articulators" – primary nodes – marked diacritically with a pointer from the Root node):

(15)



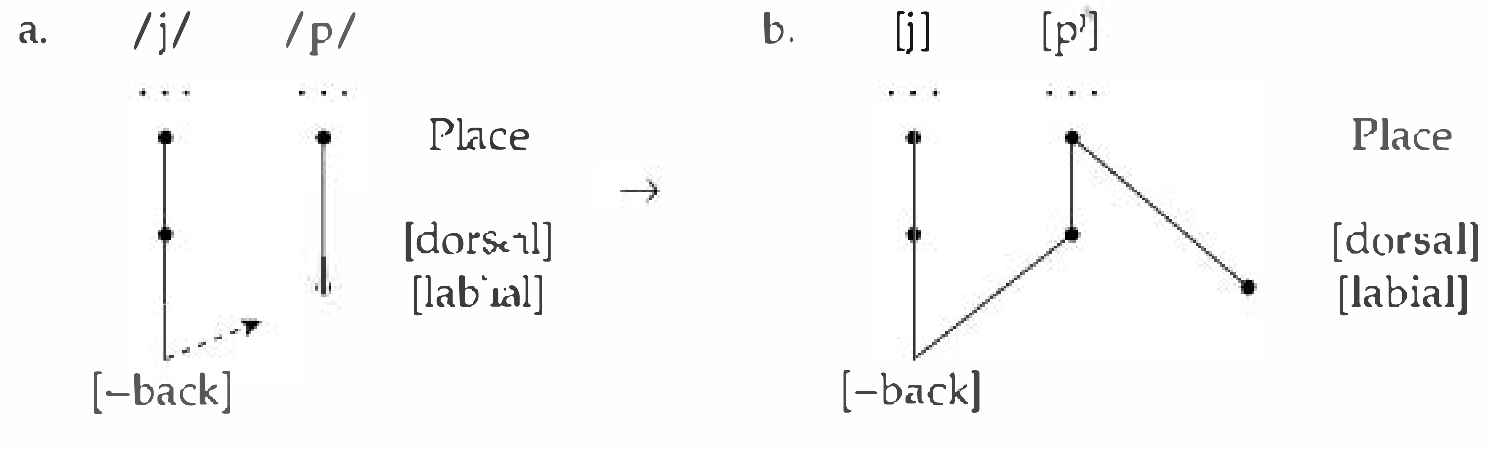
As in *SPE*, this system does not allow for palatalized velars distinct from palatals: both are designated as [kʲ], [gʲ], etc. and represented as simple segments having Place[dorsal[+high, −back]].

Given these feature specifications, palatalization processes are treated as spreading [+high, −back], either with or without the [dorsal] node. Sagey presents data from Zoque to illustrate the application of palatalization. As shown in (16), palatal glide /j/ triggers palatalization of following consonants by adding a secondary palatal articulation to labials and velars, and changing anterior coronals to posterior coronals ([t̠] = a [−anterior] alveolo-palatal stop).

(16)	a.	/j-pata/	pʲata	'his mat'
	b.	/j-kama/	kʲama	'his cornfield'
	c.	/j-tatah/	t̠atah	'his father'
		/j-tsʌhku/	ʧʌhku	'he did it'

Sagey analyzes palatalization as spreading [−back] from the preceding /j/ to all places (together with [dorsal] for labials and coronals), with a subsequent deletion of the glide. This analysis is illustrated for labials in (17). Spreading [−back] produces the required results for labials and dorsals, but not for coronals. For the latter, the addition of [dorsal[−back]] to [coronal[+anterior]] results in palatalized alveolars instead of the expected posterior coronals. What is necessary here, Sagey argues, is an additional process that would simplify the complex coronal structure Place[coronal[+anterior]]*[dorsal[−back]] to a posterior articulation, [coronal[−anterior]]. She refers to this process as "fusion," by which coronal and dorsal nodes are fused to produce a simple posterior coronal.

(17)



In sum, while the model provides a relatively simple and intuitively appealing account of secondary palatalization, its treatment of place-changing coronal palatalization as a two-stage process is arguably problematic for the same reasons as the *SPE* solution. Even more problematic, critics would argue, is the analysis of place-changing velar palatalization (Types IIa and IIb) (cf. Lahiri and Evers 1991; Hume 1992). Such an analysis is not worked out by Sagey, but would presumably involve a subsequent change of palatalized velars/palatals (Place[dorsal[−back]]) to posterior coronals (Place[coronal[−anterior]]). This, however, cannot be motivated by structural complexity, as palatalized velars (or palatals) are assumed to be simple articulations. Given this, fusion is not an option. Nor is it clear why this "simplification" should result in a posterior coronal, as opposed, for example, to an anterior coronal or a labial. Further, the model remains silent about the role of sibilancy in outputs of palatalization, and does not predict palatalization to anterior coronals (Type III) as a possible option.

Despite these and other limitations (see Kenstowicz 1994), the approach to palatalization as spreading [dorsal] has been relatively successful when dealing with contrastive palatalization, particularly with systems having both palatalized and velarized consonants. For example, both in Irish and in Russian consonants in clusters assimilate to following consonants in secondary palatalization or velarization, and vowels get fronted or backed by adjacent palatalized and velarized consonants. These facts can be easily stated as spreading the [dorsal] node with either [−back] or [+back] (Ní Chiosáin 1991; Rubach 2000). The use of the binary feature [±back] is also useful when it comes to stating morphological "exchange rules" – reversing palatality of consonants ([αback] → [−αback]) to mark certain morphological categories, as in Kildin Saami and Scots Gaelic (18) (Kert 1971; MacAulay 1992).

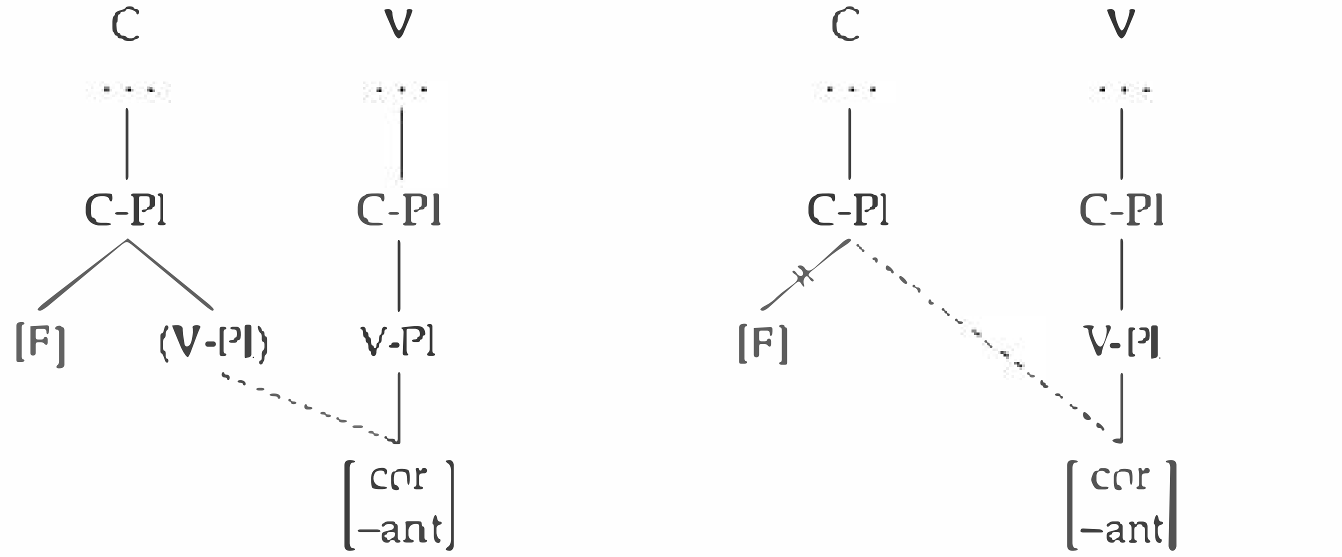
(18)	a.	kɛbb	'illness (NOM SG)'	kɛbʲbʲɛ	(DAT/ILLAT SG)
		kobʲbʲ	'pit (NOM SG)'	kobba	(DAT/ILLAT SG)
	b.	maːɫ̪	'rent (NOM SG)'	maːlʲ	(GEN SG/NOM PL)
		ahɔrʲ	'father (NOM SG)'	ahɔr	(GEN SG/NOM PL)

4.2 *Palatalization as spreading* [coronal]

The approach to palatalization as spreading [coronal] was advanced to remedy some of the inadequacies of the [dorsal] spreading model. It develops the original insight of Clements (1976) that palatalization and coronality are related, and that front vowels and coronals should form a natural class. While treatments of palatalization as spreading [coronal] were advocated in a number of works (Mester and Itô 1989; Broselow and Niyondagara 1990; Clements 1991; Lahiri and Evers 1991), the most extensive development of the idea was presented in Hume's dissertation (1992).

Hume's feature geometry model builds on Clements's (1991) proposal to use distinct tiers for consonant and vowel places, C-Place and V-Place nodes. These separate tiers were introduced for reasons largely independent of modeling palatalization – to allow for cross-consonantal assimilatory effects (such as vowel harmony and umlaut). These structures also made it possible to represent consonants with secondary articulation as having both C-Place and V-Place nodes. The V-Place node of vowels included the features [±coronal] and [±dorsal], with front vowels being [+coronal[−anterior]]. Height features were represented under a separate Stricture node, the property that will be relevant to our further discussion. Unlike the binary V-Place features, C-Place features were assumed to be primitive: [labial], [coronal], and [dorsal]. The [+anterior] under the [coronal] nodes referred to dentals and alveolars (as in Sagey's framework), while [−anterior] referred to various posterior coronal articulations, crucially including palatals. Despite some formal inconsistency in the use of binary and primitive features, the model allows for representing front vowels, coronal consonants, and palatalized consonants as a natural class – all sharing [coronal], specified either at the V-Place or C-Place. This is clearly a considerable advance in the theoretical modeling of palatalization, as both secondary palatalization (Type I) and place-changing palatalization (Types IIa and IIb) can be stated as assimilatory processes, virtually involving a single step. According to this analysis, secondary palatalization is triggered by spreading V-Place[coronal[−anterior]] from a front vowel or glide to the consonant. In the case of place-changing palatalization, this spreading is accompanied by delinking the original C-Place and promoting V-Place to the position of the former. Changes in other features, such as stridency or continuancy, are not considered to be part of the assimilation process per se, being specified as a rule parameter (the "constriction status change"). Hume's analysis of the two general processes is illustrated in (19).

(19) a. *Constriction status change: No* b. *Constriction status change: Yes*



The key insight of the [coronal] spreading approach is that secondary palatalization and place-changing palatalization (also known as "coronalization" with non-coronal targets) are essentially the same general process. Hume notes that both are cross-linguistically common, and in fact may optionally apply under the same phonological conditions in a given language, as in Acadian French (20).

(20) a. ki ~ kʲi ~ ʧi 'who' cf. [ka] 'case', [kut] 'cost', [kote] 'side'
kɛ ~ kʲɛ ~ ʧɛ 'quay'
b. tjed ~ tʲed ~ ʧed /tied/ 'lukewarm' cf. [dyp] 'dupe', [typ] 'type'

While these data nicely illustrate the similarity between secondary palatalization and place-changing palatalization, they also highlight some problems with the model. The triggers of the processes involving dorsals (20a) and coronals (20b) are different: front vowels in the first case and [j] in the second case. The target–trigger dependencies (see (8c)) are therefore not predicted by the model (cf.

Kenstowicz 1994). While the same is true for Sagey's and Chomsky and Halle's models, Hume's model has a structural limitation – stricture features are assumed to be independent of place features, and therefore statements of such dependencies are not possible. In fact, the model predicts that vowel height is not a factor in the process and any front vocoid can equally well palatalize a consonant of any place of articulation. While correctly capturing the important role of front vowels in palatalization processes, Hume's model does not allow for finer-grained frontness/height distinctions and rules out some of the attested processes. Among such processes are vowel raising next to palatalized consonants (as in Russian (11)) and a shift of velars to anterior coronals – the phenomena that could be relatively straightforwardly handled in the *SPE* approach.

4.3 *Further developments*

Subsequent work in the framework of feature geometry included attempts to resolve some of the problematic aspects of either approach, or to combine the insights of both. Lahiri and Evers (1991) propose to revise the [coronal] spreading approach by simplifying the two-tier place system and dispensing with the tier promotion mechanism used by Clements (1991) and Hume (1992). While maintaining the treatment of place-changing palatalization as due to spreading [Coronal[–anterior]], they analyze secondary palatalization as spreading [+high] (specified under the Tongue Position node) – a representationally elegant, yet arguably empirically problematic approach (Hume 1992; Jacobs and van de Weijer 1992). Calabrese (1993) uses alternative feature geometry representations and markedness filters in an attempt to address some of the issues largely overlooked in the Sagey and Hume approaches. Among these are the propensity of palatalization to produce sibilant affricates and fricatives, and the possibility of anterior coronals as outputs of the process. Jacobs and van de Weijer (1992) propose that front vowels are complex articulations, having both [coronal] and [dorsal] nodes (cf. Halle 2005). Palatalization may involve spreading only dorsal features, as in the case of velar fronting ([x] → [ç]), or both coronal and dorsal features, as in the case of place-changing palatalization of velars. This specification is also intended to characterize the class of coronals and dorsals as common targets of palatalization, as opposed to labials. While the move to specify front vocoids for both features adds flexibility to analyses of palatalization, its implications for analyses of other processes, such as vowel harmony and consonant harmony, and the interactions of these processes with palatalization, still remain to be explored. For example, is the patterning of front vowels in palatalization (as triggers) consistent with their patterning in backness vowel harmony (as targets or transparent vowels)? Do palatalized consonants always block backness harmony (as in Turkish: Kenstowicz and Kisseberth 1979)? Why do front vocoids fail to block coronal consonant harmony in some languages (Sanskrit: Calabrese 1993), while triggering it in other languages (Rundi: Broselow and Niyondagara 1990)? Finally, none of the above reviewed approaches seems to address the important question of why palatalization is special among consonant–vowel interactions – that is, why front vowels systematically displace consonant primary place of articulation, while other vowels hardly ever do so (cf. Ní Chiosáin and Padgett 1993).

To conclude this section, palatalization has played an important role in the development of a feature geometry framework, serving as a testing ground for competing proposals. While the rigidly constrained featural representations combined with a set of simple operations have contributed to a more empirically adequate account of cross-linguistic patterns of palatalization, it became clear that the same representations have often stood in the way of further empirical coverage of the phenomenon (and sometimes created problems for accounts of other phenomena). This particularly applies to cases of palatalization that can be considered less phonetically natural, such as place-changing processes resulting in anterior coronals or involving labial consonants. Ironically, some of the processes that could be easily stated in the *SPE*-style approach (although not always in a natural and insightful way) could no longer be stated in the feature geometry approach without making some ad hoc stipulations. At the same time, the discrete and binary feature geometry representations have also turned out to be incapable of capturing finer-grained, presumably phonetically motivated, scalar phenomena and trigger–target dependencies. This subsequently led some phonologists to (at least partly) revise the traditional view of representations as fixed and universal, and to explore ways of capturing cross-linguistic generalizations and variability in phonological processes through underspecification (Steriade 1995), contrastive specification (Avery and Rice 1989), contrastive feature hierarchies (Dresher 2009), or a system of parameterized rules (Archangeli and Pulleyblank 1994); see CHAPTER 2: CONTRAST; CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION).

5 Constraints and representations in Optimality Theory

The advent of Optimality Theory (OT; Prince and Smolensky 1993) brought back phonetic substance into phonology, now in the form of violable markedness constraints. While feature geometry-style representations and feature spreading assumptions have continued to play an important role in most OT accounts of palatalization, the task of capturing relevant feature asymmetries was partly relegated to constraints and constraint hierarchies. For example, the labial/non-labial target asymmetry could now be formalized as a universally fixed hierarchy of constraints prohibiting palatalized labials, dorsals, and coronals (21a) (Chen 1996; Rose 1997), while the trigger height asymmetry was represented as a fixed hierarchy of PALATALIZE (spread V-Place) constraints indexed for vowel height (21b) (Rubach 2003). Meshing these two hierarchies and combining them with different rankings of other markedness (e.g. AFFRICATION and POSTERIORITY; Rubach 2000) and faithfulness constraints can generate a restrictive factorial typology of palatalization patterns (cf. (14)), to some extent approximating the actual typology of palatalization (see §2). However, as the objects of constraint manipulation were the same inviolable feature geometry representations, some of the earlier noted problems persisted into OT analyses.

(21) a. *[lab]/VPL[cor] >> *[dors]/VPL[cor], *[cor]/VPL[cor]
b. PAL/j, PAL/i >> PAL/e >> PAL/æ

One possible solution to these problems was sought in the use of more detailed, phonetically realistic representations. Chen (1996), for example, uses articulatory gestures in conjunction with the traditional feature geometry representations to analyze palatalization in Japanese, Polish, and Swati. All palatalization processes are assumed to involve spreading V-Place[coronal] from front vocoids (following Hume 1992) and resulting in abstract complex segments with a secondary place and the original primary place (e.g. [Dorsal]/V-Place[Coronal]). The cross-linguistic diversity in outputs of palatalization arises, according to Chen, from language-particular phonetic implementation via articulatory gestures (Browman and Goldstein 1989). Bateman's (2007) OT analysis of cross-linguistic patterns of palatalization fully replaces the traditional feature geometry representations with articulatory gestures. She models secondary palatalization and place-changing palatalization as resulting from two different gestural coordination strategies: the coordination of the vowel gesture at the release of the consonant gesture or at the center of it – producing either consonants with secondary articulation or simple articulations of intermediate constriction location and degree, respectively. The appeal of both proposals is in the use of independently motivated, physically concrete representations and a simple mechanism of gestural overlap. Problems arise, however, as before, with treatments of articulatorily less natural cases of dorsal and labial place-changing palatalization. In Chen's analysis, velar palatalization results in the abstract phonological structure [Dorsal]/V-Place[Coronal], which can be phonetically interpreted as [kʲ], [c], [ʧ], or [tɕ], depending on the language. Yet it is not clear how this mapping would work in languages with more than one velar palatalization process (as Russian (4)). In Bateman's analysis, the process [k] → [ʧ] cannot be reasonably analyzed as resulting from gestural blending only (which would give only [kʲ] or [c]), and requires additional markedness stipulations (cf. Chomsky and Halle 1968 on [c] → [ʧ]). While Chen analyzes labial palatalization in Swati as a case of phonological neutralization to the default coronal place, this is not an option for the gestures-only framework of Bateman. As gestural blending is technically impossible between the mechanically uncoupled gestures of the lips and the tongue body, labial palatalization is in principle ruled out by the model. Bateman contends that the few attested cases of labial–coronal alternations (as in Southern Bantu and Moldova Romanian) can be explained diachronically. Yet, arguably, these cases still require a synchronic analysis.

A different approach – exploring phonetically detailed, scalar auditory features – is taken by Flemming (2002). He analyzes palatalization as a process driven primarily by constraints requiring perceptual enhancement of phonological contrasts (as part of his Dispersion Theory; see CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). In this analysis, secondary palatalization is an optimizing strategy, as it enhances the contrast of the vowel with other vowels by extending the span of its second formant (F2) to the preceding consonant (e.g. Nupe [egʲe] *vs.* [ega] compared to [ege] *vs.* [ega]). The change of the fronted velar or palatal stop to a palato-alveolar affricate is yet another step in the enhancement of the contrast (e.g. [edʒe] *vs.* [ega]), by which the duration of frication and its loudness are increased, while the contrast with the non-palatalized counterpart in F2 remains relatively large. Thus, sibilants as outputs of palatalization are fully expected, as affrication is part of contrast enhancement: "It is easier to enhance a contrast by exaggerating a difference that would be present anyway as an articulatory side-effect, rather than attempting to reverse the articulatorily motivated pattern" (2002: 106). The same kind of enhancement through affrication is also possible for coronals, but is unlikely for palatalized labials, since the production of these does not involve as much frication. While the actual implementation of this analysis of palatalization is relatively complex, it does capture some important generalizations about palatalization processes that have evaded many previous analyses. The Dispersion Theory approach thus provides an interesting insight into how palatalization may arise through auditory enhancement of phonological contrasts (cf. Padgett 2001, 2003). It remains to be seen, however, how the approach can model synchronic alternations, and particularly more complex cases of morphophonological palatalization.

6 Recent alternatives

Despite the greater flexibility and apparent naturalness provided by violable substantive constraints in OT, some of the problems with the formal modeling of palatalization have not been resolved. In part, these difficulties appeared to stem from a more fundamental problem – the persistent use of traditional featural representations (with some modifications), which were assumed to be inviolable, universal, and innate. These assumptions about representations were clearly important in the development of generative phonology, as the universal set of features provided a simple formal tool to state phonological rules and to capture significant cross-linguistic generalizations about natural classes of segments. Yet the basis for these assumptions has hardly been questioned or systematically investigated until recently. As Mielke's (2008) survey of phonological processes shows, unnatural classes are widespread in languages, with some of them being more common than typical natural classes. As traditional feature theories are incapable of characterizing many of these classes, the usefulness of maintaining the assumptions about feature universality and innateness is in serious doubt. Mielke's proposal is that features are not innate but emergent, arising from language learners' phonetic generalizations (cf. Hayes and Steriade 2004 on OT constraints). If features, and phonological representations in general, are indeed emergent, this has some wide-ranging implications for phonological theory, and for formal modeling of phonological processes. Specifically with respect to palatalization, languages may be expected to vary in how they define features and natural classes involved in the process, while at the same time showing many similarities, given the similar articulatory and acoustic properties of alternating consonants and vowel triggers. One may also expect that featural representations are not immutable within a given language, but possibly reflect local generalizations, specific to certain morphological domains or lexical strata (as, for example, in cases of multiple palatalization processes targeting the same consonants). However, these and many other implications for analyses of palatalization have not yet been explored.

Another notable recent development reflects a resurgence of interest in diachronic explanation of synchronic phonological patterns. This approach is most systematically represented by Blevins's (2004) Evolutionary Phonology, where cross-linguistically common, "natural" sound patterns are explained exclusively diachronically – as a by-product of recurrent phonetically motivated sound changes. Given the well-established phonetic motivation for palatalization in co-articulation and auditory misperception (see §2.3), synchronic patterns of palatalization can be interpreted as arising from sound changes involving these phonetic factors. As such, these patterns arguably do not require synchronic explanation – either structural or substantive (cf. Kochetov 2002 on the phonotactics of palatalization contrasts). Taking velar place-changing palatalization as an example, the unidirectional nature of this change ([ki] → [ʧi], *[ʧi] → [ki]) and its common result (a postalveolar affricate) has little to do with phonological grammar per se, as it can be attributed to common errors in the perception of fronted velars (Guion 1996). The same applies to the asymmetry between high and non-high front vowels as triggers – listeners simply make more errors of the type [ki] → [ʧi] than [ke] → [ʧe]. By the same token, listeners rarely make errors like [pi] → [ʧi], unless under some specific phonetic conditions (see Ohala 1978) – the fact that explains the labial/non-labial asymmetry in palatalization. If most or all the cross-linguistic generalizations about palatalization in (8) can be accounted for by phonetically based sound changes, the goal of synchronic grammar becomes much simpler – to state language-particular generalizations about the patterning of segments in alternations or their phonotactic distribution. What specific form these language-particular synchronic grammatical generalizations would take, however, is not clear, and has not been sufficiently explored by the proponents of Evolutionary Phonology. One interesting implication of the approach is that synchronic patterns of palatalization alternations should mirror sound changes involving the process. Whether this is true, however, is subject to further typological research. Another related question is how to reconcile the substance-free grammar envisioned by Evolutionary Phonology with apparent evidence that speakers possess some phonetic knowledge and seem to use it to make higher-level grammatical generalizations (Hayes and Steriade 2004). An interesting relevant case is provided by the cross-linguistically common use of palatalization in baby talk and diminutive sound-symbolism – presumably reflecting bottom-up generalizations, grammaticalized associations between the phonetics of palatalized consonants and the meaning of smallness and childishness (Kochetov and Alderete, forthcoming). Whether phonetic knowledge plays a role in phonological generalizations, and specifically whether phonetic naturalness considerations are part of the grammar, are important questions that could possibly be answered through systematic psycholinguistic experimentation and computer simulations (see some relevant work by Wilson 2006). The challenge for future work is, therefore, to tease apart synchronic phonological and phonetic knowledge of palatalization and historical influences shaping cross-linguistic patterns of palatalization over time.

72 Consonant Harmony in Child Language

Clara C. Levelt

1 Introduction

Consonant harmony (CH) in child language production data has attracted a great deal of attention in the phonological literature. It has been defined as an "assimilation-at-a-distance" process between consonants (Vihman 1978), in which consonants affect other, non-adjacent consonants. The assimilating features in child language CH are mostly primary place of articulation features, like Labial and Dorsal, but cases where other features are involved have also been observed. Over time, several analyses of this phenomenon have been proposed in the literature, the nature of the analysis changing with the theoretical state of the art: a phonological rule (Smith 1973), autosegmental spreading (Menn 1978; McDonough and Myers 1991; Stemberger and Stoel-Gammon 1991; Levelt 1994), a connectionist account (Berg and Schade 2000), and constraint interaction (Goad 1997; Pater and Werle 2003; Fikkert and Levelt 2008).

Consonant Harmony as such is not a phenomenon specific to child language (see CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS). However, the nature of CH in child language differs from that in the languages of the world in an important way: unlike in the world's languages, in child language it appears that *primary* place of articulation features can assimilate between non-adjacent consonants. This constitutes a challenge for a phonological account, because it clearly violates the principle of locality (see e.g. Archangeli and Pulleyblank 1987). According to this principle, only segments that are adjacent at some level of analysis can interact.[1] For primary place of articulation features (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION) of consonants that are not string-adjacent such a level can only be assumed under special circumstances, such as planar segregation (McCarthy 1989; see §3 below). Of course, CH in child language would violate locality only if a strong form of continuity is assumed, i.e. if the phonological systems of language learners and adults make use of the same units and obey the same set of principles. Therefore, as we will see, some accounts of child language

[1] For an overview of the different definitions of locality, and the ways in which accounts of CH in the world's languages deal with this principle, see CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS.

CH refer to a child-language-specific aspect of the developing phonological system, which allows for a local interpretation of the interaction. Alternatively, the locality problem can be circumvented by denying that the data are the result of an assimilation-at-a-distance process. Instead, some – mostly child-specific – form of feature licensing is invoked to account for the data.

This interesting and sometimes controversial topic will be discussed in the following way. First, in §2 the main similarities and differences between CH in adult language and in child language will be pointed out. Because in child language CH involving primary place of articulation features is the most salient and systematic phenomenon, and forms a challenge for most phonological theories, I will focus on this type of harmony in the remainder of the chapter. In §3, different accounts of CH in child language will be discussed, focusing on the way in which phonological theory has highlighted different – problematic – aspects of the phenomenon. In §4, a view on CH in child language will be presented that sets it apart from CH in adult languages, and it will be discussed how such a child-specific phenomenon can come about during language acquisition. §5 concludes this chapter.

2 Consonant harmony in adult and child language

The prevalent view on consonant harmony is that it is a widespread phenomenon in child language, while it is rare in the world's languages. This view is not totally supported by facts, however. Hansson (2001) describes different types of CH processes in 127 languages, while descriptions of systematic CH processes in child language can be found for only a handful of children (Smith 1973 and Goad 1997 (Amahl); Cruttenden 1978 (one child); Menn 1978 (Daniel); Berg and Schade 2000 (Melanie); Levelt 1994 and Fikkert and Levelt 2008 (Eva, Robin); Rose 2000 (Clara); Pater and Werle 2001, 2003 (Trevor)). Some studies discuss larger groups of children (Vihman 1978 (13 children); Stemberger and Stoel-Gammon 1991 (69 children)). However, it is unclear from Stemberger and Stoel-Gammon's study how many of these children actually had CH productions or to what extent the phenomenon occurred systematically in the data. Vihman studied CH forms in vocabularies that contained between 109 and 372 words. In only four of the 13 children did she find a relatively high number of CH productions, i.e. between 18 and 32 percent of the productions in the vocabulary studied. Of the remaining nine children, three scored around 10 percent and the other six scored between 1 percent and 5 percent. In the study, almost half of all the CH forms were provided by two of the children, Amahl and Virve. All in all, if we base ourselves on facts, i.e. cases reported in the literature, then "rare in languages of the world" is supported, but "widespread in child language" is less obvious. It is widespread in the sense that an occasional CH form will probably show up in the speech of many children. Systematic CH patterns, however, i.e. CH forms that show up predictably for a longer period of time, have, up to now, only been described for a handful of children.

2.1 *Features involved in harmony*

Most CH processes, in child and adult language alike, involve place of articulation features. In the languages of the world, CH always concerns *secondary* place of articulation features. Feature-geometrically speaking, these features are usually dependents of the coronal node: [anterior], [distributed], and [strident]. CH of features that are dependents of the labial or dorsal node exists too, but is very rare. Place of articulation harmony in the world's languages occurs mostly between consonants that are already very similar: within a word, the feature value for [anterior] is shared between sibilants, or the feature values [anterior] and [distributed] are shared between stops. For a more extensive review see CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS and Hansson (2001).

In child language, however, the CH phenomenon that is discussed most often concerns *primary* place of articulation features, specifically Labial and Dorsal. The existence of a systematic Coronal harmony process in child language is less evident. For one thing, neutralization to a coronal place of articulation, as in Velar Fronting, where /k/ is replaced by [t], often occurs as an independent process during phonological development (CHAPTER 12: CORONALS). Utterances with multiple coronal consonants are thus often the result of neutralization rather than assimilation. Below, in §3.2.2, we will see that underspecification of Coronal in the lexicon has been invoked to account for the absence of coronal harmony in child language. Unlike in adult CH, the consonants involved are not necessarily highly similar in other respects: primary place of articulation features are shared between any combination of nasals, fricatives, and stops.

Concerning place of articulation, then, the two groups of speakers appear to have almost contrasting sets of features that are active in CH: adult speakers only show CH involving *secondary* place of articulation features, mostly dependents of Coronal, while children show CH involving *primary* place of articulation features, most commonly Labial and Dorsal. Typical examples of these two types of harmony are given in (1).

(1) *Place of articulation harmony*

Adult speakers

a. *Sibilant* [anterior] *harmony in Ineseño Chumash*
(Applegate 1972, cited by Hansson 2001)
/k-su-ʃojin/ [kʃuʃojin] 'I darken it'
/s-api-ʧʰo-it/ [ʃapiʧʰolit] 'I have a stroke of good luck'

b. *Coronal* [anterior] *harmony in Päri*
(Andersen 1988, cited by Hansson 2001)
[dè:l] 'skin' [dè:nd-á] 'my skin'
[t̪ùol] 'snake' [t̪úon̪d̪-à] 'my snake'

Child speakers

c. *Dorsal harmony* (English)
(Trevor at 1;5: Compton and Streeter 1977, cited by Pater and Werle 2003)
dog [gɔg]
bug [gʌg]
coat [kok]

d. *Labial harmony* (Dutch)
(Robin at 1;10: Levelt 1994)
tafel /tafəl/ [pafy] 'table'
zeep /zep/ [fep] 'soap'
neef /nef/ [mef] 'cousin'

In (1a) we observe that two sibilants that underlyingly carry different feature values for [anterior] at the surface both show up as [−anterior]. In (1b) the feature value for [anterior] of the stop consonant in the stem is shared with the prenasalized stops in the derived forms. The examples in (1c) from child language show Dorsal CH in data from an English-speaking child. Both underlying Labial and Coronal consonants show up as Dorsal consonants on the surface. In (1d) Labial CH is illustrated with examples from a Dutch-speaking child. Here we see that the interacting consonants do not necessarily agree in their manner features.

Harmony involving other features is quite rare, both in languages of the world and in child language. In languages of the world, systematic patterns of long-distance assimilation have been attested for laryngeal features, nasality, and continuancy. In Hansson's (2001) overview we also find languages that show some form of liquid harmony. This form of harmony, or rather lateral harmony, is the only other type of consonant harmony that apparently, occurs in a systematic way in the speech of a child, Amahl, discussed in Smith (1973). In Amahl's case a target word with a combination of an /r/ or /j/ and a lateral results in a production with two laterals, as illustrated in (2).

(2)	*really*	[li:li:]
	lorry	[lɔli]
	yellow	[lɛlɔu]

Some less evident forms which have been listed as CH forms, involving other features, are given in (3) (from Spanish child language; Vihman 1978).

(3)	*comiendo*	[kabiendo]	'eating'	nasal is assimilated to stop
	llorando	[ɲrdardɲo]	'crying'	nasal harmony
	telefono	[ɸweɸwʌno]	'telephone'	continuant harmony

However, no systematic patterns of CH in child language have been described that involve these features. For forms like in (3), which are probably just produced once, there is no predictable relation between the form of the adult target and the resulting production. More examples of occasional CH productions are given in (4), from the speech of Jiři (Czech; Vihman 1978).

(4)	*balonek*	[babo:nek]	'ball'
	ježek	[ʒeʒek]	'hedgehog'
	gramofon	[gagafo:n]	'gramophone'

According to Vihman (1978), forms like these seem analogous to speech errors or alliterations in adult speech. Up to now, the reported set of occasional CH forms has been so diverse and fragmented that it has been impossible to come up with a comprehensive analysis.

Since CH in child language involving features other than place of articulation features presents such an unclear picture, the remainder of the chapter is concerned solely with primary place of articulation harmony.

2.2 *Directionality of the process*

Consonant harmony comes in two varieties in the languages of the world. Most commonly it takes the form of a morpheme structure constraint (CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS): certain combinations of consonants within a stem are allowed, while others are disallowed (Hansson 2001). In these cases, determining the direction of assimilation is not always evident, since underlying and surface forms are identical with respect to these harmonic consonants. The direction can sometimes be reconstructed from diachronic and cross-linguistic comparisons, which have shown that the default direction of harmony is anticipatory, i.e. right to left. Furthermore, Hansson (2001) establishes a Palatal Bias effect in adult CH. An underlying – or former – alveolar–palatal combination is likely to become a palatal–palatal combination. The morpheme structure constraint can be accompanied by a morphological harmony rule, i.e. a productive harmony process. Here, harmony is most commonly stem-controlled: the consonant of an affix will carry a certain feature value, depending on the feature value of consonants in the stem (CHAPTER 104: ROOT–AFFIX ASYMMETRIES).

In child language, the CH phenomenon is usually present in the period before any productive morphology has been developed. We therefore do not find CH forms that can be analyzed as being either stem- or affix-controlled. Rather, certain combinations of sounds within a stem appear to be disallowed on the surface. In this sense, CH in child language seems to take the form of a morpheme structure constraint. However, under the assumption that children's underlying forms are similar to the adult target forms, and given that these adult target forms can contain the disallowed combination of sounds, child CH is often assumed to be an active process. As in adult CH, the default direction of the process is right to left. Instead of the Palatal Bias effect that was found in languages of the world, in child language we find a strong Labial or Dorsal Bias effect: if the C_2 in a target $C_1VC_2(V)$ combination is Labial, the C_1 will end up being Labial too, or if C_2 is Dorsal, C_1 will be Dorsal.

2.3 *Summary*

What can be concluded from the above comparison between adult CH and child CH? Are the phenomena similar or different? Hansson (2001) pulls together adult CH, child CH, and speech errors. He states that the underlying source for CH must lie in the domain of phonological encoding for speech production. Both speech errors and CH show a default right-to-left directionality, and, as in adult CH, assimilatory speech errors are more likely to occur between segments that are already very similar. According to Hansson, then, CH in languages of the world is a phonologized form of speech error. With a little twist, this could also apply to CH in child language. The occasional forms are speech errors (as proposed in Vihman 1978) and in some cases a systematic, i.e. phonologized, type develops. According to Hansson, the difference in place of articulation bias between adult CH and child CH is caused by the nature of the sound inventory. In child language, the sound inventory is much smaller, and minor place of articulation features do not yet play a role. This impoverished inventory also puts "similarity between consonants" in a different perspective. Pairs of segments that are judged as very different by adult speakers, like /t/ *vs.* /k/, could be judged as relatively similar by children. This would account for the fact that major place harmony is child-language-specific, and is not found in languages of the world. In this view, then, CH in the world's languages and CH in child language are of the same kind, and the different surface appearance can be attributed to the impoverished segment inventory in the developing phonological systems of young children. Although this is an elegant perspective, which makes it possible to view phonological development as being continuous, by invoking and adhering throughout to identical principles and processes, a different account of the child-specificness of the phenomenon will be proposed in §4. Taking into account the developing place of articulation structure of young children's entire vocabulary, it appears that CH in child language is of a very different nature than CH in the world's languages.

In the remainder of this chapter we will concentrate on consonant harmony in child language, starting in §3 below with an overview of the accounts of CH that have been proposed in the literature.

3 Theoretical approaches to consonant harmony in child language

Several grammatical accounts have been presented of child language CH. These accounts are in terms of rules, autosegmental representations, activation spreading, or constraints. I will pay special attention to the way the account deals with the issue of *locality*: how is the intervening vowel dealt with, and which part of the process, if any, is deemed child-language-specific?

3.1 Consonant harmony as the result of a phonological rule

Smith (1973), working in the tradition of *SPE* (Chomsky and Halle 1968), presents a series of "realisation rules" that derive the consonant harmony forms of his son Amahl from "English Standard Pronunciation," i.e. the adult forms. In fact, Smith argues that one of the general functions of realization rules is to implement both consonant and vowel harmony, and he suspects that it is universal in child language. Of the eight realization rules that have consonant (and vowel) harmony as their motivation, the one in (5) results in labial and dorsal harmony:

(5) $$[+\text{coronal}] \rightarrow \begin{bmatrix} -\text{coronal} \\ \alpha\text{anterior} \end{bmatrix} / \_\_ \ [+\text{syllabic}] \begin{bmatrix} -\text{coronal} \\ \alpha\text{anterior} \end{bmatrix}$$

This rule initially applied systematically before velars, but was optional if $\alpha = +$, i.e. before labials. The intervening vowel, i.e. the [+syllabic] element in the rule, does not play any role and is not considered to be an obstacle to the process. The rule undergoes a couple of changes over time, capturing the fact that fewer and fewer coronal segments are affected. As a first change, for example, the rule split into two parts, operating in the original way in case of [−anterior], but applying only to nasals and continuants when [+anterior]. In its different forms, the rule is operative in Amahl's system from stage (1), when the data collection started at 2 years and 60 days, until stage (14), when Amahl was 2 years and 247 days. The rule can be considered child-language-specific, in that it disappears from Amahl's system over time. However, according to Smith, it is a genuine phonological rule in the sense that the formal properties of the realization rules are the same as those of phonological rules in mature grammars.

3.2 Consonant harmony in the autosegmental framework

3.2.1 Output templates

The first account in an autosegmental framework (CHAPTER 14: AUTOSEGMENTS) is presented by Menn (1978). She views CH as one of the child's strategies to comply with a general constraint on his or her output structure. The proposed, child-language-specific, output constraint is termed a "consonant harmony constraint" and states that consonants within a word should be of one place type. There are different ways to comply with this constraint. If an adult target word contains consonants with different place features, the child can either delete all but one consonant, or the child can render all the consonants in a word of one place type. This perspective integrates CH in the child's phonological system as a whole, instead of treating it as an isolated phenomenon: CH is just one of the possible ways of satisfying the constraint. In §4 a similar integrated view is elaborated. Menn posits the following "output lexical entry" for the words *stuck*, *duck*, and *truck*, which are all produced [gʌk] by the child Daniel:

(6) *Output lexical entry for* stuck, duck, *and* truck

tier 3	stop position	#		velar		#
tier 2	fricative	#		Ø		#
			C	V	C	
tier 1	word structure	#	+voice	low-mid	−voice	#

The child has the output representation in (6), resulting from the rule: "If an entry in the recognition lexicon contains a velar, then select [velar] as the stop-position specification for the corresponding entry in the output lexicon" (1978: 167). As in Smith's account, above, the underlying stored form is altered if conditions apply; in case a stored form contains [coronal] or [labial] and [velar], only the feature [velar] will end up being linked to the consonant positions in the word. Although this seems to be a classic case of autosegmental spreading, in this account the intervening vowel is not perceived as posing a potential problem.

A slightly different templatic approach to CH is taken by Iverson and Wheeler (1987). Following Moskowitz (1971), among others, who posited that words appear to be unanalyzed units, they argue that many phonological phenomena in child language are the result of the association of features with suprasegmental constituents, like words, syllables, and rhymes. The child's output representations are viewed as well-formedness templates, which characterize and filter the set of permissible words in the child's language (1987: 249). The well-formedness template that would result in the CH productions [kok] for *coat* and [gag] for *dog* is given in (7):

(7) *Output template for* coat *and* dog

WORD
[–anterior]
C V C

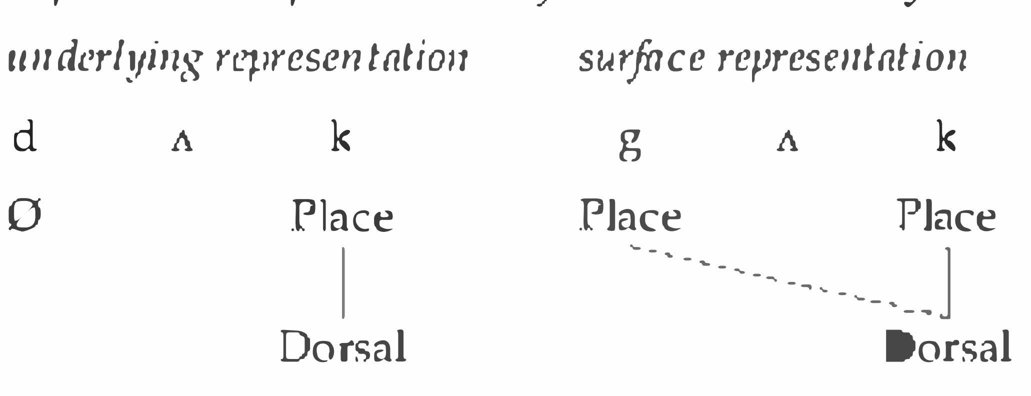
For the child in question, any word having a [–anterior] consonant will be associated with the above word structure, resulting in the harmonized forms. In Iverson and Wheeler's view, CH is actually not a derivational process, linking an adult-like input representation to a harmonized child output representation. The output form actually represents the child's knowledge of the phonological system of his or her target language, and it thus equals the underlying representation. What the child needs to learn, then, is that features should be associated with segments instead of larger units like syllables or words. The child-language-specific aspect of the account is the fact that features link to entire words, rather than segments.

Apart from the fact that the proposed constraint behaves like a morpheme structure constraint rather than as a constraint on output forms only, the account is almost exactly parallel to Menn's account: there is a child-specific template and a floating place feature that will be linked to the C-slots in the template (CHAPTER 54: THE SKELETON). Although the notion of association line is appealed to in Iverson and Wheeler's paper, the intervening vowel is still not viewed as potentially problematic for the account. As long as [anterior] is the feature being associated, the intervening vowel will not disrupt the linking process, since vowels are not normally specified for [anterior]. In this case, the association of [–anterior] with the vowel will simply have no effect. In this account, then, the locality problem is circumvented because only consonant-specific features are used.

3.2.2 *Underspecification*

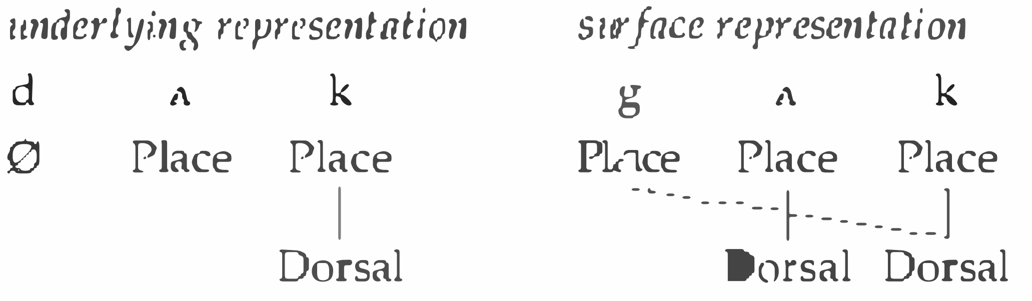
A more theoretically detailed autosegmental analysis of CH is presented in Stemberger and Stoel-Gammon (1989, 1991) and in Stoel-Gammon and Stemberger (1994). Here, CH is considered to be an "unconscious" process, caused on the one hand by underspecified consonants in the child's inventory, and on the other hand by a tendency for unmarked segments to assimilate to marked segments. CH is thus viewed as a feature-filling process, whereby a place feature spreads from a consonant specified for place, to a consonant unspecified for place. This is illustrated for the form [gʌk] for *duck* in (8):

(8) *A procedural representation of consonant harmony*



However, in the model of feature representation adopted by Stemberger and Stoel-Gammon and that of Sagey (1986), vowels also have a Dorsal place specification. This entails that spreading Dorsal from /k/ to the initial consonant position would lead to crossing association lines, as in (9), which is ruled out by the Line Crossing Prohibition (Goldsmith 1976).

(9) *Consonant harmony and crossing association lines*

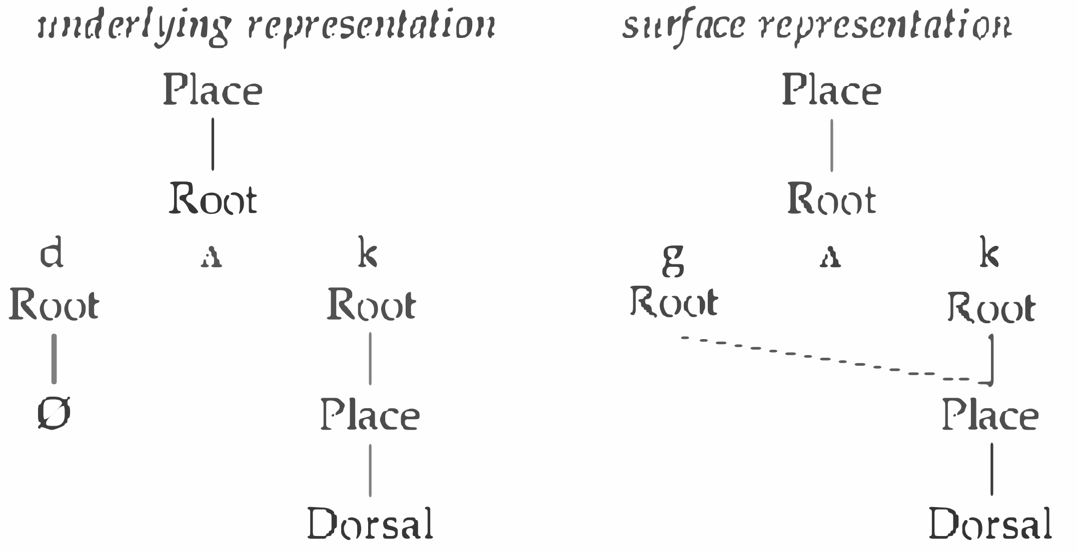


Stemberger and Stoel-Gammon recognize this locality problem. They argue that since these intervening vowels apparently do not block the harmony process, they should be transparent in one way or another. To achieve this, consonants and vowels should either reside on different planes when the process takes place, i.e. there is planar segregation (McCarthy 1989), or vowels and consonants should have different sets of place features (see also CHAPTER 105: TIER SEGREGATION; CHAPTER 27: THE ORGANIZATION OF FEATURES). They opt for the last solution and turn to the feature model proposed by Clements (1985), where consonants and vowels are partially segregated. Place features are divided into a "primary" place tier containing consonantal place features, and a "secondary" place tier containing vocalic place features. In this model, place features of consonants can be spread across vowels, and place features of vowels can be spread across consonants. Consonant harmony can thus be characterized as feature spreading, affecting only the primary place node. Interference with vowels, specified for place on the secondary place node, is avoided. In Clements's later elaboration of his feature model (Clements 1991), however, both vowels and consonants now have this primary consonant-place node. One of Clements's arguments for the change is precisely to exclude the possibility of consonants spreading their place features across vowels, which does not occur in the world's languages.

3.2.3 Planar segregation

McDonough and Myers (1991) take the planar segregation option seriously. Planar segregation can only be invoked if the relative order of consonants and vowels is predictable (McCarthy 1989). According to McDonough and Myers, many children at this stage of development have quasi-templatic constraints on the structure of words, and they conclude that therefore consonant–vowel planar segregation can be assumed. Their representation of CH is as in (10) below, and involves spreading a specified place node onto an adjacent root node unspecified for place on the consonant plane.

(10) *Consonant harmony and planar segregation*



The problem for this account is the background assumption, namely that CH is present in child language at the stage in development where the order of consonants and vowels in a word is predictable. Although children initially often do reduce the syllable structure of adult target words to simple consonant–vowel sequences, this does not necessarily happen at the time they have CH productions, as the Dutch examples in (11) show:

(11) *CV sequences and Robin's (1;9.21) consonant harmony forms*

a. CV *structure*

CVC	*niet*	/nit/	[nit]	'not'
VCC	*eend*	/ent/	[ɪnt]	'duck'
CVCC	*fiets*	/fits/	[fits]	'bicycle'
VCV	*auto*	/oto/	[oto]	'car'

b. *Consonant harmony*

schommelen	/sχɔmələ/	[vomə]	'to swing'
Grover	/χrovər/	[fofɔ]	(name)
stoep	/stup/	[fup]	'sidewalk'

The data in (11) show that the position of the vowel *vis-à-vis* the consonant is not predictable at the stage where CH forms are produced. Planar segregation can thus not be invoked either at the segmental level or at the feature level.

Locality is clearly a serious problem for accounts of CH in child language. In the literature discussed below the problem is dealt with in different ways.

3.3 *Consonant harmony as the result of a speech-processing problem*

There is no locality problem in the connectionist account of Berg and Schade (2000), since it is not a representational, but a local connectionist processing account. CH is viewed as a mispronunciation – i.e. a speech error – due to a speech plan that is carried out imperfectly. It is not, however, a low-level articulatory plan, precisely because the harmony is not co-articulatory, but involves units at a distance. The basic idea is that the level of activation differs between segments. Depending on their developmental status, links between phoneme-like units and their constituting features can be stronger or weaker. Weak links lead to hypo-activation, and hypo-activated features can be too weak to be available for production. This problem is then solved by inspecting activation levels in the network of nodes constituting a word, and picking out the element that has the highest activation level. In production, the hypo-activated feature is thus replaced by a more strongly activated feature in the word network, and this is one way in which consonant harmony can result. This can be seen as the processing version of the representational underspecification account of Stemberger and Stoel-Gammon, discussed above in §3.2.2. The other way is when a certain feature is hyper-activated because excessive weight has been attributed to the link between this feature and a segmental unit. A hyper-activated node in the network can mask the less activated nodes, leading to consonant harmony. Direction of harmony – which is usually right to left – is accounted for by self-inhibition. As soon as an onset consonant is selected, the activation level is temporarily set to zero, due to self-inhibition. The onset is thus unable to interfere with a following consonant. When production of an onset is eminent, however, the following consonant is already active due to parallel activation. Both hypo- and hyper-activated states are characteristic for a developmental system, accounting for the fact that consonant harmony is typical for child language.

Although there is no locality problem for this account formally speaking, the question remains what the effect of hyper- and hypo-activity levels of intervening vowels would be. Unfortunately, the intervening vowels are completely ignored in this account. The locality problem is formally circumvented, but in practice it is still there.

3.4 Consonant harmony as the result of an optimality-theoretic constraint

3.4.1 *Agreement*

Pater and Werle (2003) give a detailed account of the CH pattern in the longitudinal data of Trevor (Compton and Streeter 1977) within Optimality Theory (OT: McCarthy and Prince 1993; Prince and Smolensky 1993). According to Pater and Werle, consonant harmony in child language is related to place agreement in consonant clusters in adult languages (see CHAPTER 81: LOCAL ASSIMILATION). Both phenomena are due to a constraint AGREE, which requires two successive consonants to be homorganic. The domain of application differs for children and adults: in child language the successive consonants can be separated by a vowel, in adult languages the process is strictly local and only applies to adjacent consonants. Development in this view consists of narrowing down the domain in which the constraint applies to this strictly local domain.

The fact that we usually find labial and dorsal consonant harmony is independently regulated by a universal faithfulness hierarchy for place, whereby FAITH[Dors] and FAITH[Lab] are ranked above FAITH[Cor]. That is, if in order to comply with AGREE one place feature from the input form needs to be left out in the output form, it will be coronal rather than dorsal or labial. Examples from Pater and Werle illustrating this are given in (12):

(12) *Interaction of* AGREE *and* FAITH

/dɔg/	AGREE	FAITH[Dors]	FAITH[Cor]
☞ a. [gɔg]			*
b. [dɔd]		*!	
c. [dɔg]	*!		

/tap/	AGREE	FAITH[Lab]	FAITH[Cor]
☞ a. [pap]			*
b. [tat]		*!	
c. [tap]	*!		

However, since this general AGREE constraint would lead to both progressive and regressive consonant harmony, a more specific form of AGREE is invoked to capture regressive harmony, namely AGREE-L, which mentions the direction of agreement. In addition, when the regressive harmony has a specific trigger, like dorsal in the case of Trevor, this feature is mentioned in the directional AGREE constraint. In (13) the working of AGREE-L[Dors] is shown (from Pater and Werle 2003). While the general AGREE constraint would lead to harmony both in the case of *dog* and *coat*, the specific AGREE constraint affects only *dog*:

(13) AGREE-L[Dors] *for* dog *and* coat

/dɔg/	AGREE-L[Dors]	FAITH[Cor]
☞ a. [gɔg]		*
b. [dɔg]	*!	

/kot/	AGREE-L[Dors]	FAITH[Cor]
☞ a. [kot]		*
b. [kok]	*!	

Trevor's data show a developmental pattern, where Dorsal consonant harmony is initially both progressive and regressive, and Labial triggers both progressive and regressive harmony when other target consonants are coronals. Later, there is only regressive dorsal harmony. This development is captured by the demotion of markedness constraints below faithfulness constraints, the general way in which developmental changes are captured in OT (Gnanadesikan 2004; for an overview see Boersma and Levelt 2003). In this case, AGREE is demoted below FAITH[Cor], and AGREE-L[Dors] is demoted below FAITH[Lab].

A strictly local version of AGREE-L[Dors] also plays a role in Korean, where labials and coronals assimilate only regressively to dorsals, as can be seen in (14):

(14) AGREE-L[Dors] *in Korean* (de Lacy 2002, cited in Pater and Werle 2003)

a.	/əp+ko/	→	[əkko]	'bear on the back+CONJ'
	/kamki/	→	[kaŋki]	'a cold/influenza'
b.	/pat+ko/	→	[pakko]	'receive+CONJ'
	/han+kaŋ/	→	[haŋkaŋ]	'the Han river'
c.	/kot+palo/	→	[koppalo]	'straight'
	/han+bən/	→	[hambən]	'once'
d.	/paŋ+to/	→	[paŋto]	'room as well'
	/kuk+pap/	→	[kukpap]	'rice in soup'

This gives support to the analysis. However, there are also some concerns with an analysis in terms of agreement between two (non-adjacent) consonants. First, the domain of the constraint AGREE has to change in the course of development. Pater and Werle (2001) suggest that the domain for AGREE changes from "Word" in childhood to "string-adjacent consonants" in adulthood. It is not obvious how this domain change of AGREE would come about, however. A concern is the extra set of rerankings the learner would need to perform. Because of the initial Word-domain, the child's grammar has to go through different rankings in order to get the different FAITH[Place] constraints in higher positions in the constraint hierarchy than the AGREE constraint, which will over time rule out CH candidates. However, at the point where the child domain of AGREE changes into the string-adjacent adult domain, the grammar needs to undo all the rerankings of the FAITH[Place] constraints with respect to AGREE, in order to allow, or rather force, string-adjacent consonants to agree in primary place of articulation – as will often be the case in the target adult language. A second concern is the child-language-specific, non-local domain for AGREE itself. In this domain, the intervening vowel forms no obstacle for agreement between the non-adjacent consonants. This seems to imply that the solution to the locality problem of the proposal comes down to assuming that there is no locality requirement in child language.

3.4.2 Licensing

Rose (2000) and Goad (1997, 2001, 2003) view CH as resulting from the relation between features and prosodically strong positions. CH is a consequence of the requirement that place features within the domain of a foot should be licensed by the foot head (CHAPTER 40: THE FOOT). Place features in prosodically weak positions can surface through being associated with, and therefore licensed by, prosodically strong positions. According to Goad, the directionality of CH follows from prosodic structure; in English, word onsets of trochaic words are prosodically strong positions and consequently they can license marked features that cannot be licensed in weak prosodic positions. A marked feature in a weak prosodic position, i.e. a coda or an intervocalic consonant, needs to be licensed by this strong onset position, resulting on the surface in regressive harmony. In Rose (2000), where both English and French child language data are analyzed, high-ranked faithfulness constraints on input place of articulation features can force the direction of harmony to go from head to dependent.

In order to circumvent the problem of crossing association lines with an intervening vowel, association with the strong position is accomplished by *melody copy*, instead of spreading: a new instance of the harmonic feature is inserted in the harmonizing position. According to Goad (2001), this makes the process similar to reduplication in mature grammars. The drive to copy a melody is different in the two systems. In languages of the world, reduplication is morphologically driven: there is a reduplicative affix that needs melodic content. In child language, however, CH is usually present before morphology kicks in, and melody copy here is driven by prosodic licensing.

A prediction is that languages with different prosodic structures exhibit different types of CH. This claim is defended by Rose (2000). English children have CH in both C_1VC_2 and C_1VC_2V words, because C_1 and C_2 are within the domain of the foot in both types of words. In contrast, for French the prediction is that CH only occurs in CVCV words, because of the claim that in French the second consonant of CVC words lies outside the foot, it being extra-prosodic. It will therefore not be involved in CH patterns. Indeed, in the data of the French subject Clara, a word like *goutte* 'drop (N)' does not undergo CH even though it has the same sequence of features, Dorsal . . . Coronal, as *gâteau* 'cake', which does undergo harmony. This is illustrated in (15)–(17), with three examples from Rose (2001):

(15) *Dependent-to-head consonant harmony in English* (Coronal . . . Dorsal)

dog		MAX [Dors]	LIC (Dors,Ft)	MAX [Lab]	LIC (Lab,Ft)	MAX [Cor]	LIC (Cor,Ft)
a. [dɔg]			*!				
b. [dɔd]		*!					
☞ c. [gɔg]						*	

(16) *Head-to-dependent consonant harmony in French* (Dorsal . . . Coronal)

gâteau		MAX [Lab]	LIC (Dors,Ft)	LIC (Cor,Ft)	MAX [Cor]	MAX [Dors]	LIC (Lab,Ft)
a. [gæto]			*!				
b. [gæko]					*!		
☞ c. [dæto]						*	

(17) *No consonant harmony in CVC words in French* (Dorsal . . . Coronal)

goutte		MAX [Lab]	LIC (Dors,Ft)	LIC (Cor,Ft)	MAX [Cor]	MAX [Dors]	LIC (Lab,Ft)
a. [guk]					*!		
b. [dut]						*!	
☞ c. [gut]							

In (15) Dorsal is in the weak position of the foot, and needs to be licensed by the head position. This can be done by copying Dorsal into the head position, replacing input Coronal. Since faithfulness to input Coronal is low-ranked, this solution is optimal, and the output shows regressive Dorsal harmony. In (16), from French, Dorsal is again in the weak position and needs a licensor in the strong position of the foot. In this case, however, faithfulness to input Coronal is ranked higher than faithfulness to input Dorsal. The optimal candidate therefore does not show progressive Dorsal harmony, like the English example in (15), but regressive Coronal harmony. Finally, in (17), the second consonant is not in the foot. The licensing constraints do not apply in this case, and the optimal output candidate shows no harmony.

Although the idea of a licensing requirement seems attractive, in the end it does not seem to work. In practice, the combination of licensing and faithfulness constraints leads to a situation in which in English there is always regressive, dependent-to-head CH, while in French there is always regressive, head-to-dependent CH. The constant factor in CH, then, appears to be the regressive direction, rather than the licensing requirement. In addition, it remains unclear why the constraint ranking leading to CH forms in child language is not found in mature grammars. According to Goad, the drive to copy is different in developing and mature grammars, but as far as I can see nothing would preclude mature grammars from having a prosodic licensing drive. Finally, other French children do appear to have CH in both CVC and CVCV words (Wauquier-Gravelines 2003).

3.5 *Summary*

We have now seen that it is hard to convert the view of consonant harmony as agreement, spreading, or harmony between two non-adjacent consonants into a sound theoretical account.

We have seen three types of approach to the child-language specificness of the data: (i) the account has no child-language-specific aspects (Stemberger and Stoel-Gammon; Goad; Rose), leaving the issue unsolved; (ii) the account presents a child-language-specific aspect that could in principle also be present in mature grammars, i.e. planar segregation (McDonough and Myers), or a specific rule (Smith). Why mature grammars do not have this specific rule, or why a mature language with planar segregation probably does not have the specific type of CH we find in child language, still needs to be resolved; (iii) a formal change takes place in the grammar, which from then on precludes it from outputting CH forms (Menn; Pater and Werle; Iverson and Wheeler). This approach resolves the issue, but also introduces a new one: how does this formal change come about?

The intervening vowel, leading to the locality problem, is treated in four different ways: (i) it is not acknowledged as a problem (Menn; Smith; Iverson and Wheeler; Berg and Schade; Pater and Werle). In some cases this is because in the theoretical framework of the time consonants and vowels had different sets of place features; (ii) separate sets of place features are assumed for consonants and vowels (Stemberger and Stoel-Gammon); (iii) planar segregation is invoked to make CH a local process (McDonough and Myers); (iv) feature copying is assumed instead of feature speading (Goad; Rose). Only this last solution is able to circumvent the problem of crossing association lines in child language CH. However, crossing association lines is assumed to preclude the spreading of primary place of articulation features of consonants across vowels in mature languages. The copy solution thus solves the problem for child language, but creates a problem for the account of the absence of primary place of articulation CH in mature languages.

4 A re-analysis of consonant harmony in child language

It is clear that researchers have struggled to find an account that can explain the presence of primary place of articulation CH data exclusively in child language, without compromising the available theoretical tools.

While not abandoning these principles, there are advantages in assuming that the learner's developing phonological system differs from the adult system in certain respects (CHAPTER 101: THE INTERPRETATION OF PHONOLOGICAL PATTERNS IN FIRST LANGUAGE ACQUISITION). Levelt (1994) and Fikkert and Levelt (2008) stress the fact that consonant harmony in child language is not an isolated phenomenon (see Menn 1978 and Iverson and Wheeler 1987 for a similar view). The goal is therefore not to come up with an exclusive account of CH data, but to come up with a comprehensive account of developing place of articulation patterns in child language. When looked at in this way, it turns out that data that could be branded as instances of consonant harmony are present in child language at two different developmental stages. Since the data are, in both stages, clearly the result of a grammatical state specific to development, the fact that similar data are not found in adult languages is no longer puzzling.

In the remainder of this section, an overview of this approach is presented, focusing on the stages where so-called consonant harmony data are produced, and illustrated with longitudinal data from children acquiring Dutch (data from the CLPF database[2] and *Phon* (Rose *et al.* 2006)).

4.1 Place of articulation features

The place of articulation (PoA) features that play a role in this account are Labial, Coronal, and Dorsal. These features are monovalent and refer to both consonants and vowels (Clements 1991; Lahiri and Evers 1991; Hume 1992; Clements and Hume 1995). Thus Labial refers to both labial consonants and rounded vowels, Coronal to coronal consonants and front vowels, and Dorsal to dorsal consonants and back vowels (CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). Front rounded vowels like /y/ thus have a complex specification [Coronal, Labial], and back rounded vowels like /u/ have a complex specification [Dorsal, Labial]. The assumption here is that these vowels initially have a non-complex specification: Coronal for front vowels, and either Dorsal or Labial for back vowels. Front rounded vowels are acquired late, and are often replaced by front unrounded vowels. The low vowels /a/ and /ɑ/ are not specified for place of articulation – the idea being that place of articulation cannot be expressed in low vowels.[3]

4.2 Stage I: One word, one feature

In the CLPF corpus, in the first sets of meaningful words no combinations of different PoA features were found within words (CHAPTER 51: THE PHONOLOGICAL WORD), i.e. consonants and vowels within a word are all produced with the same PoA feature. The low vowels /a/ and /ɑ/ can be combined with either coronal, labial, or dorsal consonants. This is illustrated by data from Robin in (18):

(18) *Robin's (1;5.11) initial vocabulary*

a.	*die*	/di/	[ti]	'that one'
	huis	/hœys/	[hœys]	'house'
	niet	/nit/	[n̩t]	'not'
	thuis	/tœys/	[tœs]	'home'
	zes	/zɛs/	[sɛs]	'six'
	tiktak	/tɪktɑk/	[tita]	'tick-tock'
	aan	/an/	[an]	'on'
	daar	/dar/	[ta]	'there'
b.	*pop*	/pɔp/	[pɔ]	'doll'
	mamma	/mɑma/	[mɑma]	'mommy'
	aap	/ap/	[ap]	'monkey'

[2] CLPF database: data collected by Levelt (1994) and Fikkert (1994) of 12 children acquiring Dutch as their first language. Recordings were made every other week over a 12-month period. The database contains over 20,000 spontaneous utterances.

[3] In Dutch vowels also have a tense/lax specification, distinguishing /a e i o u/ from /ɑ ɛ ɪ ɔ u/. This specification is not relevant here.

The productions in (18a) all consist of coronal consonants (or placeless /h/) and coronal or low vowels, while the productions in (18b) have labial consonants and round or low vowels. A salient aspect of these data is that the adult target words have this same pattern. New words produced by Robin in the next two recording sessions also follow this pattern, as can be seen in (19):

(19) *New words produced by Robin (1;5.21–1;6.9)*

a.	*Coronal forms*			
	deze	/dezə/	[tis]	'this one'
	televisie	/teləvisi/	[zizi]	'television'
	trein	/trɛin/	[tin]	'train'
	ijs	/ɛis/	[æis]	'ice-cream'
	sesamstraat	/sesɑmstrat/	[zisa]	'Sesame Street'
	uit	/œyt/	[œyt]	'out'
b.	*Labial forms*			
	boom	/bom/	[bom]	'tree'
	mooi	/moi/	[bo:i]	'beautiful'
	bal	/bɑl/	[bɑo]	'ball'

This initial stage, then, can be characterized as "one word, one PoA feature." According to Levelt (1994) and Fikkert and Levelt (2008), this is caused by the fact that the initial unit for specification of PoA in the child's phonological system is the unsegmentalized word (see also, among others, Moskovitz 1971; Waterson 1971; Iverson and Wheeler 1987; de Boysson-Bardies and Vihman 1991). In Levelt (1994) early productions, like the ones in (18) and (19), are therefore represented as {WORD, Coronal} and {WORD, Labial}.

The data in (18) and (19) clearly do not resemble consonant harmony data at all. This is because the adult target words can be characterized by the same whole-word representations. Robin thus appears to select words for production that fit his phonological system. However, the data from Eva in (20) illustrate what happens in this whole-word stage when no selection takes place:

(20) *Whole-word stage: Eva (1;4.12)*

Coronal words

a.	*bed*	/bɛt/	[dɛt]	'bed'
b.	*kijk*	/kɛik/	[tɛĭt]	'look!'
c.	*prik*	/prɪk/	[tɪt]	'injection'
d.	*beer*	/ber/	[dɛ]	'bear'
e.	*dicht*	/dɪχt/	[dɪ]	'closed'
f.	*neus*	/nøs/	[nɛs]	'nose'
g.	*sleutel*	/sløtəl/	[høtœẙ]	'key'
h.	*trein*	/trɛin/	[tɛin]	'train'
i.	*eend*	/ent/	[en]	'duck'
j.	*eten*	/etə/	[etɪ]	'to eat'
k.	*konijn*	/konɛin/	[tæĭn]	'rabbit'
l.	*teen*	/ten/	[ten]	'toe'
m.	*vlinder*	/vlɪndər/	[ɪnə]	'butterfly'
n.	*auto*	/ɑuto/	[ɑŭtɑŭ]	'car'
o.	*patat*	/pa'tɑt/	[tɑt]	'French fries'

Labial words

p.	*brood*	/brot/	[bop]	'bread'
q.	*buik*	/bœyk/	[bop]	'stomach'
r.	*poes*	/pus/	[puf]	'cat'
s.	*sloffen*	/slɔfə/	[pɔfə]	'slippers'
t.	*schoenen*	/sχunə/	[umə]	'shoes'
u.	*oma*	/oma/	[oma]	'grandma'
v.	*op*	/ɔp/	[ɔp]	'on'
w.	*open*	/opə/	[opə]	'open'
x.	*aap*	/ap/	[ap]	'monkey'

Here we see that the productions both of adult target words that fit and of adult target words that do not fit a whole-word representation are represented as either {WORD, Coronal} or {WORD, Labial} in the child's phonological system. The productions in (20a)–(20c) and (20p)–(20t), of target adult forms that do not fit a whole-word representation, are forms that resemble CH forms consonants within a word that have different PoA features in the target form have identical PoA features in the produced form. However, with the possible exception of the account of Iverson and Wheeler (1987) discussed in §2.2.3, none of the above accounts can account for these forms. First, there is no fixed direction of assimilation, as illustrated below in (21a) and (21b). In (21a) a target Labial C–Coronal C combination becomes Labial C–Labial C, while the same target combination in (21b) leads to a Coronal C–Coronal C production. Second, sometimes the two "harmonized" consonants share a feature that is not present in the target form: the target Labial C–Dorsal C form in (21c) results in a Coronal C–Coronal C production.

(21) *Problems for a CH account*

a.	*brood*	/brot/	[bop]	'bread'
b.	*bed*	/bɛt/	[dɛt]	'bed'
c.	*prik*	/prɪk/	[tɪt]	'injection'

This is where the role of the target vowel becomes evident: the harmonizing feature does not originate with one of the target consonants, but with the target vowel. In case the target vowel is coronal, the child's production ends up being coronal throughout. In case the target vowel is labial, the child's production ends up being labial throughout. In (20a)–(20m) and (21b)–(21c), the target vowels are all coronal, and so are the consonants in the child's production. In (20p)–(20w) and in (21a), the target vowel is labial, and so are the produced consonants. This also accounts for the form in (20t), where the target word *schoenen*, containing the labial vowel /u/ but no labial consonants, is produced as [umə], with a labial [m]. The same applies to the form *beer* in (20d), which contains the coronal vowel /e/, but no coronal consonants, and is produced as [dɛ], with a coronal [d]. Low vowels, which do not carry a PoA specification, can be combined with either coronal consonants (20n), (20o) or labial consonants (20x).

The idea put forward in Levelt (1994) and Fikkert and Levelt (2008) is that at this developmental stage, the PoA specification of the representational unit WORD is provided by the target, non-low, vowel. In case the vowel is low, the PoA specification is provided by a consonant. This could have a perceptual background. The age group in which these homorganic productions are found, between 14 and 17 months, is the same age group that has been found to have difficulty discriminating similar-sounding words, e.g. *bin vs. din*, in perception studies (Stager and Werker 1997; Fikkert *et al.* 2003; Pater *et al.* 2004). Children in this age group have just started to build up their lexicon. It appears that at this point, the PoA information of perceptually salient segments, like vowels, can be mapped successfully onto a lexical representation, overriding the PoA information of less salient segments (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION).

To summarize, apparent CH data can be found in the initial vocabularies of children. As argued by Levelt (1994) and Fikkert and Levelt (2008), however, these data are not due to any interaction between non-adjacent consonants – hence "apparent CH" – but to the way in which early representations appear to be structured. The initial unit of specification is word-sized and carries a single PoA feature provided by the most salient segment of the target adult model, usually the vowel.

4.3 *Stage II: Overgeneralization*

After the initial stage in which words are unsegmentalized units, segmentalization gradually takes place, and at some point consonants and vowels within a word can be independently specified for place of articulation. This does not entail that all combinations of PoA features are immediately possible. Focusing on consonants, Labial + Coronal, Labial + Dorsal, and Coronal + Dorsal sequences are possible for quite some time, while Coronal + Labial and Dorsal + Labial sequences are absent from the data. It is at this stage that "typical" cases of CH start to appear in the data of some children. In this case too, it will be argued that the data are not due to a harmonic relation between non-adjacent consonants – hence the use of the quotation marks above.

(22) *"Typical" cases of consonant harmony: Robin (1;10.7)*

a.	*sop*	/sɔp/	[fɔp]	'suds'
	sloffen	/slɔfə/	[bɔfə]	'slippers'
	tafel	/tafəl/	[pafy]	'table'
	neef	/nef/	[mef]	'cousin'
	zeep	/zep/	[fep]	'soap'
b.	*klimmen*	/klɪmə/	[pɪmə]	'to climb'

At this stage in Robin's development, the PoA make-up of a produced word, given the PoA sequence of the adult target form, is completely predictable: any target word with a consonant sequence Coronal + Labial (22a) or Dorsal + Labial (22) will be produced with a consonant sequence Labial + Labial.

Interestingly, Fikkert and Levelt (2008) observe, in the longitudinal data of Robin and four other children, that these typical cases of consonant harmony only occur after a period in which attempted, non-homorganic sequences of consonants are exclusively of the types Labial + Coronal/Dorsal and Coronal + Dorsal. These attempted adult target words are always rendered faithfully with respect to the PoA structure in the children's productions. Adult target words with Coronal/

Dorsal + Labial sequences are simply not attempted in earlier stages. CH is thus an emerging phenomenon.

In Robin's data, for example, Fikkert and Levelt observe that around the age of 1;7.15 more and more adult target words with a Labial + Coronal consonant sequence, such as *bed* 'bed', *boot* 'boat', and *maan* 'moon', are attempted. Words with this PoA structure are highly frequent in Dutch. These targets are produced faithfully, i.e. with the same PoA structure. In Robin's production, then, the consonant sequence Labial + Coronal occurs frequently. One month later, in the recording at 1;8.12, the first cases of Labial CH appear. According to Fikkert and Levelt, there is a relation between these two events.

Their proposal is that, as soon as words can be segmentalized, after the initial stage in which words are unanalyzed wholes, the Dutch language learner analyzes his own active vocabulary and observes that Labial consonants are always found at the left edge of the word.[4] On the basis of this observation the learner overgeneralizes that Labial should always at least be aligned with the left edge of a word.

In OT terms this overgeneralization results in the emergence of a high-ranked constraint in the learner's grammar, requiring Labial to be aligned with the left edge of the word. This constraint is termed [Labial (Levelt 1994; Fikkert and Levelt 2008). The definition of the constraint is that an output word containing the feature Labial should always have an instance of Labial aligned with the left edge of the word. At this point, unfaithful, CH-like output forms for attempted input forms where there is no left-aligned Labial are deemed optimal by the grammar. This grammar is illustrated in (23):

(23) *Developmental grammar with emerged* [Labial

a. *poes* 'cat'

/pus/	[Labial	Faith
☞ i. pus		
ii. puf		*!

b. *tas* 'bag'

/tɑs/	[Labial	Faith
☞ i. tɑs		
ii. pɑs		*

c. *soep* 'soup'

/sup/	[Labial	Faith
☞ i. fup		*
ii. sup	*!	

[4] Even the few words in the Dutch learner's vocabulary with a Labial consonant at the right edge always have a Labial consonant at the left edge too: *pop* 'doll', *boom* 'tree', *mamma* 'mommy', *pappa* 'daddy'.

In (23a), the faithful candidate [pus] is the optimal candidate: a left-aligned instance of Labial is available without jeopardizing faithfulness. In (23b) the faithful candidate [tɑs] does not contain Labial, vacuously satisfying high-ranked [LABIAL. In (23c) the faithful candidate contains Labial, but there is no instance of a left-aligned Labial. The faithful candidate thus fatally violates high-ranked [LABIAL. The "CH" candidate [fup] does contain a left-aligned instance of Labial, at the cost of a faithfulness violation. However, faithfulness is ranked below [LABIAL, and [fup] is the winning candidate.

The very general constraint FAITH in (23) needs to be elaborated to show why other possible output candidates for input /sup/ that do not violate [LABIAL, like [sus], or metathesized [pus], are blocked (CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). In (24), a more detailed version of (23c), FAITH is split up into FAITH[Lab], requiring faithfulness to input Labial, a lower-ranked FAITH[Cor], requiring faithfulness to input Coronal, and LINEARITY, requiring faithfulness to the linear order of input segments.

(24) *Interaction of* [LABIAL *and Faithfulness constraints*

/sup/	[LABIAL	LINEARITY	FAITH[Lab]	FAITH[Cor]
☞ a. fup				*
b. sup	*!			
c. pus		*!		
d. sus			*!	

The hypothesis that CH data are due to an alignment requirement rather than to a harmony requirement is strengthened by data from other children, who appear to use metathesis in order to comply with the alignment requirement, as shown in (25):

(25) *Metathesized forms in child language*

Dutch	*kip*	/kɪp/	[pɪk]	'chicken'	(Noortje; Fikkert and Levelt 2008)
English	*sheep*		[piç]		(Alice; Jaeger 1997)
	TV		[piti]		
Spanish	*sopa*	/sopa/	[pwɔta]	'soup'	(Si; Macken 1979)
	libro	/libro/	[pɪtɔ]	'book'	

For these children, the faithfulness constraints LINEARITY and FAITH[Cor] are ranked in the opposite order from the one in (24), i.e. FAITH[Cor] >> LINEARITY. Of the output candidates complying with [LABIAL, this grammar prefers a metathesized form over a CH form. The relation between consonant harmony and metathesis is also noticed by Goad (2001) and Rose and dos Santos (2004).

To summarize, according to Levelt (1994) and Fikkert and Levelt (2008), the apparent CH data arising at this stage of development are, again, not the result of an assimilation process between non-adjacent consonants. Instead, they appear to result from the overgeneralization of a frequent PoA pattern in the active vocabulary of the learner, where Labial segments are either exclusively – or additionally, in case of Labial + Labial target words like *mommy* – found at word onsets. The pattern in the learner's vocabulary, in turn, reflects a highly frequent PoA pattern in the surrounding language.

This makes a testable prediction, namely that, depending on the distribution of PoA patterns in the language to be acquired, language learners will show different types of PoA alignment. Highly frequent patterns in the language enter the developing vocabulary first, and overgeneralization – if present – will be based on these language-specific frequent patterns. Fikkert *et al.* (2003) show that different distributions of PoA patterns in Dutch and English can indeed account for the different types of PoA-alignment data in Dutch and English child language. In English child language data, both Labial and Dorsal alignment occur, while in Dutch child language data only Labial alignment has been attested. This promising initial result should be elaborated.

Detailed studies of the development of PoA in longitudinal data of children acquiring languages other than Dutch are now needed to test the validity of the perspective discussed in this section.

5 Conclusions

Hansson (2001) tries to pull together consonant harmony in languages of the world and in child language, by pointing out that the source of these data is probably found in speech processing; consonant harmony productions are in fact phonologized speech errors. According to Hansson, the difference in place of articulation bias between adult CH and child CH is caused by the nature of the sound inventory. The sound inventory of language learners is small, and doesn't require the secondary place features that harmonize in adult languages to distinguish sounds.

Based on a detailed study of the longitudinal development of PoA patterns in child language productions, Levelt (1994) and Fikkert and Levelt (2008) come to a different conclusion. Consonant harmony forms in child language are not phonologized speech errors, but products of an immature phonological system. In the earliest stages of word production, CH-like forms result from an as yet unanalyzed representational unit Word, which can be specified for a single place of articulation feature. At a later stage, when words have segmental representations, CH-like forms result from the overgeneralization of a place of articulation pattern in a small vocabulary.

Instead of pulling together the two types of data, i.e. child language data and cross-linguistic data, then, it might be better to pull them apart, by providing them with different terms. *Consonant harmony* is a phenomenon that can be found in the world's languages. In child language there is an initial stage where words are *homorganic*, while *PoA alignment* occurs in later stages.

With this new perspective on child language data, it is no longer necessary to wonder why neither homorganic data nor PoA-alignment data are found in languages of the world: both types of data are due to specific developmental states of the phonological system that, because of fundamental changes, are transient and therefore no longer accessible in mature grammars. One developmental state is characterized by the initial unsegmentalized word-sized unit in early phonological representations. Later, these word-sized units are, irrevocably, replaced by segment-sized units. In the other developmental state the learner generalizes over his own – still small – vocabulary. The PoA structure of words in this developing vocabulary reflects a highly frequent pattern in the surrounding language. PoA-alignment data occur when this pattern is overgeneralized, leading to the emergence of a constraint in the developing grammar. Overgeneralization is typical for child language, and disappears when enough experience with other data is gathered. With the expansion of the learner's vocabulary, more and more evidence will be available that Labial is not necessarily always left-aligned. On the basis of this counterevidence, the learner will conclude that [Labial should not be an active constraint in the grammar. The constraint will disappear, or be demoted to the lowest ranks of the grammar, and candidates formerly called consonant harmony forms will never again be optimal.

ACKNOWLEDGMENTS

I would like to thank the editors for their invitation to contribute to the *Companion to Phonology*, and two anonymous reviewers for their detailed and helpful comments on the manuscript. Preparation of this chapter was made possible by a grant from the Netherlands Organization for Scientific Research (NWO Vidi grant 276-75-006).

73 Chain Shifts

Anna Łubowicz

1 What is a chain shift?

This chapter provides background on chain shift mappings. In a phonological chain shift, underlying /A/ maps onto surface [B] and underlying /B/ maps onto surface [C] in the same context but, crucially, underlying /A/ does not become surface [C]. Thus a chain shift has a standard representation A → B → C (see Ultan 1970; Kenstowicz and Kisseberth 1979; Labov 1994; Kirchner 1996; Parkinson 1996; Gnanadesikan 1997; Dinnsen and Barlow 1998; McCarthy 1999; Moreton and Smolensky 2002; amongst others).

The Finnish vowel shift (McCawley 1964; Lehtinen 1967; Keyser and Kiparsky 1984; Anttila 1995, 2002a, 2002b; Karlsson 1999; Harrikari 2000) provides an example. In Finnish, before the plural suffix *-i* (and before the past tense marker *-i*), long low vowels shorten (/aa/ → [a]), short low vowels undergo rounding and raising (/a/ → [o]), and short round vowels surface unchanged (/o/ → [o]). Thus we have the following chain shift effect:

(1) *Finnish chain shift*

aa → a → o ↻

Some examples are given in (2).

(2)			*sing nom*	*plural essive*	
	a.	/aa/ → [a]	*maa*	*ma-i-na*	'earth'
			vapaa	*vapa-i-na*	'free'
	b.	/a/ → [o]	*kissa*	*kisso-i-na*	'cat'
			vapa	*vapo-i-na*	'fishing rod'
	c.	/o/ → [o]	*talo*	*talo-i-na*	'house'
			pelko	*pelko-i-na*	'fear'

The key issue is that in Finnish, forms with underlying long low vowels shorten but do not round (/aa/ → [a], *[o]), but forms with underlying short low vowels undergo rounding in the same context (/a/ → [o]).

Chain shifts have been found in diverse areas, including dialectal variation (Labov *et al.* 1972; Labov 1994; Labov *et al.* 2006), language acquisition (Smith 1973; Braine 1976; Macken 1980; Dinnsen and Barlow 1998; Dinnsen *et al.* 2001; Jesney 2007), synchronic phonology (Rubach 1984; Hayes 1986; Clements 1991; Kirchner 1996; Parkinson 1996; McCarthy 1999; Moreton 2004; van Oostendorp 2004), and diachronic phonology (Bauer 1979, 1992; Lass 1999; Schendl and Ritt 2002; Minkova and Stockwell 2003; Ahn 2004).

This chapter focuses on synchronic chain shifts. A compendium of synchronic chain shifts has been compiled by Moreton (2004), and a corpus of synchronic chain shifts can be also found in Moreton and Smolensky (2002). It is important to note that some diachronic chain shifts have also been given a synchronic analysis, as in Miglio and Morén (2003).[1]

Many types of chain shifts have been described in the literature (see references in §2). There is debate on whether the description of chain shift types is accurate. This chapter will address the typology of chain shift mappings in the context of various theoretical proposals. It will describe the types of chain shifts found in the literature, and address the validity of this typology under different analyses.

Two background assumptions are made in this chapter. First, it is assumed that to describe the typology of chain shifts, it is important not only to provide an empirically correct analysis of a chain shift, but also to explain *why* chain shifts exist in phonology. That is, uncovering the motivation for chain shift mappings is essential to gain a full understanding of the genesis and acquisition of chain shifts.

The second background assumption is that the typology of chain shifts can be (largely) described in terms of markedness, where markedness motivates a phonological process (see §4). Since, as will be shown, analyses based solely on markedness fail to account for the attested types of chain shifts, it is suggested that something in addition to markedness drives chain shifts. A possible solution to this problem is provided in the form of an analysis with contrast (see §3.3), where a phonological process can take place to preserve contrast as well as satisfying markedness. This idea gives rise to potential avenues of productive research on chain shifts and phonology in general.[2]

The rest of this chapter is organized as follows. §2 introduces the typology of chain shifts. §3 describes several analyses of chain shift mappings. Finally, §4 explores implications of the various analyses for the typology of chain shifts.

2 The typology

Chain shift mappings can be categorized by type of segment (see §2.1) and mapping (see §2.2) involved in the shift.[3]

[1] For a discussion of diachronic processes in OT, see Holt (2003). See also CHAPTER 93: SOUND CHANGE.

[2] I would like to thank an anonymous reviewer for comments on this point.

[3] There are other possible ways to characterize chain shifts that are not discussed here: the number of steps involved in the shift (Gnanadesikan 1997), the trajectories of changes (Labov 1994), the extent of mergers (near mergers *vs.* full mergers) (Parkinson 1996), and the location of the mapping (the segment *vs.* the environment) (Łubowicz 2004).

2.1 *Segment type*

Both vowels and consonants can be involved in a shift. Some examples of vowel height chain shifts come from Bassá (Bantu; Schmidt 1996), Gbanu (Niger-Congo; Bradshaw 1996), Kikuria (Bantu; Chacha and Odden 1998), Lena Spanish (Hualde 1989), Nzɛbi (Clements 1991), and Servigliano Italian (Kaze 1989); see also CHAPTER 21: VOWEL HEIGHT; CHAPTER 110: METAPHONY IN ROMANCE. These are mostly mappings involving raising (Parkinson 1996). Some examples of consonantal chain shifts come from Southern Paiute (Sapir 1930; McLaughlin 1984), Toba Batak (Hayes 1986), Estonian (Ultan 1970), Finnish (Ultan 1970), and Irish (CHAPTER 117: CELTIC MUTATIONS; Ní Chiosáin 1991). These are mostly mappings involving lenition along either the voicing or consonantal stricture scale (Gnanadesikan 1997) (see also CHAPTER 13: THE STRICTURE FEATURES; CHAPTER 65: CONSONANT MUTATION; CHAPTER 66: LENITION). See (3) and (4), respectively.

(3) *Vowel shifts*

a. New Zealand English (Labov 1994) æ → e → i → ɨ
b. Nzɛbi (Bantu; Clements 1991) a → ɛ → e → i; ɔ → o → u

(4) *Consonantal shifts* (Ultan 1970)

a. Southern Paiute (Uto-Aztecan; Sapir 1930) pp → p → v
b. Toba Batak (Austronesian; Hayes 1986) np → pp → ʔp

A comprehensive account of vowel and consonant shifts is provided by Gnanadesikan (1997). The crux of Gnanadesikan's proposal is ternary scales that explain the type of segments involved in a chain shift mapping.

2.2 *Mapping type*

Another criterion for categorizing chain shifts, and the one that is the focus of this chapter, is the type of the mapping involved. This includes pull shifts, push shifts, circular shifts, and what I will refer to as regular shifts (these will be discussed in §2.2.4). All four kinds of chain shifts have been proposed in the literature. They are described below.

2.2.1 *Push shifts*

Assume that /A/ maps onto [B] (A → B) and /B/ maps onto [C] (B → C), but, crucially, /A/ does not become [C]. Thus there is a chain shift effect of the form A → B → C. One type of a chain shift is a push shift. In a phonological push shift, the latter step in the shift, /B/ → [C], is a consequence of the prior step, /A/ → [B], and not an independently motivated phonological process (see Martinet 1952, 1955; Labov 1994; Schendl and Ritt 2002; Miglio and Morén 2003; Ahn 2004; Maclagan and Hay 2004; Hsieh 2005; Barrie 2006; amongst others).

Some examples of push shifts described in the literature include the Swedish shift (Benediktsson 1970; Labov 1994): a → aː → ɔː → oː → uː → ʉː; the New Zealand shift (Bauer 1979, 1992; Trudgill *et al.* 1998; Gordon *et al.* 2004; Maclagan and Hay 2004): æ → e → i → ei/ɨ (but see Labov 1994); the Northern Cities shift (Labov 1994): ɛ → ʌ → ɔ; the Great Vowel Shift in English (Luick 1914; Jespersen

1949; Miglio and Morén 2003; Minkova and Stockwell 2003): ɛː → eː → iː → ai; ɔː → oː → uː → au; the Short Vowel Shift in Early Modern English (Lass 1999; Schendl and Ritt 2002): u → o → ɔ → ɒ; a → æ; and tone sandhi in Xiamen, a dialect of the Min language of the Sino-Tibetan family (Barrie 2006; Chen 1987) (see §4).

The basic observation is that the latter mapping takes place as a consequence of the prior mapping (hence the *push* effect). Push shifts are further described in §4.1, using the example of tone sandhi. §4.1 also evaluates various theoretical proposals with respect to push shifts.

2.2.2 *Pull shifts*

Another kind of shift found in the literature is a pull shift, also known as a drag shift (King 1969). Pull shifts are the opposite of push shifts. In a pull shift, the prior mapping in the shift, /A/ → [B], takes place as a consequence of the latter mapping, /B/ → [C], and is not an independently motivated phonological process (hence the *pull* effect).

Some examples of pull shifts reported in the literature include diachronic changes involved in the Lettish and Lithuanian Chain Shift (Endzelin 1922; Labov 1994: 134): eː → iə → iː → ij and oː → uə → uː → uw; the North Frisian Chain Shift (Labov 1994: 136): iː → i → a; uː → u → a; the Middle Korean Vowel Shift (Labov 1994: 139): e → ə → ɨ → u → ɔ → a; and the Northern Cities Shift (Labov 1994: 195): ɔ → ɑ → æ → ɪə; i → e → æ.

The arguments for pull shifts often involve historical evidence, whereby the latter mapping in the shift, /B/ → [C], historically precedes the prior mapping, /A/ → [B] (Labov 1994). It remains a question whether pull shifts are possible synchronically. This chapter will show that synchronic pull shifts are not admitted under any of the theoretical proposals to be described (see §4.2).

2.2.3 *Circular shifts*

In a circular shift, mappings form a circle or a semi-circle. Exchange processes (Anderson and Browne 1973) are examples of circular shifts: /A/ → [B] and /B/ → [A]. Circular shifts are often seen as morphologically conditioned (Anderson and Browne 1973; Moreton 1996; Alderete 2001a, 2001b; Horwood 2001).

Some examples of circular shifts, or exchange mappings, are consonantal polarity in Luo (Gregersen 1972; Okoth-Okombo 1982; Alderete 2001a), plural formation in Diegueño verbs (Langdon 1970; Walker 1970), vowel shift in Brussels Flemish (Zonneveld 1976; but see Moreton 1996), and tonal circles, also known as tone sandhi, in Xiamen (Cheng 1968, 1973; Yip 1980; Chen 1987; Moreton 1996; Hsieh 2005; Barrie 2006).[4]

It remains a question whether circular shifts have been described accurately in the literature. For example, it has been proposed that some circular chain shifts are conditioned morphologically, rather than being phonological (also CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE, but see Crowhurst 2000). Circular shifts are further discussed in §4.3.

2.2.4 *Regular shifts*

Finally, in what I will refer to as a regular shift, both mappings in the shift take place independently in the language, but form a chain shift when put together.

[4] For additional examples see Moreton (1996: 21).

For example, in Sea Dayak (Kenstowicz and Kisseberth 1979) there is a chain shift that includes cluster simplification (consonant deletion) and vowel nasalization: ŋga → ŋa → ŋã. Both nasalization and cluster simplification are found independently in the language, but nasalization fails in the context of consonant deletion. A similar process interaction is found in Ulu Muar Malay (Hendon 1966; Lin, forthcoming). Regular shifts are discussed further in §4.4.

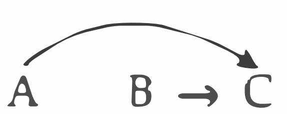
The following sections will address the validity of the typology of chain shifts described above.

3 Theoretical accounts of chain shifts

Chain shifts are a type of opaque process (Kiparsky 1973; Rubach 1984). Chain shifts are opaque because in a phonological chain shift one (or more) of the phonological processes simply do not apply as they should, based on the phonology of the language. Depending on the perspective taken by the analyst, in a chain shift mapping a phonological process underapplies (it does not apply where expected) or overapplies (it applies where it should not). Both underapplication and overapplication have been shown to be examples of opaque processes (Benua 1997; McCarthy 1999, 2003a, 2003b). Underapplication and overapplication are also known as counterfeeding and counterbleeding opacity, respectively (Kiparsky 1973). In the following discussion, opaque processes are considered with respect to synchronic phonologies.

Assuming a phonological chain shift A → B → C, the key property of chain shifts is that in the same context /A/ and /B/ map onto different outputs: /A/ goes to [B] and /B/ goes to [C]. This is unexpected. One might expect the two inputs to map onto the same output in one and the same grammar.[5]

(5) *Expected mapping*



A theoretical account of chain shifts has been sought for a long time. The rest of this section describes several accounts of chain shifts found in the literature, such as rule ordering (§3.1), local conjunction (§3.2), and Optimality Theory with contrast (§3.3). The predictions of these approaches will be compared in §4.[6]

3.1 Rule ordering

In rule-based phonology (Kenstowicz and Kisseberth 1979; Rubach 1984), chain shifts are most commonly accounted for by rule ordering. In a phonological chain shift A → B → C, it is proposed that /B/ → [C] precedes /A/ → [B]. Thus, derived [B]s do not map onto [C]. This is illustrated by the following derivation. There are two rules that apply in a fixed order: B → C / __ D precedes A → B / __ D. This ordering results in a chain shift effect.

[5] Another possibility would be for /B/ → [C] not to occur, so both /A/ and /B/ would map onto [B].
[6] Chain shifts have also been accounted for by underspecification in rule-based phonology. The underspecification account of chain shifts is not discussed here but see Kiparsky (1993).

(6) *Chain shift in rule ordering*

Input	/AD/	/BD/
Rule 1: B → C / __ D	does not apply	CD
Rule 2: A → B / __ D	BD	does not apply
Output	[BD]	[CD]

In Sea Dayak (Kenstowicz and Kisseberth 1979: 298, 308), there is a rule of nasalization which specifies that a vowel nasalizes immediately after a nasal, and a rule of nasal cluster simplification that deletes an obstruent following a nasal. Kenstowicz and Kisseberth propose that the rule of nasalization precedes the rule of nasal cluster simplification. Therefore nasalization fails in forms where the consonant deletes. Due to the specific rule ordering, the form /naŋga/ 'set up a ladder' maps onto [nãŋaʔ], while /naŋa/ 'straighten' maps onto [nãŋãʔ], with glottal insertion in both forms.

(7) *Sea Dayak in a rule ordering analysis*

Input	/naŋga/	/naŋa/
Vowel nasalization	nãŋga	nãŋã
Nasal cluster simplification	nãŋa	does not apply
Output	[nãŋaʔ]	[nãŋãʔ]

The predictions of rule ordering for the typology of chain shifts will be discussed in §4.

3.2 Local conjunction

There are different ways to account for chain shifts in Optimality Theory (OT) (Prince and Smolensky 1993; Kager 1999; McCarthy 2002). This section describes a common way of accounting for chain shifts in OT, "local constraint conjunction." Other OT approaches to chain shifts include more general accounts of opacity in OT, such as Sympathy Theory (McCarthy 1999, 2003a), Stratal or Derivational OT (Kiparsky 2000; Rubach 2003; Bermúdez-Otero 2007), output–output correspondence (Benua 1997; Burzio 1998), targeted constraints (Wilson 2001), comparative markedness (McCarthy 2003b), turbidity (Goldrick and Smolensky 1999), gestural coordination theory (Lin, forthcoming), and candidate chain theory (McCarthy 2007).

According to Gnanadesikan (1997) and Kirchner (1996), the solution to chain shift mappings in OT lies in an enriched theory of faithfulness (CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). Both researchers propose special types of faithfulness constraints that block two-step movements like /aai/ → [oi], thereby accounting for the discrepancy in phonological mappings between identical derived and underlying segments. Kirchner uses locally conjoined faithfulness constraints (Smolensky 1993, 1997), whereas Gnanadesikan distinguishes between classical IDENT-type constraints and novel IDENTADJACENT-type constraints on some scale of similarity.

Local conjunction is defined in (8) (Smolensky 1993).

(8) The Local Conjunction of C_1 and C_2 in domain D, $C_1 \&_D C_2$, is violated when there is some domain of type D in which both C_1 and C_2 are violated.

If the domain of local conjunction is a segment, both C_1 and C_2 cannot be violated together in the same segment.

The following tableaux give a schematic overview of the local conjunction analysis of chain shifts. A phonological process, /B/ → [C], applies only if there is no double violation of faithfulness in the same segment, $[F(A \rightarrow B) \& F(B \rightarrow C)]_{Seg}$.[7]

(9) *Chain shifts in local conjunction*

No violation of local conjunction (/B/ → [C])

/BD/	$[F(A\rightarrow B) \& F(B\rightarrow C)]_{Seg}$	*BD	F(B→C)	F(A→B)
a. BD		*!		
☞ b. CD			*	

Violation of local conjunction (/A/ → [B], *[C])

/AD/	$[F(A\rightarrow B) \& F(B\rightarrow C)]_{Seg}$	*BD	F(B→C)	F(A→B)
☞ a. BD		*		*
b. CD	*!		*	*

Local conjunction blocks /A/ from mapping all the way onto [C] (see the second tableau in (9)). In other words, /B/ → [C] is blocked for underlying [A]s, but applies to underlying [B]s (compare the two tableaux in (9)).

Applied to Sea Dayak (shown in (7)), the local conjunction analysis would be as follows:[8]

(10) *Sea Dayak in a local conjunction analysis*

No violation of local conjunction

/naŋa/	$[\text{IDENT[nas]} \& \text{MAX}]_{AdjSeg}$	*NV	IDENT[nas]	MAX
a. nàŋa		*!	*	
☞ b. nāŋā			**	

Violation of local conjunction

/naŋga/	$[\text{IDENT[nas]} \& \text{MAX}]_{AdjSeg}$	*NV	IDENT[nas]	MAX
☞ a. nàŋa		*	*	*
b. nāŋā	*!		**	*

[7] Faithfulness constraints in the conjunction $[F(A\rightarrow B) \& F(B\rightarrow C)]_{Seg}$ refer to the dimensions of similarity between segments and do not require that [B] is visible in the output. As suggested by an editor of the *Companion to Phonology*, it can be rewritten as $[F(A\rightarrow B) \& F(A\rightarrow C)]_{Seg}$. The difference lies in the formulation of the latter faithfulness constraint, F(B→C) *vs.* F(A→C). For notational convenience, I have chosen to refer to the latter conjunct as F(B→C).

[8] The constraints are as follows: *NV (no nasal followed by a non-nasal vowel), MAX (no deletion), IDENT[nas] (no change in nasality compared with the input), and $[\text{IDENT[nas]} \& \text{MAX}]_{AdjSeg}$ (no change in nasality and deletion in adjacent segments).

Due to local conjunction, there is no nasalization in the form that undergoes cluster simplification (see the second tableau in (10)). However, nasalization applies in the form with no cluster simplification (see the first tableau).

3.3 *OT with contrast*

An alternative explanation for chain shifts in OT starts from the observation that chain shifts always preserve one underlying contrast at the expense of neutralizing another underlying contrast (Łubowicz 2003). In Finnish (shown in (1) and (2)), the contrast between underlying /aai/ and /ai/, originally one of length, is preserved, albeit in a different form – as a rounding contrast (underlying /aai/ *vs.* /ai/, surface [ai] *vs.* [oi]). The contrast between underlying /ai/ and /oi/, the original rounding contrast, is lost (both become [oi]). Thus:

(11)	*Input*		*Output*
	length contrast	→	rounding contrast
	rounding contrast	→	neutralized

This is referred to as *contrast transformation.*[9]

This observation has given rise to Preserve Contrast (PC) theory (Łubowicz 2003, 2004, 2007, forthcoming).[10] The key idea is that contrast exists as an imperative in a phonological system formalized as a family of rankable and violable constraints which demand that contrast be preserved, "PC constraints" (cf. Flemming 1995, 2004; Padgett 1997, 2003; Padgett and Zygis 2007; amongst others). PC constraints demand that pairs of words that contrast underlyingly with respect to a given phonological property P contrast on the surface (not necessarily with respect to P). Such constraints are defined in (12).

(12) PC(P)

For each pair of inputs contrasting in P that map onto the same output in a scenario, assign a violation mark. Formally, assign one mark for every pair of inputs, in_a and in_b, if in_a has P and in_b lacks P, $in_a \rightarrow out_k$, and $in_b \rightarrow out_k$. (Informally, if inputs are distinct in P, they need to remain distinct in the output (not necessarily in P).)[11]

P is a potentially contrastive phonological property, such as a distinctive feature, length, stress, or presence *vs.* absence of a segment. The properties P, then, are essentially the same as the properties governed by faithfulness constraints in standard OT. Indeed, PC(P) constraints are like faithfulness constraints in that they look at two levels of representation. But they are novel in that they evaluate contrasts for pairs of underlying words and corresponding output words instead

[9] Earlier works on contrast include Kaye (1974, 1975), Gussmann (1976), and Kisseberth (1976).

[10] Other works on PC theory include Tessier (2004), Barrie (2006), Flack (2007), and Riggs (2008). Similar ideas are expressed in the Dispersion Theory of Contrast (Flemming 1995, 2004; Padgett 1997, 2003; Itô and Mester 2004; Bradley 2001; Padgett and Zygis 2007).

[11] What it means to contrast in P is defined as follows: a pair of inputs, in_a and in_b, contrast in P when corresponding segments in those inputs, seg_a and seg_b, are such that seg_a has P and seg_b lacks P.

of evaluating individual input–output mappings. To evaluate constraints on contrast, candidates must be sets of mappings, called *scenarios*.

There are also generalized faithfulness constraints in PC theory that will become important in the discussion of circular shifts in §4.3.

The following tableau shows how PC theory accounts for chain shifts. The tableau compares three scenarios: a chain shift scenario, an identity scenario where all inputs map onto identical outputs, and a transparent scenario with no /B/ → [C]. The constraint ranking proposed below captures the observation that the initial mapping in the shift, /A/ → [B], is due to markedness, but the subsequent mapping, /B/ → [C], is facilitated by contrast preservation. The relevant ranking is: *A, PC(A/B) >> PC(B/C).[12]

(13) *Chain shifts under contrast*

	Scenarios	*A	PC(A/B)	PC(B/C)
☞ a. Chain shift	/A/ → [B] /B/ → [C] /C/ → [C]			*
b. Identity	/A/ → [A] /B/ → [B] /C/ → [C]	*!		
c. Transparent	/A/ → [B] /B/ → [B] /C/ → [C]		*!	

The identity scenario, scenario (13b), loses because it violates markedness *A. The transparent scenario, scenario (13c), neutralizes contrast, thus violating PC(A/B). The chain shift scenario, scenario (13a), wins under the proposed constraint ranking. In the chain shift scenario, the /B/ → [C] mapping applies to preserve contrast between /A/ and /B/.[13]

The predictions of PC theory will be further discussed in the following section.[14]

4 Implications for the typology of chain shifts

The goal of this section is to examine what chain shifts are predicted to occur under various approaches. Chain shifts will be subdivided on the basis of the relationship between various stages in the shift. This typology can be referred to as *teleological*, because it differentiates reasons as to why a chain shift takes place, rather than merely describing the chain shift. This view is not novel, and is also

[12] It is important to point out that not all chain shifts are push shift mappings in this approach to phonology. PC theory can also describe the "regular" shifts (see §4.4).

[13] A competing derived environment scenario where A → C and B → B incurs the same violations of PC and markedness constraints as the winning chain shift scenario. It has been proposed that the two scenarios would be differentiated in the second stage of Eval by generalized faithfulness constraints (Łubowicz 2003).

[14] For a comprehensive discussion of PC theory and its predictions, see Łubowicz (2003, forthcoming).

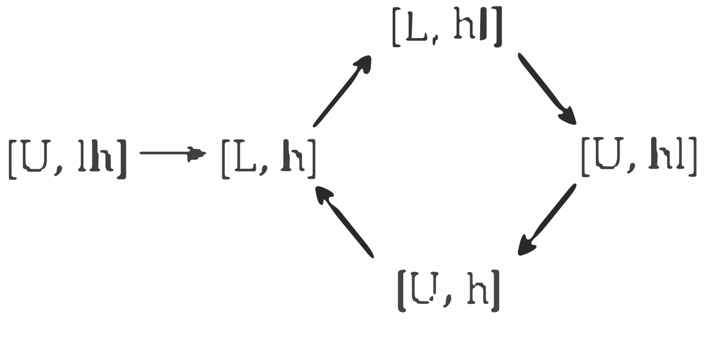
taken by Optimality Theory. Rule-based approaches are non-teleological, since rules do not look for the reason why a phonological process takes place. Predictions of both rule-based approaches and OT approaches to chain shifts are described below.[15]

4.1 Push shifts

Recall that in push shift mappings (see §2.2.1), the latter mapping in the shift is a consequence of the prior mapping and not an independently motivated phonological process. To argue that A → B → C is a push shift mapping, one must show that there is no independent motivation for the latter mapping in the shift, B → C (in OT, no markedness constraint that favors [C] over [B]). In addition, one must establish that the mapping /B/ → [C] is always linked with /A/ → [B].

The tonal system of Xiamen, a dialect of the Min language of the Sino-Tibetan family (see Chen 1987; Barrie 2006; CHAPTER 107: CHINESE TONE SANDHI) provides an example of a push shift mapping. The diagram below (14) uses the following notation: [U] is upper register, [L] lower register, [lh] rising pitch, and [hl] falling pitch. Thus [U, lh], for example, is a high-rising tone, where the pitch moves from the low end of the upper register to the high end.

(14) *Xiamen tone sandhi*



Barrie (2006) observes that the tonal shift above is an example of a push shift, because the latter mapping in the shift, [L, h] → [L, hl], is a result of the prior mapping, [U, lh] → [L, h]. Specifically, the initial mapping in the shift, [U, lh] → [L, h], is due to markedness improvement, such as avoidance of rising tones (*[U, lh]). However, the subsequent mapping, [L, h] → [L, hl], does not improve on markedness, since it creates a contour tone from an input level tone, and research on tonal markedness has shown that contour tones are more marked than level tones (Alderete 2001a; Yip 2004; CHAPTER 45: THE REPRESENTATION OF TONE). Barrie proposes that the latter mapping in the shift, [L, h] → [L, hl], is a result of the initial mapping, [U, lh] → [L, h], and the need to maintain contrast between tones of various registers, [U] *vs.* [L]. In other words, due to the chain shift effect, the input tones [U, lh] and [L, h] map onto [L, h] and [L, hl], respectively. Otherwise, if there was no shift both input tones would map onto the same output, [L, h]. The remaining mappings in the shift are analyzed in a similar manner (for a complete analysis see Hsieh 2005 and Barrie 2006).

Push shifts are problematic for rule-based approaches to phonology. In rule-based approaches, chain shifts are accounted for by rule ordering (see §3.1). But in a push shift mapping, there is no separate rule that accounts for the latter

[15] Thanks to a reviewer for comments on this point.

mapping in the shift. If there was a separate rule for the latter mapping in the shift, it would be predicted that the process would occur outside of the chain shifting context. But in a push shift, the latter process is always linked with the prior process, and does not apply independently. In consequence, synchronic push shifts cannot be described under a rule-based analysis.

Similarly, push shifts are problematic to OT without contrast (see §3.2). This approach does not admit push shifts, because in OT, a phonological process can only apply if there is a high-ranked markedness constraint against it (Moreton 1996). But in a push shift, /B/ → [C] is not due to markedness. In Xiamen (see (14)), both the initial mapping in the shift, [U, lh] → [L, h], and the subsequent mapping, [L, h] → [L, hl], would need to be forced by markedness constraints. The problem here is that [L, h] → [L, hl] cannot be accounted for by markedness improvement. Thus, OT without contrast would not account for push shifts, because in a push shift mapping there is no high-ranked markedness constraint that triggers the latter mapping in the shift.[16]

OT with contrast (see §3.3), on the other hand, proposes a solution to push shift mappings which makes use of contrast as an independent principle in a phonological system. The key observation is that the initial mapping in the shift, /A/ → [B], takes place to improve on markedness, but the latter mapping in the shift, /B/ → [C], is due to contrast preservation. In tone sandhi (shown in (14)) OT with contrast proposes that the latter mapping in the shift, [L, h] onto [L, hl], takes place to preserve contrast between tones of various registers, [U] *vs.* [L] (Barrie 2006). Thus, OT with contrast, unlike other approaches, admits push shifts. Depending on further evidence on push shift mapping, OT with contrast is promising in this respect.

4.2 *Pull shifts*

Another type of chain shift found in the literature is a pull shift mapping. In a pull shift mapping, also known as a drag shift, the prior mapping in the shift, /A/ → [B], takes place because the latter mapping, /B/ → [C], occurs (King 1969). In OT, the prior mapping in the pull shift does not occur due to markedness. Unlike push shifts, pull shift mappings are ruled out in all approaches to chain shifts discussed so far.

Rule-based approaches do not allow pull shifts, because they require that there is a separate rule that accounts for each mapping in the shift (see §3.1). In a pull shift mapping, however, there is no separate rule that accounts for the initial mapping in the shift. Rather, the initial mapping in the shift is always linked with the latter mapping, and does not occur independently. Thus, pull shifts are predicted not to occur by rule ordering.[17]

[16] In response to a reviewer's comments, it is important to point out that additional mechanisms in OT such as strata, candidate chains, sympathy, etc. do not admit push shifts. All these models *require* markedness to force a phonological process, and in a push shift markedness is not enough. As discussed here, by the introduction of contrast constraints into Con, a possible account of push shifts is provided.

[17] A reviewer points out that a rule-based approach to phonology is inherently non-teleological, unlike OT, and thus would not differentiate chain shifts based on what is the cause of a particular process, such as pull shifts *vs.* push shifts.

In OT without contrast (see §3.2), similarly, pull shifts cannot be described. The only way to obtain a phonological mapping in standard OT is by markedness improvement (Moreton 1996). But in a pull shift mapping, it has been proposed that the initial mapping in the shift cannot be explained by markedness improvement and thus is not predicted to occur.

OT with contrast (see §3.3) also rules out pull shifts. In OT with contrast, a phonological mapping can take place to improve on markedness or to preserve contrast. However, as will be shown below, in a pull shift mapping there is no improvement on either markedness or contrast.

Consider A → B → C as an example of a pull shift. The mapping /B/ → [C] is forced by markedness, but the initial mapping /A/ → [B] is not. This is illustrated in the following tableau, which compares a no shift scenario, scenario (15a), to a pull shift scenario, scenario (15b), under the constraint ranking PC(A/B), *B >> PC(B/C). The crucial point is that there is no markedness constraint that compels the /A/ → [B] mapping.

(15) *Pull shifts cannot be described in OT with contrast*

	Scenarios	PC(A/B)	*B	PC(B/C)
☞ a. No shift A B → C	/A/ → [A] /B/ → [C] /C/ → [C]			*
b. Pull shift A → B → C	/A/ → [B] /B/ → [C] /C/ → [C]		*!	*

Both scenarios preserve the contrast between /A/ and /B/, because underlying /A/ and /B/ map onto different outputs in both scenarios. Both scenarios map /B/ onto [C] in accordance with the ranking of the markedness constraint *B above PC(B/C). But the pull shift scenario, scenario (15b), incurs a fatal violation of *B, and is thus harmonically bounded by the no shift scenario, (15a).[18] Thus, in OT with contrast, pull shifts are predicted not to occur.[19]

In summary, synchronic pull shifts cannot be described in any of the approaches described above. Diachronic pull shifts are different, as they can be seen as different processes that apply at different stages in the development of the language (Holt 2003).

4.3 *Circular shifts*

Another type of chain shift found in the literature is a circular shift, also known as an exchange process (Anderson and Browne 1973). Examples of circular shifts

[18] A harmonically bounded scenario incurs a superset of violation marks in comparison to a competing scenario. This is under the assumption that there is no other constraint in Con that favors scenario (15b) over (15a).

[19] Though not allowing for pull shifts, OT with contrast admits a sequence of changes that *resemble* a pull shift effect. Take a situation where /A/ → [B] "wants to happen" (due to *A) but is blocked by /B/ → [B] (to avoid neutralization). Then /B/ → [C] comes along. Now the /A/ → [B] map can emerge. This scenario is what I refer to as a regular shift. It is not a pull shift, because there is a markedness constraint *A that drives /A/ → [B].

were given in §2.2.3. There is a debate in the literature on whether circular shifts exist and to what extent they are conditioned by morphology. Many of the circular shifts have been reanalyzed (see Moreton 1996) or, as we saw in Xiamen (see (14)), do not constitute a complete circle, as they contain a termination (neutralization) point.

Rule-based approaches can describe circular shifts with no termination point (see McCarthy 1999).[20] Unlike rule-based approaches, both standard OT (see §3.2) and the contrast approach (see §3.3) rule out circular shifts with no termination point, for example /A/ → [B] and /B/ → [A]. As shown by Moreton (1996), a circular shift is not admitted to non-contrast OT, since it does not improve on markedness.

As will be shown below, another feature that makes circular shifts with no termination point incompatible with OT with contrast is the fact that they do not improve on markedness or contrast, and involve an unmotivated violation of generalized faithfulness. The following tableau compares a circular shift scenario, scenario (16a), to an identity scenario, scenario (16b).

(16) *No circular shifts: Unmotivated violations of faithfulness*

	Scenarios	PC	Markedness	Faith
a. Circular shift A B ↑↓ ↑↓ D C	/A/ → [D] /B/ → [C] /C/ → [B] /D/ → [A]		[A] [B] [C] [D]	****! /A/ → [D] /B/ → [C] /C/ → [B] /D/ → [A]
☞ b. Identity ↻ ↻ A B ↻ ↻ D C	/A/ → [A] /B/ → [B] /C/ → [C] /D/ → [D]		[A] [B] [C] [D]	

The circular shift is harmonically bounded by the competing identity scenario. Both scenarios satisfy PC constraints and incur the same violations of markedness (they have the same outputs). But the circular shift scenario, scenario (16a), is ruled out by generalized faithfulness. There are unmotivated violations of faithfulness in this scenario.[21]

Circular shifts *with a termination point*, for example /A/ → [B], /B/ → [C], /C/ → [B], are predicted to occur in OT with contrast, since the initial step in the shift improves on markedness (see §4.1). A circular shift *with a termination point* refers to a shift where one of the original inputs is never used as the output. In the example cited here, the input /A/ is never used as the output in the shift. The tone sandhi analyzed in Barrie (2006) and Hsieh (2005) is of that form. It is important to note that such a scenario would not be harmonically bounded by a no shift scenario, /A/ → [B], /B/ → [B], /C/ → [C], because the two scenarios differ as to whether they preserve contrast between underlying /A/ and /B/.

[20] McCarthy (1999) characterizes these shifts as involving the "multi-process Duke of York gambit."

[21] Some instances of circular shifts are also ruled out by relational PC (see Łubowicz 2003).

To sum up, circular shifts are not admitted to OT, with or without contrast. But they are predicted to occur in rule-based approaches.

4.4 *Regular shifts*

Finally, there are regular shifts where each mapping occurs independently, but one of the mappings is blocked when they co-occur (see §2.2.4). All approaches to chain shifts predict regular shifts. Rule-based approaches predict regular shifts by rule ordering (see §3.1). Standard OT describes regular shifts by blocking an otherwise regular phonological process, for example by special faithfulness constraints (see §3.2). Similarly, OT with contrast (see §3.3) accounts for regular shifts by blocking an otherwise regular phonological process by PC constraints, as shown below.

Consider a regular chain shift A → B → C, where each step in the shift is forced by markedness constraints. But the process /B/ → [C] is blocked for underlying /A/ to maintain the contrast between underlying /A/ and /B/. The ranking and the relevant tableau are given below. A no shift scenario, scenario (18a), where both /A/ and /B/ map onto [C], is compared with a regular shift, scenario (18b).

(17) *The role of contrast*

PC(A/B) >> *B >> PC(B/C) (also *A >> *B)

(18) *Regular shifts exist*

	Scenarios	PC(A/B)	*B	PC(B/C)
a. No shift A B → C	/A/ → [C] /B/ → [C] /C/ → [C]	*!		*
☞ b. Regular shift A → B → C	/A/ → [B] /B/ → [C] /C/ → [C]		*	*

Scenario (18a) loses since it merges the contrast between underlying /A/ and /B/, thus violating PC(A/B). Scenario (18b) wins because in this scenario /A/ and /B/ map onto distinct outputs. This is at the expense of violating the markedness constraint *B. Thus, OT with contrast predicts regular shifts to occur.

To summarize, this section has contributed to the debate on what chain shift mappings are possible. It has provided an analysis on what types of chain shifts are predicted to occur under different theoretical proposals. OT with contrast has been shown to predict push shift mappings which are attested, but cannot be described under any of the other analyses.

5 Summary

This chapter has provided a typology of chain shift mappings in the context of a number of theoretical approaches to chain shifts. Chain shifts have puzzled researchers for a long time. Many types of chain shifts have been described in the literature (see §2) and numerous theoretical approaches have been put forward to account for them (see §3). The goal of this chapter has been to evaluate the various approaches to chain shifts and compare their implications for the typology of chain shift mappings (see §4).

Four types of chain shifts have been examined: push shifts, pull shifts, circular shifts, and regular shifts. Out of those, regular shifts have been the easiest to account for (see §4.4). Circular shifts are only allowed in rule-based phonology (see §4.3). Pull shifts are left with no straightforward phonological explanation (see §4.2). Push shifts are only admitted by OT with contrast (see §4.1). Depending on further evidence on push shifts, the contrast approach seems to be promising in this respect and differs crucially from other existing accounts of chain shifts in the predictions which it makes.

ACKNOWLEDGMENTS

I would like to thank Marc van Oostendorp, Beth Hume, and two anonymous reviewers for their comments and valuable suggestions.

74 Rule Ordering

Joan Mascaró

1 The bases of rule ordering

The distributional properties of sound in natural languages are explained by appeal to a level of underlying structure in addition to the level of observed phonetic or surface representation (CHAPTER 1: UNDERLYING REPRESENTATIONS), and to a function that maps underlying representations into surface representations. This function has been conceived since the beginning of generative grammar as an ordered set of rules. In this chapter I will first introduce the main properties of rule ordering and the arguments for ordering rules (§1), and I will review various proposals to modify rule ordering in early generative phonology (§2), including cyclic ordering (§3). In §4 I discuss feeding, bleeding, and similar interactions in more detail, §5 discusses serial ordering and parallel approaches, and §6 draws some conclusions.

A rule expresses a significant generalization about the sound structure of a given natural language. The rules of generative phonology, as formalized in Chomsky and Halle (1968; *SPE*) and subsequent work, were formalized adaptations of descriptive statements about phonology of earlier frameworks, even though their function was not the same. Both the relationship of generative rules to statements of descriptive grammars and the reasons for imposing ordering on them can be gathered from the following example, taken from Halle (1962: 57–58). (1a)–(1d) are taken from the description of Sanskrit vowel sandhi in Whitney (1889). The rules in (1e)–(1h) are a formalization of the corresponding generative rules. For simplification, in (1e)–(1h) I have included only the rules that apply to front vowels.

(1) a. Two similar simple vowels, short or long, coalesce and form the corresponding long vowel. (§126)

b. An *a*-vowel combines with a following *i*-vowel to *e*; with a *u*-vowel, to *o*. (§127)

c. The *i*-vowels, the *u*-vowels, and the *r* before a dissimilar vowel or a diphthong are each converted into its own corresponding semi-vowel, *j* or *v* or *r*. (§129)

d. Of a diphthong, the final *i*- or *u*-element is changed into its corresponding semi-vowel *j* or *v* before any vowel or diphthong: thus *e* (really *ai* . . .) becomes *aj*, and *o* (that is *au* . . .) becomes *av*. (§131)

e. $V_iV_j \rightarrow V_i$: $V_i = V_j$
f. ai → e
g. i → j / __ V_i $V_i \neq$ i
h. i → j / V_i __ V_j $V_j \neq$ i

The similarity of the rules to the descriptive statements is obvious. But, as Halle notices, if the ordering (e)–(g)–(f) is imposed on the rules in (1), "significant simplifications can be achieved." A similar comment is made by Chomsky and Halle (1968: 18) with respect to ordering: "it [is] possible to formulate grammatical processes that would otherwise not be expressible with comparable generality." Indeed, the condition on dissimilarity of (1g) can be eliminated, since when (1g) applies, all similar VV sequences will have coalesced by the application of (1e). Moreover, (1h) can be dispensed with, because V*i*V sequences will not be turned into *e*V by (If), since (1g) will have changed the vowel into a glide. We find here one of the main reasons for imposing ordered rules: ordering allows for simplification of grammars and for a better expression of linguistically significant generalizations.

Another typical argument in favor of rule ordering is language variation. Since *SPE* relates underlying and surface representations via a set of ordered rules, it follows that language variation must be due to differences in underlying representations, in the set of rules and in their ordering. A famous example of difference in grammars stemming from different orderings of the same rules is Canadian Raising, an example introduced in Halle (1962: 63–64), based on data from Joos (1942), which is also discussed in Chomsky and Halle (1968: 342).[1]

In certain Canadian and US dialects the first elements in the diphthongs /aɪ aʊ/ are raised to [ʌɪ ʌʊ] before voiceless consonants.[2] At the same time there is regular change of /t/ to [ɾ] in the American English flapping environment. The interaction of these phenomena gives different results in two dialects, A and B. This causes, according to Joos, a dilemma: in a word like *writer*, which is pronounced [rʌɪɾɚ] in dialect A, Joos's generalization that "/a/ is a lower-mid vowel ... [only] in diphthongs followed by fortis [≈ voiceless] consonants" is not true – and in Joos's view, descriptive statements are about surface representations, hence true of surface representations. Halle's solution to the dilemma stems from the recognition that statements of regularities ("rules") should be true of steps in the derivation, but need not be true of surface representations. This is the case if rules are ordered, and hence the application of a later rule can change the context that conditioned an earlier rule, as in this case, or the result of the rule itself. In other words, rule ordering solves Joos's dilemma. (2) shows the derivation of *typewriter* with the diphthong /aɪ/ both before non-flapping (/p/) and flapping (/t/) environments in both dialects. The statement in (2c) (also in (2f)) is true of surface representations (2d) and (2h), but the rule in (2b) (also in (2g)) is true of (2h), but not of (2d), which contains the sequence [ʌɪd], if we

[1] The opaque case (dialect A) had already been discussed by Harris (1951: 70–71) and Chomsky (1962: 156–157).

[2] I transcribe the first vowel of the diphthong as [ʌ], and the voiced *t* as [ɾ], following Chambers (1973, 2006); Joos's phonetic description is slightly different (basically [ɐ] and [d], respectively). Canadian Raising has generated a great deal of discussion. Kaye (1990) casts some doubts on the existence of dialect B, which are not clearly formulated. Mielke *et al.* (2003) claim that the difference has been phonemicized, e.g. as /nʌjf/ *vs.* /najv/, but Idsardi (2006) argues convincingly that there are actual alternations.

interpret the rule in the sense that "/ᴀɪ ᴀʊ/ appear [phonetically] only before voiceless consonants." In (2) I simplify the flapping context to V__V.

(2) *Dialect A*

a.		/taɪpraɪtə/
b.	a → ᴀ / __ [C, −voice]	tᴀɪprᴀɪtə
c.	t → ɾ / V __ V	tᴀɪprᴀɪɾə
d.	*output*	[tᴀɪprᴀɪɾə]

Dialect B

e.		/taɪpraɪtə/
f.	t → ɾ / V __ V	taɪpraɪɾə
g.	a → ᴀ / __ [C, −voice]	tᴀɪpraɪɾə
h.	*output*	[tᴀɪpraɪɾə]

Another example of the same argument for imposing ordering on rules, grammars differing only in rule ordering, is examined in Kiparsky (1982b: 65–66). German devoices obstruents in coda position (3a) (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION) and simplifies /ŋg/ clusters to [ŋ] (3b). Two of the inflectional forms of the adjective meaning 'long', *lang* and *lange*, contrast in two dialect groups, one showing [laŋk], [laŋə], the other [laŋ], [laŋə], respectively. Application of any of the two rules renders the other rule inapplicable (a case of mutual bleeding, see §2), therefore only the first rule applies in each ordering in every instance:

(3) a. Devoicing $[+\text{obstr}] \rightarrow [-\text{voice}] \;/\; \_\_ \begin{Bmatrix} +\text{C} \\ \# \end{Bmatrix}$

b. *g*-deletion g → Ø / [+nasal] __

c. *Dialect group I*

	/laŋg/	/laŋg+ə/
Devoicing	laŋk	—
g-deletion	—	laŋə

d. *Dialect group II*

	/laŋg/	/laŋg+ə/
g-deletion	laŋ	laŋə
Devoicing	—	—

Rule ordering is closely connected to rule application. As shown by Whitney's example, descriptive grammars and many versions of structuralist phonology implicitly assume simultaneous rule application (see Postal 1968: 140–152). This follows from the assumption that rules (or descriptive statements) are true of surface representation, i.e. they are generalizations about surface representation. In simultaneous rule application, the string is scanned for the structural description of each rule and all the rules whose structural description is met apply simultaneously. Chomsky and Halle (1968: 19) provide an interesting abstract example of simultaneous application, which is compared to rule ordering.[3] I adapt

[3] Chomsky and Halle's (1968) example consists of the rules B → X / __ Y and A → Y / __ X and the input representations /ABY/ and /BAX/.

it with a hypothetical example. Consider rules (4a), (4b), the underlying representations (4c) and (4d), and the results of simultaneous application (4e) and of ordered rules (4f), (4g):

(4) a. t → tʃ / __ i
b. e → i / __ tʃ

	Underlying	*Surface* e. Simultaneous application	f. Rules ordered (a)–(b)	g. Rules ordered (b)–(a)
c.	/eti/	etʃi	itʃi	etʃi
d.	/tetʃ/	titʃ	titʃ	tʃitʃ

The problem is now empirical, i.e. the question to ask is whether natural languages have input–output relations like (4c), (4d) to (4e), or rather like (4c), (4d) to (4f) or (4c), (4d) to (4g). In the case of ordered rules, the first rule creates a representation that allows the application of the second rule (feeding). With the ordering (4a) < (4b) ("<" denotes "is ordered before") feeding takes place in /eti/ → etʃi → [itʃi]; with the ordering (4b) < (4a) feeding takes place in /tetʃ/ → titʃ → [tʃitʃ]. Simultaneous application makes these feeding relationships impossible. Thus, since feeding relations are clearly observable in natural languages, the rule-ordering hypothesis receives more support than the hypothesis of simultaneous application.

A similar example can be constructed with two rules, each of which prevents the application of the other if applied first (mutual bleeding; §2). Consider a language with palatalization of velars before /i/ (CHAPTER 71: PALATALIZATION) and backing of /i/ to [u] after velars, and the underlying representation /ki/:

(5) a. k → tʃ / __ i
b. e → i / __ tʃ

	Underlying	*Surface* d. Simultaneous application	e. Rules ordered (a)–(b)	f. Rules ordered (b)–(a)
c.	/ki/	tʃu	tʃi	ku

Under rule ordering, for order (5a) < (5b) we can only apply palatalization (/ki/ → tʃi → (*n/a*)). For order (5b) < (5a), we can only apply backing (/ki/ → ku → (*n/a*)). Here simultaneous application makes bleeding impossible: both rules must apply. Simultaneous application faces another problem. A set of ordered rules assigns one and only one surface representation to any underlying representation. But consider simultaneous application of two rules, one lowering mid nasalized vowels (e.g. [ẽ] → [ã]), another raising mid unstressed vowels (e.g. [e] → [i]). They will force /'ẽ/ → ['ã], /e/ → [i], under any application mode. But unstressed /ẽ/ will satisfy both rules. Under ordering, the first rule applied always wins (we have again mutual bleeding): with the ordering lowering–raising the vowel is lowered; with the reverse ordering it is raised. Under simultaneous application, since /ẽ/ meets the structural description of both rules, two simultaneous contradictory changes must apply to /ẽ/: it has to be lowered *and* raised.

2 Total strict order and other ordering relations

Rule ordering has been a formal property of generative phonology since its beginnings (Chomsky 1951; Chomsky *et al.* 1956; Halle 1959). As defined in *SPE*, the set of rules form a total (or linear) strict order, i.e. the relation "precede" or "is ordered before" relating two rules has the properties (6a)–(6d) (see CHAPTER 34: PRECEDENCE RELATIONS IN PHONOLOGY for formal discussion of a different interpretation of precedence):

(6) Precedence (A < B, or "rule A precedes rule B") is:

- a. asymmetric: given any two rules A, B, it is not the case that A precedes B and B precedes A;
- b. (hence) irreflexive: given any rule A, it is not the case that A precedes A,
- c. transitive: given any three rules A, B, C, if A precedes B and B precedes C, then A precedes C;
- d. total (or connected): for any pair of rules A, B, either A precedes B or B precedes A.

Notice that in many cases some rules are not *crucially* ordered: the same surface form will result with the ordering A < B and B < A. Still, we assume that in the generation of the derivation that begins with the underlying form and ends with the surface form they apply in a given order. In *SPE* there were small departures from total strict order, most notably in the case of disjunctive ordering and simultaneous application in the case of infinite rule schemata, both discussed below.

Rule ordering generated a lot of discussion in the 1960s and the beginning of the 1970s. Some of the questions that were asked were whether ordering of processes was justified, whether it could be partially or totally derived from general principles, and what were the possible types of ordering. I examine now some of the proposals that were advanced in this period.

2.1 *Eliminating extrinsic ordering*

Since in many cases rules are not crucially ordered, a first question that was asked is whether extrinsic ordering could be dispensed with. The ordering between two rules A and B is *extrinsic* if it is imposed language-specifically, as in the Canadian Raising examples. On the other hand, *intrinsic* ordering refers to an ordering imposed by universal properties of grammars and by formal properties of rules. Consider the interaction of /ɣ/-deletion (7a) and Diphthongization (7b) in Finnish, analyzed by Kiparsky (1968: 177) as the interaction of two extrinsically ordered rules. But Koutsoudas *et al.* (1974) argue that if we assume that rules apply sequentially, but are unordered extrinsically in the sense that they are "simply applied to every representation that satisfies its structural description," we get the right results, no matter which rule we try to apply first ((7a) or (7b)). Consider the derivation of /vee/ and /teɣe/ in (7). /ɣ/-deletion will not be able to apply in the derivation of /vee/ either before or after Diphthongization, and we will get /vee/ → [vie]. In the second example, Diphthongization cannot apply to /teɣe/, but /ɣ/-deletion can, with the result /teɣe/ → tee. Now Diphthongization can apply, deriving the final output, tee → [tie]. Here the ordering /ɣ/-deletion < Diphthongization is not established extrinsically, but it is determined intrinsically by the form of the rules.

(7)					/vee/	/teɣe/
a.	ɣ	→	Ø / V __ V		—	tee
	ee	→	ie		vie	tie
b.	ee	→	ie		vie	—
	ɣ	→	Ø / V __ V		—	tee
	ee	→	ie		—	tie

Using this and other examples, Koutsoudas *et al.* (1974) conclude that rules are unrestricted in their application, every rule applying to every representation that satisfies its structural description, and that no extrinsic ordering needs to be imposed on them. They base their argumentation on four possible situations that derive from the possible orderings in terms of feeding, counterfeeding and counterbleeding relations. I will analyze such relations in more detail in §3; here I only give the basic definitions:

(8) Given rules A, B, where A < B:

a. A feeds B (or A and B are in feeding order) iff A can increase the number of representations to which B can apply;
b. A bleeds B (or A and B are in bleeding order) iff A can decrease the number of representations to which B can apply;
c. B counterfeeds A (or A and B are in counterfeeding order) iff B would feed A if the order were B < A;
d. B counterbleeds A (or A and B are in counterbleeding order) iff B would bleed A if the order were B < A.

Cases of pure feeding order (when it does not involve counterfeeding or counterbleeding at the same time), can be dealt with under these assumptions, as we have seen in (7). The second possible situation is a pure counterbleeding relation. Consider Koutsoudas *et al.*'s example, taken from Kiparsky (1968: 199). In certain Low German dialects, post-vocalic voiced stops spirantize. A word like *Tag* 'day' spirantizes the underlying /g/ in the plural [ta:ɣə], but in the singular it spirantizes and devoices by Final Devoicing, yielding [ta:x]. Kiparsky proposes a pair of ordered rules (9a), (9b) that determine the derivation in (9c). But Koutsoudas *et al.* argue that if the rules apply simultaneously the same result is achieved, as shown in (9d): since /g/ is a post-vocalic voiced stop and also a word-final obstruent, it meets the structural description of both rules.

(9) a. Spirantization $\begin{bmatrix}\text{+stop}\\ \text{+voice}\end{bmatrix} \rightarrow [\text{–stop}]$ / V __

b. Devoicing [+obstruent] → [–voice] / __ #

c.		/ta:g/	d.		/ta:g/
	Spirantization	ta:ɣ		Spirantization, Devoicing	ta:x
	Devoicing	ta:x		(applied simultaneously)	

A third set of cases involves two rules that are in both bleeding and counter-bleeding order. One such case is the Latin American Spanish [l ~ j] alternation in pairs like [a'kel] ~ [a'kejos] 'that (MASC SG ~ MASC PL)', analyzed by Saporta (1965) with two extrinsically ordered rules. Given underlying forms /akeʎ/, /akeʎos/ the first rule depalatalizes underlying /ʎ/ word-finally; the second turns any remaining /ʎ/ into [j].

(10)			/akeʎ/	/akeʎos/
	Final Depalatalization	ʎ → l / __#	akel	—
	Delateralization	ʎ → j	—	akejos

Cases like these are dealt with by Koutsoudas *et al.* (1974) by invoking a universal principle, very similar to Kiparsky's Elsewhere Condition (see §2.3), the Proper Inclusion Precedence Principle, which determines intrinsic ordering for a certain class of rules:

(11) *Proper Inclusion Precedence*

For any representation R, which meets the structural descriptions of each of two rules A and B, A takes applicational precedence over B with respect to R if and only if the structural description of A properly includes the structural description of B.

Given Proper Inclusion Precedence, the rules in (10) can be left (extrinsically) unordered; since the structural description of Final Depalatalization (ʎ# = "any word-final ʎ") is included in the structural description of Delateralization (ʎ = "any ʎ"), Final Depalatalization takes precedence. Notice that this is similar to disjunctive ordering in *SPE*, where a rule containing abbreviatory parentheses like A → B / __ C(D) stands for two rules, A → B / __ CD and A → B / __ C, the first rule applying first and application of one rule excluding application of the other rule. Disjunctive ordering, though, is limited to rules that are adjacent in the ordering.

The fourth set of cases is formed by pairs of rules which are in some other ordering relation. For such cases Koutsoudas *et al.* argue that there are alternative analyses in which no extrinsic ordering is necessary.

The proposal that extrinsic ordering should be dispensed with was also made by Natural Generative Phonology, a theory that began with work by Theo Vennemann and was presented in detail in Hooper (1976). In Natural Generative Phonology, many ordering relations just disappeared, because typical *SPE* phonological rules became either morphophonemic rules or "via rules," rules relating surface representations and hence not taking any part in derivations. In addition, the "No-Ordering Condition" explicitly prohibited extrinsic ordering.

2.2 *Multiple application, local ordering, and global rules*

Although based on total strict ordering (6), *SPE* allowed for multiple application of a rule in the case of infinite schemata (Chomsky and Halle 1968: 343–348), an abbreviatory convention by which X_n stands for an infinite set of sequences of *n* or more instances of X. Thus given a rule like C → Ø / __ C_1# (where C_1

abbreviates the infinite set {C, CC, CCC, . . .}) and a string . . . VCCC, both the first and the second C meet the structural description of the rule, which applies simultaneously to both and derives . . . VC#.

Another case of multiple application of a rule that was introduced after *SPE* is iterative application. In iterative rule application, which is usually directional, after the first structural change takes place, the string is scanned again and if the structural description is met, the rule reapplies, the string is scanned again, etc., until the rule is no longer applicable. Processes like harmony (CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY; CHAPTER 110: METAPHONY IN ROMANCE), stress (CHAPTER 40: THE FOOT; CHAPTER 41: THE REPRESENTATION OF WORD STRESS; CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE), tone spreading (CHAPTER 45: THE REPRESENTATION OF TONE; CHAPTER 114: BANTU TONE), and metrical structure construction are cases of iterative application. Notice that iterative rules do not follow strict ordering because a rule can precede itself, hence the property of irreflexivity in (6b) is abandoned. Kenstowicz and Kisseberth (1977: 180–183) present the following case of iterative application. In Gidabal, a long vowel shortens after another long vowel. In a word like /djalum-baː-daːŋ-beː/ 'is certainly right on the fish', simultaneous application would derive the wrong form, *[djalum-baː-daŋ-be], with two vowels shortened, but iterative left-to-right application yields the correct derivation. We see /djalum-baː-daːŋ-beː/ → djalum-baː-daŋ-beː in the first iteration, and no change, because the structural description is not met, in the second iteration. Different versions of iterative application are discussed in Anderson (1974: 124–133) and Kenstowicz and Kisseberth (1977: 177–195).

Another case in which precedence can be reflexive, against strict order (6), is the case of "anywhere" or "persistent" rules.[4] These are rules that apply in the derivation whenever their structural description is met. A typical case is (re)syllabification. If a rule A establishes some syllabic properties to which rule B is sensitive, and rule B introduces changes, like insertion, deletion, or changes in sonority properties, to which the syllabification rule A is sensitive, A has to apply before and after B. Myers (1991) argues for several other cases of iterative ordering.

The asymmetric property of strict order (6a) is also abandoned in the case of *local ordering*, a specific type of ordering proposed in Anderson (1969) and also discussed in Anderson (1974). He proposes that two rules might have to apply in different orderings to different representations. The ordering in which they apply is the *unmarked order*. Relative to a given representation, feeding is unmarked with respect to a neutral ordering, and bleeding is marked with respect to a neutral ordering, hence the unmarked orderings are feeding and counterbleeding. This proposal stems from the observation in Kiparsky (1968) that when a linguistic change consists of a reversal in the ordering of two rules, feeding order tends to be maximized and bleeding order tend to be minimized. To see how this works, consider Icelandic Umlaut and Syncope (Anderson 1969, 20–27, 1974: 141–147) applying to [kœtlum] 'kettle-DAT PL' and [bœggli] 'parcel-DAT SG':

[4] The term "persistent rule" is due to Chafe (1968).

(12) *Local ordering: (a) applies before (b) in (c); (b) applies before (a) in (d)*

a. Umlaut a → œ / __C_0u

b. Syncope $\begin{bmatrix}+\text{syll}\\ -\text{stress}\end{bmatrix} \rightarrow \varnothing$ / C __ C+V

	c.		d.	
	/katil+um/			/bagg+ul+e/
Syncope	Ø		Umlaut	œ
Umlaut	œ		Syncope	Ø
output	kœtlum			bœggli

Notice that in (12c) for the representation /katil+um/, Syncope feeds Umlaut, and if the order were the opposite, Umlaut would either feed or bleed Syncope, i.e. order would be neutral. Hence the unmarked order Syncope < Umlaut is chosen. In (12d), for the representation /bagg+ul+e/, the first rule, Umlaut, doesn't either feed or bleed the second rule, Syncope, i.e. the order is neutral. But if the order were the opposite, Syncope would bleed Umlaut. The neutral ordering Umlaut < Syncope is therefore preferred.

There is yet another type of rule that relates to rule application and to ordering, the global rule. A global rule must be applied at the level at which it appears in the ordering, but crucial information for its structural description is ordered elsewhere in the derivation. Kisseberth and Abasheikh (1975) present the following case. In Mwini the perfect is formed by adding the suffix /-iːɫ ~ -eːɫ/ to the verb base, as shown in (13). After a base-final sibilant or /ɲ/, the /ɫ/ in the suffix spirantizes to [z] (13b). The final consonant of the verb base undergoes Mutation, which turns coronal and labial stops into [s], /k/ into [ʃ], and a nasal voiced stop sequence into [nz] (13c) (the data are from Hyman's 1993 analysis of the processes).

(13)	*Root*	*Perfect*	
a.	/jiːb/	jib-iːɫ-e	'he answered'
	/soːm/	som-eːl-e	'he read'
b.	/aːnz/	anz-iːz-e	'he began'
	/t̪oʃ/	t̪oʃ-eːz-e	'he thought'
c.	/fuːɲg/	-fuːnz-il-e	'he closed'
	/pik/	-piʃ-il-e	'he swore'

As shown by the examples in (13c), the vowel in the suffix undergoes a further change: it shortens. But shortening cannot be determined by the base-final sibilant because the derived sibilants in (13b) do not cause shortening. Hence the correct generalization seems to be that shortening applies just in case Mutation has applied, and therefore we need to make reference to another stage in the derivation instead of being restricted to the local stage of application.[5]

2.3 *The Elsewhere Condition*

The *SPE* formalism distinguishes between conjunctive ordering of two rules (the normal mode of application) and disjunctive ordering, where only one of the rules

5 Hyman (1993) discusses the Mwini case and the alternatives to a global analysis.

can apply. In *SPE*, disjunctive ordering derives from abbreviatory devices: . . . A(B) . . . corresponds to two disjunctively ordered rules, . . . AB . . . and . . . B . . . , the first immediately preceding the second, and the application of one rule excluding the application of the other rule. Disjunctive ordering was later derived as an effect of a more general principle, the Elsewhere Condition, originally formulated by Kiparsky (1973a: 94). (14) gives the revised formulation in Kiparsky (1982a: 136):

(14) Rules A, B apply disjunctively to a form Φ if and only if:

a. The structural description of A (the special rule) properly includes the structural description of B (the general rule).

b. The result of applying A to Φ is distinct from the result of applying B to Φ.

In that case, A is applied first, and if it takes effect, then B is not applied.

Consider, as an illustration, the interaction of lengthening and shortening in English (Myers 1987; Halle 1995). Lengthening and shortening affect stressed non-high vowels in branching feet. They are lengthened if, in addition, they are followed by an open syllable ending in an /i/, which in turn must be followed by a vowel in hiatus (15c), (15d); lengthened vowel underlined). Otherwise, they are shortened (15e) (see also CHAPTER 88: DERIVED ENVIRONMENT EFFECTS):

(15)	a.	$\begin{bmatrix} \text{V} \\ -\text{high} \end{bmatrix} \rightarrow \text{V:} \ / \ [\ \_\_ \ \text{C}_0 \ \text{i}]_{\text{StressFt}} \ \text{V}$	c.	*re[medi]al* *co[loni]al*	*[radi]al* *De[voni]an*
	b.	$\begin{bmatrix} \text{V} \\ -\text{high} \end{bmatrix} \rightarrow \text{V:} \ / \ [\ \_\_ \ \text{C}_0 \ \text{V}]_{\text{StressFt}}$	d.	*[trivi]al* *[natu]ral*	*di[vini]ty* *ex[plana]tory*

(15a), (15b) are two rules applying in the general context "disyllabic stress foot with stressed non-high vowel." (15a) being more restrictive, it applies only when, in addition, the second vowel is *i* and it is in hiatus with a following vowel. Since $[[\text{V}, -\text{high}]\ \text{C}_0\ \text{i}]_{\text{StressFt}}\ \text{V}$ is a subset of $[[\text{V}, -\text{high}]\ \text{C}_0\ \text{V}]_{\text{StressFt}}$, (15a) and (15b) are in an Elsewhere relationship: (15a) is the specific rule applying in $[[\text{V}, -\text{high}]\ \text{C}_0\ \text{i}]_{\text{StressFt}}$ V and (15b), the general rule, applies elsewhere in the general common context.

Kiparsky (1982a) makes ingenious use of the Elsewhere Condition to predict blocking of general morphological processes by more specific ones, and strict cyclic effects like non-derived environment blocking (NDEB). An example of the first case is the plural rule in (16c), which applies to the singular form *person*, but shouldn't apply to the lexical plural *people*. Kiparsky assumes that every lexical item L is an identity rule L $\leftrightarrow$ L. Since the structural description $[\textit{people}]_{\text{Noun, +Pl}}$ in (16a) is a proper subset of the structural description $]_{\text{Noun, +Pl}}$ in (16c), the identity rule applies (vacuously) and blocks the application of the plural rule. The structural description $[\textit{person}]_{\text{Noun, +Pl}}$, on the other hand, is not a lexical item, but the pluralization of the lexical item, so that the plural rule applies regularly to derive *persons*.

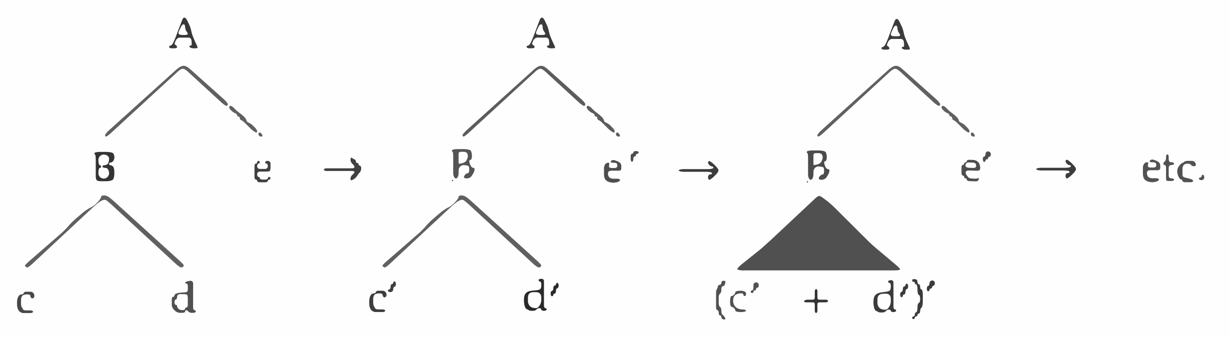
(16)	*Rules*	*Derivations*	
		$[\textit{people}]_{\text{Noun, +Pl}}$	$[\textit{person}]_{\text{Noun, +Pl}}$
a.	$[\textit{people}]_{\text{Noun, +Pl}} \leftrightarrow [\textit{people}]_{\text{Noun, +Pl}}$	$[\textit{people}]_{\text{Noun, +Pl}}$	
b.	$[\textit{person}] \leftrightarrow [\textit{person}]$		—
c.	$\emptyset \rightarrow \text{z} \ / \ \_\_ \ ]_{\text{Noun, +Pl}}$	—	$[\textit{person}]_{\text{Noun, +Pl}}$ /-z/

The Elsewhere Condition can also prevent rule application in non-derived environments (non-derived environment blocking, or NDEB; CHAPTER 88: DERIVED ENVIRONMENT EFFECTS), an effect which is also predicted by the Strict Cycle Condition (see next section). Thus the shortening rule (cf. (15b)) shortens [[*san*]*ity*] to [[*săn*]*ity*], because it is derived, but fails to apply to [*nightingale*] (*[*nĭghtingale*]), because it is underived. Again the identity rule [*san*] ↔ [*san*] cannot block shortening, because the structural description of the identity rule, [*san*], and the structural description of shortening, $[V\ C_0\ V]_{SUF}$, are not in a proper inclusion relation, but in intersection. But [*nightingale*] properly includes $[V\ C_0\ V]_{StressTr}$. Cyclic effects in later cycles/levels derive from the assumption that the output of every cycle/level is a lexical item, hence an identity rule.[6]

3 Cyclic ordering

In cyclic application the input to the set of rules is a phonological representation organized by constituent structure (CHAPTER 85: CYCLICITY). Consider a structure $[[c\ d]_B\ e]_A$, which is represented in (17) by a tree diagram; A, B are categories, and d, e, c are phonological strings, matrices, or structures.

(17)



(17) shows a cyclic derivation of $[[c\ d]_B\ e]_A$. The set of ordered rules $\mathfrak{R}$ applies first separately to the innermost constituents, i.e. to c, to d and to e, giving as a result c′, d′, e′. This is the first cycle. We now proceed to the second cycle, the next degree of embedding, namely B, and apply the set of rules to its domain, the concatenation c′ + d′, whose output is (c′ + d′)′. The domain of the following (and in this case the final) cycle is whatever is dominated by A, namely (c′ + d′)′ + e.

The cycle was first proposed in phonology (Chomsky *et al.* 1956) to deal with stress in compounds like *blackboard eraser*, showing primary–tertiary–secondary stress distinctions (stress levels are indicated above the vowel in (18), and as subscripts in the text below):

(18) 1 3 2
$[[[black]\ [board]]_B\ [eraser]]_A$

[6] Given Optimality Theory, some properties of Elsewhere-type interactions follow as a theorem, Pāṇini's Theorem on Contraint-ranking (PTC) (Prince and Smolensky 1993: §5.3, §7.2.1). PTC relates the activity of two constraints, S and G, in a constraint hierarchy relative to an input *i*. Assume that S applies non-vacuously to *i* (i.e. it distinguishes the set of candidates Gen (*i*)). If G >> S and G is active on *i* (i.e. it distinguishes the set of candidates Gen(*i*) when it applies) then S is not active on *i*. For a clear and interesting discussion of the relation between the Elsewhere Condition and PTC, see Baković (2006); also Prince (1997).

After stress has applied to individual words, the compound stress rule locates stressed vowels and maintains primary stress on the leftmost stressed vowel and weakens other stresses by one degree. After assigning vacuously primary stress in the first cycle to [*bla$_1$ck*], to [*boa$_1$rd*] and to [*era$_1$ser*], it applies in the second cycle in the domain B to [*black board*], yielding [*bla$_1$ck boa$_2$rd*], and in the last cycle in the domain A to [*bla$_1$ck boa$_2$rd era$_1$ser*] to give the final [*bla$_1$ck boa$_3$rd era$_2$ser*].

Cyclicity was later applied in syntax as a result of the elimination of generalized transformations and the generation of embedded sentences by base rules (Chomsky 1965). Later on, Chomsky (1973) proposed a limitation on cyclic application in syntax, the Strict Cycle Condition (SCC, or "strict cyclicity"), by which no rule can apply to a constituent I in such a way as to affect solely a subconstituent of I. Kean (1974) presented two cases that argued for the application of this version of the SCC also in phonology. In (17), for instance, in the second cycle, cycle B, a rule cannot apply to the domain of B if it affects just c′. An actual example is the interaction of Glide Formation and Destressing in Catalan (Mascaró 1976: 24–36). Glide Formation applies to post-vocalic unstressed high vowels. In *produirà* 'it will produce' it cannot apply to [[prudu'i]$_1$'ra]$_2$ at cycle 1, because post-vocalic /i/ is stressed. At cycle 2, a following stress causes destressing of /i/. Therefore at cycle 3, and at later cycles, the sequence /ui/ meets the structural description of the rule; but /ui/ is entirely within cycle 1 and the SCC blocks application, resulting in [pruðui'ra] *[pruðuj'ra].

The SCC was further refined in Mascaró (1976: 1–40), as in (19). Case (19b.i) corresponds roughly to the SCC as formulated in Chomsky (1973) and used by Kean (1974).

(19) Given a bracketed expression [. . . [. . . , [. . .]$_1$, . . .]$_{n-1}$ . . .]$_n$, and a (partially ordered) set of cyclic rules C:

a. C applies to the domain [. . .]$_j$ after having applied to the domain [. . .]$_{j-1}$, each rule in C applying in the given order whenever it applies properly in j.

b. *Proper application of rules*. For a cyclic rule R to apply properly in any given cycle j, it must make specific use of information proper to (i.e. introduced by virtue of) cycle j. This situation obtains if (i), (ii), or (iii) is met:

i. R makes specific use of information uniquely in cycle j. That is, it refers specifically to some A in [XAY [. . .]$_{j-1}$ Z]$_j$ or [Z [. . .]$_{j-1}$ XAY]$_j$.

ii. R makes specific use of information within different constituents of the previous cycle which cannot be referred to simultaneously until cycle j. R refers thus to some A, B in [X [. . . A . . .]$_{j-1}$ Y [. . . B . . .]$_{j-1}$ Z]$_j$.

iii. R makes use of information assigned on cycle j by a rule applying before R.

A states the general procedure for cyclic application; B gives the conditions for proper application: morphologically derived environments in inflection (19b.i), derived environments by compounding or syntax (19b.ii), and rule-derived environments (19b.iii). Effects of derived environments on application of processes, irrespective of the theoretical mechanism they derive from, are usually referred to as *derived environment effects* (DEE). We just saw a case, the interaction of glide formation and destressing in Catalan, which falls under (19b.i). The rule of /t/ → [s] assibilation in Finnish illustrates both (19b.i) and (19b.ii). Assibilation (20a) applies in morphologically derived environments like (20c): the structural description [ti] is met by material in the root cycle and in the inflected word cycle. It also applies in rule-derived environments (20d): here the structural description [ti] is met because at its cycle of application, the rule of raising (20b) has created it. But it fails to apply in the non-derived environments (20e), because none of the conditions for proper application in (19b) is met:

(20)	a.	t → s / __ i				
	b.	e → i / __##				
	c.	/halut-i/ → halus-i		'wanted'	cf. halut-a	'to want'
	d.	/vete/ → veti → vesi		'water (NOM SG)'	cf. vete-næ	'water (ESS SG)'
	e.	tila	'place, room'			
		æiti	'mother'			
		itikka	'mosquito'			

An instance of (19b.ii) is the application of glide formation in Central Catalan to vowels of different words. As we have just seen, glide formation applying to post-vocalic high vowels is blocked in *produirà* [[pɾuðu'i]$_1$'ɾa]$_2$. Consider now *produirà oxidació* 'it will produce oxidation':

(21)		[[[pɾuðu'i]$_1$ 'ɾa]$_2$	[[['ɔksið]$_1$ 'a]$_2$ 'sjo]$_3$]$_4$
	Cycle 2	[[pɾuðu'i]$_1$'ɾa]$_2$	[['ɔksið]$_1$ 'a]$_2$
		[[pɾuðui]$_1$ 'ɾa]$_2$	[[uksið]$_1$ 'a]$_2$
	Cycle 3		[[[uksið]$_1$ ə]$_2$ 'sjo]$_3$
			[[[uksið]$_1$ ə]$_2$ 'sjo]$_3$
	Cycle 4	[[[pɾuðui]$_1$ 'ɾa]$_2$	[[[uksið]$_1$ ə]$_2$ 'sjo]$_3$]$_4$
		[[[pɾuðui]$_1$ 'ɾa]$_2$	[[[wksið]$_1$ ə]$_2$ 'sjo]$_3$]$_4$

In the second word, at cycle 2, the initial /'ɔ/ is destressed by a following stress and becomes [u] by a rule of vowel reduction. At cycle 4, the sequence /au/ meets the structural description of glide formation and the SCC does not block Glide Formation, the application being proper by (19b.ii), because /au/ is not within the domain of a single previous cycle: /a/ is in cycle 2; /u/ is in cycle 3. Hence the rule applies, yielding ['aw].

It was assumed that the SCC applied to cyclic, obligatory neutralization rules, and dealt with DEEs. These were previously accounted for by the Alternation Condition proposed by Kiparsky (1973b: 65), according to which "neutralization processes apply only to derived forms . . . [i.e.] if the input involves crucially a sequence that arises in morpheme combinations or through the application of phonological processes." Cyclic application and derived environment effects were reformulated within Lexical Phonology through lexical strata and post-lexical phonology, which correspond to cycles and to the effect of the Elsewhere Condition from which DEEs are derived. In Stratal Optimality Theory (see CHAPTER 85: CYCLICITY), cycles correspond to strata to which Gen and Eval apply successively. Within OT, output-output faithfulness constraints (Benua 1997) ensure similarity of larger constituents to its inner components. Strict cycle effects (DEEs) are also obtained by local conjunction of markedness and faithfulness constraints (Łubowicz 2002). To see how DEEs are derived from local conjunction, consider the interaction of Velar Palatalization and Spirantization in Polish (Łubowicz 2002: §3). We find the following descriptive generalizations. Spirantization applies to rule-derived [ʤ] (22a), but not to underlying /ʤ/ (22b); similarly, in (22c) Velar Palatalization applies only to morphologically derived velar + [e i] sequences.

(22)	a. /rog-ek/ 'horn'	b. /banʤ-o/ 'banjo'	c. /xemik-ek/ 'chemist-DIM'
Velar Palatalization	roʤ-ek	—	xemiʧ-ek *blocked in* xe
Spirantization of /ʤ/	roʒ-ek	*blocked*	—
output	roʒ-ek	banʤ-o *banʒ-o	xemiʧ-ek *ʃemiʧ-ek

Let us examine rule-derived environments first. Given the ranking *ʤ >> IDENT[cont], we will normally have the mapping /ʤ/ → [ʒ]. The difference from derived and non-derived environments stems from the fact that in the first case the mapping is /g/ → ʤ → [ʒ], whereas in the second case it would be /ʤ/ → [ʒ]. The candidate with [ʤ] deriving from /g/ will violate both *ʤ and IDENT[cor], hence also the constraint conjunction *ʤ & IDENT(cor). But if /ʤ/ is underlying, *ʤ will be violated, but not IDENT[cor], therefore the conjunction *ʤ & IDENT[cor] will be satisfied.

For morphologically derived environments, as in the example in (22c), Łubowicz uses conjunction of markedness and ANCHOR. Velar palatalization applies to the morphologically derived sequence [k–e], but not to the non-derived sequence /xe/ in /xemik-ek/. Since the velar /k/ is stem-final, but not syllable-final, in $[xe.mi.k]_{Stem}$-ek, the sequence $k]_{Stem}$-e will violate R-ANCHOR(Stem, s), and it will also violate PAL, the constraint against velar + {e i} sequences that forces palatalization. It will therefore also violate $[$PAL & R-ANCHOR(Stem, s)$]_D$. But since morphologically underived /xe/ satisfies R-ANCHOR(Stem, s), the conjunction will be satisfied in this case and palatalization will not take place.

4 Rule interaction, ordering, and applicability: Feeding and bleeding

In a system in which rules are ordered, rules can interact: both the applicability and the result of application of a rule can depend on the application of previous rules. The notions of *feeding* and *bleeding* that I made reference to in §2 were introduced by Kiparsky (1968) in order to explain the direction of linguistic change. These concepts have been widely used since. In this section I examine them in some detail.

Since it is not uncommon to detect terminological inadequacies in the literature, in order to avoid confusion I will start with some terminological observations. In Kiparsky's original terminology, feeding and bleeding relations between rules are distinguished from feeding order and bleeding order. Feeding and bleeding relations (or the terms "X feeds/bleeds Y") are defined as functional relations between two rules, with no actual ordering between them presupposed. A feeds B if A "creates representations to which B is applicable"; A bleeds B if A "removes representations to which B would otherwise be applicable," where "representations" means *possible* representations (Kiparsky 1968: 37, 39). The terms *feeding order* and *bleeding order* are relations between rules that are in a specific order. Since feeding and bleeding relations are functional relations between rules, whether two rules are in a *feeding* or *bleeding relation* can be determined by mere inspection of the rules.[7] I will keep this distinction (feeding/bleeding relation *vs.* feeding/bleeding order), but I will reserve the use of the predicates *feed* and *bleed* applied to arguments A and B for feeding/bleeding *order*, and I will make use of the predicates *p-feed* and *p-bleed* ("p" for "potentially") in the case of feeding/bleeding *relations*. (23) provides an illustration using our previous German example (3):

(23) *German, group II* (*g*-deletion < Devoicing)

a.

Feeding/bleeding relation	A p-feeds/ p-bleeds B	devoicing p-bleeds *g*-deletion *g*-deletion p-bleeds devoicing
Feeding/bleeding order	A feeds/ bleeds B	*g*-deletion bleeds devoicing

b.

Devoicing	$[\text{obstr}] \rightarrow [-\text{voice}] \ / \ \_\_ \begin{Bmatrix} +\text{C} \\ \# \end{Bmatrix}$
g-deletion	$g \rightarrow \emptyset \ / \ [+\text{nasal}] \ \_\_$

c. *Dialect group II*

	/laŋg/
g-deletion	laŋ
devoicing	—

Devoicing p-bleeds *g*-deletion by devoicing *g* in [+nasal] + *g*, and *g*-deletion p-bleeds devoicing by deleting *g* in the same context. Given the ordering *g*-deletion < devoicing, *g*-deletion bleeds devoicing, as shown in the derivation in (23).

Feeding and bleeding relations can be formally defined as follows:

(24) *Feeding and bleeding relations*

a. Rule A is in feeding relation with respect to B (or A p-feeds B) iff there is a possible input I such that B cannot apply to I, A can apply to I, and B can apply to the result of applying A to I.

b. Rule A is in bleeding relation with respect to B (or A p-bleeds B) iff there is a possible input I such that B can apply to I, A can apply to I, and B cannot apply to the result of applying A to I.

[7] Of course one might want to to relativize these notions to a given set of representations, e.g. the lexicon. For instance, a rule A that centralizes the place of articulation of all consonants in word-final position feeds a rule B that vocalizes /l/ to [w] in coda position, because it can create the representation . . . Vl]_{Coda}## from /. . . $\text{V}ʎ\text{]}_{\text{Coda}}$##/, to which B is applicable. But in a language with a single lateral *l*, the feeding interaction will never take place. In such cases, in order to avoid terminological ambiguities we can say that A feeds B, but A doesn't feed B for lexicon L, or that A doesn't l-feed B. Similarly, if we relativize feeding and bleeding to specific derivations, we can say that a rule A does/does not d-feed or d-bleed a rule B, meaning that the feeding or bleeding relation is/is not actually instantiated in that particular derivation.

It is important to notice that in the definitions in (24) "apply" is usually interpreted as "apply non-vacuously." In the German example in (3), in dialect group I, Devoicing bleeds *g*-deletion, (/laŋg/ → /laŋk/ → (*n/a*)). But for the word *Bank* 'bank', whose derivation is /baŋk/ → (vacuous devoicing) baŋk → (*n/a*), we don't want to say that Devoicing bleeds *g*-deletion, because the input to Devoicing didn't meet its structural description. Kiparsky's (1968) terms "creates" and "removes," cited above, already indicate that vacuous application doesn't count.

On the other hand, *feeding order* and *bleeding order* (or the terms A *feeds* B and A *bleeds* B) refer to relations between two rules A and B which presuppose both feeding/bleeding relations and the specific ordering A < B (i.e. A precedes B) in the grammar. Most definitions are formulated for cases in which A immediately precedes B, or cases in which intervening rules don't interact with A and B. In such a situation the definitions become simpler: A is in feeding/bleeding order with respect to B iff A < B and A p-feeds/bleeds B. For the general case the definitions have to be refined as follows:

(25) *Feeding order and bleeding order*

Let G be a grammar, A, B rules, and D a derivation of G.

a. A is in feeding order with respect to B (or A *feeds* B) in grammar G iff
   i. A < B
   ii. There is a derivation D by G such that B would not apply to the input to A, and B applies to the output of A and would apply to all intermediate stages up to its own input.

b. A is in bleeding order with respect to B (or A *bleeds* B) in grammar G iff
   i. A < B
   ii. There is a derivation D by G such that B would apply to the input to A, and B does not apply to the output of A and would not apply to all intermediate stages up to its own input.

When A immediately precedes B or in cases where intermediate rules don't interact we get derivations like those in (26): (26a.i) is in feeding order with respect to (26a.ii) because the second rule (26a.ii) wouldn't apply to AQ, but applies to BQ, the output of the first rule (26a.i); (26b.i) is in bleeding order with respect to (26b.ii) because the second rule (26b.ii) would apply to AQ, but doesn't apply to BQ, the output of the first rule (26b.ii).

(26) a. *Feeding order*
(No intervening interacting rules)

		AQ
i.	A → B / __ Q	BQ
ii.	Q → R / B __	BR

b. *Bleeding order*

		AQ
i.	A → B / __ Q	BQ
ii.	Q → R / A __	—

The case of feeding order for two adjacent rules can be illustrated with the interaction of /æi̯/ → [aː] and Umlaut in a group of Swiss German dialects (Kiparsky 1982b: 190). Bleeding order, also for adjacent rules, can be illustrated with our earlier example (2e)–(2h), Canadian Raising, in the word *writer* in dialect B:

(27) a. *Feeding: Swiss German (dialect group I)*

		/æi̯-li/	'egg-DIM'
i.	æi̯ → a: / __ {C, ##}	a:li	
ii.	Umlaut (fronting)	æli	(does not apply non-vacuously to /æi̯-li/)

b. *Bleeding: Canadian Raising (dialect B)*

		/raɪtə˞/	
i.	t → ɾ / V __ V	raɪɾə˞	
ii.	a → ʌ / __ [C, −voice]	—	(applies non-vacuously to /raɪtə˞/)

Consider now the cases with interacting rules intervening between (i) and (ii) that motivate the definitions in (25). (28a) exemplifies feeding cases and (28b) bleeding cases. The rules (i.) and (ii.) are the rules in feeding/bleeding relation; (iii) is the intervening rule.

(28) a. *Feeding order* (Intervening interacting rules)

		QA
i.	Q → R / __ A	RA
iii.	A → B / R __	RB
ii.	A → C / R __	—

b. *Bleeding order*

		QA
i.	Q → R / __ A	RA
iii.	R → Q / __ A	QA
ii.	A → B / Q __	QB

In the feeding example, rule (i) p-feeds rule (ii) and precedes (ii), but given conditions (25a.ii) and (25b.iii), it does not feed rule (ii), because some rule ordered between them, namely (iii), undoes the change that caused the feeding (it bleeds rule (ii)). In terms of the definitions in (25), there are representations between the two rules, in particular the input to rule (ii), to which the second rule cannot apply. Similarly, in the bleeding example, rule (i) p-bleeds rule ii. and would indeed bleed rule (ii), if it were not for (iii), which feeds rule (ii).

Of course a pair of rules can show non-feeding or non-bleeding interactions like those in (28) in some derivations, but feeding or bleeding interactions in other derivations. As already indicated in note 7, I will use the terms d-feed and d-bleed when feeding and bleeding is relativized to a specific derivation. English stress provides an actual example for bleeding. Stress is assigned twice in words like *context* ['kan,tekst] or *Ahab* ['eɪ,hæb]. But after a light syllable the second stress is removed (the "Arab rule"; Ross 1972), as in *Arab* ['ærəb], and the destressed vowel reduces to [ə]. Stress bleeds vowel reduction, but in the derivation of *Arab* destressing undoes the bleeding (/ærəb/ → 'æ,ræb → 'æræb → ['ærəb]). Here we must say that stress bleeds reduction, because there are derivations that show actual bleeding, as in ['eɪ,hæb], but if we relativize bleeding to specific derivations, some of them do not show a bleeding interaction: in these derivations stress doesn't d-bleed reduction.[8]

There is yet another interesting case of p-feeding/bleeding with no actual feeding/bleeding. If a rule A p-feeds a rule B and precedes it, and there is a

[8] Notice that the example is adequate only if we assume that the underlying /ærəb/ has no stress structure and the unstressed character of the second vowel is introduced by the stress rule.

representation to which A applies and B would not apply, it is possible, according to (25), to have no feeding order even if, contrary to what happens in the previous examples, B actually applies. The same is true, *mutatis mutandis*, of bleeding order. This happens in Duke of York derivations (Pullum 1976; McCarthy 2003), which are derivations in which a rule reverses the action of a previous rule, e.g. . . . A . . . → . . . B . . . → . . . A . . . Consider the derivations in (29), which contain a Duke of York subderivation, highlighted in bold (notice that (28b) above is also an instance of a Duke of York derivation):

(29) a. *Feeding order* b. *Bleeding order*
(Intervening interacting rules; Duke of York derivations)

		QA			**QA**
i.	Q → R / __ A	**RA**	i.	Q → R / __ A	**RA**
iii.	A → B / R __	**RB**	iii.	R → Q / __ A	**QA**
iv.	B → A / R __	**RA**	iv.	A → B / Q __	QB
ii.	A → C / R __	BC	ii.	A → C / Q __	—

In (29a) (i) p-feeds and precedes (ii), and (ii) does apply, but (i) does not feed (ii), because there is an intermediate representation to which the second rule would not apply, namely RB, created by (iii). In fact it is the other intervening rule, (iv), that now feeds (i). Similarly, in (29b) (i) p-bleeds the last rule (ii), but it does not bleed it, even if the rule does not apply, because of the intermediate representation QA created by (iii), to which the rule would apply. Here it is rule (iv) which actually bleeds (ii).

Feeding and bleeding interactions have been used in different contexts and for different purposes, so it is conceivable to have slightly different changes in the definitions. One such change is desirable in cases in which usual definitions do not yield a feeding/bleeding relation, and yet this relation is intuitively correct. Consider a case like (30), in which glide formation, vowel reduction, and destressing interact in Central Catalan. (30a)–(30c) show that glide formation affects postvocalic high unstressed vowels (30a), but not non-high vowels (30b), where *Osiris* is a lexical exception to vowel reduction, or stressed vowels (30c). It also affects high unstressed vowels that are not underlying, as in (30d).

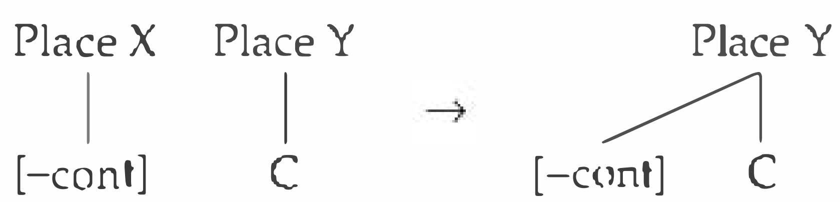
(30)

	a.	*ser*['a] [u]*mid* 'it will be wet'	b.	*ser*['a] [o]*siris* 'it will be Osiris'
Destressing				
Vowel Reduction				
Glide Formation		'a w		
output		*ser*['a] [w]*mid*		*ser*['a] [o]*siris*
	c.	*ser*['a] ['u]*til* 'it will be useful'	d.	*ser*['a] ['ɔ]*ciós* 'it will be idle'
Destressing				'a ɔ
Vowel Reduction				'a u
Glide Formation				'a w
output		*ser*['a] ['u]*til*		*ser*['a] [w]*ciós*

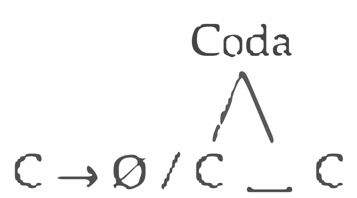
Notice now that the structural description V V[+high, −stress] is met in (30d), because vowel reduction has turned [ɔ] into a high vowel, but also because destressing has created the other condition for gliding. In such a case we want to say that these two rules jointly feed glide formation. The definitions in (25) can be changed accordingly, to meet such situations.

Notice also that a rule can stand in both feeding and bleeding order with respect to another rule. In Majorcan Catalan stops assimilate in place to a following consonant (place assimilation), and the second consonant in a two-consonant coda cluster deletes before another consonant (cluster simplification). As shown in (31), deletion of the medial C causes bleeding when the medial C is the target of assimilation, and feeding when it intervenes between the trigger and the target of assimilation.

(31) a. *Place assimilation*



b. *Cluster simplification*



c.

	Bleeding	*Feeding*
input	/'bujd 'trens/ 'I empty trains'	/'trens 'bujds/ 'empty trains'
Cluster simplification	'buj 'trens	'tren 'bujds
Place assimilation	—	'trem 'bujds
output	'buj 'trens	'trem 'bujts

It should be observed that the fact that two rules A, B do not have a feeding or bleeding interaction does not mean that they don't interact. In (32) rule (a) deletes final consonants, while (b) stresses the final syllable if it is heavy, otherwise the penult. Different orderings give different results, but the interaction isn't either a feeding or a bleeding relation.

(32) a. C → Ø / __ ## /satopek/ $\xrightarrow{a}$ satope $\xrightarrow{b}$ sa'tope
b. V → [+stress] / __ C(V)## /satopek/ $\xrightarrow{b}$ sato'pek $\xrightarrow{a}$ sato'pe

I will now examine *counterfeeding* and *counterbleeding*. These notions refer only to rules that are in a specific order (potential situations don't make sense in this context). Basically, a counterfeeding/bleeding order is an order that would be feeding/bleeding if the order of the rules were reversed. Since there is some confusion in the use of the predicates, I will follow the practice in Koutsoudas *et al.* (1974) and use as subject of "counterfeed/counterbleed" the second rule in the ordering, e.g. B counterfeeds A means that A < B, and B would feed A if B < A.

(33) a. A and B *are in counterfeeding order* (B *counterfeeds* A) in grammar G iff
i. A < B
ii. B p-feeds A

b. A and B *are in counterbleeding order* (B *counterbleeds* A) in grammar G iff
i. A < B
ii. B p-bleeds A

Counterfeeding order can be illustrated with the same processes of Swiss German presented in (27) in another dialect group, group II, which shows the opposite ordering. Counterbleeding is illustrated with Canadian Raising in dialect A (2a):

(34) a. *Counterfeeding: Swiss German (dialect group II)*

	/æi̯-li/	'egg-DIM'
i. Umlaut (fronting)	—	
ii. $\text{æi̯} \rightarrow \text{aː} \;/\; \_\_ \begin{Bmatrix} C \\ \#\# \end{Bmatrix}$	aːli	

The opposite, feeding ordering would yield /æi̯-li/ → aː-li → æː-li

b. *Counterbleeding: Canadian Raising (dialect A)*

	/raɪtə/
i. a → ʌ / __ [C, −voice]	rʌɪtə
ii. t → ɾ / V __ V	rʌɪɾə

The opposite, bleeding ordering would yield /raɪtə/ → raɪɾə → (*n/a*)

"Counter" orderings have important properties. Assume the simple case where rules A and B are adjacent, and A < B. Since in feeding order (B < A) there must be at least one input I such that B is applicable to I, A is not applicable to I, and A is applicable to the output of B (35a), it follows that in the corresponding counterfeeding order where A < B there must be an input (namely I) to which the first rule, now A, does not apply and to which the second rule, now B, applies (35b). Hence the generalization expressed by A does not appear in the output: we can say, using McCarthy's (1999) terms, that it is *not surface-true*, it is not true of the output of B, usually the surface representation. In the bleeding order B < A there must be by definition at least one input I such that both A and B are applicable to I (giving different results, I′ and I″, respectively), and A is not applicable to the output of B (35c). It follows that in the corresponding counterbleeding order A < B there can be an input to which the first rule, now A, applies and to which the second rule, now B, might apply and change the context of application of the first rule (35d). Hence the generalization expressed by A about the input I does not appear in the output: following McCarthy we can say that it is *not surface-apparent*, because the generalization A about I is not apparent in the output of A, usually the surface representation.

(35)

a. *Feeding*		b. *Counterfeeding*		c. *Bleeding*		d. *Counterbleeding*	
	I		I		I		I
B.	I′	A.	—	B.	I′	A.	I″
A.	I″	B.	I‴	A.	—	B.	— /I‴

In our previous example in (34) for counterfeeding in Swiss German, the fronting dictated by Umlaut is not true in the surface form [a:li]; for the counterbleeding in Canadian Raising, dialect A, the fact that [ʌ] derived from /a/ appears before voiceless consonants is not apparent in the surface form [rʌɪɾə].

It is also important to notice that the existential quantification in the definitions in (25) of feeding and bleeding orders (hence also of counterfeeding and counterbleeding orders) allows for the existence of multiple feeding and bleeding relations between two rules. For feeding, and given two ordered rules A < B, the requirement (25a.ii) that there be an input I whose derivation D meets the conditions required in (25a.ii) does not prevent the existence of another input I′ that meets the condition (25b.ii) for bleeding. Hence A can both feed and bleed B (and B can both counterfeed and counterbleed A).

5 Serial and parallel approaches

Rule interactions of the sort just discussed have become important in the theoretical comparative analysis of serial and parallel approaches, in particular in relation to *opaque* rule interactions. If we compare a standard serial theory like *SPE* with a parallel theory based on constraints like Optimality Theory (OT), pure feeding and pure bleeding order effects (i.e. those that are not also counterfeeding or counterbleeding) are *transparent* interactions and can be derived from both. Consider the well-known case of *e*-raising and /t/ → [s] interaction in Finnish (Kiparsky 1973b: 166–172), partially repeated from (20):

(36)		vete 'water-NOM SG'	halut-i 'wanted'
	a. e → i / __##	veti	—
	b. t → s / __ i	vesi	halus-i

Because both (36a) and (36b) are statements that are true of surface forms, constraints of the form *e##, *ti, dominating conflicting faithfulness constraints, together with other constraints determining the choice of [i] and [s], will derive the output of /vesi/, /halus-i/.

But counterfeeding and counterbleeding are opaque interactions and cause problems for a parallel approach. A process (37a) is opaque (Kiparsky 1973b: 79) to the extent that there are phonetic forms in (37b) or (37c); otherwise it is transparent. The derivations (37d) and (37e) illustrate (37b) and (37c), respectively.

(37) a. *Rule:* A → B / C __ D

Opaque surface forms

b. A in the environment C __ D

c. B derived by (a) in an environment different from C __ D

d.		/EAD/
	A → B / C __ D	—
	E → C / __ A	CAD
e.		/CAD/
	A → B / C __ D	CBD
	C → E / __ A	EBD

In (37d) the generalization "A does not appear in C __ D; B appears instead" expressed by (37a) is not surface-true; the rule *underapplies* with respect to surface representations. In (37e) the generalization "underlying (or intermediate) A is represented by B in C __ D" is not true of the derivation, it is not surface-apparent; the rule *overapplies* with respect to surface representations, since it applies outside its environment. To illustrate with a real example, consider counterfeeding in Madurese (Austronesian, Indonesia) (McCarthy 2002: 174–175). Nasality spreads rightwards onto following vowels, but is blocked by oral consonants, and voiced stops delete after a nasal (CHAPTER 78: NASAL HARMONY):

(38)	a.		/naŋgaʔ/	/naŋaʔ/
	b.	V → [+nas] / N __	nãŋgaʔ	nãŋãʔ
	c.	/b d g/ → Ø / N __	nãŋaʔ	—
		Surface	[nãŋaʔ]	[nãŋãʔ]

In the first derivation, rule (38c) has deleted an oral consonant and has thus partially changed the context of application of rule (38b); rule (38b) underapplies, because if it did apply to the surface representation it would nasalize the second vowel, *[nãŋãʔ]. The generalization that a nasal vowel nasalizes following vowels across non-oral consonants is not surface-true.

Such an opaque interaction is derivable in an ordered rule system, but not in a system in which markedness generalizations are about surface forms. Consider now a model like OT. For an input /nãŋaʔ/ (cf. the second derivation in (38)), the constraint hierarchy must favor candidate [nãŋãʔ] over candidate *[nãŋaʔ] (nasalization spreads across non-oral consonants). Therefore it will also favor the non-opaque candidate *[nãŋãʔ] over candidate [nãŋaʔ] if the input is /nãŋgaʔ/. Similar considerations apply to counterbleeding opacity. Consider our earlier example, Canadian Raising in dialect A. The change /aɪt/ → [ʌɪt] does not appear as such in the phonetic representation of *writer*, because the second rule has modified the result of the change, turning the triggering voiceless /t/ into [ɾ]:

(39)	a.		/raɪtə/		/taɪp/
	b.	aɪ → ʌɪ / __ [C, −voice]	rʌɪtə		tʌɪp
	c.	t → ɾ / V __ V	rʌɪɾə	(ʌɪɾ, *not* ʌɪt)	tʌɪp

Here in order to obtain the transparent [tʌɪp] in *type*, both *aɪ[C, −voice] and *VtV must be active. But for *writer* the input /raɪtə/, where both constraints are relevant, cannot have as output [rʌɪɾə], because the candidate [rʌɪtə] also satisfies both markedness constraints and is, in addition, more faithful to the input:

(40)

/raɪtə/	*aɪ[C, −voice]	*VtV	Faith[aɪ]	Faith[t]
a. raɪtə	*!	*		
b. rʌɪtə		*!	*	
☞ c. raɪɾə				*
d. rʌɪɾə			*!	*

6 Conclusion

Rules are generalizations about the distribution of sound in natural languages. Rule ordering is a specific theory about how these generalizations interact to derive a surface representation. The intensive study of many phonological systems using rule ordering has not only produced a rich body of descriptive work, but has also unveiled many deep properties of phonological systems and many theoretical problems that go beyond the model that generated them. When the problem of the theoretical status of phonology was first addressed seriously, it was immediately realized that phonological generalizations could not have two properties at the same time: they could not be absolute generalizations and generalizations about the surface representation. In other words, they could not map a lexical representation to a surface representation in one step (simultaneous rule application), as illustrated by Joos's paradox discussed at the beginning of §1. The response to this fact was that the requirement that generalizations be true of surface representations should be abandoned, and hence that phonological processes had to be ordered. The conviction of many present-day phonologists that the right response is to abandon the other requirement, i.e. that generalizations be absolute, and keep the idea that they apply to surface representations, has been made possible by many decades of work in a framework based on rule ordering. Even if many things have changed since the days in which a phonological description could be based on a system with a depth of ordering of 20 or 30 (i.e. 20 or 30 rules that had to be linearly ordered),[9] serial approaches haven't achieved a total elimination of ordering through mechanisms like the ones described in §2.3. At the same time, many of the properties of phonological systems that have been discovered as the result of work on rule ordering – the existence of opacity, disjunctivity as predicted by the Elsewhere Condition, derived environment effects, and many morphology–phonology interactions – are still important problems that will stimulate further research, for both serial and parallel approaches.

75 Consonant–Vowel Place Feature Interactions

Jaye Padgett

1 Introduction

Both consonants and vowels are formed with constrictions in the oral cavity, made by the lips, the tongue blade, the tongue body, and/or the tongue root. Since they make demands on the same organs, it should not be surprising that the place features of consonants can influence those of vowels and vice versa. Indeed, such interactions are common: consonants and vowels frequently assimilate in place to one another, or dissimilate. But the empirical territory is not simple, and attempts to understand consonant–vowel place interactions (henceforth "C–V interactions") have led to much unresolved debate in phonological theory.

The questions most debated have had to do with the nature of the phonological features we assume, with questions of feature structure and with claims about the locality of phonological processes. However, as the field of phonology gravitated toward questions of constraint interaction under the influence of Optimality Theory (Prince and Smolensky 1993), attention toward these representational questions faded without having been resolved. Whatever the theoretical framework though, the empirical puzzles underlying the debate about C–V interactions remain, and remain interesting.

The discussion in this chapter will necessarily reflect the open-endedness of the historical discussion, as well as the framework in which that discussion was held – autosegmental phonology and feature geometry. §2 begins by presenting a typology of C–V interactions. §3 puts forward an influential model of feature geometry as a point of departure and reviews the challenges raised for that model by C–V interactions. §4 discusses a prominent approach to these challenges, a "unified feature" approach to consonants and vowels advocated by Herzallah (1990), Clements (1991), Hume (1994, 1996), Clements and Hume (1995), and others. In §5 we pause to consider issues of locality and transparency in C–V interactions. §6 covers an alternative to the unified feature approach, due to Ní Chiosáin and Padgett (1993) and Flemming (1995, 2003), called the "inherent vowel place" approach here. §7 concludes.

2 A typology of C–V interactions

The typology given here is not meant as an exhaustive survey of the kinds of C–V interaction known. Instead the goal is to classify processes according to the challenges they have presented for phonological theory. In particular, a key distinction will be made between "within-category" C–V interactions and "cross-category" C–V interactions.[1] Also, for space reasons the main focus will be on assimilations (CHAPTER 81: LOCAL ASSIMILATION), with only occasional reference made to dissimilatory cases (see CHAPTER 60: DISSIMILATION).

2.1 *Within-category interactions*

It may seem incoherent to posit "within-category" interactions between the distinct categories of consonant and vowel. However, it is well known that consonants can have secondary articulations that are essentially vocalic in nature: vowel- or glide-like gestures, produced along with a consonant's primary place of articulation. Some representative examples are illustrated in (1) (see also CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION; CHAPTER 71: PALATALIZATION; CHAPTER 121: SLAVIC PALATALIZATION).[2]

(1) *(Semi-)vocalic secondary articulations*

labialization	palatalization	velarization	pharyngealization
t^w	t^j	t^{γ}	$t^{ʕ}$

Indeed, glides themselves are consonants with vocalic properties (CHAPTER 15: GLIDES). "Within-category" interactions are those between a vowel and another (semi)-vocalic element, whether the latter is a secondary articulation or a primary one (a glide).

Let us begin with interactions between vowels and glides. The examples in (2) are from Kabardian (Colarusso 1992: 32–33). Kabardian has a "vertical" vowel system arguably consisting of only the two phonemes /ə a/. These vowels assimilate in backness and roundness to a following coda glide. According to Colarusso, the triggering glide is elided in all but careful speech, with some compensatory lengthening (not shown). Effects like this of glides on vowels, affecting either vowel color (backness and/or roundness) or height (CHAPTER 19: VOWEL PLACE; CHAPTER 21: VOWEL HEIGHT), seem common in languages.

(2)	/q'əw/	[q'uw]	'swan'	/bəj/	[bij]	'enemy'
	/psaw/	[psow]	'alive'	/tsaj/	[tsej]	'one of wool (kind of coat)'

Turning to vocalic secondary articulations, non-low short vowels in Irish are front before palatalized consonants and back before non-palatalized consonants; the

[1] These terms are borrowed from Clements (1991). Compare the "Type I" *vs.* "Type II" distinction of Ní Chiosáin and Padgett (1993).

[2] This presentation simplifies reality in some ways. For example, sounds transcribed C^w or C^{γ} might be labial-velarized and not just labialized or velarized. In addition, "pharyngealized" sounds are more accurately described as "uvularized" in at least some cases (McCarthy 1994).

latter are velarized. The symbols "I/E" denote underlying high and mid vowels (respectively) of indeterminate backness.

(3)	/mˠIdʲ/	[mˠɪdʲ]	'we/us'	/pˠIntˠ/	[pˠuntˠ]	'pound'
	/sʲIvʲ/	[ʃɪvʲ]	'you (PL)'	/skʲIbˠ/	[skʲubˠ]	'snatch'
	/tˠEtʲ/	[tˠɛtʲ]	'smoke'	/bˠEsˠ/	[bˠʌsˠ]	'palm (of hand)'
	/tʲEpʲ/	[tʲɛpʲ]	'fail'	/lʲEmˠ/	[lʲʌmˠ]	'with me'

Similarly, labialized consonants can cause a neighboring vowel to be round, as in Kabardian /dəʁʷ/ → [doʁʷ] 'thief' (Colarusso 1992: 30). In a case involving pharyngealization (or uvularization; see note 2), emphatic consonants in Palestinian Arabic cause /a/ to ablaut to [u] instead of [i] in first measure imperfect verbs (Herzallah 1990): the imperfect form of [naðˤam] 'compose' is [ji-nðˤum] rather than the expected *[ji-nðˤim] (cf. [katab], [ji-ktib] 'write'). Herzallah argues that secondary pharyngealization involves a component of backness that spreads to the vowel in these cases. In a more typical case of emphasis spread, vowels in Ayt Seghrouchen Tamazight Berber are backed and lowered next to emphatic consonants (Rose 1996), as shown in (4). Rose argues that emphasis spread is the spreading of the feature [RTR] ([Retracted Tongue Root]) (see also CHAPTER 25: PHARYNGEALS; CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS).

(4)	a.	[izi]	'fly'	b.	/izˤi/	[ezˤe]	'bladder'
		[llef]	'to divorce'		/tˤtˤef/	[tˤtˤɛf]	'to hold'
		[nðu]	'to be shaken'		/nðˤu/	[nðˤo]	'to cross'

Consonants commonly acquire vocalic secondary articulations by assimilating to adjacent vowels. For example, Russian consonants are palatalized before certain suffixes beginning in [i] or [e] (Padgett, forthcoming; see also CHAPTER 121: SLAVIC PALATALIZATION):

(5)	*Nom sg*	*Nom sg (dim)*	*Loc sg*	
	stol	stolʲik	stolʲe	'table'
	dom	domʲik	domʲe	'house'
	ʂar	ʂarʲik	ʂarʲe	'ball'
	zont	zontʲik	zontʲe	'umbrella'

A similar palatalization occurs in Nupe (Hyman 1970). Also in Nupe, consonants are rounded (or labial-velarized) before rounded vowels, e.g. [egʷũ] and [egʷo] for /egũ/ 'mud' and /ego/ 'grass' (tones not shown).

It is worth noting that the examples of within-category assimilation presented above never involve a vowel changing the features of a glide or of a consonant's secondary articulation. Such cases seem at best rare, but it is not clear why that should be.

Again, what all within-category interactions have in common is interaction among overtly (semi-)vocalic elements. Glides are [−consonantal] in the feature theory of Chomsky and Halle (1968; *SPE*). Vocalic secondary articulations are likewise basically vocalic in constriction degree, even if they accompany primary constrictions that are [+consonantal]. For reasons that will become clear below, C–V interactions of this sort have created little controversy in phonological theory. This is in contrast to C–V interactions in which the *primary* articulation of a [+consonantal] segment (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION) appears to interact with the place of a vowel, cases called "cross-category" here.

2.2 *Cross-category interactions*

Numerous cases are known in which plain (not rounded) labial consonants cause vowels to be round. This happens, for example, in a dialect of Mapila Malayalam described by Bright (1972).[3] In this dialect, a vowel is inserted for apparently phonotactic reasons. The vowel is generally something like [ɨ] (not a phoneme of the language), as shown in (6a); but it surfaces as [u] after [o] or [u] (6b) or after a labial consonant (6c). The rule is productive, applying even in borrowings like [trippu].

(6)	a.	pa:lɨ	'milk'	b.	onnu	'one'	c.	ʧa:vu	'death'
		pandɨ	'shake'		nu:ru	'hundred'		ʤappu	'pound'
		kurva:nɨ	'Koran'		uɳɳu	'dine!'		isla:mu	'Islam'
		dressɨ	'dress'		o:ɖu	'run!'		trippu	'trip'

Another well-known case occurs in Turkish (Lees 1961; Lightner 1972). Within historically native Turkish roots, a high vowel following [ɑ] and any intervening consonants is normally [ɯ] (sometimes transcribed [ɨ]). But it is [u] when a labial consonant intervenes, e.g. [jɑvru] 'cub, chick', [ɑrmud] 'pear'. Cross-category dissimilations also occur. For example, in Cantonese a syllable rhyme cannot have both a rounded vowel and a labial coda, e.g. *[up] (Cheng 1991). Other languages showing C–V interactions involving vowel rounding and plain labial consonants are discussed by Hyman (1973), Campbell (1974), Sagey (1986), Clements (1991), Selkirk (1993), Flemming (1995), and Anttila (2002).

There seems to be a similar connection between coronal place of articulation (CHAPTER 12: CORONALS) and front vowels. A frequently cited example comes from Maltese Arabic (Brame 1972; Hume 1994, 1996). In imperfective Measure I verbs, the prefix vowel is normally identical to the vowel of the stem, as shown in (7a). However, when the stem begins with a coronal obstruent, the prefix vowel is [i], (7b). Note that some of the verbs in (7b) undergo an independently existing ablaut by which the imperfective stem vowel becomes [o]; this occurs in verbs without initial coronal obstruents too, e.g. [barad] *vs.* [jo-brod] 'to file'. In these verbs the prefix vowel is normally [o].

(7)		*perfective*	*imperfective*		
	a.	kotor	jo-ktor	'to increase'	
		ʔasam	ja-ʔsam	'to break'	
		ħeles	je-ħles	'to set free'	
		nizel	ji-nzel	'to descend'	UR = /nizil/

[3] Bright relies on Upadhyaya (1968) for data. The Mapila Malayalam data resemble the more often-cited Tulu facts also discussed by Bright; in fact, Bright suggests that the Mapila Malayalam facts are due to contact with Tulu.

b.	daħal	ji-dħol	'to enter'
	talab	ji-tlob	'to pray'
	seħet	ji-sħet	'to curse'
	ʤabar	ji-ʤbor	'to collect'

Hume (1994, 1996) treats the general vowel copy as a case of feature stability: when the first vowel of the imperfective stem is deleted (by a normal syncope rule), its vowel place features surface on the underlyingly featureless prefix vowel. In (7b), however, a rule applies by which the prefix vowel acquires its frontness from a coronal obstruent; this rule takes precedence over the feature stability rule.

In another widely cited case, non-low vowels in Cantonese must be front when between coronal consonants (Cheng 1991); next to [tit] 'iron' and [tøn] 'a shield' there are no forms like *[tut] or *[ton]. Similarly, in Kabardian the vowels /a/ and /ə/ are allophonically fronted before coronal consonants, e.g. /ʃəd/ 'donkey' and /zaz/ 'bile' become [ʃɛd] and [zæz], respectively (Colarusso 1992: 30). Discussion of other cases can be found in Clements (1976, 1991), Hume (1994), and Flemming (1995, 2003).

Dorsal consonants can trigger backing of vowels. This is clearly true when the consonants in question are uvular, analyzed by many as having a [pharyngeal] (Herzallah 1990; McCarthy 1994) or [RTR] (Rose 1996) component in their place of articulation, as well as a [dorsal] one. In fact, uvulars, which are [+back, –high] in the *SPE* framework, can trigger backing and/or lowering. The data in (8) from Inuktitut are taken from Buckley (2000), who cites Schultz-Lorentzen (1945) and Fortescue (1984). The high vowels seen in (8b) are lowered to mid before either of the language's uvular segments, [q] and [ʀ], (8a). This is an allophonic change, since the vowel phonemes of Inuktitut are /i u a/. According to Rischel (1974), this rule involves retraction as well as (or even more than) lowering, though this is not obvious from the transcriptions. As Elorrieta (1991) notes, this is consistent with the notion that uvulars are pharyngealized dorsal consonants.

(8)	a.	seʀmɛ-q	'glacier'	b.	seʀmi-t	'glaciers'
		ikɛ-ʀput	'our wound'		iki-t	'your wound'
		uvdlɔ-q	'day'		uvdlu-t	'days'

In Kabardian, the phonemes /ə a/ are backed before uvulars, e.g. /baq/ → [bɑq^{h}] 'cow shed' (Colarusso 1992: 30).[4]

Velar consonants, which are also [dorsal], can also cause backing, and/or raising. One example is from Maxakalí (Gudschinsky *et al.* 1970; Clements 1991). Tautosyllabic VC sequences tend to display an excrescent vowel which either replaces the consonant or forms a transition from vowel to consonant, depending on aspects of the environment. The place of this excrescent vowel depends on the place of the consonant. As shown in (9a), that vowel is /ə/ before alveolars. But it is a high back vowel before velars, (9b). (The vowel is also [i] before "alveo-palatals," and something like [ʌ] before labials.)[5]

[4] Colarusso states that backing affects /ə/ also, and his rule predicts [ɣ], but he transcribes [ə].

[5] The relevant excrescent vowel is underlined. Along with the excrescent vowel, a preceding glide can appear. A breve indicates the vowel is non-syllabic. Gudschinsky *et al.* actually indicate a good deal of variation in these excrescent vowel qualities.

(9)	a.	/mit/	[mbijə̲t̚]	'sound of a jaguar's footsteps'
		/kot nak/	[kowə̲ daɯ̆ɨx]	'dry manioc'
	b.	/noʔok/	[ndoʔoɯ̲̆x]	'to wave (something)'
		/kɯcakkɯk/	[kɯʃaɯ̲kɯx]	'capybara (species of rodent)'

If Clements (1991) is right that [ə] represents the basic quality of the excrescent vowel, then [k] (and also [ŋ]) seem to cause it to raise and back. Similarly, in Yoruba, certain *i*-initial nouns show the /i/ backing to [u] when a velar precedes. This occurs in a reduplicative context, e.g. /ki + isɔ/ → [isɔku̲sɔ] 'saying, foolish/loose talk' (Pulleyblank 1988: 245–246; tones omitted). Other cross-category cases involving velars are discussed in Ní Chiosáin and Padgett (1993), Clements and Hume (1995), and references therein.[6]

Finally, pharyngeal consonants often cause vowels to lower and back, particularly to [a]. In fact, this can be a property of all "guttural" consonants – uvulars, pharyngeals, and (for some languages) laryngeals – which can all be analyzed as having a [pharyngeal] component to their place of articulation (McCarthy 1994) (see also CHAPTER 25: PHARYNGEALS). The examples in (10), taken from Rose (1996), who cites Cowell (1964), are from Syrian Arabic. The feminine suffix /-e/, seen in (10a), is realized as [a] after gutturals, (10b).

(10)	a.	daraʒ-e	'step'	b.	waːʒh-a	'display'
		ʃerk-e	'society'		mniːħ-a	'good'
		madras-e	'school'		daggaːʀ-a	'tanning'

The examples of cross-category assimilation discussed so far involve consonants affecting vowels. A striking fact is that consonant-to-vowel cross-category assimilations are notably missing (Ní Chiosáin and Padgett 1993). The one clear exception to this claim is the case of palatalizing mutations. As many have noted (e.g. Clements 1976; Mester and Itô 1989), front vowels, especially higher ones, often trigger mutations of velars or dentals/alveolars to palato-alveolar (or a similar) place of articulation. Hume (1996) cites a case of velar mutation in Slovak (Rubach 1993) by which /k g x ɣ/ become [ʧ ʤ ʃ ʒ] respectively before any of [j i e æ] (see CHAPTER 65: CONSONANT MUTATION for more on mutations):

(11)	a.	vnuk	'grandson'	vnuʧik	(DIM)
	b.	tsveng	'sound'	tsvenʤat[j]	'to sound'[7]
	c.	strax	'fright'	straʃit[j]	'frighten'
	d.	boɣ	'god'	boʒe	(VOC)

Such cases are common, and clearly involve assimilation of a velar consonant to a front vowel. The existence of these cases might lead us to expect equally frequent assimilations to round vowels, such as /ku/ → [pu], or assimilations to [a], such as /fa/ → [ħa]. But assimilations like these, or the many others that

6 Some researchers have suggested that cross-category assimilations of vowels to velars like these are unexpectedly rare, compared to cases involving labial or coronal consonants (Ihiunu and Kenstowicz 1994; Flemming 1995). This seems possible, but no comprehensive comparative survey has been done. Flemming's claim that they do not exist at all seems too strong.

7 The triggering vowel is assumed to be /æ/, which backs later in the derivation.

can be imagined if vowels can cause place assimilation of a consonant, are glaringly absent.[8]

Apart from this asymmetry, another interesting fact about cross-category assimilations should be noted. Compared to within-category assimilations, they seem "weak" in several respects. First, they appear to be much less frequent. This seems especially clear if we compare within-category effects in which a consonant's secondary articulation affects a vowel to cross-category effects in which a consonant's *primary* articulation affects a vowel, e.g. /k^{w}ɨ/ → [k^{w}u] *vs.* /pɨ/ → [pu]. If we keep in mind that consonants with secondary articulations occur in a minority of languages while *all* languages have plain consonants (see e.g. Maddieson 1984), the difference is very striking. The seeming exception to this generalization involves gutturals, which, when present in a language, seem likely to trigger assimilation of a vowel (McCarthy 1994; Rose 1996).

Second, cases in which a consonant's primary place takes precedence over its secondary place in determining a vowel's place features, e.g. /p^{j}ɨ/ → [p^{j}u], seem non-existent (Ní Chiosáin and Padgett 1993; Flemming 1995, 2003).

Third, cross-category effects often seem to involve vowels that are "underspecified" (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION) in the sense of being either epenthetic (CHAPTER 67: VOWEL EPENTHESIS), reduplicative (CHAPTER 100: REDUPLICATION), or central (see also CHAPTER 58: THE EMERGENCE OF THE UNMARKED). The case of Mapila Malayalam is typical: the vowel [ɨ] is not one of the language's phonemes /i e a o u/, it is predictably inserted, and it is central. Central vowels (whether predictable or not) are often hypothesized to lack specification to some degree, whether phonetically (Browman and Goldstein 1992) or phonologically (Kaye *et al.* 1985; Clements 1991; Lombardi 2003) (see also CHAPTER 26: SCHWA). That cross-category effects often seem to be linked to central and epenthetic vowels suggests that they often can be feature-filling, but not feature changing.

Fourth, cross-category effects generally seem to be highly local: the consonant and vowel must be immediately adjacent or nearly so (CHAPTER 81: LOCAL ASSIMILATION). Though some within-category effects seem to have this property too (e.g. rounding or palatalization of consonants by vowels), some clearly do not. For example, consonants can dissimilate across vowels, and yet cross-category dissimilations are local.

Finally, some cross-category effects seem to need to "gang up" in order to apply. In the case of Cantonese vowel fronting mentioned above, the vowel must be *surrounded* by coronals in order to undergo the rule. In Feʔ-feʔ-Bamileke, a labial consonant causes an adjacent reduplicating vowel to be round, but only when a round vowel is also present; likewise, a coronal consonant causes it to be front only when a front vowel is also present (Hyman 1972).[9]

These facts about cross-category effects, suggesting that they are in some sense "weak," should arguably follow from any account of them.

[8] Some apparent counterexamples are discussed below and in Ní Chiosáin and Padgett (1993). (See also CHAPTER 72: CONSONANT HARMONY IN CHILD LANGUAGE for a discussion of this possibility in child language.)

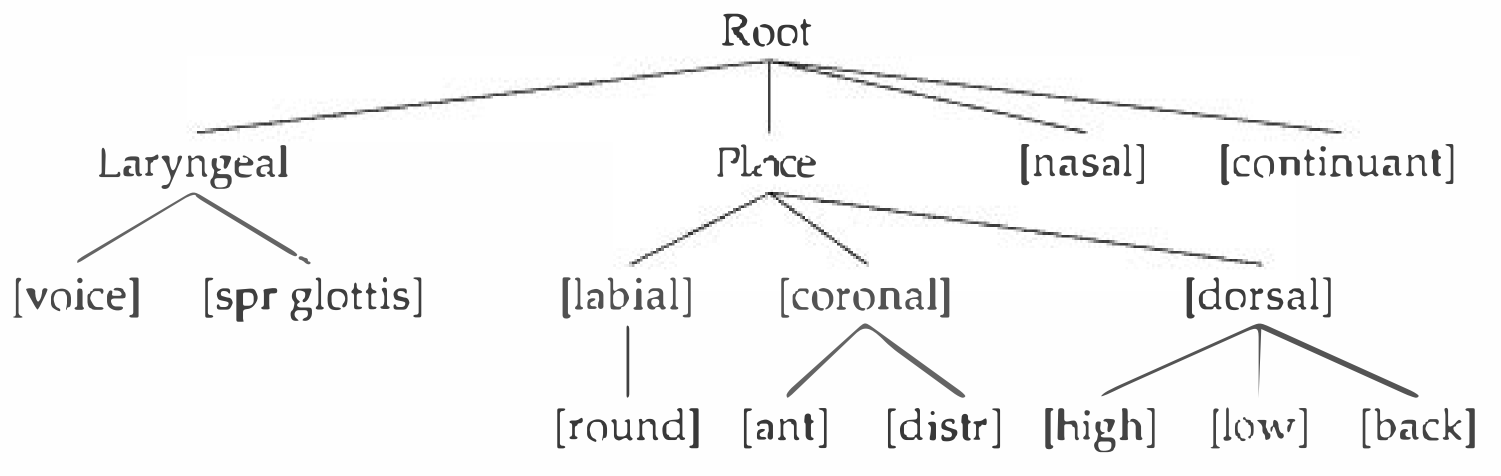
[9] If the neighboring vowel is high, it is sufficient to cause the change. Otherwise the vowel and consonant together cause it.

3 C–V interactions and feature theory

Research on C–V interactions became particularly active within the context of the development of feature geometry theory. This chapter assumes a basic familiarity with the workings of autosegmental phonology and feature geometry (see CHAPTER 14: AUTOSEGMENTS and CHAPTER 27: THE ORGANIZATION OF FEATURES.)

A good starting point for our discussion is a feature geometry representation based on the influential work of Sagey (1986), with some modifications suggested by McCarthy (1988), shown in (12) (some details omitted).

(12) *Feature geometry*



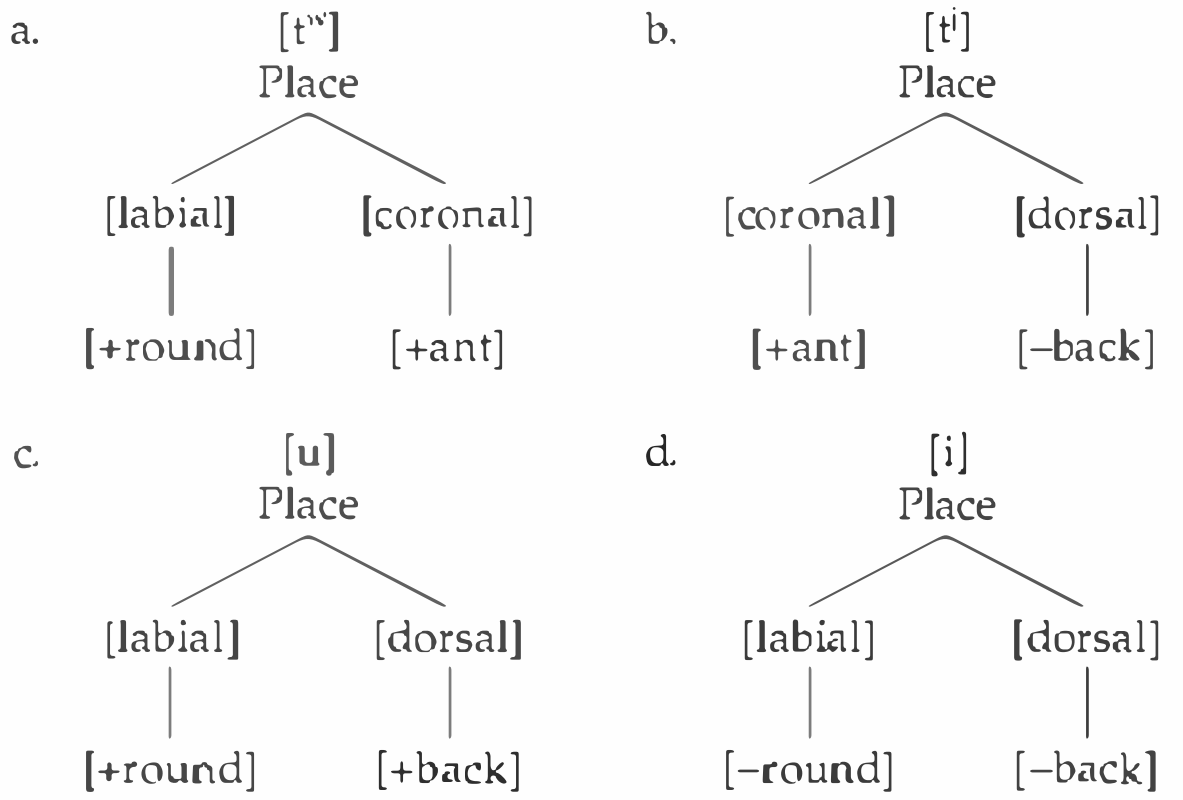
Focusing on the place of articulation features, one notable property of Sagey's model is its basis in active articulators of the vocal tract: [labial], involving the lips, [coronal], involving the tongue tip and/or blade, and [dorsal], involving the tongue body. In its grounding in articulation the model is in the tradition of *SPE*. However, Sagey's model departs from *SPE* in various respects, including in holding that the articulator nodes [labial], [coronal], and [dorsal] are privative, and that they are organizational nodes in feature geometry, as shown in (12).[10]

As Sagey argues, an advantage of an articulator-based model like this is that it easily represents complex segments – segments that have more than one place of articulation, such as [g͡b] (CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION). In *SPE*, by comparison, velars are [−anterior, −coronal] and labials are [+anterior, −coronal]. In such a system it is unclear how to specify a segment that is both labial and velar. This point is relevant to us, since consonants bearing vocalic secondary articulations are complex segments. For example, in Sagey's terms the segments [t^w] and [t^j] are represented as in (13a) and (13b), focusing only on place features.[11] Vowels are also specified in terms of the features in (12) and are often complex segments themselves. The vowels [u] and [i], for instance, are specified as in (13c) and (13d). The representation in (13d) assumes that [i] has an active lip-spreading gesture, which requires involvement of the lips. Since all vowels are specified for tongue body features, all vowels have a [dorsal] specification.

[10] For Sagey they are privative because they are *class nodes* rather than features. Like Clements (1991) and others, I interpret them as features and assume features can be dependent on other features.

[11] Some features are omitted for simplicity, including [distributed], [high], and [low]. [t^w] is understood as labialized, not labial-velarized.

(13)



To give a more complete understanding of this feature system, Table 75.1 shows place specifications for plain, palatalized, and rounded consonants of all three major places of articulation and for five representative vowels. The symbol "✓" indicates specification of a privative (major) place feature. In this theory, specification of a feature such as [round] or [back] is possible only if the relevant major place – here [labial] or [dorsal] respectively – is specified. Otherwise, full feature specification is assumed for the sake of discussion. For our purposes, what is particularly worth noticing is the disjointedness of the consonantal *vs.* vocalic place specifications. Unless they are labialized or palatalized, coronal consonants have nothing in common with vowels. Plain labials are like rounded vowels in having a [labial] specification – but not in being rounded. The exception to this disjointedness is with [dorsal] consonants, which, following *SPE*, are specified for vocalic tongue body features. This is in fact how velars are distinguished from uvulars ([–high, –low]) and pharyngeals ([–high, +low]).

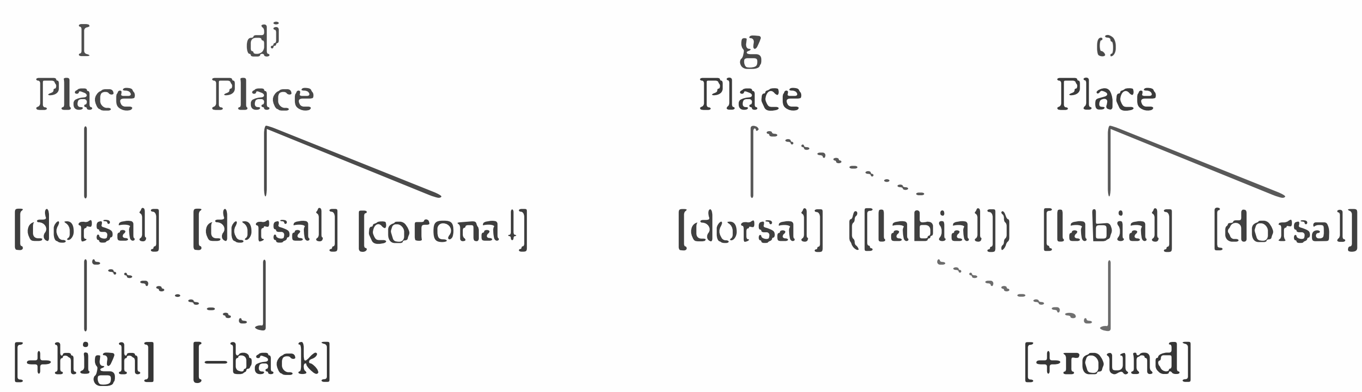
Within such a model, many within-tier interactions are straightforward to represent. For example, the dependence in Irish of a short vowel's backness

Table 75.1 Feature specifications (Sagey 1986)

		p	pʲ	pʷ	t̪	t̪ʲ	t̪ʷ	k	kʲ	kʷ	i	y	a	o	u
[labial]		✓	✓	✓			✓			✓	✓	✓		✓	✓
	[round]	–	–	+			+			+	–	+		+	+
[coronal]					✓	✓	✓								
	[anterior]				+	+	+								
	[distributed]				+	+	+								
[dorsal]			✓			✓		✓	✓	✓	✓	✓	✓	✓	✓
	[high]		+			+		+	+	+	+	+	–	–	+
	[low]		–			–		–	–	–	–	–	+	–	–
	[back]		–			–		+	–	+	–	–	+	+	+

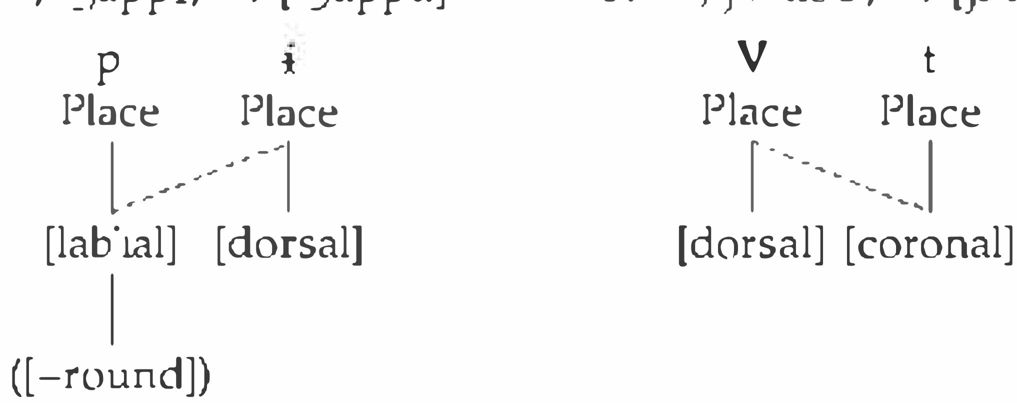
on the following consonant (see (3)) is an assimilation as shown in (14a).[12] The assimilation of a plain consonant to a round vowel, as in Nupe [egʷo] 'grass', is as in (14b). (The rule spreads [+round], and [labial] is inserted on the consonant by Node Interpolation (Sagey 1986). Alternatively, [labial] spreads to the consonant.) Apart from the advantages of an articulator-based representation, it is not the particular geometry assumed here that makes within-category effects easy to represent. The point is that vowels, glides, and (semi-)vocalic secondary articulations on consonants are assumed to employ the very same set of place features. If that is true, then whatever the geometry, there is no (at least general) difficulty in representing within-category processes.

(14) a. /mˠɪdʲ/ → [mˠɪdʲ] b. /ego/ → [egʷo]



Compare the situation with cross-category assimilations. Recall that in Mapila Malayalam the vowel /ɨ/ is rounded after a plain labial consonant (see (6)). Since it is a plain (not labialized) labial consonant in question, it cannot be specified [+round]. Whether the consonant is specified [–round] or unspecified for [round], spreading [labial] as in (15a) will not cause the vowel to round. In the case of Maltese Arabic (see (7)), the problem seems even worse. The feature [–back] needed to achieve [i] is not part of the representation of a coronal consonant.[13] Spreading [coronal], the only seeming option, is of no help. The issue once again is not about the feature geometry pursued. The problem is that the place features that are assumed to define consonantal place are largely disjoint from those assumed to define vocalic place. There is therefore no straightforward way to explain why plain consonants can affect vowels in this way.

(15) a. ??/ʤappɨ/ → [ʤappu] b. ??/jV-tlob/ → [ji-tlob]

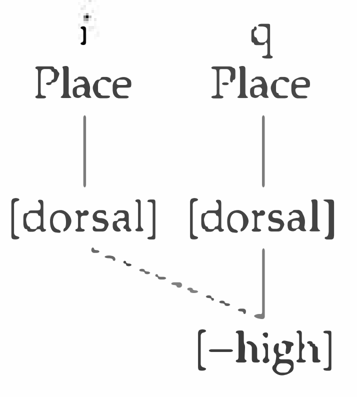


This problem of disjoint place features for consonants and vowels has been noted for some time. For example, before the advent of autosegmental phonology or feature geometry, Campbell (1974) and Clements (1976) had pointed out the

[12] Irrelevant detail will often be omitted in representations shown.
[13] Hume (1994) argues that the vowel's height is a default value and so doesn't need to be spread.

problem for the *SPE* feature theory of processes like those of Mapila Malayalam and Maltese, respectively. Campbell noted the lack of connection between the features [labial] and [round], and Clements did the same for [coronal] and [back]. By comparison, cross-category effects involving [dorsal] consonants make sense in the feature theory of *SPE*/Sagey (1986), because such consonants are specified for [high], [low], and [back]. For example, the vowel lowering of Inuktitut (see (8)) can be represented as in (16). The point holds equally if Inuktitut is better interpreted as [RTR] spread from a consonant. To put it differently, according to this theory assimilations by vowels to [dorsal] consonants are, in a sense, within-category effects: the influence of [dorsal] consonants is accomplished through vowel place features.

(16) /seʀmi-q/ → [seʀmɛ-q]



4 Unified feature theory

The idea that consonants and vowels should be specified by the same set of place features has been motivated by researchers in diverse frameworks, including Schane (1984, 1987), Kaye *et al.* (1985), Anderson and Ewen (1987), Selkirk (1988, 1993), van der Hulst (1989), and Clements (1991). Selkirk and Clements cast the idea roughly in terms of the features of Sagey (1986), as shown in Table 75.2.[14] Following McCarthy (1994), a feature [pharyngeal] is now included. McCarthy argues that uvular, pharyngeal and, for at least some languages, laryngeal consonants have in common a [pharyngeal] specification.

Table 75.2 Unified place features for consonants and vowels (Clements 1991)

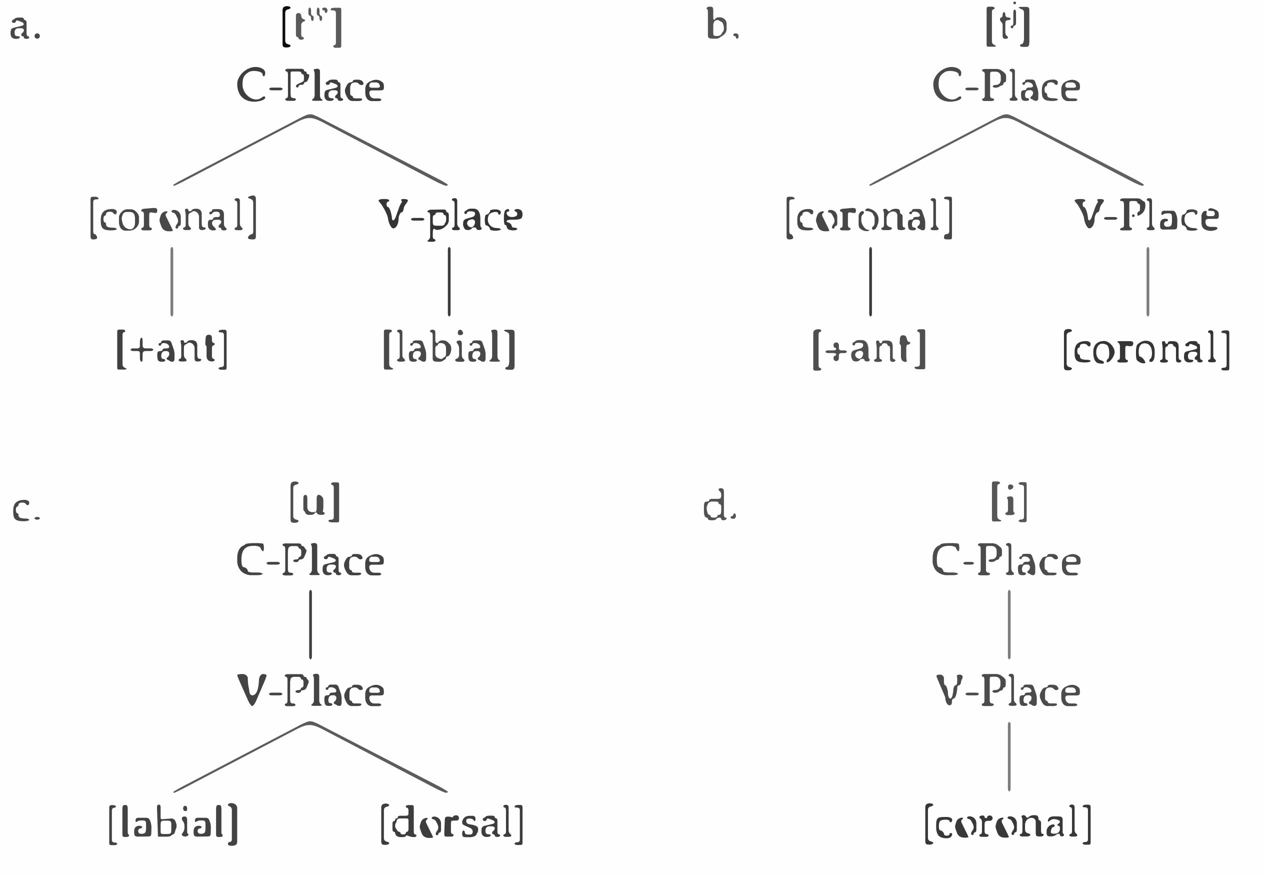
		p	pʲ	pʷ	t̪	t̪ʲ	t̪ʷ	k	kʲ	kʷ	ħ	i	y	a	o	u
C-Place	[labial]	✓	✓	✓												
	[coronal]				✓	✓	✓									
	[dorsal]							✓	✓	✓						
	[pharyngeal]										✓					
V-Place	[labial]			✓			✓			✓			✓		✓	✓
	[coronal]		✓			✓			✓			✓	✓			
	[dorsal]													✓	✓	✓
	[pharyngeal]													✓		

[14] However, Clements treats these features as binary valued. The features [anterior] and [distributed] are not shown here.

The unified feature approach capitalizes on the apparent articulatory parallelism between consonants and vowels: both labial consonants and round vowels involve a constriction at the lips; both coronal consonants and front vowels involve a constriction at the tip/blade/front of the tongue; both dorsal consonants and back vowels involve a constriction at the tongue dorsum; and both pharyngeal consonants and low vowels involve a constriction between the tongue root and the pharynx wall. (The parallelism in the case of [coronal] is the most questionable, as we will see later.) For Clements (1991) and others working within this framework (including Herzallah 1990; Hume 1990, 1994), the consonant–vowel parallelism does not extend to vowel height (or stricture features in consonants). Distinct features are still needed for these properties of segments. This means that the unified feature approach obviates the vowel color features [back] and [round], but not [high] and [low].

Of course, vocalic rounding is not articulatorily identical to the labial constriction of a consonant; likewise for the other parallel features. For these unified features to be phonetically interpreted we require reference to a segment's manner features. For example, if a sound is specified as [−consonantal] then [labial] is interpreted as lip rounding. Alternatively, the relevant information is read off feature-geometric structure. Thus Herzallah (1990), Clements (1991), Hume (1994, 1996), and Clements and Hume (1995) locate [labial], [coronal], [dorsal], and [pharyngeal] under separate C-Place and V-Place nodes, depending on whether a consonantal or vocalic constriction is intended. In these terms, the segments seen above in (13) are now rendered as in (17). Segment (17a) is interpreted as [t^w] because [labial] is a V-Place feature while [coronal] is a C-Place feature; and so on for the other representations.[15]

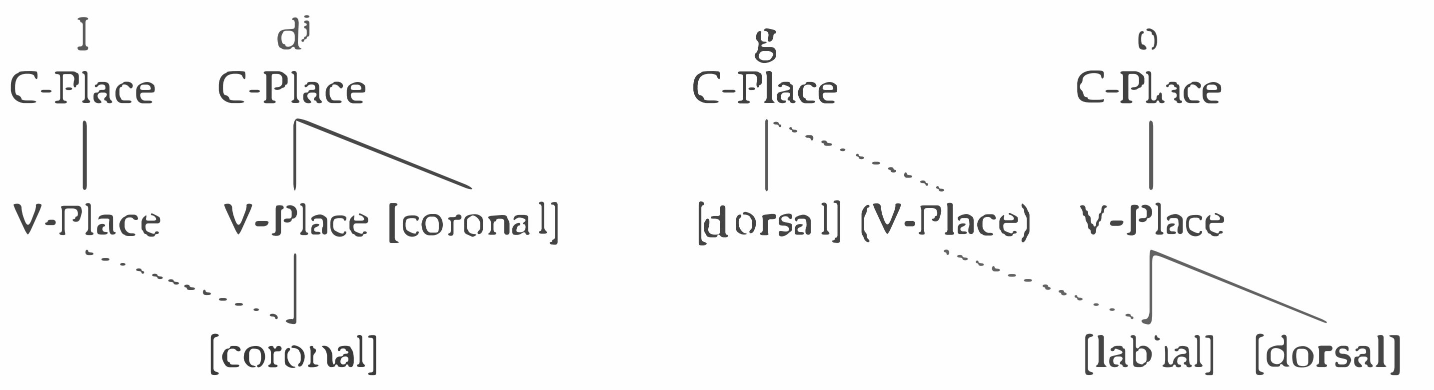
(17)



[15] These representations simplify the full geometry assumed by the references cited, to focus on what is crucial here. There are reasons for assuming that V-Place is a dependent of C-Place (or "Place" according to some), instead of a sister, for example, but a consideration of these would take us too far afield. See Clements (1991), Odden (1991), and Ní Chiosáin (1994) for discussion of this issue and for motivation of V-Place as a feature-geometric constituent.

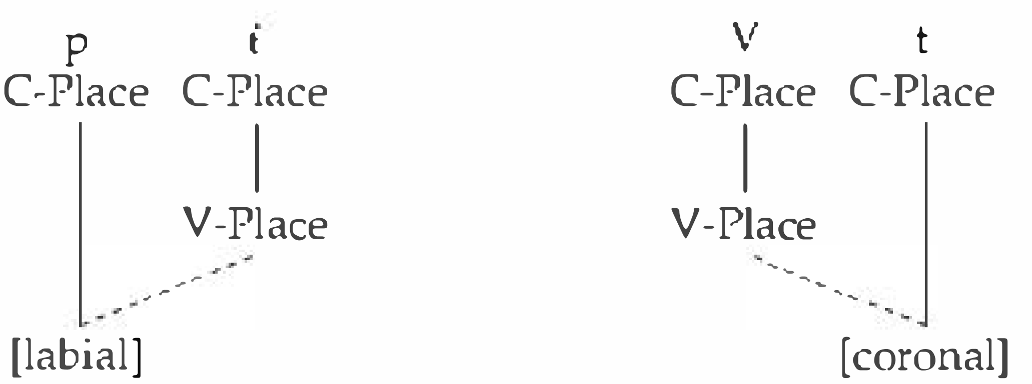
Naturally, it remains true in this theory that vowel place features and secondary vocalic articulation features on consonants are the same. Therefore it remains straightforward to characterize within-category assimilations as seen in (14) above, now understood as in (18). Cases such as Inuktitut (see (8)) are also arguably within-category, as noted above.

(18) a. /ɪnˠɪdʲ/ → [ɪnˠɨdʲ]   b. /ego/ → [egʷo]



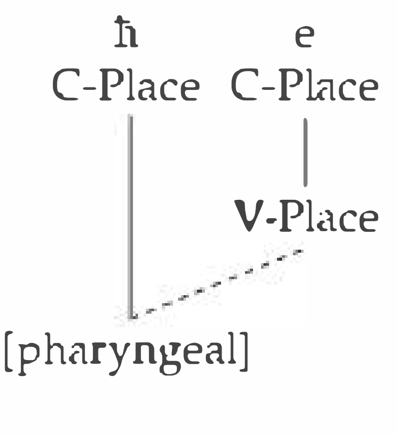
What is new with unified features is the possibility of directly capturing cross-category assimilations too. Compare the representations in (19) to the problematic (15) above. In (19a) (Mapila Malayalam), [labial] spreads from a consonant to a vowel. Notice that [labial] is linked to C-Place for the consonant and to V-Place for the vowel. It is therefore interpreted as consonantal lip constriction for the consonant and as rounding for the vowel. Similar reasoning holds for (19b) (Maltese; see Hume 1994, 1996). Cases of backing around dorsal consonants, as in Maxakalí (see (9)), similarly involve the spreading of [dorsal] from consonant to vowel.

(19) a. /ʤappɨ/ → [ʤappu]   b. /jV-tlob/ → [ji-tlob]



Finally, cases in which a vowel becomes [a] around a guttural consonant, as in Syrian Arabic (see (10)), are analyzed as the spreading of [pharyngeal] (Herzallah 1990; McCarthy 1994; Rose 1996), as shown below.

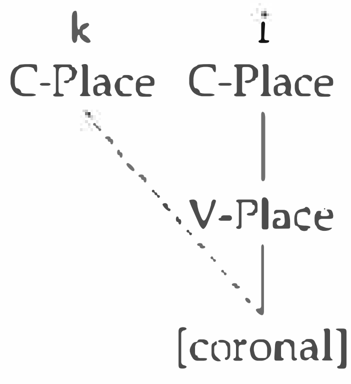
(20) /mniːħ-e/ → [mniːħ-a]



In short, unified feature theory solves the problem of cross-category interactions by eliminating the disjointedness of consonantal and vowel place features.

If features can spread from C-Place to V-Place, as in (19) and (20), then we might expect that the reverse can happen. This is just what is proposed for palatalizing mutations of the sort seen in Slovak, where /k g x ɣ/ become /ʧ ʤ ʃ ʒ/ respectively before any of /j i e æ/ (see (11)). Since front vowels are characterized as [coronal] instead of [−back] in the unified theory, this kind of mutation can be viewed as assimilation, specifically "coronalization" (Broselow and Niyondagara 1989; Mester and Itô 1989; Pulleyblank 1989; Lahiri and Evers 1991; Hume 1996):

(21) /vnuk/ → [vnuʧik]



The outputs of the Slovak rule are not simply [coronal]; they are fricated or affricated palato-alveolars. Hume (1994, 1996) reasonably assumes that front vowels are [−anterior] coronals. This entails that "coronalization" will output [−anterior] coronals too. The rest must follow from redundancy rules like [−anterior] → [+delayed release].

As noted above, this approach to unified features does not attempt to unify features for vowel height and consonantal stricture. This means that, when such features are affected by cross-category assimilation, it must be for independent reasons. For example, Hume (1994, 1996) argues that the front vowel derived in Maltese is [+high] [i] because this is the default height for vowels in the language.

On the other hand, since [+low] is not a likely default height in Arabic, Herzallah (1990: 185) assumes that [pharyngeal] spreading as in (20) leads to a low vowel because of a redundancy rule [pharyngeal] → [+low].[16] Since gutturals seem to cause assimilation to [a] typically, this redundancy rule will be needed for other cases too. This might be seen to somewhat undermine the argument of unified feature theory. The point of unified features is to capture the assimilatory nature of cross-category effects. The lowering that occurs around gutturals seems just as assimilatory as the spreading of the pharyngeal constriction, so why treat it differently? The case of Maxakali (see (9)) also supports the view that consonants can affect vowel height as well as vowel color. Recall that the inserted vowel in that language is [ə] before alveolars; Clements (1991) suggests that this is the default inserted vowel. But before velars the inserted vowel is both back and high, [ɯ]. A redundancy rule [dorsal] → [+high] might work, but, side-by-side with [pharyngeal] → [+low], it begs the question why we do not allow that consonants directly affect height as well as color.

This question aside, unified features have a clear appeal. They explain cross-category effects, because they assume that coronal consonants and front vowels form a natural class, as do labial consonants and round vowels, etc. Apart from

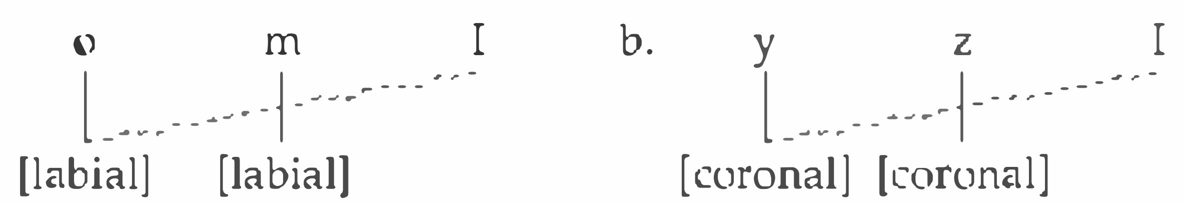
[16] Herzallah discusses Palestinian Arabic in this context. She also employs the vowel aperture features of Clements (1991), rather than [high] and [low].

assimilations and dissimilations like those already seen, more evidence for such natural classes comes from instances of vowel strengthening or consonantal weakening. For example, when the vowel [i] and glide [j] are strengthened to consonants, they are strengthened to coronal consonants, or at least consonants with a coronal component – palatals or palato-alveolars. This occurs in Porteño Spanish when the (semi-)vowel is in onset position, as in /jelo/ (or /ielo/) → [ʒelo] 'ice' (see Harris and Kaisse 1999 and references therein). A relevant example of weakening comes from Irish lenition (CHAPTER 66: LENITION), whereby /b m/ are reduced to [w] (see Ní Chiosáin 1991). If front vowels and palato-alveolars are both [coronal], and if labial consonants and [w] are both [labial], then these processes can be understood as the "promotion" or "demotion" of those features in the C-Place/V-Place representation. As with the assimilations, however, such accounts will often need the help of redundancy rules.

5 Non-interaction and locality

Our discussion of C–V interactions has so far ignored an important issue. There are ways in which consonants and vowels apparently *fail* to interact, and our theory needs to explain these too. Perhaps the most basic question arises from the simple observation that consonants typically seem to be transparent to vowel harmonies and other kinds of vowel-to-vowel place assimilations (CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY). In Turkish, for example, vowels harmonize for roundness as well as backness (Lees 1961; Clements and Sezer 1982). Most consonants are transparent to the harmony.[17] Particularly relevant to the discussion here, labial consonants are transparent to round harmony, as in [somun] 'loaf', and coronal consonants are transparent to backness harmony, as in [økyz] 'ox'.[18] The issue raised by such cases is schematized in (22).

(22) a. b.



Unification of place features for consonants and vowels is motivated by the cross-category interactions we have seen so far. However, the ability to *block* spreading is also a kind of interaction (if a passive one), and the principles of autosegmental phonology imply that spreading as in (22) *should* be blocked. A similar implication arises for vocalic [dorsal] spreading through dorsal consonants (not shown). These representations cross lines, a maneuver ruled out within autosegmental phonology for features on the same tier.[19]

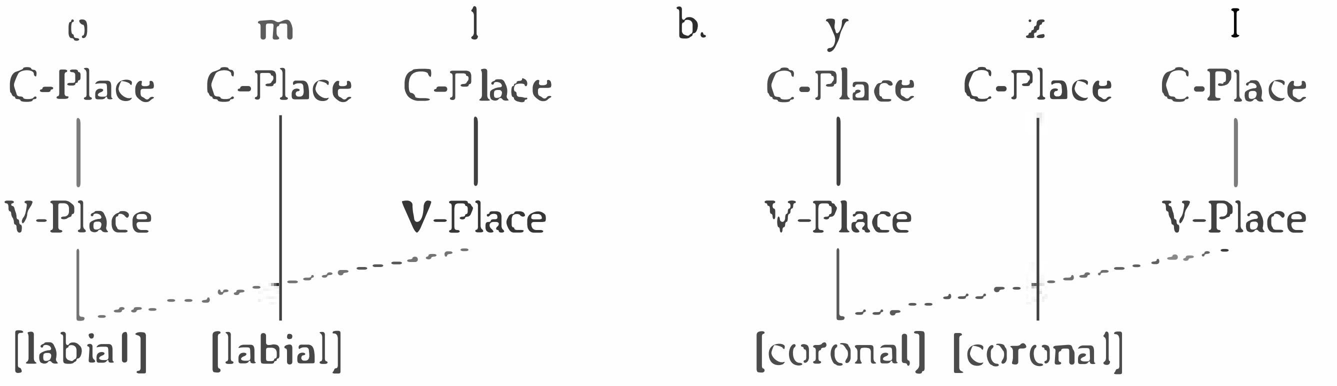
[17] The exceptions are palatalized consonants in certain limited circumstances. Since palatalization is a V-Place specification, this blocking is *within*-category. Blocking in such cases is the rule across languages, in contrast to the situation with plain consonants.

[18] These examples involve harmony in the root, but the observation about transparency holds equally for harmony between a stem and a suffix.

[19] See Hammond (1988), Sagey (1988), Bird and Klein (1990), Coleman (1991), Scobbie (1991), and Archangeli and Pulleyblank (1994) on deducing the ill-formedness of line crossing within the theory.

As we have seen, Clements (1991), Clements and Hume (1995), and others working within this unified features framework locate vocalic and consonantal place features under distinct nodes in feature geometry, V-Place and C-Place respectively. The full representations for the scenarios in (22) (modulo some irrelevant simplifications) are shown in (23) below. In feature geometry, a *plane* on which association lines spread is defined by adjacent tiers. Therefore, the plane defined by the [labial] tier and the C-Place tier in (23a) is different from that defined by the [labial] tier and the V-Place tier. Clements (1991) and Clements and Hume (1995) suggest that, even when the same feature such as [labial] is involved in the spreading, line crossing is prohibited only *within a plane*. Therefore spreading, as in (23a) and (23b), is allowed. (Put differently, apparent line-crossing is only a problem when the crossed lines link to the same mother node in the geometry.)

(23) a. b.



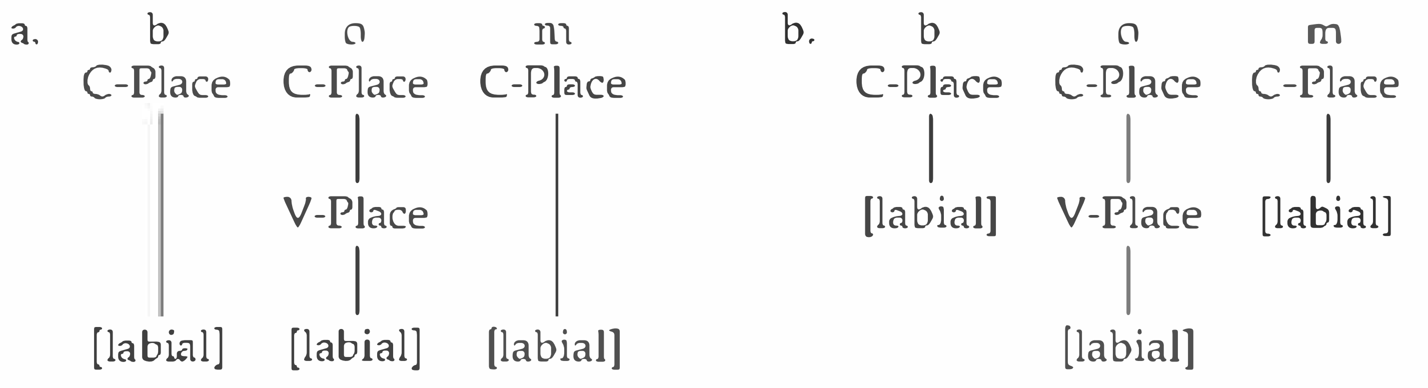
This suggestion raises questions about the formal understanding of tiers and planes that have not been fully explored. In any case, the worry about non-interaction of C-Place and V-Place features goes beyond this kind of spreading. For example, many languages place restrictions on homorganic consonants occurring within forms (CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS). In autosegmental phonology these have been explained by means of the Obligatory Contour Principle, which prohibits tier-adjacent identical feature specifications (see for example McCarthy 1986; Mester 1986; Yip 1989; Frisch *et al.* 2004 and references therein) (see also CHAPTER 14: AUTOSEGMENTS). Such restrictions can apply to consonants separated by vowels, and, crucially, do not seem to be blocked even by vowels of the "same" place of articulation; that is, forms such as [bom] are as ill-formed as [bam].[20] But given unified features, the consonants' [labial] features in (24a) are not tier-adjacent, since the vowel's [labial] intervenes. Why should this form be dispreferred? (The answer is *not* because sequences such as [bo] or [om] themselves are ruled out; they are not in most languages having this kind of dissimilation.) Analogous issues arise with front vowels and coronal consonants, etc., and the same general issue arises in reverse when vowels dissimilate across all consonants, as in Ainu (Itô 1984).[21] To deal with this question, Clements (1991) suggests that instances of a feature are not on the same tier when they are dominated by different mother nodes, and in fact to highlight this point he

[20] One exception is Akkadian (McCarthy 1979; Yip 1988; Hume 1994; Odden 1994). A prefix /m/ dissimilates to [n], given another labial consonant in the stem. The sounds [u w] do not trigger dissimilation, but they *do* block it.

[21] There are other theoretical approaches to dissimilation that do not appeal to tier-adjacency, including the idea of local self-conjunction advocated by Itô and Mester (1996) and Alderete (1997). Such approaches might avoid the question raised by (24).

draws representations as in (24b).[22] Hume (1994, 1996) and Clements and Hume (1995) frame a similar idea differently: there is one [labial] tier, as in (24a), but two instances of a feature can fail to interact when they are dominated by different mother nodes. Therefore the [labial] features dominated by C-Place may interact with each other and may each fail to interact with the intervening [labial].

(24)



Obviously there should be concern at this point about losing the gains made with unified features. If C-Place and V-Place features are on different tiers, or if they can fail to interact because C-Place and V-Place are different mother nodes, then why do C-Place and V-Place features *ever* interact? Selkirk (1988, 1993) considers many of the same issues, and makes the important observation that cross-category dissimilations and co-occurrence restrictions seem to hold only under segmental adjacency.[23] Both Selkirk and Clements suggest that this observation be elevated to a principle. A similar, though more general, observation was made at the end of §2 above: cross-category dissimilations *and* assimilations, unlike within-category cases, are always highly local.

To summarize: according to a unified features view of C–V interactions, consonant and vowel place features are unified, and so can interact. But cross-category interaction seems limited to (near-)segmental adjacency, and a unified feature theory must address this limitation by separate stipulation (e.g. interaction can happen across tiers/with different mother nodes only under (near-)segmental adjacency). If the empirical observations here are on the right track, one might still raise questions about the account. In particular, the very motivation for unified features seems weakened by the need to stipulate *non-interaction* except under close adjacency. In addition, the latter stipulation does not follow from anything else in the theory; cross-category effects are limited in a way not really explained.

6 Inherent vowel place specifications

An alternative approach to cross-category C–V interactions, also couched within feature geometry theory, is proposed by Ní Chiosáin and Padgett (1993) and Flemming (1995, 2003): perhaps "plain" consonants are not as plain as they are assumed to be.

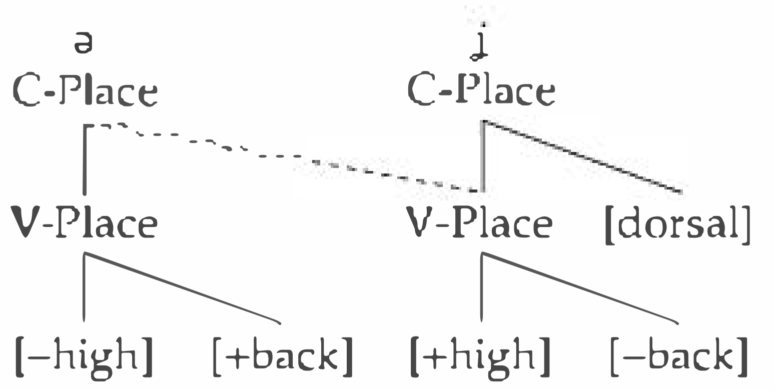
[22] This redefinition of the notion "tier" may render unnecessary the reference to planes in (23). If consonantal and vocalic [labial] are on different tiers, then there is by definition no line crossing (in the relevant sense) in such cases.

[23] Selkirk's notion of "cross-category" is actually more abstract than that employed here. Her notion makes some different empirical predictions.

To begin with, many consonants have been claimed to be complex segments, specified for both consonantal and vowel place features, even though they are "plain" in the sense of lacking secondary articulations that are transcribed. For example, there is a long-standing view that palatals, alveolo-palatals, and at least certain palato-alveolars are inherently specified for features indicating a high and front tongue body, and studies of their articulatory properties support this view (see Keating 1988, 1991; Keating and Lahiri 1993). This fact also explains why these segments are the most common outputs of palatalizing mutations of velars and coronals, assuming these mutations involve assimilation. Similarly, uvulars and pharyngeals may involve inherent specifications for vocalic tongue body and/or root position. In this view, they cause lowering or retraction of vowels because they are themselves specified for a feature like [−high] or [RTR] (see Chomsky and Halle 1968; and more recently Elorrieta 1991; Halle 1995; Rose 1996). If these consonants involve inherent vowel place specifications – in addition to independent consonantal specifiications – then effects such as the lowering or retraction of vowels before uvulars in Inuktitut, or the raising and fronting of vowels before palatals and palato-alveolars in Kabardian, e.g. /ʒəʝ/ → [ʒɪʝ] 'tree' and /ʒaʃ/ → [ʒɛʃ] '(to) be bored, tired' (Colarusso 1992: 30), are not cross-category assimilations at all.

For example, the raising and fronting seen in Kabardian might be understood as in (25). For the sake of discussion, we revert to the familiar vowel place features of *SPE*, but following the literature on V-Place constituency (see note 15) continue to assume this aspect of the geometry. The palatal fricative [ʝ] is assumed to have (at least) a primary [dorsal] specification. The point is that what spreads in this case are features of tongue body height and frontness that are uncontroversially relevant to vowels; in effect, palatals (and palato-alveolars in Kabardian) are understood as inherently palatalized segments.

(25) /ʒəʝ/ → [ʒɪʝ]



The question raised by work such as Ní Chiosáin and Padgett (1993) and Flemming (1995, 2003) is to what extent features relevant to vowel place might inhere within other "plain" consonants. If all cross-category C–V interactions were caused by such inherent features, then "cross-category," though a useful classificatory term, would lose any theoretical import: all C–V interactions would be within-category.

Ní Chiosáin and Padgett (1993) approach the phonetic claim from an articulatory point of view, following the general articulatory approach to features in the *SPE* tradition. They note that consonantal constrictions involve offsets and onsets, i.e. movement from a previous position into the consonant, and movement from the consonant into a following position. The idea is diagrammed as in (26), for a labial consonant in an intervocalic context such as [ɨbɨ]. During the onset transition there is a short period of time when the constriction is not yet consonantal, and yet this vocalic period is shaped by the impending consonant. Likewise, early in the release the constriction becomes vocalic while still shaped by the preceding consonant. As the diagram implies, this must have effects on the quality of the vowel near the closure.

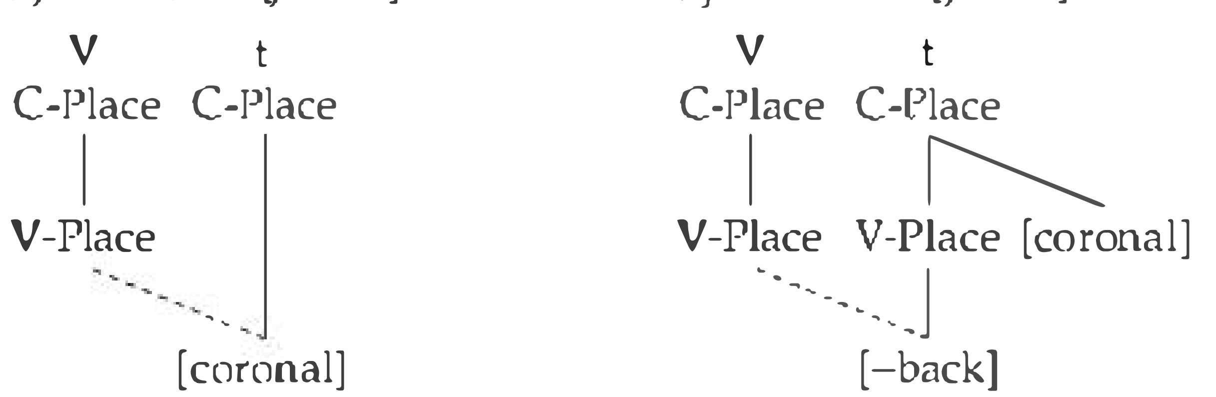
(26) *Stages of consonant production*

ɨ " b " ɨ
vowel onset closure offset vowel
→→→→→→→→→→→

Flemming (1995) emphasizes these acoustic or auditory effects of the transitions into and out of consonants, and in fact argues for the incorporation of auditory-based features into phonological theory. It is well known that consonantal offsets and onsets influence vowel formants; in fact, the resulting dynamic formant transitions are an important cue to both vocalic and consonantal place. Flemming notes that labial consonants, for example, lower vocalic F2 (second formant) values, while dental and alveolar coronals raise F2.[24] Since vowel place (particularly vowel color) is cued by the location of F2, consonants therefore have the inherent ability to affect perception of vowel place.

Flemming (2003) discusses the articulatory basis of the acoustic effects in more detail, focusing on coronal consonants. According to his survey of relevant studies, anterior coronals and palato-alveolars tend to cause tongue body fronting, due to coupling between the tongue blade/tip and the tongue body, and this is the reason for the rise in F2 around such consonants. With this in mind consider once again the fronting of vowels by coronal consonants, as in Maltese Arabic (see (7)). The idea is that fronting happens not because the consonant spreads its primary [coronal] articulation as in (27a), but because the consonant has some inherent tongue fronting, with a concomitant effect on F2, and this is what spreads to the vowel, (27b). For the sake of discussion this is formalized in terms of the traditional feature [back].

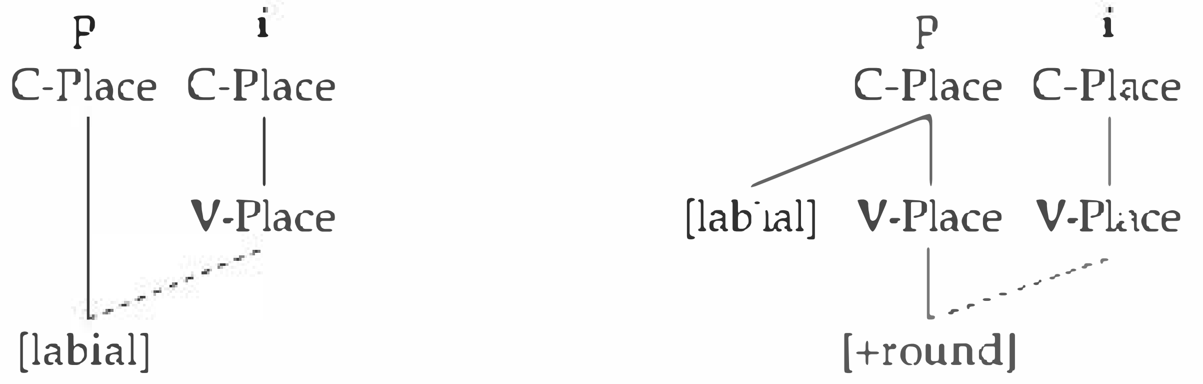
(27) a. /jV-tlob/ → [ji-tlob] b. /jV-tlob / → [ji-tlob]



Similarly Mapila Malayalam (see (6)) involves not spreading of primary [labial] as in (28a) but spreading of the inherent vocalic labial constriction, and lowering of F2, formalized here by means of [+round], (28b).

[24] Discussion of vowel formants and of formant transitions can be found in e.g. Stevens (1998) and Johnson (2003). Another advocate of auditory features in phonology is Boersma (e.g. 1998).

(28) a. /dʒappi/ → [dʒappu] b. /dʒappi/ → [dʒappu]



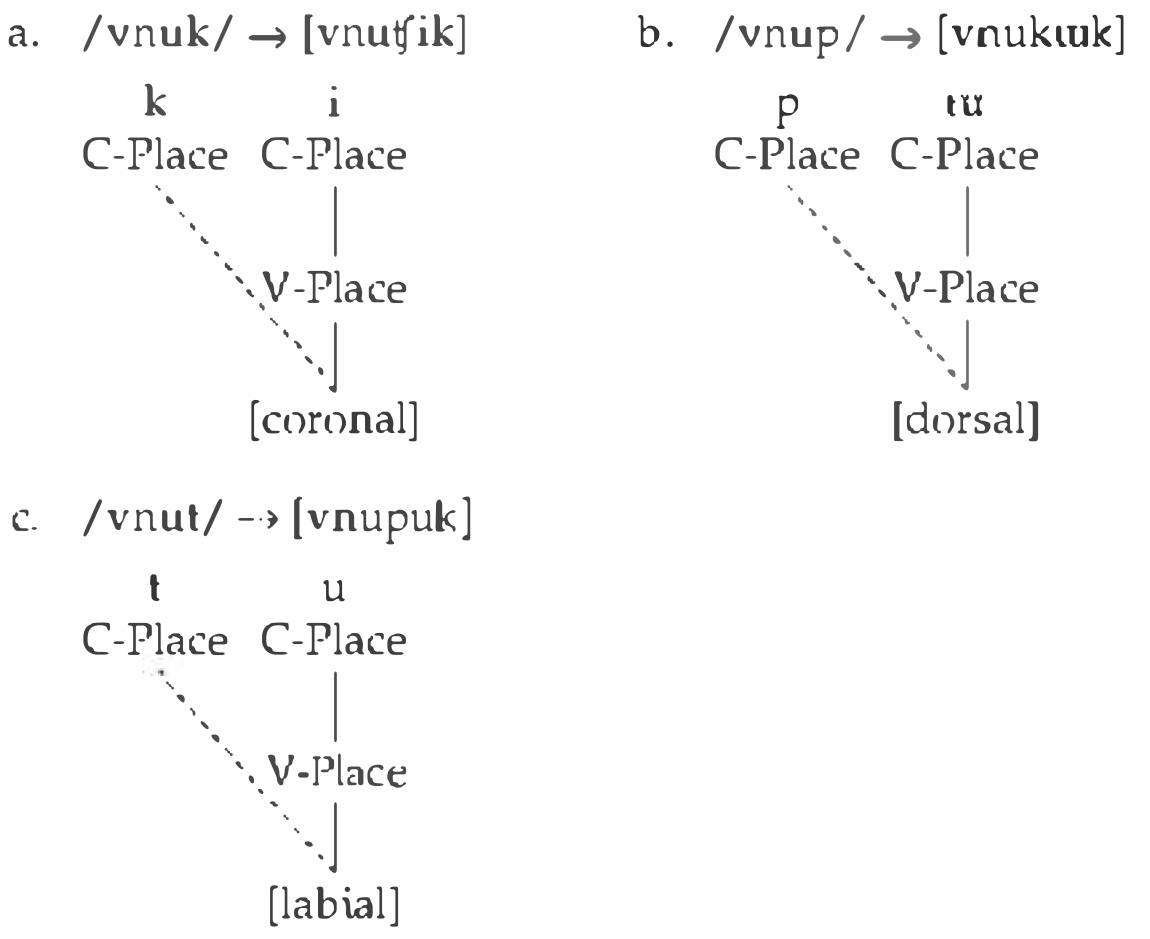
In an analogous fashion, velars can spread inherent [+back] and/or [+high] in cases like Maxakalí (see (9)), and gutturals can spread inherent [+low] in cases like Syrian Arabic (see (10)).

It is uncontroversial that consonants phonetically affect vowels both articulatorily and acoustically, as this approach to "cross-category" interactions assumes. However, incorporating these relatively small phonetic effects into phonology raises questions. One question is prompted by our use of the conventional vowel place features [back], [round], etc. in the account above. How are we justified in specifying the Maltese [t] as [−back] if it isn't palatalized [tʲ], or the Malayalam [p] as [+round] if it isn't rounded [pʷ]? The answer suggested by Ní Chiosáin and Padgett (1993) is that such specifications are realized as bona fide secondary articulations when they are contrastive, but not when they are redundant. In a language such as Russian, where palatalized coronals contrast with non-palatalized ones, [−back] on [t] is realized as [tʲ]; in a language without this contrast, redundant [−back] is realized as [tʲ] (notation borrowed from Ní Chiosáin and Padgett 2001; Flemming 2003), a coronal with only the inherent tongue body fronting described above. This answer to the question predicts that non-palatalized coronals in Russian could not be [−back] even inherently, since this specification is reserved for palatalization. This prediction is correct; in fact, non-palatalized sounds in Russian are velarized, i.e. [tˠ].

The inherent vowel place approach to "cross-category" effects arguably has some advantages over the unified feature approach. First, it helps explain an asymmetry in cross-category assimilations noted in §2: while vowel-to-consonant assimilation occurs, apparent consonant-to-vowel assimilations are strikingly underattested (Ní Chiosáin and Padgett 1993). The most robust example of the latter, as we saw, involves palatalizing mutations as in Slovak, where /k g x ɣ/ become [tʃ dʒ ʃ ʒ], respectively, before any of [j i e æ]. Within a unified features approach, some have argued that these are instances of "coronalization" (Broselow and Niyondagara 1989; Mester and Itô 1989; Pulleyblank 1989; Lahiri and Evers 1991; Hume 1996), as in (29a). A challenge for this claim is the absence of mutations resembling those in (29b) and (29c), or indeed resembling most of the logically possible consonant-to-vowel assimilations, if place features can link to both V-Place and C-Place.[25]

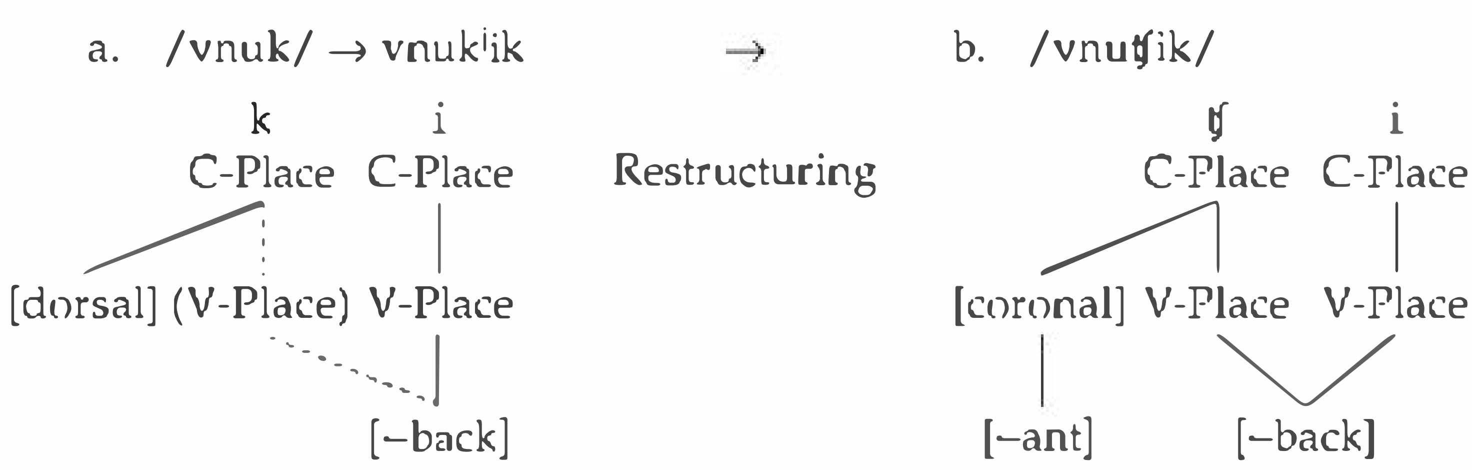
[25] Ní Chiosáin and Padgett (1993) dismiss some claimed cases that are attested as sound changes but have no synchronic reflex. See that work for discussion of other apparent counterexamples.

(29)



Ní Chiosáin and Padgett (1993) argue that consonants simply do not assimilate to vowels in this way, having their primary place displaced, and that the theory should not allow them to. There is a natural explanation within inherent vowel place theory for this asymmetry in the direction of "cross-category" assimilations: consonants can affect vowels because they can have secondary vocalic articulations (whether distinctive or redundant). But vowels by definition do not have C-Place features with which to affect a consonant; they only have V-Place features, features that can only impose secondary vocalic articulations on consonants. Put differently, *all* C–V interactions are interactions between vowel place features. To handle palatalizing mutations, Ní Chiosáin and Padgett, following many others, assume that assimilation only partially derives the output, as in (30a). Further changes from /k^j/ to e.g. [ʧ] must be due to language-particular segmental well-formedness conditions, leading to something like (30b).[26]

(30)



As Clements and Hume (1995: 295–296; see also references therein) point out, however, such restructuring fails to explain why [coronal] in particular results in the context of a front vowel, just the fact that unified feature theory

[26] Though expressed as a rule here, in line with all of this discussion, the idea is commonly expressed in Optimality Theory by means of constraint rankings such as *k^j >> ʧ. This ranking, along with a high-ranking constraint driving [–back] assimilation, will lead to the output [ʧ].

explains. On the other hand, one might seek perceptual explanations for such arbitrary articulatory connections, by means of auditory-based features (see Flemming 1995 for this case in particular), or perhaps via the "p-map" (Steriade 2001).

Another advantage to the inherent vowel place approach is that it allows for more nuance in the ways that consonants can affect vowels (Flemming 1995, 2003). For example, Flemming (2003) (citing Emeneau 1970; Ebert 1996) notes that vowels are backed before retroflex coronals in the Dravidian language Koḍagu. Therefore there are words having central or back rounded vowels before retroflex consonants, as in (31a) and (31b), respectively, but there are no forms with front vowels before them, such as (31c).

(31)	a.	ɯɖi	'the whole'	b.	uɖɯ-	'to put on (sari)'	c.	*iɖ
		kɯːɭɯ	'lower, below'		kuːɭɯ	'cooked rice'		*iːɭ
		ɤɳe	'double'		oɳak-	'to dry'		*eɳ
		kɤːɖɯ	'ruin'		koːɖɤ	'monkey'		*eːɖ

Flemming cites studies showing that retroflexes can be articulated with a retracted tongue body. Unlike other coronals, they tend not to be articulated with a *fronted* tongue body, because this leads to articulatory difficulty. As Flemming points out, unified feature theory predicts that even retroflex coronals should cause vowel fronting, if fronting is [coronal] spreading. But this does not occur.

Third, because it posits that all C–V interactions are within-category, by means of vowel place features, inherent vowel place theory does not require any adjustment of our understanding of tiers or interaction. Vowels do not block consonantal place dissimilations, because they do not have consonant place features. Consonants block vowel dissimilations or assimilations only when they *do* have vowel place specifications.

What about the "weakness" of "cross-category" effects? As we noted at the end of §2, they are weaker than "within-category" effects by a range of diagnostics. Why are they comparatively infrequent? Why are they confined to roughly segmental adjacency? Why do "within-category" effects always win out over "cross-category" ones when both are in theory possible (*/p^ji/ → [p^ju])? Why do "cross-category" effects often seem to target only "underspecified" vowel types? Why do they sometimes need to "gang up" to cause effects?

We might attribute these signs of weakness to the intrinsic weakness of inherent vowel place features. As discussed at the outset of this section, the effects that "plain" consonants have on neighboring vowels are rather brief and slight. The hypothesis here has been that such effects can play a direct role in the phonology. However, feature theory, at least as traditionally conceived, provides no means of encoding this hypothesized difference between, e.g. "strong" (contrastive) and "weak" (inherent, redundant) [+round]. Until this idea is fleshed out, it is only a promissory note of the inherent vowel place approach.

Another weakness of the inherent vowel place approach to C–V interactions is that it has no immediate explanation for the natural classes of consonants and vowels evidenced by vowel strengthenings, as in Porteño Spanish /jelo/ (or /ielo/) → [ʒelo] 'ice', and consonant lenitions, as in Irish /b m/ → [w] (see §4). For processes like these, the unified feature approach has a clear advantage.

7 Conclusion

Consonant–vowel interactions are a rich source of data for phonological theory. This chapter has focused on the ways in which they have influenced the theory of feature make-up and structure, and for reasons of space it has approached even this circumscribed area selectively. Though much of the field has shifted its focus away from these representational questions in recent years, with a concomitant rise in the focus on questions of constraint interaction, this shift has not tended to shed new light on the questions raised in this chapter. It is to be hoped that new trends in the field will eventually allow us to address these questions in a newly productive way.

88 Derived Environment Effects

Luigi Burzio

1 Introduction

Derived environments often exhibit peculiar phonological properties. Notable effects can be identified relative to various senses of "derived" in the expression "derived environment" (DE). In all cases, "environment" refers to some phonological context. Such environment or context can be "derived" in a phonological sense, by virtue of some phonological process having applied to obtain it or, in a morphological sense, by virtue of it being the result of the combination of morphemes or other morphological operation. The following sections will first review the different cases from a descriptive point of view, and then turn to their respective theoretical accounts. §2 and §3 review the basic facts, arguing that there are three subcases overall. §4 turns to contemporary analyses of the two better-known subcases, while §5 reviews pre-Optimality Theory accounts of the same. §6 presents an account of the third subcase.

2 Phonologically derived environments

Environments that are derived by some phonological process can differ from underived environments relative to further phonological processes. An English example of this effect is provided by the following contrasting pair.[1]

(1)

	verb	-able *adjective*
a.	*'remedy*	*re'meːdiable*
b.	*'levy*	*'leviable*

In (1) we assume that in both cases the calculation of the adjective proceeds from the surface form of the verb concatenated with the suffix *-able*. Such calculation

[1] The symbol "ː" is used here and elsewhere in orthographic forms to refer to a long vowel. Stress is also marked in such forms. In (1) the vowel is diphthongized in accordance with the Early Modern English Great Vowel Shift, here the diphthong [ij].

would find a stage in which the position of the stress is changed in (1a) (*'remedy* → *re'medi* . . .), but not in (1b). This phonologically *derived* status of (1a) correlates with the occurrence of vowel lengthening in the adjective in (1a), compared with its absence in (1b). It is clear that it is the restressing that licenses vowel lengthening and not the opposite, because the restressing is independently predictable. Specifically, the stress of both adjectives in (1) simply conforms with the English norm, by which the rightmost stress can be at most antepenultimate, but a syllable like *ble* (= [bḷ], with syllabic *l*) can evade syllable count (Burzio 1994), hence *re.'me.di.a<ble>*, *'le.vi.a<ble>*. The lengthening of (1a) reflects a process of English phonology, which is relatively regular aside from its non-occurrence in cases like (1b), affecting vowels in the context / __ CiV (cf. *Bost*[ow]*nian*, *Can*[ej]*dian*, etc.) except for the vowel *i*, which is immune, e.g. *Palestinian* (see Chomsky and Halle 1968: 47; Halle and Mohanan 1985). Non-restressing cases like (1b) confirming the generalization are *'bury/'burial*, not **b*[ij]*rial*; *Ma'lawi/ Ma'lawian*, not **Mal*[ej]*wian*; *Ken'tucky/Ken'tuckian*, not **Kent*[uw]*ckian*, although exceptions – which I will put aside – exist both ways (Wolf 2008: 302), e.g. restressing but short *Trini'dadian*, *I'talian*, *Chau'cerian*, *He'gelian*, and non-restressing but long *Alab*[ej]*mian*, *Bah*[ej]*mian*.

In addition, both adjectives in (1) constitute environments that are *derived* morphologically, by way of affixation. The latter is evidently not relevant to the phenomenon at hand, else no difference between (1a) and (1b) would be expected. Finally, note as well that characterization of the difference between (1a) and (1b) would not be possible unless it was indeed the *surface* form of the verb that enters into the calculation of the adjective. Direct calculations from bare-bone underlying representations (CHAPTER 1: UNDERLYING REPRESENTATIONS) containing no stress information would predict no difference, since there would then be no *restressing* in either case, just regular assignment of stress. In sum, assuming the surface forms of the verbs are relevant in (1), then the adjective in (1a) would undergo phonological restressing unlike the one in (1b), and thus the latter would represent a case of phonologically *non-derived environment blocking* (henceforth NDEB) relative to the process of CiV lengthening.

The literature documents several other cases of this general type across a significant spectrum of languages. Łubowicz (1999, 2002) reports the cases in (2a) to (2d) below, to which we may add the Finnish case in (2e). The original sources for these data are Rubach (1984) for Polish; Kenstowicz and Rubach (1987) and Rubach (1993, 1995) for Slovak; Bolognesi (1998) for Campidanian Sardinian; Prince (1975) for Tiberian Hebrew; and Kiparsky (1973a, 1993) for Finnish.

(2)		*Processes*	*General process/ DE-only process*
a.	*Polish*		
	i. *kro*[k] / *kro*[ʧ]-*ek* 'step / little step'	k → ʧ	Velar palatalization
	ii. *dron*[g] / *dron*[ʒ]-*ek* 'pole / little pole'	g → ʤ → ʒ	Spirantization of voiced palatal affricates
	iii. *bri*[ʤ] / *bri*[ʤ]-*ek* 'bridge / little bridge'	ʤ → *ʒ (underived)	

b. *Slovak*

i.	*lop*[a]*t-a* / *lop*[a:]*t* 'shovel-NOM SG / GEN PL'	a → a:	Vowel lengthening
ii.	*kazet-a* / *kaz*[ie]*t* 'box-NOM SG / GEN PL'	e → e: → ie	Diphthongization of long [e:]
iii.	*dc*[e:]*ra* 'daughter'	e: → *ie (underived)	

c. *Campidanian Sardinian*

i.	[f]*amilia* / *sa* [v]*amilia* 'family / the family'	f → v	Post-vocalic voicing of obstruents
ii.	*pisci* / *belu* [β]*isci* 'fish / nice fish'	p → b → β	Post-vocalic spirantization
iii.	[b]*ia* / *sa* [b]*ia* 'road / the road'	b → *β (underived)	

d. *Tiberian Hebrew*

i.	ktab'tem / ka:'tab 'we-MASC write' / 'he writes'	a → a:	Pre-tonic, open syllable lengthening
ii.	ʃimi'ka: / ʃe:'m-ot 'your names / names'	i → i: → e:	High long V lowering
iii.	qi:'to:r 'smoke'	i: → *e: (underived)	

e. *Finnish assibilation*

i.	*joke-nä* / *joki* 'river-ESS / NOM'	e → i	*e*-raising, word-finally
ii.	*vete-nä* / *vesi* 'water-ESS / NOM'	te → ti → si	*t*-assibilation before *i*
iii.	*äiti-nä* / *äiti* 'mother-ESS / NOM'	ti → *si (underived)	

In each of the cases in (2), row (i) documents the existence of a process that occurs independently of whether or not the environment is phonologically derived, analogously to the restressing in (1a) above. Then, row (ii) documents the existence of a second process that occurs when the first process has applied, analogously to the CiV lengthening of (1a), while row (iii) further documents the fact that the second process does *not* apply unless the first one has (NDEB), analogously to the failed CiV lengthening of (1b) above. Hence, in Polish, voiced palatal affricates spirantize to fricatives only when they are derived from velar stops before front vowels (CHAPTER 121: SLAVIC PALATALIZATION); in Slovak, long /e:/ diphthongizes to [ie] only if derived via a lengthening process (induced by specific affixes); in the Sardinian case, voiced stops spirantize only when they are derived via post-vocalic voicing; in Tiberian Hebrew, high long vowels lower only when they are derived via a lengthening process; and in Finnish, *t* assibilates to *s* before *i*, but only when the latter is derived from *e*.

In sum, certain phonological changes appear to occur only in conjunction with other specific phonological changes, and not by themselves (NDEB).

3 Morphologically derived environments

Phonological processes may be conditioned not only by other phonological process, but by morphological processes or structure as well. Two subcases need to be distinguished, and are reviewed in turn below. In one subcase, the context of application of the phonological process spans across morphemes, as in *criti*[s]-*ism*, where the velar of *criti*[k] softens before the *i*, across a morpheme boundary. In the other subcase, the phonological process occurs in environments that are morphologically derived, but without reference to the specifics of the morphological structure. For instance, the nouns or adjectives *altern*[ə]*te*, *moder*[ə]*te*, *design*[ə]*te* are presumably derived from the corresponding verbs in *-ate*, but without any overt morphology. Hence the vowel shortening in these cases must depend purely on derived status, without reference to any particular morphological material or boundaries.

3.1 *Boundary contexts*

Kiparsky (1973a, 1993) notes that, in addition to the case in (2) above, Finnish assibilation also displays the pattern in (3).

(3)	a.	*halut-a*	'want-INF'	*halus-i*	'want-PAST'
	b.	*tilat-a*	'order-INF'	*tilas-i*	'order-PAST'
	c.	*äiti*	'mother'		

Here, assibilation turns *t* to *s* before *i*, but only when the latter belongs to a different morpheme, as in each of (3a) and (3b). In particular, the failed assibilation in *ti* of *tilas-i* (3b) shows that being in a morphologically derived form is not sufficient, and that it is necessary for the assibilation environment itself to be created morphologically. The non-assibilating form in (3c) establishes that assibilation does not just single out final syllables, confirming the relevance of the derived environment.

The already noted English *velar softening* (CHAPTER 71: PALATALIZATION), illustrated in (4), appears to be similarly restricted to morphologically derived environments.

(4)	a.	Derived	/k/ → [s]	*critic / critic-ism; electric / electric-ity; opaque / opac-ity*
	b.	Underived	[k]	*kinetic, kidney, kitchen, Viking, . . .*

I note here the item *kinematic-ity*, which constitutes a proper counterpart to Finnish *tilas-i* in (2e), velar softening affecting only the [k] adjacent to the morpheme boundary, and not the initial one. A complicating factor in this classification is that velar softening has exceptions, like *monarch-ist, anarch-ist*, and several others, raising the possibility that items like (4b) may in fact also just be lexical exceptions, rather than being indicative of NDEB. Hence in this case, as in others below, classification will be dependent on the choice of analyses. I will, nonetheless, assume that items like those in (4b) are *not* lexical exceptions, and therefore that the classification of velar softening as operating only across morpheme boundaries like Finnish assibilation is correct. In addition, and with the same caveats, I will assume that each of the phenomena in (5) below also instantiates that same type of NDEB, while the references cited in each case may be consulted for specific analyses.

(5) *Further cases of NDEB, for DEs including morpheme boundaries*

a. *Korean palatalization* (Kiparsky 1993; Iverson and Wheeler 1988)
/hæ tot-i/ → [hæ doj-i] '(sun)rise-NOM' /mati/ 'knot'

b. *Polish velar palatalization* (Łubowicz 2002; Rubach 1984)
/krok-i-ć/ → [krotʃ-i-ć] 'to step' /k'iśel/ 'jelly'

c. *Polish dental palatalization* (Kenstowicz 1994; Rubach 1984)
/serwis-e/ → [serwiś-e] 'auto service-LOC' /serwis/ (NOM)

d. *Pre-coronal laminalization in Chumash* (Kiparsky 1993; Poser 1982, 1993)
/s-tepuʔ/ → [ʃ-tepuʔ] 'he gambles' /stumukun/ 'mistletoe'

e. *Sanskrit (ruki rule) retroflection after r, u, k, i* (Kiparsky 1973a, 1993)
/agni-su/ → [agni-ṣu] 'fire-DAT PL' /kisalaja/ 'sprout'

f. *Indonesian nasal substitution* (Pater 1999)
/məN-pilih/ → [məm-ilih] 'to choose' /əmpat/ 'four'

g. *Finnish cluster assimilation* (Kiparsky 1973a)
/pur-nut/ → [purrut] 'bitten' /horna/ 'hell'

h. *Mohawk epenthesis* (Kiparsky 1973a)
/k-wi'stos/ → [kewi'stos] 'I am cold' /rú:kweh/ 'man'

In each of the cases in (5), the morphologically derived environment affected by the change is compared with an otherwise identical but non-derived environment in which the change fails to occur (see portions in boldface). In all cases, the morphologically derived environment includes a morpheme boundary.

3.2 *Non-boundary contexts*

Turning now to cases where morphologically derived status appears to make a difference without implicating material contributed by the morphology, English vowel shortening, e.g. as in *di'vin-ity vs.* underived *'ivory*, will serve as the prototype, although its exact analysis, given below, will be critical to this role.

Burzio (1993, 1994, 2000a) argued that, while tradition had focused on individual shortening processes, like the "trisyllabic" shortening of *di'vin-ity* or of (6a) below, the actual generalization is in fact found over non-shortening contexts or the "exceptions," while the shortening is otherwise fully general. Given the variety of vowel length changes illustrated by the left-hand cases in (6), including not only shortening but also lengthening, as in (6h), separate characterization of each case would result in a colossal conspiracy. By contrast, such distribution can receive a unitary analysis in terms of vowel length being allophonic in this sector of the lexicon, rather than contrastive, as in the rest of the language. On this view, long vowels would be disallowed in general and produced only under specific contextual demands. The factor responsible for long vowels appears to be stress, and specifically the stress that would be inherited from the respective morphological bases given in (6) in parentheses. A review of each case in (6) will drive this point home.

(6) *Vowel length in the English Latinate-derived lexicon*

		stress preserved		
a.	*'**natur**-al* (*'na:ture*)	yes		
b.	*o'**blig**-aˌtory* (*ob'li:ge*)	yes		
c.	*ˌdefa'**m**-a:tion* (*de'fa:me*)	no		
d.	*ar'ticulaˌ**t**-ory* (*ar'ticuˌla:te*)	no		
e.	*'alternate*$_{N/A}$ (*'alterˌna:te*$_V$)	no		
f.	*'**aspir**-ant* (*as'pi:re*)	no	yes	*de'**si:r**-ous* (*de'si:re*)
g.	*'**generat**-ive* (*'geneˌra:te*)	no	yes	*'legisˌ**la:t**-ive* (*'legisˌla:te*)
h.	*Eˌliza'**be:th**-an* (*E'lizabeth*)	yes	no	*Her'**culean*** (*'Hercules*)

The cases in (6a) and (6b) preserve the stress of their bases, and the short vowel in each case will follow from the fact that such stress patterns are independently known *not to* require a long vowel. The pattern of *'natural* is the same as that of *A'merica*, with stress on an antepenultimate light syllable (short vowel), while that of *o('bliga)ˌtory* is relevantly like that of *(ˌAri)'zona*, the parentheses here marking a binary foot in non-word-final position, evidently also not needing a long vowel/heavy syllable to bear stress. Like the cases in (6a) and (6b), those in (6c)–(6e) also do not need long vowels, but for different reasons. Here, a stress on the vowel in boldface *cannot* be preserved from the base. Given the stress of affixes *-'a:tion*, *-ˌory* (American English), which apparently must take priority, stress preservation is excluded in (6c) and (6d) by the ban on stress clashes. Similarly, given the independent fact that nouns tend to avoid the final stress of verbs (cf. *per'vert*$_V$ / *'pervert*$_N$; *per'mit*$_V$ / *'permit*$_N$), the stress of the base verb is presumably excluded in (6e). Hence, on the "allophonic" hypothesis, vowels are short in each of (6c)–(6e), because nothing motivates the long allophones (CHAPTER 11: THE PHONEME).

Matters are different in the derived forms in (6f)–(6h), where all boldface vowels are in penultimate syllables. Like other languages, English is well known to stress penultimates only if heavy, and antepenultimates otherwise (*ˌA.ri.'zo:.na*, *a.'gen.da* vs. *A.'me.ri.ca*, *'as.te.risk*), if we put aside verbs, which require a separate discussion (Chomsky and Halle 1968; CHAPTER 102: CATEGORY-SPECIFIC EFFECTS). The derived forms in (6f)–(6h) all conform with this generalization. The left/right variation in each case, however, reveals that the general mandate for vowels to be short competes evenly with preservation of stress, some outcomes favoring the former, and others the latter – a case of lexically controlled phonological variation (Burzio 2006). Lengthening as in *Eˌliza'be:than* in (6h) is on this analysis just like the non-shortening of *de'si:rous* in (6f) and other cases, since it allows preservation of the stress of *E'lizabeth*, albeit as a secondary. The alternative **'Eli'zabethan* with a short *e* would lose that stress altogether, given again the ban on stress clashes, as in fact happens in *Her'culean* of (6h) (though the equally expected *ˌHercu'le:an* is also attested). The point at issue is that long vowels occur in the Latinate lexicon *only* to preserve stress, though variably, as in (6f)–(6h), and are banned otherwise, ignoring occasional cases like *o'be:sity*, which are exceptions to the pattern in (6a), but are an effect of different granularity from the variation in (6f)–(6h), which is very robust (giving roughly a 50–50 split; Burzio 1993, 2000a).

The conclusion holds that in this morphologically derived domain vowels are required to be short, except, and variably, under stress demands. It is therefore this general requirement, statable as *V:, that "blocks" in environments that are not so derived, e.g. *'di:nosaur*, *'i:vory*, etc.

The cases listed below would appear to be of the same a-contextual type as argued for the English cases in (6), while, again, the specific analyses may be ultimately critical to the correct classification.

(7) *Further cases of NDEB, for DEs not including morpheme boundaries*

a. *Italian participles* (Burzio 1998)
as.cen.dere 'ascend' *as.ce.so* 'ascended' (less marked syllable)

b. *Turkish disyllabicity condition* (Inkelas and Orgun 1995: 770)
ham 'unripe' **fa-n* '(note) fa-2SG POSS'
fa-dan 'fa (note)-ABL'
(avoidance of marked prosodic structure)

c. *Japanese two-mora requirement* (Itô 1990; Kiparsky 1993)
su 'vinegar' *choko* 'chocolate (truncation)'
**cho* (two-mora requirement satisfied)

d. *Catalan stressed vowel lowering* (Mascaró 1976; Kiparsky 1993: 293)
'sentrə 'center' 'sɛntr-ik 'centric'
direk'to 'director' direk'tɔr-i 'directory' (preferred segment)

e. *Catalan unstressed mid-vowel reduction* (Mascaró 1976; Kiparsky 1993: 294)
bo'ston 'Boston' bustun-'ja 'Bostonian'
'katedrə 'academic chair' katə'drat-ik 'holder of academic chair'
(preferred segment)

f. *French* h-aspiré (Kiparsky 1993: 294)
Hitler 'Hitler' *(h)itlérien* 'hitlerian'
(loss of marked segment)

As in the English case, where the presumably more marked long vowels are avoided, each of the derived cases in (7) would appear to avoid some choice that is relatively more marked either prosodically, as in (7a)–(7c), or from the point of view of segmental inventories, as in (7d)–(7f), as indicated in parentheses. As suggested above, alternative analyses of some of these cases are conceivable. In particular, the cases in (7b) and (7c) are amenable to an account in terms of prosodic requirements imposed by the morphology (Downing 2006). Also, the specific analysis of cases like (7b) will depend on the general solution to the issue of "ineffability" (absence of an output for certain inputs; see van Oostendorp 2009). The lower vowels in (7d) are argued by Wolf (2008: 264f.) to be a general property of oxytonic and paroxytonic stress (though cases like ['sentrə] would require further comment) rather than derived environments. In addition, Wolf (2008: 267f.) attributes cases like (7e) and (7f) to a mechanism under which "roots can lose exceptional properties in morphologically derived contexts." Technical details aside, the latter view is effectively equivalent to the present one, however. In sum, at least some of the cases in (7) are likely to be genuine instances of the proposed class, while others may be more questionable. See also Wolf (2008: 246–248) for cases of NDEB additional to those listed here and in the previous section.

4 Proposed analyses

I now turn to concrete analyses of the different types of NDEB, beginning with contemporary attempts, and turning later to more traditional ones. Here, I will focus in particular on the analyses of Łubowicz (1999, 2002), Burzio (2000a, 2000b, 2002b), and Wolf (2008), all cast within the general framework of Optimality Theory (OT; Prince and Smolensky 1993). However, see Kula (2008) for an account based on Dependency Phonology. A more comprehensive review of the literature on NDEB is provided in Wolf (2008: §4.3).

4.1 Phonologically derived environments

4.1.1 The entailments-based approach

Burzio (2000b, 2002a, 2002b, 2005) argues that a pervasive property of phonological and morphological representations is that they constitute attractors to their neighbors. This attraction effect is achieved formally by means of the hypothesis in (8).

(8) *Representational Entailments Hypothesis* (REH)

Mental representations of linguistic expressions are sets of entailments. For example, a representation consisting of A and B corresponds to the entailments: A ⇒ B, B ⇒ A (if A then B; if B then A).

The "entailments" in (8) are types of violable constraints as in OT, but, unlike OT's "strict" ranking of constraints, underlying the REH in (8) is the assumption that entailments of the same type, like "$x \Rightarrow A$," for any x, directly undergo summation, producing entailments of higher strength or rank. This is analogous to the workings of neural networks, in which activation on a node A is the sum of the activation received from all nodes x to which A is connected.

The workings of attraction can be illustrated with the case of "parasitic" assimilation in Sudanese Arabic in (9), from Kenstowicz (1994: 54).

(9)	a.	*kitaa*[b]	'book'	*kitaa*[f] *Fáthi*	'Fáthi's book'
	b.			*kitaa*[p] *Samíir*	'Samíir's book'

In (9), assimilation in continuancy (/b/ → [f]) is shown to occur only contingently, or "parasitically," on agreement in place (same labial place (9a); for the relation between continuancy and place, see CHAPTER 13: THE STRICTURE FEATURES). Otherwise only voicing assimilation occurs, as in both (9a) and (9b). The initial C of the possessor noun ([f] or [s]) thus appears to act as an attractor on the final C of the head noun [b]. If the latter is close enough to the attractor (same place), it is then drawn closer (same continuancy). Evidently, even the weaker attraction (different place) must be sufficient for voicing assimilation, which we can put aside.

Such attraction effect would follow from the entailments of (8) in the way illustrated in (10).

(10)	A B C D	A ⇒ D	B ⇒ D	C ⇒ D	*Components in* (9)
a.	A B C –D	*	*	*	A: [α consonantal]
b.	A B –C –D	*	*		B: [β sonorant]
c.	A –B –C –D	*			C: [γ place]
d.	–A –B –C –D				D: [δ continuant]

Consider that an attractor consisting of the four components A, B, C, D will generate, relative to its fourth component, D, the three entailments given in the top row in (10). Line (a) then shows how a target representation differing only by that fourth component (–D standing for "minus D" or "not D") would violate all three of those entailments, while subsequent lines show how progressively more distant representations violate fewer and fewer of those entailments. In general, the REH (8) predicts that the number of entailments violated by each component on which a target differs from an attractor will equal the number of components on which target and attractor agree. Overall violation per differing component will therefore be proportional to overall similarity, hence the notion of "attraction." Applicability to (9) above is by way of conversion of the abstract components A, B, C, D into appropriate distinctive features, as shown on the right-hand side in (10), the cases in (9a) and (9b) corresponding in particular to lines (10a) and (10b), respectively. An OT-style account of the contrast in (9) incorporating attraction can be given in terms of the schema "CC-Ident^3[cont] >> IO-Ident[cont] >> CC-Ident^2[cont]," where CC-Ident[cont] refers to the assimilatory pressure in continuancy, and the superscripts give a measure of the pressure in terms of entailments (attraction), translated into OT ranking. Note that no commitment is made here as to the relative strength of individual entailments (only that summation of like entailments will always yield greater strength), and hence no prediction is made that agreement on some other feature (e.g. voicing) must have the same triggering effect as agreement in place in (9), or that any assimilation will necessarily bring about further assimilation by a domino effect.

The case in (9) is by no means unique. It is in fact virtually duplicated by English nasal place assimilation, where the failed assimilation of *in-famous* calls for the assumption that identity in place automatically induces identity in continuancy, just as in (9). This assumption is needed to correctly exclude **im-famous* (same place but different continuancy; cf. *im-possible*), while the alternative **i*[ɱ̃]-*famous* will be excluded by the ban on nasal fricatives in English. Furthermore, Wayment (2009) argues, on a broad empirical basis, that *all* assimilatory phenomena are parasitic in the manner of (9), and thus all involve attraction, as just described. However, sequential proximity also appears to contribute to overall similarity and hence to attraction, so that, when proximity is maximal as in (9), the prerequisite similarity in features may be slight and not immediately detectable, while long-distance phenomena, like long-distance consonant assimilation (Hansson 2001; Rose and Walker 2004; chapter 77: long-distance assimilation of consonants) and vowel harmony (van der Hulst and van de Weijer 1995; chapter 91: vowel harmony: opaque and transparent vowels; chapter 110: metaphony in romance; chapter 118: turkish vowel harmony; chapter 123: hungarian vowel harmony), will predictably exhibit more robust feature-based similarity as a triggering condition, as the references just cited confirm.

Beside assimilations, Burzio argues that attraction underlies further morphophonological phenomena: in particular, that it can reconstruct the "dispersion" account of segmental inventories (Liljencrants and Lindblom 1972; Flemming 1995; chapter 2: contrast), as maximal distance among members of the inventory corresponds to minimal attraction/entailment violation. In addition, under the reduction of contextual neutralization effects to dispersion principles advocated by Steriade (2009) and Flemming (2008), attraction would also speak to those effects in turn. In particular, segmental neutralizations (like coda devoicing) would occur in those environments that attenuate critical perceptual cues, as argued by Steriade (1994, 1999, 2009), and thus compromise distance from the nearest attractor in the inventory. The latter attractor will then exert its influence, neutralizing the contrast. Attraction thus represents a formal alternative to Steriade's (2009) "perceptual map" and, as argued in Burzio (2000b), is a variant interpretation of Wilson's (2000, 2001) "targeted constraints," which are also a formal alternative to Steriade's perceptual map. Attraction has also been argued to underlie morphological syncretisms (also a type of neutralization; see Burzio 2005, 2007; Burzio and Tantalou 2007).

From this point of view, the NDEB of (1) would then be naturally interpreted as another attraction effect, parallel, in fact, to the one in (9). While the relevant relation in (9) is between two segments in the same sequence, the one in (1) is between the adjective's stem and the corresponding verb. Just as in (9), identity in one respect, here stress, results in identity in another, here vowel length, as in (1b). The REH and attraction have in fact been argued to subsume the general OT notion of "faithfulness" (CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS), and at the same time also to derive the set of relations to which faithfulness has been shown to apply (input–output; base–derivative; base–reduplicant; paradigms; similarity of consonants). Similarity can define all such relations, with sequential adjacency/proximity also contributing to similarity, as noted (Wayment 2009). However, morphology also plays a role in further defining faithfulness (§6).

In OT notation, the attraction accounts of (9) and (1) may then be rendered as in the parallel (11a) and (11b), respectively.

(11) a. CC-Ident^{+}[cont] >> IO-Ident[cont] >> CC-Ident[cont]
b. Ident^{+}(V-length) >> *V̆CiV >> Ident(V-length)

The schema in (11a) is the same as the one given above, except that superscript "3, 2" have been replaced with just "+" and no superscript, respectively. In (11b), Ident(V-length) applies between input (verb) and output (adjective) in (1). As in (11a), the "+" version corresponds to the stronger attraction, here due to identity in stress. The second constraint in (11b) promotes a long vowel before "CiV" and prevails in (1a) by competing only with the lower-ranked Ident (weaker attraction), but is ineffective in (1b), where the higher-ranked Ident is involved. The attraction account of (1) as in (11b) seems applicable in transparent ways to the other cases of this type cited in (2) and (3) above.

4.1.2 *The "local conjunction" approach*

An account of NDEB based on the formal device of local conjunction (LC) of constraints in OT (CHAPTER 62: CONSTRAINT CONJUNCTION) is proposed in Łubowicz (1999, 2002). When deployed in a case like (1), such an account would feature the hierarchy in (12), which can be compared with the one in (11b).

(12) [*V̆CiV & Ident(stress)] >> Ident(V-length) >> *V̆CiV

The conjunction in (12) combines one faithfulness constraint, Ident(stress), and one markedness constraint, *V̆CiV. Simultaneous violation of both conjuncts would thus invoke the higher-ranked conjunction, forcing the repair as in the stress-unfaithful (1a), while the markedness constraint alone would be low-ranked, hence failing to induce the repair, as in (1b). As with the account in the previous section, stress constraints must exclude un-restressed *'*remediable* (Burzio 1994).

It is easy to see that this approach also covers the cases in (2a)–(2d), as Łubowicz shows, and possibly the one in (2e) (but see below), given appropriate choices of markedness and faithfulness constraints that make up the conjunction. The LC solution seems ingenious and has interesting typological properties, predicting that not only conjunctions of markedness and faithfulness constraints, but conjunctions of two markedness constraints, as well as conjunctions of two faithfulness constraints, should prove equally useful. These predictions seem to be supported to the extent that conjunctions of markedness constraints have frequently been proposed in the OT literature (see McCarthy 2002: 18f.; Łubowicz 2002: note 4; and, for general reviews, Fukazawa 1999), while conjunctions of faithfulness constraints have also been proposed, in particular to account for counterfeeding chain shifts (Kirchner 1996; CHAPTER 73: CHAIN SHIFTS).

The LC approach cuts the empirical domain differently from the attraction-based approach. While it may relate NDEB to the other "conjunctive" effects just noted, it does not relate them to other phenomena in the domain of attraction, like the parasitic character of assimilations shown in (9). The reason a schema along the lines of (12) will be silent on (9) is that in the latter case the crucial difference, i.e. same place [. . . b#f . . .] (9a) *vs.* different place [. . . b#s . . .] (9b) is not one created by some process, but rather one already present in the input. Hence there is no difference in terms of IO-faithfulness that could be recruited for a LC like the one in (12).[2] To make the LC approach applicable to cases like (9), we might import from the attraction framework the notion that faithfulness may also hold across segments within the same input sequence, but further arguable attraction effects (like dispersion or syncretism) would remain recalcitrant. Other cases, like those in (13), from Burzio (2002b), may, like the one in (9), also involve differences without an actual process, and may thus also pose a challenge to the LC approach.

(13)	*base*	*derivative: more similar*	*derivative: less similar*	*interacting dimensions*
a.	*com'pare*	*com'parable*	*'comparable*	stress; semantics
b.	*di'vide*	*di'vidable*	*di'visible*	vowel length; segmentism
c.	*ap'ply*		*'applicable*	vowel length; segmentism
	de'ny	*de'niable*		
d.	*'larynx*	*'larynxes*	*la'rynges*	stress; segmentism

The case in (13a) features, in the "less similar" column, an idiosyncratic semantic change, as the derived adjective *'comparable* means "roughly equal" rather than

[2] The same predicament would face McCarthy's (2003) "Comparative Markedness" (CM) approach, which distinguishes markedness violations that are present in the input (old markedness) from those that are not (new markedness). As Łubowicz (2003) shows, this approach has similar effects to those of the LC approach. Conceivably, a higher-ranked "new" *V̆CiV could in particular apply to (1a) given the changed stress, but not to (1b). In (9), however, nothing is independently "new" in (a) any more than in (b), yielding no account in these terms. Further difficulties with CM are noted in Wolf (2008: §4.2.3).

"able to be compared," while the cases in (13b)–(13d) exhibit idiosyncratic segmental changes. In each case, such changes cluster with other changes, in stress, vowel length, or both. These further changes are then roughly predictable, though space prevents a full discussion here. For instance, the form *la'rynges* displays regular stress (heavy penultimate) rather than the stress of its base. By comparison, the same changes "block" in the absence of the first type of change, as shown in the "more similar" column. Such cases of NDEB are covered by attraction, which responds to difference/distance regardless of its source. By contrast, the LC approach will require an extension of the formal notion of faithfulness to the domain of suppletion and semantic idiosyncrasy.

The two approaches reviewed so far may also differ in the degree of locality that they impose on possible interactions. The LC approach enforces the locality required by the notion of "local conjunction." For instance, LC would be applicable to (1a), due to the fact that both changes, in stress and vowel length, occur in the same vowel. The theory of LC is not fully explicit, however, on what exactly counts as a local domain (Smolensky 1997), and we may note that in fact not all cases of phonological NDEB involve the same segment. For instance, the two relevant changes in the Finnish case in (2e) *vete* → *veti* → *vesi* occur in different segments. See, however, Łubowicz's (2002: note 29) appeal to an alternative analysis that would bring this case in line. An apparently similar challenge is also posed by Sanskrit retroflexion of s after the disjunction {*r, u, k, i*} (Kiparsky 1973a; Kenstowicz 1994: 202; CHAPTER 119: REDUPLICATION IN SANSKRIT).

As for the predictions of the REH on the exact range of interaction of changes, they are also not very clear at the present stage, but perhaps some inference can be drawn from the fact that the REH aims to characterize inventories as sets of attractors, combined with the independent fact that inventories are attested for segments and morphemes. If these are the attractors, then attraction effects should be observable at both of these levels. Then the cases in (2a)–(2d) and perhaps (1), would instantiate cases where attraction occurs between corresponding segments, while those in (2e) and (13) may instantiate attraction between corresponding allomorphs (note that several of the latter cases involve more significant structural changes than those in (2a)–(2d)).

4.1.3 *Serial Optimality Theory*

Wolf (2008) develops an approach to NDEB based on the serial OT of McCarthy (2007), in which different potential sequences of operations ("candidate chains") are evaluated by constraints on derivations. This approach receives its primary motivation from phonological opacity (counterfeeding and counterbleeding effects; see CHAPTER 74: RULE ORDERING). Given, for instance, an opaque derivation like that of Serbo-Croatian /okrugl/ → okrugal → [okrugao] 'round' (Kenstowicz 1994: 90f.), in which vocalization of /l/ to [o] counterbleeds the epenthesis of [a] that would break up a final cluster, this approach would postulate a "precedence" constraint PREC(DEP, IDENT[consonantal]) prescribing that a violation of IDENT[consonantal] (i.e. vocalization) must be preceded by a violation of DEP (i.e. epenthesis), whenever the latter violation would be harmony-improving (i.e. in final CC environments). The case in (1) would then be handled in this perspective via the schema in (14).

(14) PREC(IDENT(stress), IDENT(V-length)) >> *V́CiV >> IDENT(V-length)

The top-ranked constraint in (14) will demand that a violation of IDENT(V-length) (i.e. lengthening) be preceded in the derivation by a violation of IDENT(stress) (i.e. restressing), thus blocking lengthened but un-restressed **le:viable*. While using different theoretical means, this requirement is parallel to that imposed by IDENT+(V-length) in (11b) on the basis of the attraction approach (expressing the stronger attraction/IDENT requirement if stress is unchanged), while the rest of the schema in (14) remains the same as that of (11b).

Major differences lie again in the way this approach relates to phenomena other than NDEB. As noted, it links NDEB directly with phonological opacity, while this link is more indirect in the alternative approaches. In the attraction approach, it is natural to see segmental neutralizations (like the /l/–/o/neutralization of Serbo-Croatian) as attraction effects due to phonetic similarity. In turn, neutralizations (and perhaps other processes) have been shown to yield opacity effects within the theory of Targeted Constraints of Wilson (2000, 2001), which is arguably interpretable as a formalization of segment-level attraction effects (Burzio 2000b). As for the LC approach, it has so far been shown to provide an account of only a subset of the opacity effects, in particular, and as already noted, that of counterfeeding chain shifts, by means of a LC of faithfulness constraints (Kirchner 1996).

Like the LC approach, the serial OT approach is potentially challenged by cases where representational distance does not arise through a specific phonological process. In particular, the schema of (14) will not be applicable to the parasitic assimilation of (9), where there is no derivational step that would precede place assimilation and could account for the contrast. Likewise, (14) may not extend to cover the cases in (13), where the relevant (attraction-weakening) differences are suppletive or semantic.

4.2 *Morphologically derived environments in boundary contexts*

4.2.1 The entailments-based approach

Burzio (2000a) analyzes the Finnish case in (3b) above, repeated in (15a), as in (15b).

(15) a. *tilat-i* → *tilas-i* 'order'-PAST
b. FAITH[ti] >>*TI (assibilation) >> FAITH[t]

In (15a), the first *t* in *tilat-i* is subject to higher-ranked FAITH[ti] and thus resists the effects of the assibilation constraint, while the second *t* is subject only to lower-ranked FAITH[t], and thus undergoes the assibilation. This analysis assumes that faithfulness only applies to the form of morphemes, not to morpheme combinations. Hence the output form *tilas-i* in (15a) would only be faithful, independently, to the stem *tilat-*, and to the past tense affix *-i*, but not to their concatenation, making the top-ranked constraint in (15b) inapplicable to heteromorphemic *t-i*.

While the analysis in (15b) predates the introduction of the representational entailments of (8) above, the latter can be recruited to improve it. The reason is that the constraint FAITH[ti] of (15b) will now consist of the entailment $i \Rightarrow / t$ __ (*i* entails a preceding *t*, or *i* must be preceded by *t*), an entailment generated by any surface occurrence of the stem *tilat-* or its allomorph *tilas-*. The reason there is no heteromorphemic counterpart to that entailment is that affixal -*i* occurs in heterogeneous environments, attached to stems of all sorts. Any entailment of a preceding *t* would be contradicted by entailments generated by other stems that do not end in *t*, and thus effectively suppressed under algebraic summation of entailment. Of course one must assume that the *i* involved in such entailment is not just the phoneme *i* of Finnish. Rather, it must be the *i* of *tilat-*, which is in turn entailed by the rest of the representation of the stem *tilat-*, including its semantics. It is that *i* which will then entail a *t* by transitivity of entailments, while suffixal -*i* will not. See Wolf (2008: 326f.) for a review of other attempts in the literature, some of which bear resemblance to the one being described.

The remaining question is still which sequences of segments may count, which now takes the form of "what entailments matter, exactly?" For instance, why shouldn't an entailment from *a* to *t* in (15a) prevent the second *t* from spirantizing while allowing the first, hence yielding **silat-i*? Here, the REH (8) has been shown to yield one other critical effect besides attraction: "binding," tying together components that are relatively similar to one another. While a formal demonstration is beyond the goals of this chapter, an intuitive grasp can be attained by considering similarity as a sharing of subcomponents. Given two co-occurring components A, B, the REH will prescribe that each of A and B will entail its own internal structure, as well as each other. But when A and B are similar, the former effect will contribute to the latter, resulting in a stronger mutual entailment between A and B. See Burzio (2005: §4.5) and Wayment *et al.* (2007) for more discussion.

Now, if all assimilations are parasitic on similarity, as suggested above, then the "*t-i* → *s-i*" process of Finnish will suggest, along with articulatory considerations, that there is some level of similarity between *t* and *i*, with a consequent binding effect. A tautomorphemic sequence *ti* would then be simultaneously subject to two effects. One would be attraction, with the potential for assimilation, and the second the "binding," or enhanced mutual entailment, of *t* and *i*, opposing assimilation and evidently sufficient to block it. On the other hand, heteromorphemic *t-i* would experience only attraction, thus leading to assimilation. The reason is that "binding" only describes an enhancement effect over the entailment $i \Rightarrow / \ t \ \_\_$, an entailment which, however, is effectively false for the heteromorphemic case, for the reasons discussed. While the OT analysis thus remains as in (15b), with Faith[ti] describing the enhanced entailment (binding) and *TI describing attraction, the "grounding" just provided narrows the range of applicability of sequential constraints of type Faith(xy), and hence the range of pathological predictions re segmental inventories.

4.2.2 *The "local conjunction" approach*

Łubowicz (1999, 2002) proposes a "local conjunction" analysis of this case as well. When applied to the Finnish case in (15a), that analysis would be as in (16).

(16) [*TI (assibilation) & R-Anchor(Stem, σ)] >> Ident[cont] >> *TI (assibilation)

The constraint R-anchor(Stem, σ) in (16) requires that the right edge of the stem line up with a syllable boundary, and is violated in (15a). Hence the repair in (15a) is triggered by the fact that the conjunction of the latter constraint with the assibilation constraint dominates the relevant faithfulness constraint, IDENT[cont]. No repair affects the initial *ti* sequence, because in that case violation of the assibilation constraint is not in the same local domain as the violation of the right-anchor constraint, making the local conjunction inapplicable, while the assibilation constraint by itself is ranked lower than IDENT[cont] and hence ineffective.

The prediction that syllable boundaries play the role characterized by (16) seems disconfirmed by several of the cases in (5) above, however. This is true in particular in the following cases: Chumash pre-coronal laminalization, which alongside the example in (5d) also features /s-is-lusisin/ → [ʃ-iʃ-lu-sisin] (from Poser 1982, 1993, with presumed syllabification [ʃiʃ.lu . . .], with no misalignment); Sanskrit retroflexion (5e), as in /agni-su/ → [agni-ṣu]; Finnish cluster assimilation (5g), as in /pur-nut/ → purrut; and Mohawk epenthesis (5h) /k-wi'stos/ → [kewi'stos]. It is possible that these cases could be analyzed as processes that affect only affixal material due to a lower-ranked AFFIX-FAITH and that block in underived environments simply because those environments are stems, hence not for the reasons provided by (16). Yet this alternative does not seem viable for the case in (5f), repeated in (17).

(17) *Indonesian nasal substitution* (Pater 1999)

/məN-pilih/ → [məm-ilih] 'to choose' /əmpat/ 'four'

Here the stem is affected as much as the affix, and yet a faithful candidate *[mən-pilih] would feature no misalignment (though in any event a "left" rather than a "right-anchor" constraint would be needed).[3] Pater (1999) in fact analyzes the asymmetry in (19) not in terms of LC, but rather in term of a ROOT LINEARITY constraint that aims to preserve sequential relations within a root. The mapping /əmpat/ → *[əmat] 'four' would violate such a constraint with respect to the input sequence /mp/, while a comparable heteromorphemic sequence is not in the scope of the constraint. This type of analysis is in fact essentially subsumed by the above entailment-based discussion (/m/entails /p/).

4.2.3 Serial OT

Wolf (2008: ch. 4) provides an account of the now familiar Finnish test case in (15a) based on the ranking schema in (18):

(18) PREC(insert-affix, IDENT[cont]) >> *TI (assibilation) >> IDENT[cont]

Again, the schema in (18) differs from the entailment-based one in (15b) only by the top-ranked constraint, parallel to the one Wolf deploys in (14) above to handle phonologically derived environments. In both of Wolf's analyses, the top-ranked constraint imposes a specific order of processes, here demanding that a violation of IDENT[cont] (i.e. assibilation) be preceded by affixation. Such constraint is obviously satisfied by the heteromorphemic assibilation *t-i* → *s-i*. It would,

[3] Łubowicz (2002: 265) acknowledges this prediction with regard to simple nasal assimilation, which would not be expected to "block" since morpheme and syllable boundaries line up, finding no counterexamples, but does not discuss nasal substitution. However, English nasal assimilation does in fact seem to exhibit NDEB, judging from *Finland, Henry, only*, compared with *illegal, irrational*. But these cases too could perhaps be attributed to lower-ranked AFFIX-FAITH.

however, be violated by a tautomorphemic assibilation yielding **silas-i*. The reason is essentially that in the latter case affixation does not provide any material critical to the assibilation, and is thus taken not to count as establishing the required order in Wolf's formal system.

In sum, this approach provides a unitary account of two of the cases of NDEB in terms of the PREC constraints of Wolf's framework. We will see in §6 below, however, that it appears not to extend to the third.

5 Pre-Optimality Theory accounts

5.1 *Strict cyclicity*

This subsection reviews the most influential of the early accounts of NDEB, the one based on "strict cyclicity," as developed by Mascaró (1976) as part of the conception of the phonological "cycle." Other accounts, carefully reviewed in Kiparsky (1993), include the "(Revised) Alternation Condition" and specific applications of the "Elsewhere Condition," briefly discussed below.

The traditional motivation for the phonological cycle comes from the observation that underlying representations (URs; CHAPTER 1: UNDERLYING REPRESENTATIONS) are insufficient for correct phonological derivations, and that reference to surface forms is also necessary (CHAPTER 85: CYCLICITY), as in the familiar English example in (19), from Chomsky and Halle (1968: 117).

(19) a. *cond*[ɛ]*nsation* cf. *con'd*[ɛ]*nse*
b. *comp*[ə]*nsation* cf. *comp*[ə]*nsate* **com'p*[ɛ]*nse*

The two nouns in (19) would have fully parallel URs, and yet exhibit different degrees of reduction in the bracketed vowels, a difference that seems predictable only by reference to the corresponding verbs in parentheses. The "cycle" thus required the phonology to apply first to inner morphological layers, first calculating *con'd*[ɛ]*nse* within *cond*[ɛ]*nsation*, and then move on (see Kenstowicz 1994: 204 for exact derivations, and Cole 1995; CHAPTER 85: CYCLICITY for a full review of the motivations for the cycle).

On the other hand, in the parallel approach that OT embraces, it becomes possible to argue that the reference to surface forms that cases like (19) make necessary is also sufficient, thus simply dispensing with the traditional URs, rather than requiring an additional notion like that of the cycle (Burzio 1996, 2000a). On this view, the lexicon is constituted of full surface forms, whose well-formedness, including their morphological relatedness, is calculated in parallel by a grammar that effectively just "checks" them, rather than deriving them step by step.

The ability to refer directly to surface forms has been forcefully advocated in the OT literature by way of the notion of output-to-output faithfulness (Benua 1997; McCarthy 2005; and many others), which has then been used to account for the effects of the derivational cycle like those in (16). However, many practitioners have continued in the tradition of considering the lexicon as being constituted of morphemes, which give rise to URs when assembled together.

In contrast to cyclicity, "strict cyclicity" effects, to which NDEB effects were in turn related, can perhaps be illustrated with the simple English series in (20), but see Kenstowicz (1994; §5.3) and Mascaró (1976) for the Catalan data that were actually utilized.

(20) a. *de'si:re* b. *de'si:r-able* c. *de,si:r-a'bil-ity*

Assume for present purposes that *-able* is one of the affixes that trigger vowel shortening, as shown for instance by *admi:re / admir-able*. As discussed above, shortening is only variable rather than systematic in stressed penultimate syllables, whence unshortened (20b) *de('si:ra)<ble>*, assuming an extrametrical syllable *<ble>*, as in (1) above. The point of note is that further derivatives of *de'si:rable* such as (20c) maintain this choice despite the fact that *-ity* is itself a shortening affix, witness *divin-ity* (cf. *divi:ne*), or *promiscu-ity* (cf. variant *pro:miscuous*), and the fact that metrical environments identical to that of (20c) (medial foot (σ σ)) shorten quite regularly, as in *pro(,nunci)'ation* (cf. *pronounce*). The conclusion drawn from facts of this sort was thus that certain processes "block" in environments that are not "properly" derived. The one in (20c) would be one of them, since the shortening environment is already present in (20b) (let us say), attachment of *-ity* thus contributing nothing further. But if shortening blocks for those reasons in (20c), it may well block for the same reasons in (20a), or "trisyllabic" *i:vory*, which are not derived at all. In addition, since it is the definitional property of cyclic rules to apply *when* there is a new morphological environment, it will only be a matter of strengthening this definition to *only when* (thus making the cycle "strict"), to derive the blocking of both (20c) and (20a) or *i:vory*. Along with such cases, Strict Cyclicity would provide presumptive accounts of the cases of §3.2 above (non-boundary contexts), assuming all relevant processes can refer to the added morphological structure so as to activate the cycle and block elsewhere, and would similarly also account for "boundary context" cases of §3.1 above, like Finnish *tilas-i* of (3b). As for the cases that appear to be phonologically but not morphologically derived, like Finnish /vete/ → [vesi] of (3), a clause like (21b) below was from the inception added to the already established (21a).

(21) *Applicability of cyclic rules*

a. Contexts that are newly created morphologically.
b. Contexts that are newly created phonologically.

This definitional fiat extended the account to phonologically derived cases such as (2) and (3) above (I leave (13) aside), but it did so at a cost. The two forms of NDEB are now predicted to be co-extensive, an incorrect conclusion, as Łubowicz (2002: 271) points out. While there are cases, like Finnish assibilation and Sanskrit *ruki* retroflexion, that can be argued to occur in both types of derived environments, others do not. The problem is perhaps best illustrated by the English cases in (1). The case in (1a) *re'me:di-able* was argued above to be phonologically derived via restressing. Under (21), this would be because of clause (b). But the simultaneous presence of clause (a) would now incorrectly predict lengthening in (1b) **'le:vi-able* as well, since both cases involve affixation of *-able* and hence are both "derived" in one way or another. This problem persists under Kiparsky's (1982) attempt to reduce Strict Cyclicity to the Elsewhere Condition (Anderson 1969; Kiparsky 1973b; also referred to as the Pāṇini Principle), according to which processes that refer to more specific contexts trump processes that refer to more general ones. This principle was conjoined with the assumption that lexical items (morphemes) undergo identity rules. In a case like Finnish /tilat-i/, cf. above, the assibilation rule would be blocked relative to tautomorphemic /ti/ since the identity rule would apply to /tilat/, a more specific context than just /ti/. In the case of heteromorphemic /t-i/, however, the context of the assibilation rule would not be contained within the context of the identity rule, allowing that rule to apply with no inhibition, yielding [tilasi]. Similarly, in Finnish /vete/ → [vesi], the assibilation rule would find no obstacle once /e/ raised to [i], since the identity rule would apply only to /vete/, which does not contain the assibilation context /ti/. However, again, a case like *levi-able* of (1b) above would not be accounted for, since the context for CiV lengthening obtains here thanks to combination of morphemes, hence is beyond the reach of an identity rule for *levy*. Nonetheless, the Elsewhere Condition account appeared to solve the puzzle posed by the stress rule which, while seemingly cyclic in light of cases like (19), did not block in underived environments. This could now be attributed to the fact that, in the case of regular stress systems, lexical items would not contain stress information, which could therefore not be referred to by the identity rules.

Still working within a rule-based system, Kiparsky (1993) rejects the Strict Cyclicity account of NDEB, not only because of the incorrect predictions of the disjunction in (23), but also because various other hallmarks of cyclicity failed to correlate with NDEB effects. For instance, one diagnostic of cyclicity would be sequential orders like P_1, P_2, P_1, where a process P_1 is found to apply both before and after P_2. The cycle would enable such orders so long as the two occurrences of P_1 could be placed in different cycles. Other properties attributed to cyclic rules, though essentially by stipulation, were application at "lexical" as opposed to phrasal levels, and their contrastive, as opposed to allophonic, character. Kiparsky shows clearly that NDEB does not correlate with these attributes, and thus proposes the alternative I review next.[4]

5.2 *Underspecification*

Kiparsky's (1993) proposal can be illustrated for the Finnish cases as in (22), where upper-case *T* is assumed to be underlyingly not specified for continuancy, while lower-case *t* is fully specified as [−continuant] (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION).

(22)	a.	tilaT-i			→	tilas-i	'order-PAST'	(cf. *tilat-a* 'order-INF')
	b.	veTe	→	veTi	→	vesi	'water-NOM'	(cf. *vete-nä* 'water-ESS')

Correct derivations in (22) are ensured by assuming that the assibilation process can fill in the value [+continuant] in the context / __ *i*, yielding [s], but not change fully specified *t*. At the same time, one must also assume that [−continuant] can be filled in by a later default rule to any representation that may remain unspecified after the assibilation rule has had a chance, so as to yield *t* rather than

[4] Note that parallel OT does not predict any of the formerly stipulated distinctions between lexical and post-lexical processes. A discussion of this issue is beyond present goals, but see below for some discussion of phonology–morphology interaction.

s in the parenthesized forms on the right, as in /tilaT-a/ → [tilat-a]; /veTe-nä/ → [vete-nä].

On the one hand, this proposal bears some similarity to the one in (15b) above and its entailment-based version, in that immunity of the first /t/ comes from a greater amount of information associated with it. On the other, however, this approach does not appear to be fully workable. If the forms on the right in (22) were the sole determinants of the URs on the far left, then, indeed, the latter URs could be correctly obtained. In the course of acquisition, the *i* of *tilat-a* would force full specification of the preceding *t*, lest the expected form be **silat-a*, given knowledge of the assibilation. Elsewhere, however, *t* (as given in upper case) could remain underspecified, correctly yielding assibilation when a following *i* shows up. This dynamic is parallel to the one based on the entailments, where a following *i* would also confer additional resilience to a *t*. However, as argued in Burzio (2000a), the assumption that the parenthesized forms are privileged sources for the URs cannot be maintained. In *divine* / *divin-ity*, the presumed UR *div*/iː/*ne*/, with a long vowel, must be inferred from the base, but in *dam(n)* / *damn-ation*, the UR /dæmn/, with /n/, would only be inferrable from the derivative. On the other hand, in [pærənt] / [pərɛntəl], the full set of underlying vowels is only inferrable from base and derivative combined. The fact of the matter is that, in general, there is no independent principle or a priori restriction on what surface forms can contribute to a UR in a theory that has URs. It totally depends on where neutralization processes occur down the line. This means that hypothetical **tilat-i* could also contribute to its UR, yielding full specification of the second *t* incorrectly, making the account of (22) circular (the initial premises rest on the final results). This liability is not shared by the entailments. As we have seen, affixal -*i* would not entail a preceding *t* even in a hypothetical *tilat-i*, the reason being that, as a past tense affix, -*i* will entail to its left whatever results from entailment summation over all of its stems, most of which do not end in *t*.

The inadequacy of the underspecification account is even more apparent if one attempts to extend it to other cases of phonologically derived environments beside (22b). For example, to handle *remediable* in (1a), this account would have to underlyingly underspecify the lengthened vowel while fully specifying (as short) the one of *leviable* (1b). But, again, there is no independent basis for such an asymmetry. The fundamental reason for this inadequacy is that, in general, an underspecification account will predict asymmetries based on some coherent theory of what can be marked *vs.* default values. Hence, it cannot under any circumstance predict the true generalization, which appears to be whether or not some change has occurred in the same segment or morpheme, as in each of (1), (2), and (13).

6 Morphologically derived environments in non-boundary contexts

I turn now to the case in §3.2 above, whose prototype was taken to be English vowel shortening.

Burzio (2000a) argues that such effects simply result from the parallel interaction of morphology and phonology in the absence of any level of UR. Consider in particular that regular/productive morphological systems generally exert an inhibitory effect on phonological processes, as shown in (23).

(23) a. *'effort-less-ness* (exceptional stress)
b. *beep-ed* [bijpt] (exceptional syllable size)

Stress patterns such as the one in (23a) are unattested among morphologically underived items, as are syllables like the one in (23b), where a long vowel is followed by two consonants. These effects would be types of "DEB," namely reversals of NDEB. Here, otherwise regular processes "block" exactly in the derived environments. Burzio (2002a) argues in this connection that one can simply interpret the selectional properties of the relevant affixes, expressible for example as in (24), as types of constraints.

(24) *-less* ⇒ / Noun __ (*-less* attaches to a noun)

If there are no URs, then the context "Noun" in (24) can only refer to surface forms, affix *-less*, thus demanding identity between its stem and any such form. Then, cases like (23a) will be accounted for by taking (24) to dominate the constraints responsible for regular stress, the irregular one of (23a) simply coming from identity with that of *'effort*, as imposed by (24), and similarly for the past tense affix in (23b) and syllabification constraints.

If morphology and phonology compete this way, so that (23a) and (23b) result from the morphology winning, then effects in the opposite direction should result when the morphology loses, and this would be the case of vowel shortening, as illustrated in (25).

(25) a. *natur-al* (cf. *na:ture*)
b. *V: >> *-al* ⇒ / Noun __ (*-al* attaches to a noun)

In (25b), a general markedness constraint banning long vowels outranks the morphological constraint demanding identity with the independent noun *na:ture*, resulting in a short vowel. The difference between the high-ranked selectional constraint in (24) and the low-ranked one in (25b) reflects the general difference between (roughly) Germanic and Latinate affixes, termed respectively "Level 2" and "Level 1" in Kiparsky's (1982) Lexical Phonology framework. This ranking-based characterization of the two morphological systems is independently supported by the fact that the two systems also differ with respect to morphological idiosyncrasy (Burzio 1994, 2002a; Benua 1997), as well as productivity, which can also be correlated with rank, though more indirectly (see Burzio 2006). Latinate affixes like the one in (25) tolerate massive amounts of morphological idiosyncrasy, as in *arbore-al* (cf. absence of **arbore*), *crimin-al* (cf. *crime*, not **crimin*). By contrast, the Germanic affixes exhibit virtually no idiosyncrasy like hypothetical **arbore-less* (cf. *tree-less*) or **crimin-less* (cf. *crime-less*).

Hence there exists an inverse correlation between phonological and morphological regularities (Burzio 2002a), as Germanic affixes exhibit tight morphological regularity along with abundant phonological irregularity as in (23), while the Latinate ones reverse both effects, exhibiting much morphological irregularity along with regular phonology (CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE). This includes regular stress aside from a specific range of cases discussed below, as in *pa'rent-al* (not *'*parent-al*, which would parallel *'effort-less*), regular syllabification, the shortening of (25), and other processes like the velar softening of (4) above (*electri*[s]-*ity*), all absent from the Germanic class (cf. *froli*[k]-*ing*, *crime-less*). The overriding generalization is thus in terms of the requirement that a stem be identical to an independent surface form, referred to as output-output (OO) faithfulness in the literature (Benua 1997), which is strong for one class of affixes, but weak for the other (Burzio 1994). Two ingredients are critical to a successful account. One is that morphology (interpretable as OO-faithfulness) must be constraint-based to compete with phonology this way. The other is that there must be no UR. The first ingredient, constraint-based morphology, can be taken to result from the REH, as argued in Burzio (2002b). Constraints like those in (24) and in (25b) and their ranking can be viewed as the result of summation of identical entailments across the lexicon. The second ingredient, absence of a UR level, is a natural hypothesis for a constraint-based system. To see how it is critical to the analysis, consider first that, in the Germanic/Level 2 case of (23), the UR would be simply superfluous. One only needs to assume a high-ranked OO-faithfulness (expressed here by (24)) to express the identity of each stem to the independent words. The effect of a lower-ranked faithfulness to a UR (termed input-output (IO) faithfulness) would be cancelled by the higher-ranked OO-faithfulness. In the case of (25), however, a hypothetical UR is not just superfluous, but false. To account for the long vowel in *na:ture*, one must assume the ranking "IO-Faith >> *V," the standard OT schema for marked choices. But if the same UR was input to both *na:ture* and *natur-al*, as is the case by the standard definition of UR as the common input to all allomorphs of the same morpheme, then *natur-al* should also have a long vowel. Just supplementing IO-Faith with OO-Faith is therefore not sufficient in this case. Rather, IO-Faith as faithfulness to a UR must be removed from the scene altogether, and the only principled way to do so is to drop the already unnecessary as well as insufficient UR. Hence, *na:ture* will be faithful to its own input with whatever rank the language at large has. The form *natur-al* will also be faithful to its input, but that input (except for *-al*) is the word *na:ture* and not a UR, and that ranking is determined by the particular morphological system, not by the language at large. Affixes like *-al* in (25), which are relatively unproductive and prone to idiosyncrasy, evidently establish relatively weak/low-ranked associations.

The notion of "cyclic" derivation would therefore have seemed right here in a way, requiring that *na:ture* be derived from a UR, while *natur-al* would be derived from *na:ture*. But such a notion has turned out to be right only when it reproduces (in a more complicated way) the effects of just dropping the UR from the theory, which forces reference to surface forms directly. In other respects, the cycle, and its cluster of attribute properties, prove to have been incorrect, as Kiparsky (1993) shows for the association "cyclic = blocking in NDE." The presumed further association "cyclic = lexical" (see discussion in Kenstowicz 1994: 195f.) also fails to hold. Here the notion "lexical" defines the presence of idiosyncrasy, while the property "cyclic" identifies, by its core definition, preservation of phonological structure, as in *cond*[ɛ]*nsation* (19a) above. As argued for (23), it turns out that such preservation is massive with Germanic/Level 2 affixes (no changes compared with the base word). This would make them "cyclical" if one took those definitions seriously. But idiosyncrasy is absent in the presence of those affixes, which would make them "non-lexical" (i.e. more like phrasal constructs). Conversely, Latinate/Level 1 affixes would be part of the "lexical" morphophonology by virtue of the noted idiosyncrasies, but the preservation effects they generate are in fact tenuous, *cond*[ɛ]*nsation* notwithstanding, making them only marginally "cyclic." As argued in Burzio (1991, 1993, 1994), such effects consist of only minimal distortions of the standard footing, as in e.g. *phe*(ˌ*nome*)'*nology* (to match *phe'nomenon*), or *a'merica*(ˌ*nist*Ø) (to match *A'merican*). As in underived items, adjacent stresses are ruled out, for example as in ˌ*cata'strophic*, ˌ*infor'mation*, ˌ*consul'tation* (*ca'tastrophe*, *in'form*, *con'sult*). This contrasts with the more robust distortion of cases like (23a) '*effort-less-ness*. As for the apparent preservation of stress in *cond*[ɛ]*n'sation* of (19a), it is argued in Burzio (1994: 185) that in fact it only concerns the details of vowel reduction rather than stress itself, though the relation with *con'dense* remains relevant.

This means that, when faithfulness to a base word specifically refers to stress, it is relatively low-ranked for the Latinate affixes, consistently with (25b) above, but not so low-ranked as to be totally ineffective. This accentual faithfulness, referred to as Metrical Consistency (MC) in Burzio (1994), is what accounts for long vowels in this sector of the lexicon, as argued in §3.2 above. Consider here the contrast between (26a) and (26b), along with the partial hierarchy in (26c).

(26) a. *de'si:rous*, *ad'he:rent*, *ex'tre:mist*, *di'vi:sive*, '*medi*ˌ*ta:tive*, . . .
 b. '*blasphemous*, '*aspirant*, '*hypnotist*, '*relative*, '*generative*, . . .
 c. MC, *V: >> IDENT(V-length)

The hierarchy in (26c) is taken to be dominated in turn by constraints mandating well-formed metrical feet which exclude, along with adjacent stresses and other degeneracies, stress on light penultimate syllables. This means that, when a long vowel and the stress of the base word both end up in a penultimate syllable in a derivative, as in all of the cases in (26a) and (26b), the two leftmost constraints in (26c) cannot be simultaneously satisfied. Either the vowel will have to fail to shorten, as in (26a), or the stress of the base will be lost, as in (26b). The variation between the cases in (26a) and those in (26b) then reveals that the grammatical system is indeterminate on the relative ranking of the two leftmost constraints in (26c), allowing lexical information to choose outcomes (see Burzio 2006). The effect observed for some of (13) above may also be at work, however. That is, items that are semantically very close to their base, as perhaps those in (26a) are to a greater extent than those in (26b), may end up accentually faithful as well, with no shortening.

In sum, the main class of exceptions to vowel shortening finds the principled account in (26c) leading to the conclusion that vowel shortening is – on its own – perfectly general (further scattered exceptions aside) in the Latinate lexicon. On the analysis in (26c), this would then be a case of what is referred to in the OT literature as "The Emergence of the Unmarked" (TETU; McCarthy 2002: 129f.; CHAPTER 58: THE EMERGENCE OF THE UNMARKED).

Other approaches to NDEB do not cover this type of case. Wolf (2008) refers to putative cases of this sort, in which the phonological process does not appear to depend on the specifics of the morphological operation, as "pseudo" DE effects, and suggests the existence of analyses that would bring them in line with the non-pseudo cases. Successful re-analysis is critical to his approach, which predicts non-existence of pseudo DE effects. The reasons for this prediction by Wolf's serial OT approach are effectively the same as the reasons excluding assibilation of tauto-morphemic /ti/ in the Finnish case discussed above. Specifically, and for example, if vowel shortening as in *div*[ɪ]*n-ity* was due to an a-contextual

"*V:" constraint, then the same output will be produced whether shortening applies before or after affixation of *-ity*. But then a mechanism of "chain merger" would remove any ordering between the two operations, so that a putative precedence constraint PREC(insert-affix, IDENT[cont]) will always be violated if shortening applies, thus keeping all vowels long if high-ranked, while allowing all to shorten, including in **div*[ɪ]*ne*, if low-ranked.[5] However, while Wolf (2008: §4.3.5) does review the above "TETU" analysis of vowel shortening, he provides no alternative to it. He also concedes the existence of other cases of markedness reduction under affixation, such as those in (7e) and (7f) above, which the TETU analysis can handle, but which he attributes to failure of a feature to "percolate" up the morphological structure (2008: 268), an additional mechanism, in his perspective.

76 Structure Preservation: The Resilience of Distinctive Information

Carole Paradis
Darlene LaCharité

1 Introduction

All languages have a phonemic inventory, including a set of distinctive vowels and consonants, i.e. linguistic sounds that contribute to the meaning of a word. For instance, *chip* [ʧʰɪp] contrasts with *cheap* [ʧʰip] in English, on the basis of the vowel quality; in the first case, the high front vowel is lax, whereas in the second one it is tense. We therefore say that /ɪ/ and /i/ are two distinct phonemes (segments) in English (CHAPTER 11: THE PHONEME) and that [tense] is a distinctive feature (CHAPTER 17: DISTINCTIVE FEATURES) for high vowels in this language.[1] While phonemic inventories are built in agreement with the principles of Universal Grammar (UG), the exact composition of a phonemic inventory varies from one language to another. Along with the suprasegmental inventory, the phonemic inventory is a good part of what allows a listener to identify a language at first glance and to distinguish it from other languages. We expect speakers to resist either dropping phonemes or phonemic contrasts from their language's inventory, or introducing new phonemes and phonemic contrasts – although this constitutes the bread and butter of language change – since the automatic consequence of such moves is a different system. We believe that resistance to change cannot be due simply to inertia – it is not passive. In this chapter we will try to show that resistance to change is, above all, a question of contrast/category pattern resilience in the mind of the speaker, which is expressed intralinguistically (i.e. resistance to change due to the passage of time, dialect contact, etc.) and also interlinguistically (between L2 and L1, as will be illustrated in §3 with respect to loanwords). We will link contrast resilience to the traditional notion of Structure Preservation, providing a history of this notion in generative grammar in §2, and considering in §3 the question of whether it is still pertinent now that phonological rules have given way to constraints. We will also address the relation between Structure Preservation and phoneme/structure resilience in loanword adaptation from the point of view of L1 and L2. We conclude in §4.

[1] Even if /i/ and /ɪ/ were to be distinguished by vowel length instead of tenseness, as proposed by some authors, the point made here would stand.

2 The history of Structure Preservation

It has long been noted that, intralinguistically, languages (or, more properly, their speakers) resist phonemic change before succumbing to and accepting a new phonemic contrast. Changes to a given phonemic inventory follow defined steps, which are gradual, and characteristically occur over a long period of time (CHAPTER 2: CONTRAST). Although such sound changes can sometimes occur relatively rapidly, it is not unusual for them to take centuries to complete. Broadly speaking, a small phonetic detail becomes sufficiently large over time that what begins by distinguishing phonetic variants ends up being categorical, i.e. phonemic (see Harris 1990 and Bybee 2008 for a detailed description of these steps). Clearly, though, the forces of change are counterbalanced by resistance to change, or intralingual change would typically proceed at a much faster rate and produce much more dramatic results than it usually does (CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME).

The lexicon is the crucial place where the battle between the forces of change and resistance to change takes place. In Lexical Phonology, the resistance to using non-phonemic sounds or sound combinations at the lexical level was expressed through the notion of Structure Preservation (SP). In Kiparsky (1982, 1985), SP regulated the application of phonological rules, constituting a ban on the introduction of phonemes at the lexical level that are not part of the underlying inventory.

(1) *Structure Preservation* (Kiparsky 1985: 88)

If a certain feature is non-distinctive in a language we shall say that it may not be specified in the lexicon. This means that it may not figure in non-derived lexical items, nor be introduced by any lexical rule, and therefore may not play any role at all in the lexical phonology.[2]

The model assumed by Kiparsky is basically that in Figure 76.1:

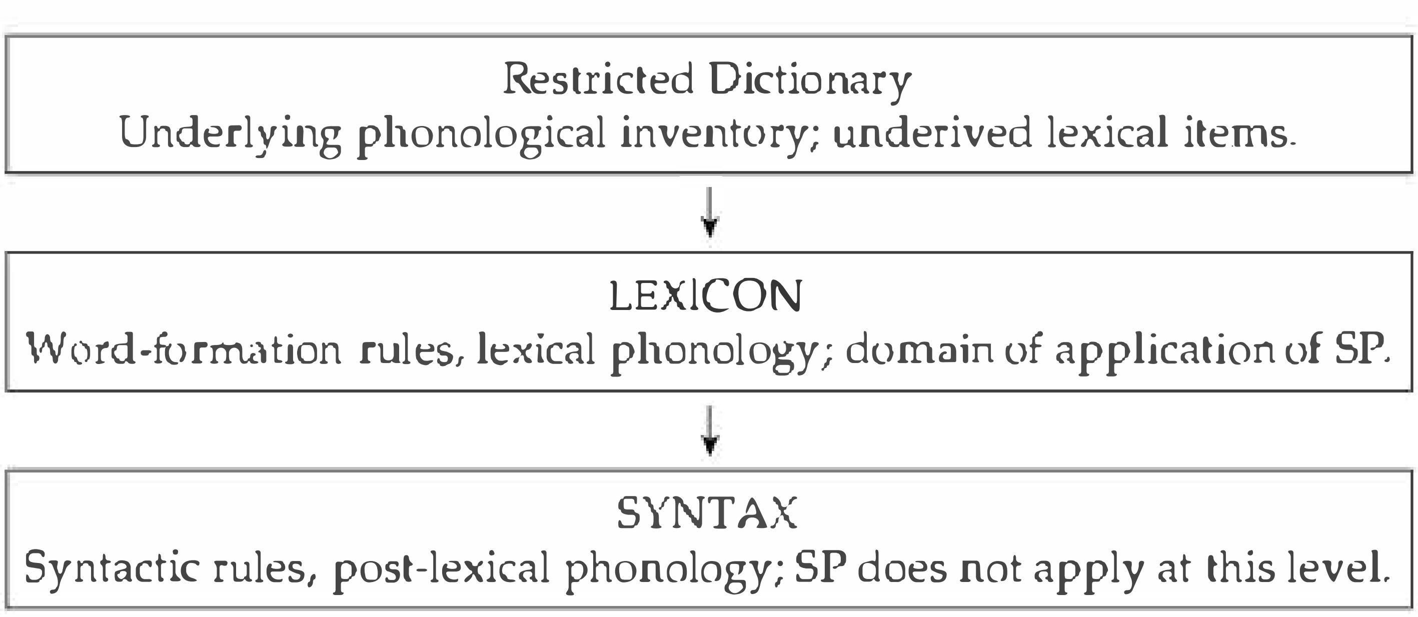

Figure 76.1 Lexical Phonology (Kiparsky 1982)

[2] Kiparsky does not present this constraint formally. The constraint given here is a description of SP as presented in the text by Kiparsky (1985: 88).

As Harris (1987: 255) puts it, "the lexical segment inventory of a language (the output of the lexical rules) must be isomorphic with the underlying inventory." Bybee (2008: 111) adds: ". . . alternations that are restricted to the word level involve only contrastive features. Segments or feature combinations that are non-contrastive must be introduced by postlexical rules . . ."[3]

Mohanan (1986) considers the formulation of SP given in (1) to be too restrictive. According to Mohanan, the Malayalam and English facts cannot be explained if SP is interpreted as in (1), so he softens it, saying instead, "the alphabet used for syntactico-phonological representations is the lexical alphabet" (1986: 174). The lexical alphabet refers to the phoneme inventory at the lexical level, which is the result of lexical (as opposed to post-lexical) application of phonological rules.[4] In Figure 76.1, Mohanan's lexical alphabet would be generated in the lexicon module by phonological rules that apply at this level. Of particular present relevance, the lexical alphabet in the view of Mohanan and Mohanan (1984) and Mohanan (1986) can contain distinctions that are absent from the underlying inventory (found in the restricted dictionary in Figure 76.1). The Malayalam case, detailed in Mohanan and Mohanan (1984), focuses primarily on contrasts in the system of nasals. The crux of the issue is that to achieve an elegant analysis of apparently complicated surface distributional restrictions on stops and nasals in Malayalam, one needs to assume that at the underlying level there are three nasals (bilabial, alveolar, retroflex), but that at the lexical level there are seven (bilabial, dental, alveolar, palato-alveolar, retroflex, palatal, velar). At the heart of their analysis is the clearly lexical application of two phonological rules (one that changes post-nasal voiced stops to nasals, and another that changes intervocalic [−continuant] velars to palatals when preceded by front vowels), which produces nasals with places of articulation that are not underlying for that class of sounds.

Still, the most widespread interpretation of SP in Lexical Phonology remains essentially the same: phonological rules are not expected to generate new phonemes or phonemic contrasts at the lexical level, nor are phonemes expected to undergo absolute neutralization at this level (CHAPTER 80: MERGERS AND NEUTRALIZATION). Any operations that introduce features that are not distinctive underlyingly are predicted to be necessarily post-lexical. For instance, French has a rich vocalic system that includes the mid-back lax and tense vowels /ɔ/ and /o/ (e.g. *hotte* [ɔt] 'hood' *vs.* *haute* [ot] 'high'). Although both vowels are frequent, /ɔ/ is prohibited word-finally in French (*/ɔ/#), at the lexical level. If a morphological operation produces a word-final /ɔ/ in the course of a derivation in French, it is systematically turned into [o]. Various morphological operations generate such a result; they include abbreviation (e.g. *Caroline* [kaʀɔlin] → *Caro* [kaʀo], *condominium* [kɔ̃dɔminjɔm] 'condominium' → *condo* [kɔ̃do]), gender inflection (e.g. *sotte* [sɔt] 'silly (FEM)' *vs.* *sot* [so] 'silly (MASC)'), verbal and adjectival derivation (e.g. *roter*

[3] Sproat (1985: 454) says that Structure Preservation could be interpreted as a restriction on contrasts that are the output of lexical rules, rather than a restriction on underlying representations. However, as Harris (1987: 259) points out, "given its inherent circularity [this interpretation] of Structure Preservation is hardly worthy of serious consideration."

[4] Mohanan and Mohanan (1984: 590) and Mohanan (1986: 12) consider that phonological rules are all part of a single independent phonological module and that they interact with either the lexical or post-lexical level or both, according to their domain specifications. Application in one domain or the other is subject to different restrictions. Notably, lexical application is subject to SP, provided that SP is interpreted in the less stringent manner indicated above.

[ʀɔte] 'to belch' *vs. rot* [ʀo] 'belch' (N)), reduplication (e.g. *dormir* [dɔʀmiʀ] 'to sleep' > *dodo* [dodo] 'sleep (N, child language)'), etc. The result is always the same: /ɔ/# → [o]#. Nonetheless, the restriction */ɔ/# in French does not apply at the post-lexical level. For instance, in Quebec French, final /a/s are systematically pronounced either as [ɑ] or [ɔ] (e.g. *chocolat* [ʃɔkɔlɑ], [ʃɔkɔlɔ] 'chocolat'; *matelas* [matlɑ], [matlɔ] 'mattress') or something in between, despite the fact that the lexical restriction */ɔ/# also applies in this variety of French. We know that [ɔ] and [ɑ] are variants of /a/ in such cases because derivatives such as *chocolaté* [ʃɔkɔlate] 'with chocolat' and *matelassé* [matlase] 'padded' indicate that the underlying vowel is /a/. Gradient and unstable rules such as /a/ → [ɑ] or [ɔ] in Quebec French are typically post-syntactic rules that are predicted not to occur at the lexical level (Mohanan 1986: 174). The existence of clearly necessary categorical constraints, such as */ɔ/#, alongside the existence of forms that clearly do not obey them is the kind of case that SP is intended to explain: a phonetic process can apply at the post-syntactic level in spite of the fact that its effect contradicts that of a phonotactic constraint at the lexical level.

Another classic example of a lexical (hence structure-preserving) rule, is velar softening in English (and also in French), where /k/ yields [s] before a high front vowel (e.g. *electric* [ilɛktrɪk] *vs. electricity* [ilɛktrɪsɪti]). As reiterated by Bybee (2008: 112), this rule does not apply between words, is unproductive, lexically restricted, and morphologically conditioned. In contrast to this lexical alternation, /k/ in English, as in French, has a palatal variant [c] before a front vowel, as in *key* /ki/ → [ci], *kiss* /kɪs/ → [cɪs], etc. (in French, *qui* /ki/ 'who' → [ci], *quitter* /kite/ 'to leave' → [cite], etc.). The emergence of the palatal variant in both languages is automatic, productive, and neither lexically nor morphologically restricted. SP embodies the claim that such an assimilation rule could not apply at the lexical level because, in both French and English, it would introduce at this level a sound, [c], that is not part of the phonemic inventory of either language (see Kiparsky 1985 for a discussion of many other assimilation and harmony processes that are non-structure-preserving and which he shows are post-lexical).

However, SP has been challenged on a variety of fronts. Its domain of application has been debated vigorously. Kiparsky (1982, 1985) proposes that lexical rule application is subject to SP but post-lexical application is not. However this neat division of territory between structure-preserving and non-structure-preserving rule application has proven to be doubtful. For example, Kaisse (1990), Rice (1990), and Hyman (1993) agree that SP is not necessarily turned off in the post-lexical component. In other words, post-lexical rules can be subject to SP. On the other hand, Harris (1987: 256) argues, mainly on the basis of a certain type of vowel harmony in southern Bantu languages, that "failure to preserve structure cannot be reliably considered proof of a rule's postlexical status." That is, lexical rule application is not necessarily subject to SP.

Harris (1987, 1989, 1990) discusses other allophonic processes that must be lexical, but that are not structure-preserving (see also discussions in Mohanan 1995 and Steriade 1995), but one of the best-known problematic cases is the distribution of [ç] and [x] in modern German. According to Hall (1989), there is no underlying contrast between velar and palatal fricatives in German; the feature [back], though distinctive for vowels in German, is not distinctive for fricatives. The [ç] *vs.* [x] contrast results from a rule of fricative assimilation that spreads the backness feature from a vowel to a following voiceless high fricative. Crucially, fricative assimilation applies lexically and it produces a phoneme/phoneme contrast that is not underlying. Hall (1989: 1) concludes that the rule of fricative assimilation is "a blatant counterexample to SP." We will address this case more thoroughly later.

Macfarland and Pierrehumbert (1991) propose an alternative view, which is intended to salvage the integrity of SP. In their view, non-distinctive features introduced at the lexical level stem from spreading, resulting in doubly linked structures. In the German case just discussed, the [back] feature of the vowel spreads to the feature matrix of the following fricative /X/, which is unspecified for backness. This results in the feature [back] being simultaneously linked to the vowel and the following fricative consonant. By virtue of their double linking, such structures are technically exempt from SP (as well as from a condition they call the marking condition). Though the solution might work for this and some other problematic cases that challenge SP, it does so at the cost of seriously weakening the SP constraint. Iverson (1993) proposes instead an approach that re-examines the relationship among some of the constellation of properties originally intended to distinguish between lexical and post-lexical rules or rule application, namely SP, and the restriction of applying to derived environments. In classical Lexical Phonology, a lexical rule had certain properties, two of which were that it preserved structure and that it applied in derived environments. SP is a consequence of a rule's lexical status in that view. Iverson turns this relationship on its head (1993: 265); if a given rule preserves structure, then it observes the derived environment constraint. This arguably explains the clustering of properties previously considered to be diagnostics of a rule's lexical or post-lexical status, but it implies that SP is a property of some, but not necessarily all, lexical rule applications. Indeed, Iverson concludes (1993: 270) that "... structure-building applications of lexical rules need not (though may) be structure-preserving."

As the previous discussion suggests, SP, as formulated by Kiparsky (1982, 1985) was inextricably linked to the overall architecture and other principles (e.g. the Strict Cycle Condition and the Derived Environment Constraint) and theoretical tools (e.g. underspecification) of Lexical Phonology. To reiterate, SP was part of a set of properties that distinguished lexical from post-lexical rule applications. Like many other notions of Lexical Phonology, SP was found to be problematic for a variety of reasons. For instance, even if we accept the view of Mohanan and Mohanan (1984: 589) that phonological rules whose domain of application is lexical yield the "lexical alphabet" – to be distinguished from the underlying one, found in the restricted dictionary in Figure 76.1 – it seems clear, as indicated by the work of a number of phonologists working on several different languages, that we cannot uphold the position that lexical rule application is necessarily structure-preserving while post-lexical rule application is not. For example, as mentioned previously, Iverson (1993) argues that lexical rules are not necessarily structure-preserving, while Rice (1990) argues that post-lexical rules may be. However, this is only one problem facing SP. Another is that SP has resisted formulation, interpretation, or application in any way that can be universally applied to yield felicitous results. Different attempts, including reformulation (e.g. Mohanan 1986: 174; Borowsky 1989: 148), reinterpretation (e.g. Macfarland and Pierrehumbert 1991: 179; Iverson 1993: 265), or restriction of its application to some, but not all, lexical levels – often on a language-specific basis (e.g. Borowsky 1986, 1989) – yield no universally satisfactory outcome. Moreover, such attempts often have extremely damaging consequences for the theory and the SP principle. For example, the effect of Mohanan and Mohanan's (1984) analysis of Malayalam and their distinction between an underlying and a lexical alphabet is to allow rules to introduce contrasts that are not underlying. This is clearly at odds with Kiparsky's (1982) view of the role that SP plays. A closely related problem is that, under no formulation or interpretation, in any language through which the principle has been test-driven to any extent, has SP been found to be exceptionless (see the discussion of Bybee 2008 below).

What has the outcome of the challenges to SP been? Sproat (1985), who rejects Lexical Phonology's approach to word formation altogether, considers SP completely dispensable, along with the rest of the theory. However, few phonologists would go this far. Although some, such as Mohanan (1989: 609) and Hall (1992: 233), have given up on reformulating SP, or tweaking the conditions of its application, and concluded that it is not a linguistic universal, they still consider it a cross-linguistic tendency. As Steriade (2007: 146) asserts, "... Structure Preservation cannot be abandoned altogether. ..."

Bybee (2008) has picked up the idea of SP as a cross-linguistic tendency rather than a true synchronic generalization or principle of language. She proposes to interpret the constraint as a result of "paths of change," saying "Three well-documented universal paths of change occur in parallel and lead to the synchronic situation that is described as Structure Preservation" (Bybee 2008: 114). She also says that it is some sort of restatement of the older structuralist principle of "separation of levels" where phones are distributed by phonetic criteria and phonemes by lexical and morphological ones.[5] In Bybee's view, because SP is an emergent property of recurring mechanisms of language change (that feed and complement each other), counterexamples to this constraint are unavoidable and expected. The thinking behind this is that since the transition from phonetic to phonemic status is gradual, there will always be linguistic sounds that are introduced in a language lexicon with the initial status of phone, either native or foreign, which will later acquire the status of phoneme. However, while some instances make the transition from variant to phoneme, others instances do not, or at least not at the same time. More concretely, Bybee explains that purely phonetic sounds can gradually be disassociated from their phonetic conditioning and become associated with particular lexical or morphological conditions. An example discussed extensively in the structuralist and generativist literature, and already pointed out in this section, is the case of German [x] and [ç] (see Bybee 2008: 112 for a synopsis and Hall 1992 for more detailed discussion). In brief, [ç] and [x] were originally variants, with [ç] occurring after a front vowel in German. When the German diminutive suffix *-ichen* [içən] lost its conditioning front vowel and the shortened suffix *-chen* [çən] started to appear after a back vowel, [x] and [ç] (arguably) became distinctive (e.g. *Kuhchen* [kuːçən] 'little cow' *vs. Kuchen* [kuːxən] 'cake').[6] The distinctiveness of /ç/ *vs.* /x/ was reinforced by the fact that /ç/ could also occur at the beginning of loanwords in some German dialects, where

5 Except that SP avoids the duplication problem that classical phonemics (structuralists) faced. Indeed, in classical phonemics, a generalization had to be stated twice, once at the level of phonemes and once again at the level of phones, because of the separation of levels.

6 However, Macfarland and Pierrehumbert (1991: 171) do not recognize this as a minimal pair because "*Kuchen* is a monomorphemic noun [as opposed to *Kuhchen* 'little cow']." They maintain that there are no true minimal pairs distinguishable only by [ç] *vs.* [x] in German.

the initial phonetic conditioning (the preceding front vowel) is obviously absent.[7] To take another example, this time from English, the non-anterior voiced fricative /ʒ/, which initially occurred in the Early Modern English Period as a result of stress-conditioned palatalization (/zj/ > [ʒ]; e.g. *pleasure* [pleʒəɹ] from French *plaisir*), has begun to be allowed in word-final and even word-initial position under the influence of more recent French borrowings such as *rouge* [ruʒ], *beige* [beʒ], *garage* [gəɹɑʒ], *massage* [məsɑʒ], *camouflage* [kæməflɑʒ], *luge* [luʒ], *genre* [ʒɑ̃r], *joie de vivre* [ʒwɑdeviv], etc. (see Millward 1996: 252–253). Similar to the German situation, the appearance of /ʒ/ in these environments cannot be due to phonetic conditioning. In short, the picture that emerges is that what originated as phonetic variants in the German and English examples might have become phonemes (albeit ones with sometimes restricted distribution) due to, among other things, the pressure of loanwords.

This is one path of change; concurrent with that are two others. The second is that small phonetic changes tend to become larger ones over time, leading to a greater phonetic distance between the original sound and its variant. If we take the [ç] ~ [x] alternation, the variant [ç], which is unstable and phonetically close to /x/, is becoming more stable and more clearly distinct phonetically from /x/ over time (see Bybee 2008: 113). The third related path of change discussed by Bybee is loss of productivity as phonetic processes become lexicalized. To sum up, variants come to occur at the lexical/morphological level because of the diachronic tendency of phonetic changes to become linked to particular lexical items or morphological processes, creating a shift from the purely phonetic to the lexical level. As a result of being linked to particular morphological or lexical conditions, the phonetic conditions that originally give rise to the variant can lose their automatic productive power. Once the link between a sound and its (phonetic) conditioning environment is broken, the sound is "liberated," as it were, and free to enjoy wider phonotactic/syllabic distribution, giving it phonemic as opposed to purely phonetic status (see also Harris 1990: 93). SP has exceptions because such change does not affect the entire vocabulary at once, but rather proceeds via normal processes of lexical diffusion (see e.g. Phillips 2006 on lexical diffusion and its links to various sound-based phenomena).

Is that the end of the story? Kiparsky (2008) clearly disagrees with the diachronic view. He summarizes the situation as follows:

> An increasingly popular research program seeks the causes of typological generalizations in recurrent historical processes, or even claims that all principled explanations for universals reside in diachrony. Structural and generative grammar has more commonly pursued the reverse direction of explanation, which grounds the way language changes in its structural properties. (Kiparsky 2008: 52)

Kiparsky points out (2008: 27) that, once spelled out, historical explanations like those proposed by Neogrammarians or, more recently, those working in the diachronic view (e.g. Bybee 2008) often turn out to appeal implicitly to tendencies that are themselves in need of explanation. In other words, there must be principles

[7] According to Marc van Oostendorp (personal communication), there might remain some sort of phonetic conditioning in loanwords, however, since [ç] can occur only before a front vowel word-initially.

governing the nature and extent of change, which are ultimately responsible for the tendencies that are observed. He proposes criteria to distinguish true universals, which constrain language change, from typological generalizations, which result from language change, and adds: "The issue goes well beyond the simple question how cross-linguistic generalizations originate. It is about the nature of those generalizations themselves" (Kiparsky 2008: 27). He also raises the possibility (2008: 25) that functional explanations for language change might have become biologized within UG itself, through language use, thereby constraining change also via acquisition.

Though the argument we present below does suggest that a guiding principle of grammars is the pressure to preserve structure, which cannot be simply a side-effect of sound change over time, our goal in this chapter is not to argue whether SP is a basic principle of UG, as opposed to an emergent property of converging processes of language change. Rather, we hope to show, using primarily the phonological treatment of loanwords, that distinctive information is, indeed, highly resistant to destruction or alteration at the lexical level, not only intralinguistically, but interlinguistically too. Whatever problems SP has faced, or continues to face, there is no doubt that distinctive phonological information is resistant to change, so some notion of Structure Preservation is still needed, even under current constraint-based approaches, both derivational and non-derivational. The essence of our argument is that if there were no notion of Structure Preservation synchronically active in grammars, we could not explain why a borrower works so hard to preserve distinctive information from a foreign system (L2) in his/her own language (L1). Why should he/she care in the first place?

3 A broader perspective of Structure Preservation

3.1 *Structure Preservation in loanword adaptation*

> Languages . . . which have undergone striking changes in their lexicons through the additions of thousands of borrowed words can no doubt be expected to trouble phonologists for some time. (Kaisse 1990: 141)

Because borrowing normally takes words conforming to the sound patterns and restrictions of one language (the source language, L2) and makes them conform to those of another (the borrowing language, L1), loanwords routinely present the need to modify or destroy phonological information (cf. also CHAPTER 95: LOANWORD PHONOLOGY). A priori, borrowing includes three phenomena that seem to challenge the notion of Structure Preservation. These are the modification of sounds, the deletion of sounds, and, apparently paradoxically, the importation of sounds at the lexical level. Of these three phenomena, deletion and importation are, on first impression, the most problematic. However, as we will see, phoneme deletion seldom occurs and importation is respectful of L2's phonological integrity. We believe this, along with other facts to be discussed, makes loanwords especially relevant to the study of Structure Preservation, provided one accepts an enlargement of its scope. We will henceforth use the full form, "Structure Preservation," to refer to this larger conception of the constraint. SP will refer to the notion of Structure Preservation as defined by, and linked to, Lexical Phonology.

If, instead of seeing the Structure Preservation constraint as just a ban on the introduction of non-phonemic sounds or distinctions at the lexical level, we interpret it as a form of pressure to preserve any contrastive information (features, phonemes, phonemic patterns, unpredictable syllabic information, etc.), then observing the way loanwords are adapted becomes extremely relevant. This is what we propose to discuss here. As we will show in the next sections, especially in §3.2 where the statistics from a large loanword database, that of the CoPho Project,[8] are presented, L2 distinctive information is very seldom squarely destroyed in L1. Instead, L2 distinctive information, when it is not imported, is normally phonologically "adapted" in the borrowing language, with as few adjustments as possible, i.e. minimally. If there were no constraint on synchronic grammars to preserve structure, then there should be no reason for phoneme deletion to be so scarce in loanwords and for adaptations to be minimal.

The notion of minimal adaptation is closely tied to the generally agreed idea that in loanword adaptation, languages normally seek to replace unacceptable foreign sounds with those that are "closest." There is disagreement over how closeness is defined: a matter of some contention in the field of loanword adaptation is whether closeness is determined primarily on phonological grounds, as we maintain, or whether it is determined mainly phonetically (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). Our present purpose is not to debate this issue, but rather to present statistics from large corpora of loanwords in several languages that indicate that L2 distinctive information is routinely maintained to the maximum allowed by the L1 phonological constraints. In the parlance of the Theory of Constraints and Repair Strategies (TC),[9] this is attributable mainly to two principles, the Preservation Principle and the Minimality Principle, which conspire, we believe, to produce this result. As we will endeavor to show, both principles could be instantiations of the pressure to preserve structure in the larger sense that we propose here.

3.2 *Adaptation, deletion, and Structure Preservation*

The data used to illustrate the effects of preservation in loanwords are taken from the CoPho Project's loanword database, which includes general corpora of French borrowings in Canadian English, Moroccan Arabic, Kinyarwanda, and Lingala, and English borrowings in Calabrese Italian, Japanese, Mexican Spanish, Quebec French, Parisian French, etc. The main findings yielded by the analysis of the CoPho database are summarized in Table 76.1.

The first relevant point to note about the figures in Table 76.1 is that L2 distinctive phonological information is systematically adapted in L1 (34,070/50,092 cases, i.e. 68 percent), as opposed to being deleted (3.3 percent of cases). Phonological adaptation, which is simply called "adaptation" here, is the modification/replacement (i.e. repair) of an L2 sound or structure to comply with one or more L1 phonological constraints. Adaptation is linked to Structure Preservation insofar as it is geared to ensuring that the L1 contrastive system remains unchanged (see

[8] CoPho stands for constraints (Co) in phonology (Pho). The project is supervised by Carole Paradis at Laval University, Quebec City.
[9] TC (previously TCRS) was originally proposed by Paradis (1988).

Table 76.1 The CoPho Project loanword database of phonemic and supraphonemic malformations (updated August 2009)

General information				*Malformations*				
Corpora	*Loans*	*Forms*	*Total*	*Phonological cases*[a]				*Non-phonological cases*
				Total	*Adaptations*[b]	*Importations*	*Deletions*	*Total*

[a] Percentages of phonological and non-phonological cases are calculated on the total number of malformations.
[b] Percentages of adaptations, non-adaptations, and deletions are calculated on the total number of phonological cases.

LaCharité and Paradis 2005, Paradis and Tremblay 2009, and Paradis and LaCharité, forthcoming, for discussion), and is the norm.

Table 76.1 also shows that if foreign sounds are not adapted, they are normally imported, i.e. left unadapted, as opposed to being deleted. Importations/non-adaptations account for 14,391/50,092 (28.7 percent) of the phonological cases (importation is discussed in §3.5). Deletions, which might be seen as *prima facie* counterexamples to the idea that structure is preserved in loanword adaptation, are rare in the database overall. Deletions that have been classed as phonological are those that can be explained by the phonological principles of the theory; the others have been classed as non-phonological precisely because they cannot be predicted on phonological grounds. In the phonological cases, the rate is well below 10 percent in any individual corpus and is only 3.3 percent in the corpora overall (1,631/50,092 phonological cases). Non-phonological cases represent only 4,351/54,443 cases (8 percent). Therefore, whether we consider only phonological cases, or we include non-phonological cases (8 percent) as well, deletion of a phoneme is uncommon in the CoPho loanword database. Moreover, not all non-phonological cases involve deletions, and those that do may not always be best explained as such. As shown in Paradis and LaCharité (2008), who address the treatment of non-phonological cases in three corpora of old and recent Quebec French, phoneme deletion is uncommon even in non-phonological cases. Very often, it results from analogy, real or false (e.g. QF [lɪpsɪŋ] instead of [lɪpsɪŋk] for English *lip-sync*; the absence of /k/ in the QF borrowing is not a case of phoneme deletion per se, but rather a case of false analogy to the English verb *to sing*). Lexical truncation, such as QF *tan* for English (*sun*) *tan*, is also sometimes responsible for the disappearance of L2 phonemes (here *sun*); cf. also lexical truncation in QF *parking* from English *parking lot* and French *pull* from English *pullover*. In our view, these lexical truncations should not be seen as phoneme deletion, since deletion does not occur on the basis of phonemes, but of lexical items. Paradis and LaCharité (2008, forthcoming) suggest that these non-phonological processes, along with hypercorrection, phonetic approximations, etc., are responsible for many so-called "divergent repairs" and "unnecessary repairs" (see CHAPTER 95: LOANWORD PHONOLOGY).

We attribute the rarity of deletion to the Preservation Principle in (2) (see e.g. Paradis *et al.* 1994; Paradis and LaCharité 1997).

(2) *Preservation Principle*

Phonemic information is maximally preserved, within the limits of constraint conflicts.

The Preservation Principle is a TC mechanism first proposed by Paradis *et al.* (1994) and used extensively to analyze the CoPho loanword database (see e.g. Paradis and LaCharité 1997).[10] However, we are not the only ones working in loanword adaptation to have seen the need for such constraints; for example, Calabrese (2005)

[10] TC is not restricted to loanwords; we do not maintain that the processes observed in loanwords are independent of general phonology. Nonetheless, it might be that the Preservation Principle is more evident in loanword adaptation than in native phonology, where the influence of morphology and residual historical processes play a greater role.

invokes comparable mechanisms, the Principles of Economy and Last Resort.[11] As previously stated, deletions are *prima facie* violations of (2). However, not only are L2 phoneme deletions rare in the CoPho database, but most are also highly predictable. As we will try to show, deletion is, for the most part, phonologically predictable, and most phonologically predictable deletion can be reconciled with the notion of Structure Preservation.

There are two main scenarios in which phoneme deletion occurs. The first scenario involves deletion of a guttural – sounds characterized by a Pharyngeal node – by languages that do not use this primitive in the representation of the sounds of their native inventories. A language that does not employ this primitive cannot adapt a guttural (see Paradis and LaCharité 2001 for a detailed discussion on the treatment of gutturals in loanwords). For instance, neither French nor Italian have a guttural in their phonemic inventories,[12] so neither language is equipped to adapt a phonemic guttural such as English laryngeal /h/. Instead, they delete it (e.g. English *hamburger* [hæmbəɹgəɹ] yields Quebec French (QF) [_ambəɹgəɹ] and Italian [_amburgər]). The systematicity of guttural deletion is indicated by the figures of the three contemporary QF corpora (see Paradis and LaCharité 2001: 264). There are, overall, 173 cases of /h/ in English loanwords in QF; deletion applies in 163 cases (94.2 percent). The remaining ten cases are importations in the Montreal French corpus. The figures for the Calabrese Italian corpus reinforce this point and further illustrate the fact that guttural deletion accounts for the preponderance of deletions in the CoPho database. In the Calabrese Italian corpus of English loanwords, there are 296 cases of /h/ in the English input. In only 23/296 cases (7.8 percent) is English /h/ imported; the rest of the time it is deleted, meaning that there are 273 /h/-deletions in the Calabrese Italian corpus. Since there are only 278 deletion cases in that corpus overall, this means that /h/-deletion accounts for 98.2 percent of them (273/278). The vast majority of the 3.3 percent of deletions in the CoPho database concern guttural consonants in languages that do not exploit the Pharyngeal node. Such deletions would not be a violation of Structure Preservation from the point of view of L1, because the borrowing languages do not have a native guttural contrast to preserve and are not phonologically equipped to preserve that of L2, as argued in Paradis and LaCharité (2001).

The second general source of phoneme deletion involves the loss of a coda /r/ in borrowings by languages that do not allow (rhotic) codas (CHAPTER 30: THE REPRESENTATION OF RHOTICS).[13] This is the case in Japanese, which allows only N or the first part of a geminate in codas (see Itô 1986 for details of the coda condition in Japanese). Coda consonants in English borrowings in Japanese are systematically adapted by vowel insertion; this has the effect of moving the problematic coda consonant to the onset of the following new syllable (e.g. English

[11] Calabrese's (2005: 20) principles of Economy ("Use the minimal amount of maximally relevant units") and Last Resort ("Use a maximally relevant operation minimally") are highly reminiscent of TC's Preservation and Minimality Principles, and serve the same structure-preserving function.

[12] French [ʁ] and [ʀ] are just two of the numerous variants for the coronal /r/ in French; in contrast with /ʁ/ in Arabic, these sounds are not phonemic in French.

[13] Another predictable, but statistically marginal, source of deletion results from violation of the Threshold Principle (Paradis and LaCharité 1997). This principle offers an explanation for several "atypical" deletion cases, including vowel-initial deletion in French polysyllabic loans introduced in Moroccan Arabic (see Paradis and Béland 2002 for an in-depth discussion of this case and, more generally, Paradis and LaCharité, forthcoming).

optimism [ɑptəmɪzəm] > Japanese [opɯtimizɯmɯ]). However when the coda is a rhotic, instead of having vowel insertion, merger of the rhotic with the preceding vowel occurs (804/804 cases; e.g. English *order* [ɔɹdəɹ] and *corner* [kɔɹnəɹ] > Japanese [oːdaː] and [koːnaː]).[14] Deletion of /r/ also causes vowel lengthening in Thai, where it is not permitted in the coda. For instance, English *care* [kɛɹ], *carbon* [kɑɹbən], *cartoon* [kɑɹtun], *party* [pɑɹti], *poker* [pokəɹ], and *star* [stɑɹ] are pronounced [kʰɛː], [kʰaːbɔn], [gaːtuːn],[15] [paːti], [pokəː], and [sətaː], respectively.[16] Deletion of /r/ is not limited to loanwords that come from English. It also occurs in loanwords from French. For instance, French *Argentine* [aʀʒɑ̃tin], *arrière* [aʀjɛʀ], *beurre* [bœʀ], *carte* [kaʀt], *carton* [kaʀtɔ̃], *orchidée* [ɔʀkide], and *radar* [ʀadaʀ] yield Khmer [aːzɑ̃tin],[17] [aːjaː], [ɓəː], [kaːt], [kaːtɔ̃], [oːkiːɗeː], and [raːɗaː], respectively. In some cases, the French rhotic is replaced with /a/ or a glottal stop, as in [oːpaːlua] and [pɛʔmiː] from French *haut-parleur* [oparlœʀ] and *permis* [pɛʀmi]. As can be seen, the deletion of /r/, which is prohibited in coda position in Khmer, causes vowel lengthening even in closed syllables, as in [kaːt] from French *carte*.[18] This latter set of examples in Khmer shows that apparent /r/-deletion is not influenced by the pronunciation of /r/ in the donor language, since French and English have very different rhotics. Vowel lengthening suggests that /r/ might not really be deleted but rather fused with the preceding vowel, when it is not replaced with /a/ or a glottal stop. This is why we have not incorporated these cases in the deletion column of the statistics in Table 76.1. If we are correct in viewing vowel lengthening as /r/-adaptation rather than /r/-deletion, it does not contradict the idea of Structure Preservation that is invoked here. However, even if we did consider these cases of deletion, the deletion rate would still remain very low (2,435/50,091 – 4.9 percent instead of 3.3 percent).

In Paradis and LaCharité (forthcoming), we attribute /r/-deletion to the fact that /r/ is vowel-like and can easily be fused with the preceding vowel, whether it results in vowel lengthening or not. We envision that, perhaps, as in the case of /h/-deletion in English loanwords in French, Italian, Portugese, etc., the answer lies in the phonological structure of /r/. Rhotics with a variety of phonetic realizations are prone to deletion, cross-linguistically, and they exhibit several phonological behaviors that are not yet well understood. For example, in many different languages, where the rhotics exhibit diverse phonetic realizations, a coda /r/ is deleted, or merged with, transformed into, or replaced by, a vowel. To cite just a few of many possible examples, in German, where /r/ is phonetically uvular, coda /r/ can lower to something akin to a low vowel, so that *tür* 'door' is realized as [tyːɐ] in the singular (Wiese 1996) but *türen* [tyrən] in the plural, that is with the full rhotic, where it is in onset position. In Quebec French, coda /r/, which can be realized as a uvular or a coronal, is often deleted word-finally in informal speech (e.g. *bonjour* /bɔ̃ʒur/ 'good day' → [bɔ̃ʒu(ː)]). During the Middle Ages, /r/-deletion prevailed for so long in French that /r/ almost disappeared

[14] Tones are omitted here, because they are irrelevant.

[15] [g] is a variant of unaspirated /k/ in Thai.

[16] Data gathered during fieldwork in Thailand in February and March 2010.

[17] Even though French is no longer spoken by young people in Cambodia and Laos, Lao and Khmer speakers, both young and old, almost always import the French nasal vowels in French loanwords, which are very numerous in both languages.

[18] Data gathered during fieldwork in Cambodia in March 2010.

as a coda phoneme (Zinc 1986). The deletion of /r/ also applies in many Spanish dialects (Moreno de Alba 1988; Rojas 1988; e.g. *mar* 'sea' → [ma] in Caribbean Spanish and *cliquear* from English *to click*, which is realized as [klikea] in Spanglish). Interestingly, English *short* is realized [ʧo] in Spanglish when it is singular but [ʧores] in the plural, i.e. with the full rhotic when it is no longer in coda position, thus indicating that the rhotic is present in the L1 lexical representation of the borrowing. Examples of this type are common cross-linguistically. It could be that a post-vocalic rhotic is actually part of a diphthong, as proposed by several phonologists (e.g. see Nikiema and Bhatt 2003 for their analysis of post-vocalic /r/-deletion in Haitian Creole).

Nonetheless, we know there are some languages where coda /r/ is ill-formed, but its deletion does not yield vowel lengthening. Although the general CoPho loanword database does not include such languages, we would view these cases as true deletions and, as such, challenges to the idea that structure is preserved in loanword adaptation. Our targeted corpus on aspiration in Mandarin Chinese (MC) (see also Hall-Lew 2002 on this) shows that this is what happens in English loans in Mandarin Chinese.[19] The English coda rhotic, which is disallowed in Mandarin Chinese, is dropped without yielding systematic vowel lengthening (e.g. English *laser* [lezəɹ], *cigar* [sɪgɑɹ], *cartoon* [kɑɹtun], and *sardine* [sɑɹdin], which yield MC [lej ʂə_], [sjə tsja_], [kʰa tʰuŋ] and [ʂa_ tiŋ], respectively). The coda rhotic is not adapted in /l/, as in onset position (e.g. English *radar* [ɹedɑɹ] and *trust* [tɹʌst] > MC [ləj ta] and [tʰ(w)ə las]). The net result with respect to a discussion of Structure Preservation is that one must consider /r/-deletion/fusion to be very common across languages in both native and borrowed words, and that there seems to be a phonological explanation for many such cases that avoids conflicts with Structure Preservation.

However, even when /r/-deletion does not lead to lengthening, it may not be a problem for Structure Preservation from the point of view of loanword adaptation, because in many cases such deletions stem from a native process. For example, it is common for rhotics to be deleted when they are included in a complex onset (CHAPTER 55: ONSETS). For instance, Quebec French *trois* [tʀwa] 'three', *Lacroix* [lakʀwa] (a proper name), and *fruit* 'fruit' [fʀɥi] are often pronounced [twa], [lakwa], and [fɥi] in casual speech. In Thai, /r/ in complex onsets is only pronounced in very formal speech (on television, for instance). In less formal/casual speech it might be replaced with /l/, but most of the time the liquid disappears altogether. For instance, the famous shopping center of Bangkok, *Maboonkrong*, is pronounced with the rhotic only in very formal speech. Otherwise, it is pronounced [maːbuːŋkʰɔŋ], with no rhotic; this is what taxi drivers say, with [maːbuːŋkʰlɔŋ], a more prestigious pronunciation with the lateral, being used much less frequently. The same happens with the Thai city *Trat*, which is systematically pronounced [tat]; cf. also Thai [pʰroːm] 'carpet', which is pronounced [pʰoːm] except in very formal speech (this information on /r/-deletion, as well as on /l/-deletion, is readily available in any grammar of Thai). Native /r/-deletion in complex onsets is frequent in Asian languages, so it is not surprising to see /r/-deletion apply to

[19] A targeted corpus, as opposed to a general one, is a (normally smaller) corpus of loanwords collected to test a particular hypothesis (e.g. aspiration in MC, Hindi, Thai, and Lao, palatalization in Russian, etc.). Therefore, all borrowings in a targeted corpus contain a particular sound or contrast of interest to the hypothesis being tested.

their loanwords (e.g. French *crème* [kʀɛm] 'cream' which yields [kem] in Vietnamese, according to CHAPTER 95: LOANWORD PHONOLOGY; cf. also English *credit card* [kɹɛdɪt kɑɹd] and *brake* [bɹek], which are pronounced [kʰ(l)eːdit gaːt] and [b(l)ɛːrk] in Thai, respectively, and French *programme* [pʀɔgʀam] 'program' and *groupe* 'group' [gʀup], which yield Lao [pog(l)am] and [g(l)up], respectively). Rhotic deletion in cases such as English loanwords in Thai should not be interpreted as a repair of an ill-formed L2 structure or as an "unnecessary loss," since it stems from a very productive native process related to speech register/dialectal differences.

To sum up this discussion, the vast majority of deletions are phonologically predictable and thus, despite initial impressions, pose little threat to the idea that input structure is preserved in loanword adaptation. However, the real story is that, together, predictable and unpredictable deletion affect only a small percentage (less than 5 percent) of input phonemes in the CoPho loanword database. We conclude from this that the loss of L2 phonemes is strongly avoided in loanword adaptation.[20] In the case of ill-formed sounds, feature adjustments apply systematically; in the case of ill-formed clusters, that are perceived as unsyllabifiable by L1, phoneme insertion is the norm. For instance, French *drapeau* [dʀapo] yields [darapo] in Fula, not *[dapo] or *[rapo] (see also French *force* [fɔʀs] > Fula [fɔrsɔ], not *[fɔs] or *[fɔr], and French *ministre* [ministʀ] > Kinyarwanda [ɪninisitiri], not *[mini]). This pattern consistently predominates in the general corpora of the CoPho loanword database, as well as in more recently assembled targeted corpora such as the Kashmiri one. When an English borrowing contains a cluster that is disallowed in Kashmiri, the sequence undergoes vowel insertion, not consonant deletion, despite the fact that consonant deletion would solve the problem equally well. For instance, English *silk* [sɪlk], *snow* [sno], and *flag* [flæg] result in Kashmiri [silik], [sono], and [fəlag], and not in *[sik], *[so/no], or *[fag], for example.[21]

Why does L1 resort to phoneme insertion instead of phoneme deletion when it has to handle a problematic L2 cluster? We attribute this to the Preservation Principle in (2), which seeks to safeguard contrastive information, and which can be seen as a constraint in the Theory of Constraints and Repair Strategies to preserve structure. However, TC is a derivational constraint-based theory. One might immediately wonder whether Optimality Theory (OT), a non-derivational (non-serial) filter-based theory, can dispense with the need for SP. The crux of the issue is that standard OT posits that, underlyingly, anything goes (cf. Richness of the Base, following Prince and Smolensky 1993). The patterns that emerge from the lexicon are the result of universal surface filters, which are ranked on a language-specific basis. In short, the basic architecture and tenets of classical OT, with constraints acting as filters, suggest that there should be no particular underlying phoneme or structure inventory to protect. Itô and Mester (2001: 265) examine the possibility that some of the devices and principles of Lexical Phonology might have outlived their usefulness and have no place in a putatively non-serial framework such as OT. Is SP one such device? Itô and Mester argue for recognizing, within OT, the need for stratal organization, with lexical outputs

[20] Phoneme deletion outside the context of malformations, that is when the phoneme and structure that contains it are both permissible in L1, is also very rare (see Paradis and Prunet 2000). As shown by Paradis and LaCharité (2008) and Paradis and LaCharité (forthcoming), these rare cases result mostly from analogy, morphological truncation, phonetic approximation, and hypercorrection.

[21] Data gathered during fieldwork in North India in April 2009.

being structure-preserving, which they define (2001: 289) as "limitation to a restricted inventory of elements and structures. . . ." Bermúdez-Otero and McMahon (2006) work within the framework of stratal OT and maintain, *contra* Itô and Mester, that ". . . the issue of Structure Preservation does not arise in Stratal OT . . ." (2006: 396). However, even if one agrees with that, and rejects Itô and Mester's point of view, OT analyses still rely on some notion of preservation, in the form of faithfulness constraints, which occupy a high-ranked – though not necessarily undominated – place in most OT analyses (CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). All this clearly suggests that OT requires some notion of contrast preservation, an issue that some OT analyses have confronted directly (e.g. Krämer 2006). Our goal here is to point out that no current constraint-based or filter-based theory completely does away with the need for some notion closely related to Structure Preservation. Indeed, it seems more likely that, for all phonologists, it will be important to reconsider the idea of Structure Preservation and to determine its mandate in the context of our particular theories. The remainder of the discussion is framed in the TC model, because Structure Preservation has been more directly addressed in this framework, but we assume that all phonological theories need to confront the same observations concerning what appears to be preserved, as evidenced in loanword adaptation. In other words, our focus will be on the facts, not the theory used to handle them.

The preceding discussion has shown that L2 phonemes are adapted rather than deleted, that the repair of illicit clusters via epenthesis is preferred over their repair via deletion, and that when deletion does occur, it is largely predictable on phonological grounds. The study of loanword adaptation reveals a further implication of Structure Preservation: the violation of L1 constraints is generally solved with as little loss of phonological information as possible. Thus, an ill-formed L2 phoneme is not deleted if a feature can be added or deleted to solve the problem; an ill-formed syllabic structure is not deleted if insertion of a phoneme or, in the case of a constraint conflict, the loss of a phoneme will suffice, etc. Another key observation in loanword adaptation (we see this as another side-effect of Structure Preservation), for which any theory must account, is the limited range of adaptations that predominate cross-linguistically. This issue is addressed in LaCharité and Paradis (2005). For example, English /æ/ is systematically adapted as /a/, not as /i/, /e/, /o/, or /u/, in the CoPho database.[22] In Mexican Spanish, adaptation of */æ/ to /a/ occurs in 354/360 cases (98.33 percent); in French it occurs in 1,405/1,405 cases (100 percent), in Japanese it occurs in 536/536 (100 percent) cases, and in Calabrese Italian 1,121/1,214 cases (92.3 percent). As another example, English /ɪ/ is predictably adapted as /i/. In Mexican Spanish, */ɪ/ adapts to /i/ in 387/388 adaptation cases (99.7 percent); in Japanese, adaptation of */ɪ/ to /i (iː)/ occurs in 631/649 adaptation cases (97.2 percent); in Calabrese Italian, this adaptation occurs in 1,588/1,588 adaptations (100 percent). Even when more than one adaptation for a given sound is attested, either cross-linguistically or within a single language, the range of results is small and predictable. For

[22] In Quebec French, there are cases where English /æ/ surfaces as [ɛ] in loans such as *band*, *gang*, and *pantry*. We believe that this is because these words are often pronounced with the variant [ɛ] in English (e.g. [bɛnd], [gɛŋ], and [pɛntɹi]). In these cases, we say that the English variant is imported. It sounds more "anglophone" i.e. more "in," to pronounce these words with [ɛ], although they can be pronounced with [a] too.

example, English /v/ is adapted as /b/, /f/, or /w/ cross-linguistically. English /ʌ/ is adapted as either /a/ or /o(ɔ)/. Why should a borrowing language not simply replace any illicit sounds arbitrarily, or with default/high-frequency sounds, if there were no pressure to remain close to the input? Even though particular sounds are illicit from the point of view of the borrowing language, as much as possible is salvaged or, conversely, as little as possible is lost. For instance, in the common cross-linguistic adaptation of */v/ to /b/, only the continuant value changes; in the adaptation to /f/, which is also found cross-linguistically in loanword adaptation, only the voicing value is modified, whereas in the adaptation to /w/, a slightly less frequent but nonetheless common adaptation, it is the sonorant value which is targeted. The adaptation of /v/ to /w/ is systematic in Fula (French *civil* [sivil] 'civilian' > Fula [siwil]; Paradis and LaCharité 1997) and in several Asian languages, including Thai in word-initial and intervocalic positions (e.g. English *vitamin* [vajtəmɪn]/[vɪtəmɪn] and *travel agent* [tɹævəl edʒənt] > Thai [wittamin] and [t(r)awəl ejɛn], respectively; word-finally it is adapted as /p/ for phonotactic reasons; e.g. English *serve* [səɹv] > Thai [səːp]). Within the context of TC, this has been attributed to the Minimality Principle in (3).

(3) *Minimality Principle*

a. A repair strategy must apply at the lowest phonological level to which the violated constraint refers.
b. Repair must involve as few strategies (steps) as possible.

The lowest phonological level referred to in (3a) is determined by the phonological level hierarchy (metrical level > syllabic level > skeletal level > root node > feature), an independently required organization of phonological information. Clearly, the Minimality Principle (whose effects are addressed in Paradis and LaCharité 1997) is intrinsically related to the notion of preservation. If preservation were not an issue, then why should repair not often, or even routinely, operate at a higher-than-needed level, guided by some notion of "better safe than sorry"?

3.3 Preservation of L2 phonemic contrast patterns in L1: English loanwords in Chinese and Hindi

Not only are individual L2 phonemes conserved, to the greatest extent possible within the limits allowed by the L1, but L2 phonemic contrast patterns are also maintained to the greatest extent possible permitted by the phonology of L1. For example, Chinese does not have a voicing distinction among stops; it does, however, distinguish stops on the basis of another laryngeal feature, aspiration. In the adaptation of English loanwords in Mandarin Chinese (MC), English voiceless stops (/p t k/) systematically yield aspirated voiceless stops (/p^h t^h k^h/), and English voiced stops (/b d g/) are systematically replaced by unaspirated voiceless ones (/p t k/; see Paradis and Tremblay 2009 for an in-depth discussion of this issue, with figures and statistics). For example, English *pizza* [pitsə], *hippies* [hɪpiz], and *tank* [tæɪŋk] yield MC [p^hi sa], [si p^hiʂ], and [t^han k^hɤ], respectively, whereas English *Boeing* [boɪŋ], *radar* [ɹedɑɹ], and *golf* [gɑlf] are adapted as MC [pəin], [ləj ta], and [kaw ər fu]. This pattern of adaptation is not restricted to English loans; it also applies to French loans in MC (e.g. French *Pierre Cardin* [pjɛʀkaʀdɛ̃] and *Chirac* [ʃiʀak] >

MC [pʰi ər kʰa tan] and [si la kʰə]), despite the fact that voiceless stops are not aspirated in French as they are in English before a stressed vowel. The same type of pattern transfer is found in other Chinese dialects, such as Cantonese. This indicates that Chinese borrowers are aware of the systematic distinction between voiced and voiceless stops in English, and that adaptation seeks to preserve this L2 distinctive pattern, using the contrastive resources provided by the L1.

Comparable facts are found in Hindi. Hindi has a voicing distinction for stops. Thus English voiced and voiceless stops yield Hindi voiced and voiceless stops, respectively (e.g. English *bellboy* [bɛlbɔj], *baggage* [bægədʒ], *coffee* [kɑfi], and *frock* [frɑk] > Hindi [bɛlbɔj], [bagedʒ], [kɔfii], and [frɔk]). However, English voiced and voiceless alveolar stops are adapted as retroflex stops /ʈ/ and /ɖ/, which contrast with dental stops /t/ and /d/ in Hindi (e.g. English *agreement* [əgɹimənt], *beauty parlor* [bjuti pɑɹləɹ], *badminton* [bædmɪntən], and *baking powder* [bekɪŋ pawdəɹ] > Hindi [agrimənʈ], [bwuʈi pɑɽləɽ], [baɖminʈən], and [bekɪŋ pawɖəɽ], respectively), while English interdentals /θ/ and /ð/ are adapted as plain dental stops, that is /t/ and /d/, respectively (e.g. *Thatcher* [θætʃəɹ] and *brother* [bɹʌðəɹ] yield Hindi [tatʃər] and [brɔdər]). Again, the L2 contrast pattern is preserved in L1, using the contrastive resources provided by the latter. Adaptation of interdentals to fricatives would yield a greater loss of information because Hindi has only /s/, not /z/ (except in borrowings, especially from Arabic). The voicing contrast of English interdentals would then be lost. On the other hand, if English alveolar stops were adapted as phonetically more expected dental /t/ and /d/ in Hindi, there would not be any slot left for the adaptation of the interdentals, which would have to merge with the English alveolar stops in Hindi.

3.4 Preservation of L2 syllabic contrasts in L1: French loanwords in Russian

The adaptation of French loanwords in Russian suggests that unpredictable syllabic structure might also be preserved in loanword adaptation. French diphthongs have to be marked underlyingly, as they are unpredictable. Pairs such as *oiseau* [waso] 'bird' *vs. watt* [wat] 'watt' show this. In *oiseau*, *wa* is a diphthong (e.g. *l'oiseau* [lwazo] 'the bird'), making the word vowel-initial, whereas in *watt* it is an onset–nucleus sequence, as it is in English, making *watt* consonant-initial (e.g. *le watt* [lə wat]; see Kaye and Lowenstamm 1984 on diphthongs in French). The presence or absence of an onset is shown by, among other things, the choice of singular and plural definite articles. Before vowel-initial words the singular definite article is [l], as with *l'arbre* [laʀbʀ] 'the tree'. Moreover, the plural definite article triggers liaison (*les oiseaux* [lɛ zwazo] 'the birds', as with *les arbres* [lɛ zaʀbʀ] 'the trees'). Preceding a consonant, the definite articles are *le* [lə] and *les* [lɛ], respectively (*le watt* [lə wat] 'the watt', not *[lwat], and *les watts* [lɛ wat] 'the watts', not *[lɛ zwat], as with *le bateau* [lə bato] 'the boat' and *les bateaux* [lɛ bato] 'the boats').

In French loanwords in Russian, /wa/ is adapted as a bisyllabic sequence of /u+a/ when it is part of a diphthong (e.g. French *voile* [vwal] 'veil', *mémoire* [memwaʀ] 'memory', and *couloir* [kulwaʀ] 'corridor' > Russian [vual], [mʲemuarʲi], and [kuluarʲi]), whereas when /w/ constitutes an onset, it is systematically adapted as /v/ (French *watt* [wat] > Russian [vat];[23] English *whisky* [wɪski] and

[23] This loan was introduced via French, even though it originates from English.

tramway [træmwej] > Russian [vʲiskʲɪ]) and [tramvaj]). These examples might suggest that the difference in adaptation is due to the fact that /wa/ in French loans is preceded by a consonant, whereas in English loans it is not. However, English borrowings such as *sweater* [swɛtəɹ], *swap* [swɑp], and *swing* [swɪŋ], which yield Russian [svʲitɛr], [svop], and [svʲiŋ],[24] not *[suʲitɛr] or *[suatɛr], etc., invalidate this hypothesis. The fact that /wV/ is treated differently when it is a diphthong than when it is an onset–nucleus sequence is interesting, because it suggests that where syllabic affiliation is unpredictable – when it is contrastive and would have to be indicated underlyingly – it is preserved. This interesting question remains to be investigated more thoroughly.

3.5 *Importation and Structure Preservation*

Non-adaptations in loanwords – that is the importation of foreign phonemes in words borrowed from another language (L2) – present a challenge to SP since they consist in the introduction of new phonemes at the lexical level. Two cases that were previously mentioned are /ç/ in German and /ʒ/ in English. One might object that the German case as presented here is oversimplified and does not present an uncontroversial picture of the facts (consider, for example, the contradiction between Hall's 1989 position and the scenario advanced by Bybee 2008), or that, in English, the phonemic status of /ʒ/ is not well established, given that its distribution is restricted to intervocalic position, except in loanwords (see Iverson and Salmons 2005: 210 on /ʒ/ in English). However, the German case seems to be problematic for SP no matter which view one takes; either a sound/sound distinction ([ç] *vs.* [x]) that does not exist at the underlying level is introduced at the lexical level (Hall's view) or non-native /ç/ has become phonemic in German over time, under the influence of loanwords (Bybee's view). As for the voiced palatal fricative in English, even if /ʒ/ were validly considered a phonetic variant intervocally in native English words, the fact that it is tolerated (unadapted) at the end and now at the beginning of borrowings indicates that it is a phoneme in English, though a marginal or peripheral one, in the terminology of Itô and Mester (1995).

The challenge goes beyond German and English: the literature on loanwords reports abundant cases of importation (see e.g. Ulrich 1997: 432 on the importation of an English coda palatal in Lama, and Mohanan and Mohanan 2003 on the importation of English /f/ in Malayalee English). In the case of particular phonemes, importation can even be the norm. In the Moroccan Arabic corpus of the Project CoPho loanword database, /p/ is widely imported (320/454 cases, 70.5 percent) (e.g. French *pape* [pap] 'pope' > Moroccan Arabic [pap] instead of expected [bab]). Another example is /ʃ/ in the CoPho corpus of English loanwords in Mexican Spanish, which is imported in 102/138 cases (74 percent) (e.g. English *shorts* [ʃoɹts] and *carwash* [kaɹwaʃ] > Mexican Spanish [ʃɔɹts] and [karwɔʃ], not [ʧɔrts] and [karwɔʧ], as expected). While some foreign sounds are only occasionally, or never, left unadapted, others are imported more often than they are adapted. In some language situations, such as Spanish loanwords in Guarani, importations from Spanish are systematic, i.e. Spanish phonemes are never adapted (see Oñederra 2009 for a similar situation with Spanish loans in Basque).

[24] [svɪŋk] also exists as a variant; it is perceived by some Russian speakers as more "English," possibly because of hypercorrection.

We must remember, though, that in phonological situations involving language contact, including loanword adaptation, two languages are in play. Our hypothesis is that under certain sociolinguistic conditions, such as when borrowers are highly bilingual and society generally tolerant of importations (such as when the L2 enjoys widespread prestige), the preservation of the L2 system also becomes an issue, one that can be at odds with the preservation of the L1 system. In cases of adaptation, preservation of the L2 system becomes subordinated to the preservation of the L1 system; in cases of importation, the reverse occurs. This, and the fact that loanword adaptations are generally minimal, supports the view that the structural integrity of L2 is rarely left out of consideration altogether, so it is not unlikely that such concern may sometimes come to predominate. If this interpretation is correct, then identification and preservation of contrastive information is important in both L1 and L2, despite inevitable conflicts between the demands of each of the two linguistic codes.

4 Conclusion

As shown in §2, SP, as referred to in Lexical Phonology, was regularly challenged by the facts, even though most phonologists agree that it plays some role, i.e. nonphonemic sounds are generally not generated in the lexicon. Languages tend to preserve their phonemic integrity at this level. Nonetheless, the numerous exceptions to SP reported by many different authors, providing evidence from numerous different languages, might give the impression that Structure Preservation is either misguided or just an artifact of some other principles/processes with no intrinsic validity. There remains little doubt these days that SP as conceived in Kiparsky (1982, 1985) is too restrictive, not to mention its being linked to a network of other assumptions and principles that have themselves been seriously challenged. In fact, even the notions of phonological rules and their application has been subjected to a major rethinking. SP limited the power of phonological rule application, but modern frameworks eschew rules in favor of constraints; if rules have not been abandoned altogether, they have certainly lost their driving force. In a derivational constraint-based theory, such as TC, rules are context-free and functionally motivated, being limited to repairing constraint violations. Thus, their power is intrinsically more circumscribed than was the case of *SPE*-type rules that were, in and of themselves, the motivation for phonological change (i.e. they were essentially descriptive devices with little or no explanatory power). In a filter-based theory, such as OT, filters, including any that favor the preservation of input structure or contrasts (i.e. faithfulness filters), are ranked on a language-specific basis. Given that feature of the theory, it is not obvious how OT would deal with a cross-linguistic tendency to preserve input structure/contrasts (see Paradis 1996 on this issue). If the faithfulness constraint Max-X (which prevents deletion of a phoneme or feature that is in the input; previously Parse) is shown to play a consistently high-ranked (though, as already mentioned, not necessarily undominated) role in OT analyses, then OT too might need to appeal to a mechanism that accounts for Structure Preservation. Therefore, the real question is: does Structure Preservation have any kind of intrinsic validity for phonological theory? We maintain that it does.

In §3, we used the adaptation of loanwords to underline the continued need for some notion of Structure Preservation. However, we see this principle as having a broader scope than that defined for SP in Lexical Phonology. Not only do languages tend to preserve their own phonemic inventories at the lexical level as much as possible (in the spirit of SP in Lexical Phonology), but they also tend to maximally preserve the phonemic contrasts and contrast patterns of the languages from which they borrow words. Thus, the resistance to change is, above all, a question of contrast/category pattern preservation, which is expressed interlinguistically (i.e. between L2 and L1, as was illustrated in this chapter with the treatment of loanwords), as well as intralinguistically (as was illustrated with the [ɔ/o] alternation case in French and Velar Softening in the English and French cases). As mentioned at the outset of the chapter, it is not just a question of inertia. Speakers work hard to preserve L1 or L2 phonological patterns.[25]

If there were no (universal) pressure to preserve an input's contrastive information, then why would deletion be so rare in loanword adaptation? Why would it not occur randomly in some 50 percent of the cases? Moreover, when deletion does occur, why is it so largely predictable on the basis of phonology? Among adaptations, why are the changes to ill-formed sounds and structures so consistently predictable in terms of minimality, and why is there such a limited range of adaptations found cross-linguistically? This is because distinctive information is as resilient and resistant to change in L1 as it is in L2 in the mind of borrowers. When L2 wins, the result is an importation (a non-adaptation), i.e. the introduction of a new phoneme or structure in L1, as discussed in §3.5. Extensive language contact is required for this to happen, though. When L1 wins, which is more generally the case in the first stages of borrowing, we obtain an adaptation, whose goal is to produce a form that meets the phonological demands of the borrowing language's phonology. This means that some L2 contrastive information will inevitably, though minimally, be sacrificed, because the preservation of the L2 contrastive information is often at odds with preservation of the contrasts of the L1 phonological system. However, in focusing on phoneme modification (i.e. adaptation), we risk undervaluing the fact that, to the greatest extent possible, an adaptation retains most properties of the source form. In this chapter, the properties referred to have included distinctive phonemic information, as illustrated with loanwords from French and English in many different languages (Japanese, Khmer, Thai, Fula, Kinyarwanda, Kashmiri, etc.), phonemic contrast patterns from English loans in Chinese and Hindi, and syllabic contrast pattern from French loans in Russian. This is not intended to be exhaustive though. Other types of contrastive information are expected to show similar resilience. In this chapter, we have tried to emphasize that contrast resilience extends to L2; it is not limited to L1. L1 adapters feel strongly concerned about preserving L2 contrastive information; in the case of importations this is to the detriment of their own (L1) contrast system, which is forced to change.

Ultimately, we suggest that what might salvage SP, after all, is to consider it in a much broader perspective in order to deepen our understanding of its purpose and functioning. It will then be easier to circumscribe its effects in native and borrowed words and formulate it more formally, even if it is in terms of a statistically significant tendency instead of an absolute generalization.

[25] Structure Preservation obviously does not have the same impact in L2 acquisition as in loanword adaptation. Its influence is necessarily reduced in L2 acquisition, since L2 learners (especially beginners) are not as knowledgeable about the L2 code as are the borrowers (see Paradis and LaCharité 1997 on the borrowers' bilingualism issue) and thus cannot be as protective of a code with which they are not sufficiently acquainted.

ACKNOWLEDGMENTS

We would like to thank K. P. Mohanan for his comments on a draft of this chapter and for several discussions about Structure Preservation. We are grateful to Joan Bybee for sending comments on this notion, along with a scanned version of a relevant document. We also benefited from discussions with Zhiming Bao and Haruo Kubozono on phoneme preservation/deletion in loanwords. Finally, we would like to thank the editors, in particular Marc van Oostendorp and Keren Rice, and the reviewers for their comments. We remain solely responsible for the views expressed here as well as for any remaining errors or omissions. Research for this chapter was made possible by SSHRCC grant #410-2008-1128 to the fiirst author and by SSHRCC grant #410-2007-0566 to the second author.

77 Long-distance Assimilation of Consonants

Sharon Rose

1 Introduction

There are numerous patterns in languages in which consonants assimilate at a distance for some acoustic or articulatory property. When vowels and consonants intervening between the assimilating consonants show no observable effect of the assimilating property, such patterns are labeled "consonant harmony." Other terms such as "consonant agreement" have been used (Rose and Walker 2004) in order to distinguish them from cases of harmony involving both vowels and consonants, such as emphasis harmony (Shahin 2002; CHAPTER 25: PHARYNGEALS) or nasal harmony (Walker 2000a; CHAPTER 78: NASAL HARMONY). Consonant harmony has played a central role in debates concerning harmony patterns in general (Rose and Walker, forthcoming) with respect to several issues: locality of interaction, transparency or blocking in long-distance assimilation, and directionality. In this chapter, the main typological patterns of consonant harmony are outlined, highlighting the challenges that the typology presents, including a discussion of harmony domains and directionality. Two main theoretical approaches to consonant harmony are then explored: analyses involving *spreading* an assimilating feature or extending a gesture across all segments within a string, and analyses advocating distinct *correspondence* relationships between consonants independently of intervening segments. The role of contrast in determining harmony interaction is examined within both of these frameworks. Finally, experimental approaches to consonant harmony are discussed, showing how they shed light on the analysis of consonant harmony.

2 Typology of long-distance assimilation of consonants

Long-distance assimilation of consonants or "consonant harmony" can be defined as:

(1) *Consonant harmony*

Assimilation for an articulatory or acoustic property between two or more non-adjacent consonants, where intervening segments are not noticeably affected by the assimilating property.

An example is given in (2) from Tahltan, an Athabaskan language (Shaw 1991). The 1sg subject prefix /s-/ (2a) is realized as [θ] when a dental fricative or affricate follows (2b), or as [ʃ] when a lamino-post-alveolar fricative or affricate follows (2c). Intervening consonants and vowels, including other coronal consonants, are transparent to the harmony:

(2) *Tahltan coronal harmony*

a.	ɛsk'aː	'I'm gutting fish'
	nɛstɛɬ	'I'm sleepy'
b.	xaʔɛθt'aθ	'I'm cutting the hair off'
	ɛθduːθ	'I whipped him'
c.	ɛʃdʒɪni	'I'm singing'
	jaʃtɬ'ɛʧ	'I splashed it'

Consonant harmony can involve morpheme alternations, as in (2), but may also occur as a morpheme structure constraint (CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS), requiring consonants within a root to share featural properties. In Ngizim (Chadic) roots, non-implosive obstruents must have the same voicing property (3a), unless the linear order of the obstruents is voiced . . . voiceless (3b) (Schuh 1997):

(3) *Ngizim laryngeal harmony*

a.	kùtə́r	'tail'	
	tàsáu	'find'	
	zə̀dù	'six'	(Hausa /ʃídà/)
	gâazá	'chicken'	(Hausa /kàazáa/)
b.	bàkú	'roast'	
	gùmʧí	'chin'	

The asymmetrical nature of the restriction points to a harmonic process. Voiceless . . . voiced combinations are not sanctioned, and Hausa words with such sequences are realized as voiced . . . voiced in Ngizim. The Ngizim harmony is therefore a regressive harmony, in which voiceless consonants assimilate to voiced, but not vice versa.

The definition of consonant harmony provided in (1) excludes other types of long-distance harmony that also involve assimilation spanning several segments, including both vowels and consonants, such as nasal harmony (Piggott 1988, 1992, 2003; Piggott and van der Hulst 1997; Walker 2000a, 2000b, 2003; CHAPTER 78: NASAL HARMONY) or post-velar or emphasis harmony (Younes 1993; Watson 1999; Zawaydeh 1999; Shahin 2002; CHAPTER 25: PHARYNGEALS). See also CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS on consonant–vowel interactions in general. In these harmony systems, assimilation affects both vowels and consonants, and certain types of segments can block harmony. Transparency of consonants is observed only under very restricted conditions. Conversely, transparency is routine in consonant harmony, whereas blocking is rare.

There are several types of long-distance consonant assimilation identified in typological studies of consonant harmony, laid out in detail in Hansson (2001a) and summarized in Rose and Walker (2004). The main types are outlined in the following sections.

2.1 *Laryngeal harmony*

Laryngeal harmony requires consonants to agree in aspiration, glottalic airstream, or voicing. Laryngeal distinctions are characterized by the features [spread glottis], [constricted glottis], and [voice], respectively, although different feature specifications are possible. Laryngeal harmony is most frequently observed in morpheme structure constraints (MacEachern 1999).

Laryngeal harmony is found in Chaha, a Gurage Semitic language of Ethiopia (Rose and Walker 2004), in which oral coronal and velar stops in roots match for both [constricted glottis] and [voice]:

(4) *Chaha laryngeal harmony*

a.	jɨ-t'ək'ɨr	'he hides'		
	ji-t'əβk'	'it is tight'		
	ji-t'ək'ik'	'it is being crushed'	cf. Endegegn (Gurage)	ɨ-dəkk'
	ji-t'ərk'	'it is dry'	cf. Masqan (Gurage)	ji-dərk'
b.	jɨ-kətf	'he hashes (meat)'		
	jɨ-kəft	'he opens'		
	jɨ-təks	'he sets on fire'		
c.	jɨ-gədɨr	'he puts to sleep'		
	jɨ-dərg	'he hits, fights'		
	jɨ-gəda	'he draws liquid'	cf. Amharic	ji-k'ada-l

Cognates in related languages show laryngeal mismatches, giving insight into the direction and implementation of the harmony. Harmony was regressive, and either ejectives or voiced stops could trigger harmony. Exceptions to laryngeal harmony involve non-adjacent combinations of an ejective and a voiced stop, e.g. [ji-gəmt'] 'he chews off'.

Voicing and aspiration harmony is found in (non-click) stops in disyllabic roots of Zulu (Bantu), as in (5a) (Khumalo 1987; Hansson 2001a). Zulu contrasts plain stops (which may be realized as ejective), voiced stops (described as "depressors," as they can lower tone),[1] and aspirated stops. Loanwords (5b) are adapted to conform to laryngeal harmony.

(5) *Zulu laryngeal harmony*

a.	ukú-peta	'to dig up'	
	úku-p^{h}át^{h}a	'to hold'	
	uku-guba	'to dig'	
b.	í-k^{h}ôt^{h}o	'court'	
	um-bídi	'conductor'	< English *beat*

Ngizim voicing harmony was illustrated in (3). Kera (Chadic) appears to have voicing alternations in affixes conditioned by voiced stops or affricates in the stem (Ebert 1979; Rose and Walker 2004), e.g. [kə-sár-káŋ] 'black (coll.)' *vs.*

[1] Zulu voiced stops may be phonetically voiceless (Traill *et al.* 1987), so this is not a clear case of "voicing" harmony.

[gə-dʒàr-gáŋ] 'colorful (coll.)'. However, Pearce (2005) argues that voicing is conditioned by a neighboring low tone rather than the voiced stop in the stem, so this does not constitute a case of voicing harmony. Hansson (2004) argues that in Yabem, a Huan Golf language of Papua New Guinea, voicing restrictions arose from tonal patterns, and only superficially resemble consonant harmony.

Laryngeal harmony is often restricted to apply between subclasses of obstruents. Harmony operates between pulmonic obstruents in Ngizim, whereas in Chaha and Zulu, it applies between stops with differing airstream mechanisms, but excludes fricatives. In Kalabari Ijo (Jenewari 1989; Hansson 2001a) and Bumo Izon (Efere 2001; Mackenzie 2005, 2009), Ijoid languages of Nigeria, plain voiced stops and implosives may not co-occur in roots. Other cases of laryngeal harmony require homorganicity or complete identity between consonants. In Bolivian Aymara, laryngeal harmony for aspiration and ejectivity occurs between homorganic stops, so they are identical, e.g. [k'ask'a] 'acid to the taste', whereas no harmony occurs between heterorganic stops: e.g. [t'aqa] 'flock, herd' (Hardman *et al.* 1974; Davidson 1977; de Lucca 1987; MacEachern 1996, 1999). Similar effects are found in Mayan languages, such as Chol (Gallagher and Coon 2009), Modern Yucatec (Straight 1976), and Tzutujil (Dayley 1985; Gallagher 2010).

In conclusion, laryngeal harmonies are attested in numerous languages, most typically those that exhibit a three-way contrast in laryngeal features. Laryngeal harmony is usually root-restricted, may be subject to homorganicity requirements, and appears to be regressive for those cases in which directionality can be identified.

2.2 *Coronal harmony*

Coronal harmonies involve articulations both for tongue tip/blade posture (apical *vs.* laminal) and tongue position (dental, alveolar, post-alveolar). Sibilant harmony is the most commonly attested type of consonant harmony and requires sibilant coronal fricatives and affricates to match for tongue tip/blade posture and location. It is widely attested in Native American languages, particularly in Athabaskan and Chumash languages, but it also occurs in Basque, Berber, Bantu, Cushitic, and Omotic languages. An example of sibilant harmony in Tahltan was illustrated in (2).[2] In Sidaama, a Cushitic language of Ethiopia (Kawachi 2007), the causative suffix /-is/ (6a) is realized as [iʃ] when palato-alveolar fricatives or affricates appear in the preceding stem (6b).

(6) *Sidaama sibilant harmony*

a.	dirr-is	'cause to descend'
	hank'-is	'cause to get angry'
	raʔ-is	'cause to become cooked'
b.	miʃ-iʃ	'cause to despise'
	ʃalak-iʃ	'cause to slip'
	ʧ'uf-iʃ	'cause to close'

[2] Tahltan harmony may be only partially sibilant, since it is not clear the fricatives [θ] and [ð] are sibilant. They are described as predorsal alveolar in Nater (1989).

Sibilant harmony operates across vowels and non-sibilant consonants, including other coronals. In (6b), the intervening segments do not block and do not participate in the harmony.

In some languages, such as Ineseño Chumash (Applegate 1972; Poser 1982; McCarthy 2007), both alveolar and post-alveolar sibilants may trigger harmony. The rightmost sibilant determines the tongue tip-blade realization of all sibilants in the stem. In (7a) and (7c), the 3rd singular subject prefix is /s-/, but it is realized as [ʃ] if there is a palatal sibilant to its right, (7b) and (7d). In contrast, the dual marker /iʃ-/ (7e) is realized as [is] if followed by an alveolar sibilant (7f).

(7) *Ineseño Chumash sibilant harmony*

a.	/s-ixut/	[sixut]	'it burns'
b.	/s-ilakʃ/	[ʃilakʃ]	'it is soft'
c.	/ha-s-xintila/	[hasxintila]	'his gentile'
d.	/ha-s-xintila-waʃ/	[haʃxintilawaʃ]	'his former gentile'
e.	/p-iʃ-al-nanʔ/	[piʃananʔ]	'don't you two go'
f.	/s-iʃ-tiʃi-jep-us/	[sistisijepus]	'they two show him'

Dental harmony is found in Nilotic languages such as DhoLuo (Stafford 1967; Yip 1989; Tucker 1994), Anywa (Reh 1996), Mayak (Andersen 1999), and Päri (Andersen 1988). It operates between dental and alveolar stops, including nasals if a contrast exists in the language, and may be triggered by either. In Päri (Andersen 1988; Hansson 2001a), dental harmony is respected in roots (8a). Root-final stops that are the product of final mutation combined with affixation match the dental or alveolar property of the initial stop (8b).

(8) *Päri dental harmony*

a.	n̪ɔt̪	'sucking'		
	àtwá:t̀	'adult male elephant'		
b.	dè:l	'skin'	dè:nd-á	'my skin'
	t̪ùol	'snake'	t̪ùon̪d̪-á	'my snake'

In Mayak (Andersen 1999), harmony is triggered by an alveolar and optionally affects suffixes of the shape /-Vt̪/, as in (9). Intervening stops that are noncontrastive for the dental–alveolar distinction are transparent to the harmony.

(9) *Mayak dental harmony*

a.	leɣ-it̪	'tooth'
	wʌð̆-it̪	'buttock'
	ʔi̪n-ʌt̪	'intestine'
b.	tiɗ-ʌt̪ ~ tiɗ-ʌt	'doctor'
	kɛt-ɪn-ɛt̪ ~ kɛt-ɪn-ɛt	'star'

Retroflex harmony is reported for several languages. In Gimira (Benchnon), an Omotic language of Ethiopia (Breeze 1990), retroflex harmony restricts combinations of sibilants, requiring them to agree for retroflexion. In Malto (Dravidian) (Mahapatra 1979; Hansson 2001a), retroflex harmony operates between oral stops.

In Australian languages such as Arrernte (Arandic) (Henderson 1998; Tabain and Rickard 2007), apical alveolar and retroflex stops match for retroflexion in a root. Retroflex harmony is also reported in Kalasha (Indo-Aryan) (Trail and Cooper 1999; Arsenault and Kochetov, forthcoming), where it operates between stops, between fricatives, or between affricates in a root, but combinations of different manners of articulation may disagree for retroflex. Kalasha contrasts dentals, retroflex, and palatals; dentals and palatals also tend not to co-occur, so this is a general coronal harmony.

(10) *Kalasha retroflex/palatal harmony*

a.	stops	dental	tʰedi	'now'
		retroflex	ʈoʈ	'apron'
b.	fricatives	dental	sastirek	'to roof a house'
		palatal	ʑoɕi	'spring festival'
		retroflex	ʂuʂik	'to dry'
c.	affricates	dental	tsètsaw	'squirrel'
		palatal	tɕʰatɕi hik	'to take care of'
		retroflex	ɖʐaʈʂ	'spirit beings'

Other cases of coronal harmony involving alveolar stops and alveo-palatal affricates are reported in Hansson (2001a), and include Aymara (de Lucca 1987), Kera (Ebert 1979), and Pengo (Dravidian) (Burrow and Bhattacharya 1970). In each case, harmony rules out /t . . . ʧ/ sequences, but allows the reverse, /ʧ . . . t/.

In terms of directionality, Hansson (2001a) points out two main directionality effects with respect to sibilant harmony. First, sibilant harmony shows a strong tendency to be regressive. In some cases, harmony is triggered by the rightmost sibilant, regardless of its location within a root or affix, as in Chumash (7) or Navajo (11) (McDonough 1991). The 1sg subject prefix /-iʃ/ is variably realized as [is] or [iʃ], depending on whether /s/ follows.[3]

(11) *Navajo sibilant harmony*

/j-iʃ-mas/	jïsmas	'I'm rolling along'
/dz-iʃ-ɬ-taːɬ/	ʤiʃtaːɬ	'I kick him (below the belt)'
/dz-iʃ-l-ts'in/	dzists'in	'I hit him (below the belt)'

Hansson (2001a, 2001b) relates the regressive bias of sibilant harmony to speech production. In speech production studies, anticipatory errors and assimilations are more common than are perseverative (Dell *et al.* 1997). This is modeled in a serial order theory of speech production, whereby one segment activates a consonant being planned and anticipates its production. There are cases of progressive sibilant harmony, as in the Sidaama case in (6), but in such cases, a suffix alternates in agreement with a root. The same pattern holds for dental harmony; no strong evidence for regressive patterns in dental harmony or retroflex harmony has been detected.

3 Navajo actually has examples of progressive sibilant harmony in the prefix string. See McDonough (1990, 1991) and Hansson (2001a: 193–198) for discussion.

The second directionality effect concerns the nature of the trigger. While some cases of sibilant harmony are like Navajo in that either alveolar or post-alveolar consonants can trigger harmony, other languages only allow /s/ to become [ʃ] and not the reverse. Hansson (2001a: 472) cites sixteen cases of the /s/ → [ʃ] pattern, but only one case of /ʃ/ → [s]. Hansson connects this effect to speech planning and the *palatal bias* effect reported in speech error research (Shattuck-Hufnagel and Klatt 1979). The palatal bias effect refers to the higher frequency with which alveolar consonants act as targets of speech errors by palatals.

2.3 *Nasal harmony*

Nasal consonant harmony is attested primarily in Bantu languages. Nasal stops harmonize with voiced stops and oral approximants. If voiceless stops harmonize, they do so only if voiced stops harmonize. In Kikongo (Dereau 1955; Ao 1991; Odden 1994), a nasal stop in a verb root causes a [d] in the active perfect suffix (12a) or [l] in the applicative suffix to be realized as [n] (12b).

(12) *Kikongo nasal harmony*

a.	n-suk-idi	'I washed'	tu-nik-ini	'we ground'
	m-bud-idi	'I hit'	tu-sim-ini	'we prohibited'
b.	ku-sakid-il-a	'to congratulate for'	ku-nat-in-a	'to carry for'
	ku-toot-il-a	'to harvest for'	ku-dumuk-is-in-a	'to cause to jump for'

Intervening vowels and other consonants are transparent to the harmony. Yaka has a similar nasal harmony pattern (Hyman 1995). In other languages, the nasal harmony is restricted to apply only across an intervening vowel, as in Lamba (Odden 1994), Bemba (Hyman 1995), Ndonga (Viljoen 1973), and Herero (Booysen 1982), and may be restricted to roots only. The main distinctions between nasal consonant harmony and general nasal harmony are (i) vowels are not nasalized, (ii) the trigger is a nasal consonant that targets a similar consonant (voiced stop or approximant), and (iii) other consonants and vowels do not block harmony. See CHAPTER 78: NASAL HARMONY for more extensive discussion of the distinction between the two kinds of nasal harmony.

Nasal harmony operates progressively from root to suffix. However, it cannot be reduced in all cases to a stem-control effect. In Kikongo, roots such as /dumuk/ are possible, with a voiced stop preceding a nasal. The reverse order of nasal followed by voiced stop is not attested (Ao 1991; Piggott 1996), indicating that nasal harmony applied progressively within the root. The same pattern is attested in Yaka (Rose and Walker 2004).

2.4 *Liquid harmony*

Liquid harmony involves alternations between /r/ and /l/ (CHAPTER 31: LATERAL CONSONANTS). In Bukusu (Bantu), liquid harmony is attested in roots (Hansson 2001a). In addition, the benefactive suffix /-il-/ is realized as [-ir-] following a stem with [r] (Odden 1994). Vowel height harmony applies to the suffix.

(13) *Bukusu liquid harmony*

teex-el-a	'cook for'	reeb-er-a	'ask for'
lim-il-a	'cultivate for'	kar-ir-a	'twist'
iːl-il-a	'send thing'	resj-er-a	'retrieve for'

In Sundanese (Malayo-Polynesian), /l/ triggers harmony of /r/ to [l] (Cohn 1992), as illustrated with the plural infix /-ar-/ in the final form in (14).

(14) *Sundanese liquid harmony*

kusut	'messy'	k-ar-usut	'messy (PL)'
rahit	'wounded'	r-ar-ahit	'wounded (PL)'
ləga	'wide'	l-al-əga	'wide (PL)'

Liquid harmony is also attested in Pohnpeian (Rehg and Sohl 1981). There are cases in which liquids alternate with glides in Bantu languages, such as in Basaa (Lemb and de Gastines 1973) and Pare (Odden 1994), and in which /l/ alternates with a lateral tap in ChiMwiini (Kisseberth and Abasheikh 1975). All cases of liquid harmony are either root-restricted or involve suffiix alternations, so no directionality bias can be detected.

2.5 Dorsal harmony

Dorsal harmony is found in Malto, Gitksan (Tsimshianic), Aymara, and the Totonacan languages, and involves alternations between velar and uvular consonants. In Tlachichilco Tepehua (Watters 1988; Hansson 2001a), a uvular /q/ causes a preceding velar to become uvular, which in turn conditions lowering of the preceding high vowel (15b).

(15) *Tlachichilco Tepehua dorsal harmony*

a.	ʔuks-k'atsaː	[ʔuksk'atsaː]	'feel, experience sensation'
b.	ʔuks-laqts'-in	[ʔoqslaqts'in]	'look at Y across surface'

Hansson (2001a) notes that intervening vowels are not affected by the harmony even though uvulars lower adjacent vowels. In the word /lak-puːtiq'i-ni-j/ → [laqpuːteʔenij] 'X recounted it to them' (the /q'/ is realized as [ʔ]) the vowel /uː/ fails to lower to [oː], despite appearing between two uvulars. Compare this with (15b). In Gitksan (Brown 2008), the harmony effect is a static co-occurrence restriction that can operate at a distance. Dorsal harmony causes velars to become uvular. While most dorsal harmony cases are regressive and target roots, this could be either a directionality effect or due to the trigger consonant, the uvular, being in an affix.

2.6 Stricture and secondary articulation harmony

In addition to the main types reported in §2.2–§2.5, Hansson (2001a) also lists stricture and secondary articulation harmonies. Stricture involves alternations between stops and fricatives, as in Yabem, e.g. /se-dàgùʔ/ → [tédàgùʔ] 'they follow (REALIS)'. Secondary articulation refers to labialization, palatalization, velarization, or pharyngealization. There are a few reported cases discussed in Hansson (2007a): pharyngealization in Tsilhqot'in (also known as Chilcotin, Athapaskan) (Cook 1983, 1993), which interacts with sibilant harmony, velarization in Pohnpeian (Micronesian) (Rehg and Sohl 1981; Mester 1988), and palatalization in Karaim (Turkic) (Kowalski 1929; Hamp 1976; Nevins and Vaux 2004), as shown below:

(16) *Karaim palatal harmony*

d^{j}ort^{hj}-un^{j}tʃ^{j}u	'fourth'
alt^{h}ɯ-ntʃɯ	'sixth'

In sum, consonant harmony targets a range of segments: dorsals, liquids, and coronals, as well as segments differentiated by nasal and laryngeal features. Hansson (2001a) and Rose and Walker (2004) point out that a consistent characteristic of consonant harmony is the high degree of similarity between the interacting segments. Harmony is restricted to minor place or tongue features distinguishing among coronals and dorsals or to features that are also prone to local assimilation. Notably absent, however, is harmony for major place features such as [labial], [coronal], or [dorsal], as well as classificatory features that tend not to assimilate locally, such as [sonorant], [continuant], or [consonantal]. Rose and Walker (2004) relate the absence of place harmony to the inability of major place to change even in local assimilations, citing articulatory speech error research that shows that major place gesture errors tend to be additive rather than replacive (Goldstein *et al.* 2007; Pouplier 2007). Gafos (1999), on the other hand, argues that major place features cannot spread across vowels (*contra* Shaw 1991) without serious interruption of the vowel gestures. Only minor features such as tongue tip position can do this. See §3.1.1 for further discussion.

The lack of major place consonant harmony is intriguing in light of two related phenomena: child language and dissimilation. Consonant harmony for major place is attested in child language (Vihman 1978), and according to CHAPTER 72: CONSONANT HARMONY IN CHILD LANGUAGE, it is the most common type of consonant harmony in child language. Recent analyses and proposals are discussed in Goad (1997), Berg and Schade (2000), Rose (2000), Pater and Werle (2003), and Rose and dos Santos (2006). The same mechanisms that underlie child phonology and adult phonology may not be the same; some child productions may be due to developmental factors (Rose and dos Santos 2006; Inkelas and Rose 2008). See CHAPTER 72: CONSONANT HARMONY IN CHILD LANGUAGE for an overview.

Some authors have drawn a connection between long-distance consonant assimilation and long-distance consonant dissimilation (MacEachern 1999; Walker 2000c; Gallagher 2008), arguing that they are alternate responses to the same pressure. This does appear to be the case for laryngeal and liquid harmony. Yet there are key differences. A common dissimilation process occurs between labial consonants (Alderete and Frisch 2007), whereas labial consonant harmony is unattested. Nasal dissimilations involve prenasalized stops and nasals (Odden 1994), but these segments do not interact in nasal consonant harmony; prenasalized stops are transparent to nasal harmony and do not act as triggers (CHAPTER 78: NASAL HARMONY). A general theory of the relationship between long-distance consonant assimilation and consonant dissimilation currently appears elusive.

3 Analyses of long-distance assimilation

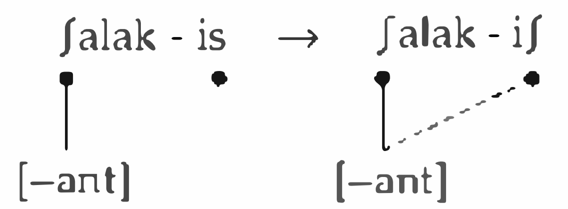
Two main theoretical analyses have been formulated for long-distance consonant harmony: *spreading* and *correspondence*. Spreading involves the extension of a gesture or feature across a string of segments, building upon early autosegmental analyses of vowel harmony and nasal harmony. Correspondence is proposed in Walker (2000b, 2000c), Hansson (2001a), and Rose and Walker (2004) and requires similar consonants to "correspond" and match each other for particular features, regardless of intervening consonants and vowels. The following sections outline these two approaches and identify the strengths of each proposal, as well as the challenges they encounter.

3.1 *Spreading*

Autosegmental phonology represented a major shift in the analysis of harmony systems. Although the distance effects of harmony systems had been explored within a Firthian prosodic analysis framework (Palmer 1970), Clements's (1980) groundbreaking analysis of vowel harmony and extension to nasal harmony launched the study of harmony systems using autosegmental spreading. Early autosegmental analyses of consonant harmony include Halle and Vergnaud (1981) on Navajo and Poser (1982) on Chumash.

In an autosegmental representation, the harmonizing feature (P-segment) is projected onto its own tier and linked to the segment (P-bearing segment) by means of an association line. Spreading involves extending the feature to other segments in the word via new association lines, as shown in (17) for the Sidaama word [ʃalakiʃ] 'cause to slip':

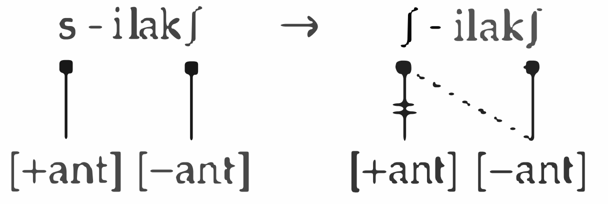
(17) *Long-distance spreading*



(17) illustrates a feature-filling rule, in which the feature [−anterior], characterizing the post-alveolar /ʃ/, spreads to the /s/, but the /s/ itself is unspecified for the feature [+anterior]. Within models of underspecification (Archangeli 1988; Paradis and Prunet 1989), the default feature [+anterior] is assumed to be filled in by a default rule at the end of the derivation if no specification is provided by a specific rule.

Consonant harmony may also be *feature-changing* where the target and trigger have opposite values for the spreading feature. Sibilant harmony in Ineseño Chumash has been analyzed as feature-changing (Poser 1982, 1993; Lieber 1987; Steriade 1987b; Shaw 1991), because harmony can be triggered by either [+anterior] /s/ or [−anterior] /ʃ/, altering the specification of the other sibilant. The target consonant acquires the specification of the trigger through spreading, and loses its own feature specification by delinking its original association line. This is illustrated in (18) for [ʃ-ilakʃ] 'it is soft':

(18) *Feature-changing harmony*



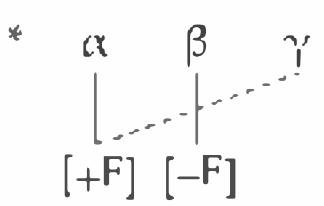
In (18), the feature [anterior] is shown linked to the rest of the segment. In more articulated models of feature geometry (Clements 1985, 1991; Sagey 1986; McCarthy 1988; Clements and Hume 1995), features link to organizing nodes, which in turn link to the root node, connected directly to prosodic structure.

3.1.1 Transparency and spreading

In both of the representations above, spreading takes place between two sibilants, despite the fact that other consonants and vowels intervene between the trigger and target. Intervening segments have the potential to block harmony, a phenomenon that is routinely observed in both vowel harmony and local vowel–consonant harmony. However, blocking is not generally observed with consonant harmony (Hansson 2001a; Rose and Walker 2004).[4]

Blocking segments, or "opaque" segments, can be characterized as those that are specified with the opposite value to the spreading feature. For example, in van der Hulst and Smith (1982a) [−nasal] segments block spreading of [+nasal] in nasal harmony. The [+nasal] feature cannot spread over the association line linking [−nasal] to a non-nasal segment, as this would violate the No-Crossing Constraint (Goldsmith 1979), a principle of autosegmental phonology (CHAPTER 14: AUTOSEGMENTS), which prevents association lines crossing. This is illustrated schematically in (19), where the symbols α, β, and γ represent segments and [+F] the spreading feature, and where the [−F] value of a feature blocks the [+F] value from spreading.

(19) *No-Crossing Constraint*

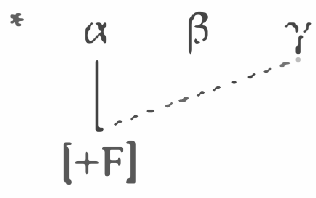


In more recent accounts, the blocking segment is assumed to be incompatible with the spreading feature due to an articulatorily grounded constraint (Archangeli and Pulleyblank 1994), preventing co-occurrence of the spreading feature and a specific feature or features of the blocking segment. For example, in nasal harmony, obstruents block nasal harmony in many languages (Walker 2000a), so [+nasal] may be restricted from associating to a [−sonorant] segment. Under this scenario, the No-Crossing Constraint does not apply; instead *locality* considerations prevent the spreading feature from skipping over the blocking segment and spreading to another segment. How locality should be defined has been a matter of debate.

[4] One identified case is a voicing alternation in Imdlawn Tashlhiyt Berber, which is parasitic on sibilant harmony. Voiceless obstruents block voicing from transferring from stem to prefix.

If locality is defined at the level of the root node or segment, such that adjacent segments are local, no segment can be skipped in spreading, a theory referred to as *strict locality*. This is illustrated schematically in (20).

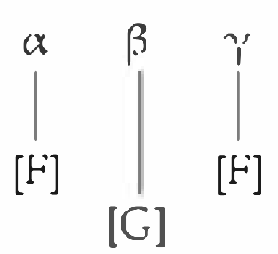
(20) *Strict locality*



Under this view, consonant harmony would be similar to local assimilation (CHAPTER 81: LOCAL ASSIMILATION), but extended over longer strings of segments.

Locality may also be defined at the level of vowel nuclei of adjacent syllables (Archangeli and Pulleyblank 1987, 1994), in which case intervening consonants would be considered transparent. This is referred to as *maximal scansion* in Archangeli and Pulleyblank (1987). A third possibility is to define locality with respect to autosegmental feature tiers, or feature node tiers in a feature-geometry model, referred to as *minimal scansion* (Archangeli and Pulleyblank 1987; Steriade 1987a). Segments that lack specification on such tiers would not be computed for locality. In the following schematized representation, the features [F] of the segments α and γ would be adjacent on the F tier, despite not belonging to adjacent segments:

(21) *Tier-based locality*



Tier-based locality lies at the heart of autosegmental spreading analyses of transparency in harmony.

Steriade (1987b) argued that intervening transparent consonants and vowels in Ineseño Chumash sibilant harmony lack specification for the feature [anterior] at the point when the harmonic spreading rule applies. Dorsal and labial consonants are excluded from participation in the harmony, as they have place feature specifications on other tiers – Dorsal and Labial. The feature [anterior] is assumed to be relevant only for coronal consonants. The same holds true for vowels in a system in which vowels are considered dorsal (Sagey 1986; Steriade 1987a).[5] Yet the coronal consonants /t l n/ are also transparent in Chumash. Steriade adopts a form of contrastive specification, wherein only segments that contrast for a given feature need to be specified for that feature. The feature [anterior] is needed to distinguish sibilants in Chumash, but /t l n/ do not have [–anterior] counterparts, and so are predictably [+anterior]. Predictable features are left unspecified and filled in as default later in the derivation. Harmonic

[5] This analysis might be problematic for feature systems in which coronals and front vowels share specification (Clements and Hume 1995), depending on how locality is defined (see Odden 1994 for discussion of vowel–consonant locality issues in this model).

spreading of the [anterior] feature operates unhindered between sibilants before a redundancy rule ([+coronal, -continuant] → [+anterior]) fills in predictable values on the other coronals. Locality is defined on the tier [anterior] as the spreading rule targets only consonants specified for [anterior], not those specified as Coronal, the organizing node on which [anterior] is dependent (Shaw 1991). Chumash is a feature-changing rule, but if spreading rules are feature-filling, targets would need to be defined with respect to other features or the node to which the feature attaches.

Harmony does not always operate at the level of individual features, however. Shaw (1991) argues that a more complex harmony system in Tahltan involves spreading the Coronal node (CHAPTER 12: CORONALS). Tahltan has a rich inventory of coronal consonants, contrasting dental stops, lateral continuants, interdental/pre-dorsal sibilants, alveolar sibilants, and palatal sibilants. The latter three sibilant classes participate in coronal harmony, but the stops and laterals do not (examples in (2)). Shaw argues that in order to distinguish among a series of three sibilants, at least two features dependent on Coronal are needed. Under the assumption that a single unified spreading rule should capture the harmony, Shaw proposes that harmony involves spreading of the Coronal node. The other two transparent classes must be underspecified for Coronal at the time the rule applies. Similar harmonic effects (e.g. /s/ → [ʃ]), therefore, involve different spreading rules, depending on the particular inventory of the language.

Gafos (1998, 1999) rejects tier-based locality, and presents a model of "Articulatory Locality," in which locality is defined in terms of articulatory gestures (Browman and Goldstein 1986, 1989, 1990). Vowel gestures are contiguous across a consonant, whereas consonant gestures are not contiguous across a vowel. Vowel harmony may appear to skip over consonants, but consonants are in fact unaffected audibly by the spreading gesture. This strict locality view is also adopted by Ní Chiosáin and Padgett (1997, 2001), Walker and Pullum (1999), and Walker (2000a). Under strict locality, only coronal harmony, which involves assimilation for a tongue tip-blade feature, is predicted to be possible, due to non-interference with vowels. The tongue tip-blade is independent of the tongue dorsum used in the production of vowels, and its exact posture has no significant acoustic effect on vowel quality. By the same reasoning, dorsal and labial consonants would be predicted to intervene as "transparent," since changes in the tongue tip-blade would not affect their production. Moreover, if the feature that distinguishes /s/ and /ʃ/ is apicality (tongue tip) *vs.* laminality (tongue blade), languages with no apical–laminal coronal stop contrast may allow stops to fluctuate between apical and laminal in different harmonic contexts, a suggestion made by Peter Ladefoged, as reported in Steriade (1995). Gafos (1999) formalizes this idea and proposes two new tongue tip-blade parameters: Tongue Tip Constriction Orientation (TTCO) and Tongue Tip Constriction Area (TTCA), gestures that do not skip over other segments, but are maintained through their production with little perceptible effect. Coronal segments /t n l/ in Chumash harmony are predicted to alter their production in accordance with the harmonic domain in which they occur, either apical [n̺] in words like /k-sunon-us/ → [ksun̺on̺us] 'I obey him' or laminal [n̻] in words like /k-sunon-ʃ/ → /[kʃun̻on̻ʃ] 'I am obedient'. TTCO is identified as tip-up (↑) for apical and tip-down (↓) for laminal. As non-sibilant coronals do not contrast on this dimension in Chumash, they are not perceived as distinct.

(22) *Gestural extension under strict locality*

	apical	*laminal*
	k - s u n̪ o n̪ - u s	k - ʃ u n̪ ● n̪ - ʃ
TONGUE TIP	TTCO ↑	TTCO ↓

Gafos argues that the strict locality view of consonant harmony explains the absence of other types of place harmonies. Major place gestures that define dorsal and labial consonants cannot spread across vowels (*contra* Shaw 1991) without serious interruption of the vowel gestures. Minor features such as tongue tip position can. Tier-based locality is unable to adequately explain why only Coronal, and not Labial and Dorsal, nodes can spread in feature geometry. In addition, the restriction of harmony to subclasses of coronals, such as sibilant fricatives and affricates, is explained, as these segments involve contrast along the tongue orientation dimension.

In conclusion, spreading approaches to harmony involve the spreading of a feature or the extension of a gestural parameter over other vowels and consonants. The non-participation of these consonants receives two explanations. In the autosegmental framework, it is due to a version of feature underspecification (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION) and tier-based locality, allowing for certain kinds of harmony interactions between specific features. In a gestural framework (Gafos 1999), transparency is illusory – articulators perform the harmonic gestures, but have little impact on consonants and vowels that do not involve those articulators, or for which changes in the articulation are non-contrastive and hence perceptually non-distinct.

3.1.2 *Challenges to the spreading approach*

While the analysis of consonant harmony as feature spreading or gestural extension seems appropriate for characterizing retroflex harmony and some sibilant harmony cases, it encounters several challenges when applied to a fuller typology of consonant harmony systems as outlined in §2. Gafos (1999) assumes that coronal harmony is the only type of consonant harmony. Shaw's (1991) typology of consonant harmony identifies only laryngeal harmony as another possibility.[6] Laryngeal features primarily distinguish among obstruents. As vowels and sonorants are inherently voiced and unspecified for laryngeal features (Itô and Mester 1986), laryngeal harmonies can operate between laryngeal tiers specified only on obstruents, thereby respecting tier locality. Gafos (1999) does not explicitly discuss laryngeal harmony within the Articulatory Locality model.

However, the larger typology outlined in §2 prompts Hansson (2001a) and Rose and Walker (2004) to conclude that autosegmental spreading is inadequate as a general model of consonant harmony. Their arguments rest on several key properties of consonant harmony not shared with vowel harmony and vowel–consonant harmony, as well as predictions that some spreading models make about the participation of intervening segments. I focus on two main properties here: (i) no blocking and transparency, and (ii) similarity of target and trigger. Hansson (2001a) also notes the lack of sensitivity to prosody and regressive

[6] Shaw does identify other harmonies, such as labial, but these are *dissimilatory* morpheme structure constraints or morphological affixation, rather than true consonant harmony as defined in this chapter.

directionality as defining properties of consonant harmony, but the prosody insensitivity may be due to other factors. Regressive directionality is a strong tendency, but progressive directionality is also observed for consonant harmony. Furthermore, regressive directionality is not an exclusive domain of consonant harmony; it has also been observed for vowel harmony (Hyman 2002) and some forms of vowel–consonant harmony – i.e. emphasis harmony exhibits more restrictions and blocking when progressive than when regressive (Watson 1999).

3.1.3 *Blocking and transparency*

Consonant harmony differs from other types of harmony with respect to blocking effects and transparency. If nasal consonant harmony is compared with nasal vowel–consonant harmony, there are two key differences with respect to the participation of segments. In nasal consonant harmony, nasal consonants harmonize with voiced stops or approximant consonants across other consonants and vowels, even obstruents. In contrast, nasal vowel-consonant harmony shows blocking effects, usually by the same segments that are skipped in nasal consonant harmony. Second, intervening vowels do not show nasalization in nasal consonant harmony, whereas they make the best targets in nasal vowel-consonant harmony and are generally not skipped. If nasal vowel–consonant harmony involves autosegmental spreading or gesture extension, how does one explain the differences with nasal consonant harmony? It does not appear to behave as if spreading of [nasal] is involved.

A similar argument can be applied to two other types of consonant harmony. Laryngeal harmony shows no extension of voicing/devoicing or glottalization over intervening segments. Dorsalization shows no effects on intervening vowels, despite the fact that uvulars routinely lower adjacent vowels. If harmony operates as advocated by Gafos (1999), with gestures extended across other segments, these facts are unexpected. If tier-based locality is the explanation, it is hard to give a reason for the neutrality of contrastive voiced and voiceless fricatives in a laryngeal harmony involving voice harmony between stops, as is the case in Chaha.[7]

3.1.4 *Similarity*

The concept of similarity is implicitly recognized in autosegmental spreading analyses of sibilant harmony, as spreading occurs only between segments specified for the spreading feature. However, it is not a formalized aspect of spreading theory. Hansson (2001a, 2001b) and Rose and Walker (2004) propose that similarity is the driving factor in consonant harmony, and has its functional roots in speech production. For example, sibilants are highly similar to one another and it is hypothesized that production is eased if they match for the position of the tongue tip-blade. Similar, but different, consonants present production difficulties that are manipulated in tongue-twisters and emerge as speech errors in both natural and experimentally induced situations (Fromkin 1971; Shattuck-Hufnagel and Klatt 1979; Frisch 1996; Rose and King 2007; Walker 2007; Kochetov and Radišić 2009). Nasal stops harmonize with oral sonorants or voiced stops, which differ

[7] One solution might be to use the feature [spread glottis] to characterize fricatives and the feature [voice] for stops (Vaux 1998). However, voiceless stops become voiced preceding voiced stops and voiced fricatives alike in Chaha (Rose and Walker 2004).

minimally from nasals. Voicing harmony occurs between obstruents, but is usually restricted to stops, excluding fricatives. Homorganicity further contributes to similarity; some laryngeal and nasal harmonies operate only between homorganic segments.[8] All cases of harmony involve strong similarity between the harmonizing segments, even in ways that local assimilations do not. For example, while local voicing assimilation operates between all obstruents, voicing harmony may be restricted to a sub-type of obstruents based on manner.

Rose and Walker (2004) determine similarity using the metric developed in Frisch *et al.* (2004), wherein similarity is assessed on the basis of shared natural classes of distinctive features in a given language. The numbers of shared and unshared natural classes of two consonants are compared. Both the size and contrastiveness of the segment inventory contribute to the similarity ratings. Natural classes, which incorporate the notion of contrastiveness, are better able to predict gradient phonotactics and capture major class subregularities than are models based simply on distinctive feature specification. However, see Mackenzie (2005, 2009) for some criticisms of this metric.

3.2 Correspondence

Given these observations about the typology of consonant harmony, Hansson (2001a) and Rose and Walker (2004), based on Walker (2000a, 2000c), developed an account of consonant harmony within Optimality Theory (OT), termed "agreement-by-correspondence." A correspondence relationship is created between similar segments, expressed as CORR-C↔C constraints (indicated in the diagram in (23) by co-indexation). This is reminiscent of Zuraw's (2002) aggressive reduplication model, although this model does not encode similarity directly. Crucially, there is no autosegmental feature spreading between the segments, so their feature specifications are distinct.

(23) C_x V C V C_x
| |
[F] [F]

The CORR-C↔C constraints are arranged in a fixed implicational hierarchy from most similar to least similar, for example CORR-T^h↔T^h >> CORR-T^h↔T >> CORR-K^h↔T (Rose and Walker 2004: 500). Separate IDENT-CC constraints require the corresponding consonants to agree for a given feature. Input–output faithfulness constraints are placed between the CORR-C↔C constraints to achieve harmony of different similarities, or below them to produce full harmony.

The following tableau illustrates an example of sibilant harmony in Sidaama for the word /ʃalak-is/ → [ʃalak-iʃ]. CORR-s↔ʃ refers to anterior and non-anterior fricative pairs, while CORR-t↔ʃ refers to anterior stop and non-anterior fricative combinations. Candidate (24a) has a CC-correspondence relationship (indicated by the subscript $_x$ on the output sibilant consonants) and sibilant agreement, thereby

[8] Hansson (2007a) has argued that secondary articulation consonant harmonies may have a diachronic explanation related to (re)interpretation of C-V co-articulation, but similarity at the level of the secondary articulation is still observed.

satisfying the two high-ranked constraints. This candidate violates IDENT-OI[ant], due to the change /s/ → [ʃ]. IDENT-OI[ant] is violated by segments that alter an input [anterior] specification in the output. Candidate (24b) has no correspondence relationship between /s/ and /ʃ/, indicated by the different subscripts $_x$ and $_y$. Due to the lack of CC-correspondence, this candidate does not violate IDENT-CC[ant]. Candidate (24c), on the other hand, does have sibilants in a CC-correspondence relationship. The sibilants do not agree for anteriority, thereby violating IDENT-CC[ant]. The [anterior] feature is used here although other features such as [distributed] or [Tongue Tip Constriction Orientation] are also possible.

(24)

/ʃalak-is/	IDENT-CC[ant]	CORR-s↔ʃ	IDENT-OI[ant]	CORR-t↔ʃ
☞ a. $ʃ_x$alak-i$ʃ_x$			*	
b. $ʃ_x$alak-is_y		*!		
c. $ʃ_x$alak-is_x	*!			

No correspondence relationship is established between the fricative and the voiceless stop /k/, or with the vowels, as these two sounds are not sufficiently similar. Other work analyzing coronal harmony systems as involving corresponding segments or feature copy includes Clements (2001) and McCarthy (2007).

The correspondence-based approach to consonant harmony allows similar consonants to agree at a distance; transparent segments are those that are not similar enough to participate in the harmony. No blocking is predicted, as lack of harmony is due to either the lack of or the low ranking of correspondence between intervening segments. This approach sets consonant harmony apart from vowel harmony and vowel–consonant harmony in using a different analytical mechanism.[9]

A more accurate typology of consonant harmony has led to alternate analytical devices, using correspondence-based relations rather than autosegmental spreading. The assumption that all harmony systems are alike and therefore subject to the same type of analysis has also been called into question, representing a significant departure in the analysis of consonant harmony *vs.* other harmony systems.

3.2.1 *Challenges to the correspondence approach*

Despite the advances of the correspondence approach in unifying the typology of consonant harmony and setting it apart from other types of harmonies, challenges to this model have arisen.

In the arena of coronal harmony, there is still debate over whether correspondence is the appropriate mechanism. McCarthy (2007) argues that Chumash harmony should be analyzed via correspondence, as it shows clear differences from local assimilations and dissimilations. Arsenault and Kochetov (forthcoming) also support the correspondence approach in their analysis of sibilant and retroflex harmony in Kalasha. They argue that since coronal harmony in Kalasha is restricted to apply only between consonants with the same manner of articulation, this

[9] Krämer (2001, 2003) develops a surface correspondence approach for vowel harmony, with adjacency defined at a moraic or syllabic level. Pulleyblank (2002) offers a different perspective that accounts for both vowel and consonant harmony using a "no-disagreement" harmony-driver (see also Archangeli and Pulleyblank 2007).

lends support to the correspondence approach, which formally encodes similarity. Spreading approaches would need to explain why harmony operates only between consonants of like manner.

Gallagher and Coon (2009) nevertheless argue that correspondence is appropriate for harmonies that require complete identity between consonants, but not for those that induce limited featural agreement, such as most sibilant harmonies. Gallagher and Coon focus on harmony data from Chol, a Mayan language of Mexico. The Chol pattern is an interaction between laryngeal harmony and coronal strident harmony. Total identity (25a) between consonants is required in two cases: (i) two ejectives in a root or (ii) two plain stridents. If the two consonants differ in terms of laryngeal features (ejective and plain), then only strident harmony is enforced (25b).

(25) a. *Total identity*

Plain stridents			Ejectives		
*ts-s	sus	'scrape'	*k'-p'	k'ok'	'healthy'
*s-ʧ	ʧiʧ	'older sister'	*t'-ts'	t'ot'	'snail'
				ʧ'iʧ'	'blood'

b. *Strident harmony*

*ts'-ʃ	ts'is	'sew'
*s-ʧ'	ʃuʰʧ'	'thief'

Strident harmony is always enforced, regardless of laryngeal specification, but laryngeal harmony requires complete identity. Gallagher and Coon's analysis requires that similar consonants (those that share certain features) are "linked" (i.e. correspond), and an identity constraint requires them to be completely identical. Ejectivity renders consonants more similar than stridency. Although the proposal accounts for the particular case of total identity seen in Mayan languages,[10] it does not extend to other cases of consonant harmony outlined in §2, which show partial identity effects, but cannot receive a spreading analysis due to the transparency of the intervening segments. Moreover, it is not clear why ejectivity in particular requires a total identity between segments. Laryngeal harmonies are often restricted to a subset of obstruents (stops) and homorganicity is also frequently involved. This signals that more research on how to define similarity is required.

In the arena of blocking, Hansson (2007b) argues that while lack of blocking is a descriptive characteristic of consonant harmony systems, it does not necessarily follow from the agreement-by-correspondence approach. Blocking could arise in scenarios in which three segments are in correspondence, but in different correspondence relationships, either different local relationships for the same feature or different featural relationships. More research is necessary to determine whether such scenarios are actually attested, or whether the correspondence analysis requires modification. If attested, this would undermine one of the strong arguments for why consonant harmony should not receive the same analysis as vowel harmony or vowel-consonant harmony.

[10] Indeed, the analysis predicts that combinations such as /ts ts'/ are acceptable as they disagree for ejectivity, when in fact they are not attested.

Despite various criticisms, the correspondence approach to harmony has stimulated new areas of research in the analysis of long-distance assimilations and has pushed researchers to examine languages in more detail, to conduct corpus studies of morpheme structure constraints, and to investigate harmony from an experimental angle.

3.3 *The role of contrast in consonant harmony*

The concept of *contrast* (CHAPTER 2: CONTRAST) has long played a role in autosegmental spreading analyses of consonant harmony, specifically in determining feature specification. Steriade (1987b) and Shaw (1991) rely on the fact that only sibilants contrast for [anterior] to explain the transparency of stops and sonorants to sibilant harmony. In the correspondence model of harmony, the role of contrast is not emphasized. Although Hansson (2001a) and Rose and Walker (2004) mention contrast, its role in determining harmony systems does not figure prominently in their model, except indirectly via the natural classes model of computing similarity (Frisch 1996; Frisch *et al.* 2004), which Rose and Walker (2004) adopt. Yet recent research has returned to the issue of contrast, both as a means of constraining harmony, and in promoting contrast as the driving force behind consonant harmony.

Mackenzie (2005, 2009) argues that similarity in consonant harmony should be formalized on the basis of contrastive featural specifications determined by a language's inventory. Segments that are similar to one another in their contrastive specifications, not necessarily segments that are most similar phonetically, interact in harmony. In the harmony system of Bumo Izon, an Ijoid language, voiced implosives and voiced stops may not co-occur, with two exceptions: /g/ and /ɡ͡ɓ/ (Efere 2001); these sounds freely co-occur with stops of the opposite pulmonic value: [ɗúgó] 'to pursue' or [ɡ͡ɓóɗaɡ͡ɓóda] 'rain (hard)'. Mackenzie points out that these sounds lack a contrastive counterpart: there is no /ɠ/ or /gb/. The natural classes model (Frisch *et al.* 2004) of calculating similarity does take phonemic inventory into account when computing natural classes and similarity, but it fares poorly with asymmetric inventories in which contrastive counterparts are missing. Hansson (2004) notes this problem with respect to laryngeal harmony in Ngizim, where implosives do not participate. Mackenzie's solution is to determine similarity via pairwise contrasts that are partially language-specific. If two sounds are not specified for a feature due to lack of contrast, they do not participate in the harmony, which references presence of features.

Hansson (2008) examines the role of contrast in the typology of vowel harmony and consonant harmony and notes that only consonant harmony has cases of "symmetric neutralization," in which a lexical [±feature] contrast emerges in affixes only with neutral roots. The regressive sibilant harmony systems of Chumash and Navajo involve neutralization of contrasts on both roots and affixes, as either /s/ or /ʃ/ can trigger harmony as long as it is the rightmost sibilant in the word. Hansson argues that systems of this type are attested in consonant harmony, but not vowel harmony, because they are *recoverable*. The loss of contrast between /s/ and /ʃ/ is minimal in the consonant inventory, and affects only a small subclass of consonants. The learner has a large number of contexts provided by neutral roots to compensate for neutralization. Hansson (2001a) notes that the specific combination of symmetric neutralization with absolute directionality of assimilation creates problems for some models of phonology, such as Declarative Phonology and standard Optimality Theory.

Finally, Gallagher (2008, 2010) argues for a notion of laryngeal contrast rooted in dispersion theory with a more global view of contrast within a language's lexicon. A constraint, Laryngeal Distance, penalizes contrasts between roots that have only one laryngeally marked stop *vs.* those with two. Plain stops are unmarked for laryngeal features. Gallagher argues that the distinction between a root with one laryngeal feature and a root with two laryngeal features is perceptually weak. Avoidance can play out as harmony (only two ejectives [k'ap'a] or two plain stops [kapa] are allowed) or as dissimilation (only one plain and one ejective are allowed [k'apa] or two plain [kapa]).

In conclusion, contrast remains a powerful and debated concept in the study of consonant harmony, one that is sure to resonate in future research.

4 Experimental approaches to consonant harmony

As debate about the most appropriate analysis of consonant harmony has come to center on hypotheses about its grounding in articulation or perception, experimental studies of consonant harmony have been conducted (CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY). The correspondence approach to consonant harmony proposes that harmony is grounded in production difficulties caused by phonological planning and the similarity of interacting consonants. Several experiments have been undertaken to test this hypothesis in the area of speech errors.

Walker (2007) conducted an experimental study inducing speech errors. Consonants that were more similar and known to participate in nasal harmony, such as nasals and voiced stops, were predicted to be more prone to speech errors than other combinations. Nonce words with combinations of nasals and voiced stops and nasals and voiceless stops were tested with English speakers, as English is not reported to have nasal consonant harmony. Indeed, more errors arose with nasal–voiced stop combinations than nasal–voiceless. Walker concluded that nasal harmony could indeed be grounded in difficulties with the production of similar sounds.

Kochetov and Radišić (2009) performed a similar experiment on combinations of four sibilant fricatives /s sʲ ʃ ʃʲ/ in Russian in a repetition task performed at a fast rate of speech. Errors (assessed by examining acoustic effects of production) were observed for both primary place of articulation and secondary articulation. The primary-place assimilation errors were generally regressive and involved /s/ changing to [ʃ], reflective of the "palatal bias" effect reported in other speech-error studies on English. Although Russian is not reported to have sibilant consonant harmony, the speech-error effect is similar to that found in harmony languages, supporting Hansson's (2001a, 2001b) observation of the correlation. However, Kochetov and Radišić (2009) also note that consonants differing only in secondary articulation did not participate in as many errors and that those errors were progressive. This seems to lend support to Hansson's (2007a) contention that speech production difficulties may not underlie secondary articulation harmonies. Kochetov and Radišić (2009) speculate that feature spreading or gestural extension may be a better analysis for these cases, paralleling vowel harmony.

Rose and King (2007) examined the impact of harmony constraints on speech errors in languages observed to have laryngeal harmony, namely Chaha and Amharic. They found higher speech-error rates for certain sequences that violated laryngeal harmony than for those that did not. In particular, the researchers compared the laryngeal pairs with consonant pairs that were also highly similar and infrequent in verb roots, but did not violate any constraints. These pairs did not show high error rates in comparison. Rose and King conclude that laryngeal harmony is not only based on production difficulties, but also, once encoded grammatically, triggers more errors when speakers encounter sequences that violate it.

Walker *et al.* (2008) investigated coronal harmony in Kinyarwanda by means of electromagnetic articulography. Kinyarwanda exhibits retroflex harmony, previously reported in the literature as an alveolar–post-alveolar sibilant harmony (Walker and Mpiranya 2006). Harmony is blocked by alveolar stops and affricates, retroflex stops, and palatal consonants. Intervening vowels and non-coronal consonants do not block the harmony and are not perceptibly affected. The blocking effect is suggestive of spreading, while the transparent vowels and non-coronals point to a correspondence analysis. This is important since retroflex harmony is recognized as both a type of consonant harmony (Arsenault and Kochetov, forthcoming) and a possible vowel–consonant harmony for which spreading may be a more appropriate analysis than correspondence (Gafos 1999; Hansson 2001a; Rose and Walker 2004). Walker *et al.* (2008) found evidence that the harmonizing retroflex posture persists during apparent transparent non-coronal consonants when they occur between harmonizing fricatives. Such a result is more supportive of a spreading or gestural analysis, in line with Gafos's (1999) Articulatory Locality model. Results were not conclusive for the intervening coronals. Research of this nature should be conducted on languages that have robust non-retroflex sibilant harmony to help address the question of whether spreading or correspondence is a more appropriate analysis. At the same time, this raises the issue of whether gradient phonetic articulatory results should be used to determine phonological representations.

Finally, Gallagher (2010) utilizes perceptual experiments to test the validity of her contrastive perceptual distance model of laryngeal harmony. American English subjects who listened to pairs of Bolivian Quechua words with combinations of ejectives and plain stops had the greatest difficulty perceiving contrasts between two words where an ejective and a plain stop contrasted with two ejectives ([k'apa] *vs.* [k'ap'a]). The two harmonic forms wherein two ejectives contrast with two plain stops ([k'ap'a] *vs.* [kapa]) were the easiest to perceive, with [k'apa] *vs.* [kapa] occupying an intermediary position. It is argued that these results provide support for a perceptual motivation for consonant harmony, with harmony viewed as a response to avoid difficult perceptual contrasts.

Experimental research in consonant harmony using a variety of techniques may help illuminate the causes of harmony (perceptual, articulatory, or both) and the best phonological analysis of this phenomenon. It may help sort out whether consonant harmony should be viewed as a unified phenomenon or as several disparate phenomena that share the common characteristic of assimilation at a distance.

5 Conclusion

Consonant harmony has intrigued researchers for many years, due to its tantalizing similarities to other types of harmony. Recognizing what distinguishes it from other harmony systems has nevertheless pushed analysis in new directions. Two competing approaches have been advanced: *spreading* of features or gestural extension and *correspondence* between segments requiring matching for features. Both analyses have positive attributes, but both are not without challenges. It is also possible that spreading is appropriate for some harmony systems but correspondence for others, as has been suggested by different researchers (Hansson 2001a; Gallagher and Coon 2009; Kochetov and Radišić 2009). Research in experimental directions may help shed light on which analysis is ultimately correct and whether altogether new analyses will eventually emerge.

78 Nasal Harmony

Rachel Walker

Nasal harmony refers to phonological patterns where nasalization is transmitted in long-distance fashion. The long-distance nature of nasal harmony can be met by the transmission of nasalization either to a series of segments or to a non-adjacent segment. Nasal harmony usually occurs within words or a smaller domain, either morphologically or prosodically defined. This chapter introduces the chief characteristics of nasal harmony patterns with exemplification, and highlights related theoretical themes. It focuses primarily on the different roles that segments can play in nasal harmony, and the typological properties to which they give rise. The following terminological conventions will be assumed. A *trigger* is a segment that initiates nasal harmony. A *target* is a segment that undergoes harmony. An *opaque segment* or *blocker* halts nasal harmony. A *transparent segment* is one that does not display nasalization within a span of nasal harmony, but does not halt harmony from transmitting beyond it.

Three broad categories of nasal harmony are considered in this chapter. They are (i) nasal vowel–consonant harmony with opaque segments, (ii) nasal vowel–consonant harmony with transparent segments, and (iii) nasal consonant harmony. Each of these groups of systems show characteristic hallmarks. Nasal vowel–consonant harmony refers to systems in which vowels and consonants participate in the pattern as either triggers or targets. Sundanese manifests one of the most limited forms of nasal vowel–consonant harmony, where vowels and laryngeal segments are targets of harmony. Other systems are more liberal in the scope of their targets, including some or all sonorant consonants, and sometimes even obstruents. In many patterns of nasal vowel–consonant harmony, Sundanese included, the segments that are not targets are blockers. In other systems, some or all obstruents are transparent, while vowels, laryngeals and sonorant consonants are targets. On the other hand, in nasal consonant harmony, only consonants participate, and vowels are transparent. Certain categories of consonants are also transparent in cases where nasal consonant harmony can occur at any distance within its domain. Nasal stops trigger harmony in these systems, and the targets are typically drawn from the set of stops and/or approximant consonants.

A core topic of theoretical debate revolves around whether systems of nasal vowel–consonant harmony with opaque segments and those with transparent segments should be analyzed as the same or different with respect to the driving force for harmony and the types of representations involved. Further, the distinct properties of nasal consonant harmony and nasal vowel–consonant harmony have led to proposals about their formal differences, such as the level at which the feature [nasal] spreads in the structure; more recently, an approach has been advocated in which consonant harmony is achieved through relations constructed between similar segments rather than feature spreading. Signposted throughout this chapter will be many other issues in phonology with which the topic of nasal harmony intersects. For instance, nasal harmony has played a significant role in discussions that concern the grounding of phonological patterns in phonetic principles, contrast and speech planning. The nature of locality in phonology is another primary theme. Directionality effects are also examined in this chapter.

1 Nasal vowel–consonant harmony with opaque segments

Nasal vowel–consonant harmony refers to nasal harmony in which both vowels and consonants participate as triggers and/or targets (see CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). A central typological observation that emerges from cross-linguistic studies is that nasal vowel–consonant harmony with opaque segments respects the implicational scale in (1). Categories further to the right are progressively disfavored as targets, and the inclusion of any category as a target in a harmony pattern implies that all categories to its left will be targets (Schourup 1972; Piggott 1992, 2003; Cohn 1993a, 1993b; Walker and Pullum 1999; Walker 2000a; see Hume and Odden 1996 for related discussion). The category "laryngeals" refers to [h ʔ].

(1) vowels > laryngeals > glides > liquids > fricatives > obstruent stops

The hierarchy in (1) summarizes a pervasive generalization that emerges from nasal vowel–consonant harmony patterns across languages. However, some fine-tuning may be needed, as discussed in connection with particular cases below. The hierarchy has been suggested to have a phonetic basis, whereby nasalization of segments that are lower on the scale is disfavored for reasons of articulation, aerodynamics, and/or perceptibility (see Walker 2000a and references therein). Maintenance of a system of contrasts has also been suggested to underlie the hierarchy in (1) (e.g. Flemming 2004). This scale shows a striking similarity to the sonority hierarchy, on which see CHAPTER 49: SONORITY. Nevertheless, they are distinct in the ranking of nasal stops, which are usually situated between liquids and obstruents in the sonority hierarchy, but could plausibly be located at the top left of the scale in (1). Furthermore, consensus is lacking on the placement of laryngeals in the sonority scale. I return to this issue later in this section, in the context of the impedance hierarchy proposed by Hume and Odden (1996); for further discussion, see Cohn (1993a), Gnanadesikan (1995), Boersma (1998, 2003), and Walker (2000a).

Following the exemplification of hierarchical effects in the typology, some ways of formalizing them are discussed. The exemplification of nasal vowel–consonant harmony with opaque segments begins with patterns that show a narrower set of blockers and progresses to ones with blocking by more categories.

The dialect of Scottish Gaelic spoken in Applecross (Ross-shire), henceforth "Applecross Gaelic," displays a nasal harmony where nasalization is reported to target all segment categories except obstruent stops (Ternes 2006). Nasalization spreads from a stressed nasal vowel. Stress is usually – but not always – assigned to the initial syllable. Progressive nasalization is halted by an obstruent stop. In addition, consonants in the onset of a syllable with a stressed nasal vowel are nasalized except obstruent stops.

(2)	a.	*Monosyllables*		
		l̃ˠɔ̃ũ·m	'bare, naked'	
		l̃ˠãːɟ̃	'hand'	
		mĩã·r̃	'finger, toe'	*lenited* ṽĩã·r̃
		kʰr̃ɛ̃ãk	'maggot'	
		str̃ãĩ·ɣ̃	'string'	
		tãɣ̃	'●x, stag'	
	b.	*Polysyllabic words*		
		'f̃r̃ĩãũn	'root (PL)'	
		'kãnã·x̃	'sand'	
		'l̃ˠã·h̃ũk	'axe, hatchet'	
		's̃ɔ̃h̃ĩ	'tame'	
		'tʰr̃ĩĩʃ̃ãr̃	'plate'	
		'ʃ̃ɛ̃nɛ̃·ṽãr̃	'grandmother'	
		'kʰɔ̃ĩs̃paxk	'wasp'	
		'mĩnĩʃtʲar	'minister (clergyman)'	
		's̃nˠã·nʲdʲan	'thread'	

Transcriptions of nasalized fricatives in Applecross Gaelic follow Ternes; however, the realization of such segments in general have been the subject of debate. Nasalized fricatives present an aerodynamic confound with consequences for perception: an increase in velopharyngeal opening tends to reduce frication and a decrease in velopharyngeal aperture can reduce perceptible nasalization (CHAPTER 28: THE REPRESENTATION OF FRICATIVES). Gerfen (1999, 2001) has brought instrumental research to this question for the nasal harmony of Coatzospan Mixtec. See Shosted (2006) and Solé (2007a) for recent reviews of the issues and experimental investigations. Whether and how the gradient trade-offs in realization should be represented in phonology remains an open question.

Color and height distinctions in nasal vowels of Applecross Gaelic are a proper subset of those in its oral vowels. The mid-high vowel series /e ə o/ is always oral, and, like the obstruent stops, they block nasal harmony. Examples with blocking by [ə] are given in (3). All other vowel qualities in the language ([i ɨ u ɛ ɔ a]) can be phonemically oral or nasal and can become nasalized through nasal harmony.

(3)	's̃ãũl̃ˠəxkənʲ	'to compare'
	'ãɟ̃əlˠ	'angel'
	'nʲĩən	'girl, daughter'
	kʰa'tʰr̃ĩãnə	'Catherine'

Blocking of nasal harmony by mid vowels is also attested in Mọ̀bà Yoruba, discussed in §2. The resistance of mid-high vowels to contrastive or contextual nasalization has plausible origins in effects of nasalization on the perception of vowel height. The perceived distance of a height distinction between two oral vowels is reduced when those same vowels are nasalized (e.g. Wright 1986), which could give rise to the restriction of nasalization to a subset of the oral vowel heights in Applecross Gaelic (Homer 1998; Walker 2000a). In general, the number of nasal vowels in a language never exceeds the number of oral vowels, and it is relatively common for one or more mid nasal vowels to be missing relative to the oral inventory in a language. Nasalization may interfere most with detection of height distinctions involving mid vowels; also perceptual integration of nasalization and height in vowels disfavors mid percepts (Kingston 2007). This suggests the possibility that the descriptive hierarchy in (1) could be moderated by or interact with the effects of contrast, an issue to which I return later in this section.

Given that Applecross Gaelic has nasal stops, the question arises whether they too can trigger nasal harmony. When they occur in the onset to a stressed syllable with an oral vowel, they do not.

(4) mur 'sea'
mara·v 'dead person'

These examples do not necessarily demonstrate that triggers of nasal harmony in Applecross Gaelic must be stipulated to exclude nasal stops. It is conceivable that stressed vowels not only trigger nasal harmony when they are nasal, but also block it when they are oral; that is, they can spread nasalization but do not alter their own phonemic oral/nasal quality. A situation of this kind in Guaraní is discussed in §2. I found no examples in Applecross Gaelic with a stressed oral vowel and a following nasal with which to test whether a nasal stop triggers harmony in a following unstressed syllable. The scarcity of such forms is likely because vowel nasalization in Applecross Gaelic in most cases arose historically from a nasal consonant in the vicinity that was either retained, lost, or lenited. In some cases, the nasal consonant is still reflected in the orthography: [tãɣ̃] *damh* 'ox, stag', ['s̃ã·h̃ũx̃] *sàmhach* 'quiet'.

A pattern of nasal harmony that includes a supralaryngeal fricative among its blockers is found in Epena Pedee (Saija), a Chocó language of Colombia (Harms 1985, 1994). Nasal vowels trigger progressive nasal harmony, as shown in (5a). Certain consonants in the onset of a syllable that contains a nasal vowel also become nasalized, as will be discussed presently. Of particular relevance is the set of consonants that block progressive nasal harmony, seen in (5b); this includes /s/, which is the only supralaryngeal fricative phoneme in the language, as well as other obstruent phonemes and the trill /r/.[1] Within the stem, non-continuant obstruents become prenasalized following a nasal vowel (Harms 1994). The phonemic analysis and phonetic description for these examples follow Harms. Some phonemic forms are constructed on the basis of his orthography, which is close to phonemic.

[1] The description of Harms (1985: 16) states that /s/ blocks progressive nasal harmony. The later description by Harms (1994: 8) seems to indicate that /s/ does not always block spreading, but includes the example ['mĩʔ̃ãsu] 'spear', where it is opaque (1994: 6). Another example, ['s̃ĩʔ̃ãs̃õ] 'sugarcane' (1994: 5), could be regarded as showing that /s/ does not block spreading, since Harms's phonemic transcription of this word posits only the first syllable as underlyingly nasal. However, it is also compatible with a treatment in which both the first and last syllables contain nasal vowels underlyingly.

Regressive nasalization occurs within syllables containing a nasal vowel but does not usually transmit beyond the onset.[2] Syllables in Epena Pedee are open and begin with a consonant; consonant clusters are infrequent. A consonant that is tautosyllabic with a nasal vowel becomes nasalized except for [pʰ tʰ kʰ ʧ] ([p t k] and [r] do not occur preceding a nasal vowel). In contrast to their behavior in the progressive harmony, /s/ is characterized as nasalized when preceding a nasal vowel and voiced stops become full nasals. Harms analyzes [m n] as allophones of voiced stops; they are not part of the phonemic inventory. Harms includes [ʔ] in the category of segments that do not become nasalized in the onset to a nasal vowel. While nasalization would not be audible during [ʔ], it is possible that the velum is lowered during this segment. The status of [ʔ] in nasal harmony in general is discussed later in this section.

(5)	a.	/ˈdãw̃e/	[ˈnãw̃ẽ][3]	'mother'
		/peˈɾõɾa/	[peˈɾ̃õɾ̃ã]	'guagua (a groundhog-like animal)'
		/kʰãˈjaɾa/	[kʰãˈɲãɾ̃ã]	'than'
		/hẽˈsã:/	[h̃ẽˈs̃ã:]	'stinging ant'
		/hebẽˈdẽ/	[hemẽˈnẽ]	'to play'
	b.	/kʰĩˈsia/	[kʰĩˈsiə][4]	'think'
		/ˈbĩãsu/	[ˈmĩə̃su]	'spear'
		/ˈãʧi/	[ˈʔãⁿʧi]	'they'
		/ˈhõpʰe/	[ˈh̃õᵐpʰe]	'fish (sp.)'
		/kʰũˈtra:/	[kʰũˈⁿtra:]	'young man'
		/ĩˈbɨsi/	[ʔĩˈᵐbɨsi]	'neck'
		/w̃ãhiˈda/	[w̃ãh̃ĩˈⁿda]	'go (PAST PL)'
		/ˈãĩgi/	[ˈʔãĩᵑgɨ]	'daughter-in-law'
		/ˈtũ:ra/	[ˈtũ:ra][5]	'pelican'

Blocking of nasal harmony by /r/ is likely due to the aerodynamic and perceptual difficulties that a nasal trill would present (Solé 2002, 2007b). Solé points out that "an open velopharyngeal port would bleed the intraoral pressure required to make a relaxed oscillator vibrate for trills" (2002: 677). In addition, a velopharyngeal opening that was small enough to not impair a trill would likely be of insufficient size to produce perceptible nasalization. However, Solé observes that a tap is compatible with nasalization. This is consistent with the pattern that Epena Pedee displays. The distinct behavior of taps and trills suggests that the category of liquids in the scale of targets for nasal harmony should be segregated into a category that includes taps, flaps, and lateral approximants and another lower-ranked category that contains trills. A case where taps and laterals are both targets to the exclusion of obstruents occurs in Ịjọ, a Niger-Congo language of Nigeria (Williamson 1965, 1969, 1987).

2 Harms (1985: 16) describes "a minor degree" of nasalization on a vowel that precedes a nasal syllable, but he characterizes it as "so slight" that he does not represent it in transcription.

3 A fricative variant [β] of /w/ does not block harmony: [ˈnãw̃ẽ] ~ [ˈnãβ̃ẽ].

4 This form is transcribed in Harms (1985) with a prenasalized [s], but later description in Harms (1994) indicates that [s] is not prenasalized following a nasal vowel.

5 Harms (1985: 16) transcribes this form without aspiration of [t]; however, given his description of voiceless stops before a nasal vowel (1985: 15), it is presumably aspirated.

The prenasalization of non-continuant obstruents following a nasal vowel raises questions about their representation. One issue is whether the feature [nasal] is specified for a portion of these segments, and if it is, how the nasal-oral sequence is represented.[6] Prenasalized segments have been represented by some researchers as a single root or slot with specifications for both [+nasal] and [−nasal] (e.g. Bivin 1986; Sagey 1990), but Padgett (1995) and Piggott (1997) have analyzed prenasalization as a combination of nasal and oral segments. Steriade (1993) proposes aperture-based representations in which the closure and release phases of a stop can each form a separate anchor for [nasal], in which case a prenasalized stop has [nasal] associated with the closure but not the release. Tied in with Steriade's representation is a claim that [nasal] is a privative feature (see also Trigo 1993; Steriade 1995), which supports a bipositional representation for prenasalized plosives. Beckman (1999) applies the aperture-based approach to prenasal stops in Guarani, which may occur at the boundary between a nasal span and an oral span (see §2). While much contemporary research concurs with the need for a sequence of segments or phases within a segment, the specifics of the representation remain at issue. On a related topic, Botma (2009) proposes that post-nasalized stops that trigger nasal harmony in Yuhup are underlyingly nasals that have undergone denasalization in a particular context.

Epera (also known as Ẽperã) has a nasal harmony that is roughly similar to Epena Pedee, to which it is related, but it differs in the respect that voiced stops do not block progressive nasal harmony within a morpheme (Morris 1978; Bivin 1986). Thus, nasal harmony transmits through vocoids, laryngeals, flaps and voiced stops, but is blocked by voiceless obstruents, as illustrated in (6). The availability of this pattern could be connected to the lack of contrast between voiced and nasal stops in the language. Like Epena Pedee, nasal stops [m n] have been analyzed as allophones of voiced stops. However, not all languages that lack this contrast target voiced stops, as Epena Pedee shows. Nasalization in the underlying form is shown on the first vowel in a segment sequence that shows nasal harmony.

(6)	/bẽa/	[mẽã]	'bush'
	/hĩ-/	[h̃ĩ-]	'to tie'
	/bẽɾa/	[mẽɾ̃ã]	'greetings'
	/põsoa/	[põ^{n}soa]	'termite'
	/sãki/	[sã^{ŋ}ki]	'which'
	/ĩbaba/	[ĩmãmã]	'tiger'[7]

Nasal harmony that affects voiced stops (in some cases ones that are prenasalized in oral contexts) and that is blocked by voiceless obstruents is also reported for Orejon (Pulleyblank 1989) and Parintintin (Pease and Betts 1971; Bivin 1986). These languages, too, seem to lack a contrast between oral and nasal voiced stops, although more detailed descriptions are needed. These patterns suggest that when voiced

[6] I will use [nasal] to cover a privative nasal feature or a [+nasal] specification. Where an equipollent *vs.* privative distinction is relevant, I will disambiguate with ± notation or in surrounding discussion.

[7] For this example, the consonants' phonetic realization is based on the description provided by Morris and Bivin.

stops and nasals are not in contrast, voiced stops are more prone to undergo nasal harmony. Whether the voiced stops in such patterns should be analyzed as obstruents is open to debate. For particular cases where oral stops that alternate with nasals in nasal harmony have been analyzed as sonorants, see Piggott (1992), Rice (1993), Piggott and van der Hulst (1997), Botma (2004, 2009), and Botma and Smith (2007), although most often voiceless obstruents are transparent in such patterns (see also CHAPTER 8: SONORANTS).

Arabela, a Zaparoan language of Peru, shows a nasal harmony that targets only vowels and glides, as illustrated in (7) (Rich 1963). Nasalization spreads progressively from nasal stops and /h̃/. The glottal fricative is nasal in all contexts in this language and lacks an oral counterpart. [ʔ] occurs to close a phonological phrase and is non-phonemic.

(7)	'nẽẽnũʔ	'to turn over'
	'h̃ãnũʔ	'to fly'
	'mj̃æ̃nũʔ	'swallow'
	'nũw̃ãʔ	'partridge'
	'h̃ĩj̃æ̃nĩʔ	'old woman'
	'nj̃æ̃æ̃'riʔ	'he laid it down'[8]
	'kıronĩʔ	'deep'
	'komãh̃ĩʔ	'over there'
	'mɯ̃w̃ẽẽgur'h̃ũnũʔ	'wiggling'
	'h̃ẽẽgıʔ	'termites'
	'nẽj̃æ̃'tuʔ	'daughter'
	'nĩ'tjænũʔ	'to carry on the back'

Sundanese, an Austronesian language spoken in Western Java, has a progressive nasal harmony that targets only vowels and glottals (Robins 1957; Cohn 1990, 1993a). Nasal stops are the triggers.

(8)	ɲãĩãn	'wet (ACTIVE)'
	ɲãũr	'say (ACTIVE)'

The status of the laryngeals, [h ʔ], in nasal harmony systems deserves comment. Laryngeals rarely – perhaps never – block nasal harmony (Walker and Pullum

[8] Rich does not distinguish degrees of stress in her transcription.

1999; Walker 2000a). Blocking by a glottal stop has been reported for Rejang (Austronesian) (McGinn 1979: 187), but field research by Robert Blust suggests otherwise (Walker and Pullum 1999: 776, n. 17). In Kaiwá (Tupí-Guaraní), nasal harmony transmits through [ʔ] at a normal speech rate, but [ʔ] is reported to block nasal harmony in slow speech (Harrison and Taylor 1971: 17). It would be valuable to verify these descriptions with modern investigative techniques. Across languages, the overwhelming tendency is for nasal harmony to transmit through laryngeals. This has prompted researchers to situate laryngeals above the category of glides in the hierarchy that characterizes cross-language variation in targets of nasal vowel–consonant harmony, as in (1) (Schourup 1972; Piggott 1992; Walker and Pullum 1999). Levi (2005) has proposed a refinement in which laryngeals are situated higher than phonemic glides in particular, that is, higher than glides that are not derived from vowels rather than glides that are the non-syllabic realization of vowels.

Laryngeals have sparked discussion about the representation of nasal segments and the definition of the feature [nasal] (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION; CHAPTER 17: DISTINCTIVE FEATURES; CHAPTER 27: THE ORGANIZATION OF FEATURES). If [nasal] reports to the supralaryngeal node in the feature geometry, then laryngeal segments could not be phonologically nasal, whereas if [nasal] were a dependent of the root node, any segment could potentially be specified for [nasal] in the phonology (Cohn 1990, 1993a). Cohn assumes the former representation, but leaves the issue open for further research. Under the assumption that [nasal] is dependent on the supralaryngeal node, laryngeals are phonetically nasalized in the context of nasal segments but they do not participate in nasal processes in the phonology or have the capacity to show nasal contrasts. Piggott (1992) takes a different perspective, in which laryngeals can be phonologically [nasal], and may therefore undergo nasal harmony. In the geometry that he assumes, [nasal] can be dependent on a soft palate node, which reports to the root. He supposes, however, that a nasalized glottal stop is not phonetically possible, because of its lack of egressive nasal airflow. Accordingly, Piggott postulates a feature co-occurrence restriction over [nasal] and [constricted glottis] that applies at the later level of phonetic implementation.

Walker and Pullum (1999) also contend that laryngeals can be phonologically specified for [nasal]. Support they cite for this claim includes patterns in which [h̃] triggers nasal harmony (e.g. Arabela) or contextual vowel nasalization. For two such languages (Kwangali, Seimat), they note evidence for a phonemic contrast between [h] and [h̃]. In addition, Walker and Pullum observe that the scarcity of blocking of nasal harmony by laryngeals points to their being highly compatible with acquired nasalization, a tendency that can be straightforwardly captured if laryngeals can be phonologically nasal. To allow the possibility of nasalized laryngeals, they conclude that [nasal] should be defined as corresponding to an open velopharyngeal port rather than requiring nasal airflow (see also Cohn 1993a; Padgett 1995; Hume and Odden 1996). Therefore, a glottal stop can be nasalized by virtue of the lowered velum posture even though there is no airflow through the nasal cavity. In accordance with this perspective, laryngeals are transcribed as nasalized in this chapter when they occur within a nasal harmony span. It is plausible that [ʔ] at the periphery of a nasal harmony span, e.g. in Epena Pedee and Arabela, should likewise be treated as specified for [nasal]. Because of the lack of airflow, nasalization will not be perceptible during [ʔ̃]. This makes it unlikely that glottal stops will show a phonemic contrast in nasality (but see Walker and Pullum 1999 for a hypothesized scenario).

The language data presented above illustrate the scale of targets in patterns of nasal harmony that show blocking. All of the particular cases considered show progressive harmony, with regressive harmony in the syllable in some instances. However, some patterns show more robust regressive harmony, as discussed in §4. The scalar effects for targets have been analyzed by Walker (2000a) as the result of a hierarchy of feature co-occurrence constraints abbreviated as in (9) (excluding laryngeals, discussed below). The constraint *Nas-ObstruentStop prohibits a lowered velum during a segment that also has the features that characterize an obstruent stop, a segment that is highly difficult if not impossible. Nasalization during an articulation with stoppage in the oral cavity usually results in a sonorant stop (e.g. [m n ɲ ŋ], etc.).

(9) *Nasalized segment constraint hierarchy*

*Nas-ObstruentStop >> *Nas-Fricative >> *Nas-Liquid >> *Nas-Glide >> *Nas-Vowel

In addition to nasal harmony surveys, this markedness scaling gains support from other facts about nasal patterns, such as segment inventories and nasal place assimilation (e.g. Pulleyblank 1989; Cohn 1993a; Padgett 1995). The constraint hierarchy can be used to obtain cross-language differences in the sets of targets and opaque segments by ranking a harmony-driving constraint at different breaks in the hierarchy. Feature co-occurrence constraints that dominate the harmony driver will correspond to blocking segments and ones that are dominated will correspond to targets.

Walker suggests that the hierarchy of constraints is grounded in factors of articulatory compatibility, aerodynamic difficulty, and ease of perceptibility. However, some researchers have observed that conflating these factors is problematic with regard to inventory contrasts and laryngeals. Ní Chiosáin and Padgett (1997) point out that with respect to articulatory compatibility, a constraint against [ʔ̃] is expected to be low-ranked, likely at the same level or even below *Nas-Vowel. However, because of the lack of perceptibility of nasalization during a glottal stop, [ʔ̃] *vs.* [ʔ] makes a poor phonemic contrast. If the hierarchy in (9) included *[ʔ̃] at or near the bottom, it would correctly predict the lack of blocking by [ʔ] in nasal harmony, but it would not account for the disfavored status of a contrast between [ʔ̃] and [ʔ]. Ní Chiosáin and Padgett propose that *[ʔ̃] is low-ranked in the articulatory markedness hierarchy, but attribute the contrastive distribution to the activity of a separate constraint Contrast[nas], which penalizes a [ʔ̃]/[ʔ] distinction. Flemming (2004) goes a step further, suggesting that blocking effects in nasal harmony are a consequence of constraints governing the maintenance of contrasts, a possibility also noted by Ní Chiosáin and Padgett (chapter 2: contrast). Under Flemming's formalization, the constraint hierarchy in question scales nasalized segments according to their proximity to a nasal stop. Thus nasalized fricatives are conceived as highly indistinct from nasal stops, but nasalized vowels and laryngeals are at the upper end of the scale of distinctness from a nasal stop. Boersma (2003) proposes an account of the nasal glottal stop that distinguishes its articulation and perception but with different implementation.

Other work that emphasizes the role of segmental distinctions includes Homer (1998), who employs contrast-sensitive constraints to obtain blocking in nasal harmony. Piggott (2003) proposes faithfulness constraints specific to categories of blocking segments (stop, fricative, liquid, glide) that simultaneously prohibit segment deletion and feature change (CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). He argues that this prevents the possibility that a less favored segment category could undergo nasal harmony to the exclusion of preferred targets, by replacement of the less favored category with a nasal stop. For example, replacement of a liquid with a nasal stop would bypass the violation of a feature co-occurrence constraint on nasalized liquids, in which circumstance a nasal harmony system could be expected to exist that allows liquids to undergo harmony, but not glides. A faithfulness-based approach to hierarchical nasal harmony effects is also proposed by Boersma (1998, 2003), using constraints that penalize adding nasalization in consonants. Constraints for consonants with greater oral constriction are generally ranked higher, as nasalization is posited to have a greater perceptual effect in these segments.

Another perspective on the basis of an implicational scale of targets makes a connection with its similarity to the sonority hierarchy, mentioned earlier. Hume and Odden propose that the effects of both hierarchies reduce to an impedance hierarchy, where impedance is defined as "the resistance offered by a sound to the flow of air through the vocal tract above the glottis" (1996: 358), a concept reminiscent of Boersma's reference to degree of oral constriction. Among supralaryngeal segments, obstruent stops have the greatest impedance, and vowels and glides the least. Segments with low impedance values are favored as syllable peaks, a characteristic traditionally diagnostic of high-sonority segments, and they show greater susceptibility to nasalization. Laryngeals have an impedance value of 0. This renders them highly susceptible to nasalization, but their inability to constitute a syllable peak follows from an assumption that a syllable peak has some impedance value, i.e. a non-zero value. This addresses the earlier-mentioned discrepancy concerning laryngeals in scales governing nasal harmony and what are traditionally sonority-based phenomena (i.e. syllabification), yet it posits a common underlying basis from which scalar effects across these phenomena are derived. This approach is extended by Clements and Osu (2003), who interpret resistance to nasalization in terms of a scale of obstruence, a near-synonym of impedance. Their study revolves around Ikwere, an Igboid language of Nigeria, in which nasal harmony transmits through vowels, approximants, and non-explosive stops, but is blocked by fricatives and obstruent stops. This leads them to add a category consisting of implosives and other non-explosive stops between liquids and fricatives on the nasalizability scale.

Despite the differences in formal perspectives on patterns of nasal harmony with opaque segments, there is broad consensus that groups of targets *vs.* blockers essentially conform to the descriptive hierarchy in (1). In addition to new case studies, like that of Ikwere, future research bearing on these approaches may rest largely on the scope of coverage and emphasis, for example the treatment of sonority or contrast in the theory, which situate the account of nasal harmony in a wider context. Where explanatory overlap exists, general issues of theoretical implementation will also be relevant. For instance, future work on the division of labor between contrast, segmental markedness, and faithfulness in the theory could inform the types of constraints that are expected to be possible.

2 Nasal vowel–consonant harmony with transparent segments

Patterns of nasal vowel–consonant harmony with transparent segments are also attested. Whether the hierarchy in (1) is relevant for these patterns is a matter of debate, intersecting with fundamental questions about the kinds of representations that are involved and whether these systems are of the same basic "type" as ones with opaque segments.

A well-known pattern of nasal vowel–consonant harmony with transparent segments is widely attested in the Tucanoan family. Typically, all voiced segments in a morpheme are either nasal or oral. Voiceless obstruents are consistently oral. They may occur in nasal morphemes, and do not prevent nasal harmony from operating among flanking voiced segments. Examples of nasal harmony in morphemes and words of Tucano, spoken in Colombia, are given in (10a), and oral items are provided in (10b) (West and Welch 1967; Noske 1995).[9] Although not marked as nasal in the sources, I show laryngeals as nasalized in nasal morphemes (see discussion in §1). Noske notes that [h̃] occurs in nasal contexts in other Eastern Tucanoan languages and she tentatively postulates that /h/ is likewise realized as nasal in Tucano.[10]

[9] On the operation of nasal harmony from roots to certain suffixes in Tucano, see Trigo (1988) and Noske (1995).

[10] An off-glide [h], realized predictably in word-final position, is not shown in these transcriptions.

In Tucano, a complementary distribution exists between nasal stops and voiced stops (realized as oral or prenasalized, depending on context), with the former occurring in nasal morphemes and the latter in oral morphemes. In nasal morphemes, Noske (1995) postulates that [+nasal] is a feature of the entire morpheme, and it is floating, i.e. unassociated, in the underlying representation. She assumes that [+nasal] links to the first vowel in the word and spreads within the morpheme, as illustrated in (11).[11]

(11) 
Tucano has a small number of disharmonic roots that contain both nasal and oral vowels, e.g. [kõ'^{m}pɛ] 'left', [semẽ] 'paca'. Noske treats these with [±nasal] features that are specified for individual segments underlyingly. She argues that [−nasal] specifications are needed in addition to [+nasal], to prevent [+nasal] from spreading to all voiced segments. This is shown in (12). /B/ represents the phoneme that is variously realized as a nasal or voiced labial stop.[12]

(12) 
In systems where voiceless obstruents do not impede harmony, descriptions largely converge on the realization of these consonants as voiceless obstruents in nasal harmony contexts. Consider the case of nasal vowel–consonant harmony in Guaraní, where voiceless consonants are reported to be transparent.[13] An acoustic study of voiceless stops in nasal harmony contexts in unsuffixed Guaraní words found no evidence of nasal airflow energy during the stop closure, nor was the closure fully voiced (Walker 1999). On the ongoing debate about instrumental evidence for nasalized fricatives, see the aforementioned references on that topic. Examples of nasal harmony in Guaraní are given in (13). The data are from Gregores and Suárez (1967), Rivas (1975), Piggott and Humbert (1997), and Kaiser (2008). Nasal harmony that targets voiced segments and laryngeals is triggered by a stressed nasal vowel (a, b), and stressed syllables that contain an oral vowel block harmony (b). Harmony is robust in the regressive direction and is also triggered by a prenasalized stop (c).[14] Progressive harmony might be more restricted.[15] There is

11 [ɛ] is an allophone of [e] in Tucano.

12 Noske assumes an intermediate stage in this derivation that is not relevant to the issues under focus.

13 However, the locative suffix shows an alternation between [-pe] and [-mẽ]. See Piggott and Humbert (1997) for discussion.

14 Kaiser (2008) finds that word-initial vowels often do not undergo nasal harmony in words over two syllables long. She speculates that a morpheme boundary might be blocking harmony in these forms.

15 Kaiser (2008) observes that the data available do not confirm whether progressive harmony can affect more than one syllable. See also Piggott and Humbert (1997) on observed asymmetries in progressive *vs.* regressive harmony in Guaraní. If it were determined that progressive harmony does not advance beyond one syllable, then the second two examples in (13b) would be most relevant to establish blocking by a stressed syllable, for regressive harmony from the following nasal vowel or prenasalized stop.

a long history of discussion of the Guaraní pattern in the theoretical literature. For overviews, see Piggott and Humbert (1997), Beckman (1999) and Walker (2000a).

Mọ̀bà Yoruba has a regressive nasal harmony in which both voiced and voiceless stops are transparent, as well as fricatives, as shown in (14). The harmony targets vowels, glides, and liquids (Ajíbóyè 2001; Piggott 2003; Archangeli and Pulleyblank 2007). However, as mentioned in §1, mid vowels block harmony. Mid vowels are always oral, with the exception of [ɔ̃] when it is an allophone of /ã/. In addition, despite the occurrence of phonemic /ã/ in the language, /a/ is opaque to harmony: [ìsasũ̀] 'kind of pot', [agũ̀ɪtã̀] 'sheep'.

(14)	/uwã́/	[ũw̃ɔ̃̀]	'lie'
	/jṹ/	[ɲṹ]	'go'

Piggott suggests that voiced stops are underlyingly obstruents in Mọ̀bà Yoruba, unlike languages where voiced stops alternate with nasals in nasal harmony, for which he analyzes the voiced stops as sonorants (see also Botma 2009).

The patterns of nasal harmony in Guaraní and Mọ̀bà Yoruba are also revealing with respect to possible domains of nasal vowel-consonant harmony. In Guaraní, harmony can be bounded at an edge by a stressed syllable, as seen in (13b). This has led some researchers to analyze some or all of Guaraní nasal harmony as operating within metrically defined constituents or via them (e.g. Sportiche 1977; Halle and Vergnaud 1978; van der Hulst and Smith 1982; Flemming 1993; Piggott and Humbert 1997; see also CHAPTER 40: THE FOOT; CHAPTER 41: THE REPRESENTATION OF WORD STRESS). Beckman (1999) offers a different perspective, in which the role of stressed syllables in Guaraní is attributed to the preservation of the underlying oral/nasal quality of segments in these positions. That approach also accounts for the limitation of phonemic nasality in vowels to stressed syllables.

Another level of prosodic structure has been suggested to be relevant for harmony in Mọ̀bà Yoruba. In this language, nasal harmony can span a word boundary.

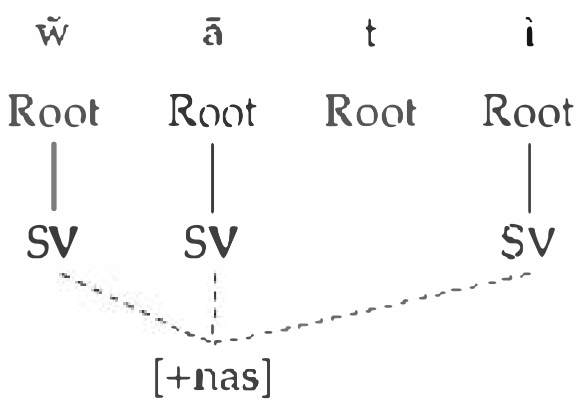
[16] The vowel sequence [ei] in this form is tautosyllabic (Kaiser 2008).

Examples are given in (15). Ajíbóyè (2001) describes /lĩ/ as a particle and analyzes the domain of harmony as the prosodic word, a constituent that can contain more than a morphological word.

(15)	/ki lĩ/	[kĩ́ nĩ]	'what is it?'	/kí à/	[kí à]	'what is it?'
	/ìsí lĩ/	[ĩsĩ́ nĩ]	'who is s/he?'	/isí à/	[ìsí à]	'who is s/he?'

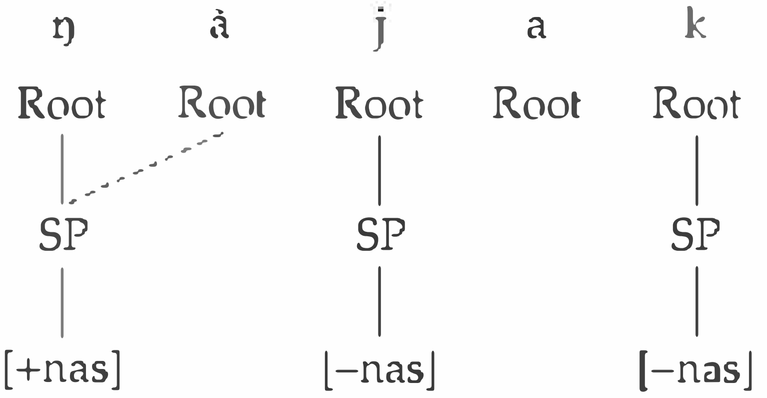
Returning to issues surrounding transparent segments and targets, for the Tucano-type patterns in particular, debate has surrounded their analysis and the conception of where they fit in the typology of nasal harmony. One primary approach to these systems posits that they involve different segmental representations from systems like those described in §1, with opaque segments (Piggott 1992). Specifically, they differ in the dependency of the feature [±nasal] in the feature geometry, and in the node that spreads in nasal harmony. In systems with transparent voiceless obstruents, [±nasal] is dependent on a spontaneous voicing node (SV), which is present in sonorant segments. Harmony results from the spreading of [+nasal] among adjacent SV nodes, as depicted in (16). Voiceless stops are transparent to harmony because they lack an SV node. Voiced stops are treated as sonorants in these systems (see discussion in §1).[17] Piggott suggests that sonorancy is the source of prenasalization of these consonants in certain oral contexts. The realization is attributed to an articulatory configuration needed to produce spontaneous voicing. Prenasalization in this circumstance thus does not involve a specification for [+nasal] but rather is an epiphenomenon of the sonorant stops' phonetic implementation.

(16)



In nasal harmony with opaque segments, [±nasal] is dependent on a soft palate (SP) node. An SP node is underlyingly specified in some consonants. Nasal harmony ensues from spreading of the SP node to segments that lack it, as shown in (17) for a Sundanese form. Under this approach, differences in the set of opaque segments arise from differences in the segments that are underlyingly specified for an SP node (governed by Piggott's Contrastive Nasality Principle).

(17)



[17] For other assumptions about the representation of sonorant stops in the context of nasal harmony systems, see Botma (2004, 2009) and Botma and Smith (2007).

In other work, nasal vowel–consonant harmony systems with transparency *vs.* blocking have been divided along the lines of relations between syllables and segments (Piggott 1996, 2003; Piggott and van der Hulst 1997). In nasal harmony with transparent consonants, [nasal] is considered to be licensed as a property of the syllable, whereas in harmony with blocking segments, the host for [nasal] is the segment. In the case of syllable licensing, [nasal] is associated with the syllable head – the nucleus (see CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE) – and becomes associated with all other sonorant segments in the syllable (Piggott 2003; see Botma 2004, 2009 for a related claim). Locality is respected in harmony with transparent consonants, because no syllable heads are skipped in the propagation of nasal harmony. Noske (1995) also assumes a licensing relation between the syllable and [±nasal] for the Tucano pattern, but with some different specifics in her assumptions.

In another approach that posits a basic difference between nasal vowel–consonant systems, those with opaque segments are caused by articulatory spreading, whereas those with transparent consonants involve spreading that is perceptually based (Boersma 1998, 2003). Patterns with blocking are claimed to be driven by an articulatory constraint that penalizes shifts in the position of the velum. This constraint can favor persistence or early onset of a lowered velum in a word that contains a nasal segment. For patterns with transparent obstruents, such as the Tucano type of system, Boersma proposes that a perceptually based constraint drives harmony, causing nasalized segments that are interrupted by an oral segment to be perceived with a single value of [+nasal]. This perceptual representation is distinct from the articulation in which the nasalized segments are interrupted by a velum-raising gesture. Boersma suggests that the reason all sonorants become nasalized in patterns with transparency is connected to the lexical-level specification of nasality in these languages (see (11)). Boersma reasons that if [±nasal] is a suprasegmental feature, it is less likely to be specified for individual segments. Segments are thus less likely to have a [–nasal] specification to which to be faithful, and segments that do not become nasalized will be the ones that are inherently problematic in combination with nasalization, i.e. fricatives and plosives.

The notion that nasal vowel–consonant harmony patterns with transparency are tied to perception is also pursued in work by Sanders (2003). He proposes that nasal harmony in Tucano-type languages is driven by dispersion constraints on the perceptual distance of systemic contrasts. These constraints favor words that differ to the greatest extent possible in the perception of a nasal/oral contrast, while obeying higher-ranked constraints that prohibit nasalized voiceless obstruents, i.e. they favor the morphemes in which all segments besides voiceless obstruents are the same in nasality.

In contrast to analyses where patterns with transparent segments are analyzed as involving representations or harmony imperatives that are different from those with opaque segments, another approach analyzes these systems as having a common source (Walker 2000a, 2003). This account emphasizes a complementarity in the patterns: there is no nasal vowel-consonant harmony in which all of the segments become nasalized, yet there are systems in which obstruents are transparent and the remaining segments are targets. Obstruents form the focus of the complementarity. All segments except (some) obstruents have the potential to be targets in nasal vowel–consonant harmony and only obstruents are transparent. Walker proposes a treatment of the patterns that analyzes systems with transparent obstruents as cases that correspond to the right endpoint of the hierarchy in (1), where nasalization transmits through all segment categories. Walker adduces typological evidence in support of conceptualizing transparent obstruents as on a par with targets. She observes that when obstruents are transparent, all other segment categories are targets, a generalization that would be expected if obstruents were targets in these systems, because they are lowest-ranked on the target scale. More generally, a survey of over 75 languages with nasal vowel–consonant harmony reveals that if a segment is "permeated" by nasal harmony, that is, if it is targeted or behaves as transparent, then all segments belonging to categories that are higher-ranked in the target hierarchy of (1) are also permeated.

A pattern involving voiced stops is brought to bear on the claim that obstruent stops can be targets in nasal vowel–consonant harmony. The nasal harmony of Tuyuca, another Tucanoan language, has been characterized as showing a difference in blocking and transparency effects when it occurs across morphemes *vs.* within them. Like Tucano, in harmony within a morpheme, voiced stops alternate with nasals and voiceless obstruents are transparent to harmony. However, harmony from stem to suffix is blocked by fricatives and voiced and voiceless stops (Barnes 1996; Walker 2000a).[18] Opaque voiced stops are realized as oral or nasal, depending on the nasality of the suffix to which they belong. (See Trigo 1988 and Walker 2000a on the separate phonological treatment of voiced/nasal velar stops.) Walker interprets the blocking of harmony by voiced stops across a morpheme boundary as evidence of their underlying obstruent status in Tuyuca (cf. Botma 2004); all suffixes that alternate in nasal harmony issuing from the stem therefore begin with a continuant sonorant or laryngeal.[19] When voiced stops undergo harmony within a morpheme, they would then be an instance of voiced obstruent stops that are targets in nasal harmony.

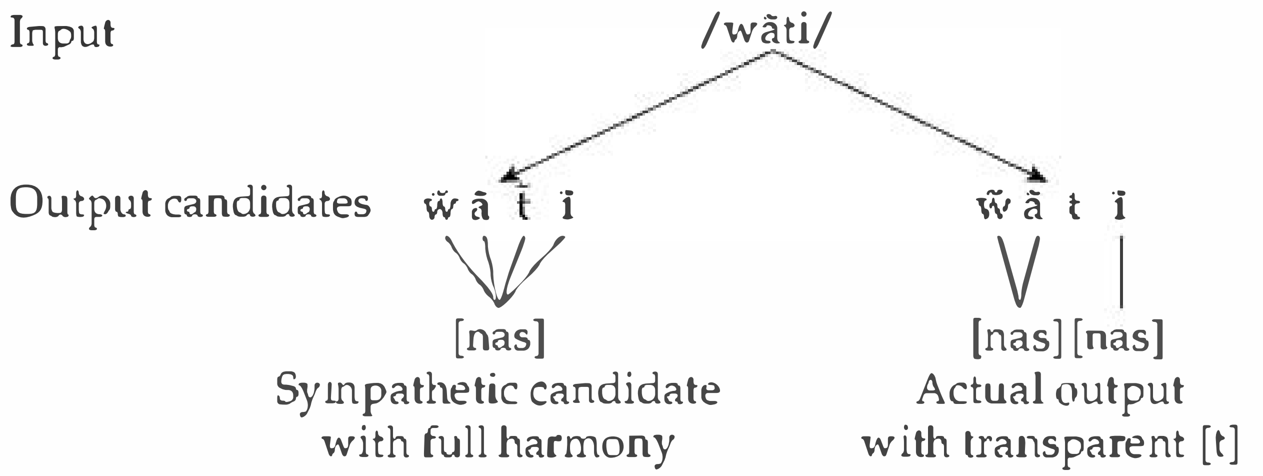
In this approach, feature spreading is analyzed as strictly local at the level of the segment (CHAPTER 81: LOCAL ASSIMILATION). This implies that segments cannot be skipped in harmony; they must either participate in harmony or block it. As a consequence, it is assumed that a phonological representation is available in which a "transparent" obstruent is nasalized (see CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS). The model that Walker proposes is illustrated in (18), implemented using the concept of a sympathetic candidate (McCarthy 1999). A sympathetic candidate is a designated form to which the actual output is encouraged to be similar via the activity of a candidate-to-candidate correspondence relation between this form and the actual output. Arrows represent the existence of correspondence relations among representations, which mediate the enforcement of identity between related forms. Among the candidate outputs generated for an input with a [nasal] specification is one where the feature spreads to all segments in the morpheme, satisfying the constraint that drives harmony. This is the candidate that becomes designated as "sympathetic." However, as [nasal] is not compatible with an obstruent stop, this candidate is not selected. Instead, a form is selected that is identical to the full harmony candidate except that the stop is

[18] Tucano has also been analyzed in this way by Trigo (1988), but it has come to light that a suffix beginning with a labial voiced stop alternates in nasal harmony in this language (Piggott and van der Hulst 1997; Botma 2004), which indicates that voiced stops do not systematically block harmony from the stem to suffix in this language.

[19] Whether laryngeals should be treated as sonorants is an open question.

oral. Because feature associations may not skip a segment, this candidate must have separate [nasal] specifications flanking the oral stop. The actual output is thus chosen not directly by the harmony-driving constraint but rather because of its similarity to a candidate that fares best with respect to that constraint.

(18)



This approach makes use of an abstract phonological representation in which obstruent stops are nasalized. Such representations do not occur within the actual output but they influence its selection. Another analysis that is similar in spirit posits the full harmony form as an intermediate level of representation that is generated as the product of a nasal spreading rule (Piggott 1988). A clean-up rule that prevents nasalized obstruents then causes the stop to be denasalized, to generate the derivational series: /w̃ati/ → w̃ãt̃ĩ → [w̃ãtĩ].

In summary, systems of nasal vowel-consonant harmony with transparent consonants have formed the center of discussion on several theoretical themes. One basic question is whether they should be considered the same "type" of nasal harmony as systems with opaque segments. Also at issue are the segmental representations involved, including the organization of [nasal] in the feature geometry, the level of structure at which [nasal] spreads, the locality of feature associations, and what kinds of abstract representations are involved. Questions about levels of representation have been touched upon, including whether there are distinct articulatory and perceptual representations and the possibility of intermediate or sympathetic forms. Finally, blocking and transparency effects in nasal vowel–consonant harmony have given rise to different perspectives on the harmony imperative and the sources that cause segments to block harmony or behave as transparent.

3 Nasal consonant harmony

In nasal consonant harmony systems, nasal harmony involves consonants only. Moreover, the participant consonants have been characterized as ones that are phonologically similar. These systems have been considered to differ from nasal vowel–consonant harmony in locality and the nature of participant segments, giving rise to proposals in which nasal consonant harmony involves a different harmony-driving imperative and/or different representations.

A prototypical case of nasal consonant harmony is found in Kikongo, a Bantu language spoken in the Democratic Republic of the Congo (Bentley 1887; Dereau 1955; Ao 1991; Odden 1994; Piggott 1996; Rose and Walker 2004; see also CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS). The nasal stop phonemes of

Kikongo are [m n]. Nasal consonant harmony causes voiced stops and /l/ to become nasal when following a prevocalic nasal stop at any distance in the stem. The stem constituent in Kikongo consists of the root and suffixes. Examples of alternations in the perfective active and applicative suffixes induced by nasal consonant harmony are shown in (19). The consonant in these suffixes is analyzed as /l/ underlyingly. In words where the conditions for nasal harmony are not met, /l/ is realized as [d] before [i]. Vowel quality alternations are due to vowel height harmony. Vowels and voiceless consonants are transparent to the nasal harmony; they remain oral when occurring between harmonizing consonants. The forms in (19) consist of stems, as indicated by the initial hyphen according to convention.

(19) a. *Perfective active forms*

-suk-idi	'wash'	-nik-ini	'grind'
-bud-idi	'hit'	-sim-ini	'prohibit'
-bak-idi	'catch'	-futumuk-ini	'revive, rise'
-sos-ele	'search for'	-le:m-ene	'shine'

b. *Applicative forms*

-sakid-il-a	'congratulate for'	-nat-in-a	'carry for'
-to:t-il-a	'harvest for'	-dumuk-is-in-a	'cause to jump for'

In addition to inducing alternations in suffixes, nasal consonant harmony is considered to operate within roots, which do not show a voiced stop or [l] after a prevocalic nasal stop.

Nasal stops that occur in an NC cluster do not trigger nasal consonant harmony (20a), nor do they prevent it from operating across them (20b). In addition, a voiced oral stop in an NC sequence does not undergo nasal harmony from a preceding prevocalic nasal.

(20) *Perfective active*

a.	-bantik-idi	'begin'
	-kemb-ele	'sweep'
	-biŋg-idi	'hunt'
	-tond-ele	'love'
b.	-mant-ini	'climb'
	-meŋg-ini	'hate'

Setting aside NC clusters, the targets of nasal consonant harmony are frequently voiced stops and approximant consonants (/l/ is the only approximant consonant in Kikongo). In some cases, nasal harmony is restricted to consonants separated by no more than a vowel. The Bantu language Ndonga shows this pattern (Viljoen 1973; Rose and Walker 2004). In Ngbaka, a Niger-Congo language spoken in the Democratic Republic of the Congo, the lack of co-occurrence of certain nasals and prenasalized stops within a morpheme has been analyzed as the product of nasal consonant harmony (Hansson 2001; Rose and Walker 2004). Ngbaka contrasts nasal, prenasalized, voiced, and voiceless stops (Thomas 1963, 1970; Wescott 1965). Nasals may occur together with voiced and voiceless stops in a morpheme but not with a prenasalized stop that has the same place of articulation as the nasal (Mester 1988; Sagey 1990; van de Weijer 1994; CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION).

Certain root co-occurrence restrictions (see CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS) on consonants in Ganda (Bantu), discussed by Katamba and Hyman (1991), have also been analyzed as the outcome of nasal consonant harmony (Hansson 2001; Rose and Walker 2004). The patterns in question involve nasals, voiced stops, and voiceless stops. Some of the voiced stops display approximant variants: [b/β], [d/l], [ɟ/j]. Within a root, nasals do not usually occur with a voiced stop (or its approximant variant) that has the same place of articulation. This restriction is observed regardless of the order of the nasal and voiced oral consonant.[20] In addition, the combination of a nasal and a voiceless stop with the same place of articulation is systematically absent if the nasal precedes the stop. In attested roots, identical nasals co-occur, as do oral voiced stops/approximants with the same place of articulation, as shown in (21a). Also attested are roots that combine a nasal and voiced consonant with different places of articulation (21b), and roots in which a voiceless stop precedes a nasal (21c).

(21)	a.	-mémèká	'accuse, denounce'
		-nónà	'fetch, go for'
		-bábùlá	'smoke over fire to make supple'
		-gùgá	'curry favor with'
	b.	-bónèká	'become visible'
		-màlà	'finish'
	c.	-táná	'grow septic, fester'

In the harmony-based analysis of the Ganda pattern, nasal consonant harmony operates within a root among oral stops and nasals with the same place of articulation. For voiced stops the harmony is bidirectional, whereas for voiceless stops it is progressive only. Hansson's (2001) treatment also takes into consideration restrictions on the co-occurrence of nasal stops and voiced prenasalized stops within a root in Ganda.

With respect to non-contour stops, surveys of nasal consonant harmony in Hansson (2001) and Rose and Walker (2004) reveal the following implications: (i) patterns that target voiceless stops with the same place of articulation as the nasal trigger also target voiced stops with the same place of articulation, and (ii) patterns that target voiced stops with a different place of articulation from the nasal trigger also target voiced stops with the same place of articulation as the nasal. An interpretation that has been brought to these generalizations is that nasal consonant harmony favors targets that are similar to nasals (Walker 2000b; Hansson 2001; Rose and Walker 2004). These patterns are suggested to have a basis in speech planning (i.e. the organization and sequencing of abstract units) and its physical execution (i.e. the motor controls that carry out the "plan"). The similarity hypothesis finds support from speech error research. It is well established that the likelihood of a speech error between two phonemes increases with their phonological similarity. A series of speech error elicitation tasks conducted by Walker (2007) found that consonants that are more likely to interact in nasal consonant harmony are also more likely to participate in speech errors with speakers of English.

[20] Ganda also shows a dispreference for particular pairs of voiced stops and nasals in a root when the voiced stop and nasal have a different place of articulation and the voiced stop follows the nasal (Katamba and Hyman 1991; Hansson 2001).

Prior to the extensive typological studies of consonant harmony by Hansson (2001) and Rose and Walker (2004), analyses of nasal consonant harmony were developed that involved nasal feature spreading at a node within the feature geometry (Ao 1991; Odden 1994; Hyman 1995) or at a suprasegmental level (Piggott 1996). The typological studies in question sharpened the characterization of the differences between nasal consonant harmony and nasal vowel–consonant harmony, leading the authors of those studies to analyze nasal consonant harmony as the product of a different harmony-driving mechanism and as involving different representations from those usually assumed for nasal vowel-consonant harmony.

Two of the chief differences between nasal consonant harmony and nasal vowel–consonant harmony involve locality and types of triggers and targets. Nasal consonant harmony targets segments that are phonologically similar to the nasal stop trigger, i.e. stops and approximant consonants. The harmonizing segments are usually non-adjacent, with at least a vowel intervening and sometimes longer transparent sequences. In contrast, in nasal vowel–consonant harmony, harmony affects a (near-)continuous sequence of segments, and vowels are never skipped. In the latter systems, favored targets follow the scale in (1), with vowels ranked at the top, a scaling suggested to have a basis in the segments' phonetic compatibility with nasalization or in maintaining distinct contrasts. Consonants that do not become nasalized in nasal vowel–consonant harmony most often block harmony, although in some systems, (some of) the obstruents behave as transparent.[21]

The role of phonological similarity and the capacity for action-at-a-distance are emphasized in the correspondence-driven approach to nasal consonant harmony (Walker 2000b; Hansson 2001; Rose and Walker 2004). In this account, the occurrence of high phonological similarity between consonants can spur a formal correspondence relation to be established between them. Corresponding segments are co-indexed with one another, as illustrated in (22). Nasal harmony is effected via the correspondence relation. Constraints for individual features, such as [nasal], are postulated that enforce identical specifications in corresponding segments, thus producing nasal consonant harmony, as in (22b). Because nasal assimilation is accomplished through the correspondence relation in this structure, the harmonizing segments are not required to share a single [nasal] specification, unlike the outcome of [nasal] spreading, which is usually assumed for nasal vowel–consonant harmony. A representation like that in (22b) is suggested to accommodate the potential for nasal consonant harmony to occur among non-adjacent segments.

(22) a. n_α i k-i l_α i — n_α linked to [nas]

b. n_α i k i n_α i — each n_α linked to its own [nas]: [nas] [nas]

In the correspondence-based approach, patterns that show harmony only between consonants in adjacent syllables are analyzed using proximity-sensitive constraints governing corresponding segments. The neutrality of preconsonantal nasals

[21] Some additional differences are that nasal consonant harmony never has opaque segments (Hansson 2001; Rose and Walker 2004), whereas many nasal vowel-consonant harmony systems do. Also nasal consonant harmony does not appear to show sensitivity to metrical structure, such as stress and foot boundaries, and it does not extend across word boundaries (Hansson 2001), although these characteristics are attested in some patterns of nasal vowel–consonant harmony.

in a Kikongo-type system has been attributed to their dissimilarity from the potential target oral consonants, either in terms of their role in syllable structure (the nasals in NC clusters are codas, whereas the oral consonants are onsets) or in terms of their release status (the nasals in NC clusters are unreleased, whereas the oral consonants are released). It is suggested that a voiced stop in an NC cluster does not undergo harmony because of avoidance of geminate nasals, which do not occur in Kikongo. In Ngbaka, prenasalized stops are considered to be singleton consonants – not NC clusters, as in Kikongo – so these issues do not arise. Whether the representation and patterning of nasal contours in Ganda fall in line with these treatments has yet to be closely considered.

The correspondence approach to nasal consonant harmony has been applied to consonant harmony systems in general. The basis for that proposal is that other systems of consonant harmony also show effects of similarity and action-at-a-distance. See Hansson (2001), Rose and Walker (2004), and CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS.

4 Directionality

This section turns to directionality in nasal harmony. Some systems can be considered bidirectional, with no apparent difference in the pattern of harmony in either direction. Nasal consonant harmony involving voiced stops in roots of Ganda is an example of this kind. Such patterns do not necessitate an overt statement of directionality. Also, root- or stem-controlled harmony where affixes in the domain of harmony occur only following or only preceding the root or stem can give the appearance of directional harmony but without requiring formal reference to a direction for harmony. However, other systems of nasal harmony show evidence of asymmetrical directionality, where harmony operates in only one direction or shows different patterns in its progressive *vs.* regressive operation.

A contrast in the direction of nasal vowel-consonant harmony with opaque segments is seen in the patterns of the Johore dialect of Malay, an Austronesian language of Malaysia, and Capanahua, a Panoan language spoken in Peru. Johore Malay shows a harmony from nasal stops that targets vowels, laryngeals and glides (Onn 1980). Liquids and obstruents block harmony. Examples in (23) show that the harmony is progressive only.

(23)	pənãŋãh̃ãn	'central focus'
	pəŋãw̃ãsan	'supervision'
	pəmãndaŋãn	'scenery'
	mãkan	'to eat'
	baŋõn	'to rise'
	mə̃nãw̃ãn	'to capture (ACTIVE)'
	mãj̃ãŋ	'stalk (palm)'
	mə̃ratappi[22]	'to cause to cry'
	mĩnõm	'to drink'
	mãʔãp	'pardon'

22 Vowel nasalization in this word is assigned according to Onn's description and harmony rule. Because vowel nasalization is predictable in Johore Malay, Onn only marks it when demonstrating rule applications.

Like Johore Malay, Capanahua displays a nasal harmony that targets vocoids and laryngeals and is blocked by other segments (Loos 1969; Piggott 1992); however, the direction is regressive. The regressive direction cannot be predicted from the position of triggers in the syllable structure, as they occur in both syllable onsets and codas. Word-final nasals are enclosed in parentheses because they are deleted but still trigger harmony.[23]

(24) h̃āmawi 'step on it'
h̃āmã̄ʔōna 'coming stepping'
kajatānaiʔ[24] 'I went and jumped'
wɯrãnai 'I pushed it'
bĩmi 'fruit'
ʧipōŋki 'downriver'
kɯ̃ɯ̃nʧap 'bowl'
bãw̃ĩ(n) 'catfish'
warã(n) 'squash'
pōj̃ã(n) 'arm'
ʔ̃ōnāmpā(n) 'I will learn'

An instance of directionality in nasal vowel-consonant harmony with transparent segments is found in Siriano, a Tucanoan language spoken in Colombia and Brazil (Bivin 1986). Suffixes in Siriano become nasalized following a nasal stem (excluding certain suffixes that are invariant in nasality). Examples of suffix alternations are given in (25). Underlying forms are as provided by Bivin.

(25) a. /wehe-gɨ/ [wɛhɛgi] 'when he is fishing'
to fish-3SG MASC
/w̃èhẽ-gɨ/ [w̃ɛ̃h̃ɛ̃ŋĩ] 'when he is killing'
to kill-3SG MASC
b. /igo-ɾe/ [ʔigoɾe] 'she (COMPLEMENT)'
/ĩgɨ̃-ɾɛ/ [ʔĩŋɨ̃nɛ̃][25] 'he (COMPLEMENT)'

The data in (25) are compatible with nasal harmony where directionality is an epiphenomenon of root or stem control. However, a small group of suffixes harmonize with a following suffix rather than the root, as shown in (26). The suffixes that exhibit this behavior are /-ju/ (SECOND HAND INFORMATION), /-de:/ (PAST NOMINALIZER), /-bu/ (INCEPTIVE), and /-ku/ (PROBABILITY).

(26) a. /wa:-ju-pi/ [waʔjupi] 'they say he left'
to go+EVID:SECOND HAND+3SG MASC
/wa:-ju-ɾã/ [waʔɲũɾ̃ã] 'they say they left'
to go+EVID:SECOND HAND+3PL ANIMATE
/w̃ēhē-ju-pɨ/ [w̃ɛ̃h̃ɛ̃jupi] 'they say he killed'
to kill+EVID:SECOND HAND+3SG MASC

[23] Capanahua also manifests a bidirectional nasal harmony triggered by a nasal stop that is deleted preceding an oral continuant consonant. For discussion, see Loos (1969), Safir (1982), and Trigo (1988).
[24] Vowel nasalization in this word and the next one is assigned according to Loos's description and rules.
[25] Bivin (1986: 71) transcribes the suffix consonant here as [n], but in other transcriptions that he provides for flaps that have undergone nasal harmony in Siriano the consonant is a nasalized flap.

b. /waː-bu-gɨ/ [waˀbugɨ] 'about to go (SG MASC)'
to go+INCEPTIVE+SG MASC
/waː-bu-ɾã/ [waˀɪnũɾ̃ã] 'about to go (PL)'
to go+INCEPTIVE+3PL ANIMATE
/w̃ẽhẽ-bu-gɨ/ [w̃ɛ̃h̃ɛ̃bugɨ] 'about to kill (SG MASC)'
to kill+INCEPTIVE+SG MASC

c. /waː-deː-ɾo/ [waˀaⁿdɛˀɾo] 'where he went'
to go+NOMINALIZER+LOC
/waː-deː-ɾã/ [waˀanɛ̃ˀɾ̃ã] 'the ones who went'
to go+NOMINALIZER+3PL ANIMATE
/w̃ẽhẽ-deː-ɾo/ [w̃ɛ̃h̃ɛ̃ⁿdɛɾo] 'where he killed'
to kill+NOMINALIZER+LOC

d. /waː-ku-a/ [waˀakoa] 'it left'
to go+PROBABILITY+INANIMATE
/waː-ku-bĩ/ [waˀakũmĩ] 'he left'
to go+PROBABILITY+EVID:3SG MASC
/w̃ẽhẽ-ku-a/ [w̃ɛ̃h̃ɛ̃kua] 'it killed'
to kill+PROBABILITY+INANIMATE

Bivin notes that /-ju/ and /-ku/ are evidentials, which must appear with a person-number suffix. Although he does not have data to verify the facts for /-deː/ and /-bu/, he speculates that they too must be used with an additional suffix. We may wonder whether a stipulation for Siriano is needed that harmony with these suffixes is regressive or whether this directionality could be made to follow from morphological structure. Both possibilities have been considered. Bivin suggests that the suffixes in question form a separate lexical class. He treats regressive nasal harmony using a left spreading rule for [nasal] that applies to that lexical class. He also considers an approach that posits an internal word boundary at the left of these particular suffixes. This would block them from harmonizing with the root, as harmony occurs only within words. Bivin disprefers this account because he finds no evidence from other Tucanoan languages to support the presence of an internal word boundary, nor does he find evidence for an analogous occurrence of internal word boundaries elsewhere in Siriano. On the other hand, for Desano, a language closely related to Siriano, Kaye (1971) treats a similar directionality phenomenon as an epiphenomenon of morphological constituency. Like Siriano, Desano has a limited number of suffixes that derive their nasality from the following suffix rather than the preceding morpheme. Three of these suffixes are the same as those in Siriano (Bivin 1986). Kaye suggests that the suffixes targeted by regressive nasal harmony form a morphological constituent with the following suffix that is separate from the preceding stem.[26] He pairs this assumption with a bidirectional nasal assimilation rule that applies cyclically to obtain differences in the direction of harmony. Siriano and Desano, then, are cases where directionality in nasal harmony can perhaps be reduced to the organization of morphological structure, but further study on this issue is needed.

There is possible evidence of directionality in nasal consonant harmony. In the nasal consonant harmony of Kikongo, introduced in §3, harmony is progressive in the stem. The examples in (27) show apparent directionality; a voiced stop or

[26] Miller (1999) treats the regressive nasal harmony in Desano as lexicalized.

consonantal approximant precedes a nasal in the stem but remains oral. (See also the discussion in CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS.)

(27) -dumukina 'jump for'
-bilumuka 'assemble in crowd'

Hansson (2001) speculates that progressive directionality in canonical Bantu nasal consonant harmony, like that of Kikongo, might be reducible to a system of harmony that is stem-controlled and that preserves the underlying oral/nasal quality of root-initial segments (e.g. using a faithfulness constraint specific to this position). However, this hypothesis has been questioned. Although the canonical Bantu root structure is CVC, Rose and Walker (2004) cite evidence that [bilum] is lexically stored as a whole. For the similar pattern of nasal consonant harmony in Yaka, another Bantu language, they point to evidence of stored forms with the sequences /CVlVN-/ and /CVbVN-/, which likewise do not show nasal harmony. Because the /l/ or /b/ is not root-initial in these cases, nor does it belong to a different cycle from the nasal, it would be expected to undergo nasal harmony that was not strictly progressive. Within a correspondence-based approach, Rose and Walker propose to analyze directional harmony in these patterns using a precedence-sensitive identity constraint for the feature nasal in corresponding segments.

In sum, there are systems of nasal vowel–consonant harmony and nasal consonant harmony that seem to display directionality effects that cannot be attributed to independent aspects of the system or structure. Differences in directionality in certain patterns of nasal vowel–consonant harmony with opaque segments present the strongest evidence for these effects. In some cases, certain researchers have suggested that morphological structure and/or prosodic position could obtain the effect of directional harmony, but there is not consensus on this explanation for the various patterns discussed above.

5 Conclusion

To conclude, at the heart of research on nasal harmony are patterns that fall into three descriptive categories: nasal vowel–consonant harmony with opaque segments, nasal vowel–consonant harmony with transparent segments, and nasal consonant harmony. Across languages, patterns belonging to the first category respect an implicational scale that governs favored targets. Whether nasal vowel–consonant harmony with transparent segments and systems with opaque segments share a common source remains in question. Studies bearing on this issue have generated diverse perspectives on the harmony imperatives, the levels of representation that are involved, and the nature of locality. Nasal consonant harmony presents differences from nasal vowel–consonant harmony in showing action-at-a-distance and in favoring harmony between segments that are phonologically similar. This has given rise to a correspondence-driven approach to nasal consonant harmony, situated in a general typology of consonant harmony. This approach is distinct from the treatment of nasal vowel–consonant harmony, which is most often assumed to involve spreading.

The study of nasal harmony can illuminate not only the nature of long-distance phonological assimilation but also themes in phonology that are more general in nature. Whereas in the last couple of decades the broad strokes of the typological characteristics of nasal harmony patterns have been reasonably well delineated, the details of many specific systems remain unknown. Future research could be fruitfully applied to developing more case studies. The resulting findings will doubtless in turn shed new light on the theoretical debates and the cross-linguistic characterization of nasal harmony, both alone and in the larger picture.

79 Reduction

Natasha Warner

1 Introduction

[b̥ɹʌʒləɪ̯] is a four-word phrase of American English (Figure 79.1). What might it be? How could a listener map this phonotactically improbable string back to the speaker's intended four-word phrase? Why would a native speaker produce this realization? The intended phrase was *but I was like*, using the quotative *like* in the utterance *but I was like, "why wouldn't you just go home?"*. The speaker was a young female native speaker holding a casual telephone conversation with a friend. The fact that /bʌt aɪ wʌz laɪk/ can be produced as [b̥ɹʌʒləɪ̯] is surprising, but

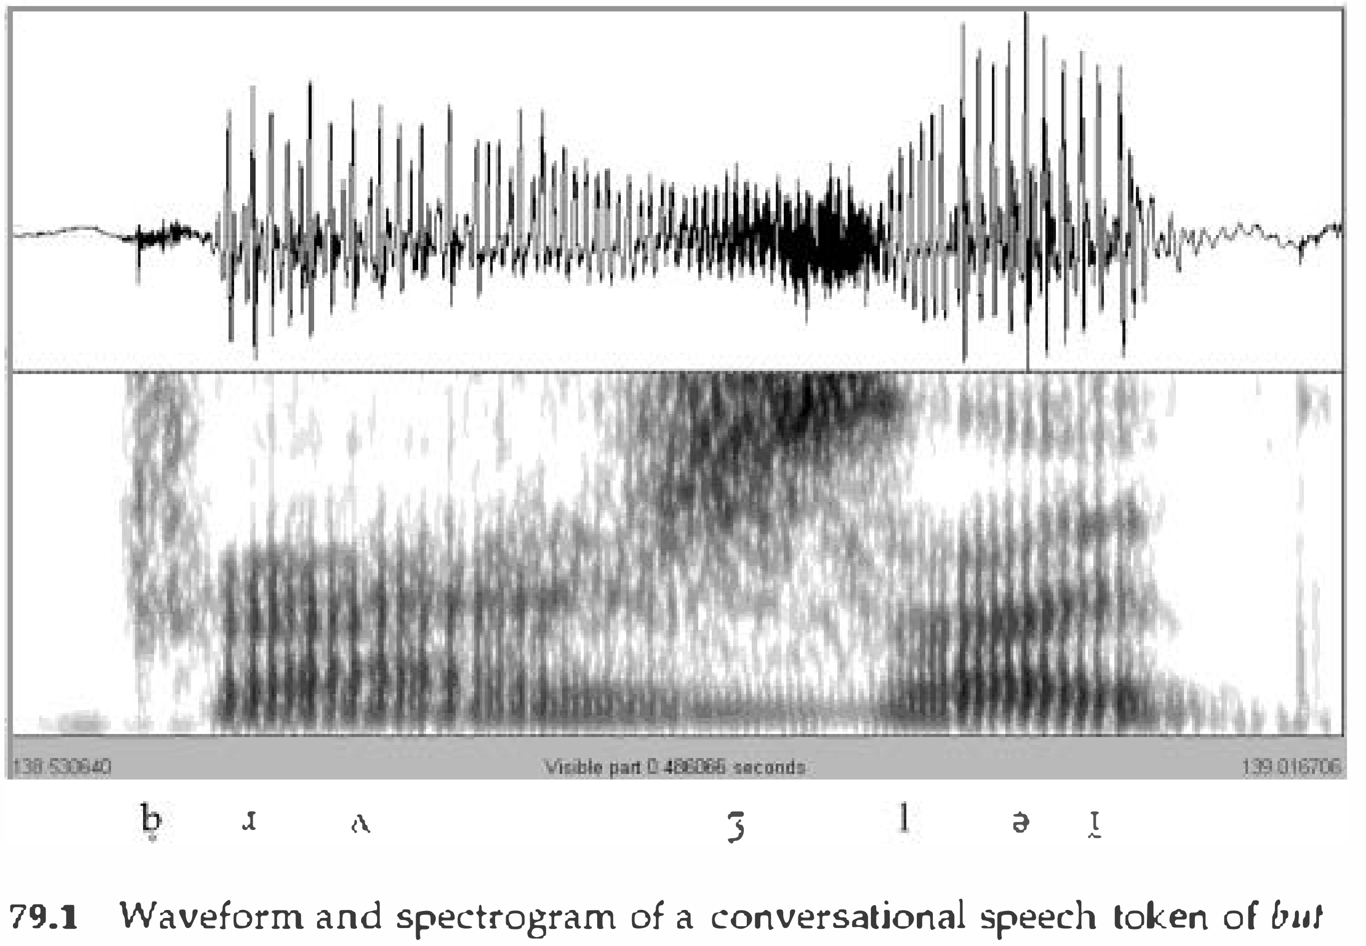

Figure 79.1 Waveform and spectrogram of a conversational speech token of *but I was like*, demonstrating numerous deletions, mergers, and changes to segments, as well as insertion of unexpected /r/-coloring, perhaps as a reflection of the flap of *but*. All spectrograms show a 0–5000 Hz range

perhaps even more surprising is that when a native listener hears the utterance, it sounds like a normal pronunciation of the phrase. While one might not expect this realization, when one examines spontaneous conversation, such surprising reductions are rather common. The fact that a surface realization can depart so drastically and in variable ways from the underlying representation poses problems for phonological theory. The fact that listeners find it unproblematic brings up further questions regarding what a phonological underlying representation is, and how speakers and listeners use it. There are three directions from which one might approach the topic of reduction: what sounds the speaker produces (acoustics of reduction), how the speaker produces them (reductions and changes in articulations), and how the speech is perceived.

Phoneticians and phonologists have long known that speakers sometimes produce reduced speech, at least in casual speech situations. [ʤiʔjɛʔ] for *did you eat yet?* is often used as a plausible example. However, such examples are sometimes presented in phonetics and phonology classes as something that occurs when one is at home talking with one's spouse, perhaps when one is not fully awake, not as a normal phenomenon. Such speech has often been removed from the realm of phonology, and left for phonetic implementation. Yet phoneticians have often paid hardly more attention to reduced speech, considering it too uncontrolled to give good results. Ladefoged (2003) suggests avoiding connected speech such as storytelling when documenting a language, and advises sticking to word lists in controlled frame sentences. Many of the chapters in the *Companion* summarize a debate about how phonological theories should handle a particular phenomenon. This one, instead, summarizes a debate about whether a phenomenon is even relevant.

The default assumption may be that reduction is not linguistically relevant. Speech style (e.g. casual, formal) and speech rate seem like non-linguistic factors, outside the boundaries of the abstract system that makes up the grammar. Or perhaps speech reduction really does occur primarily when conversing with one's spouse, at home, when tired – perhaps it is the exception. However, there is also reason to think that reduced speech is anything but peripheral to the linguistic system. It may be in fact the normal, typical way for humans to communicate information. Furthermore, neither phonetic nor phonological theories were built to handle reduced speech, so reduced speech raises large theoretical questions.

First, I will discuss terminology. There are many overlapping terms falling along more than one dimension, such as reduced, conversational, connected, spontaneous, fast, casual, and natural speech. One could separate a speech rate dimension (fast–slow) out from the dimension of formality (casual–formal) (see also CHAPTER 92: VARIABILITY). Neither of these is exactly a dimension of "reduction": some speakers talk very quickly in both formal and informal settings, yet seem to maintain almost all of their consonantal articulations. However, reduction is probably more common in casual conversation and fast speech.

Another dimension might be spontaneity. In my own understanding of the term, "spontaneous speech" refers to any speech in which the words are not chosen ahead of time. This excludes read speech, speech in a talk one has given repeatedly (e.g. politicians' campaign speeches), and speech that is explicitly prompted (e.g. shadowing tasks). When the Oregon Graduate Institute (OGI) collected its Japanese corpus (Muthusamy *et al.* 1992), for example, speakers were instructed to talk about themselves (e.g. hobbies, work) for a minute, which leads to spontaneous monologue speech. I take "connected" speech to be broader than "spontaneous speech," including anything where words form part of a longer utterance, perhaps even target words in a frame sentence.

"Conversational" speech sets a stricter requirement, meaning speech that occurs while two or more speakers are conversing, whether by telephone or in person, and whether they know each other or not. Speech can be spontaneous and connected but not conversational, as in the OGI monologues. "Conversational" speech excludes any scripted speech, even reading a scripted conversation. "Casual" speech goes one step further, requiring that the speakers be comfortable in the setting, comfortable with the topics and comfortable with their interlocutors. A job interview or a discussion of governmental policy is usually conversational and spontaneous, but not casual. However, monologues about hobbies or friends can be casual without being conversational if the speakers are comfortable with the recording setting.

Three terms differ from the rest: fast, natural, and reduced speech. Speech rate, measurable in intended syllables per second, for example, does seem to be a separate but usually correlated dimension. For example, some parts of spontaneous conversational speech are very fast, while others may be very slow (perhaps if the speaker is tired or uninterested in the topic). However, one may expect that casual conversation would usually have a faster rate in intended syllables per second than most careful read speech. "Naturalness" defies a simple definition. One can refer to natural speech as the opposite of synthesized speech, so that even nonsense CV syllables can be natural if produced by a human. Alternatively, linguistic anthropologists may put very strict requirements on the setting of "natural speech," such as the speakers not being seated in a sound booth, or not having head-mounted microphones on, as these things might make the speakers self-conscious, and affect their speech. Thus I will not attempt to fit "natural speech" into the other dimensions.

I take "reduced speech" to refer to changes in the segments or suprasegmentals relative to what would be expected in a careful pronunciation of the same word or phrase. "Reduction" thus includes changes to sounds (CHAPTER 66: LENITION; e.g. [ɣ̞] or [ɰ] for [g] in *gonna*; Figure 79.2), deletions of expected segments (CHAPTER 68: DELETION; e.g. [wɪə] for *we were*; Figure 79.2), and shrinkage of contrast space (e.g. a smaller overall vowel space, or a specific centering like [wʌ̃] for *when*; CHAPTER 2: CONTRAST). Types will be discussed below. Clearly, however, not all alterations of segments are reduction: speech errors, dialectal differences, historical sound change (CHAPTER 93: SOUND CHANGE), and obligatory (morpho-)phonological changes (e.g. /k/ becoming /s/ in *electric/electricity*; Chomsky and Halle 1968) are not reduced speech. "Reduction" refers to changes relative to a clearly pronounced surface form, not relative to the underlying form. Thus, spontaneous or conversational speech can be defined based on the setting in which it is produced, but I define reduced speech based on its acoustic or articulatory form. Notably, reduction does occur in relatively careful speech, although not as often as in spontaneous casual speech, so setting or style alone does not define it. I do not define reduction based on it being easier to articulate, or requiring less movement of the articulators, because it is difficult to define objectively for each situation what "easier to articulate" would mean.

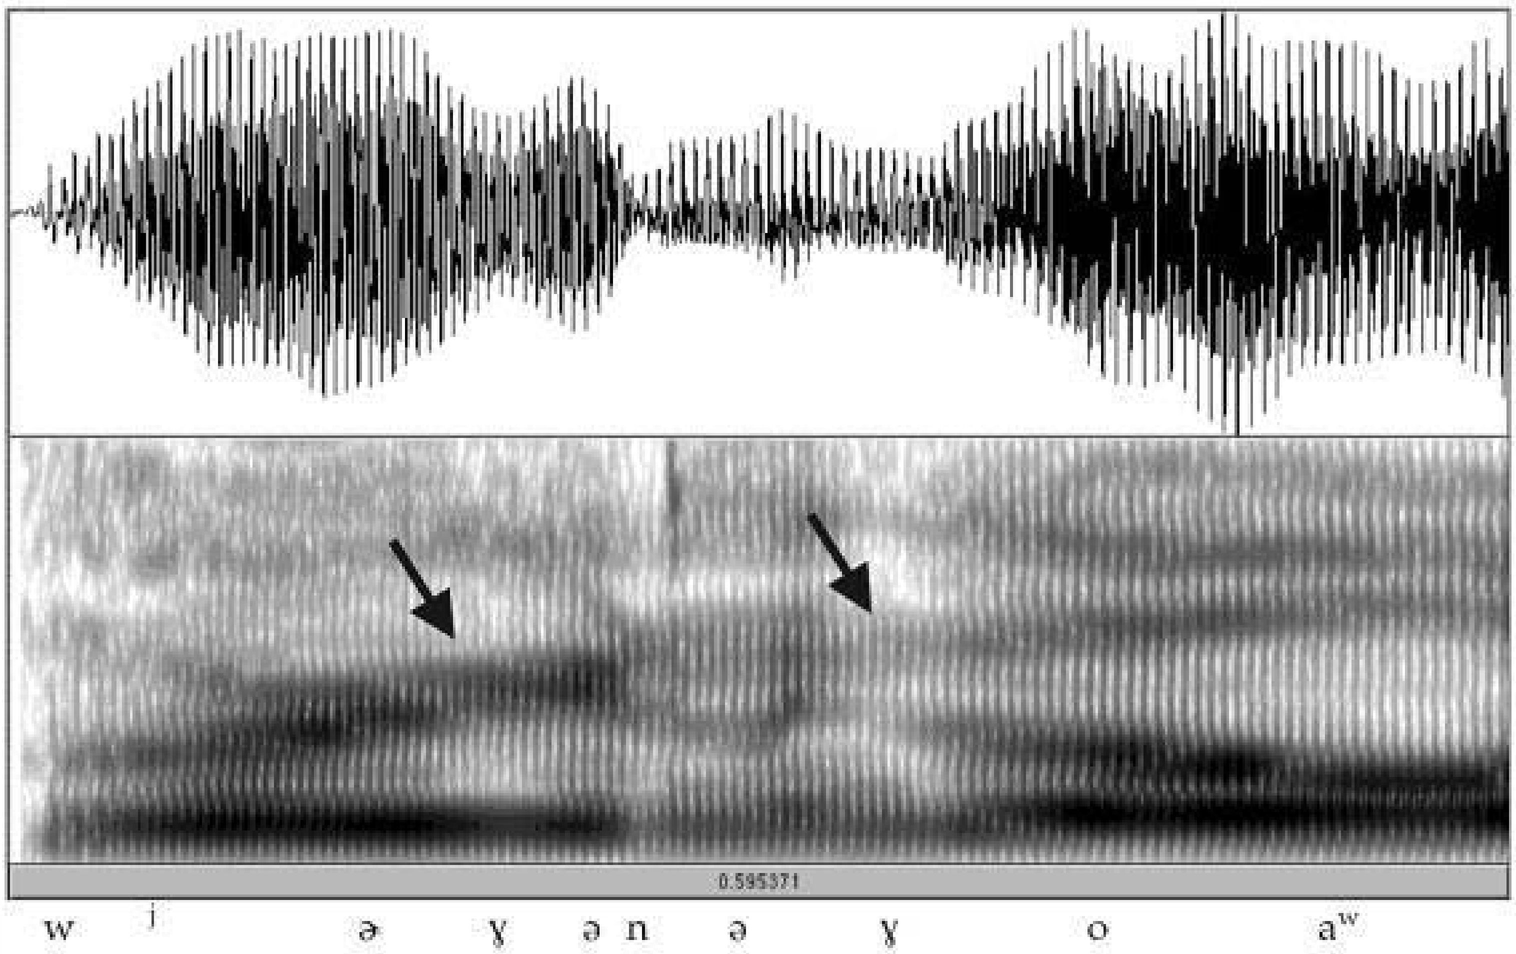

Figure 79.2 Waveform and spectrogram of a conversational token of *We were gonna go out*, demonstrating approximant realizations of the /g/ phonemes (marked with arrows)

2 Historical perspective

Scholars have long noticed that expected speech sounds are not always produced. Richter (1930) gave numerous examples of reduction in French, although from relatively careful speech. She notes severe reductions like the deletion of the entire syllable *-ble* in *impossible*, as well as single-segment deletions, assimilations, etc. Early scholars like Richter had to develop creative methods to detect reductions, since in context reductions sound notoriously unremarkable. Richter recorded speech on phonograph records, then played the records backwards while transcribing the sounds she heard. While this may have biased her results in some ways, it was a creative way to determine what kinds of reductions were present, without the benefit of spectrograms.

For several subsequent decades in phonetics and phonology, many scholars acknowledged that speech reduction exists and gave a few examples of reductions that might occur in conversation or in "sloppy" speech. However, they usually considered reduction phenomena as outside the area of interest, stating that one should analyze the full form of a word rather than the "elliptic," "slovenly," or "slurred" forms one finds in "rapid speech" or "familiar talk" (all terms from quotations in Johnson 2004). Johnson (2004) cites Hockett (1955) as giving examples [dɪʤə] for *did you?* and [wuʤə] for *would you?*. Johnson also discusses how Chomsky and Halle's focus on competence rather than performance removed speech reduction from the field of data to be analyzed. Johnson (2004) provides an excellent historical summary. Johnson does point out that European phonology (he emphasizes Stampe's Natural Phonology) gave more attention to reduction. For example, Dressler (1975) discusses implications of reduction for analysis of historical sound change, and advocates Natural Phonology as the best formal phonological approach to reduction. Shockey (2003) presents numerous transcriptions of reductions, and discusses how various phonological theories, including Natural Phonology, would handle reduction. Zwicky (1972) and Bolozky (1977) also address how to generate variable reduced surface forms in phonology. However, the publications that do address reduction represent a minuscule proportion of the work in the field, and papers not explicitly on reduction generally only mention careful speech forms. The training which new members of the field receive can also give an impression of the field's stance on reduction: one graduate introductory phonology course in an American linguistics department in the 1990s included a few examples of minor reductions such as [mɪʃʲu] *miss you* and a statement that what we should be studying is the clear speech form of words, not reductions. Overall, the field of phonology is primarily characterized by work that stops at the careful speech surface level. Many of the phonological works that do address reduction, furthermore, discuss reductions of a single segment, rather than the more drastic deletions of multiple syllables found in conversational corpora.

Turning to phonetics, Johnson (2004) notes that phoneticians have discussed reductions. The earliest example he cites is Dalby (1986), who examined how often schwas (CHAPTER 26: SCHWA) were deleted in English television talk-show speech and in a fast speech task in the lab. Richter (1930), mentioned above, gives an early example. Ladefoged *et al.* (1976) recorded speech styles ranging from conversational interviews to isolated word-list reading, and failed to find reduction of the vowel space. Koopmans-van Beinum (1980), however, found exactly that effect (in Dutch), in a wide variety of speech styles. A search of the *Journal of the Acoustical Society of America*'s database, going back to 1929, does show early studies of conversational speech, although often for engineering purposes, e.g. earplug effectiveness (Kryter 1946).

Still, the vast majority of phonetic research for many decades has been on carefully read speech. To take just one example, Löfqvist and Gracco's (1999) work using read sentences such as *Say "ipa" again* is more representative of the field than Dalby's (1986) work using television talk-show recordings. This is not a fault of the field. In part, technological limitations hindered analysis of large amounts of spontaneous conversational speech. Furthermore, there are many interesting questions that are more appropriate to answer with carefully controlled speech than with open, uncontrolled, variable conversation.

To confirm objectively that research using spontaneous or non-careful speech is still the exception in phonetics, I examined every article in a recent volume of the *Journal of Phonetics* (vol. 36, 2008). This volume contains 36 research articles, including a special issue on phonetics of North American indigenous languages (six articles). Of the 36, a total of four articles use speech material occurring in a relatively natural setting. Notably, two of those are on infants' speech productions during play (isolated words and babbling). The other two are from the special issue on indigenous languages and use field recordings (interviews, monologues, and elicitation) as corpora. One additional indigenous languages article uses a sentence translation task. Thus, in this volume of the journal, relatively natural speech settings seem to be used when it would be difficult or impossible to obtain data otherwise: with infants and with highly endangered or non-written languages. (One additional article on an African language uses a sentence repetition task rather than reading.) The remaining 32 articles use careful speech. The majority use target words or non-words in repetitive frame sentences of the *Now I say X again* type. Thus, although the sources discussed below demonstrate that there is now a substantial body of research on spontaneous speech and reduction, such research represents a small percentage of work in the field.

Until recently, speech perception and spoken word recognition research has also largely avoided speech that might be reduced. Speech perception stimuli tend to be even more careful and less natural than the speech for acoustic phonetics: a common type of stimulus might be synthesized /ba da ga/ nonsense syllables, or perhaps isolated words with one segment gated out. One would be unlikely to use stimuli collected from natural conversation unless perception of reduction were the topic. Turning to psycholinguistics, much of Cutler and colleagues' work is about how listeners segment words out of connected speech. Still, Cutler points out (1998; see also Mehta and Cutler 1988) that one usually uses carefully pronounced stimuli with little context (e.g. *apple* embedded in *vufapple* for a word-spotting task) to study the segmentation of connected speech, reducing experimental variability. Thus, even work that sets out to examine how one deals with connected speech uses rather careful speech as the testing ground.

Recently, phonetic investigation of reduced speech has been expanding rapidly. Three studies quantify how much reduction takes place overall by comparing pronunciations in corpora of spontaneous speech to expected careful pronunciations. Shattuck-Hufnagel and Veilleux (2007) surprisingly emphasize how *few* of the expected acoustic landmarks are deleted in spontaneous speech (14 percent in their study), while Greenberg (1999) emphasizes how *many* expected segments are deleted (12.5 percent in his study). Johnson (2004) finds 20 percent of words having at least one segment deleted and 5–6 percent of words having at least a syllable deleted. Although one paper concludes that deletions are rather rare and the other two conclude that they are common, the difference in deletion rate is not large, and the methods differ (deletion of Stevens-style landmarks *vs.* deletion of segments, in a map task – where speakers viewing a map give directions to listeners – as opposed to conversation). Thus, whether deletion is frequent may be a question of whether the glass is half full or half empty: is 12.5–14 percent deletion a lot? Is it enough to make listening challenging? Work such as that by Raymond *et al.* (2006) examines deletion of particular segments, also showing substantial rates of deletion, even for word-medial consonants. Reduction is not solely about deletion: Greenberg finds 117 pronunciations for the word *that*, for example, an astounding demonstration of the variability that listeners encounter in normal conversation. Strik *et al.* (2010) show a similar result for Dutch. Shockey (2003) contributes transcriptions of reductions from many dialects of English.

Ernestus and colleagues have conducted extensive research on reduction in Dutch (beginning with Ernestus 2000). Some of their studies locate all tokens of particular high-frequency words or suffixes in a corpus, such as *eigenlijk* 'actually' or its suffix *-lijk*, and analyze what affects their duration (Pluymaekers *et al.* 2005a, 2005b). Research on reduction has favored English and Dutch thus far, but does exist for other languages. Some examples are Tseng (2005) and Cheng and Xu (2008) on Mandarin, Furui and colleagues (e.g. Nakamura *et al.* 2007) and Maekawa and Kikuchi (2005) on Japanese, Kohler (2001) and colleagues on German, Engstrand and Krull (2001) for Swedish, Lennes *et al.* (2001) on Finnish, and Nicolaidis (2001) on Greek. The Nijmegen Speech Reduction Workshop (June 2008) included several talks on French, and Barry and Andreeva (2001) compare reduction phenomena in six languages. Furthermore, Keune *et al.* (2005)

find that degree of reduction can differ even for dialects, with more reduction in Belgian Dutch than in Netherlands Dutch. It is promising that there are data in an array of languages, although Europe still dominates. Another consideration about the past literature is that much of the spontaneous speech has been from the Map Task (Bard *et al.* 2001; Shattuck-Hufnagel and Veilleux 2007), monologues (Arai 1999), or other relatively careful speech, which may lead us to underestimate reduction. There has also been phonetic research on speech style in the opposite direction from reduced speech, specifically on the "clear" speech that speakers use to address hard-of-hearing or second-language listeners (Bradlow and Bent 2002; Smiljanić and Bradlow 2005, 2008).

Most phonetic research on reduction is on what is produced (articulatory or acoustic phonetics), but perception research is now increasing rapidly. Mehta and Cutler (1988) test perception of spontaneous *vs.* read speech, using a phoneme monitoring task, and find that the coherent intonation of planned speech facilitates processing, relative to the pauses and self-corrections of spontaneous speech. Koopmans-van Beinum (1980) finds that identification accuracy for Dutch vowels presented in isolation, cut out of the speech stream, is extremely low for casual speech. Arai (1999), on Japanese, and Ernestus *et al.* (2002), on Dutch, both investigate perception of severe reductions (e.g. syllable deletions, such as [ɛik] for Dutch [ɛixələk] 'actually'). Both Arai and Ernestus *et al.* find that listeners cannot retrieve the intended words well without context, but can with context. Shockey (2003), using a single conversational utterance, indicates that listeners usually misperceive reduced speech unless extensive conversational context is present.

Turning to perception of specific types of reduction, Mitterer and Ernestus (2006) find that listeners take patterns of where reduction is produced into account when recognizing reduced final /t/. Ranbom and Connine (2007) investigate recognition of English words with /nt/ reduced to nasal flap, as in *gentle* rhyming with *kennel*. They find that words which listeners hear more often with nasal flap are not as hard to recognize with the nasal flap as other words. However, the reduced form is still more difficult overall. Tucker (2007) finds that having heard fast, reduced speech in the preceding frame sentence can, to some extent, mitigate the reduced-speech difficulty. This suggests that listeners use information about reduction in the context to adjust their acoustic criteria for recognition of upcoming sounds. Isabelle Racine presented on recognition of French words with schwa deletion at the Nijmegen Speech Reduction Workshop. Oliver Niebuhr, also at that workshop, discussed listeners' use of lengthening in neighboring segments to recognize otherwise deleted segments. Warner *et al.* (2009b) test the contribution of various acoustic aspects of flap reduction to whether listeners hear a medial consonant in pairs such as *needle–kneel*.

Past research has also examined processing of flapped *vs.* extremely careful /t d/ pronunciations, e.g. recognition of *pretty* with flap *vs.* [t] in American English (McLennan *et al.* 2003, 2005; Connine 2004; CHAPTER 113: FLAPPING IN AMERICAN ENGLISH). However, since flap is the normal careful pronunciation, that work is more about the processing of phonological alternations than about reduction.

Speech reduction borders on other fields besides linguistics and psychology. It is particularly relevant for engineering, for purposes of automatic speech recognition (ASR), because speakers may expect ASR systems to respond correctly to their requests even if they use reduced speech. Some of the works cited above relate particularly to ASR (Greenberg 1999; Strik *et al.* 2010; Nakamura *et al.* 2007).

Within the field of linguistics itself, but beyond phonetics and phonology, speech reduction is of particular interest for sociolinguistics.

To sum up the historical perspective on reduction, formal phonology has long excluded reduction from its domain. Phonetics has long included the topic, but as a very small proportion of all phonetic research. Psycholinguistics has addressed questions of connected speech, although usually by means of careful speech stimuli. The last few years, however, have shown an explosion of research on reduction, speech style, and large connected speech corpora.

Perhaps it is not surprising that conversational speech and reduced speech make up a small proportion of research, even in phonetics. The field uses an astounding range of speech carefulness, from nonsense sequences such as /ipa, ipu/, possibly with articulograph pellets glued to the speaker's tongue, to spontaneous conversation between close friends, or even natural interactions outside the lab (e.g. Hicks Kennard's 2006 work on male and female marine corps drill instructors' phonetics). The former will yield extremely stable data with little random variability, with obvious statistical advantages (increased power) when the question is not about more natural speech. However, once there is a background literature on a given topic, we may be able to move to more spontaneous speech. We are then likely to encounter more reductions, even if reduction is not the topic of the work.

3 Reduction phenomena

3.1 *Duration*

Shorter duration of segments is perhaps an obvious meaning of reduction (duration is literally reduced), but if the segments are acoustically otherwise unaltered, overall shorter durations might stem from fast speech rather than reduction. However, shorter duration is usually correlated with reduction in manner of articulation, so duration may provide a convenient way to measure reduction. For example, we find a good correlation between intervocalic stop duration and how approximant-like the "stop" is (Warner and Tucker 2007). Ernestus and colleagues have made extensive use of duration as a simple, one-dimensional indicator for reduction (e.g. Pluymaekers *et al.* 2010). Figure 79.3 shows a phrase taken from casual conversation, with reduction of several syllables to very short durations, and the same phrase in careful speech. Ernestus and colleagues often use a partially automated system (automatic speech recognition, given phonetic transcription as input) for duration measurement (Pluymaekers *et al.* 2010).

3.2 *Alterations to segments*

Changes in the manner of articulation or voicing of a segment are extremely common in reduced speech. Warner and Tucker (2007), studying realizations of expected intervocalic stops and flaps, find that a great many tokens in all speech styles are actually produced as approximants (Figure 79.4a, even in read speech). Figure 79.4b shows an expected flap that is barely visible, and a second visible but extremely short flap. Figure 79.5 shows a Japanese example in which reduction causes devoicing rather than voicing (in an environment where vowel

(a) First pair with transcription

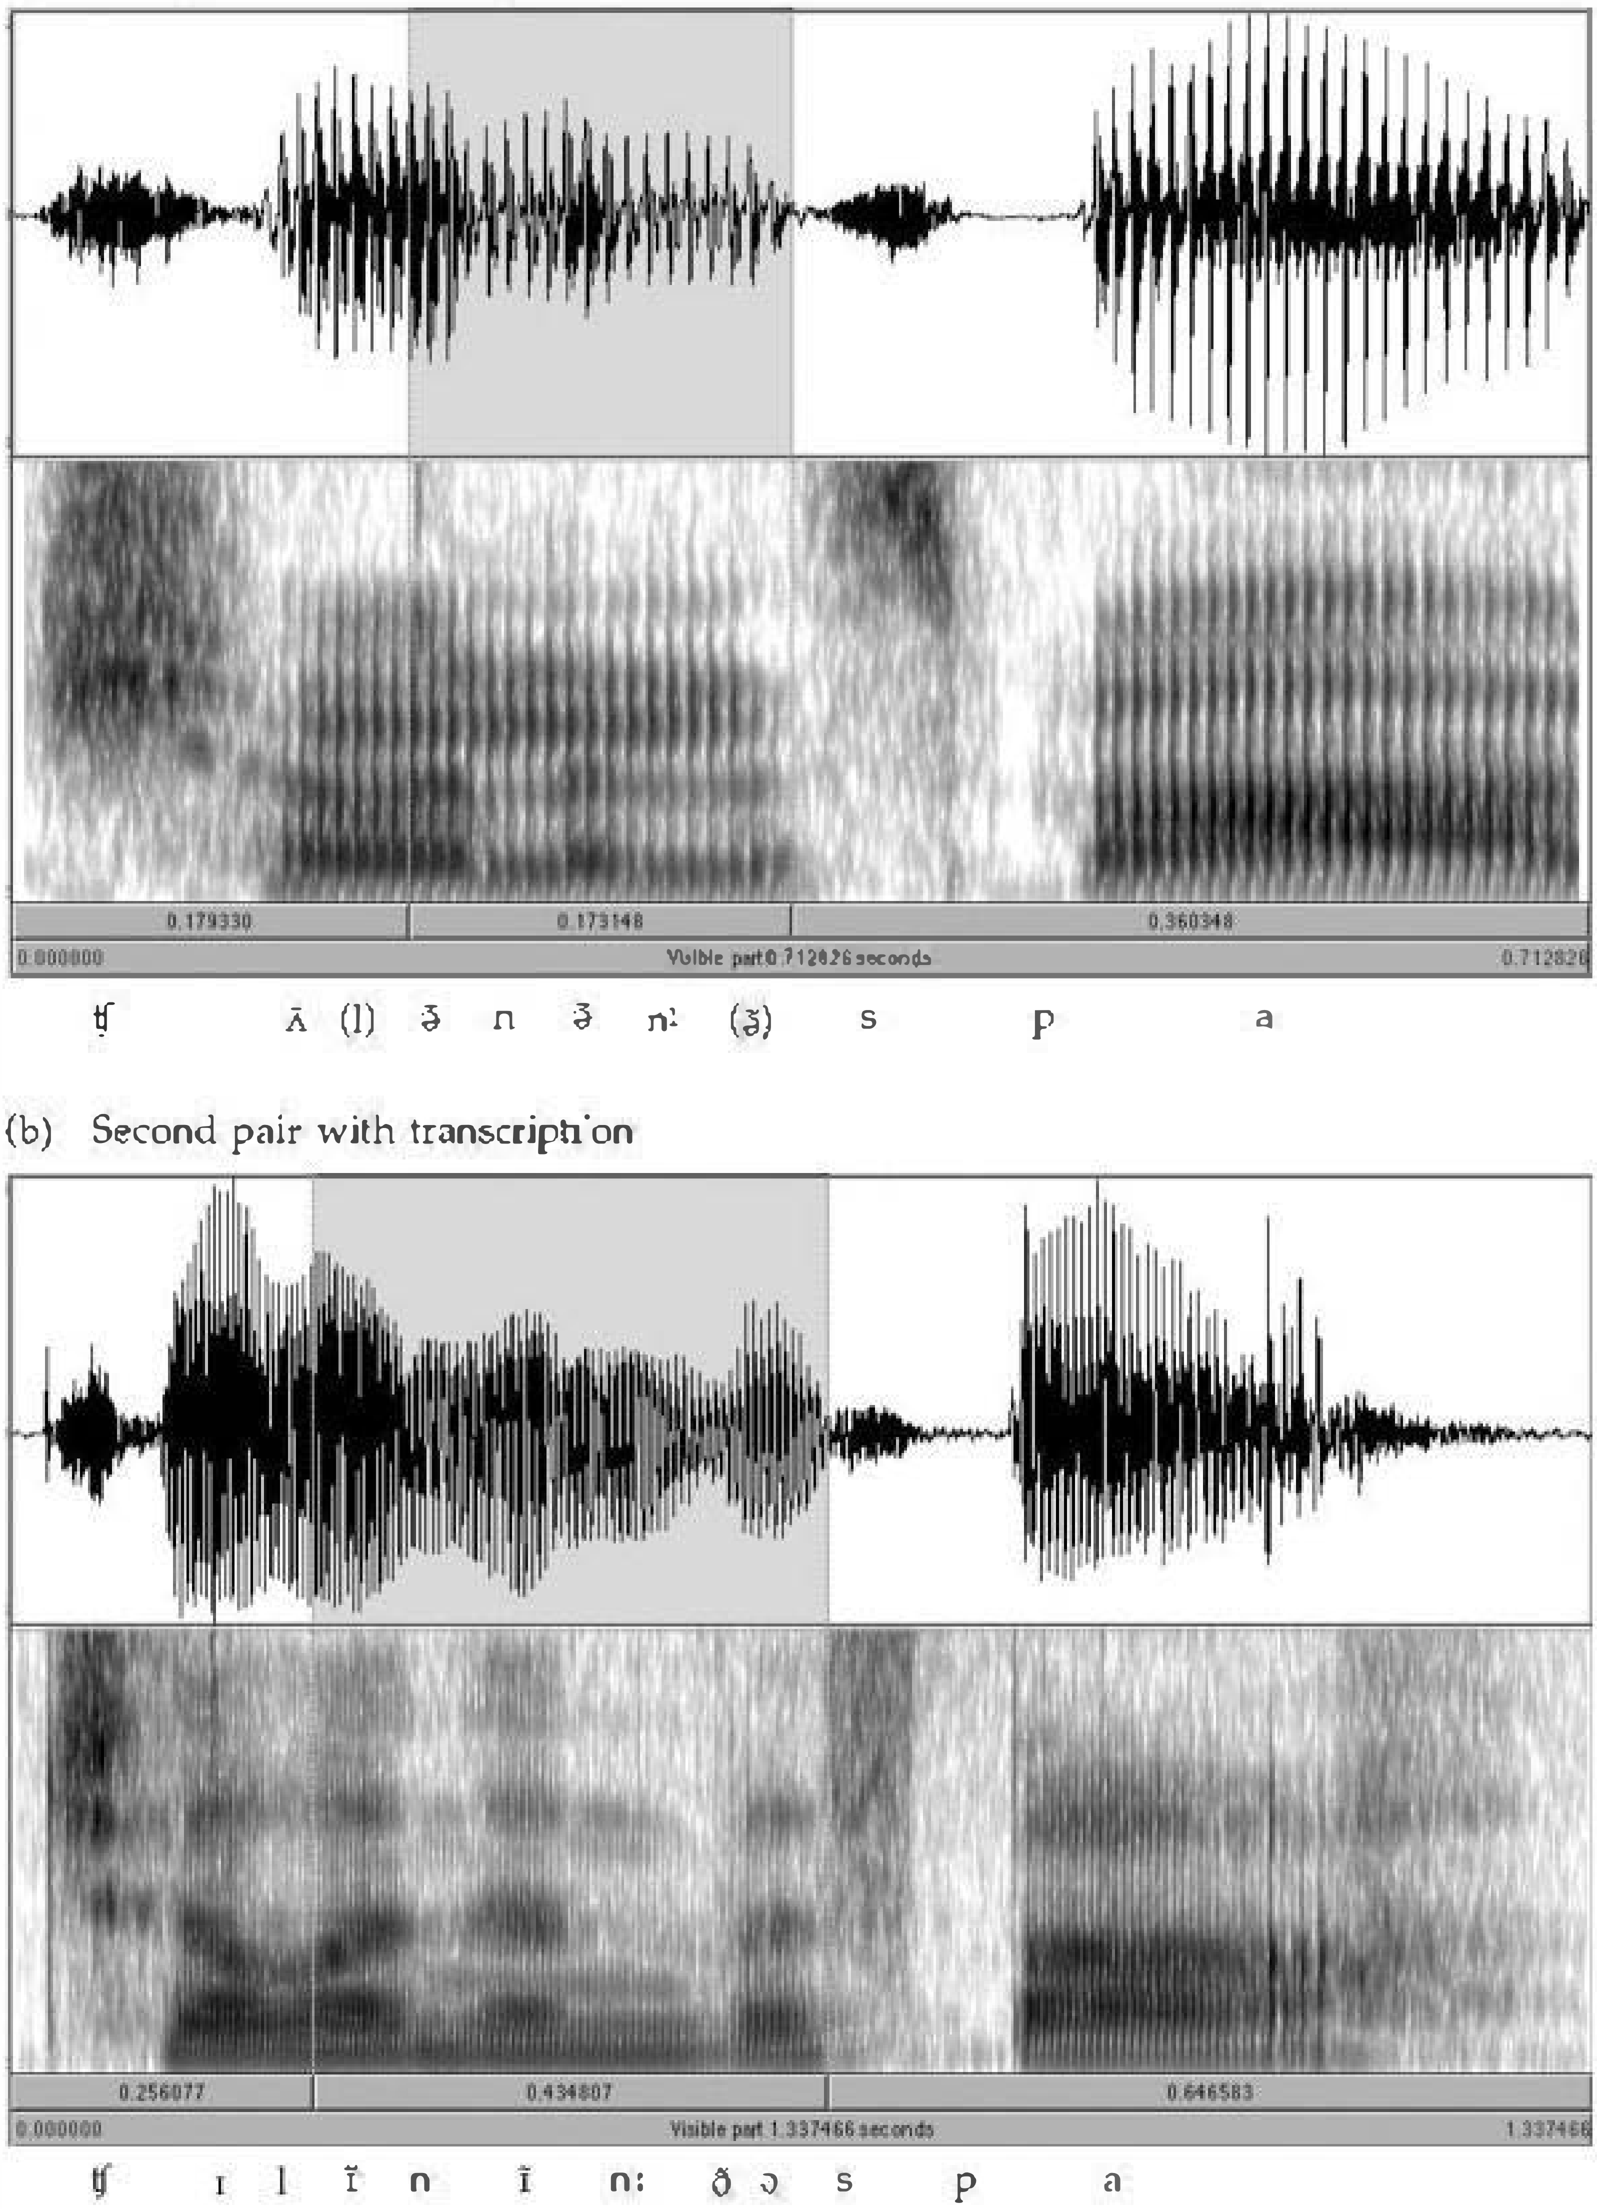

Figure 79.3 Waveforms and spectrograms of two tokens of *chillin' in the spa.* The highlighted portion corresponds to *-in' in the*. In all figures, phonetic symbols in parentheses indicate sound for which there is some evidence, but either they have extremely low amplitude or their presence is in doubt. (a) Utterance taken from conversation (highlighted portion: 173 msecs). (b) Carefully produced utterance of the same words (highlighted portion: 435 msecs)

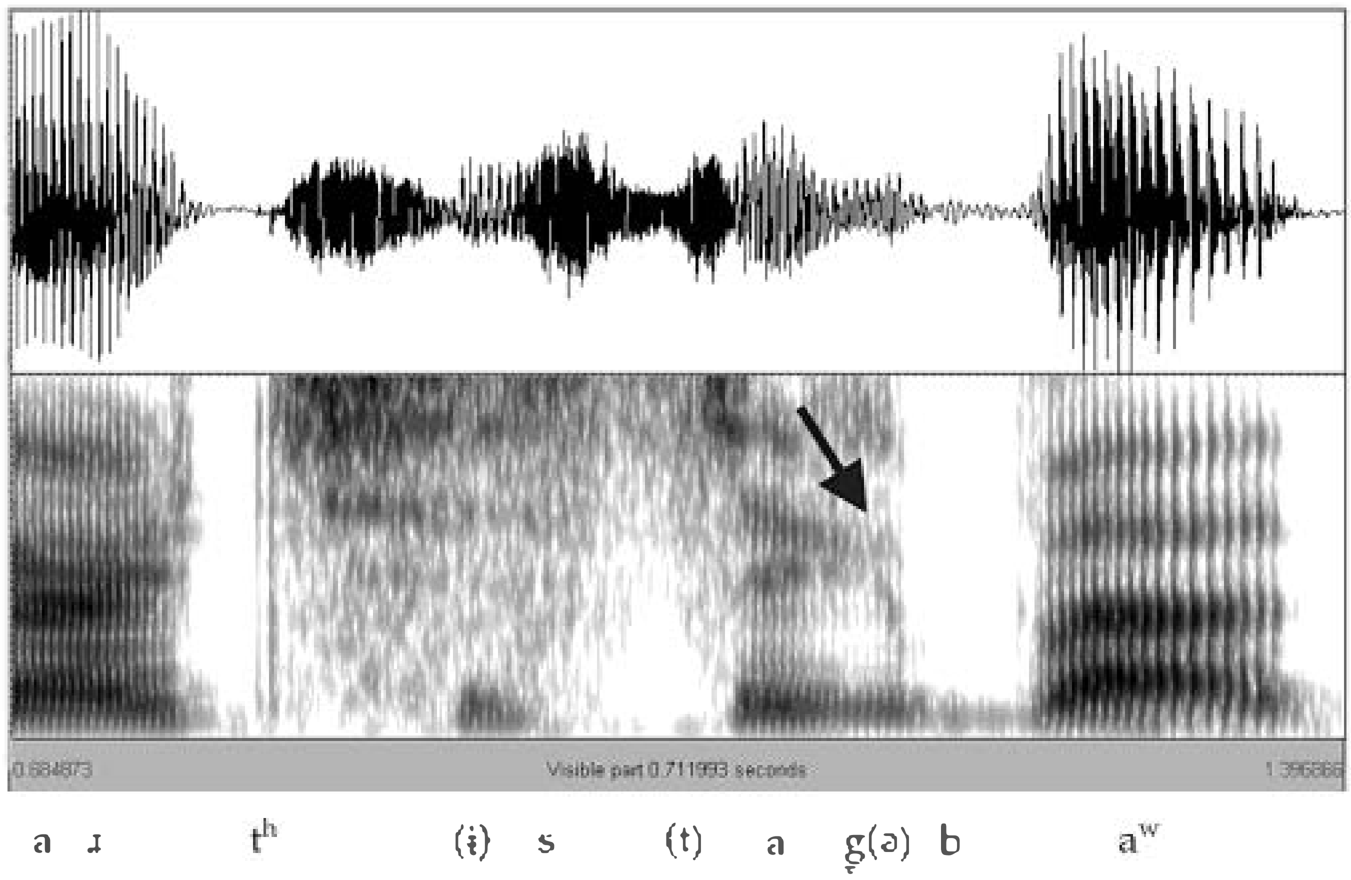
(a) First pair with transcription



(b) Second pair with transcription

(a) . . . *artistic about* (read speech from a list of phrases), with /k/ marked by an arrow.
(b) . . . *get out, er* . . . (conversation), with arrows at expected flaps

devoicing should be phonologically impossible). The entire final syllable of the utterance, /ru/, is effectively devoiced, although the /u/ could be argued to have 3–4 extremely low-amplitude pulses.

If manner of articulation (CHAPTER 13: THE STRICTURE FEATURES) and voicing (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION) can change as part of reduction, one wonders whether place of articulation (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION) can as well. One might hesitate to consider most

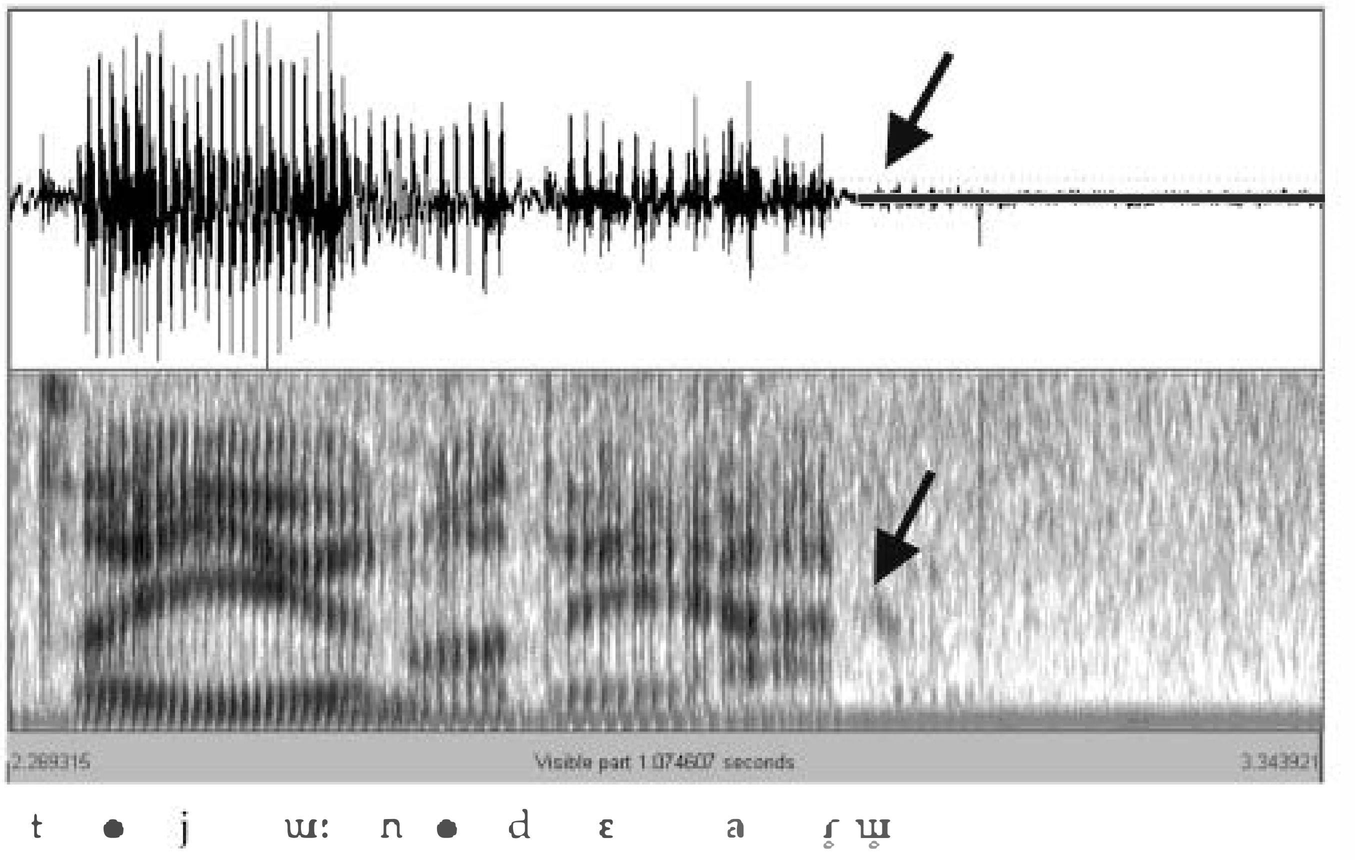

Figure 79.5 Waveform and spectrogram of a Japanese partial utterance . . . *to iu no de aru* 'it's that it's the case that' (from a cassette tape accompanying a third-year language textbook, read speech by a professional speaker). The arrow marks a consonant and vowel that are devoiced where not phonologically expected

assimilations (e.g. English /ɪn-/ in *impossible*; CHAPTER 81: LOCAL ASSIMILATION) to be reductions. However, variable phonetic assimilations may be part of reduction: *seve*[m] *plus* for *seven plus* would happen less often in careful speech, even though the tongue tip still makes an unperceived alveolar gesture (Browman and Goldstein 1989). This type of example has influenced the field through Articulatory Phonology (CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS), although it is not generally presented as being "reduced" speech.

3.3 *Deletion and syllable count*

In reduced speech, one almost always finds deletions of segments (Figures 79.1–79.3), as quantified by Greenberg (1999), Johnson (2004), Raymond *et al.* (2006) and others. Some scholars might propose that deletion is not a type of reduction, because reducing something does not mean removing it. However, it is impossible to separate deletions from other reduced speech phenomena. Even for a given segment, it can be difficult to say whether there is some trace of the segment present. Figure 79.6 shows several examples ranging from reduced to probably deleted (even in Figure 79.6c, one perceives some trace of a consonant for the expected flap, although it is not visible in the spectrogram).

Furthermore, Browman and Goldstein (1989) review findings that, even when a segment appears to be fully deleted acoustically, there may still be a reduced-size articulatory gesture for it, as in the apparent deletion of the final /t/ in *perfect memory*. This is very similar to the *seve*[m] *boys* type of assimilation example above, and in Articulatory Phonology, the difference between deletion (*perfect memory*) and this assimilation is solely a matter of whether the following labial gesture overlaps a voiceless stop, rendering it inaudible, or a nasal, making it audible with

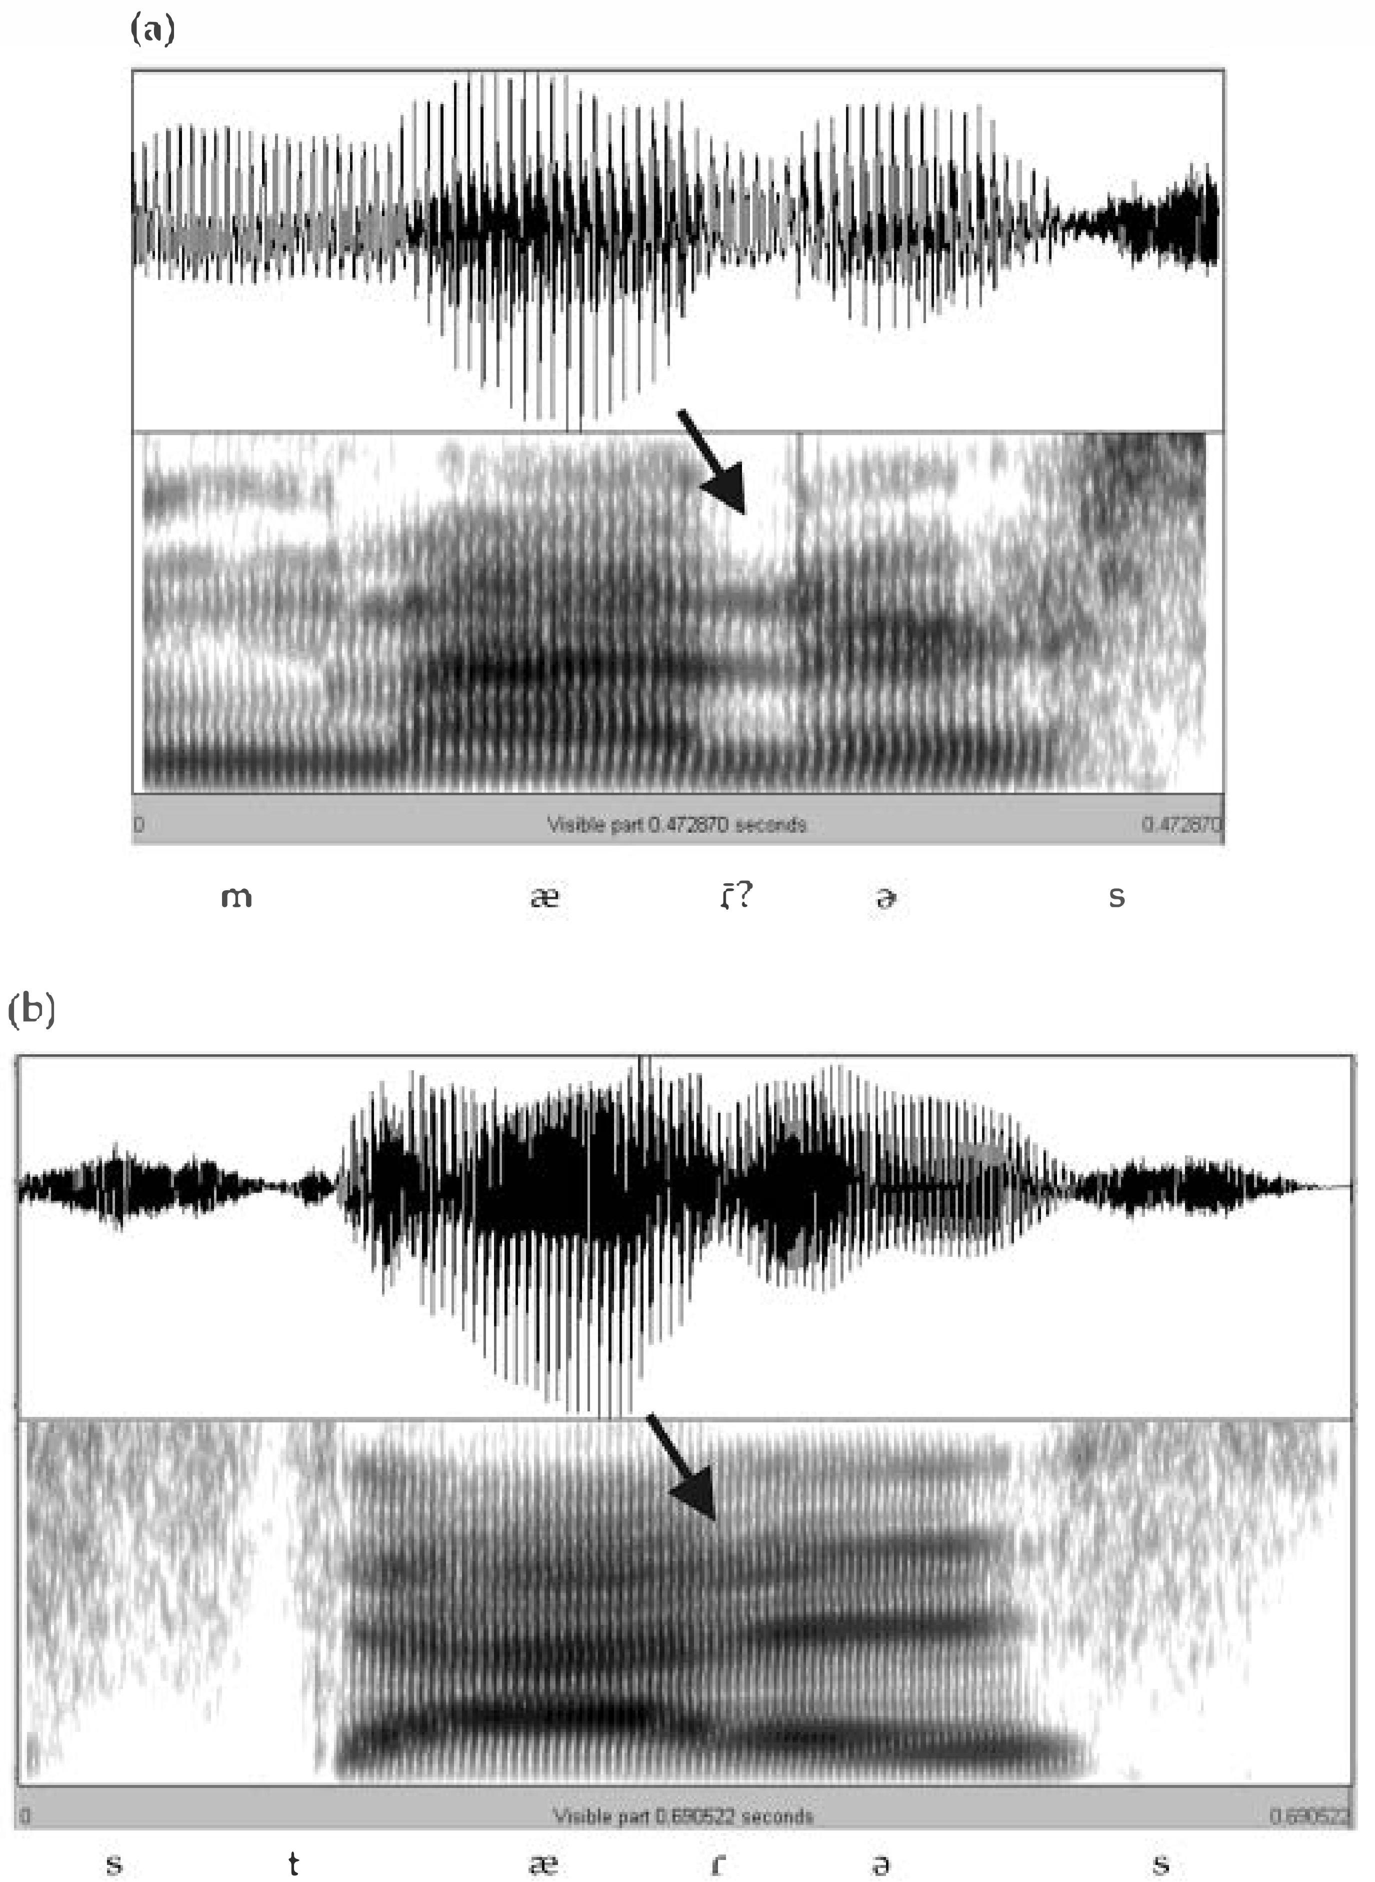

Figure 79.6 Waveforms and spectrograms of a variety of reductions of flap. Arrows mark the location, visible or expected, of the flap. All are from read speech ((a) from the reading of a story; (b) and (c) from word-list reading). (a) *matters*, with the flap slightly nasalized. (b) *status*, with the flap approximated. (c) *capitalist*, with the flap so reduced that no trace is visible, although there is some suggestion of a consonant perceptually

(Cont'd)

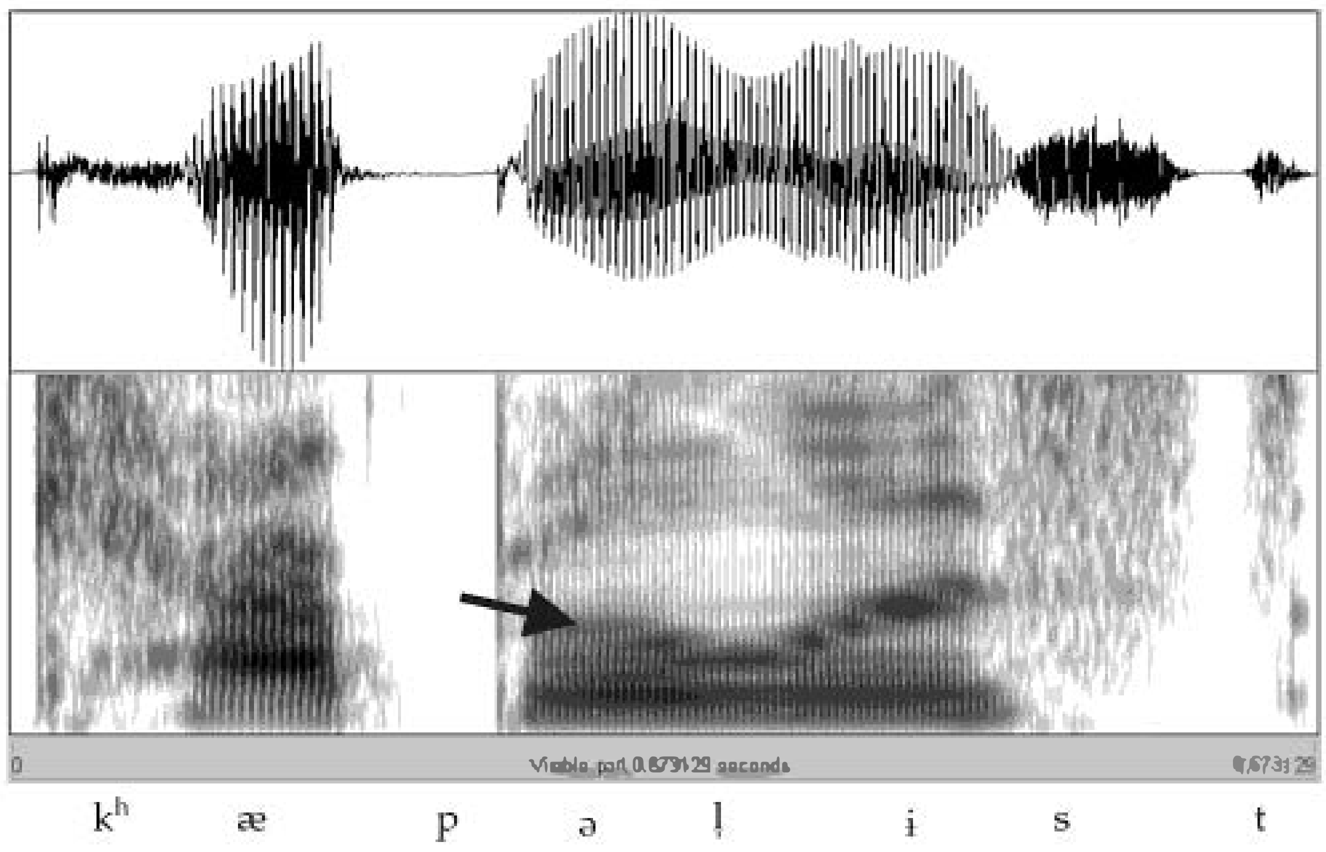

Figure 79.6 (*Cont'd*)

a different place. Thus there are several reasons to consider apparent segmental deletions to be quite literally a type of reduction: reduction *vs.* deletion is a continuum (Figure 79.6), acoustic deletions are known to often have small residual gestures (Browman and Goldstein 1989), and gesturally there is no difference between some deletions and some assimilations. Furthermore, deletion and reduced segments go together: in conversational or spontaneous speech, if we are finding many changes of manner or voicing in a recording, we will also be failing to find some expected segments at all.

Often, reduced speech overlaps gestures and perceptual cues so much that one cannot say which segments have been deleted and which are present. One hears some trace of expected segments, but on close examination of the spectrogram, and despite close listening, one cannot be sure what sounds are present at all (Figure 79.7). In *weekend were you* in Figure 79.7, there is a voiceless palatal fricative for the /k/, and later a high F2 for the /j/ of *you*. Between those, there is a vocalic stretch, then a low F2 that suggests a /w/, and one hears substantial nasalization and some r-quality. This unclear stretch must be a reduction of /ɛndwɚ/, and one can identify features such as nasalization, but it is very difficult to identify segments or transcribe it in order to determine what has been deleted. Any transcription of this stretch forces unjustified and artificial clarity onto the speech. Still, this utterance sounds completely normal and intelligible. Such examples make the issue of whether deletion and assimilation are part of reduction moot. Gestures and perceptual cues are highly overlapped, yet something remains of many of them. Both assimilation and deletion must be happening, but the speech is simply not clear enough to point to specific assimilations or deletions.

As a result of deletions, syllable count often drops relative to careful speech. As discussed above, Johnson (2004) finds that 5–6 percent of words in a spontaneous

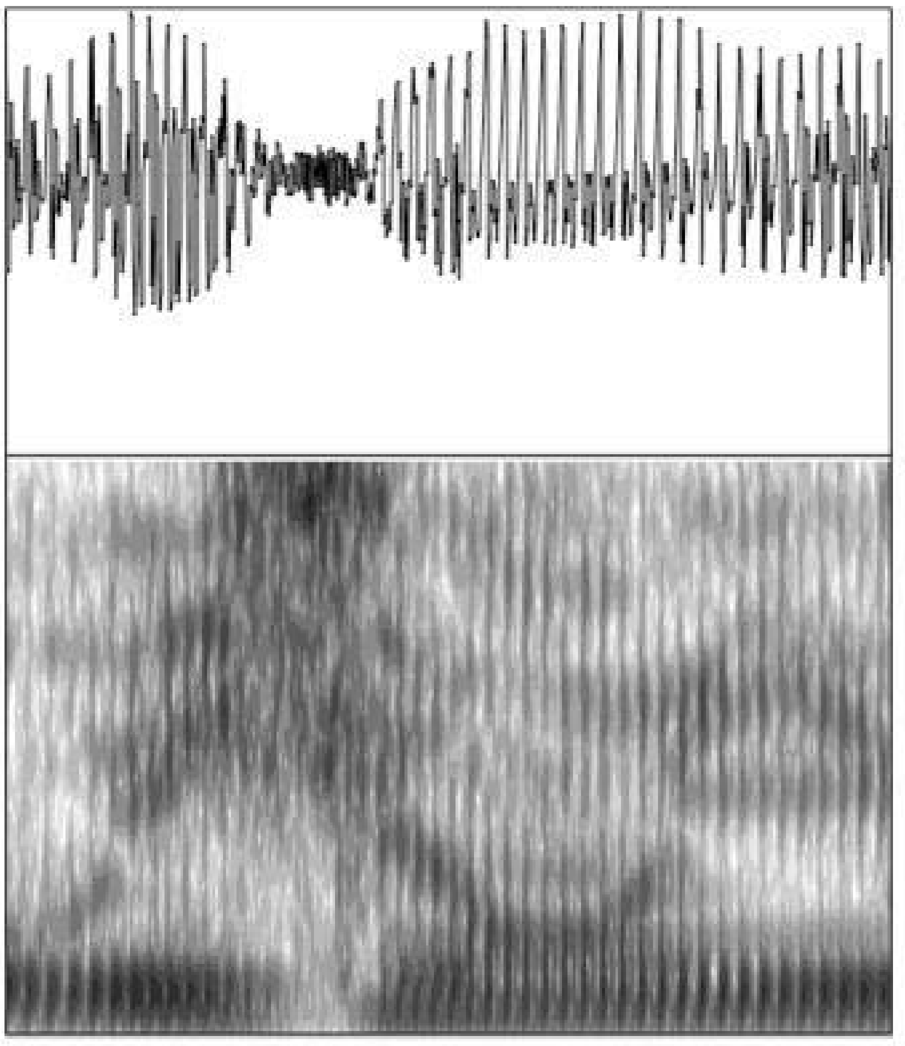

Figure 79.7 Waveform and spectrogram of . . . *weekend were you*, from conversational speech

English corpus have at least one syllable deleted, as determined from phonetic transcriptions. Arai (1999) studies perception of spontaneous Japanese speech, using the fact that the Japanese mora writing system allows one to evaluate perceived mora (or syllable) count. Arai (1999) presented a stretch of conversational speech, with varying amounts of context. Listeners were simply asked to write down what they had heard. Out of context, a stimulus which would have five moras in careful speech was perceived as containing an average of slightly more than two, but with even a little context, the same stretch was reported as constituting an average of nearly five moras. This study concurs with others that listeners cannot recognize reduced words or sounds well out of context, yet do so quite successfully in context. It also provides direct evidence that listeners perceive fewer moras or syllables for the same reduced acoustic material out of context.

3.4 *Shrinkage of acoustic spaces*

Literature on reduced speech often focuses on changes from one segment to another or deletions (e.g. Greenberg 1999; Johnson 2004; Shattuck-Hufnagel and Veilleux 2007). This is partly because of the method of transcribing a corpus, then comparing the transcription to dictionary listings for the words (Warner, forthcoming). However, some types of reduction do not result in a different transcription, as when the overall vowel space shrinks (Koopmans-van Beinum 1980). Many of the vowel tokens in Koopmans-van Beinum's work would probably be perceived as the full vowel phonemes (e.g. /i u a/, etc.) and not as /ə/, yet the vowel space shrinks with each step away from careful speech. Ladefoged *et al.* (1976) are unable to find this effect in Southern California English, but theirs is a relatively small study.

Other acoustic spaces may also compress, without causing changes in the transcribed segments. Berry (2009) shows reduction of the tonal space in spontaneous Mandarin speech (also demonstrating how reduction applies to suprasegmentals). Furui and colleagues (e.g. Nakamura *et al.* 2007) quantify reduction in spontaneous Japanese through a measure of spectral difference among phonemes, showing lesser spectral difference in reduced speech. This method is particularly useful for its ability to quantify reduction across all segment types, regardless of either underlying or surface manner of articulation.

4 The driving force behind reduction

What motivates reduction? Several motivations have appeared in the past literature, although some have primarily been proposed as explanations of other phenomena, and simply extend easily to reduction. The most obvious potential explanation may be "ease of articulation." In the 1990s, a trend developed that proposed speakers' desire for ease of articulation as an opposing principle to their wish for listeners to understand them, with these two wishes sometimes described as ranked constraints in Optimality Theory (reviewed and criticized by Hale and Reiss (2000); see also CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). While these constraints were not developed to describe spontaneous speech, their applicability is obvious. This would, however, be tantamount to saying that reduced speech is sloppy speech. Furthermore, what constitutes "ease" in articulation is neither clearly defined nor readily measurable.

Target undershoot is perhaps a more measurable version. Reduction in the size of gestures provides a convenient way to describe many reductions, such as expected stops being realized as approximants. Combining target undershoot and gestural overlap (discussed above), one could describe lowered syllable counts, as in *beret* realized as *bray* (Browman and Goldstein 1989). One would have to use gestural overlap and target undershoot considerably more heavily to model extreme reductions as in Figures 79.6c and 79.7, but this would be readily possible. However, the idea of reduced size and greater overlap of gestures does not provide a *motivation* for reduction, just a description. Task dynamic modeling, with its interaction among stiffness, targets and time, might do so, but gestures may be a better description of reduced speech than they are an explanation of what causes it. As far as the author is aware, the exact relationship of speech rate, stiffness, speech reduction, and speaker's choice of speech style remains for future research.

"Ease of articulation" and gestures focus on the speaker. One can alternatively focus on the listener. The OT account mentioned above suggests that listeners want clearer speech, and the perceptual literature does confirm that listeners find clearer speech easier to process (Ranbom and Connine 2007; Tucker 2007). However, listeners may not uniformly "want" unreduced speech. Speakers might accommodate the listener's specific informational needs in choosing when to reduce. This could be viewed as an overall motivation: overlap the segments (or gestures, or perceptual cues) during low-information portions of the signal, then use clearer speech for high-information portions, maximizing the speed and efficiency with which information is conveyed. Some results, such as Ernestus and colleagues' work on high-frequency words and suffixes (e.g. Dutch *eigenlijk* 'actually', mentioned above), support this view. In some items, they find greater reduction for higher-frequency words (CHAPTER 90: FREQUENCY EFFECTS), for words that have already occurred in the conversation, and for words that are more predictable from surrounding words (Pluymaekers *et al.* 2005a, 2005b). All of these support the idea that speakers reduce where the information will not be too important, or difficult to retrieve, for the listener. Kuperman *et al.* (2007) find an opposite effect of predictability for a specific set of data, though. Greenberg (1999) finds that low-frequency words tend to be pronounced canonically, regardless of speech rate, but that high-frequency words show more reduction with faster speech rate. However, Bard *et al.* (2001) find quite surprising results by cleverly manipulating what the listener actually knows and what the speaker knows, suggesting that speakers decide how much to reduce based more on what the speaker him/herself knows than on what the listener knows. These results together suggest that information structure certainly has an effect, but not a straightforward one, on speech reduction. It seems safe to conclude that reduction is only partially motivated by how information can be conveyed efficiently.

Furthermore, reduction itself probably conveys information. Bradlow (2002) argues that CV co-articulation conveys information to the listener and is part of the speaker's intentional strategy, rather than being simply a necessary consequence of inability to move articulators instantaneously from one place to another. Ogasawara (2007) and Tucker (2007) both find that listeners make use of reduction or speech rate in the context to help them decide on the acoustic criteria for later sounds in the speech stream. Putting these separate ideas together with the commonsense notion that speakers are more likely to reduce when talking with a close friend than with a prospective employer, for example, it seems likely that part of the motivation for reduction is to convey something about the speech style to the listener, rather than to eliminate unnecessary gestures for the speaker.

Overall, there is no definitive explanation for what drives reduction. It seems very likely that articulatory factors (e.g. task dynamic stiffness, articulator movement rate), information structure (greater reduction where information is less important), and intentional use of reduction as a feature that conveys information in itself all contribute to how much reduction a given utterance contains. The possible interactions of these factors are too complex to be disentangled in a single experiment.

5 Representational consequences of reduction

5.1 Formal phonology

As discussed in the section on historical perspectives above, formal phonology (whether OT or rule-based) has largely ignored reduction. Assuming that language is divided into competence *vs.* performance, all reduction may be a performance phenomenon, outside the grammar. However, one must know how to reduce in order to be a native speaker of a language, particularly if anything about reduction is language-specific. Barry and Andreeva (2001) show cross-linguistic similarities in reduction types, but there has been little quantitative comparison of reduction across languages, and stress *vs.* syllable *vs.* mora rhythm at least are likely to cause language-specific differences in reduction. Keune *et al.* (2005) find more reduction in Belgian Dutch (Flemish) than Netherlands Dutch. To the extent that how to reduce is language-specific, it may have to be part of the grammar, although at the phonetic level (Pierrehumbert 1994).

However, formal phonology rarely reaches a detailed enough surface level to reflect reductions, nor does it attempt to generate as many variants for each word as reduction produces. Formal phonology usually takes written broad transcriptions of single-word careful pronunciations as the data to be accounted for. If a particular token of *we were* as in Figure 79.2 sounds like *were* out of context but like *we were* in context, a formal phonological analysis is likely to lose that information before the analysis ever starts. Formal phonology examines an abstract version of how a word might be pronounced (carefully), not how it was pronounced on a particular occasion.

However, the 1990s saw a huge increase in the number of formal phonological models that integrate gradient, quantitative phenomena. Pierrehumbert (1994) lays out the reasons for addressing quantitative variability within the phonological competence. Flemming's (1995) work includes constraints that specify by how many Hertz two vowels' formants must differ. Warner (2002) addresses (but argues against) the possibility of modeling low-level phonetically variable acoustic events such as epenthetic stops (e.g. [k] in *young*[k]*ster*) within Optimality Theory. Nagy and Reynolds (1997) suggest ranking constraints variably to obtain multiple possible outcomes (see also CHAPTER 92: VARIABILITY). Boersma's version of OT (Boersma and Hayes 2001) adds noise to constraint rankings, so that how an underlying form is pronounced on a particular occasion can vary in a specific distribution. None of these works focuses on reduced speech, but the overall development of including gradience provides a mechanism for modeling the variability of reduction in formal phonology.

Using Boersma and Hayes's (2001) approach, one could easily model deletions (e.g. [wɚ] for *we were*; (Warner *et al.* 2009a) by ranking the deletion-preventing constraint MAX only slightly higher than the markedness constraints that work against realization of various segments or sequences (e.g. *LAB, *COR, *NÇ, NOCODA, etc. (Kager 1999). Markedness constraints are unviolated if the relevant segments are deleted, and MAX is unviolated if the underlying segments are maintained. Thus, if MAX were ranked just slightly above a collection of many markedness constraints, the random noise which Boersma and Hayes's system adds to rankings would sometimes place MAX lower than some of the markedness constraints, making a form with deletions optimal. Since random noise is added to the constraint rankings each time a speaker produces a form, MAX would be demoted beneath a different collection of markedness constraints on different productions, modeling the variability of which deletions occur in a given token. Furthermore, by varying how much random noise is added to constraint rankings, one could model varying amounts of deletion. Perhaps spontaneous, casual speech involves adding more noise to constraint rankings at evaluation time than careful speech does, supplying a direct way to model a speaker's choice of speech styles and degree of reduction. By ranking the IDENT constraints that prevent changes to manner of articulation and voicing appropriately relative to the markedness constraints, one could perhaps model reduction of stops to approximants and other such changes.

If reduced speech becomes part of "the business" of phonology, it could be modeled in OT in the way tentatively suggested here, or in some other way, or it could be modeled in a rule-based formalism. It would require far more detailed surface forms than are typically encoded, variable rules or variably ranked constraints (Boersma and Hayes 2001), and perhaps acoustically detailed rules or constraints (e.g. "overlap the gestures by at least *x* msecs or percent").

It is an open question in the field of psycholinguistics and spoken word recognition whether words have a single underlying representation in the lexicon or a wide variety of lexical listings (discussed below). Greenberg (1999) finds that the word *that* occurs with 117 distinct pronunciations in his spontaneous speech corpus, of which the most common is [ðæ], accounting for just 11 percent of all tokens. Is there just one abstract underlying representation stored for *that*, from which 117 different forms are derived? (See CHAPTER 1: UNDERLYING REPRESENTATIONS for more discussion.) How to write phonological rules or constraints that can produce the wide array of surface forms from a single underlying representation would be a mind-boggling problem. How can one change /ðæt/ into any of 117 forms, without allowing all words to become simply [ə]? One might need rules or constraints that effectively map any vowel onto any central vowel quality, any consonant onto an approximant, and any segment onto null. While it is not true that anything is possible in reduced speech, so many different things *are* possible that any formal phonological system might severely overgenerate, if set up to generate attested reduced forms.

5.2 Articulatory Phonology

Articulatory Phonology (Browman and Goldstein 1989 and many other publications) is better equipped to handle reduction and variability than many theories, as discussed above. Articulatory Phonology allows for reduction in the size or temporal span of gestures, and allows overlap, readily accommodating most or perhaps all reductions, as discussed above. It does require that all gestures present in the underlying representation (which consists of a gestural score), and only those gestures, be present in the surface form. This means that it is not literally possible for a gesture to be deleted. However, the theory does not prevent reducing a gesture until it is not measurably different from deletion. There is ample evidence that speakers often make articulatory gestures even if there is no audible acoustic consequence (e.g. the *seve*[m] *plus* and *perfe*[k] *memory* examples discussed above, with some tongue tip gesture maintained). This supports the idea that speakers would reduce the size of gestures in reduced speech whether listeners hear them or not. Heavily overlapping gestures might remove most sudden acoustic changes in the word, leaving one long vocalic stretch with minor acoustic variation throughout and no clear segments, as in portions of Figures 79.3a, 79.4b, and 79.7. The fact that Articulatory Phonology incorporates time as a continuous scale (gesture duration, rather than simply linear order of segments or features) is an important factor in its success with speech variability.

Articulatory Phonology may seem a perfect theory for describing reduced speech. However, this may be because it is actually more adept at describing phonetic implementations than at describing most abstract phonological alternations. With its prohibition on adding or removing gestures from the underlying representation, it is not meant to account for abstract morphophonemic alternations. (As one example, Navajo has certain suffix combinations in which all segmental material of one suffix deletes, but a high tone is added (Young and Morgan 1987). This is clearly not a matter of altering underlying gestures.) Instead, the theory shows its strength in areas that traditional formal phonology might have relegated to phonetic implementation, such as casual or fast speech reduction. It is clear, though, that inclusion of speech reduction would have no *representational* consequences for Articulatory Phonology: the use of gestural scores as representations works extremely well for reduced speech. Articulatory Phonology is simply based in the gradience and variability of real speech, which includes reduced speech, whereas other phonological theories are not.

5.3 *Abstractionist theories of spoken word recognition*

Moving beyond models of phonology, we can ask what representational consequences reduced speech has for spoken word recognition models. Greenberg (1999) finds that in data from the Switchboard corpus, the word *and* has 87 distinct pronunciations, including [æn, ɛn, ən, ænt, an, əm, i]. He also finds that the most common pronunciation of *them* is [əm]. How does a listener get from the possible surface forms back to the lexical entry *and* without creating massive confusion with *ant, on, them, hand, a, I'm,* etc.? The problem is more extreme for high-frequency function words, but is not limited to them. Models of spoken word recognition such as TRACE, SHORTLIST, etc. traditionally assume that each word has a single underlying form (e.g. Norris *et al.* 2000), although listing multiple forms is sometimes adopted (Spinelli *et al.* 2003). Listeners would recognize [ɨ] as [ænd], despite their dissimilarity, through a combination of finding the closest segmental match in the lexicon and weighting high-frequency words. For example, listeners might recognize [ɪs] as *this* despite the poor segmental match, because *this* has higher frequency than *hiss*. However, many high-frequency words reduce to similar forms: *this, just,* and *is* can probably all be realized as something like [ɨs], and realizations of *and* overlapping with *ant, on, them,* and *a* above also demonstrate this. Thus best match plus frequency may not solve the problem, and neither would multiple lexical listings.

For somewhat less ambiguous forms such as [wiçə̃] *weekend* (Figure 79.7), listeners could try to apply a rule-like conversion to get from the surface string back to the single lexical representation. However, the problem would be just as for formal phonology in reverse: rules would have to allow for insertion and alteration of almost any segments. Since reduction creates such varied forms, it might be impossible to systematically derive a single invariant underlying form by working backwards from them.

Another approach is to list every possible form of each word in the lexicon, or at least several forms. Thus, the word *that* might have at least 117 underlying representations, or at least some substantial number from which the rest of the possible surface forms can be derived. The exact number is dependent on the narrowness of the transcription system, but the effect on the lexicon is the same: the number of forms would multiply greatly. This solution is a drastic departure from the traditional view of what a lexicon contains, and assumes that speakers and listeners do very little abstraction.

Taking the logic of multiple underlying listings further, the forms listed need not be limited to those that receive differing transcriptions in a phonetics lab. Why should *that* be limited to the 117 forms Greenberg (1999) found for it? Perhaps it should have a separate listing for every acoustically distinct pattern that can be realized for the word. This leads us to whole-word-based exemplar models of spoken word recognition (Goldinger 1998). In such a theory, every incoming speech token is measured on various acoustic characteristics, and placed into a "covering map" on all the relevant acoustic dimensions (Johnson 1997), with this information saved about each token a listener hears.

Exemplar models were not developed to account for reduced speech. However, they already use an unusually detailed version of lexical representation, which can be viewed as the word category plus all the acoustic information about exemplars of that word heard in the past. An exemplar model would also save information about the speech style in which the listener heard a particular token. For example, if a listener hears a highly reduced token of *and* in fast, casual speech that was realized just as [ɨ], and successfully recognizes it, the acoustic properties of this token and the fact that it was a token of *and* will be stored, and the fact that it occurred in casual, fast speech would also be stored. This might help the listener to avoid recognizing the acoustic pattern [ɨ] as *and* in slow formal speech. It remains to be explicitly tested though whether an exemplar model of spoken word recognition would do any better than other models at identifying reduced speech tokens. Whether token-specific information is saved or not, identifying [ɨs] as the word *this vs. just*, for example, would present a challenge to any model. If past exemplars of these two words happen to fall into acoustically somewhat distinct clusters, an exemplar model might succeed (but other models would as well). However, if information about long-term speech rate across the utterance and syntactic and semantic context are more important than acoustic differences within the word, then an exemplar model might have no advantage.

To sum up the issue of whether reduced speech affects our understanding of what constitutes a lexical representation, this depends on the degree of phonetic detail included in a theory's representations. Theories that include considerable detail in lexical representations or memory (e.g. Articulatory Phonology, exemplar models) can readily accommodate reduced speech without a change to what constitutes a representation, although this does not guarantee that these models would succeed in generating or recognizing the correct forms. Theories with exclusively abstract lexical representations may require moderate or large numbers of separate underlying representations for each word in order to accommodate the variety of reduced surface forms that occur in normal speech.

6 Conclusions

At the outset, I suggested that the controversy over reduced speech is not one of how phonological theories should handle a particular phenomenon, but rather one of *whether* phonetic or phonological theories even should attempt to handle the phenomenon. It is clear that reduction exists, is extremely common, and is not peripheral to the system. But is reduced speech of any interest to phonetics or phonology? We return now to the possible answers to this question.

Within applied work, there is a reason to include reduced speech: if we would like speech technology systems (speech synthesis or automatic speech recognition (ASR)) to make use of what we know about language, we should know as much as possible about the everyday connected speech which humans use. While speakers may speak somewhat clearly to ASR systems in some applications, ASR systems have to recognize a great deal of reduction. The acoustic findings on reduction show that even relatively careful speech contains quite a number of reductions (Warner and Tucker 2007), so ASR systems are unlikely to escape the task of recognizing reduced forms. Another application for findings about reduction is language teaching. Students acquiring a second language in a classroom usually hear careful speech. Many of us have had the experience of arriving in the country of our L2, only to find that we cannot understand much at all. While that problem has many sources, pronunciation variability from casual speech reduction is likely to be one of them. (See also Shockey 2003 on the importance of reduced speech for both of these applications.)

The second reason for considering reduction to be of interest to phonetics and phonology is theoretical. While no theory needs to account for every phenomenon, it seems reasonable for theories of phonology to be able to reach detailed surface forms that actually occur in corpora, unless the theory is intended to stay entirely at a level of abstraction. If the general purpose of phonology is to relate what speakers know about words to how they pronounce them, one might want the theory to be equipped to discuss and represent attested forms; if obtained from a corpus, these forms will include reduction. Some phonological theories can represent reduced forms, at least as transcriptions and perhaps with acoustic values. The modifications to these theories that allow them to model reduction usually were not introduced for that purpose, but the necessary formal mechanisms are now in place.

For a theory of phonetics to rule out reduced speech as being outside its area of interest would be surprising. Phonetic theories clearly "are responsible for" speech as it is produced and perceived. Thus, theories of gestural coordination, of segment perception, of speaker normalization, of phoneme distinctiveness, etc. should be adaptable for reduced speech. Fortunately, many phonetic theories are less sensitive to representational issues than formal phonological theories, and Articulatory Phonology already provides a thoroughly implemented theory that can represent and model reduction, as discussed above.

Models of segment perception (whether exemplar or more abstract; cf. Smits *et al.* 2006) can also potentially accommodate the detail of reduced segments, although these models have not generally been tested on reductions. One might argue that reduced speech should be considered during the development of all phonetic theories, even if reduction is not the primary interest, to see whether the theory would adapt to the speech that speakers and listeners use daily. Even if connected speech data would be too variable to test a theory on, it should at least be able to apply to more natural speech. For example, the stimuli used by Smits *et al.* (2006) are synthesized non-speech noises, because the exact controlled distribution of synthesized acoustic characteristics allows them to contrast several models' predictions. However, one could test each model on how it distinguishes the reduced realizations of flap in Figures 79.4b and 79.6 from /ð/ or from a vowel–vowel sequence, and the mechanism behind each theory could, in principle, work for reductions.

When one spends a lot of time looking at reduced, spontaneous speech, the difference between that and careful speech can seem so pervasive that one begins to wonder why there is so much research on abstract, careful forms. The exact details of, for example, locus equations (phonetic theory, involving the relationship between formant frequencies near a consonant and at vowel mid-point) or sonority sequencing (phonological theory) might be obscured or obliterated by the deletions, overlaps, mergers, and alterations of reduction. How can one determine a reliable locus equation for a place of articulation when the vowels can shift toward schwa, be deleted, or merge into a neighboring vowel, and the consonant might be deleted, or might surface with unexpected acoustic characteristics? How can one determine the sonority sequencing requirements when the number of syllables is unstable (two on the surface, five underlyingly, as in Arai 1999, or two *vs.* four in Figure 79.1), and manner and voicing of each consonant varies (e.g. Figure 79.2, where everything has become nasals and/or approximants)? The fields of phonetics and phonology have both invested considerable effort into working out the details of theories based on careful speech forms, with an assumption that those forms are representative. Spontaneous speech might make these detailed theories of careful speech seem pointless. Instead of asking whether theories should accommodate spontaneous speech reduction, one might ask whether theories should accommodate the forms of careful speech.

However, it is clear that native speakers' judgments of syllable structure are tapping into some real property of language, and that experimental findings on locus equations are as well. The same could be said of other phenomena in phonetics and phonology: spontaneous speech obscures the phenomenon, yet the phenomenon is clearly a real part of language. Also, it is easy to focus on the extreme reductions in spontaneous speech, but even casual conversation contains clearly articulated focused words as well. Furthermore, when one does not yet know much about a topic the field is starting to explore, it is certainly advisable to work with speech that is as controlled as possible. Phonetic and phonological studies that consider exclusively careful speech patterns do tell us about a real type of human language. However, what they tell us about is probably not the most common form of human language our auditory processing systems encounter in daily life, inside or outside the classroom, the lab, or our homes. Even when hearing professional newscasting, we are likely to encounter far more reduction than most phonetics experiments or phonological data consider. There are arguments for both perspectives: that reduced speech is a specific facet of phonetic implementation irrelevant to formal phonology and to most topics of phonetics, and also that it is important to test and model reduced speech in phonological and phonetic theories. What is clear, though, is that reduced speech is a normal part of our daily experience as speakers and hearers, not a rare or marginal phenomenon.

80 Mergers and Neutralization

ALAN C. L. YU

1 Introduction

The notions of mergers and neutralization presuppose the concept of contrast. Two sounds are phonologically contrastive if they are in opposition with each other, i.e. if they are capable of differentiating the lexical meanings of two words in a particular language. The plosives [p] and [p^h], for example, are in opposition in Cantonese (Yue Chinese) (e.g. [paː˥] 'father' *vs.* [p^{h}aː˥] 'to lay down') but [b] and [p] are not. Contrast is not restricted to pairs of segments; classes of segments contrast as well. The aspiration opposition between [p] and [p^h] finds analogs in other pairs of segments ([t] ~ [t^h], [k] ~ [k^h], [k^w] ~ [k^{wh}]). When a phonological opposition is suspended, neutralization or merger obtains. For example, Cantonese has no aspiration opposition between plain and aspirated plosives in syllable-final position; all syllable-final plosives are voiceless and unreleased (e.g. [t^{h}aːp̚˧] 'pagoda', [paːt̚˧] 'eight', [kɔːk̚˧] 'corner, horn').

The terms *merger* and *neutralization* are often employed in complementary contexts; *merger* often characterizes a diachronic and *neutralization* a synchronic collapse of contrast. The diachronic–synchronic divide between merger and neutralization is more apparent than real, however; the two notions are the two faces of the same coin. The notion of merger is often applied in the context where a contrast reduction leaves no trace of the contrast in the synchronic system; a context-free contrast reduction is the clearest example of this. Neutralization applies to context-dependent contrast reduction; traces of a contrast remain in some contexts, but not in others. Certain varieties of English, for example, merge the voiceless labial-velar fricative /ʍ/ with its voiced counterpart /w/ (Minkova 2004). Thus the words *whine* and *wine* are homophonous; no remnant of this /ʍ/ ~ /w/ contrast is evidenced in the grammar of speakers of these dialects. In certain dialects of Cantonese (most prevalently in Guangzhou, Hong Kong, and Macao; Bauer and Benedict 1997), the distinction between plain and labial velars is not maintained before the back rounded vowel /ɔ/. The collapse of the plain *vs.* labial velars distinction is referred to as a matter of neutralization because the contrast remains before vowels that are not /ɔ/ (e.g. [kɐn˥] 'tight' *vs.* [k^{w}ɐn˥] 'boil'). These instances of contrast reduction in English and Cantonese transpire diachronically, but one results in a merger (i.e. the /ʍ/ ~ /w/ merger) and the other in neutralization (i.e. /k$^{(h)}$/ ~ /k$^{w(h)}$/ neutralization). In this chapter, I shall collectively refer to mergers and neutralization in terms of *contrast reduction*. I shall further assume that the term *neutralization* refers to contrast reduction that results in alternation, while the term *merger* will refer to any reduction of contrast, both synchronically and diachronically. Thus, in the case of the /k$^{(h)}$/ ~ /k$^{w(h)}$/ contrast in Cantonese, /k$^{(h)}$/ and /k$^{w(h)}$/ *merge* before /ɔ/ diachronically. The outcome of this *merger* is the *neutralization* of /k$^{(h)}$/ and /k$^{w(h)}$/ before /ɔ/.

This chapter begins with a review of the range of contrast reduction (§2). §3 surveys several theories that attempt to explain the sources of contrast reduction. §4 concludes with a discussion of the challenges to a purely phonological conception of contrast reduction.

2 Typology of contrast reduction

Contrast reduction manifests itself in three different ways: structure-preserving reduction, structure-building reduction, and free variation.[1] *Structure-preserving reduction* characterizes scenarios where two or more distinct sounds have, after the reduction, a form that is physically similar to that of one of the sounds appearing in the position of differentiation (e.g. /k$^{(h)}$/ ~ /k$^{w(h)}$/ neutralization; cf. Kiparsky 1985; CHAPTER 76: STRUCTURE PRESERVATION: THE RESILIENCE OF DISTINCTIVE INFORMATION). Formally, a reduction of contrast *m* is structure-preserving if and only if *m* turns two (or more) distinct sounds into only one of the two sounds, to the exclusion of the other. The merger of /ʍ/ and /w/ is structure-preserving, since the result of the merger leaves /w/ as the surviving sound. Regressive assimilation of voicing is another instance of structure-preserving contrast reduction. For example, in Dutch, the distinction between voiced and voiceless plosives is suspended preconsonantally (Ernestus and Baayen 2003). However, the result of neutralization differs depending on the nature of the following consonant. For example, before a voiced plosive, the /t/ ~ /d/ contrast in *verwijten* [vɛrʋɛitən] 'reproach-INF' and *verwijden* [vɛrʋɛidən] 'widen-INF' neutralizes toward /d/ (*verwijt bijna* [vɛrʋɛid bɛinaː] 'reproach almost' *vs. verwijd bijna* [vɛrʋɛid bɛinaː] 'widen almost'). However, before a nasal, neutralization is toward /t/ (*verwijt niet* [vɛrʋɛit nit] 'reproach not' *vs. verwijd niet* [vɛrʋɛit nit] 'widen not').

Contrast reduction is structure-building when the outcome of contrast reduction is a sound intermediate between the normal realization of the two phonemes. Final-consonant voicing neutralization in Cantonese is a case in point. Stops in syllable-final position are unreleased, and thus phonetically non-contrastive in terms of aspiration (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). Another celebrated case of structure-building reduction is flapping in English. The /t/ ~ /d/ contrast in English is suspended intervocalically where the coronal in question is immediately followed by an unstressed vowel (e.g. *heed* ['hiːd] *vs. heat* ['hiːt], but *ladder* ['læɾɚ] *vs. latter* ['læɾɚ]) (CHAPTER 113: FLAPPING IN AMERICAN ENGLISH).[2]

1 Unless noted otherwise, I shall abstract away from the issue of context-sensitivity in what follows.

2 The definition of neutralization adopted here differs from Kiparsky's (1976: 169) formulation of a neutralizing rule, which states that a rule of the form A → B / XC __ DY is neutralizing iff there are strings of the form CBD in the input to the rule. Certain structure-building neutralizing rules, such as flapping in English, are not considered neutralizing from Kiparsky's perspective, since the product of the rule is not phonemic in the language.

When contrast reduction leads to a form varying between two or more variants, this is referred to as *free variation* (see CHAPTER 92: VARIABILITY). For a large number of Cantonese speakers, syllable-initial [n] is in free variation with [l] (Bauer and Benedict 1997). Thus, words like [nej˩˧] 'you' and [naːn˨˩] 'difficult' are often pronounced with initial [l], thus merging with [lej˩˧] 'Li (surname)' and [laːn˨˩] 'orchid', respectively. The rate of [n] *vs.* [l] usage varies according to age and gender of the speaker, as well as the register of speaking (e.g. read speech *vs.* conversational speech).

2.1 *Positions of contrast reduction*

Contrast (CHAPTER 2: CONTRAST) is often restricted to certain positions within the word: the syllable peak (rather than the margin; CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE), the onset (rather than the coda; CHAPTER 55: ONSETS), the stem (rather than the affix; CHAPTER 104: ROOT–AFFIX ASYMMETRIES), the stressed syllable (CHAPTER 40: THE FOOT), or the edge of the morphological domains (CHAPTER 50: TONAL ALIGNMENT). Washo (Hokan), for example, only allows voiceless liquids and nasals in onset position (Jacobsen 1964). Isthmus Zapotec (Oto-manguean) contrasts glottalized and modal-voiced vowels, but only in stressed positions (Bueno-Holle 2009). Hausa (Chadic) has a five-vowel system (/i e a o u/), with a long–short distinction which is reliably distinguished only in final position (Steriade 1994). Ngalakan (Australian) has a five-vowel system (/i e a o u/), but mid vowels in Ngalakan are restricted to the edges of roots (Baker 1999: 72–73); if there is only one mid vowel in a root, it must appear in an edgemost syllable (i.e. initial /ceraṭa/ 'woman's ceremony' or final /curuwe-/ 'rush'). If there is more than one mid vowel, they must occur in contiguous syllables (/caworo/ 'patrilineal clan') or every vowel in the root must be a mid vowel (/koweleŋ?(-mi+)/ 'beckon to'). !Xóõ (Bushman) contrasts consonants with clicks and consonants without click accompaniment, but only in initial syllables (Traill 1985). In Etung (Bantu), falling and rising tones (HL, HꜜH, LH) are restricted to the final syllable of phonological words, but there is no restriction on the occurrence of level tones (Edmondson and Bendor-Samuel 1966). In Lushootseed (Central Salishan), glottalized consonants are only found in roots and lexical suffixes; grammatical suffixes never have glottalized consonants (Urbanczyk 1996: 46). Contrast restrictions might also differ across word types. For example, in a cross-linguistic survey of 32 languages having 26 consonants or more, Willerman (1994) found that pronouns made significantly less use of the palato-alveolar, retroflex, uvular, and pharyngeal places than other places of articulation and of fewer laterals, affricates, trills, clicks, ejectives, and aspirated segments (see also CHAPTER 102: CATEGORY-SPECIFIC EFFECTS for differences between nouns and verbs).

Loci of contrast reduction are not always characterizable in structural terms. Steriade (1994) observes that languages with a retroflexion contrast in the apicals (e.g. /t/ *vs.* /ʈ/) often neutralize the contrast in initial or postconsonantal positions, but allow the contrast in post-vocalic position (CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS). The position of retroflexion neutralization is difficult to capture in prosodic terms, since post-vocalic position can be either within or across a prosodic domain (e.g. the coda of a syllable and a syllable onset in intervocalic position). Obstruents in Lithuanian contrast in terms of voicing (Senn 1966; Steriade 1997). However, the voicing contrast is supported only before sonorants (*skobnis* 'table'; *bãdmetys* 'year of famine') and not elsewhere. Voicing is neutralized word-finally (*daũg* [dauk] 'much'; *kàd* [kat] 'that') and in pre-obstruent position (*dèg-ti* [kt] 'burn-INF', *míelas draũgas* [zd] 'dear friend').

2.2 Common triggers and targets of contrast reduction

Languages with contrast reduction often exhibit striking parallelism in the direction of merger and neutralization. Non-assimilatory neutralization of laryngeal contrasts in word-final and preconsonantal positions is often structure-preserving; the preserved segments are generally voiceless. Neutralization toward voiced or ejective is rare, if not non-existent.[3] Reduction of vocalic contrasts in unstressed positions is commonplace across the world's languages (CHAPTER 26: SCHWA). The vast majority of such reductions involve the neutralization of vowel nasalization, quantity, or height. Nasal and oral vowels, for example, are often only contrastive in stressed syllables (e.g. Copala Trique (Hollenbach 1977); Guaraní (Beckman 1998: 158)). Contrasts in vocalic quantity are frequently neutralized toward the short variant in unstressed syllables. Kolami, for example, only contrasts long and short vowels in initial syllables, which are always stressed (Emeneau 1961: 6–7). Quantity contrasts may also neutralize toward the long variant under certain circumstances. For example, a vowel following a consonant–glide sequence must be long (/ak-a/ 'ask!' *vs.* /kw-a:k-a/ 'to ask'; Myers and Hansen 2005: 318) in Rwanda (Bantu), which has a contrast in vowel length ([gusi:βa] 'to be absent' *vs.* [gusiβa] 'to erase'; Kimenyi 1979: 1). Reduction in vowel height in unstressed position often favors one of two outcomes: the unstressed vowel may become either [a] or [ə]. In Belarusian, for example, mid vowels /e o/ reduce to [a] (['noɣi] 'legs' *vs.* [na'ɣa] 'leg'; ['reki] 'rivers' *vs.* [ra'ka] 'river'; Crosswhite 2004: 192); thus the five vowels found in stressed syllables, /i e a o u/, are reduced to three, [i a u], in the unstressed syllables. The seven-vowel system in Central Eastern Catalan (/i e ɛ a ɔ o u/) is only evident in stressed syllables; in unstressed syllables, only three vowel qualities, [i ə u], are allowed; underlying /e ɛ a/ become [ə], while /u o ɔ/ become [u], as shown in (1). Vocalic contrast reductions along other featural dimensions are rare and are often secondary to height neutralization in the same system (Barnes 2002).

(1) *Central Eastern Catalan* (Barnes 2002: 37)

'riw	'river'	ri'wɛt	'river (DIM)'
'new	'snow'	nə'wɛtə	'snow (DIM)'
'mɛl	'honey'	mə'lɛtə	'honey (DIM)'
'palə	'shovel'	pə'ɛtə	'shovel (DIM)'
'rɔðə	'wheel'	ru'ðetə	'wheel (DIM)'
'mɔnə	'monkey (FEM)'	mu'nɛtə	'monkey (FEM DIM)'
'kurə	'cure'	ku'rɛtə	'cure (DIM)'

The targets of assimilatory neutralization show cross-linguistic similarities as well (Cho 1990; Ohala 1990; Jun 1995; Steriade 2001; de Lacy 2002, 2006). For

[3] Yu (2004) reports a case of final neutralization toward the voiced series in Lezgian (North Caucasian); the neutralization is restricted only to monosyllabic nouns, however. The default direction of neutralization in final position is toward the voiceless aspirated series.

example, obstruents are often voiced after nasals (Pater 1999). Nasals in turn frequently assimilate to the place of articulation of the following consonant, as illustrated by the examples from Yoruba (Niger-Congo) in (2).

(2) *Yoruba nasal assimilation* (Pulleyblank 1995: 5)

a.	bá	ḿbá	'overtake'
	fɔ́	ɱ́fɔ́	'break'
b.	tà	ńtà	'sell'
	sū	ńsū	'sleep'
c.	j●	ɲ̄j●	'dance'
	jɛ	ɲ̄jɛ	'eat'
d.	kɔ	ŋ̀kɔ	'write'
	wí	ŋ́wí	'say'
e.	gbɔ́	ŋ́mgbɔ́	'hear, understand'
	kpa	ŋ́mkpa	'kill'

Among obstruents, coronals are most susceptible to place assimilation. In Korean, for example, morpheme-final coronals assimilate to dorsals or labials (3a). Morpheme-final labials assimilate to dorsals (3b), but no assimilation is observed when the following consonant is coronal. Dorsals are inert; they assimilate neither to a following labial nor to a following coronal (3c) (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION).[4]

(3) *Korean place assimilation* (Hume 2003: 7–8)[5]

a.	/mit+ko/	[mikk'o]		'believe and'
	/mith+pota/	[mipp'ota]		'more than the bottom'
b.	/ip+ko/	[ikk'o]		'wear and'
	/nop+ta/	[nopt'a]	*[nott'a]	'high'
c.	/nok+ta/	[nokt'a]	*[nott'a]	'melt'
	/kuk+pota/	[kukp'ota]	*[kupp'ota]	'more than soup'

3 Theories of contrast reduction

Early discussions of contrast reduction focused on how to characterize the outcome of context-specific contrast reduction. That is, how would a theory of phonemics capture the fact that the contrast between two or more sounds in some positions of a word or a syllable is not maintained in other positions (CHAPTER 11: THE PHONEME)? The main analytic puzzle neutralization presents to structuralist phonemics concerns the violation of the bi-uniqueness condition (i.e. of one-to-one mapping between allophones and phonemes). The Prague School resolves this indeterminacy by positing archiphonemes in contexts of neutralization (Trubetzkoy 1939); archiphonemes are units that represent the common features of phonemes whose contrastive property is neutralized in specific contexts. In Yoruba, for example, a preconsonantal nasal would be treated as an archiphoneme, N (e.g.

4 See Silverman (2010) for a thorough review of neutralizing processes in Korean.

5 C' indicates a tense consonant.

[ḿbá] /Ńbá/ 'overtake'). The archiphonemic treatment of neutralization anticipates the underspecification treatment of neutralized segments made possible by the reconceptualization of the phonemes as sets of distinctive features. In an underspecification model (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION), a preconsonantal nasal in Yoruba, for example, would be specified for the feature [+nasal], while the surface realization of this underspecified nasal would be specified contextually.

In addition to the issue of representation, theories of neutralization also attempt to explain the causes for neutralization. That is, why do cross-linguistic parallelisms abound in cases of contrast reduction? Two main approaches have been advanced: structure-based and cue-based. This section reviews how these two approaches conceptualize the problem of contrast reduction and what mechanisms account for the observed typological tendencies.

3.1 *Licensing and markedness*

Structure-based approaches maintain that certain prosodic or structural positions disfavor the maintenance of phonological contrasts. The phonological grammar may either prohibit a contrast in a given structural position in terms of a filter constraint (4) or impose a licensing condition which specifies how a phonological contrast must be configured in order to be realized in a given position within the word (5) (see also CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS).

(4) *Positional neutralization: Filter/negative version* (Steriade 1995: 120)

$^*\alpha F$ in x, where x is defined prosodically or morphologically.

(5) *Positional neutralization: licensing/positive version* (Steriade 1995: 121)[6]

αF must be licenced in x, where x is defined prosodically or morphologically.

Codas in Pali, for example, must be the first half of a geminate structure (6a) or nasal (6b). Coda nasals must be placeless, or homorganic with the following stop.

(6) *Pali cluster simplification* (Zec 1995: 157)

a.	sup+ta	sutta	'to sleep'
	tap+ta	tatta	'to shine'
	caj+ta	catta	'give out'
b.	dam+ta	danta	'to tame'
	vam+ta	vanta	'to investigate'

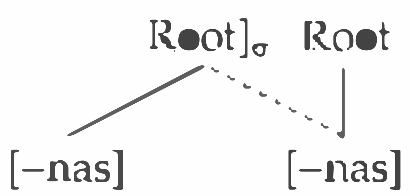
Coda constraints such as those in (7) prevent illicit codas. (7a) states that "if there is a syllable-final consonant which is singly linked, its melody cannot be [−nasal]"; (7b) states that "if there is a syllable-final consonant which is singly linked, its melody must be [+nasal]."

[6] Within Optimality Theory, two types of constraints have been posited to account for positional asymmetries in the realization of segmental features. See CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS for discussion.

(7) *Codas in Pali* (following Itô 1986)

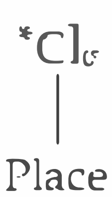
Geminates, where the melody is doubly linked both to the coda of one syllable and to the onset of the following syllable (CHAPTER 37: GEMINATES), violate neither (7a) nor (7b), because the melody is not uniquely linked to a [nasal] feature.

(8)



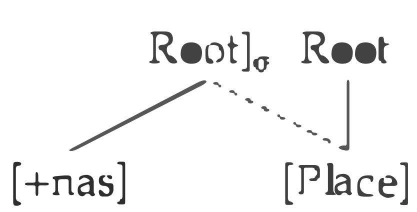
The same approach can be applied to the fact that codas in Pali are either placeless, as in the case of nasal codas, or homorganic with the following stop (9).

(9) *Coda place in Pali* (following Itô 1989: 224)



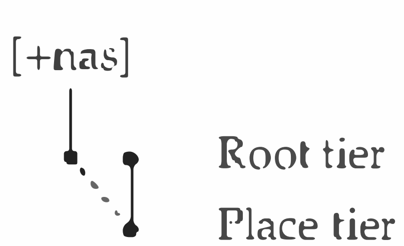
A coda consonant can be specified for place as long as the Place node is not uniquely linked to the coda consonant. If a coda nasal cannot share Place with another segment, it will remain placeless.

(10)



The restrictiveness of potential triggers and targets of neutralization have provided fruitful venues for discovering the organization of features at the phonological level. There have been many proposals for the organization of features into a hierarchical set structure within Autosegmental Phonology (see McCarthy 1988 and Clements and Hume 1995 for overviews of proposals in feature geometry; see also CHAPTER 27: THE ORGANIZATION OF FEATURES). By assuming that the different features for place of articulation are hierarchically linked to a Place node, nasal place assimilation in Yoruba can be elegantly and economically modeled in terms of the spreading of the place node (11).

(11) *Place assimilation in a feature-geometric organization* (Pulleyblank 1995: 9)



Within this type of feature-geometric framework, non-assimilatory contrast reductions are generally treated as a matter of delinking of branches of a feature free. In the Kelantan dialect of Malay (Austronesian), for example, /p t k/ neutralize to [ʔ], and /s ʃ/ become [h] (12).

(12) *Kelantan Malay place neutralization* (Teoh 1988)

/ikat/	ikaʔ	'tie'	/səsak/	səsaʔ	'crowded'
/dakap/	dakaʔ	'embrace'	/hampas/	hapah	'husk'

Debuccalization to [ʔ] and [h] can be viewed as delinking of the Place node (13). The fact that /p t k/ debuccalize to [ʔ], but /s/ to [h], can be attributed to the fact that non-place features of the underlying segment (e.g. [continuant]) are left intact.

(13) *Formalization of* /s/ → [h] *and* /p t k/ → [ʔ]

Adopting the framework of Optimality Theory (OT; Prince and Smolensky 1993), which determines the contrastive status of a feature F via the interaction of a constraint that requires the preservation of F and constraints on the rest of the system (Kirchner 1997), Lombardi (2001b) analyzes place neutralization such as (12) in terms of the interaction between consonantal place faithfulness and a family of universally ranked place markedness constraints ((14); cf. Prince and Smolensky 1993; Smolensky 1993; see also CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). Unlike the position-specific markedness constraints in (4) and (5), this family of markedness constraints captures the idea that pharyngeals, including /ʔ h/ (McCarthy 1994), are less marked than coronals in general, irrespective of position. The tableau in (15) illustrates a markedness-based treatment of coda place neutralization.

(14) *Place hierarchy*

b. ikati		*!	*	*		
c. ika	*!		*			*
☞ d. ikaʔ			*		*	*

[7] The CodaCons constraint, which bans any Place feature in coda consonants, is omitted from this tableau, because it is not directly relevant in the present evaluation.

The position-specificity of place neutralization is captured by the universal ranking of IDENT(OnsPlace) >> MAX(Place). IDENT(OnsPlace) requires that an onset consonant have the Place of its input correspondent, while MAX(Place) requires that an underlying Place feature have an output correspondent. Assuming that ID(OnsPlace), which preserves underlying place features in the onset only, always outranks the place hierarchy in (14), a place distinction in coda position is neutralized due to the dominance of the markedness constraints in (14) over MAX(Place). Markedness violations in coda position cannot be resolved by deleting the offending coda due to the high ranking of MAX, which penalizes deletion, nor can it be resolved by the addition of a final vowel due to the high ranking of DEP, which penalizes epenthesis. Place distinctions neutralize toward [ʔ], since *PHAR, which penalizes /ʔ/, among other things, is ranked lower than the other place markedness constraints; the candidate with a /ʔ/ coda (15d) is thus preferred over the fully faithful candidate (15a), which has a coronal coda.

3.2 *Richness of cues and contrast maintenance*

As the last case study illustrates, the notion of markedness is often invoked to account for the directionality of contrast reduction (CHAPTER 4: MARKEDNESS). Laryngeal neutralization in coda position is said to favor voicelessness, because laryngeal features such as [voice] and [constricted glottis] are more marked than voicelessness (Lombardi 1991; CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). Similarly, the fact that vowels in unstressed position often neutralize to schwa is often attributed to the unmarkedness of schwa (CHAPTER 26: SCHWA). The definition of markedness is a matter of great debate, however, see CHAPTER 4: MARKEDNESS.

In an effort to provide an objective basis for markedness, some scholars have proposed to ground the notion of markedness in terms of speakers' partial understanding of the physical conditions under which speech is produced and perceived. This phonetically based notion of markedness leads to the development of a cue-based approach to contrast reduction (see Hayes *et al.* 2004 and references therein). The basic assumption of cue-based approaches to contrast reduction is that a contrast is suspended in positions where the relevant contrast-supporting cues are diminished; a contrast in such cue-impoverished environments may be maintained only at the cost of additional articulatory maneuvers. A contrast is licensed in positions that are rich in perceptual cues that maximize the contrast's perceptibility. Alveolars and retroflexes, for example, are most easily distinguished by their VC transition profiles. Positions where VC transition is impoverished or non-existent, such as word-initial and postconsonantal positions, tend to be loci where the alveolar ~ retroflex contrast is eliminated (Steriade 1994). For example, the Australian language Bunuba contrasts apical alveolar and retroflex word-medially (e.g. /biɖi/ 'thigh' *vs.* /widigi/ 'stick insect'), but only apical alveolars are found word-initially (Rumsey 2000). The only exception to this restriction is when a subsequent syllable contains [ɖ ɳ ɭ]; in such instances (e.g. /ɳaɖʌ/ 'short', /ɖuɭu/ 'heart'), long-distance retroflexion is assumed to be what licenses the presence of retroflexion word-initially (Hamann 2003). Even when VC transitions are present, however, retroflexes are often avoided in the environment of /i/. For example, retroflex fricative and affricate series in several Chinese dialects are in complementary distribution with the alveo-palatals: before a high front vowel, only alveo-palatals are found, while the retroflexes occur elsewhere (Yip 1996). Hamann (2003) explains this avoidance of retroflexes in the environment /i/ as a result of the articulatory incompatibility between the production of these segments; a flat tongue middle and retracted tongue back configuration for retroflexion cannot be combined with the high tongue middle and fronted tongue back necessary for front vowels. Languages often restrict the distribution of contour tones to phonemic long vowels (e.g. Somali and Navajo), stressed syllables (e.g. Xhosa and Jemez), and word-final positions (Zhang 2001, 2002). While it is difficult to characterize these positions in structural or prosodic terms in a unifying way, they have in common rhyme durations that are long, sonorous, and high in intensity. This fact has led some researchers to hypothesize a long sonorous rhyme duration as the unifying factor for privileged contour tone licensers (Gordon 1999, 2001; Zhang 2001). Obstruents are often voiced after a nasal, resulting in voicing neutralization (Luyia (Niger- Congo) /N + p t k ts c/ → [mb nd ŋg nz ɲj]; Herbert 1986: 236). Hayes and Stivers (1995) attribute the preference for post-nasal voicing to the effects of "velar pumping," which arises from vertical motion of a closed velum, and of "nasal leak," the leakage of air through a nearly closed velar port during the coarticulatory period between oral and nasal segments.

Structure-based accounts have difficulties accounting for languages, such as Lithuanian, which licenses laryngeal contrasts in pre-sonorant position, regardless of whether the following sonorant is tautosyllabic or heterosyllabic (see also Ancient Greek and Sanskrit; Steriade 1997). From a cue-based perspective, the reduction of laryngeal contrasts in preconsonantal and final positions follows from the fact that many of the relevant cues for the perception of voicing (closure voicing, closure duration, duration of preceding vowel, F0 and F1 values in preceding and following vowels, VOT values, burst duration, and amplitude) are endangered in those positions (see also CHAPTER 8: SONORANTS). The more impoverished the available perceptual cues are, the less sustainable the laryngeal contrast is. Thus, word-initial preconsonantal position is least hospitable to a contrast in voicing, while inter-sonorant position is most ideal for voicing realization. Formally, a cue-based account of contrast reduction may be modeled as the interaction between constraints on contrast maintenance and markedness constraints induced from phonetic knowledge (Steriade 1997; Hayes 1999). Steriade (1997), for example, models [voice] neutralization in terms of the interaction between the constraint PRESERVE[voice], which demands faithfulness to input voice values, and a fixed hierarchy of *VOICE constraints, aligned to a voice perceptibility scale (16).

(16) *Scale of obstruent voicing perceptibility according to context* (Steriade 1997: 11)[8]

V __ [+son] > V __ # > V __ [−son] > [−son] __ [−son], [−son] __ #,
__ [−son]

A language with voicing licensed only before sonorants would have the following ranking:

[8] The > symbol in (16) indicates that voicing is more perceptible in the context to its left than to the context on its right.

(17) *Voice licensed before sonorants* (Steriade 1997: 12)

*Voice / [−son] __ [−son], [−son] __ #, # __ [−son] >> *Voice / V __ [−son] >> *Voice / V __ # >> Preserve[voice] >> *Voice / V __ [+son]

Given that the ranking of constraints projected from a phonetically grounded perceptibility scale has been argued to be universal (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY), such a model makes strong predictions about the typology of laryngeal neutralization patterns. For example, it predicts that a language with a voicing contrast in word-initial preconsonantal position must also allow a voicing contrast in word-initial, intervocalic, and word-final positions. The Mon-Khmer language Khasi, spoken in the Assam province of India, shows that such a strong prediction does not obtain. As illustrated in (18), Khasi contrasts voiced and voiceless plosives in word-initial preconsonantal position.

(18) *Voicing contrast in initial clusters in Khasi* (Henderson 1992: 62)

bti		'to lead by the hand'	*pdot*	'throat'
bthi		'sticky'	*pdeng*	'middle'
dkar		'tortoise'	*tbian*	'floor'
dkhar		'plainsman'	*tba*	'to feel'
dpei		'ashes'	*pjah*	'cold'
bshad	[bʃaːt]	'civet'	*bdi*	'twenty'

Using evidence from a Frøkjær-Jensen combined oscilloscope and mingograph, Henderson (1992) confirmed the voicing contrast in word-initial preconsonantal position and ruled out the possibility of a svarabhakti vowel between the two stops. What is of interest here is the fact that in syllable-final position there is no distinction between voiced and voiceless stops; final stops are unreleased and frequently accompanied by simultaneous glottal constriction (Henderson 1967: 567). Since a voicing contrast is allowed word-initially before another obstruent, a highly impoverished environment for the maintenance of a voicing contrast, a cue-based approach that maintains the universality of voicing perceptibility necessarily predicts that a voicing contrast should also be maintained in less impoverished environments, such as post-vocalic word-final positions. It is worth noting that counterexamples of this sort do not obviate the validity of a cue-based approach to contrast reduction per se, since the assumption of the universality of cue perceptibility is logically independent of the claim that cue maintenance is the driving force behind contrast maintenance and reduction (see Hume and Johnson 2001b for discussion on the language-specificity of speech perception).

Some cue-based theorists eschew the notion of markedness at the level of the individual segment or feature, and favor instead a contrast maximization account. Dubbed "Dispersion Theory" (Flemming 1995, 1996; Ní Chiosáin and Padgett 2001; Padgett 2003) after Lindblom's (1986, 1990) Theory of Adaptive Dispersion, such a theory of contrast maintains that the selection of a phonological contrast is subject to three functional goals (see Martinet 1952, 1955, 1964 for early formulations of these functional ideas; cf. Silverman 1996, 2004, 2006):

(19) a. Maximize the distinctiveness of contrasts.
b. Minimize articulatory effort.
c. Maximize the number of contrasts.

From this perspective, the dispreference for sound *x* is conceptualized as a dispreference for the sub-maximally distinct contrasts between *x* and other sounds in the particular sound system. As schematized in the ranking in (20), a contrast is formally neutralized in some context if it cannot be realized with a distinctiveness of *d* without violating *Effort, an effort-minimization constraint penalizing some articulation.

(20) MinDist=*d*, *Effort >> MaximizeContrasts

In Belarusian, for example, a five-vowel inventory /i e a o u/ is observed in stressed syllables. In unstressed syllables, /e a o/ reduce to [a] or [ɐ], depending on the position of the vowel relative to the stressed syllable (Barnes 2002: 65). Flemming (2004) argues that this type of vowel reduction is motivated by difficulties in producing distinct F1 contrasts in unstressed positions. Specifically, increasing difficulty in producing a low vowel as a result of vowel duration shortening in unstressed positions leads to the raising of short low vowels; the smaller range of the F1 dimensions for distinguishing F1 contrast then leads to the selection of a smaller number of contrasts. Flemming captures this intuition in terms of the ranking in (21).

(21) Unstressed vowels are short, *ShortLowV, MinDist=F1:3 >>
MaximizeContrasts >> MinDist=F1:4

The constraint Unstressed vowels are short requires unstressed vowels to be shorter than stressed ones. This constraint will be omitted in the subsequent discussion, since it is assumed to be undominated, so that no vowel systems violating this constraint will be permitted in the present context. *ShortLowV (abbreviated *a) is an effort-minimization constraint that penalizes low vowels. The MinDist=Y:X constraints are satisfied by contrasting sounds that differ by at least X distance on the Y dimension. The highest-ranking MinDist constraint that outranks the MaximizeContrasts constraint sets the threshold distance, and the optimal inventory is the one that packs the most contrasting vowels onto the relevant dimension (here F1) without any pair being closer than this threshold.

With the relative positioning of vowels on the F1 dimension stated in (22), Belarusian's three-way vowel height distinction in stressed syllables is predicted in (23). Since the present evaluation concerns only distinctions in vowel height, the back counterparts of vowels in the inventory candidate set are left out for ease of reference. The tableau in (23) shows that a four-way height distinction is suboptimal (23c), because vowels are not distinct enough according to the constraint, MinDist=F1:3. Reducing the height inventory too much (23a) results in excessive contrast reduction, thus incurring more MaximizeContrasts violations relative to the optimal inventory set (23b).

(22)	F1	7	6	5	4	3	2	1
		a	ɐ	ɛ	e	e̝	ɪ	i
				a	ə			

(23) *Belarusian: Vowels in stressed syllables*

	*a	MinDist= F1:3	Maximize Contrasts	MinDist= F1:4
a. 'i 'a			✓✓!	
☞ b. 'i 'e 'a			✓✓✓	**
c. 'i 'e 'ɛ 'a		*!	✓✓✓	****

In the unstressed syllables, the constraint *ShortLowV (*a) becomes applicable. It rules out the candidate vowel inventory [i e a], because of the presence of [a]. The three-way height distinction cannot be maintained even if the low vowel [a] is avoided, the distance between [e] and [ɐ] being insufficient, due to the high ranking MinDist=F1:3 constraint. The winning candidate has only two vowel heights, which fares worse by MaximizeContrasts, but satisfies the higher-ranked minimum distance requirements.

(24) *Belarusian: Vowels in unstressed syllables*

	*a	MinDist= F1:3	MinDist= F1:4	Maximize Contrasts
☞ a. i ɐ				✓✓
b. i e ɐ		*!	**	✓✓✓
c. i e a	*!		**	✓✓✓

Within Dispersion Theory, the objects of analysis are systems of oppositions. The notion of contrast reduction is thus given a genuine expression in such an analysis. Whereas most other approaches view mergers and neutralization as the results of the application of constraints or rules that prevent the expression of individual segments or features, Dispersion Theory holds that mergers and neutralization follow from the number of oppositions a language makes available in different contexts. It should be noted that, because of its insistence on looking at systems of contrast from the perspective of the language as a whole, Dispersion Theory raises questions regarding how phonological derivation is implemented in such a model (Boersma 1998: 361; but see Ní Chiosáin and Padgett 2001 and Padgett 2003 for a response to this problem).

This section has reviewed major theories of contrast reduction, showing that proposals range from completely structure-dependent accounts to theories that embrace the full phonetic substance of sound patterns. The debate on what a proper theory of contrast reduction is, however, might ultimately rest on resolving a more fundamental question – does synchronic contrast reduction truly exist? This is the topic of the next section.

4 Do real synchronic mergers and neutralization exist?

Until recently, most theories of phonology have assumed some form of lexical minimality (the minimization of lexically stored information; Chomsky and Halle

1968: 381; Steriade 1995: 114; see also CHAPTER 1: UNDERLYING REPRESENTATIONS) and feature economy (the minimization the ratio of features to segments in an "alphabet"; Clements 2003; see also CHAPTER 17: DISTINCTIVE FEATURES). In early generative phonology, for example, the underlying alphabet is the minimal sound set needed to express surface differences between distinct morphemes; at the level of the underlying representation, no allophonic variants are present. Theories differ in the number of levels of representation allowed (e.g. Lexical Phonology and Morphology (Kiparsky 1982, 1985; Mohanan 1982) recognizes three levels of representations: underlying, lexical, and phonetic) and the degree of minimality assumed at each level. Common to these early theories of phonology, however, is the premise that, out of the vast sea of phonetic signals, only a small subset of phonetic properties are contrastive in a given language (Sapir 1933; Trubetzkoy 1939; Jakobson *et al.* 1952; Hockett 1955; Chomsky and Halle 1968; Kiparsky 1982, 1985). Contrast is encoded in terms of a difference between $+F_i$ and $-F_i$ for some finite set of features F_i, and contrast reduction corresponds to the elimination of this difference (i.e. the outcome of such a reduction is either $+F_i$, $-F_i$, or null).

Non-distinctive phonetic properties are treated in one of two ways. To begin with, features that do not distinguish lexical items may be underspecified in the lexical entries (e.g. Archangeli 1988; Pulleyblank 1995; Steriade 1995; Clements 2003; CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION). The feature [voice] in sonorants, for example, is non-contrastive, and thus redundant, in languages such as English, which do not distinguish between voiced and voiceless sonorants (CHAPTER 8: SONORANTS; CHAPTER 13: THE STRICTURE FEATURES). Sonorants are underspecified for voicing, i.e. sonorants bear no value for the feature [voice]. Such an assumption of non-contrastive feature underspecification has important theoretical consequences for the treatment of transparency effects in the phonology of the feature [voice]. For example, as seen earlier, nasals do not induce regressive voicing assimilation in Dutch, but voiced obstruents do, suggesting that only voiced obstruents are underlyingly specified for the feature [voice]. The other treatment of non-distinctive phonetic properties is to exclude them from the feature pool altogether. For example, vowels are longer before voiced stops than before voiceless ones in American English (*bat* [bæt] *vs. bad* [bæˑd]). Peterson and Lehiste (1960) suggest that the ratio of vocoid duration before voiceless consonants to that before voiced consonants in American English is 2 : 3. Such a difference in vocoid duration which covaries with the voicing of the following consonant is generally dismissed as the effect of automatic phonetics, and thus assumed to play no role in any phonological analysis; features such as [slightly long] would not be part of the universe of phonological features.[9]

As Labov *et al.* (1991: 38) point out, the assumptions that "contrasts were discrete and binary, that there was no such thing as a small difference in sound, that production and perception were symmetrical, and that introspections were reliable" have received increased scrutiny in recent years (CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). For example, Dispersion Theory's admission of phonological constraints that regulate features

[9] While these subfeatural cues might not be distinctive, they may nonetheless have enhancing functions (Stevens and Keyser 1989; Stevens *et al.* 1986; Keyser and Stevens 2001).

along scalar dimensions, rather than in terms of binary oppositions, already foreshadows the move away from a discrete and binary notion of contrasts (e.g. MinDist=Y:X constraints evaluate distances along some phonetic dimensions such as F1). Mounting evidence for near mergers and incomplete neutralization raises further questions about the validity of these abovementioned assumptions. This is the topic of the next section.

4.1 Near mergers and incomplete neutralization

Near merger describes the situation where speakers consistently report that two classes of sounds are the same, yet consistently differentiate them in production at a better than chance level. Labov *et al.* (1972: ch. 6), for example, reports that speakers in New York City differentiate words such as *source* and *sauce* in production, but report no distinction between them in perception. Similar near mergers have been reported in other varieties of English (e.g. *fool* and *full* in Albuquerque (Di Paolo 1988); *too vs. toe* and *beer vs. bear* in Norwich (Trudgill 1974); *line vs. loin* in Essex (Labov 1971; Nunberg 1980); *meat vs. mate* in Belfast (Milroy and Harris 1980; Harris 1985)). Near mergers are not restricted to segmental contrasts. Yu (2007b), for example, demonstrates that derived mid-rising tones in Cantonese show a small but statistically significant difference in F0 from underived mid-rising tones. Similar to near mergers, incomplete neutralization refers to reports of small but consistent phonetic differences between segments that are supposedly neutralized in certain environments. Flapping is often cited as a neutralizing phonological alternation in American English; underlying /t/ and /d/ surface as dental flaps or taps when followed by an unstressed vowel (chapter 113: flapping in american english). Word-final and preconsonantal obstruent devoicing is another classic example of a neutralizing sound pattern (chapter 69: final devoicing and final laryngeal neutralization).

Incomplete neutralization has been reported outside the domain of obstruent voicing as well. In Eastern Andalusian Spanish, for example, the combined effect of word-internal coda aspiration and the gemination of the consonant following the aspirated coda leads to potential neutralization (e.g. [kahtːa] for both /kasta/ 'caste' and /kapta/ 's/he captures'). Gerfen (2002), however, reports that aspirating an /s/ results in a longer duration of aspiration, while aspirating a /p/ or /k/ results in longer medial consonant gemination (see also Gerfen and Hall 2001). Bishop (2007) found that listeners make use of the length of the consonant following aspiration as a cue for making phonemic decisions regarding the nature of the underlying coda. In many languages, an epenthetic stop can occur within nasal–fricative or heterorganic nasal–stop clusters (e.g. English *dreamt* [dɹɛmt] ~ [dɹɛmpt]; *prince* [pɹɪns] ~ [pɹɪnts]). Several studies have found that such epenthetic stops are phonetically different from underlying stops in the same environment. Fourakis and Port (1986), for example, found that underlying /t/ in words like *prints* [pɹɪnts] are significantly longer and the neighboring nasal significantly shorter than epenthetic [t] in words like *prince*. Dinnsen (1985), citing Rudin (1980), reports that long vowels deriving from underlying /VgV/ sequences in Turkish are 13 percent longer than the underlying long vowel /Vː/. Simonet *et al.* (2008) report that the so-called /r/ ~ /l/ neutralization in post-nuclear position in Puerto Rican Spanish (e.g. /'arma/ → ['alma] 'weapon' *vs.* /'alma/ → ['alma] 'soul') is incomplete. Based on measurements of duration of the vowel

+ liquid sequences and examination of formant values and trajectories, Simonet *et al.* (2008) conclude that, while post-nuclear /r/ is similar to post-nuclear /l/, there nonetheless exist systematic durational and spectral differences, suggesting that the two liquids have not completely merged.

Since traditional theories of the phonetics–phonology interface assume that phonological representations in the lexicon are categorical, contrastive elements, and since the phonetic implementation component computes the degree and timing of articulatory gestures, which are gradient and variable, the discovery of near mergers and incomplete neutralization presents a curious conundrum. For a given underlying distinction +F and –F, how can an output –F that corresponds to an underlying +F display systematically different surface phonetic realization from an output –F that corresponds to an underlying –F, when information flow is supposed to be strictly unidirectional? In such a model, no articulatory plan can look backward to phonological encoding, nor can phonological encoding look back to the lexical level. No lexical information can influence the phonetic implementation directly either, bypassing the level of phonological encoding. On this view, the categorical form of a lexeme wholly determines the phonetic outcome. Phonetic variations on the surface are considered artifacts of the context or performance-induced anomalies.

In light of such conceptual difficulties, many have sought to explain away the observed sub-phonemic phonetic differences as a consequence of orthographic influence or as variation in speaking style. For example, it has been found that the less the experimental design emphasizes the role of orthography, the smaller the durational effects (Fourakis and Iverson 1984; Jassem and Richter 1989). Port and Crawford (1989) found that discriminant analysis to classify productions by underlying final voicing was most successful (78 percent correct) when speakers dictated the words, but least successful (55 percent correct) when target words were embedded in sentences that do not draw attention to the minimal pairs (whether read or repeated orally). But not all cases of near mergers and incomplete neutralization can be attributed to performance factors. Warner *et al.* (2004), for example, found sub-phonemic durational differences in the case of final devoicing in Dutch, even when possible orthographic influence was controlled for as a confound. Yu (2007b) found incomplete merger of underived and morphologically derived mid-rising tones in Cantonese, a language whose orthography does not indicate tone. Further support for the existence of a suspended contrast comes from the fact that speakers appear to have some access to subtle phonetic differences. As noted earlier, Bishop (2007) found that Andalusian Spanish speakers can make use of subtle closure duration differences to recover underlying coda consonants. In the case of final devoicing in Dutch, listeners not only can perceive durational differences (Warner *et al.* 2004), they even use these sub-phonemic distinctions to hypothesize which past tense allomorph nonce forms would take (Ernestus and Baayen 2003; CHAPTER 99: PHONOLOGICALLY CONDITIONED ALLOMORPH SELECTION).

4.2 *Approaches to sub-phonemic phonetic differences*

Sub-phonemic distinctions have been analyzed as the result of paradigm uniformity among morphologically related neighbors (e.g. phonetic analogy; Steriade 2000; Yu 2007a; CHAPTER 83: PARADIGMS; CHAPTER 87: NEIGHBORHOOD EFFECTS).

Steriade (2000), for example, argues that grammars prefer words within a paradigm to be uniform.[10] Steriade extends this paradigm uniformity preference to the phonetic level. French, for example, has an optional schwa deletion which creates ostensibly homophonous strings (e.g. *bas retrouvé* [baʁətʁuve] 'stocking found again' → *bas r'trouvé* [baʁtʁuve] *vs. bar trouvé* [baʁtʁuve] 'bar found'). Various studies have shown that the consonant to the left of the syllable of the deleted schwa maintains phonetic qualities that would only be expected if the schwa were still present (Rialland 1986; Fougeron and Steriade 1997). Steriade (2000) interprets such unexpected phonetic differences as the results of phonetic analogy; forms with schwa deletion are influenced phonetically by the corresponding schwa-full forms (e.g. /r/ in *bas r'trouvé* [baʁtʁuve] takes on onset-like articulation from the /r/ in the related phrase *bas retrouvé* [baʁətʁuve]).

Van Oostendorp (2008) argues that incomplete neutralization in final devoicing can be captured within a Containment model of OT in terms of a turbid representation of phonological outputs (Goldrick 2001). Output structures are characterized in terms of two types of relations: a Projection relation, which is an abstract structural relationship holding between a segment and the feature (represented by ↑ in (25)), and a Pronunciation relation, an output relationship that holds between the feature and the segment and describes the output realization of a structure (represented by ↓ in (25)). On this conception, a three-way distinction obtains between segments that are underlyingly voiceless (i.e. they lack the feature [voice]), segments that are underlyingly voiced and pronounced voiced, and segments that are underlyingly voiced, but are not realized as voiced on the surface (25).

(25) *A three-way voicing distinction using turbidity theory*

a.	taːt	b.	tad	c.	taːd̥
			↑↓		↑
			[voice]		[voice]

The selection of a representation like (25c) would be determined by the interaction between markedness constraints that disfavor coda voicing and the constraint RECIPROCITY(X,F), which holds that if a segment X entertains a projection relation with a feature F, then F must entertain a pronunciation relation with the segment X. Because of their structural differences, (25a)–(25c) will show different surface phonetic realizations.

These phonological approaches assume that cases of incomplete neutralization are in fact complete at the phonological level and that the output segment is phonologically unvoiced. The sub-phonemic differences observed would either be due to analogical influences from related forms that retain voicing or to covert structural differences among outputs. Is a complete neutralization interpretation of incomplete neutralization a necessity, or even desirable? The answer to this question hinges on the conception of the phonetics–phonology interface and, specifically, the nature of allophony. What should be considered extrinsic allophones (i.e. allophones that are phonologically governed), and what should be considered intrinsic (i.e. those introduced by phonetic variability; Wang and Fillmore 1961;

[10] A paradigm is defined here as "a set of words sharing a morpheme, e.g. {*bomb, bomb-ing, bomb-ard*, . . . }, or a set of phrases sharing a word, e.g. {*bomb, the bomb*, . . . }" (Steriade 2000).

Ladefoged 1971; Tatham 1971)? Must extrinsic allophones be governed by changes in discrete distinctive feature values, or can extrinsic allophones be gradient? The next section offers an alternative interpretation of near mergers and incomplete neutralization, which appeals to the notion of a covert contrast.

4.3 Sub-phonemic distinctions as covert contrasts

Near mergers and incomplete neutralization are problematic from the point of view of a model of the interface between phonetics and phonology sketched above, because, if the phonetic implementation component accounts only for variations due to biomechanical and aerodynamic factors, it is anomalous, to say the least, that speakers of a language with [voice] neutralization vary the realization of the neutralized sounds in accordance with the feature value of their non-neutralized counterparts. The above model of the phonetics–phonology interface is arguably simplistic, however. Kingston and Diehl (1994) articulate a model of the phonetics–phonology interface that affords the phonological component greater control over the range of variability in the phonetic implementation of contrasts. Elasto-inertial, biomechanical, aerodynamic, psychoacoustic, and perceptual constraints delimit what a speaker (or listener) *can* do, but not what they *must* do. Within this conception of the phonetics–phonology interface, a phonemic contrast is taken to be "any difference in the feature content or arrangement of an utterance's phonological representation which may convey a difference in semantic interpretation" and allophones are "any phonetic variant of a distinctive feature specification or arrangement of such specification that occurs in a particular context" (1994: 420, fn. 2). To illustrate this framework more concretely, consider Kingston and Diehl's summary of the phonetic variants of English stops contrasting for [voice] (see also Silverman 2004).

Table 80.1 illustrates the fact that the contrastive feature [+voice] in English shows great variability in its phonetic realization. In word-initial position, for example, [+voice] stops are often realized as voiceless unaspirated, even when the preceding word ends in a vowel (Caisse 1982; Docherty 1989). Kingston and Diehl (1994) interpret such data as showing that speakers choose between two active articulations in producing initial [+voice] stops in English: delay glottal closure until the stop release, or close the glottis but expand the oral cavity to overcome the difficulty of initiating voicing. Such controlled variation is made possible by the fact that there are typically multiple, auditorily independent correlates that serve as distinct bases for a minimal phonological distinction. As noted in Stevens and Blumstein (1981), [+voice] consonants are characterized by the "presence of low-frequency spectral energy or periodicity over a time interval of 20 to 30 msecs in the vicinity of the acoustic discontinuity that precedes or follows the consonantal constriction interval" (1981: 29). This low-frequency property, as Kingston and Diehl (1994) call it, has multiple supporting sub-properties such as voicing during the consonant constriction interval, a low F1 near the constriction interval, and a low F0 in the same region, as well as enhancing properties such as the duration ratio between a consonant and its preceding vowel. These properties do not all surface in all positions. Crucially, while [+voice] stops do not show prevoicing in word-initial position, the [voice] contrast is nonetheless maintained because [–voice] stops tend to have longer VOT, stronger burst energy and higher F1 and F0 following the consonant constriction interval.

Table 80.1 Summary of the phonetic variants of English stops that contrast for [voice]

	[+voice]	[−voice]
Utterance-initial or pre-tonic	short lag VOT	long lag VOT
	F1 lower	F1 higher
	F0 lower	F0 higher
	weaker burst	stronger burst
Intervocalic or post-tonic	closure voicing	no closure voicing
	short closure	longer closure
	longer preceding vowel	shorter preceding vowel
	F1 lower	F1 higher
	F0 lower	F0 higher
Utterance-final and post-vocalic	longer preceding vowel	shorter preceding vowel
	closure voicing possible	no closure voicing
	short closure	longer closure
	F1 lower	F1 higher

From this perspective of the phonetics–phonology interface, sub-phonemic differences observed in near mergers and incomplete neutralization are no more different from those observed between allophones appearing in different phonetic contexts. As noted in Steriade (1997), the percept of voicing hinges on a multitude of acoustic cues: burst amplitude, closure duration, voicing during the closure period, voice onset time, and vowel onset and offset. Phonetic cues that support a [voice] contrast in word-final positions are intrinsically impoverished relative to cues available in word-initial and word-medial positions. Nonetheless, many languages maintain the contrast in word-final positions because there remain sufficient cues that can differentiate the underlying phonological contrast. (See CHAPTER 113: FLAPPING IN AMERICAN ENGLISH for additional evidence on this interpretation.)

The interpretation of near mergers and incomplete neutralization advocated here suggests that traditional methods of introspection and field elicitation may not be adequate in detecting covert contrast (CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY). Self-introspection faces inherent problems of analyst bias and thus should not be taken as a definitive source of information. The phonetician's ears are, after all, human ears. Commutation tests are essentially armchair psycholinguistic tasks that require language consultants to perform a same–different task, with minimal control for potential confounds. Subject responses are inherently probabilistic; analysts insisting on dichotomizing a continuous function will find confident responses when the samples have a wide separation in the sample space. Samples that straddle regions of great overlap, as in the case of near mergers and incomplete neutralization, will elicit more ambiguous responses. Contrasts not detected by linguists using traditional methods of elicitation may nonetheless be detected by native speakers, as demonstrated in laboratory studies reviewed above.

4.4 *Covert contrasts as systems in transition*

The existence of covert contrast is readily understandable from the perspective of sound change and phonologization of phonetic variation (CHAPTER 93: SOUND CHANGE). In his seminal work on phonologization, Hyman (1976) conceptualizes the emergence of phonemic tonal distinctions as a three-stage process. At Stage 1, a language displays physiologically based consonantal voicing-induced pitch perturbations on the neighboring vowel. A language reaches Stage 2 when pitch perturbation becomes exaggerated to such an extent that the pitch variation cannot be attributed entirely to the physiological properties of the preceding consonant's voicing (e.g. *[pa] > [pá] and *[ba] > [bà]). The transition from Stage 1 to Stage 2 – when an intrinsic, thus unintended, variation in pitch associated with consonantal realization becomes an extrinsic feature of the vowel – is phonologization. A language reaches Stage 3 when the voicing distinction is lost completely, and the pitch distinction on vowels becomes the sole feature that signals a meaning difference between words. That is, the language has undergone the phonemicization of tone (i.e. */pa/ > [pá] and */ba/ > [pà]). From the perspective of this model of sound change, covert contrast represents a language at Stage 2 and possibly in transition to Stage 3. That is, the old contrast (e.g. obstruent voicing) has not completely disappeared (i.e. been neutralized), but the new contrast (e.g. tonal distinction) has not fully emerged either. A language in Stage 2 is in principle unstable. As Hyman points out, "accompanying every phonologization is a potential dephonologization" (Hyman 1976: 410). The emergence of a tonal distinction as a result of the phonologization of intrinsic pitch perturbation of obstruent voicing entails the eventual destruction (i.e. neutralization) of the original voicing contrast. The evolution of vowel duration and consonant voicing covariation provides an instructive example of phonologization and its connection to the emergence of covert contrast. As reviewed in Solé (2007), languages differ in the amount of control the speakers have over the maintenance of this sub-phonemic duration difference. Solé (2007) found that English speakers actively maintain durational differences before voiced and voiceless stops, regardless of speaking rates, while speakers of Catalan and Arabic do not exhibit similar control over such sub-phonemic duration differences. Her findings suggest that English has already partially phonologized the effect of consonant voicing on vowel duration, while Catalan and Arabic have not. Recall that one commonly observed feature of the incomplete neutralization of final devoicing is a vowel duration difference. Following Hyman's dictum that the phonologization of one feature carries the seeds of the destruction of another, the phonologization of a sub-phonemic vowel duration difference entails an eventual loss of the voicing contrast in the following stops. The reasons why such a correlation exists are still a matter of debate. Two factors are noteworthy in this context. First, the longer vowel before voiced stops and the shorter vowel before voiceless stops are, strictly speaking, in complementary distribution. Likewise, post-vocalic voiced and voiceless stops are also in complementary distribution, since they do not appear in the same context. This type of analytic ambiguity (i.e. between vowel duration and consonantal voicing) is typical of a language undergoing phonologization. Second, research on auditory category learning has shown that listeners are not only sensitive to the distributional information of the category cues, but also acquire unidimensional contrasts more readily than multidimensional ones (Goudbeek 2006; Clayards 2008; Clayards *et al.* 2008; Goudbeek *et al.* 2008). Such results suggest that, all else being equal, listeners will rely more heavily on a single cue for category identification even when multiple cues are available in the signal. For example, as voicing during stop closure becomes less prominent as a feature of voiced stops in final position, vowel length becomes the more reliable contrastive feature. When voicing in closure ceases to be a feature of final obstruents altogether, a contrast in vowel length is expected to emerge. Friulian, a Romance language spoken in northeastern Italy, provides an instructive example of this type of cue trade-off in phonologization. In Friulian, vowel length (CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH) is only distinctive in a stressed word-final syllable closed by a single consonant.

(26) *Vowel length distinction in Friulian* (Baroni and Vanelli 2000: 16)

a.	['la:t]	'gone (MASC)'	b.	['lat]	'milk'
	['bru:t]	'brother, mother-in-law'		['brut]	'ugly'
	[fi'ni:t]	'finished (MASC)'		['frit]	'fried (MASC)'
	['pa:s]	'peace'		['pas]	'step'
	['fu:k]	'fire'		['tɔk]	'piece'

Stressed vowels are always phonologically long before [r] (['la:rk] 'large (MASC)') and always short when they are not in the last syllable of a word ([kan'tade] 'sung (FEM)'), when they occur in the final open syllable ([ku'si] 'so'), and when they are in a final syllable closed by a consonant cluster, nasal, or affricate (['gust] 'taste', ['maŋ] 'hand', ['brat͡ʃ] 'arm'). Of particular relevance here is the fact that vowel length in word-final syllables before obstruents is predictable: the stressed vowel is long if the following consonant is realized as voiced in intervocalic position (27a); if the following consonant is voiceless intervocalically, the stressed vowel is short (27b).

(27) *Vowel length and consonant voicing* (Baroni and Vanelli 2000: 17)

a.	['la:t]	'gone (MASC)'	['lade]	'gone (FEM)'
	[fi'ni:t]	'finished (MASC)'	[fi'nide]	'finished (FEM)'
	['pe:s]	'snow'	[pe'za]	'to snow'
	['fu:k]	'fire'	[fogo'la:r]	'fireplace'
b.	['lat]	'milk'	[la'te]	'to breastfeed'
	['pas]	'pass'	[pa'sa]	'to pass'
	[pa'taf]	'slap'	[pata'fa]	'to slap'
	['tɔk]	'piece'	[tu'kut]	'little piece'

Based on acoustic evidence, Baroni and Vanelli (2000) establish that long vowels are more than twice as long as the short ones and word-final obstruents are indeed voiceless (i.e. no voicing during closure). While final [t] corresponding to medial [d] is significantly shorter than final [t] corresponding to medial [t], this difference is only observed after certain vowel qualities. Their findings suggest that, while Friulian final obstruent devoicing is incomplete (i.e. there remains some difference between underlying /d/ and underlying /t/ in final positions), this difference is mainly carried by the closure duration of the obstruent and only in very restricted contexts. On the other hand, a full-blown vowel quantity difference has emerged in its place. The salience of this vowel length contrast is exemplified by the behavior of vowel length in loanword adaptation. Friulian does not preserve the consonantal length contrast in borrowed Italian words. However, longer vowels before single consonants in Italian are treated as long in Friulian if they occur in word-final position: [impje'gaːt] 'clerk (MASC)', from Italian [impje'gaːto]. When such long vowels occur in word-internal position, they become short and the following obstruent is voiced ([impje'gade] 'clerk (FEM)'). When borrowed short vowels occur in word-internal position, the obstruents remain voiceless (e.g. [a'fiːt]/[afi'tut] 'rent/little rent'; Italian [a'fːitːo]). This loanword evidence suggests that Friulian has restructured its system to one with a limited vowel length contrast; voicing variation has become secondary to vowel length difference.

The possibility of a covert contrast in purported cases of neutralization raises questions about the existence of genuine instances of neutralization. Kim and Jongman (1996), for example, report that coda neutralization (i.e. word-final coronal obstruents (e.g. /t t^h s/) are all phonetically realized as [t]) is complete (CHAPTER 111: LARYNGEAL CONTRAST IN KOREAN). Based on both production and perceptual data, they conclude that complete neutralization is observed despite the fact that Korean orthography distinguishes between the different underlying consonants. The difference between genuine neutralization *vs.* covert contrasts might also be related to the nature of the evidence supporting the claim of neutralization. Evidence for neutralization may come from distributional information alone (e.g. laryngeal neutralization in coda position in Cantonese) or may additionally be supported by morphological means (e.g. obstruent devoicing in Dutch). All reported cases of incomplete neutralization pertain to morphologically sensitive neutralization. In sum, the question of how pervasive covert contrasts and complete neutralization are is ultimately an empirical one. More systematic phonetic and psycholinguistic investigations are needed to answer this fundamental question in contrast reduction research.

81 Local Assimilation

Elizabeth C. Zsiga

1 Overview

Local assimilation is a phonological alternation in which two sounds that are adjacent become more similar. Its opposite is *dissimilation*, an alternation in which two sounds that are similar become more different (see CHAPTER 60: DISSIMILATION). Local assimilation can also be contrasted with long-distance assimilation (*harmony* – see also CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS; CHAPTER 78: NASAL HARMONY; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY), in which sounds that are not immediately string-adjacent influence one another, and with *coalescence* (see Casali 1996; Pater 1999), in which two adjacent sounds merge into a single segment that shares properties of both.

Local assimilation can be illustrated by different forms of the English negative prefix /ɪn-/, as in (1). Examples in (1a) and (1b) illustrate common place assimilation: the basic form of the nasal consonant is /n/ (1a), but it assimilates to the place of articulation of a following stop (1b). When the prefix precedes a labiodental fricative (1c), assimilation of /n/ is optional, as it is with other prefixes or across a word boundary (1d). In words like *illegal* and *irregular* (1e), the /n/ is not pronounced at all: in Latin, the /n/ became identical to a following /l/ or /r/. These different aspects of the /ɪn-/ alternation illustrate many of the questions and issues that arise in the cross-linguistic description of local assimilation.

(1) *An example of local assimilation in English*

a. *i*[n]*ability*
   i[nh]*ospitable*
   i[ns]*olvent*

b. *i*[mp]*ossible*
   i[mb]*alance*
   i[nt]*erminable*
   i[nd]*ecisive*
   i[ŋk]*ongruent*

c.	*i*[nf]*requent*	or	*i*[ɱf]*requent*
	i[nv]*ariant*	or	*i*[ɱv]*ariant*
d.	*u*[nb]*alanced*	or	*u*[mb]*alanced*
	i[np]*assing*	or	*i*[mp]*assing*
e.	*i*[l]*egal*	(Latin *il-legalis*)	
	i[r]*egular*	(Latin *ir-regularis*)	

If two adjacent sounds come to share just one feature, or a subset of their features, the assimilation is termed *partial*, illustrated by the word *impossible*, where the consonants in prefix and root share place of articulation, but not nasality or voicing. If two adjacent sounds become identical, as in *illegalis*, the assimilation is *total* or *complete*. It is also useful to distinguish the direction of assimilation. In a sequence of sounds AB, if A changes to become more like B, the assimilation is termed *anticipatory*: A anticipates some feature of B. If B changes to become more like A, the assimilation is *perseverative*: some feature of A continues into B. (Anticipatory assimilation may also be called *regressive*, since the assimilating feature is moving backwards, and perseverative assimilation may be termed *progressive*, since the assimilating feature is moving forward.) The assimilations in (1) are all anticipatory.

Local assimilation is the most common type of phonological alternation, and as such has played an important role in phonological theory. Phonological issues that arise with respect to local assimilation include the following:

(2) a. What features assimilate?
  b. What groups of features assimilate together?
  c. How can directional asymmetries be accounted for?
  d. What is the influence of morphological and prosodic context?
  e. What are the roles of production and perception in local assimilation?
  f. How is local assimilation different from co-articulation?
  g. How should local assimilation be formalized?

These questions concerning the nature and representation of local assimilation will be addressed in the remainder of this chapter, which is divided into two parts. §2 provides a cross-linguistic sampling of types of local assimilation, providing the data for more general theoretical discussion that follows in §3. Issues addressed in §3 are directionality and perception (§3.1), production and co-articulation (§3.2), and formalism (§3.3). In addition to these larger questions that focus on the linguistic status of assimilation per se, other more specific issues often come up in the discussion of particular datasets or types of assimilation. Various processes of local assimilation have been important in providing evidence for and against phonological issues such as underspecification, privative *vs.* binary features, feature geometry, and Lexical Phonology. Such connections will not be treated in depth in this chapter, but will be noted, along with cross-references to other chapters where the issue is addressed more fully.

2 Examples of local assimilation

Local assimilation can affect nearly every phonological feature. In fact, participating in assimilation is considered prime evidence for featural status (McCarthy

1994; Hume and Odden 1996; see also CHAPTER 17: DISTINCTIVE FEATURES). Some of the most common types of local assimilation are exemplified below.

2.1 *Voicing and other laryngeal features*

When obstruent consonants become adjacent, they often come to agree in voice, and sometimes in other laryngeal features as well. For example, in Russian, a string of obstruents always agrees in voicing with the rightmost obstruent in the sequence (Jakobson 1978; Padgett 2002).

(3) *Voicing assimilation in Russian*

a.	[ot papɨ]	'from papa'
	[od babuʃki]	'from grandma'
	[od vzbutʃki]	'from a scolding '
	[ot fspleska]	'from a splash'
b.	[ot mamɨ]	'from mama'

A similar alternation is found in Yiddish (Katz 1987, cited in Lombardi 1999), illustrated in (4).

(4) *Voicing assimilation in Yiddish*

[vog]	'weight'	[vok-ʃoi]	'scale'
[bak]	'cheek'	[bag-bejn]	'cheekbone'
but		[nud-nik]	'boring person'
		[mit-niten]	'co-respondent'

In both Russian and Yiddish, the assimilation is anticipatory: consonants anticipate the voicing of the rightmost obstruent in the cluster, whether voiced or voiceless. This is the unmarked direction for assimilation (Lombardi 1999). Perseverative voicing assimilation, in which the voicing value is determined by the leftmost consonant, may also be seen, usually in the case of assimilation of a suffix to a stem (Lombardi 1999; Borowsky 2000). Examples from English and Turkish are shown in (5).

(5) a. *Voicing assimilation in English (plural and past tense)*

[ro-z]	'rows'	[ro-d]	'rowed'
[ræg-z]	'rags'	[bɛg-d]	'begged'
[rak-s]	'rocks'	[kɪk-t]	'kicked'

b. *Voicing assimilation in Turkish* (Lewis 1967)

[git-tim]	'go-PAST.1SG'
[kɨz-dɨm]	'got mad-PAST.1SG'
[komsu-muz-dan]	'neighbor-POSS-ABL'
[raf-tan]	'shelf-ABL'

Cases of voicing assimilation have been central to the debate over whether [voice] is a privative or binary feature. Cases like that of Yiddish, where either a voiced or voiceless cluster may be formed, and where assimilation is independent of syllable-final devoicing, have been crucial. Is it possible to account for alternations such as [vog] ~ [vokʃoi] without reference to a feature [−voice]? See Cho (1999), Lombardi (1999), and Wetzels and Mascaro (2001) for further discussion.

Another important point to note about voicing assimilation in consonant clusters is that sonorant consonants are often neutral with respect to voicing assimilation (see CHAPTER 8: SONORANTS). Thus there are sequences like [ot fspleska] in Russian and [mitniten] in Yiddish, where the rightmost consonant in the cluster is a (voiced) sonorant, but the other consonants are voiceless. (Though note that the behavior of Russian /w/, which alternates with [v] and participates only partially in voicing assimilation, has been the subject of much discussion: see Padgett 2002 and references therein.)

On the other hand, the laryngeal features of obstruents and sonorants do sometimes interact. Common cases include intervocalic (or intersonorant) voicing (6) and post-nasal voicing (7).

(6) *Intersonorant voicing in Korean* (Silva 1992)

[pap]	'rice'	[i-bab-i]	'this rice-NOM'
[kuk]	'soup'	[i-gug-i]	'this soup-NOM'
[tal]	'moon'	[pan-dal]	'half moon'
[palp]	'walk'	[palb-in]	'that is walking'

/motun kilim/ → [modun gilim] 'every picture'
/kulimul pota/ → [kulimul boda] 'to look at a picture'

(7) a. *Post-nasal voicing in Yao* (Nurse and Phillipson 2003)

[ku-pélék-a]	'to send'	[kuu-m-bélek-a]	'to send me'
[ku-túm-á]	'to order'	[kuu-n-dúm-a]	'to order me'
[ku-kwéél-a]	'to climb'	[kuu-ŋ-gwéel-a]	'to climb on me'

b. *Post-nasal voicing in Puyo Pungo Quechua* (Orr 1962; Rice 1993; Pater 1999)

[sinik-pa]	'porcupine's'	[wasi-ta]	'the house'
[kam-ba]	'yours'	[wakin-da]	'the others'

It may also be the case that obstruents cause devoicing in sonorants, as in high vowel devoicing in Japanese (8a), in which /i/ and /u/ devoice when surrounded by voiceless consonants, or sonorant devoicing in English (8b), in which /l/ and /r/ devoice when preceded by a voiceless aspirated consonant.

(8) a. *High vowel devoicing in Japanese* (Tsuchida 1997)

[koku̥sai]	'international'
[ki̥tai]	'expectation'
[aki̥ko]	'woman's name'
[ɸu̥ton]	'bed'

b. *Sonorant devoicing in English*

[pl̥e]	'play'
[pr̥e]	'pray'
[tr̥u]	'true'
[kl̥e]	'clay'
[kr̥o]	'crow'

The interaction or non-interaction of sonorants and obstruents in voicing assimilation has played an important role in feature theory. On the one hand, the non-participation of sonorants has been cited as evidence that sonorants are underspecified for voice in underlying representation, with later fill-in by rule (Hayes 1984; Kiparsky 1985; Itô and Mester 1986). Alternatively, it has been argued that cases of sonorant/obstruent interactions involve features other than [voice] or [sonorant]. Rice (1993) argues that sonorants are specified with a different feature, [sonorant voice], which may spread to neighboring consonants, accounting for cases of intersonorant or post-nasal voicing. In the case of devoicing, as in (8), the assimilating feature may be aspiration: [spread glottis] rather than [−voice]. For further discussion, see CHAPTER 17: DISTINCTIVE FEATURES, CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION, and CHAPTER 8: SONORANTS.

Another approach has been to argue that cases of apparent voicing assimilations between vowels and consonants are not featural assimilation at all, but phonetic co-articulation. Jun (1995), for example, argues that Korean intersonorant voicing comes about because the glottal opening gesture for lax voiceless consonants is weak, allowing vocal fold vibration to continue throughout a short closure duration. Browman and Goldstein (1988) point out that the large and late glottal opening gesture for English initial aspirated stops is sufficient to delay voice onset in a following liquid, without further addition of a rule assimilating either [−voice] or [spread glottis]. §3 below returns to the issue of disentangling co-articulation and assimilation.

When languages have multiple laryngeal contrasts, examples of the assimilation of multiple laryngeal features have been identified. Smyth (1920) gives examples of assimilation of both aspiration and voicing in Ancient Greek.

(9) *Ancient Greek assimilation of both voicing and aspiration* (Smyth 1920)

a.	[grap^h-o]	'I write'
	[gegrap-tai]	'has been written'
	[grab-den]	'writing/scraping'
b.	[trib-o]	'I rub'
	[tetrip-tai]	'has been rubbed'
	[etrip^h-t^{h}eːn]	'it was rubbed'

Sanskrit also exhibits assimilation of multiple laryngeal features. The pattern of assimilation of voicing and aspiration in Sanskrit is complex, and its description and analysis has a long history (Whitney 1889; Wackernagel 1896). The examples in (10) represent part of this interaction, and serve to illustrate local assimilation of voicing and aspiration from the coda of the verb root to the onset of the suffix.

(10) *Assimilation of voicing and aspiration in Sanskrit* (Calabrese and Keyser 2006)

/b^{h}aud^h-ta/ →	[budd^{h}a]	'awake-PST PART'
/rud^h-ta/ →	[rudd^{h}a]	'obstruct-PST PART'
/saːd^h-ta/ →	[saːdd^{h}a]	'succeed-PST PART'

Cases of simultaneous assimilation of more than one feature, such as those in (9) and (10), have been important in providing evidence for hierarchical organization of features. See §3.3 below, and CHAPTER 27: THE ORGANIZATION OF FEATURES.

2.2 Nasality

Assimilation of nasality is very common. Vowels generally become nasalized when adjacent to a nasal consonant, as illustrated in (11). Such nasalization may be anticipatory, as in English (11a), or perseverative, as in Sundanese (11b). Sundanese nasalization can also be iterative and in some cases long-distance, applying across an intervening /h/: see Cohn (1993) and CHAPTER 78: NASAL HARMONY.

(11) a. *Anticipatory nasalization in English*

[kʰæt]	'cat'	[kʰæ̃n]	'can'
[ɹɪb]	'rib'	[ɹɪ̃n]	'rim'
[θɪk]	'thick'	[θɪ̃ŋ]	'thing'

b. *Perseverative nasalization in Sundanese* (Cohn 1993)

[ŋãtur]	'arrange'
[mãrˈɪɑs]	'examine'
[ɲĩãr]	'seek'
[mãhãl]	'expensive'

Cohn (1993) argues that, in addition to differing in direction, English and Sundanese represent two distinct types of assimilation: the one categorical and phonological (Sundanese), the other gradient and phonetic (English). §3.2 below returns to this distinction.

Assimilation of nasality may also apply between adjacent consonants, as shown in (12).

(12) a. *Nasal assimilation from onset to coda in Korean* (Kim-Renaud 1991)

[pap]	'rice'	[pam mekta]	'eat rice'
[ot]	'clothes'	[on man]	'only clothes'
[jak]	'medicine'	[jaŋ mekta]	'take medicine'

b. *Nasal assimilation from prefix to root in Twi*

[bá]	'comes'	[m-má]	'does not come'
[gu]	'pours'	[ŋ-ŋu]	'does not pour'
cf.			
[pɛ]	'likes'	[m-pɛ]	'does not like'
[tɔ]	'does'	[n-tɔ]	'does not do'

2.3 Continuant

Stops often become continuants when surrounded by, or in some cases just preceded by, continuants. The change from stop to fricative, termed *spirantization*, may be considered assimilation of the feature [continuant] (see CHAPTER 28: THE REPRESENTATION OF FRICATIVES). Examples from Spanish and Italian are shown in (13).

(13) a. *Post-continuant spirantization of voiced stops in Spanish*

/la gata/	→	[la ɣata]	'the (FEM) cat'
/la data/	→	[la ðata]	'the date'
/la bola/	→	[la βola]	'the ball'
/las gata/	→	[las ɣatas]	'the (FEM) cats'
/las bolas/	→	[las βolas]	'the balls'

b. *Intervocalic spirantization of voiceless stops in Florentine Italia* (Villafana 2006)

/la kaza/	→	[la xaza]	'the house'
/la torta/	→	[la θorta]	'the cake'
/la palːa/	→	[la ɸalːa]	'the ball'

Similarly, continuants often "harden" to stops or affricates in post-nasal position, an alternation that may be considered assimilation of [−continuant] from the preceding nasal (Padgett 1994).

(14) a. *Post-nasal hardening in Setswana* (Tlale 2006)

[supa]	'point at'	[n-tsʰupa]	'point at me'
[ʃapa]	'hit'	[ɲ-tʃʰapa]	'hit me'
[xapa]	'capture'	[ŋ-kxʰapa]	'capture me'
[rut'a]	'teach'	[n-tʰut'a]	'teach me'

b. *Post-nasal hardening in Kikuyu* (Armstrong 1967; Clements 1985)

imperative	*1sg imperfect*	
[βur-a]	[m-bur-eetɛ]	'lop off'
[reh-a]	[n-deh-eetɛ]	'pay'
[ɣor-a]	[ŋ-gor-eetɛ]	'buy'

Spirantization and hardening are not necessarily considered to be cases of assimilation, however, but cases of a separate phonological process of *lenition* or *fortition*, in which features other than [continuant] may be involved. Spanish stops may weaken to more open approximant articulations (/la bola/ → [la υola]) and intervocalic /k/ in Florentine often weakens to [h] (/la kaza/ → [la haza]). Conversely, post-nasal fortition in Setswana involves changes in laryngeal features as well as in continuant. See Kirchner (1998), Lavoie (2001), Gurevich (2003), and CHAPTER 66: LENITION for numerous further examples and discussion.

2.4 Consonantal place of articulation

2.4.1 Nasal place assimilation

Assimilation of place of articulation is probably the most ubiquitous phonological alternation. Especially common is nasal place assimilation: nasals assimilate in place of articulation to a following consonant. Examples could be found in almost any language. Nasal place assimilation in English and in the African languages Yao, Twi, Setswana, and Kikuyu was seen in examples (1), (7a), (12b), (14a), and (14b) above. Additional examples are shown in (15): Catalan (a), Zoque (b), Malayalam (c), Sri Lankan Creole (d), and Zulu (e). Zulu is included to illustrate the point that in place assimilation to complex segments such as clicks and labial-velars, assimilation to the dorsal place of articulation is most common (Maddieson and Ladefoged 1989; see also CHAPTER 18: THE REPRESENTATION OF CLICKS).

(15) a. *Nasal place assimilation in Catalan* (Mascaró 1976; Kiparsky 1985)

so[n]*amics* 'they are friends'
so[m]*pocs* 'they are few'
so[ɱ]*felicos* 'they are happy'
so[n̪ d̪]*os* 'they are two'
so[ɳ]*rics* 'they are rich'
so[ɲ lʲ]*iures* 'they are free'
so[ŋ]*grans* 'they are big'

b. *Nasal place assimilation in Zoque* (Wonderly 1946, cited in Padgett 1994)

[pama]	'clothing'	[m-bama]	'my clothing'
[tatah]	'father'	[n-datah]	'my father'
[ʧima]	'calabash'	[ɲ-ʤima]	'my calabash'
[kaju]	'horse'	[ŋ-gaju]	'my horse'
[gaju]	'rooster'	[ŋ-gaju]	'my rooster'
cf. nasal deletion preceding fricatives:			
[faha]	'belt'	[faha]	'my belt'
[ʃapun]	'soap'	[ʃapun]	'my soap'
[ranʧo]	'ranch'	[ranʧo]	'my ranch'

c. *Nasal place assimilation in Malayalam* (Mohanan 1993)

[awan]	'he'
[awam-paraɲɲu]	'he said'
[awan̪-t̪aʈiccu]	'he became fat'
[awaɲ-caːʈi]	'he jumped'
[awaŋ-karaɲɲu]	'he cried'
[kamalam]	(proper name)
[kamalam-paraɲɲu]	'Kamalam said'
[kamalan̪-t̪aʈiccu]	'Kamalam became fat'
[kamalaɲ-caːʈi]	'Kamalam jumped'
[kamalaŋ-karaɲɲu]	'Kamalam cried'

d. *Assimilation of non-coronal nasals in Sri Lankan Portuguese Creole* (Hume and Tserdanelis 2002; Hume 2003)

Nom sg	*Gen sg*	*Dat sg*	*Verbal noun*	
[maːm]	[maːn-su]	[maːm-pə]	[maːŋ-ki]	'hand'
[miːtiŋ]	[miːtin-su]	[mitim-pə]	[miːtiŋ-ki]	'meeting'
[siːn]	[siːn-su]	[siːn-pə]	[siːn-ki]	'bell'

e. *Assimilation to the dorsal place of clicks in Zulu* (Doke 1926, cited in Padgett 2002)

/iziN-/	(class 10 plural prefix)
[izim-papʰɛ]	'feathers'
[izin-ti]	'sticks'
[iziŋ-kɛzɔ]	'spoons'
[iziŋ-ǀezu]	'slices'
[iziŋ-ǂuŋǂulu]	'species of bird (PL)'
[iziŋ-ǁaŋǁa]	'green frogs'

A number of cross-linguistic differences and similarities in nasal place assimilation are worth noting.

As in the Zoque and Zulu examples, it is often the case that a nasal (or nasal-final) affix undergoes obligatory place assimilation in every lexical item in which it occurs. In such cases, it may be impossible to determine empirically the basic or underlying form, and it is often argued that such nasals are unspecified for place (e.g. Kiparsky 1985). A segment specified only as [nasal], but with no underlying place features, may be symbolized /N/. Depending on how a particular alternation is formalized, however, underspecification may or may not be assumed. (See CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION.)

Relevant to the debate on underspecification is the observation that the coronal nasal assimilates more often than either labial or velar nasals. In many languages, such as Catalan and Spanish (Navarro Tomás 1970; Honorof 1999), only the coronal nasal assimilates, although for some languages such as Malayalam, assimilation of non-coronal nasals is also attested. In Sri Lankan Creole, all nasals *except* [n] assimilate. Asymmetries in place assimilation are discussed further in §3.1 and §3.2 below.

Another point of interest in nasal place assimilation is whether or not nasals assimilate to [+continuant] segments. In Catalan and Sri Lankan, nasals assimilate to both stops and continuants, but in Malayalam and Zoque, nasals assimilate only to stops. In Malayalam, unassimilated nasal–fricative clusters are tolerated, but in Zoque the nasal deletes when a fricative follows. In other languages, other processes may apply to repair disfavored nasal–fricative clusters. In Setswana and Kikuyu ((14) above), fricatives harden to stops or affricates in post-nasal position. In English, as was noted in (1), assimilation of /n/ to /f/ is optional: the nasal–fricative cluster in the word *infrequent* may be pronounced [nf] in careful speech or [ɱf] in less careful speech, but *impolite* is invariably [mp]. The propensity for place assimilation and continuant assimilation to occur together leads Padgett (1994), among others, to posit a dependency relation between features for place and the feature [continuant], though this requires a different explanation for cases like Spanish *so*[ɱ f]*elicos* and English *i*[ɱf]*requent* (see the discussion in §3.2 below).

Data on nasal place assimilation, probably more because it is so common than because of any inherent phonological property, has often been invoked in debates on domains of application. Catalan nasal place assimilation played an important role in arguments for cyclic rule application, and the distinction between lexical and post-lexical phonology (Kiparsky 1985). The observation that place assimilation applies to English /m-/ *impossible*, /kan-/ *congruent*, and /sɪn-/ *sympathy*, but not /ʌn-/ *unprepared*, provided important data for level ordering of affixes in English. The ability of nasal place assimilation to create sounds that are not part of the underlying inventory of the language, such as [ɱ] in English and Catalan, has informed debate on Structure Preservation, and on the lexical/post-lexical distinction (Kiparsky 1985; CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME).

Finally, data on nasal place assimilation has also been crucial in the theory of feature geometry (discussed in §3.3 below), and in development of the theory of Articulatory Phonology (discussed in §3.2).

2.4.2 *Other consonantal place assimilations*

Place assimilation most often involves nasals, but other consonants undergo place assimilation as well. In Korean, for example, optional place assimilation applies to certain obstruent clusters, as illustrated in (16): final [t] may assimilate to a following labial or dorsal stop, and [p] to a following dorsal.

(16) *Place assimilation in Korean obstruents*
(Kim-Renaud 1991; Kochetov and Pouplier 2008)

/pat^{h}-pota/	→	[pat p'oda]	or	[pap p'oda]	'rather than the field'
/pat^{h}-kwa/	→	[pat k'wa]	or	[pak k'wa]	'field and'
/pap-kɨlɨs/	→	[pap k'ɨrɨt˺]	or	[pak k'ɨrɨt]	'rice bowl'
/t^{h}op-k^{h}al/	→	[t^{h}op k^{h}al]	or	[t^{h}ok k^{h}al]	'handsaw'

cf.

/pap-to/	→	[papt'o]	*[patt'o]	'rice also'
/pak-to/	→	[pakt'o]	*[patt'o]	'outside also'
/kuk-po/	→	[kukp'o]	*[kupp'o]	'national treasury'

In other cases, subsidiary place features assimilate between adjacent consonants. Most often the features [anterior] and [distributed] assimilate in sequences of coronal consonants. It was seen above that Catalan nasals (15a) assimilate to a following consonant at all places of articulation. Catalan laterals also assimilate (17), but only to a following coronal. (See CHAPTER 31: LATERAL CONSONANTS for further discussion.)

(17) *Assimilation of laterals in Catalan* (Mascaró 1976)

e[l p]*a*	'the bread'
e[l̪ d̪]*ia*	'the day'
e[ɭ r]*ic*	'the rich'
e[ʎ ʒ]*erma*	'the brother'

In English, coronal stops and nasals assimilate the [–anterior] feature of a following [ɹ], or the dental articulation of a following dental fricative.

(18) *Assimilation of retroflex and dental in English*

train	[t̠ɹeɪn]
drain	[d̠ɹeɪn]
tenth	[t^{h}ɛn̪θ]
eighth	[eɪt̪θ]
width	[wɪd̪θ]

In Sanskrit, Murinbata, and other languages of India and Australia (Steriade 2001), place assimilation among coronal clusters is often perseverative: that is, the onset assimilates to the coda, as shown in (19). This reversal in expected direction is discussed further in §3.1 below.

(19) a. *Perseverative retroflex assimilation in Sanskrit* (Whitney 1889, cited in Steriade 2001)

/iʂ-ta/	→	[iʂ-ʈa]	'sacrificed'
/ʂaɳ-nam/	→	[ʂaɳ-ɳam]	'of six'
/giɽ-su/	→	[giɽ-ʂu]	'in songs'

b. *Perseverative retroflex assimilation in Murinbata* (Street and Mollinjin 1981, cited in Steriade 2001)

/pan-ʈal/	→	[pan-tal]	'cut it-3SG'
/ŋudu-ɭɛɭ-nu/	→	[ŋudu-ɭɛɭ-ɳu]	'roll-FUT'

As was noted with respect to nasal place assimilation, evidence from consonantal place assimilation in general has been crucial in the development of phonological theory. One point of particular interest is how place assimilation, which may involve a whole set or subset of different features, may be formalized as a unitary process (see §3.3 below). Another point is the problem of directionality (§3.1): why is it that codas usually assimilate to onsets, rather than vice versa? Place assimilation has also played an important role in the debate over assimilation *vs.* co-articulation, and in the development of the theory of Articulatory Phonology (§3.2).

2.4.3 *Vowel and consonant place interactions*

While place assimilation usually applies to consonant clusters, vowels and consonants may also assimilate to each other (see CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS for more discussion). Consonants often assimilate the properties of adjacent vocalic articulations. For example, in the Wakashan language Oowekyala (Howe 2000), velar and uvular consonants contrast in rounding in initial position and following most vowels (20a). Immediately following /u/, however, all velars and uvulars assimilate to the vowel's [round] feature (20b).

(20) *Oowekyala* (Howe 2000)

a. *Contrastive rounding*

[q^{w}ut'a]	'full'
[quɬa]	'bent'

b. *Rounding assimilation*

[pusq'a-x^{ʔ}it]	'to become very hungry'
[ƛ'u'xwalasu-x^{wʔ}it]	'to become sick'
[məja-gila]	'make (draw or carve) a fiish'
[ʔamastu-g^{w}ila]	'make kindling'

In the neighboring language Nuxalk, Howe reports that rounding assimilation is anticipatory rather than perseverative: velars and uvulars become round *preceding* /u/.

Another assimilation from vowel to consonant is palatalization of a consonant adjacent to front vowels and glides. Palatalization may take the form of an alveolar or dental (or sometimes velar) becoming alveopalatal, or it may take the form of secondary articulation, adding an additional high front tongue position without changing the consonant's primary place of articulation. Languages differ in the input sequences that trigger palatalization, and in the resulting outputs. Three examples are shown in (21); see CHAPTER 71: PALATALIZATION for further examples and discussion. In English (21a), alveolars become alveopalatals before /j/. In Japanese (21b), alveolars become alveopalatals before /i/, while velar and labial consonants become secondarily palatalized. In one pattern of palatalization in Polish (21c), labials receive secondary palatalization before [i] and [e], while velars and alveolars change their primary place. (Palatalization in Slavic languages is both common and complex: see CHAPTER 121: SLAVIC PALATALIZATION and CHAPTER 122: SLAVIC YERS.)

(21) a. *English palatalization before /j/*

[d ~ ʤ]	*grade*	*gradual*
[t ~ ʧ]	*habit*	*habitual*
[s ~ ʃ]	*press*	*pressure*
[z ~ ʒ]	*use*	*usual*

b. *Palatalization in Japanese* (Vance 1987; Chen 1996)

[kas-anai]	'lend-NEG'	[kaʃ-ita]	'lend-PAST'
[kat-anai]	'win-NEG'	[kaʧ-itai]	'win-VOLITIONAL'
[wak-anai]	'boil-NEG'	[wakʲ-itai]	'boil-VOLITIONAL'
[job-anai]	'call-NEG'	[jobʲ-itai]	'call-VOLITIONAL'

c. *Palatalization in Polish* (Szpyra 1989; Chen 1996)

[łupɨ]	'booty'	[łupʲ-ic]	'to rob'
[zabava]	'game'	[zabavʲ-ic]	'to entertain'
[zloto]	'gold'	[złoc-ic]	'to gild'
[kwas]	'acid'	[kwaç-ic]	'to make sour'
[rana]	'wound'	[raɲ-ic]	'to wound'
[sok]	'juice'	[soʧ-ek]	'juice-DIM'
[mex]	'moss'	[meʃ-ek]	'moss-DIM'

Vowels may also assimilate to adjacent consonants. In Russian (22a), palatalization on consonants is contrastive, and the vowels [i] and [ɨ] are in complementary distribution: [i] is found in initial position and following palatalized consonants, [ɨ] follows non-palatalized consonants. (See CHAPTER 121: SLAVIC PALATALIZATION for additional discussion.) In the Dravidian language Tulu (22b), the accusative suffix /-ɨ/ becomes round when it follows a labial consonant (or another round vowel).

(22) a. *Vowel backing in Russian* (Halle 1959; Padgett 2002)

[ivan]	(proper name)
[k-ɨvanu]	'to Ivan'
[italʲia]	'Italy'
[v-ɨtalʲiju]	'to Italy'

b. *Rounding assimilation in Tulu* (Bright 1957, cited in Kenstowicz 1994)

[katt-ɨ]	'bond-ACC'
[kapp-u]	'blackness-ACC'
[ucc-u]	'snake-ACC'

Another type of assimilation from consonant to vowel is vowel lowering. Vowel lowering after uvular, pharyngeal, and laryngeal consonants (the class of *guttural* consonants) is found in many Semitic, Caucasian, and North American languages (Herzallah 1990; Bessell 1992, 1998; McCarthy 1994; Rose 1996). In Syrian Arabic (23a), for example, the feminine suffix is realized as [a] after laryngeals, pharyngeals, and uvulars, and as [e] after all other consonants. In Oowekyala (23b), /i/ and /u/ are lowered to [e] and [o].

(23) a. *Vowel lowering in Syrian Arabic* (Cowell 1964; Rose 1996)

[daraʒ–e]	'step'
[ʃerk-e]	'society'
[madras-e]	'school'
[waːʒh-a]	'display'
[mniːħ-a]	'good'
[daggaːʀ-a]	'tanning'

b. *Vowel lowering in Oowekyala* (Howe 2000)

/ƛiq-ila/	→	[dliqχela]	'to give a name to someone'
/qusa/	→	[qosa]	'bent, crooked'
/hula/	→	[hola]	'heap up'
/ɢwiχila/	→	[ɢwiχela]	'to bake bread'

Vowel lowering has figured prominently in the debates over what features constitute the class of guttural consonants. In various cases the feature has been argued to be [low], [−high], or [pharyngeal]. See CHAPTER 25: PHARYNGEALS for further examples and discussion.

In general, the question of when and how vowels and consonants interact with each other has been important in the area of feature theory. Consonants are often transparent to long-distance vowel-to-vowel assimilation, yet they also interact with vowels in local assimilations, as has been illustrated. Transparency to vocalic alternations suggests that vowels and consonants have different features, or that consonants bear vocalic features only as secondary articulations: e.g. front vowels and palatalized consonants are [−back], while alveolar and dental consonants are [coronal]. Such an approach accounts for cases in which processes of palatalization and rounding result in secondary articulations. But it fails to account for cases where the vowel causes a change in the consonant's primary place of articulation, or where the consonant causes a change in the backness of a vowel. Such alternations have led to proposals (e.g. Clements 1993; Hume 1994; Clements and Hume 1995) that vowels and consonants share the same features: e.g. alveolar consonants, alveopalatal consonants, and front vowels are all [coronal]. See CHAPTER 19: VOWEL PLACE, CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION, and CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS.

2.5 *Complete assimilations*

Complete assimilation occurs when two adjacent sounds become identical. Complete assimilation is particularly common in clusters involving /r/ and /l/ (see CHAPTER 30: THE REPRESENTATION OF RHOTICS and CHAPTER 31: LATERAL CONSONANTS). Complete assimilation of the Latin prefix /in-/ to both /l/ and /r/ as in *illegalis* and *irregularis* was seen in (1) above. Similar cases are found in Ponapean and Korean.

(24) a. *Assimilation of /n/ to /l/ and /r/ in Ponapean* (Rehg and Sohl 1981; Rice 1993)

/nanras/	→	[narras]	'ground level of a feasthouse'
/nanleŋ/	→	[nalleŋ]	'heaven'
/pahn liŋan/	→	[pahl liŋan]	'will be beautiful'
/pahn roŋ/	→	[pahr roŋ]	'will listen'

b. *Assimilation of /n/ to /l/ in Korean* (Davis and Shin 1999)

/non-li/	→	[nolli]	'logic'
/tan-lan/	→	[tallan]	'happiness'
/ts^{h}ən-li/	→	[ts^{h}əlli]	'natural law'

In some cases, a sonorant may assimilate completely to a following obstruent. In Arabic (25a), /l/ assimilates to a following coronal, but not to consonants at other places of articulation. In Havana Spanish (25b), the /l/ assimilates completely to most following consonants. The exception is that if the following consonant is a voiceless stop, the /l/ assimilates in all features except [voice].

(25) a. *Assimilation of /l/ in Arabic* (Kenstowicz 1994)

[ʔaʃ-ʃams]	'the sun'
[ʔad-daar]	'the house'
[ʔan-nahr]	'the river'
[ʔaz-zajt]	'the oil'
cf.	
[ʔal-qamr]	'the moon'
[ʔal-kitaab]	'the book'
[ʔal-faras]	'the mare'

b. *Assimilation of /l/ in Havana Spanish* (Harris 1985)

albañil	*a*[bb]*añil*	'mason'
tal droga	*ta*[dd]*roga*	'such a drug'
pulga	*pu*[gg]*a*	'flea'
tal mata	*ta*[mm]*ata*	'such a shrub'
el fino	*e*[ff]*ino*	'the refined one'
el pobre	*e*[bp]*obre*	'the poor man'
el tres	*e*[dt]*res*	'the three'

A similar case of near-complete assimilation occurs in Kannada (26). The final consonant of the morpheme meaning "big" copies all features from the following consonant, except that the resulting cluster must be voiced, regardless of input.

(26) *Complete assimilation with voicing in Kannada* (Roca and Johnson 1999)

[tere]	'screen'	[hed-dere]	'big screen'
[kumbaḷa]	'pumpkin'	[heg-gumbaḷa]	'big pumpkin'
[dzenu]	'bee'	[hedz-dzenu]	'big bee'
[mara]	'tree'	[hem-mara]	'big tree'

Finally, complete local assimilation of one vowel to another can also be found. Many languages will not tolerate successive non-identical vowels (CHAPTER 61: HIATUS RESOLUTION). While vowel hiatus is often repaired by deleting one vowel or the other (see Casali 1996, 1997), another strategy is assimilation, as shown in (27).

(27) *Vowel assimilation in Yoruba* (Welmers 1973)

[owo]	'money'
[owe-epo]	'oil money'
[owa-ade]	'Ade's money'

2.6 *Instances where local assimilation doesn't apply*

The preceding list of types of local assimilation has been long. Nonetheless, there are situations where local assimilation is not typically found. These include, on the one hand, environments where the trigger and target of assimilation tend not to be immediately string-adjacent, as in tone and vowel harmony. On the other hand, there are features for which languages prefer an alternating pattern, such as CVC within a syllable, or stress–unstress within a foot.

Features such as [round], [back], and [advanced tongue root] often assimilate from vowel to vowel within a word, but such assimilation is usually not local at the level of the segment, since vowels are most often separated by consonants (see CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY). Similarly, tone assimilations are quite common, and have played an important role in the development of theories of phonological representation. Tone assimilation, however, is also generally a long-distance phenomenon, applying at least from vowel to vowel across intervening consonants, and often across stretches of multiple syllables (see CHAPTER 114: BANTU TONE; CHAPTER 45: THE REPRESENTATION OF TONE; CHAPTER 107: CHINESE TONE SANDHI). Because this chapter focuses on local processes, vowel harmony and tone assimilation are not treated further here.

It has been argued that the features [consonantal] and [sonorant] do not assimilate (McCarthy 1988). Consonants do not become vowels when adjacent to vowels, and vice versa (but see Kaisse 1992 for a possible counterexample). Although consonant clusters may come to agree in sonorancy as a result of nasal assimilation or complete assimilation, the feature [sonorant] does not assimilate independently. But see Rice (1993) for discussion of a feature [sonorant voice], which is proposed to distinguish sonorants from obstruents, and to be active in cases of sonorant/obstruent voicing interactions. See also CHAPTER 8: SONORANTS and CHAPTER 13: THE STRICTURE FEATURES.

Length does not assimilate: if anything, lengthening of one segment will induce shortening of neighboring segments, or vice versa (see CHAPTER 64: COMPENSATORY LENGTHENING). Stress does not assimilate. If two stressed syllables become adjacent, languages will often resolve the "clash" by moving or deleting a stress to restore the alternating pattern. (See CHAPTER 41: THE REPRESENTATION OF WORD STRESS.)

3 General phonological issues in local assimilation

§2 provided examples of the most common kinds of local assimilations, and pointed out theoretical issues raised by specific cases, such as privativity of the feature [voice] and the featural description of the class of guttural consonants. §3 now turns to broader questions, which are applicable to many or all kinds of local assimilation. These include directionality and perception (§3.1), the relation between assimilation and co-articulation (§3.2), and the formal treatment of local assimilation (§3.3).

3.1 *Directionality and perception*

In nearly every case discussed above, there has been a preference in the directionality of assimilation. The following principles can be deduced:

(28) a. Assimilation in consonant clusters tends to be anticipatory: the specification of the rightmost consonant dominates.
b. Codas assimilate to onsets, rather than vice versa.
c. Affixes assimilate to stems and roots, rather than vice versa.

Many phonologists have analyzed these asymmetries in structural terms. Itô (1998), for example, proposes that onsets "license" place features, and that in many languages codas can only acquire place features by sharing them with an onset consonant, thus forcing assimilation. Lombardi (1999) proposes a similar argument for laryngeal features. Beckman (1998) extends the positional analysis in proposing a theory of "positional faithfulness": certain structural positions, including onset of a syllable or word, are privileged, and changes to these privileged positions are dispreferred. Stems and roots are privileged over affixes, thus affixes tend to assimilate to stems rather than vice versa. Hyman (2008) proposes a structural account of directional asymmetries in a number of Bantu languages.

Other linguists, however, argue that asymmetries in direction of assimilation can be explained by asymmetries in perceptibility, without reference to structural positions. Steriade (2001), for example, emphasizes that consonantal place of articulation is most clearly cued by the formant transitions and burst noise that occur when a closure is released into a vowel. Steriade argues that codas most often assimilate to onsets because the phonological features of a postvocalic stop are less clearly perceived than the features of a prevocalic stop, and thus a change to the coda consonant is less obvious. In cases where a particular distinction is better cued in coda position, the direction of assimilation is reversed: there is perseverative assimilation of retroflexion in Sanskrit and Murinbata consonant clusters ((19) above), because retroflexion is best cued by formant transitions on the *preceding* vowel.

Similar arguments from perception can be applied to explain why nasals and coronals so often undergo assimilation. Nasals may be especially prone to assimilate, because nasal resonances interfere with the formant information that conveys place of articulation. Coronals may more frequently assimilate because cues to coronal place of articulation are weakest, and may be overwhelmed by the stronger cues from a following stop at a different place (Kawasaki 1982; Byrd 1992). Cho and McQueen (2008) and Sohn (2008) offer perceptual accounts of Korean place assimilation. See also Paradis and Prunet (1991) and Hume (2003) for arguments respectively for and against general coronal unmarkedness, and CHAPTER 12: CORONALS.

Integral to the discussion of perception in local assimilation is the role of *mis*-perception. A speaker may produce a word or phrase in a way that is faithful to the lexical representation, but if perceptual cues to a particular contrast in a particular position are weak or non-existent, a listener may perceive something different. That is, a speaker may say [np], but the listener may hear [mp]. If the listener assumes [mp] was the intended pronunciation of /np/, the listener may postulate a phonological alternation. For further discussion see Ohala (1981), Hume and Johnson (2001), and CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY.

3.2 Assimilation and co-articulation

Processes of local assimilation are "natural," in the sense the word is used in the theory of Natural Phonology (Donegan and Stampe 1979); that is, the phonetic motivation for such processes is clear, and the motivation works in the direction of making speaking easier. While concepts like "ease of articulation" and "articulatory effort" are difficult to quantify (see Lindblom 1983; Kirchner 1998, 2000), local assimilation has an obvious phonetic basis in co-articulation.

The term *co-articulation* describes the influence segments have on one another simply by being adjacent, apart from any featural change. Because articulators cannot change position instantly, there is necessarily either some anticipatory or perseverative effect, if not both, on neighboring segments, as articulators move from one target to the next. Two examples illustrate the point. If the velum is to be fully open by the time a consonant closure is achieved, then opening must begin during the preceding vowel, resulting in some inevitable nasal resonance during the vocalic portion. If the tongue body is to reach its target vowel position by the time the onset consonant in a CV syllable is released, articulation of vowel and consonant must begin simultaneously. Thus a [k] is made further forward in the mouth when it precedes a front vowel.

Some articulatory overlap is inevitable, but degree and direction of co-articulation will differ from language to language. Given that language-specific patterns of co-articulation must be learned as part of the grammar, some linguists have argued that there is no need to state independent phonological rules of nasalization, rounding, palatalization, or place assimilation. In particular, the theory of Articulatory Phonology (Browman and Goldstein 1992) argues that all productive phonological changes can be accounted for in terms of differences in articulatory organization, particularly gestural overlap and reduction, without invoking any phonological feature change (see CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATION). Browman and Goldstein (1990), using X-ray microbeam data, show that a coronal closing gesture is still present in English phrases which sound as though a coronal nasal had become labial: for example in the phrase *seven plus* heard as assimilated *se*[vmp]*lus*. They argue that the [n] is not deleted or changed from [coronal] to [labial], but is overlapped by the following [p], according to the general pattern of consonant coordination at word boundaries in English. The [n] and [p] articulated together sound like [m] (see also Byrd 1992). Browman and Goldstein further argue that place assimilation in *tenth* ((18) above) is also the result of overlap and blending: the tongue tip cannot be both dental and alveolar at the same time, so a compromise blended position is reached. Zsiga (1995) argues for an overlap account of palatalization at word boundaries in English. The phrase *this year* may sound like *thish year*, but data from electropalatography shows that the word-final fricative is not identical to an underlying [ʃ]. Rather, it is the acoustic result of an [s] and [j] articulated at the same time, with tongue tip and blade gestures blended together. Some proponents of Articulatory Phonology incorporate gestural dynamics into constraint-based theory (Gafos 2002; Bradley 2007).

It is not clear, however, whether all local assimilations are best described in terms of gestural overlap. One distinction that is often made is that categorical phonological alternations should be represented as the result of a change in featural specification, while partial and gradient changes are attributed to gestural overlap (see CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). Thus Cohn (1993), for example, identifies two different kinds of nasalization in English and Sundanese. Using nasal and oral airflow data, Cohn demonstrates that nasalization of a vowel in English is partial and gradient, due to co-articulation with the opening velum, and very much dependent on timing and context. In contrast, nasalization in Sundanese is categorical: a nasalized vowel must be specified with its own featural target. In a similar vein, Zsiga (1995) argues that palatalization at word boundaries in English is the gradient result of overlap, while palatalization at morpheme boundaries ((21a) above) is the categorical result of a featural change. Ladd and Scobbie (2003: 16) provide data that vowel assimilation at word boundaries in Sardinian is categorical, and conclude

> that gestural overlap is on the whole not a suitable model of most of the assimilatory external sandhi phenomena in Sardinian, and more generally that accounts of gestural overlap in some cases of English external sandhi cannot be carried over into all aspects of post-lexical phonology.

Other researchers, however, follow Browman (1995) in arguing that apparently categorical deletions and assimilations are just the endpoints of a gradient distribution: deletion being the limiting case of reduction and categorical assimilation the limiting case of overlap. Thus Kochetov and Pouplier (2008), for example, describe the categorical change of /pk/ → [kk] in Korean ((16) above), in which they show the assimilated sequence to be identical to an underlying /kk/ cluster, as full reduction of the lip closing gesture and temporal extension of the velar closing gesture. One crucial question is whether there is a theory of gestural timing and organization that is both powerful enough to account for gradient changes, and constrained enough to account for changes that result in category neutralization (see the discussion in Zsiga 1997; Ladd and Scobbie 2003; Scobbie 2007). Another challenge lies in integrating articulatory and perceptual approaches. Further discussion of co-articulation and gestural overlap can be found in CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY.

3.3 *Formalizing local assimilation*

Local assimilation has played an important role in the development of phonological formalism. McCarthy (1988: 84) states: "The goal of phonology is the construction of a theory in which cross-linguistically common and well-established processes emerge from very simple combinations of the descriptive parameters of the model." He further argues that the ubiquitous presence of assimilation, both local and long-distance, warrants assigning it a "privileged status" in phonological formalism (1988: 86). Despite its clear phonetic bases, the process of assimilation has not necessarily been simple to capture in phonological representation.

In the formal theory of Chomsky and Halle (1968), processes of assimilation were expressed with the use of alpha notation. In this formalism, Greek letters stand for variables over "+" and "–", and every instance of the variable in a rule must be filled in with the same value. Thus, a rule of obstruent voicing agreement, as would be needed for example in Yiddish (4), would be written as in (29).

(29) *Obstruents agree in voicing: α notation*

$[-\text{sonorant}] \rightarrow [\alpha\text{voice}] \;/\; \_\_ \; [-\text{sonorant}, \alpha\text{voice}]$

While the use of a special notation does convey the privileged status of the notion of "agreement," non-occurring rules can also be easily represented, with no increase in formal complexity.

(30) *Obstruent voicing must match the value for* [±back]

[–sonorant] → [αvoice] / __ [–sonorant, αback]

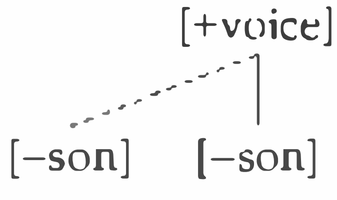
Thus, as pointed out, for example, by Bach (1968) and Anderson (1985), this rule formalism is too powerful, in that it predicts that rules (29) and (30), being equal in complexity, should be equally likely to occur. On the other hand, the common and straightforward process of nasal place assimilation (§2.4.1 above) is represented via a complicated formula (31):

(31) *Catalan nasal assimilation using alpha notation*

[+nasal] →	[αcoronal]	/ __	[αcoronal]
	[βanterior]		[βanterior]
	[γlabial]		[γlabial]
	[δback]		[δback]
	[εhigh]		[εhigh]
	[φdistributed]		[φdistributed]

It was the study of long-distance assimilation – tone and vowel harmony – that led to the introduction of autosegmental phonology (Goldsmith 1976; Clements and Sezer 1982), but this formalism was quickly adopted for local assimilations as well. In autosegmental representation, assimilation is represented by "feature spreading" through the addition of an "association line": a feature that begins as a property of one segment comes to be associated with more than one, as in the anticipatory voicing assimilation in (32):

(32) *Obstruents agree in voicing: Autosegmental notation*



Feature spreading gives assimilation a privileged status as an elementary operation, while more complicated feature switches have a correspondingly more complicated representation.

The addition of class nodes in a more elaborated *feature geometry* allows for a simple representation of rules that target a group of features. As noted by Clements (1985: 226),

> If we find that certain sets of features consistently behave as a unit with respect to certain types of rules of assimilation or resequencing, we have good reason to suppose that they constitute a unit in phonological representation.

Local place assimilation is the prime example of a set of features that behave as a unit. McCarthy (1988: 86–87) states: "The basic motivation for feature geometry [is] the naturalness of place assimilation."

Consensus has not been reached, however, on exactly which geometry is correct. The need is clear for a class node grouping consonantal place features to account for assimilations such as that in Catalan (15a), one grouping laryngeal features to account for assimilation of voicing and aspiration together as in Greek (9) and Sanskrit (10), and a ROOT node grouping all features for complete assimilation as in Ponapean (24a) or Arabic (25a). Less clear is the need for a SUPRALARYNGEAL node that groups all features except the laryngeal features. Cases like those in Havana Spanish (25b) and Kannada (26), where all features except voice assimilate, would argue for such a node (see Clements 1985); however, McCarthy (1988: 92) counters that spreading of the supralaryngeal node "is known from only one or two examples that are subject to reanalysis." Other points of contention include where to attach manner features (Padgett 1994), how to represent the class of guttural consonants (McCarthy 1994), and, probably most difficult, how to handle vowel and consonant interactions and lack of interaction. Clements and Hume (1995; see also Clements 1993; Hume 1994) suggest separate Place nodes for C-place and V-place: different patterns of interaction and transparency will depend on which nodes are targeted for assimilation. For extended further discussion, see CHAPTER 13: THE STRICTURE FEATURES; CHAPTER 14: AUTOSEGMENTS; CHAPTER 19: VOWEL PLACE; CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS; CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION; CHAPTER 25: PHARYNGEALS; CHAPTER 27: THE ORGANIZATION OF FEATURES.

Constraint-based theories (Prince and Smolensky 1993) offer a different way of formalizing assimilations. Although autosegmental representation is generally assumed, the details of feature-geometrical representations become less crucial. One way of representing local assimilation is through the mechanism of AGREE constraints: markedness constraints that state that two adjacent segments must agree with respect to the specified feature. These markedness constraints interact with constraints requiring faithfulness to underlying features, with language-specific rankings producing different patterns of assimilation (see CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). Thus Lombardi (1999) proposes the constraints in (33) to account for voicing assimilation in Yiddish ((4) above). The positional faithfulness constraint (33c) is needed to account for the fact that the coda assimilates to the onset and not vice versa.

(33) *Constraints on obstruent voicing agreement* (Lombardi 1999)

a. AGREE
   Obstruent clusters should agree in voicing.
b. IDENT(Laryngeal)
   Consonants should be faithful to underlying laryngeal specification.
c. IDENT-ONSET(Laryngeal)
   Consonants in [pre-sonorant position] should be faithful to underlying laryngeal specification.

If these are ranked such that the agreement constraint and the positional faithfulness constraint outrank general faithfulness, as in (34), the result is that the coda will assimilate in voicing to the onset.

(34) *Voicing assimilation in Yiddish* (Lombardi 1999)

/bak bejn/	AGREE	IDENT-ONSET(Lar)	IDENT(Lar)
a. bak.bejn	*!		
☞ b. bag.bejn			*
c. bak.pejn		*!	*

Steriade (2001) treats place assimilation with parallel formalism, but substitutes positional faithfulness constraints that reference differences in perceptibility rather than syllable structure (see §3.1 above).

(35) *Place assimilation with perceptibility constraints* (Steriade 2001)

/at pa/	AGREE	IDENT(Place)/C_V	IDENT(Place)/V_C
a. atpa	*!		
☞ b. appa			*
c. atta		*!	*

Place assimilation is also often handled with reference to positional markedness as well as positional faithfulness (Kager 1999). In this approach, assimilation is not driven by a constraint requiring agreement. Rather, the markedness constraint that forces the alternation is based on Itô's (1998) insight that codas may not license place features alone. Direct reference to a "coda condition" captures the insight that assimilation to the place of an adjacent onset consonant is just one way to repair the coda violation; epenthesis and deletion, which change the syllable structure rather than featural content, are others. The use of different constraints for place assimilation and voice assimilation captures the generalization that, cross-linguistically, epenthesis and deletion often occur to repair clusters that do not match in place, but they do not occur to repair clusters that do not match in voicing (see Baković 2000; Lombardi 2001). The account of nasal place assimilation in Spanish [tampoko] 'neither' in (36) and (37) is adapted from Shepherd (2003).

(36) CODA CONDITION
A coda cannot license place features.

(37) *Nasal place assimilation in Spanish*

/taN.po.ko/	CODACOND	IDENT-ONSET(Place)	IDENT(Place)
a. tan.po.ko	*!		
☞ b. tam.po.ko			*
c. tan.to.ko		*!	*

Note that in the tableaux above, there is no specific reference to feature geometry or a Place node. In keeping with a general move away from solutions based in representations and rules, the sets of features targeted for assimilation are defined within the content of the constraints, not in terms of a universal hierarchical structure that must be made to work for all cases. Padgett (1995) specifically argues against a Place node in feature geometry, proposing instead that constraints that target defined sets of features better account for partial place assimilations.

In conclusion, it may be said that questions of representation encapsulate the debates that continue over the linguistic nature of local assimilation. Phonologists are working toward finding the representation that will capture crucial cross-linguistic generalizations about assimilation in the simplest and most straightforward form, while accounting for the details of individual datasets. Debates continue over defining the features and feature classes that are active in assimilation, and whether the definition of classes should be representational or set-theoretic. It remains a question whether structural or perceptual approaches to directional asymmetries best account for the range of cross-linguistic data. Another important question is whether assimilation is featural at all: should local assimilation be defined in terms of manipulation of phonological features, in terms of articulatory organization, or in some other way? Accounting for both gradience and variability on the one hand and systematic category change on the other continues to be a challenge. Finally, theories of the phonology–morphology interface, the phonetics–phonology interface, and, most generally, theories of the overall structure and architecture of the phonological grammar continue to reference processes of local assimilation. Certainly local assimilation, the most common phonological alternation, will continue to play a central role in phonological theorizing.

ACKNOWLEDGMENT

The outline of the argument in this chapter follows that of the briefer treatment of the same subject in Zsiga (2006).

Volume I: General Issues and Segmental Phonology

Volume II: Suprasegmental and Prosodic Phonology

Volume III: Phonological Processes

Volume IV: Phonological Interfaces

Volume V: Phonology across Languages

The Blackwell Companion to Phonology is a major reference work drawing together 124 new contributions from leading scholars in the field. Led by a team of renowned international scholars, the *Companion* represents a diverse range of approaches and methodologies to key phenomena in phonological research. In contrast to other handbooks and reference works currently available for phonology, these volumes focus on phenomena and case studies that highlight past and ongoing debates in the field. Interdisciplinary connections, such as those with the social and computational sciences, are covered, as well as statistical and experimental techniques. The *Companion* will be a touchstone for future phonological theorists, giving an overview of data and insights which any theory of phonology should be able to cover.

Simultaneously offering broad coverage and a high level of detail, *The Blackwell Companion to Phonology* is a landmark work available in both print and online editions that will be indispensable to students and researchers in the field for years to come.

82 Featural Affixes

Akinbiyi Akinlabi

1 Characteristics of featural affixes

Featural affixes are phonological features that function as grammatical morphemes. The most commonly found cases are tonal (Akinlabi 1996). An example is the associative marker in Bini (Amayo 1976), exemplified in (1). (The forms before the arrow indicate the isolation forms of the nouns and the forms after the arrow are associative constructions. For clarity, the tones in the examples in (1) are indicated with both tone marks and the letters L, H for Low, High respectively. ↓ indicates a downstepped tone on the following vowel.)

(1) *Bini* (Amayo 1976)

```
òwɛ̀     ɔ̀sà        →  òwɛ́ ɔ̀sà    [òwɔ́↓sà]
| |     | |            | | | |
L L     L L            L H L L    'a chimpanzee's leg'
leg     chimpanzee

àmɛ̀     èhj̃ɛ̃́        →  àmɛ́ èhj̃ɛ̃́    [àmé↓hj̃ɛ̃́]
| |     | |            | | | |
L L     L H            L H L H    'solution of water and pepper'
water   pepper

òwɛ̀     ɔ̀nà        →  òwɛ́ ɔ̀nà    [òwɔ́↓nà]
| |     | |            | | | |
L L     L L            L H L L    'this one's leg'
leg     this one
```

However, several cases of non-tonal features functioning as grammatical morphemes have also been described in the literature. A representative list is given in (2).[1]

[1] See the references cited here for additional examples. Reviewers have pointed out a number of other examples which might have been included here. Two of them are: (a) in Coatzospan, the 2nd person familiar is marked by nasality (Gerfen 1999: 127), and (b) in Shuswap, glottalization is a floating feature (Kuipers 1974; Idsardi 1992). The list in (2) is not intended to be exhaustive.

(2) *Non-tonal examples of featural morphemes*

a. In Chaha, the 3rd masculine object is indicated by labialization. (Johnson 1975; McCarthy 1983; Hendricks 1989; Archangeli and Pulleyblank 1994; Rose 1994, 2007)

b. Nuer indicates tense/aspect distinctions with the features [continuant] and [voice]. (Crazzolara 1933; Lieber 1987; Frank 1999)

c. In Zoque, the 3rd person singular is marked by palatalization. (Wonderly 1951)

d. [nasal] is the 1st person possessive marker in Terena. (Bendor-Samuel 1960, 1966)

e. The feature of "uncontrolledness" is signaled by palatalization in Japanese. (Hamano 1986; Mester and Itô 1989; Archangeli and Pulleyblank 1994; Alderete and Kochetov 2009)

f. Noun class 5 is marked by voicing the first consonant of the root in Aka (Bantu, Zone C). (Kosseke and Sitamon 1993; Roberts 1994)

g. Noun class morphemes in Fula include the features [continuant] and [nasal]. (Arnott 1970; Lieber 1984, 1987)

h. The Athapaskan D-classifier consists solely of the feature [–continuant]. (Rice 1987)

i. In Seereer Siin, an Atlantic (Niger Congo) language, consonant mutation (involving the features [voice] and [continuant]) constitute all or part of the noun class prefix in nouns and dependent adjectives, and number in verbs. (Mc Laughlin 2000, 2005)

j. In Mafa, a central Chadic language of Cameroon, imperfectives of verbs ending in a consonant are formed with a palatal featural affix. (Ettlinger 2003, 2004)

The features in (2), like segmental morphemes, often refer to specific edges of stems, and thus are featural affixes (e.g. Chaha labialization and palatalization, Aka voicing, Zoque palatalization). While the fact that phonological features may function as grammatical morphemes is uncontroversial, the status of such features as prefixes or suffixes often remained muted in spite of traditional intuition, with some scholars contented with referring to the morphemes simply as "floating autosegments."[2] The reason why the status of featural affixes as prefixes or suffixes is often problematic is that, while segmental affixes may be phonetically realized independently, featural affixes are always phonetically realized as part of some other segment or segments of the stem. The question therefore is why featural affixes get realized as part of the stem. The answer to this is that features have to be "licensed" (i.e. their occurrences have to be sanctioned) in order to get phonetically realized, therefore featural affixes must associate with a licensor in the stem or elsewhere.

[2] Most studies on tone are exceptions to this generalization (see Clements and Goldsmith 1984; Pulleyblank 1986; Anderson 1991; van der Hulst and Snider 1993).

In this chapter I am assuming a feature geometry in which all segments have a root node, which "gathers" the features into one unit (CHAPTER 27: THE ORGANIZATION OF FEATURES). In addition, I assume that vowels (and all syllable peaks, including syllabic nasals) are dominated by a mora (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE). Finally, I assume that class nodes, such as those for place of articulation, are monovalent. However, terminal features, such as aperture features, are bivalent. Since this chapter has a constraint-based, optimality-theoretic bias, I will not be assuming underspecification here (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION).

Universally, feature licensors can (only) be either a mora or a root node (Itô 1989; Itô and Mester 1993; etc.). Therefore, while edges in tones refer to the initial or final mora, edges in nasal harmony and the like may refer to the first or last root node; i.e. a real morphological edge, since the last licensor also coincides with the last segment of the morpheme (see Archangeli and Pulleyblank 1994).[3] But, with featural affixes, an edge does not necessarily mean a morphological edge; an edge is defined for a feature on the basis of a possible licensor in a language.

Another characteristic of featural affixes, as distinct from segmental affixes, is their domain. While most segmental affixes occur at the beginning, middle, or end of a base, featural affixes often occur throughout the base, or span it. Features that commonly have this characteristic are the "prosodic" features, in the Firthian sense of the word. As is well known, such features may include pitch, nasality, roundness, palatalization, and the like (see Firth 1948). Since these are the featural spell-out (or content) of the morphological categories in question, they are featural affixes.

In their study of alignment in (regular) segmental affixation, McCarthy and Prince (1993b: 103) observe that an alignment constraint, such as one that aligns the left edge of one morpheme with the right edge of another (as in Tagalog *-um-* prefixation) may be violated when dominated by a prosodic constraint, such as one that disallows a coda. This may force a prefix to be realized as an infix. The Tagalog affix *-um-* "falls as near as possible to the left edge of the stem, so long as it obeys the phonological requirement that its final consonant *m* not be syllabified as a coda" (McCarthy and Prince 1993b: 79). Therefore, it appears as a prefix before a vowel-initial word: /um + aral/ → [um-aral] 'teach', but as an infix when the word is consonant-initial: /um + sulat/ → [s-um-ulat] 'write', /um + gradwet/ → [gr-um-adwet] 'graduate'.

A similar characteristic is found in featural affixes. One important distinction from segmental prefixes/suffixes is that featural affixes often behave like "infixes," because they frequently do not occur at an edge of the stem. A feature may be forced away from an edge when the feature cannot co-occur with another feature(s) of the segment at the edge (see Pulleyblank 1993), leading to

[3] It should be noted that the accounts in this chapter allow for affixes which involve more than one autosegmental feature, though we do not discuss such cases here. For example, in Mokulu (Eastern Chadic, Chad Republic) the completive aspect marker consists of the features [voice] and [high] (Jungraithmayr 1990; Roberts 1994). The first consonant of the stem becomes voiced while the first vowel becomes high, even if it was a low vowel in the input. In the approach taken here, both features constitute parts of a featural prefix. However, such features may be realized on the same segment in the stem or on different segments, depending on licensing. In the case in question, licensing forces [voice] and [high] on different segments.

misalignment. A featural suffix may for example be realized elsewhere in the stem, resulting in featural infixation. However, featural affixes occur as "infixes" more often than segmental affixes.

Finally, one characteristic that has recently been observed in featural affixation is one in which a grammatical category is marked by a feature which has both segmental and featural allomorphs, as in Mafa (Ettlinger 2003, 2004).

In the following sections I illustrate each of the above characteristics of featural affixes. Each case study discussed below has been selected because it illustrates a particular characteristic or characteristics of featural affixes.

In the discussion of Chaha (§2.1), I show that a featural suffix [round] is realized as a featural infix, or even as a featural prefix, when the featural suffix is forced away from the edge. The opposite effect is illustrated with Nuer mutation (§2.3).

Tonal data from Etsako, an Edoid language, and nasalization data from Terena show situations in which featural morphemes span the entire base of affixation. In the discussions of Terena nasalization and the Etsako tone, I suggest that these are still cases of prefixation and suffixation respectively, but in conjunction with harmony. Therefore there are no special treatments of featural affixes required.

Mc Laughlin (2000, 2005) notes that, taking into consideration featural affixes, a morphological category can be expressed in one of three ways: as a segmental affix, as a featural affix, or as a combination of both segmental and featural affixes (CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE).

In summary, the primary focus in this chapter will be illustrating the characteristics of featural affixes. To do this, I will provide short descriptions of several of the featural affixes listed in (2). The characteristics include (a) marking morphological categories (like segmental affixes), (b) occurring as part of other segments rather than independently, (c) varying between prefixes and suffixes, (d) occurring elsewhere in the stem (because of feature co-occurrence constraints), (e) spanning the entire base of affixation, and (f) varying occurrence as a feature or a segment in the same language. I will argue that these characteristics of featural affixes do not require any new type of morphology, because the same machinery already developed for segmental affixes can handle them as well.

I discuss seven case studies in all, divided into four groups. The first group, Chaha and Zoque, illustrates the most basic characteristics of featural affixes mentioned above, that of directionality. Chaha illustrates suffixation and Zoque shows prefixation. The second group, Nuer and Seereer Siin, combines featural affixes with consonant mutation. Nuer is suffixal, and Seereer Siin is prefixal. The third group, Etsako and Terena, shows featural affixes that span the whole stem domain. They illustrate featural affixation combined with "harmony." Again, Etsako shows the harmony from the right (suffixal), and Terena shows it from the left (prefixal). The fourth group contains only one language, Mafa. Mafa shows a special case of affixation, in that the segment involved is at the same time a segment and a feature. I refer to this as segmental realization of a featural affix.

2 Directionality

The first case studies illustrate the need to consider featural morphemes as either prefixes or suffixes, a property that is formally accounted for by the directional component of alignment. In this light, Chaha illustrates prefixation, and Zoque illustrates suffixation.

2.1 Chaha labialization

In Chaha, a Gurage language of Ethiopia, the 3rd person masculine singular object is indicated by labialization (with the suffix /n/) (Johnson 1975; McCarthy 1983; Hendricks 1989; Archangeli and Pulleyblank 1994; Rose 1994, 2007). Labialization surfaces on the "rightmost labializable consonant" of the stem. Labializable consonants in Chaha include labial and dorsal consonants, but not coronal consonants.[4] The data in (3) (from McCarthy 1983: 179) show the surface realization of this morpheme.

(3)		without object	with 3rd masc sg object	
	a.	*Rightmost consonant of the stem is labializable*		
		dænæg	dænæg^w	'hit'
		nædæf	nædæf^w	'sting'
		nækæb	nækæb^w	'find'
	b.	*Medial consonant of the stem is labializable, final is not*		
		nækæs	næk^{w}æs	'bite'
		kæfæt	kæf^{w}æt	'open'
		bækær	bæk^{w}ær	'lack'
	c.	*Only the leftmost consonant of the stem is labializable*		
		qætær	q^{w}ætær	'kill'
		mæsær	m^{w}æsær	'seem'
		mæk^{j}ær	m^{w}æk^{j}ær	'burn'
	d.	*No labializable consonant*		
		sædæd	sædæd	'chase'

A number of observations are important here. Labialization must be realized only on the rightmost labializable consonant, and on no other. This is obvious from the third example in (3a), /nækæb/ → /nækæb^w/. Both of the last two consonants of the verb root in this example are labializable, but only the root-final consonant is labialized. The medial consonant is not labialized, because of this requirement of rightmostness. In the forms in (3b), all of the final consonants of the verb roots are coronal, e.g. /nækæs/, therefore only the root-medial consonants, which are either labial or dorsal, are rightmost; and so only these receive the labialization feature. Note further that the initial consonants in the last two examples, /kæfæt/ and /bækær/, are labializable, but again are not labialized, because of the requirement of rightmostness. In (3c) the only labializable consonants of the verb root are the leftmost consonants, /qætær/ → /q^{w}ætær/, and so by rightmostness they receive labialization. Finally, in (3d) none of the consonants is labializable and so the feature is not realized.

An explanation of the above facts is as follows. Following earlier analyses we assume that the 3rd person masculine singular object marker in Chaha is

[4] This statement is from McCarthy. Rose (2007) states the labialization rule as "labialize the rightmost velar or labial consonant, unless already palatalized." The key point in both definitions is that labialization targets dorsal and labial consonants.

the feature [round]. It must be a featural suffix, as indicated by the insistence on rightmostness. The 3rd person masculine singular object [round] aligns with (or coincides with; Zoll 1996) the right edge of the stem. In Chaha, [round] may be licensed by any consonantal root node. The position explicitly treats the morpheme as a suffix, but the segmental content is a feature [round], hence what the constraint aligns is the feature [round]. The right edge of the stem has to coincide with the feature [round], the featural content of the affix. Thus the feature [round] seeks out the rightmost consonantal root node in the verb root for licensing, given the discussion of licensing and edges above. As noted in our description of the facts, coronal consonants cannot receive the labialization feature. This means that the feature [round] cannot be articulated with a coronal consonant in Chaha. We can bar this with a feature co-occurrence constraint, which forbids [round] from linking to a root node associated to [coronal].

To conclude, there are several characteristics of featural affixes, which this affix illustrates. First, it marks a morphological category, the 3rd person masculine singular object. Second, the realization is a feature, the feature [round]. Third, it must be realized as part of another segment, a consonant, because it is not a segment. Fourth, like any affix, it has a position. However, like a featural affix it seeks the rightmost dorsal or labial consonant for licensing. Therefore it is a suffix. Fifth, like segmental affixes, it can be pushed from the suffix position. As it is a featural affix, however, co-occurring with other features is what matters. It cannot co-occur with a coronal consonant; therefore it gets pushed more and more inwards until it finds the right consonant to co-occur with. Sixth, if it does not find the right licensor, it simply does not get realized. This is comparable with the null realization of certain segmental morphemes in language, as for example where a segmental affix is not realized for some phonotactic reason. One example is Dutch, which does not have geminate consonants. Here the 3rd person singular ending [-t] is not realized on verbs which end in a coronal plosive.[5]

(4) *Dutch 3rd person suffix* [-t] *absent after verb-final* [t]

a.	*ik lees*	[ɪk les]		'I read'
	hij leest	[hɛi lest]		'he reads'
b.	*ik zie*	[ɪk zi]		'I see'
	hij ziet	[hɛi zit]		'he sees'
c.	*ik eet*	[ɪk et]		'I eat'
	hij eet	[hɛi et]	*[etː]	'he eats'

2.2 *Zoque palatalization*

In this section, I consider the process of morphological palatalization in Zoque (Zoque-Mixe of southern Mexico). Zoque palatalization contrasts with Chaha labialization (§2.1) in some crucial senses. First, while Chaha labialization illustrates a case of long-distance realization of an affix, Zoque palatalization illustrates local realization; i.e. the affix must be realized at the edge, and nowhere else (Akinlabi 1996). Second, Zoque differs from Chaha in the sense that the featural affix is a prefix as opposed to a suffix.

[5] I am grateful to Marc van Oostendorp for this example from Dutch.

Wonderly (1951: 117–118) describes a process of palatalization (CHAPTER 71: PALATALIZATION) in Zoque, which marks the 3rd person singular. He represents this morpheme as a prefix [j],[6] and treats this process of palatalization as "metathesis" of [j] and the following consonant. A rule-based treatment assuming metathesis is proposed in Dell (1980). The relevant examples are listed in (5), with the morpheme transcribed as [j], following Wonderly.[7] My interpretation here is that Wonderly's [j] is a palatal feature, which I will assume is [−back].

(5) *Zoque 3rd person singular*

a.	*With labial consonants*			
	j - pata	pʲata		'his mat'
	j - pʲesa	pʲesa		'his room'
	j - buro	bʲuro		'his burro'
	j - faha	fʲaha		'his belt'
	j - mula	mʲula		'his mule'
	j - wʲakas	wʲakas		'his cow'
b.	*With alveolar consonants*			
	j - tatah	tʲatah	[catah]	'his father'
	j - tih	nʌ tʲihu	[nʌ cihu]	'he is arriving'
	j - duratsʌhk	nʌ dʲuratsʌhku	[nʌ ʤuratsʌhku]	'it is lasting'
	j - tsʌhk	tsʲahku	[ʧahku]	'he did it'
	j - sʌk	sʲʌk	[ʃʌk]	'his beans'
	j - swerte	ʃwerte	[ʃwerte]	'his fortune'
	j - nanah	nʲanah	[ɲanah]	'his mother'
c.	*With palatal consonants (no change)*			
	j - ʧoʔngoja	ʧoʔngoja		'his rabbit'
	j - ʃapun	ʃapun		'his soap'
d.	*With velar consonants*			
	j - kama	kʲama		'his cornfield'
	j - gaju	gʲaju		'his rooster'
e.	*With laryngeal consonants*			
	j - ˀatsi	ˀʲatsi		'his older brother'
	j - hajah	hʲajah		'her husband'
	j - huj	hʲuju		'he bought it'

All words in Zoque are consonant-initial. The data in (5) show that the 3rd person singular morpheme produces secondary palatalization of the first consonant of the stem if it is labial (5a), velar (5d), or laryngeal (5e); it turns alveolars into

[6] Wonderly used the symbol /y/. I have re-transcribed Wonderly's examples to be as close as possible to the IPA.

[7] The transcription here (from Wonderly 1951) is somewhat misleading, because one can be led to believe that the morpheme here is indeed /j-/, and not a feature. However, if this were a full segment as opposed to a feature, it would be completely unnecessary for the segment to seek licensing from another segment. It would also be completely accidental that metathesis is limited to glide-consonant sequences in this language. Note that this cannot be blamed on the sonority rise in an onset (i.e. [jC] → [Cj]), because the so-called metathesis also occurs in a sequence of two glides (which in many accounts are equal in sonority): /j - wakas/ → /wʲakas/ 'his cow'.

alveopalatals in (5b), and has no phonetic effect on underlying palatals (5c). As Wonderly (1951: 118) puts it, "when y [i.e. /j/] precedes an alveopalatal consonant č, š, the y is lost." In this analysis we assume that the morpheme is not "lost," but that it has no phonetic effect if the initial consonant of the stem is palatal.

I assume that the 3rd person singular in the above data is the feature [−back] (see Sagey 1986). [−back] is licensed by any root node in Zoque. It is apparently a featural prefix, given its restriction to the first (or leftmost) consonant.

The palatalization case in Zoque is completely straightforward. All consonants participate in the palatalization, regardless of place of articulation. For example, labials are not barred from being palatalized, as coronals are barred from being labialized in Chaha.

The only set of consonants that require additional comment is the set of palatal consonants, as seen in (5c) (/[−back]-ʃapun/ → [ʃapun] 'his soap'). There are two approaches to this set of consonants. One is to assume that the [−back] 3rd singular morpheme is unparsed when the first segment is underlyingly palatal. The second approach is to assume that [−back] links vacuously to a palatal segment. I adopt the second position here, since linking [−back] to a palatal consonant will not change the consonant's realization. If palatal consonants are assumed to have underlying tokens of [−back], then linking the morpheme in this case simply implies that the [−back] specification in the surface representation corresponds to two tokens of the same feature in the input. Phonetically, it will be impossible to distinguish one or two tokens of the same feature.

In conclusion, Zoque provides evidence for featural affixes which must be realized, and which must be realized at an edge and nowhere else. In Chaha, a co-occurrence constraint forces a featural affix away from the edge. In Zoque, such co-occurrence constraints (which must be universal) have no surface effect. In Chaha, a featural affix may not be realized if none of the segments can license it. In Zoque, the affix can be licensed by all consonants, and so it is always realized.[8]

In the two case studies of featural affixes discussed above, one is a suffix (Chaha [round] or Labial), and the other is a prefix (Zoque [−back] or Coronal). Both of these involve only features. I now turn to cases in which the affix has both segmental and featural content.

3 Features plus segments: Segment mutations

Systematic alternation in homorganic segment classes that reflect morphological distinction is often called mutation (CHAPTER 65: CONSONANT MUTATION; CHAPTER 117: CELTIC MUTATIONS). The second group of case studies consists of languages which combine featural affixes with consonant mutation.

[8] There are two important issues here. First, there is a technical complication for feature geometry. If [−back] is dependent on some supralaryngeal node, and if laryngeal consonants have no supralaryngeal specification, then what does [−back] dock on? A possible explanation is that the addition of [−back] automatically generates a place node. The second issue is whether palatalized sounds occur outside of the contexts described here. If they do, it will confirm that these are not clusters, but single segments. Wonderly is silent on this question.

What is interesting about these cases is that languages with consonant mutations often combine both featural and segmental affixation. That is, the featural affix may occur by itself or with additional segments. In this section, we examine two cases, Nuer and Seereer Siin. Nuer is suffixal and Seerer Siin is prefixal.

3.1 Nuer mutation

The consonant mutation process of Nuer, a Nilo-Saharan language of Sudan, presents an interesting contrast to Chaha, in that the featural suffix must be realized at the very right edge of the verb stem rather than anywhere else in the stem. If the featural suffix cannot be realized on the last consonant of the stem due to a co-occurrence constraint, it is simply not realized at all (see Chaha palatal prosody). But our interest in Nuer mutation is that the suffixes do not just consist of features, but of segments and features.

In the Nuer verb roots, final consonant mutation is associated with various tenses and aspects in the verbal paradigms, as the following examples illustrate. The alternation is only productive in verbs and not in nouns. (All data presented here are from Crazzolara 1933: 156–160; see Frank 1999 for more details on Nuer morphology.) Rule (6) summarizes the observed consonant alternations and (7) provides examples. In the following examples each place of articulation is represented by two verb paradigms. I have converted Crazzolara's representations to IPA, following his descriptions.

(6) *Nuer final consonant alternation* (Crazzolara 1933; Lieber 1987)[9]

	labial	interdental	alveolar	palatal	velar
voiced	b	ð	d	ɟ	ɣ
voiceless continuant	f	θ	r̥	ç	h
voiceless stop	p	t̪	t	c	k

(7) *Verbal paradigms*[10]

a.	*Labial final verbs*	'to overtake a person'	'to scoop (food) hastily'
	3rd sg indic pres act	cóbɛ́jɛ̈	kɛ́bɛ́ jɛ̈
	1st pl indic pres act	cɔ̀ɔfkɔ̀ jɛ	kɛ̀afkɔ̀ jɛ
	pres pple neg	cɔ̀p	kɛp
	past pple	cof	kɛ̀f

9 Following Crazzolara's descriptions, his transcriptions have been modified as follows. [dh] and [th] (interdental) are transcribed here as [ð] and [θ] respectively. [ṛ] (a trilled alveolar continuant) is [r̥]. Finally, [y] (palatal fricative) is retranscribed as [ɟ]. Cazzolara suggests that what he writes as [b] is actually the continuant [β] in final position (Crazzolara 1933: 6). One can imagine that the same is true for what he writes as [d], since he notes that Nuer stems can have up to three forms, one ending with a voiceless stop, one with a voiceless continuant, and the third with a voiced sound which in most cases is a continuant.

10 I will not discuss the vocalic changes, since they are largely unpredictable from Crazzolara's transcriptions.

b.	*Interdental final verbs*	'to suck'	'to wade'
	3rd sg indic pres act	lóðɛ̀ jɛ̀	jǽðɛ́ jɛ̀
	1st pl indic pres act	loɔ̀θkɔ̀ jɛ	jǽθkɔ̀ jɛ
	pres pple neg	lot̪	jæt̪
	past pple	loθ	jæθ
c.	*Alveolar final verbs*	'to sharpen'	'to cut a point'
	3rd sg indic pres act	paádɛ̀ jɛ́	wɨ́lɛ́ jɛ̀
	1st pl indic pres act	páar̥kɔ́ jɛ̀	wər̥kɔ̀ jɛ
	pres pple neg	paat	wɨt
	past pple	pàar̥	wɨr̥
d.	*Palatal final verbs*	'to hit'	'to dismiss a person'
	3rd sg indic pres act	jáaʝɛ̀ jɛ	ɟjéeʝɛ̀ jɛ
	1st pl indic pres act	jáaçkɔ́ jɛ̀	ɟjáaçkɔ́ jɛ̀
	pres pple neg	jaac	ɟjèec
	past pple	jaaç	ɟjeeç
e.	*Velar final verbs*	'to throw away'	'to find'
	3rd sg indic pres act	ɟǽɣɛ́ jɛ̀	jə́ɣɛ́ jɛ̀
	1st pl indic pres act	ɟæ̀kɔ̀ jɛ	jəkɔ̀ jɛ
	pres pple neg	ɟæk	jɔk
	past pple	ɟæh	jəh

First, Crazzolara (1933: 102) notes that the verb root is monosyllabic in Nuer. Second, all verbs begin and end in consonants. I assume, following Lieber (1987), that the features implicated here are [continuant] and [voice]. I will also assume that the morphemes involved in the mutation consist of the following inputs.[11]

(8) *The Nuer suffixes*

indic pres act	=	[jɛ]
3rd sg	=	[cont] [ɛ]
1st pl	=	[cont] [kɔ]
pres pple neg	=	Ø
past pple	=	[cont]

The most important illustration of the theme of this section is the past participle morpheme, which under any analysis must include the feature [continuant], and the 1st plural morpheme, which, in addition to the feature [continuant], also includes the segment sequence [kɔ]. A comparison of all the past participle forms with the 1st plural indicative present active forms shows that the latter always include the additional [kɔ]. What is interesting is that the suffix [kɔ] also triggers spirantization of the preceding stop.[12] Therefore we must assume that this suffix has a preceding floating [continuant]. Finally, we must assume that Nuer also has intervocalic voicing, as seen in all the 3rd singular forms.

[11] But see Lieber (1987) for a different assumption on input.

[12] In the case of the forms 'throw away' and 'find', there is no spirantization. I assume that this is because the final consonant of the verb and the 1st plural suffix [kɔ] are identical. Crazzolara apparently transcribes the unspirantized sequence [hk] as a single stop [k].

It is clear from the mutation cases in Nuer that the features involved are suffixes, since in two cases the free feature [continuant] is paired with traditional segmental suffixes. In the case of the past participle morpheme, the entire content of the morpheme is the free feature [continuant]. [continuant] is licensed by a root node in Nuer. This feature links to the rightmost consonant of the verb. This association formally defines the past participle morpheme in Nuer as a suffix. This morpheme happens to have just a single featural content [continuant].

The derivation of all the forms with the past participle suffix [continuant] is the same as that of the 1st plural forms, except for the additional segments [kɔ] in the suffix. This example actually shows that if we call the segments [kɔ] a suffix, we must treat the preceding [continuant] the same way, since they, together, mark the same morpheme. And if this feature [continuant] of the 1st plural is a suffix, so is the feature [continuant] that marks the past participle alone.

Crazzolara notes that a number of segments do not undergo this mutation process in Nuer. These segments are the nasals /m n n̪ ɲ ŋ/, the liquids /l r/, and glide /w/. I will split these segments into two groups, the nasals on the one hand and the liquids and glide on the other.

I suggest that the nasals do not undergo mutation because of a co-occurrence constraint forbidding the association of [continuant] to a consonant specified for [nasal]. The examples in (9) illustrate this.

(9) *Non-alternating final consonant*

	'to see'[13]	'to hear'
3rd sg indic pres act	nɛ́ɛnɛ̈̀ jɛ	lḭ̈ŋɛ́ jɛ̂
1st pl indic pres act	nɛ́ɛ̈ankɔ́ jɛ̈̀	lie̤ŋkɔ̂ jɛ
pres pple neg	nɛ̂ɛn	liŋ
past pple	nɛ̂ɛn	liŋ

Since morphemes with final nasals never alternate, and since [continuant] does not show up anywhere else, we must assume that in these cases [continuant] must remain unrealized (i.e. unparsed). This is parallel to the case of the non-realization of [round] in Chaha.

I assume that the remaining sonorants, liquids, and glide undergo the process, though the surface forms appear invariant; i.e. [continuant] links vacuously to stems whose final consonants belong to this class, but without any apparent surface effect, since they are already continuants.[14]

In conclusion, [continuant] in Nuer provides a significant contrast to labialization in Chaha and palatalization in Zoque. In both Chaha and Nuer, the featural affix is a suffix, given the insistence on linkage to the final consonant. In both languages, the featural content of the affix cannot co-occur with a class of segments.

[13] Crazzolara (1933: 124) points out that there is a separate negative particle /ci/, which occurs before the subject clitic. Forms with nasals are the only complete paradigms that Crazzolara gives, and in these cases he provides no forms in which the first consonant is an oral stop and the second is a nasal. In all the other forms where the stem consonant does not alternate he provides the 3rd singular indicative present active and the 1st plural indicative present active for the rest of the cases.

[14] This implies that a single [continuant] specification on the final consonant on the surface corresponds to two in the input. See also the discussions of Zoque palatalization (§2.2) and Edoid tone (§4.1) for similar characteristics.

This results in the non-realization of the featural suffix on the final segment. This fact is captured by the co-occurrence constraints between the feature content of the affix and the feature content of the class of segments. Thus it is co-occurrence constraints that force featural affixes from edges. The substantive difference between the two languages is seen in Chaha's insistence on realizing the featural suffix on other segments even if it cannot be realized on the edgemost segment, while Nuer will not realize the featural suffix at all.

It is important to note that other languages with consonant mutation have been identified in the literature, e.g. Fula (Arnott 1970) and North Atlantic languages (Mc Laughlin 2000, 2005), which confirm the above analysis of Nuer mutation. These languages also differ significantly from Nuer. I will briefly discuss the case of one, Seereer Siin (Mc Laughlin 2000).

3.2 *Seereer Siin consonant mutation*

In her work on several Northern Atlantic languages of Niger Congo (Pulaar, Seereer Siin, Wolof), Mc Laughlin (2000, 2005) argues that *consonant mutation* can be viewed and accounted for as the prefixation of a floating feature to the root node of the stem-initial consonant.[15] She proposes a constraint-based account to locate the feature on the left edge of a word.

Seereer Siin consonant mutation is morphologically conditioned by *noun class* in nouns and dependent adjectives, and by number in verbs. There are two patterns of consonant mutation in Seereer: (a) voicing mutation, and (b) continuancy mutation. In each, there is a three-way homorganic range of alternations, called *grades* (Arnott 1970). I will only discuss the voicing mutation, and I will discuss only the fully mutating forms. The reader is referred to Mc Laughlin's work for the partially mutating forms, and the continuancy mutation.

In the voicing mutation, the three grades are "voiced stop," "voiceless stop," and "prenasalized voiced stop." Grade-a refers to the voiced set, grade-b to the voiceless set, and grade-c to the prenasalized set.

Seereer Siin has sixteen noun classes. Of the sixteen, classes 2, 3a, 5, 7, 8, and 10 condition the a-grade mutation, while classes 3b, 6, 12, 13, and 14 condition the c-grade mutation. The remaining classes (1, 4, 9, 11, and 15) condition the b-grade mutation.

I will now illustrate the above statements with the examples in (10), from Mc Laughlin (2000: 339–340). The numbers in parenthesis beside the forms indicate the noun classes of the forms.

(10) *Voicing mutation* (fully mutating)

voiced	*voiceless*	*nasal*[16]	
a-grade	b-grade	c-grade	
ogac (10)	akac (4)	foŋgac (13)	'stone'
ɟir (5)	acir (4)	aɲɟir (3b)	'illness'
oɓaj (10)	xaƥaj (11)	foƥaj (13)	'hand, arm'

[15] For reasons of space, only a brief summary of the facts of Seereer Siin is given here.

[16] Voiceless implosives cannot be prenasalized in Seereer Siin.

I follow Mc Laughlin in assuming that the b-grade forms constitute the "underlying" forms in the stems with voicing mutation. The stem patterns show that the features involved in the class prefixation are [+voice] and [+nasal]. [+voice] drives the voicing of underlying voiceless-initial stems, which are fully mutating. In addition, one must conclude that the class 10 prefix has both segmental and featural contents: /o [+voiced]/, as Mc Laughlin does. Finally, class 13 also has both segmental and featural contents: /fo [+nasal]/. "There is a [+voice] floating feature that drives the a-grade mutations . . . and there is a [+nasal] floating feature that drives the c-grade mutations" (Mc Laughlin 2000: 340).

Comparing the Seereer Siin forms with those from Nuer, the mutating consonants in Seereer Siin are the stem-initial consonants. The mutating features [+voiced] and [+nasal] are prefixes. They must link to the stem-initial consonant and no other. In Nuer on the other hand, the mutating feature is a suffix. The system in Seereer Siin sometimes includes featural affixes alone, and sometimes featural affixes as well as segmental affixes. As seen above, the class 10 prefix includes both segmental and featural content: /o [+voiced]/, and the class 13 prefix also has both segmental and featural content: /fo [+nasal]/. These combinations are in fact more apparent than the Nuer combinations. The segmental features causing the mutation either get associated or not, and are never pushed inwards in the stem. They only occur at the edges.

4 Harmony: Featural affixes with stem domains

The third set of case studies consists of languages that combine featural affixes with featural harmony. By "harmony," I mean featural propagation that is domain-based.

The domain of a featural affix is often the entire stem. By definition, we must take these features to be affixes, since they are the featural spell-out of some morphological category. Since the domain of the featural affix is the entire stem, I take the phenomenon to be the combination of a featural prefix or suffix, plus harmony involving the feature in question. I will illustrate with two languages. I will discuss one case involving a featural suffix (Edoid tone), and one involving a featural prefix (Terena nasalization).

4.1 Edoid associative construction

Tonal data from Edoid languages (Niger Congo, Nigeria) provide the first example of featural suffixation plus harmony. Suffixation is detectable from the fact that priority is given to right alignment, and harmony is seen in the transmission of the feature throughout the entire domain.

In several Edoid languages the "associative morpheme" is a free (floating) High tone. The list includes Etsako (Elimelech 1976), Yekhee (Elugbe 1989), Bini (Amayo 1976), Isoko (Donwa 1982), and Emai (Egbokhare 1990). In this section I will only examine Etsako (Ekpheli dialect). Several other Edoid languages have similar tonal systems to that of Etsako.

Etsako is a two-tone language, with High and Low tones (Elimelech 1976: 41). (Recall that full specification is assumed in this chapter.) In this language, the associative High tone links to the head noun, replacing all Low tones in a right-to-left manner, until it reaches a segmental High tone. The examples below consist of disyllabic nouns, but they are representative of what happens in longer forms. The forms cited here (from Elimelech 1976: 55) exhaust all possible tonal combinations of disyllabic nouns. The tones in the first row in each of (11)-(14) indicate the underlying tone pattern of the head noun in isolation, and the corresponding tones after the arrow indicate its tone pattern in an associative construction. For clarity, I have indicated the tonal pattern of the first example in each set with the tone letters H and L, in addition to the tone marks. The crucial tones to focus on are those of the first noun, since the tones of the second noun remain constant.

(11)		L			H	
	a.	àmɛ̀	èθà	→	ámɛ́èθà	[ámɛ̂θà]
		L (H)	L		H L	
		water	father			'father's water'
	b.	àmɛ̀	òké	→	ámɛ́òké	[ámɔ̂kê][17]
		water	ram			'a ram's water'
	c.	ámɛ̀	ɔ́mɔ̀	→	àmɛ́ɔ́mɔ̀	[ámɔ́mɔ̀]
		water	child			'a child's water'
	d.	àmɛ̀	ɔ́dzi	→	ámɛ́ɔ́dzi	[ámɔ́dʒi]
		water	crab			'a crab's water'

(12)		H L			H(H)	
	a.	únɔ̀	èθà	→	únɔ́èθà	[únêθà]
		H L (H)	L		H L	
		mouth	father			'father's mouth'
	b.	únɔ̀	òké	→	únɔ́òké	[únɔ́kê]
		mouth	ram			'a ram's mouth'
	c.	únɔ̀	ɔ́mɔ̀	→	únɔ́ɔ́mɔ̀	[únɔ́mɔ̀]
		mouth	child			'a child's mouth'
	d.	únɔ̀	ɔ́dzí	→	únɔ́ɔ́dzí	[únɔ́dʒî]
		mouth	crab			'a crab's mouth'

[17] At the phrasal level, a phrase-final High tone is realized as a fall, hence the final falling tones in forms with underlying final Highs such as (11b), (11d), etc.

(13)		H			H	
	a.	ódzí	èθà	→	ódzíèθà	[ódʒêθà]
		\/	\/		\/ \/	
		H (H)	L		H L	
		crab	father			'father's crab'
	b.	ódzí	òké	→	ódzíòké	[ódʒôkê]
		crab	ram			'a ram's crab'
	c.	ódzí	ɔ́mɔ́	→	ódzíɔ́mɔ̀	[ódʒɔ́mɔ̀]
		crab	child			'a child's crab'
	d.	ódzí	ódzí	→	ódzíódzí	[ódʒódʒî]
		crab	crab			'a crab's crab'

(14)		L H			L H	
	a.	ɔ̀tɛ́	èθà	→	ɔ̀tɛ́èθà	[ɔ̀têθà]
		| |	\/		| | \/	
		LH (H)	L		LHL	
		cricket	father			'father's cricket'
	b.	ɔ̀tɛ́	òké	→	ɔ̀tɛ́òké	[ɔ̀tôkê]
		cricket	ram			'a ram's cricket'
	c.	ɔ̀tɛ́	ɔ́mɔ̀	→	ɔ̀tɛ́ɔ́mɔ̀	[ɔ̀tɔ́mɔ̀]
		cricket	child			'a child's cricket'
	d.	ɔ̀tɛ́	ódzí	→	ɔ̀tɛ́ódzí	[ɔ̀tódʒî]
		cricket	crab			'a crab's cricket'

The tone changes on the head noun in associative constructions may be summarized descriptively as follows:

(15)
a. L → H (11)
b. H L → H H (12)
c. H → H (13)
d. L H → L H (14)

In (11) we assume there is a single Low tone associated with both syllables (moras) of the noun, following the Obligatory Contour Principle (Leben 1973; McCarthy 1986). The associative High tone replaces this underlying Low tone, and this Low tone itself is not realized on the surface. That the assumption made here with disyllabic forms is true of longer forms is confirmed by the trisyllabic examples in (16), where the three syllables of the head noun are now realized on a High tone in the associative constructions. Therefore all adjacent Low tone syllables become High regardless of the number of syllables.

(16)
```
L                           H
àɣòɣò      ɔ̀ké      →     áɣóɣóɔ̀ké   [áɣɔ́ɣɔ̂kê]
 \ | /      | |             \ | / | |
   L   (H)  L H               H   L H
skull      rain                        'a ram's skull'

àjɛ̀jɛ̀      èθà      →     ájɛ́jɛ́èθà    [ájɛ́jêθà]
butterfly  father                      'father's butterfly'
```

In (12) (with the HL pattern), the final Low tone of the head noun becomes High. Given the forms in (16), we assume that any number of adjacent syllables with Low tones will become High. Therefore we predict that HLL head nouns will be realized as HHH. This prediction cannot be confirmed, because our sources do not have any examples with such patterns. The forms in (13) are unremarkable, since the head noun is underlyingly High-toned. Finally, in (14), underlying LH remains the same. Our assumption here is that the associative High tone links vacuously to the final syllable of the head noun, just as [−back] links to palatal consonants in Zoque.

The above facts can be analyzed as follows. Following Elimelech I assume that "the associative marker (AM) . . . is underlyingly a High floating tone" (Elimelech 1976: 42). Tone is licensed by any mora in Etsako. Only vowels and syllabic nasals can be moraic in this language. Based on the facts in (11)–(15) above (especially (14)), as well as on facts presented in the Edoid studies cited at the beginning of this section, I suggested that the associative High tone is a featural suffix. It is suffixed to the head noun. However, a (separate) process of tonal harmony transmits the associative High tone throughout the entire head noun. Therefore the domain of the associative High tone is the entire head noun, a prosodic word (Nespor and Vogel 1986; Selkirk 1986; McCarthy and Prince 1990).

This type of phenomenon must be handled with two constraints. One is a morphological alignment constraint, the type of which we have seen so far. This alignment places the featural affix at a particular edge of the stem, characterizing it as a prefix or as a suffix (see Kirchner 1993; Pulleyblank 1993, 1996; Akinlabi 1994, 1997; Cole and Kisseberth 1994). The second is phonological feature spread: harmony. This handles feature propagation by establishing the fact that the domain of the feature is a phonological category, such as the prosodic word.

It is crucial to note that the associative High tone is different from an underlyingly linked segmental High tone of a head noun (the segmental High tone). First, while the associative High tone is a morpheme, the segmental High tone is not. And second, the segmental High tone is underlyingly linked, while the associative High tone is underlyingly free, i.e. it belongs to a morpheme with no other content. Any analysis of Etsako must recognize these differences.

4.1.1 *H-tone opacity*

In Etsako, the segmental High tone is "opaque": it blocks the propagation of the suffixal High tone. That is, the suffixal H tone cannot spread through the lexical H tone. The examples in (14) demonstrate this fact. In the LH head nouns, the output associative construction begins as LH, which does not become HH, as one would expect if the suffixal H tone were to spread through the segmental H tone. This indicates two things. First, only the suffixal H tone spreads, while the segmental H tone does not; otherwise we would once again have HH on the head noun in the output. Second, the segmental H tone is opaque to the spread of the suffixal H tone. We must assume that the constraint responsible for the association of a segmental H supersedes the one for tone spreading.

4.1.2 *German sign language*

Pfau (2000) has found a parallel of this type of affix in an unexpected place, the negative morpheme in the German Sign Language (DGS).[18] Pfau proposes an analysis of the negative headshake of DGS as an autosegment, in other words as a featural affix [headshake], which is associated with a manual form. The negative headshake, he argues, behaves in a way similar to tonal prosodies in tone languages. He proposes that this feature represents the negative morpheme, in the same way as tone functions as a grammatical morpheme associated with an entire base.

The main goal of §4.1 has been to show, first, that the domain of a featural affix may be the whole lexical category, but that it can still be identified as a prefix or suffix. Second, the featural affixation, unlike segmental affixation, may combine with harmony involving the feature itself. In §4.2, we show that non-tonal featural affixes also behave the same way, using Terena nasalization as illustration.

4.2 *Terena nasalization*

The second example of a system that combines featural affixation with harmony is Terena. In this section I argue that the feature [nasal] in Terena is a featural prefix, given the insistence on association to the initial consonant of the stem (in direct contrast to the Edoid associative High tone), and that the featural prefixation is accompanied by harmony. Terena also confirms the accounts already given in the preceding sections about both featural alignment and misalignment. In contrast to the Edoid associative marker, the lexical feature [nasal] is transparent to the propagation of the featural affix [nasal] (CHAPTER 78: NASAL HARMONY).

In Terena, an Arawakan language of Brazil (Bendor-Samuel 1960, 1966), the category of the 1st person is marked through a process of progressive nasalization. Thus the difference between the Terena examples in the first and the third columns is that the latter are marked for the 1st person.

(17) *1st person in Terena*

a.	ajo	'his brother'	àj̃õ	'my brother'
	arine	'sickness'	ãr̃ĩnẽ	'my sickness'
	unae	'boss'	ũnãè	'my boss'
	emoʔu	'his word'	ẽmõʔũ	'my word'
b.	owoku	'his house'	õw̃õᵑgu	'my house'
	iwuʔiʃo	'he rides'	ĩw̃ũʔĩⁿʒo	'I ride'
	ituke	(POSS PRON)	ĩⁿduke	(1PERS POSS PRON)
	nokone	'need'	nõᵑgone	'I need'

[18] I am deeply indebted to a reviewer for helping to make sense of this section.

c.	taki	'arm'	^{n}daki	'my arm'
	tuti	'head'	^{n}duti	'my head'
	paho	'mouth'	^{n}baho	'my mouth'
	piho	'he went'	^{m}biho	'I went'
d.	ahjaʔaʃo	'he desires'	ã^{n}ʒaʔaʃo	'I desire'
	haʔa	'father'	^{n}zaʔa	'my father'
	hjiʃoe	'dress'	^{n}ʒiʃoe	'my dress'

The descriptive generalizations from the above data are as follows. The 1st person pronoun is expressed by nasalizing the noun or verb. Nasalization affects vowels, liquids, glides, and underlying nasal consonants. Therefore, nasalization spreads through underlying nasal consonants. Laryngeal stops, but not laryngeal fricatives, are affected by nasalization. That is, nasalization may spread through a laryngeal stop, but not through a laryngeal fricative.

The examples in (17b) show that nasalization proceeds in an apparent left-to-right fashion until it reaches an obstruent. The interesting thing here is that the obstruent becomes prenasalized (and voiced), as in the first example in (17b), but nothing after it is nasalized (except of course it is an underlying nasal consonant, as in the last example in (17b)). Therefore obstruents block [nasal] spreading, but not before they become prenasalized. If a form begins with an obstruent, the effect of the 1st person progressive nasalization is to turn that obstruent into a prenasalized consonant, as in (17c), and there is no nasalization of subsequent segments. I shall not be concerned with further changes in obstruents, other than prenasalization. For example, I shall not discuss the fact that laryngeal continuants change to coronals when nasalized in (17d).

Continuing the discussion in the preceding sections, an analysis of the above Terena facts may be presented as follows. The 1st person marker is a free feature [nasal]. [nasal] can be associated with any root node in Terena, consonant or vowel. Given the insistence on associating to the first segment of the noun or verb regardless of the nature of the segment, it is a featural prefix. However, a process of harmony transmits nasality from the prefix through the stem; and thus the apparent domain of the [nasal] morpheme is the entire stem, which is a prosodic word. The surface realization of this morpheme may be accounted for the same way as tone in Etsako. An alignment constraint places [nasal] as a prefix, while a feature spread constraint accounts for spreading to the end of the word.

Just like the High tone in Etsako, [nasal] is both the featural content of a morpheme and a lexically contrastive feature in Terena. These two functions must be recognized by any analysis.

4.2.1 *Nasal transparency*

Forms like /arine/ → [ãr̃ĩnẽ] in (17a) reveal that nasal stops do not block the propagation of the [nasal] morpheme in Terena, i.e. underlying nasal stops are transparent to the morphemic [nasal] spread. Our account of this transparency is that (the constraint responsible for) the domain of association of the [nasal] morpheme takes precedence over the segmentally specified [nasal], and could therefore pass "over" the segmentally specified [nasal].

This constitutes an important difference between the underlying segmental High tone in Edoid (as exemplified by Etsako) and the segmentally specified [nasal] in Terena. While the segmental High tone in Edoid blocks the propagation of the morphemic High tone, the propagation of the [nasal] morpheme in Terena is not blocked by the segmentally specified [nasal].

4.2.2 Obstruents and co-occurrence

We now turn to account for the behavior of obstruents in Terena. As noted above, obstruents block the rightward propagation of the [nasal] morpheme, while becoming prenasalized: /owoku/ → [õw̃õ^{ŋ}gu] 'my house'. To account for this, we assume a co-occurrence constraint forbidding the co-occurrence of [−sonorant] and [+nasal] in Terena (see Pulleyblank 1989: 109). Note however that, while nasality is always barred from obstruents in general (as in Orejon; Pulleyblank 1989), Terena obstruents are partly nasalized. We can account for this by assuming that nasality is barred from the release phase of obstruents in Terena, but not from closure phase (Steriade 1993). Prenasalization in Terena can be seen as the association of the [nasal] morpheme to the closure phase of the obstruent stops, and not to the release phase.

Finally, though, the domain of the [nasal] morpheme is the entire stem (a prosodic word), like the High tone in Etsako; it is formally a featural prefix, in contrast to Etsako, where H is a featural suffix.

Gerfen (1999: 127–131) describes an interestingly similar case in Coatzospan Mixtec. In this language, the 2nd person familiar is marked by a [nasal] feature. As in Terena, the entire base is nasalized. However, unlike in Terena, the free feature [nasal] is a suffix, because the spreading is from right to left. Furthermore, if spreading is blocked, only the final vowel of the base is nasalized, indicating that the feature [nasal] links to the final vowel. Spreading is blocked when the final syllable has a voiceless obstruent onset. Finally, like in Terena, lexical nasal consonants are transparent to nasal spread.

5 Segmental realization: Mafa imperfective

In our fourth case study, the featural affix is at the same time a "feature" and a "segment." I refer to this as segmental realization of a featural affix. The case is exemplified by palatalization in Mafa. This language is interesting because of its unique morphological properties. The affix expressing the imperfective in Mafa can be characterized both as a segmental affix and as a featural affix at the same time.[19] This allomorphy gives languages like this a special place in the study of featural affixes.

Ettlinger (2003, 2004) describes the morphosyntactic process of imperfective aspect formation in Mafa, a central Chadic language of Cameroon, as follows. The imperfective is formed in one of two ways, depending on whether the final segment of the root is a vowel ([a]) or a consonant. In the case of verbs ending in [a], /j/ is suffixed to the base, as seen in (18). (All vowel-final verb stems end in an /a/ and all other suffixes are positioned after the imperfective suffix.)

[19] Another language with similar properties is Yokuts (Archangeli 1984, 1991; Archangeli and Pulleyblank 1994). In Yokuts, the glottal feature can surface as a segment or as part of another segment (or not surface at all).

(18) *Palatalization of /a/-final verbs*

gudza	'tremble'	gudzaj	'is trembling'
bəra	'insult'	bəraj	'is insulting'
^{n}da	'cut a hole'	^{n}daj	'is cutting a hole'
keða	'divide'	keðaj	'is dividing'

The imperfective of verbs ending in a consonant, however, is formed with a palatal featural suffix. Apparently, the palatal prosody targets either vowels or coronal stridents, and no more. There is one complication, regarding the vowel [u]. [u] is not palatalized (to [y]) in two contexts: (a) when it occurs after a dorsal, and (b) after a coronal strident in a disyllabic root. I will not discuss this complication here. Readers are referred to Ettlinger (2003, 2004) for an explanation.

The vowel inventory of Mafa is given in (19).

(19) *Mafa vowel inventory*

i	y	ə	u
e	œ	a	o

The surface realizations of vowels under palatalization are as follows:

(20)
/ə/ → /i/
/u/ → /y/
/o/ → /œ/
/a/ → /e/

The forms in (21a) represent monosyllabic verb roots, and those in (21b) represent disyllabic forms. The last two forms in (21) show that both vowel and coronal stridents can be palatalized, if both are present in the verb root. In the forms in (22), palatalization appears to skip some segments, while other segments are palatalized (Ettlinger 2004). This is not skipping. The skipped segments are not licensors (Akinlabi 1996) of the palatal prosody in Mafa, hence the apparent skipping.

(21) a. *Palatalization of monosyllabic consonant-final verbs*

pan-	'wash'	pen-	'is washing'
təv-	'light (VB)'	tiv-	'is lighting'
dad-	'add water to'	ded-	'is adding water to'
guts-	'squirt'	gutʃ-	'is squirting'
tsap-	'speckle'	t̪ʼep-	'is speckling with clay'
sur-	'sleep with a woman'	ʃyr-	'is sleeping with a woman'

b. *Palatalization of disyllabic consonant-final verbs*

səban-	'work'	ʃiben-	'is working'
lubat	'twist'	lybet	'is twisting'
suwdək	'miss'	ʃuwdik	'is missing'

c. *No palatalization*

gum-	'carve wood'	gum-	'is carving wood'
gud-	'search with anxiety'	gud-	'is searching with anxiety'
kurk^{w}-	'carve everywhere'	kurk^{w}-	'is searching everywhere'

Following the way featural affixes work, there is no doubt that the imperfective is a featural suffix in Mafa (Akinlabi 1996), as the vowel-final verbs show. It scans the verb root in a right-to-left manner. If the last segment of the verb root is a vowel, then the imperfective is a full segment, i.e. a suffix. If the palatal prosody finds a consonant as the final segment, then it seeks out a licensor, preferably a vowel. I assume that the coronal palatalization is just a default. This is because this is the only consonant that can be changed without actually completely changing the primary place of articulation. Finally, I suggested that the vowel [u] is blocked from change after a dorsal consonant because it shares the dorsal specification with the preceding dorsal consonant.

6 Formal insights into featural affixation

In general, there has not been much disagreement about whether features can be affixes or not. What has varied is the formal approach to featural affixes. Much of the formal work on featural affixes has been carried out within autosegmental phonology, which allows for autonomous representation of features (CHAPTER 14: AUTOSEGMENTS). The featural affix is commonly represented as a floating feature, and linked to a segment by some rule. Work done on featural affixes within this approach includes McCarthy (1983), Lieber (1984), and others.

Feature geometry (Clements 1985; Sagey 1986; Clements and Hume 1995; and others; see also CHAPTER 27: THE ORGANIZATION OF FEATURES) has also provided significant insights. For example, feature geometry provides significant insight into the grouping of features, and into why some features co-occur together and others don't. In addition, certain nodes can serve as anchors for some featural affixes while others cannot. Work like Archangeli and Pulleyblank (1994) is situated within this approach.

The formal approach to featural affixation adopted in this chapter is the constraint-based Optimality Theory (Prince and Smolensky 1993). Within this theory, grammars are composed of hierarchies of ranked and violable universal markedness and faithfulness constraints. In the theory, faithfulness constraints monitor input and output to ensure that they are the same, and markedness constraints ensure that output structures are unmarked to the highest degree possible, depending on the conflict between all markedness and faithfulness constraints.

However, there are various approaches to featural affixes within Optimality Theory itself. Variations include Zoll's (1998) subsegmental approach, which proposes that the input and output correspondence of "subsegments," including "floating features" and latent segments (undominated F-element), is monitored by MAX(subseg) (see Lombardi 1998 for similar MAX(F)), stated as in (22).

(22) MAX(subseg)

Every subsegment in the input has a correspondent in the output.

As Zoll (1998: 44) notes, featural affixes are realized as part of other segments, therefore the correspondence relation returns the output segment that hosts the feature, not the feature itself. If that is the case, Mc Laughlin (2000) argues that, since subsegments do not occur as output forms, there is no evidence for positing a DEP constraint of the sort DEP(subseg). She proposes that we employ IDENT-IO(F) to monitor subsegments in general. This may be stated as in (23):

(23) IDENT-IO(F)

Correspondent IO segments have identical values for the feature F.

Kirchner (1993), Akinlabi (1996), and Zoll (1996) suggest that features are subject to the same kind of alignment, or coincide constraints as segments. Akinlabi (1996) suggests that featural affixes are subject to the same kind of alignment constraints as non-featural morphemes. He proposes that alignments constraints account for the determination of featural affixes as prefixes or suffixes. All featural affixes, he proposes, are subject to the featural alignment in (24) (see McCarthy and Prince (1993a, 1993b). The specific morphological alignment constraint in (25) accounts for Chaha labialization (Akinlabi 1996: 246).

(24) *Featural alignment*

ALIGN(PFeat, GCat)
A prosodic feature is aligned with some grammatical category.

(25) ALIGN-3MASC-SG

ALIGN (3MASC SG, R; Stem, R)
The right edge of 3MASC SG must be aligned with the right edge of the stem.
3MASC SG is a suffix in stem.

A constraint like (25) does not say whether 3MASC SG is a segment or a feature; it simply refers to the morphological category. Therefore it should not matter whether 3MASC SG is a feature or a segment. As Akinlabi (1996: 243) points out, PFeat (in (24)) is simply the featural spell-out of the morphological category in question.

Misalignment of featural affixes is controlled by feature co-occurrence constraints (Archangeli and Pulleyblank 1994). An example of this is *NASCONT (Akinlabi 1996: 254), which forbids nasal consonants from be continuants.

(26) *NASCONT

If [nasal] then not [continuant].

The above represents the core of the grammar of featural affixes. The variations are derived from ranking the constraints. This analysis also represents the point of departure for some scholars.[20]

[20] Piggott (2000) argues against the idea that features can align to word edges, like segments. He sees featural alignment as proposed by Akinlabi (1996) as an overly powerful mechanism. He proposes instead that morphological alignment be supplemented by a provision for prosodic licensing, so that, for example, features may be incorporated into a prosodic category such as a foot or a prosodic word. See McLaughlin (2000: 341–345) and Horwood (2004) for answers to Piggott's objections. Another notable counterposition is that of Kurisu (2001), who proposes a "relational morphology theory" instead of "featural alignment." I will not discuss this here, since it is an entirely different theory.

7 Are featural affixes really featural?

I will end this discussion by examining whether "featural affixes" are really "featural." We can examine this issue from the theoretical and the empirical points of view. The traditional view of an affix is that of a "whole segment" (or segments), which marks a morphological category. The affix is dependent on, or attached to, some host, a base. The category represented could be inflectional or derivational. By segment is traditionally meant a unity of several articulatory gestures that are produced simultaneously and that paradigmatically contrast with one another. By this definition [t] and [s] are segments in *tip* and *sip*. [t] and [s] are also segmental affixes (suffixes), representing the English past tense, and 3rd person singular verbal agreement in [sækt] *sacked* and [sæks] *sacks*, respectively. In this definition of an affix, it represents a timing slot or more in the paradigmatic string.

Featural affixes on the other hand, from the cases that we have been discussing, do not always occupy a timing slot. Rather they share the same time slot with one or more of the segments in the base. For example, in Zoque palatalization (Wonderly 1951) (§2.2), palatalization simply changes an alveolar consonant to a palatal ([s] → [ʃ], in [sʌk] 'beans', [ʃʌk] 'his beans'), yet that difference signifies the distinction between 'beans' and 'his beans'. In some cases, it in fact makes no sense to talk about timing slots in the string. Such is the case in Terena nasalization (Bendor-Samuel 1960, 1966) and in Mafa palatalization (Ettlinger 2003, 2004), where the featural affix attaches to more than one segment of the base. In Mafa [lubat] 'twist', [lybet] 'is twisting', the palatal feature is attached to both vowels in the base.

But even with these facts there are problems about what a featural affix really is. The problem is those features that can be realized as full segments as well as as features. These include palatalization, labialization, nasalization, and glottalization. Note that, in Mafa and languages like it, the palatal feature can be realized as a full segment [j], when the verb is vowel-final. Does this, then, mean that this is both a segmental affix and a featural affix? Or is it a featural affix that is sometimes realized as a full segment? Mafa is intriguing because, on any account, it would satisfy the definition of a segmental affix as well as that of a featural affix. The same applies to nasalization in Seereer Siin (Mc Laughlin 2000). It is easy to assume that the nasal feature in all these cases is a full segment. However, certain features are never realized as full segments. These include voicing and continuancy. There is no other way that I know of than to analyze the feature [continuant] as a featural affix marking the past participle in Nuer (Crazzolara 1933) (§3.1).

From the theoretical point of view, this question relates to the way a "segment" is defined. If segments (or feature bundles) are the contrastive elements in a language, such that the meaning contrast between [tip] and [dip] is seen as represented by the first consonants [t] and [d] in these words, rather than by the fact that [t] and [d] differ only in that [d] is voiced and [t] is not, then there *are* featural affixes, because the elements that represent featural affixes are "less than" segments, as the empirical facts above reveal.

On the other hand, the current assumption is that the contrastive elements in language are "features," and not "feature bundles." This distinction is captured by feature theory (CHAPTER 17: DISTINCTIVE FEATURES) and the internal organization of segments (e.g. Clements 1985). On this viewpoint, the meaning contrast between [tip] and [dip] is seen as represented by voicing. If we equate minimal units with contrastive units, then there are no featural affixes. The only distinction is between affixes that are feature bundles and affixes that are single features.

Empirical data from the Mafa imperfective aspect (Ettlinger 2003, 2004) suggest that the distinction between a segmental affix and a featural affix may not be real. In this case the same feature, "palatality," sometimes behaves as a feature bundle, and sometimes as a single feature. The importance of the Mafa data is that even the distinction between "single feature" and "feature bundle" may not be real.

8 Conclusions

In summary, in this chapter I have illustrated the characteristics of featural affixes. These features include (a) marking morphological categories (like segmental affixes), (b) occurring as part of other segments rather than independently, (c) varying between prefixes and suffixes, (d) occurring inside the stem (because of feature co-occurrence constraints at edges), (e) spanning the entire base of affixation, and (f) varying occurrence as a feature or a segment in the same language. I have illustrated these with facts from Dutch, Chaha, Zoque, Nuer, Seereer Siin, Etsako, Terena, Mafa, Coatzospan Mixtec, and German Sign Language.

Comparing featural affixes with traditional regular affixes, featural affixes share four characteristics with the traditional affixes: (a) marking morphological categories, (b) varying between prefixes and suffixes, (c) (sometimes) occurring as independent segments, and (d) occurring inside the stem (because of feature co-occurrence constraints at edges). Other characteristics are unique to featural affixes alone: (a) occurring as part of other segments, (b) spanning the entire base of affixation, and (c) varying occurrence a feature or a segment in the same language.

There are a number of important lessons that the unique characteristics of "featural affixes" teach us. First, the so-called "normal affixes" always contain a timing unit, while "featural affixes" do not normally contain a timing unit. Second, they raise the question of whether segments or features are the basic elements that sound systems manipulate. Finally, they reveal that all features are not the same. Some features can be morphemic but can never be realized independently of some other segments ([continuant], [voice]), while other features that are morphemic may dock on some sound in the stem but may also become segments in their own right ([glottal], [nasal], [palatal], [labial]).

ACKNOWLEDGMENTS

I am grateful to two anonymous reviewers for insightful comments, and to the editors of the *Companion* for all their help with this chapter.

89 Gradience and Categoricality in Phonological Theory

Mirjam Ernestus

1 Introduction

Within phonological theory, important roles are assigned to the notions of "gradience" and "categoricality." The opposition qualifiies sounds and sound patterns, and is crucial both for the definition of the phonological and the phonetic components of generative grammar, and for the development of alternative types of grammatical models. This chapter discusses the assumptions generative phonology and its direct successors (including Optimality Theory) have made about the role of gradience. Moreover, it presents data supporting or contradicting these assumptions, and discusses new models accounting for the conflicting data.

The most important section of this chapter (§2) discusses the opposition between categorical sounds, which are stable and represent clear distinct phonological categories (e.g. sounds showing all characteristics of voiced segments throughout their realizations), and gradient sounds, which may change during their realizations and may simultaneously represent different phonological categories (e.g. sounds that start as voiced and end as voiceless). A shorter section (§3) discusses categorical generalizations over sounds, which are fully productive, and gradient generalizations, which are less productive. The final section (§4) provides a short conclusion.

2 Sounds

2.1 *Gradience in generative grammar*

In the early days of generative grammar, the opposition between categoricality and gradience was assumed to reflect the fundamental distinction between competence and performance. Competence described speakers' categorical knowledge about their language, abstracted away from performance factors such as vocal tract size, working memory span, articulatory effort, and so on. Performance, in contrast, described speakers' actual linguistic behavior, which could be gradient, and was not in the direct focus of linguistic research (Chomsky and Halle 1968; following Saussure 1916).

The distinction between competence and performance was reflected in the distinction between the phonological and phonetic component. The phonological component contained the speaker's competence and thus represented cognition. It was believed to be language-specific and to include the phonemes of the speaker's language and language-specific phonological processes, such as final devoicing (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION) and place assimilation (CHAPTER 81: LOCAL ASSIMILATION). This knowledge was represented in the form of categorical symbols and rules operating on these symbols. Phonetic mechanisms were responsible for the speaker's performance. These phonetic mechanisms were believed to be universal and the automatic results of speech physiology (Chomsky and Halle 1968: 293; Kenstowicz and Kisseberth 1979). They thus reflected physics and included, for instance, nasalization of vowels preceding nasal consonants, palatalization of consonants preceding high vowels, and shortening of vowels preceding voiceless obstruents. Since the phonetic component did not reflect the speaker's competence, it was considered not to be part of the grammar proper.

This view on the phonological and phonetic components changed very quickly, since various studies showed that the exact realization of an abstract symbol (e.g. a phoneme or a phonological feature) might be different in different languages. Moreover, no part of a realization appeared to be the automatic and unavoidable result of speech physiology (e.g. Keating 1985, 1990a; Kingston and Diehl 1994; see also CHAPTER 17: DISTINCTIVE FEATURES). As a consequence, the traditional definition of the phonetic component as containing only universal processes automatically resulting from speech physiology implied that this component was empty. A new distinction had to be developed which was no longer based on the notions of language-specific *vs.* language-universal and non-automatic *vs.* automatic mechanisms.

The now widely accepted definitions of the phonological and phonetic components are completely based on the opposition between categoricality and gradience (e.g. Keating 1988, 1990b; Pierrehumbert 1990; Cohn 1993; Zsiga 1997). The phonological component is assumed to deal with categorical, abstract, stable, timeless symbols, such as phonemes and phonological features. Phonological processes refer to these symbols and consequently have categorical effects: they change one symbol (e.g. [+voice]) into another one ([−voice]), or they delete or insert symbols. Phonetic processes translate the abstract symbols into articulatory and perceptual targets. This may lead to sounds with acoustic characteristics that do not perfectly represent categorical phonological symbols, but rather have intermediate values, for instance, when obstruents are partly voiced due to co-articulation. These definitions of the phonological and phonetic components have been adopted in several psycholinguistic models of speech production and comprehension (e.g. Levelt 1989; Norris 1994).

Since the distinction between gradience and categoricality is crucial in the definitions of the phonological and phonetic components, it has led to many experimental studies. The following subsections discuss their findings and their implications for phonological theory (see also CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS; CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY). The first subsections discuss the domains (assimilation and segment deletion) where the evidence for gradience is most convincing but can also be relatively easily reconciled with generative grammar: the relevant processes traditionally characterized as phonological could be reclassified as phonetic. The following subsections (on incomplete neutralization and phonetic detail) discuss evidence for gradience that is less clear but has important theoretical consequences. Generative grammar cannot account for incomplete neutralization without making additional far-reaching assumptions. Further, evidence for a role for fine phonetic detail in speech processing suggests that words are not lexically represented in the form of abstract phonemes but are stored together with their detailed phonetic properties. These data have stimulated the development of accounts based on assumptions other than those of generative grammar.

2.2 *Assimilation: Data*

One of the first types of processes traditionally characterized as phonological for which researchers found evidence of gradience is formed by connected speech processes, in particular assimilation (CHAPTER 81: LOCAL ASSIMILATION). Nearly all instances of assimilation are traditionally described as the categorical spreading of a phonological feature from one segment to another segment in the phonological component. The receiving segment is assumed to be subsequently identical to segments with the same features in their underlying specifications. For instance, [m] would have exactly the same surface phonological representation and phonetic characteristics if it results from an underlying /m/ and if it results from place assimilation, as in the phrase *gree*[m b]*oat* 'green boat'.

Many articulatory studies have investigated the assumed categorical nature of place assimilation using electropalatography (EPG; Hardcastle 1972), which registers contacts between the tongue and the hard palate, or with the help of an electromagnetic midsagittal articulometer (EMMA; e.g. Perkell *et al.* 1992), which allows the tracking of individual fleshpoints by means of small transducer coils attached to various points on the speaker's vocal tract in the midsagittal plane. These studies have provided evidence for the categorical nature of some place assimilation processes. An example is regressive place assimilation in Korean, which is a characteristic of fast colloquial Korean and affects certain consonants preceding certain other consonants. For instance, the phrase /pat˺p'oda/ 'rather than the field' can be pronounced as [pap˺p'oda]. Kochetov and Pouplier (2008) showed that this assimilation results in the categorical absence of the gestures for the original articulation place of the assimilated consonant (in this example: for /t˺/) in most tokens. Another example is place assimilation of /n/ to /k/ in Italian, which categorically results in the absence of alveolar gestures (Farnetani and Busà 1994).

Other studies strongly suggest that some place assimilation processes are gradient in nature. For instance, assimilation of alveolar obstruents to the palatality of the following segments (as in American English *hi*/t j/*ou*) often does not lead to completely palatal segments ([c] in the example), but rather to segments that become more palatal during their realizations (within one and the same token) and that consequently differ in their phonetic detail from underlying palatals (e.g. Barry 1992 for Russian; Zsiga 1995 for post-lexical palatalization in American English). The same type of gradience has been reported for place assimilation of coronal obstruents in American English, as in *la*/t k/*alls* (*late calls*) produced as *la*[kː]*alls*. The assimilated obstruents often start with a coronal constriction that gradually assimilates to the articulation place of the following obstruent during their realizations (velar in the above example; Nolan 1992). Other gradient place assimilation processes include assimilation of alveolar nasals in American English (e.g. in *gree*[m b]*oat*; Ellis and Hardcastle 2002) and of /n/ to following post-alveolars in Italian (Farnetani and Busà 1994). Interestingly, some of these assimilation processes show considerable inter-speaker and intra-speaker variation. For instance, Ellis and Hardcastle (2002) found that four of their eight English speakers showed categorical place assimilation of /n/ to following velars in all tokens, two speakers showed either no or categorical assimilation, and two speakers showed gradient assimilation. Together, the data show that place assimilation processes, at least those applying across morpheme boundaries, may be gradient in nature. These processes cannot simply be accounted for by the categorical spreading of a phonological feature from one segment to another.

The evidence for gradience is clearer for place assimilation than for voice assimilation. The main reason is probably that the difference between [+voice] and [−voice] obstruents is cued by many different acoustic, and hence also articulatory, characteristics, including the duration of the preceding vowel, the duration and intensity of the obstruent, and the duration of glottal vibration during the obstruent. Voice assimilation can thus not be studied on the basis of electropalatography alone, and has been mainly investigated on the basis of the acoustic signal instead. For instance, Kuzla *et al.* (2007) studied progressive voice assimilation in German clusters consisting of a voiceless obstruent and a voiced fricative (e.g. the /tv/ cluster in *ha*/t v/*älder* 'had woods' produced as [tf]). They showed that assimilation results in shorter stretches of glottal vibration during the cluster, whereas it hardly affects the duration of the fricative, which is the most important perceptual cue to the [±voice] distinction for German fricatives. Assimilation thus does not affect all perceptual cues of the [±voice] distinction equally, and the phonetic implementation of devoiced fricatives differs from the implementation of underlyingly voiceless fricatives. This is difficult to reconcile with an abstract phonological categorical account of voice assimilation, since in such an account voice assimilation results in phonologically voiceless fricatives, which cannot be distinguished from underlyingly voiceless fricatives during phonetic implementation.

Other studies have investigated regressive voice assimilation in Dutch, that is, the voiced realizations of obstruents before voiced stops (e.g. *we*[t] 'law' is realized as *we*[d] in *wetboek* 'law book'). Ernestus *et al.* (2006) and Jansen (2007) showed that glottal vibration, which is the most important cue to the [±voice] distinction in Dutch obstruent clusters (van den Berg 1988), may be completely absent, partly present, or continuously present in clusters subject to regressive voice assimilation, suggesting that regressive voice assimilation in this language is gradient. Ernestus and colleagues (2006) also investigated the effect of a word's frequency of occurrence (i.e. the word's relative number of occurrences in speech, independent of its realization) on voice assimilation (see also CHAPTER 90: FREQUENCY EFFECTS). They found that higher frequencies correlate with shorter obstruent clusters, a perceptual cue for [+voice], but also with shorter periods of glottal vibration and longer release bursts, which are perceptual cues for [−voice]. These data also suggest that voice assimilation may result in sounds that are neither fully voiced nor fully voiceless.

In conclusion, the data on assimilation suggest that we often perceive assimilation as categorical because we are used to distinguishing between only two values of the relevant phonological feature, but that the actual results from assimilation may be gradient rather than categorical. Before discussing the theoretical implications of these data, I first discuss data showing that segment deletion may also be gradient in nature.

2.3 *Segment deletion: Data*

In addition to assimilation, many studies have investigated the nature of segment deletion (CHAPTER 68: DELETION). It is generally assumed that the absence of segments may result from three different sources. First, the lexicon may represent more than one pronunciation variant for at least some words, and segment deletion may result from speakers' selection of reduced pronunciations from their lexicons. Examples of lexicalized reduced pronunciations include English *won't* for *will not* and Dutch [tyk] for [natyrlək] 'of course' (Ernestus 2000). Second, segments may be absent due to phonological deletion processes operating on the lexically represented unreduced pronunciations. These processes result in phonological surface representations without the absent segments. Both mechanisms (i.e. selection of lexically represented pronunciation variants and phonological processes) result in pronunciation variants that do not contain any acoustic cues for the missing segments, and the absence of these segments is categorical in nature. Alternatively, segments may be absent due to gradient phonetic reduction processes, which reduce the durations and articulatory strengths of segments and make different segments overlap in time (CHAPTER 79: REDUCTION). Segments that are absent due to such reduction mechanisms typically leave some traces in the acoustic signal or in the word's articulation. In conclusion, the distinction between categoricality and gradience is also relevant for the theory of segment deletion, since it indicates which type of mechanism is responsible for a given type of deletion.

This view resulted in several studies investigating the categorical *vs.* gradient nature of segment deletion processes. Browman and Goldstein (1990) hypothesized that most highly productive casual speech reduction processes result from reduction in and overlap of articulatory gestures. They showed in an X-ray study that, for instance, the /t/ in a phrase like *perfect memory* may be acoustically absent, but still articulatorily present: speakers may close their lips for the production of the /m/ before the closure of the /t/ is released, which makes the release noise of the /t/ (its most important perceptual cue) inaudible (Browman and Goldstein 1992). Several articulatory and acoustic studies of other highly productive reduction processes support this hypothesis. Thus, Manuel (1992) and Davidson (2006) demonstrated that schwa deletion in American English is gradient (CHAPTER 26: SCHWA). They reported acoustic differences between consonant clusters resulting from schwa deletion (e.g. [sp] from schwa deletion in *support*) and underlying consonant clusters (e.g. [sp] in *sport*). For instance, clusters resulting from deletion may show aspiration, whereas underlying clusters typically do not. Similarly, Russell (2008) showed that the deletion of the first vowel of a sequence of two in Plains Cree is gradient for his two native speakers (vowels may vary in their duration on the full continuum from values typical for accented full vowels to zero, which implies that they may have clear, some, or no traces at all in the acoustic signal).

In contrast, several less productive processes appear categorical in nature. Examples are the possibly morphosyntactically governed coalescence of /a+i/ or

/aː+i/ to [eː] in Plains Cree (Russell 2008) and /e/ deletion in the highly frequent French word combination *c'était* 'it was' (Torreira and Ernestus 2009). Furthermore, segments that may also be absent in more careful speech registers are more probable to be (at least partly) categorically absent. An example is word-medial schwa in French (as in *f/ə/nêtre* 'window'; see Bürki *et al.* 2010).

2.4 Gradient assimilation and segment deletion: Theoretical implications

Together, these studies suggest that many productive connected speech processes, such as assimilation and segment deletion, are gradient in nature. If the phonological component contains only categorical processes, as is assumed in traditional versions of generative grammar, these gradient processes should be classified as phonetic, which implies a move of a substantial part of the phonological component to the phonetic component. Theoretical research is needed to understand the consequences of this move. Furthermore, the experimental data suggest that post-lexical processes, in particular, show gradience. Additional detailed articulatory and acoustic studies have to investigate whether this generalization is correct. Finally, we have to investigate why some processes are categorical and others gradient and why some processes show inter-speaker and intra-speaker variation. For instance, we have to exclude the possibility that differences result from how participants deal with the experimental situation in which they are tested, including the tools that are put in their mouths for the recording of their articulation. Some participants may show normal speech behavior, while others may adapt their speech.

The evidence for the gradient nature of many connected speech processes has stimulated the development of new theoretical accounts, which do not make a fundamental distinction between the phonological and phonetic components. One of the most influential theories is Articulatory Phonology, developed by Browman and Goldstein (1986, 1992; see also CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS). This theory assumes that lexical phonological representations consist of strings of articulatory gestures (articulatory scores), which are specified for time and space, and that languages differ in how these gestures may reduce in size and overlap in time. Gradient reduction in gestural size and gradient increase in gestural overlap naturally explain the gradient natures of assimilation and segment deletion processes. For instance, nasal place assimilation in English *gree*[m b]*oat* may result from the early onset of the bilabial closure, during the realization of the preceding nasal, which makes this nasal partly bilabial. In addition, Articulatory Phonology can account for categorical connected speech processes, either by incorporating the processes in the lexical representations of the words (e.g. the French word *c'était* 'it was' may have two lexical representations: one with, and one without, the gestures for the vowel /e/), or by processes that reduce gestural sizes to zero and make gestures completely overlap in time. Note that these different types of mechanisms make Articulatory Phonology a very powerful theory, which can basically explain any reduction pattern. More research is necessary to investigate how this theory can account only for those sound patterns that are actually attested. Furthermore, detailed research is necessary to explain how listeners translate the acoustic signal into gestural scores, which are the basic units of the phonological lexical representations in Articulatory Phonology.

While Browman and Goldstein (1986, 1992) proposed Articulatory Phonology as an alternative to theories making a sharp distinction between the phonological and the phonetic components, many researchers (e.g. Byrd and Choi 2010) do not consider this theory as a competitor for these theories. Rather, they incorporate the ideas of Articulatory Phonology (especially the idea of reduction in and overlap of articulatory gestures) into the phonetic component of generative grammar. Obviously, theoretical research is necessary to investigate the consequences of this incorporation.

2.5 *Incomplete neutralization: Data*

Final devoicing is another phonological process whose possible gradient nature has received a great deal of attention in the literature (see also CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). It has usually been assumed (e.g. Booij 1995) to imply a categorical change of voiced obstruents into voiceless ones, and thus a complete neutralization of the distinction between underlyingly voiced and voiceless obstruents in their phonological surface representations and articulatory and acoustic characteristics. Within traditional generative phonology, the output of final devoicing (i.e. final voiceless obstruents) forms the input to other categorical phonological processes (see below). Hence, if final devoicing turns out to lead to incomplete neutralization (i.e. to slightly voiced obstruents) and thus, according to the definitions of generative grammar, to be phonetic in nature, this has consequences for the theoretical accounts of these other phonological processes as well. That is, a gradient nature of final devoicing would have more important theoretical consequences than the gradient nature of the connected speech processes discussed above. Consequently, the possibility of incomplete neutralization has attracted attention from many researchers.

Most experimental studies have investigated the nature of final devoicing by comparing the acoustic characteristics of words differing only in the underlying voice specifications of their final obstruents. The acoustic characteristics that are typically investigated are known to correlate with perceived voicing. They include the duration of the vowel preceding the final obstruent, the duration of the final stop's closure, the duration of this stop's burst, the complete duration of the final fricative, and the duration of glottal vibration during the final obstruent. For instance, Port and O'Dell (1985) investigated ten minimal word pairs in German (e.g. *Rat* 'counsel' *vs.* *Rad* 'wheel'), read aloud by ten speakers, and showed that all acoustic measures mentioned above provided cues to the underlying voice specification of the final obstruent. In line with this, cluster analysis could correctly classify the underlying voice specifications of the obstruents on the basis of these acoustic measurements for 63 percent of the tokens. Similar studies have provided evidence for incomplete neutralization in Polish (e.g. Slowiaczek and Dinnsen 1985) and Dutch (e.g. Warner *et al.* 2004). They report acoustic differences between underlyingly voiced and voiceless obstruents in word-final position, but also that that these differences may be very small (e.g. Warner and colleagues observed a difference in vowel duration of only 2.5 msecs).

Other studies have cast doubt on these findings. For instance, Port and Crawford (1989) recorded five native speakers of German reading three minimal word pairs in four different contexts. The underlyingly voiced final obstruents differed in their realization slightly from the underlying voiceless final obstruents in all four contexts, which is in line with the incomplete neutralization hypothesis. However, speakers differed in which acoustic cues were relevant for the distinction, and, more importantly, in whether acoustic characteristics typically cueing voiced obstruents (e.g. longer preceding vowels) were combined with underlyingly voiced or voiceless obstruents. One possible explanation for (part of) these mixed results may be the nature of one of the minimal pairs (*seid*, a form of 'to be', *vs.* *seit* 'since'), since the final obstruent of the member *seid* never occurs in onset position in Modern German, and there is consequently no synchronic evidence that this obstruent is underlyingly voiced. Another study showing mixed results was conducted by Charles-Luce (1985), who investigated eight German minimal word pairs. Each of the words appeared in four different sentences, in which it was in sentence-final or medial position. Vowel duration appeared to be the only reliable cue to underlying voicing, distinguishing /t/ and /d/ in both sentence positions, but /s/ and /z/ only in sentence-final position.

Several studies have raised the question of whether the reported evidence for incomplete neutralization may result from the experimental tasks speakers had to perform. Participants typically read sentences aloud, and their pronunciation may therefore show spelling effects. Fourakis and Iverson (1984) investigated this possibility by asking their German participants to conjugate strong verbs after having heard the infinitives (e.g. they heard *reiten* and had to form *ritt* and *geritten*). In this task, participants' attention was not drawn to the spelling of the words to be pronounced. Only 10 percent of the statistical analyses showed a significant difference between the words ending in underlyingly voiced and underlyingly voiceless obstruents. Importantly, the differences were much smaller than those obtained for the same words in a word-reading task performed by the same speakers. Dinnsen and Charles-Luce (1984) addressed the role of spelling by studying five Catalan minimal word pairs whose members differed from each other in the underlying voice specification of the final obstruent, but not in spelling (e.g. /fat/ *fat* 'fate' *vs.* /fad/ *fat* 'silly'). The words were embedded in carrier sentences, and five speakers read the sentences five times. Two speakers showed incomplete neutralization, one in the expected direction (vowels were 10 percent longer before underlyingly voiced obstruents in one context condition), and one in the unexpected direction (15 percent longer closures for underlyingly voiced obstruents). Finally, Warner *et al.* (2006) addressed the role of spelling by comparing two types of Dutch word pairs consisting of morphologically related homophones that differed underlyingly only in the presence of the singleton /t/ *vs.* the geminate /tt/. Importantly, only one of these two types of word pairs reflects the underlying difference in spelling. For instance, /het+ən/ [hetən] *heten* 'are called' *vs.* /het+tən/ [hetən] *heetten* 'were called' reflects the underlying difference, whereas /het/ [het] *heet* 'am called' *vs.* /het+t/ [het] *heet* 'is called' does not. The results suggest that only those underlying differences that are reflected in orthography lead to pronunciation differences, and that these pronunciation differences are comparable in size to the pronunciation differences induced by incomplete neutralization resulting from final devoicing. Together, these results suggest that incomplete neutralization may be completely driven by orthography.

The nature of final devoicing has also been investigated in several perception studies, addressing the question of whether listeners are sensitive to the minimal acoustic differences assumed to be present between underlyingly voiced and voiceless obstruents. If they are, this supports the hypothesis of incomplete neutralization. Participants typically listened to words in isolation and indicated which word they heard by selecting the corresponding orthographic representation (e.g. German listeners heard [rat] and indicated whether they had heard *Rat* 'counsel' or *Rad* 'wheel'). All studies showed that participants tend to choose the intended orthographic representation at just above chance level (e.g. 59 percent in Port and O'Dell 1985; 62 percent in Warner *et al.* 2006). In another type of study (Ernestus and Baayen 2007), Dutch participants rated rhymes (i.e. monosyllabic words without their onsets) as 0.7 more voiced on a scale of one to five if the final obstruent was underlyingly voiced compared to voiceless. These studies thus suggest that listeners are sensitive to the minimal cues of incomplete neutralization.

It is legitimate to wonder to what extent the results from the perception experiments are simple task effects, reflecting unnatural linguistic behavior. All studies reported above asked participants to choose between orthographic forms, and hence drew participants' attention to spelling. Moreover, participants could not perform their tasks without taking the acoustic cues to incomplete neutralization into account. Ernestus and Baayen (2006) circumvented this problem by presenting Dutch participants auditorily with non-existing verb stems and asking them to produce the corresponding past tense forms. According to Dutch regular morphology, the appropriate past tense allomorph is *-te* if the final obstruent of the verbal stem is underlyingly voiceless; otherwise it is *-de*. Earlier research had shown that participants interpret the final obstruents of nonce words on the basis of the phonologically similar existing words (Ernestus and Baayen 2003). Ernestus and Baayen (2006) showed that, if the final obstruents differ slightly in their voicing, participants interpret these acoustic differences as resulting from incomplete neutralization and use these differences as a cue for their interpretations of the final obstruents as well. They do so even if their interpretations have no consequences for the spelling of these final obstruents. These findings suggest that listeners are sensitive to incomplete neutralization also if this is not necessary for the experimental task and has no consequences for spelling.

In conclusion, several experimental studies have shown that final devoicing may be incomplete, and that listeners are sensitive to the resulting minimal acoustic differences between underlyingly voiced and voiceless obstruents. Other studies, however, have cast doubt on these findings. Further research into this issue is necessary.

2.6 Incomplete neutralization: Theoretical implications

The possibility that final devoicing may be gradient is unexpected within generative grammar, since it has always been classified as a phonological process. If final devoicing is phonetic in nature (see e.g. Port and O'Dell 1985, who suggested that final devoicing and incomplete neutralization together form one phonetic implementation process), its output cannot form the input of purely phonological processes. This complicates the theoretical account of several other processes.

One example is the devoicing of voiced fricatives following syllable-final obstruents in Dutch (e.g. while *maa*/n+v/*is* 'angelfish' is pronounced as *maa*[nv]*is*, *gou*/d+v/*is* 'goldfish' is pronounced as *gou*[tf]*is* (see e.g. Booij 1995)). In the traditional generative account, this fricative devoicing results from phonological progressive voice assimilation, which is fed by phonological final devoicing (i.e. in the example *gou*[tf]*is*, final devoicing turns word-final /d/ into [t], which triggers devoicing of the following /v/). If final devoicing is phonetic, we have to assume that the devoicing of fricatives results from a phonological process that precedes and is independent of final devoicing. Another possibility is that progressive voice assimilation is phonetic as well, an assumption for which we do not have any acoustic or articulatory support.

A second phonological process that appears to follow final devoicing is resyllabification. In Dutch, word-final obstruents form syllables with following vowel-initial clitics (CHAPTER 84: CLITICS), and the word-final obstruents then occupy onset positions (e.g. *weet ie* 'knows he' is pronounced as /ue-ti/). Importantly, these word-final obstruents are typically voiceless, independently of their underlying voice specification. If final devoicing precedes resyllabification, this is as expected. Hence, if final devoicing is part of the phonetic component, we have to assume that resyllabification is phonetic as well, or we have to assume a phonological process, independent of phonetic final devoicing, which devoices resyllabified obstruents. In summary, if final devoicing is phonetic in nature, we have to assume that other phonological processes are also phonetic, or that there are several phonological processes doing partly the same work as final devoicing.

Since both options appear unattractive, Dinnsen and Charles-Luce (1984), as well as Slowiaczek and Dinnsen (1985), suggest that phonetic implementation rules (including final devoicing) may apply before phonological rules. Note that this solution implies that phonetic processes may be of very different types. Traditional phonetic implementation processes translate segments or phonological features into phonetic scores (for articulation) that correspond well with these symbols. Final devoicing, in contrast, would change [+voice] into (almost completely) [−voice].

Given the problems facing a phonetic account of final devoicing, some researchers have proposed that the process is phonological in nature, and that incomplete neutralization results from phonetic implementation processes. These accounts have to solve the question of how the phonetic component can distinguish between obstruents that should be realized as completely voiceless and those that should be slightly voiced. Van Oostendorp (2008) proposes that obstruents may be phonologically specified as voiced ([voice]), as voiceless (no specification for voice), or as devoiced (the feature [voice] is not in a pronunciation relation), and argues that this possibility directly results from assumptions about the phonological component that are necessary for the explanation of unrelated phenomena.

A completely different account of incomplete neutralization is proposed by Ernestus and Baayen (2007). Their account is based on the assumption that the mental lexicon contains representations for all words of the language, including morphologically complex words. Thus, the Dutch lexicon contains both the singular *man*[t] 'basket' and the plural *man*[d]*en* 'baskets'. This assumption is supported by the finding that all words of high frequencies of occurrence, including morphologically inflected and derived words, are recognized and produced more quickly and with fewer errors than words of low frequencies (e.g. Baayen *et al.* 1997; Alegre and Gordon 1999; CHAPTER 90: FREQUENCY EFFECTS). If the lexicon contains all words of a language, all word-final obstruents can be lexically represented as voiceless. The information that obstruents are voiced in morphologically related words is present in the lexical representations of these related words themselves. Thus, the Dutch word for 'basket' can be lexically represented as *man*/t/, since the plural *man*/d/*en* is stored as well. In this account, incomplete neutralization may be explained in two ways. First, lexical representations may be gradient and contain detailed information about the exact pronunciations of the segments (see also §2.7). Word-final obstruents may thus be represented as slightly voiced. Second, the realization of a word may be affected by the pronunciations of phonologically and morphologically related words. If a stem-final obstruent is voiced in most words, these voiced specifications may affect the pronunciation of the stem-final obstruent in word-final position, which is consequently produced as slightly voiced. This type of lexical analogy would also explain why, in the absence of an abstract mechanism of final devoicing, the final obstruents of new words are always produced as voiceless: this results from the influence of all final voiceless obstruents in the lexicon.

In conclusion, incomplete neutralization has attracted much attention in the theoretical literature, framed both within and outside generative grammar. This may be surprising since we saw above that the phenomenon is not yet well established. Note, however, that if future research will show that incomplete neutralization is just an artifact of our experimental paradigms, we still need to explain how these experimental effects can arise in speech production and comprehension. Incomplete neutralization will therefore remain an important theoretical topic

2.7 *Fine phonetic detail in speech processing*

Within generative grammar, lexical representations are categorical in nature, as they consist of strings of phonemes or phonological features, abstracting away from phonetic detail which is not necessary to distinguish between these units. In contrast, several researchers now consider the hypotheses that lexical representations are gradient in nature and reflect fine phonetic detail (see, for example, the account of incomplete neutralization of Ernestus and Baayen 2007, mentioned above) and that one and the same word may have many lexical representations reflecting slightly different pronunciations. These hypotheses are based on the findings that phonetic detail may play an important role in speech comprehension (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY).

First, experimental data show that listeners are sensitive to phonetic detail providing information about upcoming segments. For instance, in several languages, the relative duration of a vowel is a cue to the presence of additional syllables within the same word, as vowels are typically shorter if they are followed by more syllables. Listeners use these durational cues and predict that syllables like *ham* and *dive*, produced with relatively short vowels, are part of longer words (i.e. *hamster* and *diver*; e.g. Davis *et al.* 2002; Kemps *et al.* 2005). Similarly, listeners use fine phonetic cues in syllable onsets to predict the presence of /r/ or /s/ in syllable codas (e.g. Heinrich and Hawkins 2009).

Second, several experiments have shown that listeners remember voice characteristics and that these memory traces may affect speech processing. For instance, participants are faster in determining whether two words in a sequence are identical if these two words are presented in the same voice than if they are presented in different voices (Cole *et al.* 1974). Participants tend to complete morphological stems with those suffixes that result in words they have just heard before, especially if these complex words were produced by the same voice as the stems (Schacter and Church 1992). Furthermore, participants tend to mimic previously heard pronunciations in their phonetic detail (Goldinger 1998).

These phonetic detail effects can be accounted for within generative grammar by means of the phonetic component and performance factors. The phonetic component may translate long stretches of phonological segments, rather than single segments, into acoustic signals. Likewise, listeners may analyze acoustic signals to extract not only their segments but also information on following segments (see e.g. Norris and McQueen 2008). This would explain the existence and perceptual relevance of acoustic cues distributed over longer stretches of speech. The effects of voice characteristics may result from the storage of acoustic signals in short-term memory.

In addition, these data may be accounted for by assuming that the detailed phonetic properties of a word are stored in the mental lexicon together with all other information about that word. Thus, the lexical representation *diver* may contain the information that the first vowel is relatively short. Episodic models (e.g. Goldinger 1998) assume that the mental lexicon contains such detailed representations for all tokens of all words that a speaker has ever encountered (such representations are called exemplars). These models can easily explain the processing effects of voice characteristics: if a lexicon contains a word token with the characteristics of a given speaker, the mapping of a new token of that word produced by that same speaker with the exemplars in the mental lexicon is easier than if the mental lexicon does not already contain a token by that speaker.

Episodic models are especially popular in psycholinguistics. So far, two purely episodic models have been developed and computationally implemented for speech processing: Johnson's (1997) XMOD and Goldinger's (1998) MINERVA. The XMOD model is based on the Lexical Access from Spectra (LAFS) model developed by Klatt (1979), and assumes that the incoming speech signal is transformed into a sequence of spectra. MINERVA was originally developed by Hintzman (1986) and applied to speech by Goldinger. Both XMOD and MINERVA assume that during the recognition process, exemplars respond to an acoustic input in proportion to their similarities to this input, and that their activations spread to the abstract word nodes (XMOD) or to the working memory (MINERVA), which enables recognition.

In addition to these purely episodic models, several hybrid models have been formulated, which assume both abstract lexical representations (strings of phonemes or features) and exemplars. These models can account for all experimental evidence supporting abstract lexical representations (including categorical perception, e.g. Liberman *et al.* 1957) and for the role of fine phonetic detail in speech processing. In addition, they can account for the recent finding that speaker characteristics affect speech processing only if for some reason processing is slow. McLennan and Luce (2005) as well as Mattys and Liss (2008) showed that tokens produced by the same voice are recognized more quickly than tokens produced by different voices only if the experimental task produces delayed responses (e.g. a shadowing task with a long set response time, or a lexical decision experiment that is difficult because of the many word-like pseudowords).

An important hybrid model for speech production is proposed by Pierrehumbert (2002). She assumes that speech production involves the activation of abstract representations, the application of abstract phonological rules (e.g. Prosodic Final

Lengthening), and the activation of exemplar clouds of phonological units (e.g. phonemes and phoneme sequences). Two hybrid models for word recognition are Goldinger's (2007) Complementary Learning System and the model that McLennan *et al.* (2003) developed on the basis of the Adaptive Resonance Theory (Grossberg and Stone 1986). Both models assume that the incoming signal is first analyzed into abstract phonological units, which are matched with the abstract representations in the lexicon, and only then is the signal matched with the stored exemplars. Another hybrid model for word recognition is PolySP (Polysystemic Speech Perception), developed by Hawkins and Smith (Hawkins and Smith 2001; Hawkins 2003). This model assumes that a memory trace does not only contain acoustic information, but also multi-medial context, for instance, visual information about the speaker's gestures. In addition, the model assumes that the analysis of an acoustic input into its linguistic units (phonemes, etc.) may precede (and contribute to) or coincide with or follow word recognition or not take place at all, depending on the circumstances.

In conclusion, experimental evidence suggests that gradient acoustic characteristics play a role in speech processing. More research is necessary showing which types of acoustic characteristics are relevant, how this gradient information is accessed under which conditions, and how the role of this type of information should be accounted for in speech production and comprehension models.

2.8 *Conclusion*

Gradience appears to be a much more important characteristic of speech sounds than is traditionally assumed. Place and voice assimilation, segment deletion, and final devoicing often result in sounds showing incomplete neutralization, i.e. they result in sounds that contain characteristics of more than one phoneme or that are only partly absent. Since generative grammar assumes that gradience is a characteristic of the phonetic component, these data suggest that within this theory many processes that have always been classified as phonological actually belong to the phonetic component. Particularly in the case of final devoicing, this reclassification has consequences for the classification of other speech processes as well. Alternative theories have been developed, which assume that the phonological primitives are articulatory gestures or that lexical representations reflect the gradient nature of speech sounds. These theories are supported by data showing that fine phonetic detail affects speech processing.

3 Productive sound patterns

3.1 *Introduction*

Gradience does not only play a role in the discussion of the phonological and phonetic components and of the nature of lexical representations, but also in the theoretical discussion of the nature of productive (morpho)phonological processes. Within traditional generative phonology, a productive process applies always and to all inputs that satisfy its structural description. Productive processes are thus categorical in nature. Recent research suggests, however, that some productive processes show gradience. The following two subsections discuss evidence for gradient phonological processes, their implications for generative phonology, and alternative theories that account for the gradient data.

3.2 Phonotactic constraints

The first type of phonological processes whose categorical nature has been seriously questioned is phonotactic generalizations. Within traditional generative phonology, all illegal sequences are considered equally illegal, all legal sequences as equally legal, and there is no gradience in legality.

If this assumption is correct, differences in the frequencies of occurrence of phonemes and phoneme sequences are based on coincidence. Pierrehumbert (1994) studied the frequencies of consonants and consonant clusters at the beginning of words, at the end of words (excluding the phonological appendix), and in syllable onset and coda positions within morpheme-internal consonant clusters (e.g. the frequency of [n] in words like *vanquish*, where it is in syllable coda position within a consonant cluster, and the frequency of [st] in words like *lobster*, where it is in syllable onset position in a consonant cluster) in an American English dictionary. If the consonants are randomly distributed over the positions, the frequencies of a given consonant (cluster) in the different positions should be unrelated. This appeared not to be the case. The frequency of a morpheme-internal cluster appears highly correlated to the frequency of its first part (i.e. the consonants in coda position) in word-final position and to the frequency of its second part (i.e. the consonants in onset position) in word-initial position. Phonemes and phoneme sequences structurally differ in their frequencies in a language.

Crucially, language users reflect these frequencies in their well-formedness judgments of nonce words and parts of words (CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS). Speakers typically judge high-frequency rhymes as "phonologically" better than low-frequency rhymes (Treiman *et al.* 2000), phonotactically legal nonce words as better if they contain phoneme sequences of high frequency (e.g. Vitevitch *et al.* 1997; Frisch *et al.* 2000), and nasal-obstruent clusters as better if these clusters are more frequent (Hay *et al.* 2004). Thus, *blick* is rated as a good English word, *bnick* as an impossible word and *bwick* is rated in between. Importantly, these gradient well-formedness judgments are obtained both if participants are allowed to provide gradient responses and if they have to provide categorical judgments, with the judgments being averaged over participants (Frisch *et al.* 2000). This strongly suggests that phonotactic constraints are gradient rather than categorical.

Language users' judgments of a nonce word are also affected by the phonological distance of this word from existing words (CHAPTER 87: NEIGHBORHOOD EFFECTS). Thus, participants rate a nonce word as more well-formed if it differs in fewer phonemes from an existing word (Greenberg and Jenkins 1964; Ohala and Ohala 1986). In addition, their well-formedness judgments are related to the size of a word's phonological neighborhood (Bailey and Hahn 2001; Hammond 2004), which is typically defined as the number of existing words that can be changed into that word by the substitution, addition, or deletion of a single phoneme. Importantly, the effect of the word's phonological neighborhood is independent of the effects of the frequencies of the word's constituents (i.e. the effect is also present if words with small and larger neighborhoods are matched in the frequencies of their constituents). This shows again that well-formedness judgments are not categorical (i.e. it is not the case that a word is either completely well formed or completely ill formed). Rather, these judgments are gradient between completely well formed and completely ill formed.

Importantly, the measures affecting well-formedness judgments also play a role in other (psycho-)linguistic tasks. The frequencies of the phonemes and phoneme sequences in a word have been shown to affect speech production, recognition, and learning. For instance, participants are better at repeating nonce words made up of high-frequency rather than low-frequency phoneme sequences (Vitevitch *et al.* 1997) and at transcribing such words orthographically (Hay *et al.* 2004). Participants tend to interpret ambiguous fricatives as the most probable ones given the preceding and following segments (Pitt and McQueen 1998). Nine-month-old infants prefer to listen to words consisting of high-frequency rather than low-frequency phoneme sequences (Jusczyk *et al.* 1994). Furthermore, when both eight-month-old infants and adults are presented with continuous speech froma non-existing (artificial) language, they extract the words of this language on the assumption that frequent phoneme sequences form (parts of) words, while the less frequent ones span word boundaries (Saffran *et al.* 1996a; Saffran *et al.* 1996b). Similarly, speech production and comprehension are affected by a word's phonological neighborhood. Thus, participants recognize words with large neighborhoods more slowly in auditory lexical decision (e.g. Luce and Pisoni 1998) and produce them with more expanded vowel spaces (Munson and Solomon 2004), while pre-school-aged children produce such words more quickly and with fewer errors in picture-naming tasks (Arnold *et al.* 2005).

Several generative linguists have assumed that the gradience of well-formedness judgments may be merely a task effect, resulting from performance factors (for a discussion, see Schütze 2005). This account is in line with the finding that the variables affecting well-formedness ratings also play roles in speech production, perception, and learning, which are certainly modulated by performance factors.

In addition, there is a continuum of accounts which differ in their assumptions about the contributions of the phonological component and the mental lexicon. The models at one end of the continuum assume that the gradience of well-formedness judgments results from the gradient nature of the phonological component itself. This component would be gradient due to the probabilistic nature of its constraints or rules. For instance, Hammond (2004) frames his account of gradient well-formedness judgments within Probabilistic Optimality Theory, which is based on Stochastic Optimality Theory, developed by Boersma (1998). The idea is that the ranking of constraints is variable, and that a given (markedness or faithfulness) constraint outranks some other constraint with a certain probability. If this probability is smaller than 1, the phonological component shows variation, sometimes favoring one form and sometimes another, which results in gradient well-formedness rankings. The probability of a given ranking (and consequently the judgment of a given form) may be co-determined by the frequencies of phoneme sequences and by the exact contents of the mental lexicon. Models at the other end of the continuum assume that well-formedness judgments for a given word result only from the comparison of that word with all words in the mental lexicon and their constituents. The visual or auditory presentation of a word leads to the activation of all (phonologically) similar words in the lexicon and their constituents, and a higher total lexical activation leads to a higher well-formedness rating. In these analogical models, there is thus no role for an abstract phonological component with hardwired phonological constraints or rules (e.g. Bailey and Hahn 2001). Models positioned between the two ends typically assume that the effects of constituent frequencies result from phonotactic knowledge, and the effects of phonological neighborhood from lexical knowledge. Phonotactic knowledge is permanently stored in the phonological component, while lexical knowledge is deduced from the mental lexicon if necessary (e.g. Bailey and Hahn 2001; Albright 2009).

In summary, the evidence for gradience in well-formedness judgments is undisputed. Detailed research is necessary in different domains of phonology to establish the best theoretical account.

3.3 *Allomorphy*

A second type of productive phonological process that appears gradient is those involved in morphological processing. These morphophonological processes select affixes on the basis of the phonological properties of the words' stems (CHAPTER 99: PHONOLOGICALLY CONDITIONED ALLOMORPH SELECTION). For instance, Dutch regular past tense forms consist of a verbal stem and the suffix *-te* or *-de*. According to the traditional literature (which follows Dutch orthography), the correct allomorph is *-te* if the verbal stem ends in an underlyingly voiceless obstruent (e.g. *sta*/p+t/*e* 'stepped'), otherwise it is *-de* (e.g. *kra*/b+d/*e* 'scratched'). It has been shown recently that at least some of these apparently perfectly categorical generalizations do not do justice to the full data.

One example is the above-mentioned regular past tense formation in Dutch. Ernestus and Baayen (2004) show that the description of the selection of the past tense allomorph given in the literature is too simplistic. Speakers tend to choose the non-standard allomorph for verbal stems that are special, in that the underlying voice specification of their final obstruent is unexpected given the other stems ending in the same type of final rhyme in the lexicon. For instance, speakers often choose the non-standard allomorph for *kra*/b/ (creating *kra*/b+t/*e*), which is one of the few Dutch verb stems ending in a short vowel and a voiced (instead of voiceless) bilabial stop. The pattern "short vowel–underlyingly voiceless bilabial stop" is much more common (e.g. *sto*/p/ 'stop', *kla*/p/ 'bang', *me*/p/ 'slap', *ni*/p/ 'sip') than the pattern "short vowel–underlyingly voiced bilabial stop," and speakers tend to add the allomorph that is correct for the majority of verbs ending in a short vowel and a bilabial stop to the minority of verbs for which it is incorrect (i.e. verbs ending in a short vowel and an underlyingly voiced bilabial stop). These findings can easily be incorporated in all types of theoretical accounts, since the only adaptation necessary is that the broad generalizations are replaced or supplemented by generalizations that are more specific for the precise phonological properties of the words. Apparently, Dutch requires a generalization stating that stems ending in short vowels and bilabial stops tend to select *-te*.

Importantly, however, the facts are more complex. First, Ernestus and Baayen (2004) observe that, if participants select the standard allomorph, they do so more quickly for verbs following the majority patterns than for exceptional verbs (i.e. they produce forms of the type *stapte* more quickly than forms of the type *krabde*). Second, Ernestus and Baayen (2003, 2004; see also Ernestus 2006) find that speakers show stochastic behavior; they often do not agree with each other, and the same speaker may choose *-te* for some verbs and *-de* for other verbs of the same type. Similar results have been found, among others, for past tense formation in English (Albright and Hayes 2003), the choice of the English indefinite article (*a vs. an*; Skousen 1989), and vowel harmony in Hungarian (Hayes and Londe 2006). Apparently, the morphophonological processes that have to replace or supplement the traditional broad generalizations are not simple categorical rules that apply whenever their structural description is met. The processes are gradient in nature.

Speakers' probabilistic behavior has been accounted for in the two types of approaches (forming a continuum) that also explain the gradience of well-formedness ratings (see above). The first approach holds that constraints or rules are probabilistic in nature. Thus, in Stochastic Optimality Theory (Boersma 1998), constraint rankings are stochastic, and in the rule-based account proposed by Albright and Hayes (2003) rules differ in their confidence intervals. Both accounts assume that the probability of a constraint ranking or rule (and thus of a given form) is determined by the exact contents of the mental lexicon. While this approach can account well for the observed probabilistic effects, additional assumptions are necessary to explain why speakers are slower in selecting the standard allomorph if it receives less lexical support than the other allomorph (for a discussion, see Ernestus 2006). The second approach to speakers' stochastic behavior assumes that, when speakers select an allomorph for a word, they check all words in their lexicons online. The probability that they select a given allomorph is proportional to its support from the words in the lexicon, with words that are more similar to the target word being more influential. If the target word itself is in the lexicon as well and supports a different allomorph from the one receiving the greatest lexical support from the other words, this may result in severe competition between the two allomorphs, which may lead to the selection of the non-standard allomorph and longer response latencies (Ernestus and Baayen 2004).

In conclusion, phonologically driven allomorphy also strongly suggests that gradience is an important characteristic of phonology. The generalizations formulated in the generative literature appear too coarse-grained, given that speakers show probabilistic behavior. Several models can account for the obtained observations so far. More data are necessary to tease the different accounts apart.

4 Conclusion

In the early days of generative grammar, phonology was assumed to be completely categorical in nature. The present chapter has provided a summary of different types of corpus-based and experimental studies which strongly suggests that many processes traditionally classified as phonological are in fact gradient in nature. Sounds may contain characteristics of different categories, and speakers may show probabilistic behavior. These data have given rise to modifications of traditional generative phonology and to the development of new theories, including theories assuming different types of phonological primitives and phonological representations, and theories challenging the role of abstract generalizations. Further research is necessary to obtain a more detailed view of the role of gradience in phonology and to tease different theoretical accounts apart. Until then, we have to conclude that gradience is an important challenge for phonology.

83 Paradigms

Adam Albright

1 Introduction

Morphological paradigms are a mainstay of traditional descriptions of inflectional systems and of diachronic change. Only in recent years, however, have paradigms played a formal role in the grammatical analysis of phonological systems, in the form of correspondence constraints and contrast constraints on paradigmatically related forms. In this chapter I review some of the evidence that has been taken to indicate that paradigm structure plays an active role in synchronic phonology, and discuss some of the grammatical mechanisms that have been proposed to capture such effects, focusing especially on work within Optimality Theory (OT: Prince and Smolensky 2004).

It must be acknowledged at the outset that one cannot meaningfully discuss phonological paradigm effects without a precise definition of "paradigm." I begin by adopting a very general and widely assumed definition: a paradigm is the exhaustive set of inflected forms that share a single root or stem – e.g. inflected case and number forms of a noun, or person, number or tense/aspect/mood forms of a verb. In some cases, phonology treats all inflected forms of a root alike, and this broad definition suffices. In many cases, however, it is necessary to restrict the domain of discussion to a specific subset of inflected forms that constitute a local subparadigm – e.g. the set of verb forms that share present tense subjunctive inflection (the "present subjunctive paradigm"), or the set of noun forms that share dual inflection (the "dual paradigm"). For the purpose of illustrating paradigm effects and their analysis, I will simply stipulate the scope of the effect as necessary; in §4, I return to the issue of the formal definition of paradigms.

An important related issue is whether phonological paradigm effects are conditioned by the same type of paradigm structure that is posited by paradigm-based theories of morphology, such as Word-and-Paradigm Morphology (Hockett 1954; Matthews 1965; Zwicky 1985; Anderson 1986) or Paradigm Function Morphology (Stump 2001). On the face of it, paradigm-based theories of morphology seem especially well suited for capturing phonological paradigm effects, since they provide a representational unit (the "paradigm") that can be used to condition morphological and phonological grammar distributions. The use of phonological paradigm constraints does not presuppose the existence of paradigms as morphological representations, however. In fact, the phonological constraints described in §3 make very limited use of morphological structure: if two forms share a root and all derivational affixes, then they are treated by the phonology as members of the same inflectional paradigm. Although arguments against morphological and phonological uses of paradigms are often presented side by side (e.g. Bobaljik 2008), it appears that the question of whether morphology is paradigm-based may be orthogonal to the question of whether phonology imposes constraints on relations between inflectionally related forms. The current chapter focuses on the role that paradigmatic relations play in conditioning phonological distributions, and leaves aside arguments for and against paradigms as morphological representations. A long-term goal, beyond the scope of this chapter, would be to establish whether morphological and phonological distributions rely on a common set of representational units, or whether phonological constraints make only indirect reference to morphological representations.

In this chapter, I consider a variety of effects that demonstrate a role for paradigms in phonological grammar. Before turning to the analysis of synchronic paradigm effects, however, it is useful to review briefly the type of data that have traditionally been taken as evidence that phonological processes are sensitive to paradigm structure, drawn from the domain of language change.

1.1 *Paradigms as a factor in conditioning diachronic change*

It is often convenient to present complex inflectional systems in tabular form, with each cell in the paradigm representing a particular combination of morphosyntactic features. In some theories of morphology, paradigms are taken to be not merely a matter of descriptive convenience, but also a grammatically relevant representation of the distribution of inflectional markers (Hockett 1954; Matthews 1965; Anderson 1986; Wurzel 1989; Stump 2001; Blevins 2003; Ackerman *et al.* 2009). According to proponents of paradigm-based models, representations in terms of paradigms permit concise or insightful statements about morphological distribution that would be difficult to capture if each morpheme were represented individually. For instance, patterns of syncretism and alternation are often shared across multiple inflection classes, suggesting that a paradigmatic template is in force (Williams 1994; Baerman *et al.* 2005; Maiden 2005; though see Bobaljik 2002 and Harley 2008 for alternative approaches). An example is seen in Modern German, which has stem vowel alternations in the 2nd and 3rd singular present tense forms of many verbs. These alternations can be traced back to historically unrelated raising processes, but the conditioning context (originally, high vowels in the suffix) is no longer present in the modern language, nor can the various changes found in the 2nd and 3rd singular be straightforwardly unified as the same featural change. Thus it appears that the broadest generalization one can make is that the 2nd and 3rd singular differ from the rest of the paradigm in having a raised and/or fronted vowel. This relation cannot be captured by a single (morpho)phonological rule, but can be characterized by a template in which the 2nd and 3rd singular forms differ from the remaining forms.

(1) *Vowel alternations in German present tense indicative verb forms*

Verb	'travel'	'run'	'give'	'see'
INF	faːʁən	laʊfən	geːbən	zeːən
1SG	faːʁ(ə)	laʊf(ə)	geːb(ə)	zeː(ə)
2SG	f<u>ɛː</u>ʁst	l<u>ɔɪ</u>fst	g<u>ɪ</u>b̥st	z<u>iː</u>st
3SG	f<u>ɛː</u>ʁt	l<u>ɔɪ</u>ft	g<u>ɪ</u>b̥t	z<u>iː</u>t
1PL	faːʁən	laʊfən	geːbən	zeːən
2PL	faːʁt	laʊft	geːb̥t	zeːt
3PL	faːʁən	laʊfən	geːbən	zeːən

A compelling source of evidence for a paradigmatic effect comes from language change: in fact, verbs like [geːbən] 'give' and [zeːən] 'see' originally showed a different distribution, in which the 1st singular had the same vowel as the 2nd and 3rd singular: [gibə], [gib̥st], [gib̥t]. The change of 1st singular [gibə]→ [geːbə] to match the vowel of the plural and infinitive appears to have been motivated by the influence of verbs like [faːʁən] 'travel', in which raising has always been limited to the 2nd and 3rd singular (Paul *et al.* 1989: 243).[1] Put differently, a prevalent pattern of alternation within the paradigm (2nd and 3rd singular *vs.* others) was generalized to verbs with a similar but less robustly attested pattern (singular *vs.* plural). Such changes are often taken as evidence that speakers evaluate the relations between forms within paradigms, and that language change may enforce or regularize such relations.

1.2 *Paradigm uniformity in language change*

One common way in which paradigmatic relations are strengthened is by loss (or "leveling") of alternations among inflectionally related forms. A widely discussed example comes from immediately pre-classical Latin, in which [s] ~ [r] alternations created by rhotacism of intervocalic stridents were leveled to invariant [r] (Hock 1991: 179–190; Barr 1994; Kenstowicz 1996; Hale *et al.* 1997; Kiparsky 1998; Baldi 1999: 323; Albright 2005).

(2) *Leveling of rhotacism alternations in Latin* honor

	Stage 1	*Stage 2*
NOM SG	honoː<u>s</u>	hono<u>r</u>
GEN SG	honoːris	honoːris
DAT SG	honoːriː	honoːriː
ACC SG	honoːrem	honoːrem
ABL SG	honoːre	honoːre

[1] An alternative view, put forward by Joesten (1931) and discussed by Dammers *et al.* (1988: 449) and by Hartweg and Wegera (1989: 129), holds that the distribution in (1) is etymologically expected for all of these verbs, including *geben*, and that the use of 1st singular *gibe* in literary Middle High German represents a partial leveling of the vowel from the 2nd and 3rd singular to the 1st singular in certain dialects. Either way, the difference between dialects with 1st singular *gibe* and those with *gebe* requires some form of analogical change within the paradigm to match a pattern found in other verbs.

Crucially, the change of [s] to [r] in [hono:s] → [honor] took place only within the inflectional paradigm, while derivationally related forms such as [hones-tus] 'honorable', [hones-te:] 'honorably', and [hones-ta:s] 'honorableness' remained unchanged. Furthermore, [s]-final nouns that had no inflected forms with [r], such as the indeclinable noun [nefa:s] 'sacrilege' (related to the derived adjective [nefa:r-ius] 'wicked'), also remained unchanged, as did [s]-final words in other parts of speech, such as the adverb [nimis] 'excessively'. These facts show that the change of [s] to [r] was not part of a broader sound change extending rhotacism to the word-final position. Furthermore, if we assume that forms like [hones-tus] remained synchronically linked to the related noun [honor], the change cannot be viewed as a re-analysis to /honor/ by learners missing the presence of [s] ~ [r] alternations (Vincent 1974). Such examples are often taken as evidence that the domain of analogical leveling is the inflectional paradigm.

Another common feature of paradigm leveling is that it may affect only a subset of the inflectionally related forms. For example, several classes of Middle High German (MHG) verbs showed vowel alternations between the singular and plural, with the infinitive always matching the vowel of the plural, and the past participle frequently showing yet a different vowel. In Yiddish, these alternations have been eliminated completely in some verbs (3a), while they have been leveled only among present tense forms for others (3b). We may plausibly suppose that the infinitive and finite present tense forms of /visən/ 'know' remain synchronically related, but the identity of the 1st/3rd plural and infinitive has been abandoned in favor of an invariant verb stem within the subparadigm of present tense forms (Albright 2010).

Language change provides numerous examples of paradigmatic conditioning. However, we frequently cannot be certain whether the changes reflect a synchronic preference for non-alternating paradigms, or whether they represent lexical re-analyses on the part of learners. Such changes are difficult to interpret, because we cannot be sure that Latin speakers synchronically derived forms like [hono:s] and [hones-tus] (without rhotacism) from a single stem /hono:s/. If [hono:s] and [honestus] were derived from different stems, we could interpret the change as a re-analysis of the nominal stem from /hono:s/ to /honor/ (perhaps motivated by the preponderance of rhotacized [hono:r-] forms), while the adjectival stem /hones/ remained intact. Similarly, although there is no reason to think that MHG speakers treated the infinitive and plural stems *wiȝȝ-* and *wiȝȝ-* as distinct, if for some reason they did encode them as separate stems, then we could simply say that Yiddish lost the plural stem while retaining the infinitive stem. In order to show that a phonological process misapplies within inflectional paradigms, we must demonstrate that the forms in question are synchronically derived from the same stem, and that the process in question continues to apply except when trumped by identity among paradigmatically related forms. In the following section, we review several cases with exactly this flavor: a phonological process continues to apply straightforwardly and productively in derived forms, but is overridden just in case greater identity between inflected forms would result.

2 Synchronic paradigm effects

The literature on synchronic paradigm effects has identified two opposing ways in which phonological relations among inflected words may be regulated: on the one hand, there is a tendency to demand identity among inflected forms, so that elements of shared meaning (the stem, shared inflectional markers) have a consistent phonological form throughout the paradigm (*uniformity*). At the same time, there is a tendency to avoid total identity between forms that are morphologically distinct (*anti-homophony*) (see also CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE). In both cases, it is claimed that the requirement of identity or distinctness may be enforced within the domain of the paradigm, while violations of identity between derivationally related forms, or violations of anti-homophony among unrelated forms, are not enforced. I consider these two tendencies in turn. Paradigmatic conditions in phonology have been explored extensively in the past decade, and it would not be possible in a chapter of this length to do justice to the range and intricacy of empirical cases that have been brought to bear on the issue. For additional examples, the reader is referred to the collections of papers in Hermans and van Oostendorp (1999), Downing *et al.* (2005b), and Bachrach and Nevins (2008).

Frequently, affixation creates or destroys the context for a phonological process to apply, leading to the possibility of alternations. This section discusses cases in which regularly expected alternations are avoided, and paradigmatic identity is seen instead. As is standard in the literature on identity effects in other domains, such as reduplication (McCarthy and Prince 1995), we may distinguish between cases where identity is achieved by applying a process outside its regular context (*overapplication*), by failing to apply a process within its regular context (*underapplication*), or by applying a process differently from how it would normally apply to a given phonological string (*misapplication*). It is also important to bear in mind that these phenomena are not substantively different from those that arise in cases of cyclicity in derived forms; therefore, much of the discussion of parallel facts in CHAPTER 85: CYCLICITY is relevant here as well.

2.1 *Overapplication*

Frequently, phonological processes apply outside their regular context, if doing so can achieve greater identity between related forms. For example, Hayes (2000) discusses a process in American English (and other varieties) in which coda /l/ becomes dark and creates a diphthongized allophone of the preceding vowel (CHAPTER 31: LATERAL CONSONANTS): /fiːl/ → [fiəɫ] *feel*, /faɪl/ → [faɪəɫ] *file*,

/bɔɪl/ → [bɔɪəɫ] *boil*. This process does not normally occur intervocalically: [siːlɪŋ]/*[siəɫɪŋ] *ceiling*, [paɪlət]/*[paɪəɫət] *pilot*, [tɔɪlət]/*[tɔɪəɫət] *toilet*. However, at morpheme boundaries, coda velarization may apply. Hayes presents survey data documenting a variable or gradient pattern in which /l/ may be realized as [ɫ] before morpheme boundaries: *mai[ɫ]er*, *(touchy-)fee[ɫ]y*. The pattern that Hayes describes for his own speech involves overapplication of diphthongization and coda velarization before both inflectional and derivational affixes: [hiəɫɪŋ] *healing*, [meəɫə] *mailer*. By contrast, in at least the present author's idiolect, coda velarization always overapplies, but diphthongization overapplies (optionally) only in inflected forms. The difference is most clearly heard (and intuited) after underlying diphthongs, where "diphthongization" yields so-called sesquisyllabic outcomes such as [bɔɪəɫ] *boil*. Crucially, the overapplication of diphthongization seems to occur only in inflected forms: *boiling* [bɔɪəɫɪŋ] *patiently vs. boiler* [bɔɪɫɚ], *[bɔɪəɫɚ].

(4) *Overapplication of pre-lateral diphthongization in one idiolect of American English*

base		*inflected*	*derived*	
[bɔɪəɫ]	*boil*	[bɔɪɫɪŋ], [bɔɪəɫɪŋ]	[bɔɪɫɚ], *[bɔɪəɫɚ]	*boiler* ('water-heater')
[spɔɪəl]	*spoil*	[spɔɪɫɪŋ], [spɔɪəɫɪŋ]	[spɔɪɫɚ], *[spɔɪəɫɚ]	*spoiler* (of plot)
			[spɔɪɫədʒ], *[spɔɪəɫədʒ]	*spoilage*
[ɔɪəɫ]	*oil*	[ɔɪɫɪŋ], [ɔɪəɫɪŋ]	[ɔɪɫɚ], *[ɔɪəɫɚ]	(*Edmonton*) *Oiler(s)*
[smaɪəɫ]	*smile*	[smaɪɫɪŋ], [smaɪəɫɪŋ]		
[vaɪəɫ]	*vile*	[vaɪɫəst], [vaɪəɫəst]		
[maɪəɫ]	*mile*		[maɪɫədʒ], *[maɪəɫədʒ]	*mileage*
[naɪəɫ]	*Nile*		[naɪɫarɪk], *[naɪəɫarɪk]	*Nilotic*
[kəmpaɪəɫ]	*compile*	[kəmpaɪɫɪŋ], [kəmpaɪəɫɪŋ]	[kəmpaɪɫɚ], *[kəmpaɪəɫɚ]	*compiler*
[staɪəɫ]	*style*	[staɪɫɪŋ], [staɪəɫɪŋ]	[staɪɫɪst], *[staɪəɫɪst]	*stylist*[2]

A similar example comes from Yiddish, which generally avoids [rn] and [rm] codas by schwa epenthesis (Albright 2010): [alarəm] 'alarm', [ʃturəm] 'storm', [ʃirəm] 'umbrella', [turəm] 'tower' (CHAPTER 26: SCHWA; CHAPTER 67: VOWEL EPENTHESIS). When an /rm/ cluster is intervocalic, epenthesis does not normally occur: [alarm-ir-n] 'to alarm', [ʃturm-ɪʃ] 'stormy', [ʃirm-ə] 'screen', [turm-ə] 'prison'. This pattern is disrupted in verbal paradigms, however: (5a) shows that, if epenthesis applies somewhere within the paradigm, it systematically overapplies in the entire paradigm. This can be compared with (5b), which shows that, if

[2] A possible exception is ['staɪəˌtaɪz] *stylize*. It appears that stress clash avoidance may also play a role in conditioning [əɫ] in this form, however, since the derived noun form is [ˌstaɪɫə'zeɪʃən] *[ˌstaɪələ'zeɪʃən] *stylization*.

epenthesis is not conditioned anywhere within the paradigm, /rm/ surfaces uniformly faithfully. Overapplication in the verb [ʃturəm-ən] cannot be attributed to the influence of the related noun [ʃturəm], since the verb [alarm-ir-ən] does not show overapplication on the basis of the related noun [alarəm]. In addition, as the examples above show, epenthesis does not overapply in derived forms; additional examples include [varm-əs] 'warm food' and [refɔrm-ir-n] 'to reform'.

(5) *Overapplication of epenthesis in Yiddish*

	1PL	ʃturm-ən	ʃturəm-ən		1PL	alarmir-ən	alarmir-ən
	2PL	ʃturəm-t	ʃturəm-t		2PL	alarmir-t	alarmir-t
	3PL	ʃturm-ən	ʃturəm-ən		3PL	alarmir-ən	alarmir-ən

In both the English pre-lateral diphthongization and Yiddish epenthesis cases, phonology is blind to inflectional affixes – that is, a coda process applies as if the stem-final consonant is a coda, even if the inflectional affix should bleed epenthesis. It is not always the case that overapplication extends a process from an inner constituent to an outer constituent in this way, however. The Latin [honor] analogy discussed in §1 involved the overapplication of rhotacism, which should normally have occurred only before vowel-initial suffixes (e.g. /hono:s-is/ → [hono:ris]), but came to apply before nominative singular /s/ (or /Ø/) as well: /hono:s-s/ → [hono:r].

Another example of application of a process triggered by an inflectional affix is found in certain dialects of Korean (Han 2002; Kang 2003). In Korean, coronal obstruents regularly palatalize (CHAPTER 71: PALATALIZATION) before a suffix beginning with high front [i]: /os-i/ → [oʃi] 'clothing-NOM', /patʰ-i/ → [paʧʰi] 'field-NOM'.[3] Palatalization does not normally occur before mid front vowels ([patʰ-e] 'field-LOC') or high central vowels ([patʰ-ɨl] 'field-ACC'). Han (2002), citing data from Choi (1998), observes that in certain dialects of North Gyeongsang Korean (namely, in Sangju, Geumneung, Cheongdo, and Mungyeong), palatalization overapplies:

(6) *Overapplication of palatalization in North Gyeongsang Korean*

/patʰ/ 'field'	Conservative	North Gyeongsang
UNMARKED	pat̚	pat̚
NOM	paʧʰ-i	paʧʰ-i
ACC	patʰ-ɨl	paʧʰ-ɨl
DAT/LOC	patʰ-e	paʧʰ-e

In North Gyeongsang Korean, as in other dialects, the unmarked form obeys coda restrictions that neutralize continuancy and laryngeal contrasts (CHAPTER 69:

[3] There is some variability regarding the place of articulation of affricates, ranging from alveolar to post-alveolar or perhaps even palatal; see Cho (1967); Kim-Renaud (1974); Ahn (1998); Kim (1999); Sohn (1999).

FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). The change in North Gyeongsang consists of extending palatalization within noun paradigms, so that it overapplies before mid and central vowels. Unlike Latin or Yiddish, this case involves the overapplication of a process that is triggered by an inflectional affix.

As with Latin, we must ask whether the change could be interpreted instead as a change in the context of palatalization, or as a lexical re-analysis (CHAPTER 1: UNDERLYING REPRESENTATIONS). It is easy to demonstrate that the change is not a general expansion of the context for palatalization to include mid and central vowels. Han (2002) and Kang (2005) point out that, within verbal and adjectival paradigms, palatalization never affects /t^h-i/ sequences: /kat^h-in/ → [kat^{h}in], *[kaʧ^{h}ɨn] 'same-MODIFIER'. Thus, there is no evidence that palatalization in the accusative or locative reflects a broader change in the palatalization process itself. It is also important to ask whether the change is simply a re-analysis of the lexical entry to /paʧ^h/ – indeed, this is precisely what Kim (2005) claims. There are several reasons to think that a purely lexical account is not sufficient, however. First, assuming that the leveling in (6) has affected all /t^h/-final nouns in the relevant dialects and that speakers would reject new words with [ʧ^h] ~ [t^h] alternations, we need to account not only for the change to the specific lexical items in question, but also for the knowledge that there could be no lexical items of this type – i.e. a morpheme structure condition. McCarthy (1998) proposes to analyze such knowledge as a paradigm effect: specifically, speakers know that palatalization must apply before *-i*, and that it must overapply in the remainder of the paradigm by virtue of output–output faithfulness; therefore, no morpheme with /t^h/ could ever surface as such within its inflectional paradigm. Even more telling, it appears that overapplication of palatalization may be observed even in cases of partial leveling, where speakers continue to treat the noun as /t^h/-final in other contexts. Han (2002) and Kang (2005) discuss a related pattern found in the dialects of Gyeonggi, parts of Chungcheong, and North Jeolla, in which palatalization overapplies only before the accusative marker /-ɨl/, while the expected [t^h] surfaces faithfully before locative /-e/ and directive /-ɨlo/: unmarked [pat̚], nominative [paʧ^h-i], accusative [paʧ^h-ɨl], directive [pat^h-iro], locative [pat^h-e]. For these dialects, the use of [ʧ^h] in the accusative cannot be straightforwardly attributed to a re-analysis of the final consonant of the noun stem, since it surfaces as [t^h] elsewhere. Instead, Han (2002) claims that we are observing a more limited identity effect, in which the accusative comes to match the nominative, but the locative and directional remain identical and distinct from the other case forms. Kang (2005) attributes the identity of the locative and directive to the fact that they share locational meanings.

The Korean example shows that overapplication may extend processes that apply in inflected forms (i.e. overapplication is not "blind" to inflectional material). It also illustrates some of the difficulties in establishing a synchronic paradigm effect as opposed to a diachronic re-analysis. Many cases of overapplication that have been documented in the literature are potentially reinterpretable as lexical re-analyses or broadening of phonological processes. In order to demonstrate that a given case truly involves synchronic paradigmatically motivated overapplication, we must be able to show that the process continues to apply as expected elsewhere in the language, that the relevant lexical items have not been re-analyzed, and that the process overapplies just in those cases where paradigmatic identity would result. Similar considerations hold for identity through underapplication and misapplication, to which we now turn.

2.2 *Underapplication*

Just as in cases of underapplication of phonological processes to maintain reduplicative identity (McCarthy and Prince 1995; CHAPTER 100: REDUPLICATION; CHAPTER 119: REDUPLICATION IN SANSKRIT), it appears that phonological processes may be suppressed within inflectional paradigms in order achieve identity. An example can be seen in the behavior of Yiddish [rm] clusters. As shown in (5) above, schwa epenthesis overapplies in Yiddish verb paradigms, just in case epenthesis is expected in a suffixed form such as the 1st or 3rd singular. Interestingly, the converse pattern holds in noun paradigms. As shown in (7), noun plurals are sometimes formed by adding a consonant (/-s/), and sometimes by adding a vowel-initial suffix (usually /-ən/). In contrast to verbal paradigms, schwa epenthesis optionally *underapplies* in noun paradigms if it is not licensed in the plural.

(7) *Underapplication of epenthesis in Yiddish nouns*

	singular	*plural*	
a.	ʃturəm ~ *ʃturm	ʃturəms	'storm'
	ʃirəm ~ *ʃirm	ʃirəms	'umbrella'
	ʃvɔrəm ~ *ʃvɔrm	ʃvɔrəms	'swarm'
	vɔrəm ~ *vɔrm	vɔrəms	'worm'
	ɔrəm ~ *ɔrm	ɔrəms	'arm'
	turəm ~ *turm	turəms	'tower'
	alarəm ~ *alarm	alarəms	'alarm'
b.	fɔrəm ~ fɔrm	fɔrmən	'form'
	?unifɔrəm ~ unifɔrm	unifɔrmən	'uniform'
	*farəm ~ farm	farmən	'farm'

A similar example of parallel over- and underapplication comes from Polish diminutives, as discussed by Kraska-Szlenk (1995: 108–114) and Kenstowicz (1996). Many Polish nouns show an alternation between [u] and [ɔ] before word-final voiced non-nasal consonants, with [u] occurring in closed syllables and [ɔ] occurring in open syllables. The morphological context for raising differs depending on the gender of the noun, since different affixes create closed syllables in masculine *vs.* feminine nouns:

(8) *Regular application of o-raising in Polish nouns* (Kraska-Szlenk 1995: 108)

a. /dɔw/ 'ditch (MASC)'	*singular*	*plural*	b. /krɔv/ 'COW (FEM)'	*singular*	*plural*
NOM	duw	dɔwɨ	NOM	krɔva	krɔvɨ
GEN	dɔwu	dɔwuf	GEN	krɔvɨ	kruf
DAT	dɔwovi	dɔwom	DAT	krɔvje	krɔvom
ACC	duw	dɔwɨ	ACC	krɔvẽ	krɔvɨ
INSTR	dɔwem	dɔwami	INSTR	krɔvã	krɔvami
LOC	dɔle	dɔwax	LOC	krɔvje	krɔvax

In diminutive paradigms, raising alternations are suspended. Instead, the vowel that is expected in the nominative singular occurs everywhere. The diminutive suffix is (on the surface) [-ek] word-finally and [-k-] before a vowel, due to the presence of a fleeting yer vowel, indicated in (9) as /E/ (CHAPTER 122: SLAVIC YERS). As a result, diminutives of masculine nouns end in [-ek-Ø] in the nominative singular. Since the suffix begins with a vowel, raising does not apply in the nominative singular, and it correspondingly underapplies in the remainder of the paradigm (9a). Diminutives of feminine nouns, on the other hand, end in [-k-a]. This suffix does condition raising, and raising overapplies in the remainder of the paradigm (9b).

(9) *Under- and overapplication of raising in Polish diminutives*

a. /dɔw-Ek/ 'ditch (MASC)'	*singular*	*plural*	b. /krɔv-Ek-a/ 'cow (FEM)'	*singular*	*plural*
NOM	dɔwek	dɔ̲wkɨ	NOM	krufka	krufki
GEN	dɔ̲wka	dɔ̲wkuf	GEN	krufki	kru̲vek
DAT	dɔ̲wkovi	dɔ̲wkom	DAT	kruftse	krufkom
ACC	dɔwek	dɔ̲wki	ACC	krufkē	krufki
INSTR	dɔ̲wkjem	dɔ̲wkami	INSTR	krufká	krufkami
LOC	dɔ̲wku	dɔ̲wkax	LOC	kruftse	krufkax

As McCarthy (2005) points out (following Buckley 2001; Sanders 2003), it is not surprising that the distribution of *o*-raising has been disrupted in modern Polish: raising interacts opaquely with final devoicing, it is conditioned by an unusual set of following segments (non-nasal voiced consonants), and it is not generally applied to loanwords or nonce words. Nonetheless, the fact that raising applies normally in the non-diminutive forms of /dɔw/ and /krɔv/ (8) shows that the process is learned in some (perhaps lexically or morphologically restricted) form, and that it continues to apply in the expected contexts. Furthermore, speakers have clearly learned that these particular stems undergo raising, even in the nominative singular of the diminutive. Kraska-Szlenk (1995) and Kenstowicz (1996) argue that the lack of raising alternations in the paradigms in (9) is best attributed to a paradigm identity constraint, which holds specifically within diminutive paradigms.

2.3 *Misapplication*

In some cases, a regular phonological process applies in an unexpected fashion (misapplication). Harris (1973) argues that certain exceptions to regular stress placement in Spanish can be explained as identity effects, and that recognizing paradigmatic identity as a grammatical force could avoid the need to complicate the statement of stress rules. An example comes from the imperfect indicative forms of Spanish (discussed also by Burzio 2005: 65 and Oltra-Massuet and Arregi 2005):

(10) *Avoidance of stress alternations in the Spanish imperfect:* [terminar] 'finish'

	expected	*actual*
1SG IMP INDIC	termi'naba	termi'naba
2SG IMP INDIC	termi'nabas	termi'nabas
3SG IMP INDIC	termi'naba	termi'naba
1PL IMP INDIC	termina'bamos	termi'nabamos
2PL IMP INDIC	termina'bais	termi'nabais
3PL IMP INDIC	termi'naban	termi'naban

The stress pattern as it would have been inherited from Latin is shown in the left column of (10); this expected pattern also reflects a general pattern of penultimate stress that still holds in modern Spanish. The actual stress pattern in [termi'nabamos] is unusual in Spanish, since words with final closed syllables rarely have antepenultimate stress, the sole exceptions being learned words such as *Sócrates* and *Júpiter*, which are felt by speakers to be unusual (Hochberg 1988). This unexpected pattern is immediately explained if we look at the stress pattern of the other cells of the imperfect, where stress is penultimate according to the regular principles of Spanish stress assignment.

Harris (1987) provides another example from certain dialects of Spanish, including Chicano Spanish. As (11a) shows, stress in verbs regularly falls on the penult, both in conservative varieties and in Chicano Spanish. Within the present subjunctive paradigm, however, stress alternations have been eliminated, with stress falling on the antepenult in the 1st plural (11b) (see also Reyes 1974). Once again, a possible explanation for this subversion of the regular stress pattern is that it maintains identity among inflected forms. Note that this effect holds locally within the present subjunctive, but does not affect the present indicative, nor does it affect non-verbal forms such as ['termino] 'end'.

(11) *Avoidance of stress alternations in Chicano Spanish subjunctive:*
[terminar] 'finish'

Kenstowicz (1996) observes a similar effect for certain Russian nouns, in which stress unexpectedly avoids falling on a fleeting yer vowel in the genitive plural ("double retraction"). Like the Spanish cases, this irregular placement of stress serves to avoid stress alternations within the plural paradigm, and may likewise be attributed to a constraint demanding uniform stress.

2.4 *Anti-homophony within paradigms*

In addition to serving as the domain for identity effects, inflectional paradigms also appear to be the locus of anti-homophony effects, in which phonology applies unexpectedly in order to avoid surface identity of morphologically distinct forms. The scope and treatment of anti-homophony effects is controversial, but we mention here two examples.

The first example comes from Kenstowicz (2005), who discusses the distribution of schwa in medial open syllables in Damascus Arabic (CHAPTER 124: WORD STRESS IN ARABIC). Normally in this dialect, unstressed schwas in open syllables are deleted: /səməʕ-ət/ → ['səmʕ-ət] 'heard-3SG FEM SUBJ'. This deletion also occurs in forms that have been cliticized with object markers: both /dˤarb-ət-o/ → ['dˤarbto] 'hit-3SG FEM SUBJ-3SG MASC OBJ' and /ʃaːf-ət-o/ → ['ʃaːfto] 'saw-3SG FEM SUBJ-3SG MASC OBJ' show deletion of the underlying /ə/ in the 3rd singular feminine subject marker. However, this deletion is systematically blocked in cases where the form in question would become identical with the corresponding masculine form. For example, /ʕallam-t-o/ 'taught-3SG MASC SUBJ-3SG MASC OBJ' and /ʕallam-ət-o/ 'taught-3SG FEM SUBJ-3SG MASC OBJ' are expected to yield surface [ʕal'lamto], with syncope of the stressless schwa. Instead, syncope is blocked in the feminine form 'she taught him', and the schwa exceptionally remains and attracts stress: [ʕalla'mәto]. Kenstowicz (2005) attributes this unusual stress pattern, which violates the normal principles of stress placement in Damascus Arabic, to an anti-homophony condition that holds between the 3rd singular masculine and feminine forms. Importantly, this condition does not penalize deletion in cases such as ['dˤarbto] 'she hit him' or ['ʃaːfto] 'she saw him', because for these verbs, the 3rd singular masculine forms happen to follow different vocalic templates: [da'rab-t-o] 'he hit him', ['ʃuf-t-o] 'he saw him'.

Hall and Scott (2007) discuss another example, involving underapplication in Swabian German. In this dialect, /s/ becomes [ʃ] before a coronal: /pɔst/ → [pɔʃt] 'mail'. This process underapplies in inflectional paradigms, however: /griəs-t/→ [griəst], *[griəʃt] 'greet-3SG'. Hall and Scott attribute this underapplication to the influence of inflectionally related forms with [s], such as 1st singular [griəs]. In the 2nd singular, however, the inflectional affix is /-ʃ/. Here, underapplication of /s/ → [ʃ] would yield the illegal form [griəsʃ], which would be expected to assimilate and degeminate. The candidate [griəs], which resolves the /sʃ/ cluster in favor of [s], would create paradigmatic identity with 1st singular [griəs], 3rd singular [griəst], etc., but it would be homophonous with the 1st singular. Instead, the actual outcome is [griəʃ], in violation of paradigm uniformity. Hall and Scott argue that this is due to an anti-homophony condition, in which the 2nd singular is required to be distinct from other forms.

In both the Damascus Arabic and the Swabian German examples, the paradigm is the locus of anti-homophony effects, in the sense that homophony between forms that are not paradigmatically related (as in accidentally homophonous verbs) does not trigger unexpected phonology. If this restriction turns out to hold in a broader range of cases, it could serve as an additional source of evidence that paradigms may serve as the domain of grammatical effects.

3 Grammatical mechanisms for deriving paradigm effects

The fact that the regular application of phonological processes may be disrupted in order to achieve paradigmatic regularity was often commented on in the earlier literature on generative phonology (see, e.g. Kiparsky 1972; Harris 1973; Kenstowicz and Kisseberth 1977: 69–74). However, no formal mechanism was provided for accomplishing this effect within the rule-based approach of Chomsky and Halle (1968; henceforth *SPE*). Indeed, it is hard to see what a mechanism that explicitly enforces paradigmatic identity would look like, since the decision about whether to apply a rule or not (or to reverse the order of two rules) can be made only by "looking ahead" and seeing whether the results would create alternations within the paradigm. Instead, inflectional identity has often been analyzed as a by-product of how morphological and phonological operations are ordered, under the hypothesis that inflectional affixes are added after many phonological processes have already applied. (See Downing *et al.* 2005a for a review of alternative rule-based mechanisms, and §3.3 below for discussion of cyclic approaches employing phase-based spell-out; see also CHAPTER 85: CYCLICITY and CHAPTER 74: RULE ORDERING.)

For example, the American English pre-lateral diphthongization data in (4) ([spɔɪəɫ] *spoil*, [spɔɪəɫɪŋ] *spoiling* vs. [spɔɪɫəʤ] *spoilage*) can be seen as the result of diphthongization applying after derivational affixes like *-age* have been added, but before inflectional affixes have been added. A challenge for such approaches is to establish an internally consistent ordering of morphological and phonological operations. This is not always trivial; for example, in the author's idiolect, the fact that /l/ is at least optionally dark in words like [spɔɪɫəʤ] *spoilage* and [maɪɫəʤ] *mileage* suggests that velarization is ordered before affixation of *-age*, yet there is no option for dark [ɫ] in words like [saɪləʤ] *[saɪɫəʤ] *silage*, which arguably also contains an /l/ before the *-age* suffix. Accounts based on cyclic ordering have no direct way of referring to the fact that for *spoilage* and *mileage*, related forms such as [spɔɪəl] *spoil* and [maɪəl] *mile* contain dark [ɫ], while for *silenge*, the related form [saɪloʊ] *silo* has light [l].

Paradigm effects of this sort are readily accommodated within Optimality Theory (OT), since evaluation in this framework is carried out over surface forms, which is precisely where identity and contrast must be enforced. In this section, we review the main approaches to enforcing identity among paradigms of inflected forms in OT.

Most approaches to paradigm effects in OT employ correspondence constraints (McCarthy and Prince 1995), which place morphologically related forms into correspondence with one another, so that identity can be evaluated with the standard machinery of faithfulness constraints (IDENT, MAX, DEP; see also CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). Under this approach, paradigmatic identity effects are closely related to cyclicity effects, in which derived forms show unexpected similarity to their bases of derivation. Correspondence relations are intrinsically pairwise, so paradigm uniformity is typically enforced by requiring that each individual pair of forms be identical. Thus, in a sense, paradigm constraints are not truly "paradigmatic," since they evaluate sets of pairs rather than the entire distribution at once. A cost of this approach, however, is that the number of pairwise relations that must be considered grows factorially with the size of the paradigm – e.g. $6 \times 5 = 30$ pairwise relations for a six-member paradigm.

Since their introduction, correspondence constraints have been used to analyze the relation between derived forms and their bases in producing cyclicity effects (Burzio 1994; Kenstowicz 1996; Benua 1997; Kager 2000; Steriade 2000). Like input–output faithfulness conditions, base–derivative correspondence is usually assumed to be intrinsically asymmetrical: derived forms must be faithful to their bases, but bases are not constrained to resemble their derivatives (see also

CHAPTER 85: CYCLICITY). There are two main issues that must be resolved in applying faithfulness conditions to paradigm regularity. First, we must determine whether correspondence relations between inflectionally related forms are intrinsically symmetrical, as is generally assumed for base–reduplicant faithfulness (McCarthy and Prince 1995), or asymmetrical, as is usually assumed for other cases of base-derivative faithfulness (Benua 1997). Second, if inflected forms are faithful to a base form, we must determine which form acts as the base in an inflectional paradigm.

In this section, the predictions of a symmetrical approach to paradigm uniformity (McCarthy's 2005 Optimal Paradigms approach) are compared to those of an asymmetrical/base-prioritizing approach (Albright 2002; Kenstowicz 1996; Benua 1997), as well as to a stratal approach in which outputs are evaluated cyclically with interleaved levels of affixation and phonological evaluation (Kiparsky 1982, 2000).

3.1 Symmetrical output–output faithfulness: Optimal paradigms

One approach to enforcing paradigmatic regularity is through symmetrical correspondence relations, which simply demand that all inflected forms have identical forms of the root. This symmetrical identity requirement has gone under various names in the literature, including *consistency* (Burzio 1994, 2005; see also CHAPTER 88: DERIVED ENVIRONMENT EFFECTS), *uniform exponence* (Kenstowicz 1996), *paradigm uniformity* (Steriade 2000), and, most recently, *optimal paradigms* (McCarthy 2005). McCarthy (2005: 172) succinctly sums up the motivation for adopting a symmetrical approach to identity in paradigms: "Inflectional paradigms have no base . . . : Latin *amat* 'he loves' is not derived from *amō* 'I love' or vice versa; rather, both are derived from the lexeme /am-/." The claim that inflected forms are based on a common lexeme but not on each other rests on a morphological notion of *base of affixation*, in which affixation realizes (or marks) morphological features, and affixed forms contain a superset of the morphological information that their inner constituents contain. Under this definition, the base must necessarily contain a subset of the morphological features of derived forms. Depending on the morphological features that one assumes, it is implausible to suppose that the 1st singular "contains" the 3rd singular (though for feature systems that make use of underspecification, see Harley and Ritter 2002; McGinnis 2005). A similar point is made by Kager (1999: 282), who refrains from positing a relation between the 1st singular and the 2nd plural, since neither one appears to compositionally contain the other.

Because no individual form has priority in a symmetrical approach, paradigms must be evaluated as a set, in case a high-ranking constraint demands a modification in one form that would then overapply in the rest of the paradigm. In McCarthy's (2005) Optimal Paradigms (OP) formulation, candidates consist of entire paradigms. The stem in each cell in the paradigm stands in correspondence to the stem in every other cell, and output-output faithfulness constraints (OP-IDENT, OP-MAX, OP-DEP) evaluate every pair of surface forms in the paradigm. Paradigm uniformity effects arise when OP-faithfulness outranks the relevant IO-faithfulness constraint. This is illustrated in (12) for the overapplication of schwa epenthesis in Yiddish, discussed in (5) above.

(12) *Optimal Paradigms analysis of overapplication of schwa epenthesis in Yiddish*

/ʃturm, ʃturm-t, ʃturm-ən/	OP-Dep	*rm]	IO-Dep
a. ʃturm, ʃturmt, ʃturmən		*!*	
b. ʃturəm, ʃturəmt, ʃturmən	*!*		**
☞ c. ʃturəm, ʃturəmt, ʃturəmən			***

The tableau in (12) illustrates several important features of the OP approach. The ranking of *rm] over IO-Dep reflects the fact that there is a general process of epenthesis to repair rm] codas. If this ranking did not hold, there would be no possibility of alternations. With this ranking in place, it is possible to rank OP-Dep high, in order to favor an invariant paradigm with overapplication (candidate (12c)), or low, in order to favor normal application (candidate (12b)). Crucially, the only rankings that favor candidate (12a) (underapplication) are those in which IO-Dep outranks *rm] – but these are incompatible with the fact that the language generally has a process of epenthesis. Thus, there is no ranking in which epenthesis is found in general, but underapplies in order to maintain paradigm uniformity. McCarthy dubs this prediction *overapplication-only*. Furthermore, the relative number of intervocalic *vs.* coda /rm/ sequences in the paradigm cannot affect the outcome, since the logic of strict domination dictates that even one instance of coda /rm/ may be fixed by any number of IO-Dep violations. Thus even if we had considered a paradigm with only a single input like /ʃturm/ and many inputs like /ʃturm-ən/, overapplication of epenthesis would still be the optimal way to satisfy OP-Dep.

On the face of it, the overapplication-only prediction of OP is too strong, since, as we saw in §2.2, paradigm identity may also be achieved through underapplication – in fact, the very same process of epenthesis underapplies in Yiddish nouns. The only mechanism available to handle such cases in the OP framework is to find some higher-ranked constraint that would be violated by overapplication. As a hypothetical example of what such a constraint might be, suppose Yiddish were to borrow the English word *platform*, retaining initial stress and creating an associated plural ['platfɔrmən]. In this case, overapplication of schwa epenthesis would yield a plural form with pre-antepenultimate stress and a long stress lapse: ['platfɔrəm] ~ ['platfɔrəmən]. As it turns out, Yiddish stress, though somewhat unpredictable, must fall within the last three syllables of the word (see Jacobs 2005: 135–140), so the output ['platfɔrəmən] would be illegal. In this hypothetical example, we could analyze underapplication of epenthesis (['platfɔrm] ~ ['platfɔrmən]) as overapplication of lapse avoidance (['platfɔrəm] ~ *['platfɔrəmən]), consistent with the overapplication-only prediction.

(13) *Underapplication as overapplication of an orthogonal process (hypothetical)*

/platfɔrm, platfɔrm-ən/	OP-Dep	OP-Ident (stress)	Stress	IO-Ident (stress)	*rm|	IO-Dep
☞ a. 'platfɔrm, 'platfɔrmən					*	
b. 'platfɔrəm, 'platfɔrmən	*!*					**
c. 'platfɔrəm, 'platfɔrəmən			*!			***
d. 'platfɔrəm, plat'fɔrəmən		*!*		*		
e. plat'fɔrəm, plat'fɔrəmən				*!*		

Unfortunately, in the actual cases of underapplication in Yiddish nouns in (7b), it is not clear what such a constraint would be. In particular, the contrasting pair [vɔrəm] 'worm' *vs.* [fɔrm] 'form' do not appear to differ in any relevant way that could be capitalized on in order to block epenthesis in the latter case by means of a higher-ranked markedness constraint.

A similar point can be made about the Polish diminutive example in (9). Here, the cases in which raising underapplies in the masculine find exact counterparts in which raising applies normally in the feminine: e.g. accusative plural [dɔwki] 'little ditches' *vs.* [krufki] 'little cows'. There is no form in the paradigm of [dɔwek] in which raising would not violate a constraint that is also violated in the paradigm of [krufka]. In particular, hypothetical overapplication of raising in the nominative and accusative singular (*[duwek]) would violate the same constraints that are violated by the attested overapplication of raising in the feminine genitive plural ([kruvek]). As Kenstowicz (1996) points out, symmetric faithfulness constraints are equally well satisfied by over- and underapplication, and it is not obvious what additional constraint would break the tie. This problem leads McCarthy (2005) to suggest that raising alternations must be lexicalized in this case, reflecting the more generally unproductive nature of *o*-raising in Polish. As noted in §2, it is often difficult to determine whether an attested case of underapplication represents a synchronic paradigm effect, or whether it is the outcome of a diachronic re-analysis in which the relevant alternation simply no longer applies, even when paradigmatic identity is not at stake. Although it appears that at least some cases of underapplication demand a synchronic analysis, more careful investigation is needed to determine whether they are more appropriately interpreted as diachronic effects rather than as synchronic exceptions to the overapplication-only prediction.

Misapplication can also pose a challenge to the symmetrical faithfulness model. The stress patterns of the Spanish imperfect (10) and (dialectal) present subjective (11b) show the otherwise practically non-occurring pattern of antepenultimate stress with a closed final syllable ([termi'nabamos], [ter'minemos]). The candidate in which antepenultimate stress is avoided by placing stress too far to the right in other forms (hypothetical [termina'ba], [termina'bas], [termina'ba], [termina'bamos], [termina'bais], [termina'ban]) would fare much better by the constraint that favors penultimate stress with final heavy syllables. This candidate involves a different dispreferred pattern – namely, forms with stress on final open syllables ([termina'ba]). This stress pattern is somewhat rare, but it occurs in native monomorphemic words ([a'ki] 'here', [so'fa] 'sofa', [xo'se] 'José', etc.) to a far greater extent than antepenultimate stress in words like *Sócrates*. Moreover, invariant suffixal stress is found in other tenses, including the future ([termina're], [termina'ras], [termina'ra], [termina'remos], [termina'reis], [termina'ran]). Thus it appears that the OP approach would favor a paradigm that avoids the stress violation in (actual) [termi'nabamos] by placing stress one syllable to the right (*[termina'ba], *[termina'bamos]).

3.2 Base-prioritizing output–output faithfulness

An alternative possibility is that faithfulness among inflected forms is exactly parallel to the asymmetrical structure of faithfulness among derived forms. Asymmetrical, base-prioritizing faithfulness has been given various names in the literature, including *base identity* (Kenstowicz 1996) and *transderivational correspondence* (Benua 1997). In an asymmetric approach, dependent forms are constrained to be faithful to a designated base form, but the base form is not constrained to match the rest of the paradigm. Thus, we expect the base form to exhibit normal application of regular phonological processes, while the remaining forms may show over- or underapplication in order to resemble the base. Since surface properties of the base form must be known ahead of time in order to evaluate base-faithfulness violations, base-prioritizing faithfulness requires a form of cyclic, or recursive, evaluation. In the discussion that follows, I follow Benua (1997) in assuming that evaluation proceeds in two steps: first the base is evaluated, and then its dependent forms are evaluated. Although recursive evaluation involves more steps than a single, parallel evaluation, the evaluation of output–output faithfulness requires a fraction of the comparisons that are involved in the full pairwise evaluation of the symmetric approach.

An asymmetric approach provides a natural solution to many of the problems pointed out in the preceding section. In the case of stress in the Spanish imperfect and (dialectal) present subjunctive, the unexpected pattern in [termi'nabamos] 'we ended' can be attributed to faithfulness to other forms in the paradigm, in which stress obeys the usual pattern of penultimate stress. Deferring for a moment the question of what form should be designated as the base in general, let us assume for now that the base of Spanish verb paradigms (or, at least, of the imperfect and subjunctive) is the 3rd singular: [termi'naba]. In the base-prioritizing approach, properties of the base are determined "first" according to the general rankings of markedness and IO-faithfulness, and this pattern is then transferred to related form via base faithfulness, as shown in (14). We assume that Spanish has constraints against final stressed vowels (*'V]) and against antepenultimate stress with final closed syllables (*'σσσ̄]). We also assume that, although antepenultimate stress is sometimes found on vowel-final words, the default is penultimate stress (Aske 1990; Eddington 2000; Oltra-Massuet and Arregi 2005), and that this is favored by a constraint against final lapse (*'σσσ], not shown). These are overruled, however, by a constraint demanding faithfulness to the stress pattern of the 3rd singular base. (Following Benua 1997, the tableau for the non-basic 1st plural form is indented to show that the evaluation of BASE-IDENT requires reference to the output of the 3rd singular evaluation.)

(14) *Misapplication in the Spanish imperfect*

/termina-ba-Ø/ 'end-3SG'	*BASE-IDENT(stress)	*'σσσ]	*'V]
☞ a. termi'naba			
b. termina'ba			*

/termina-ba-mos/ 'end-1PL'	*BASE-IDENT(stress)	*'σσσ]	*'V]
☞ a. termi'nabamos		*	
b. termina'bamos	*!		

Base identity also addresses the problem of *o*-raising in Polish diminutives. Again deferring the discussion of what form serves as the base in general, let us assume that the base of Polish noun paradigms is the nominative singular. The evaluations of the masculine and feminine nominative diminutives are shown in parallel for /dɔw-(E)k/ and /krɔv-(E)k-a/ in (15). Since these forms are basic, they vacuously satisfy BASE-IDENT. The constraint RAISE is shorthand for whatever constraint motivates [u] in closed syllables; recall that the paradigms of simple (non-diminutive) [duw] 'ditch' and [krɔva] 'cow' in (8) show that both of these stems participate in raising. For brevity, the constraints that are responsible for the vocalism of the diminutive suffix are not shown.

(15) *Normal application of Polish raising in nominative singular base forms*

/dɔw-Ek-Ø/ 'ditch-DIM-NOM SG'	BASE-IDENT[high]	RAISE	IO-IDENT[high]
☞ a. dɔwek			
b. duwek			*

/krɔv-Ek-a/ 'COW-DIM-NOM SG'	BASE-IDENT[high]	RAISE	IO-IDENT[high]
☞ a. krɔfka		*!	
b. krufka			*

The remaining inflected forms are then constrained by BASE-IDENT to preserve the vowel height of the nominative singular, as in (16).

(16) *Over- and underapplication of Polish raising in non-basic forms*

/dɔw-Ek-a/ 'ditch-DIM-GEN SG'	BASE-IDENT[high]	RAISE	IO-IDENT[high]
☞ a. dɔwka		*	
b. duwka	*!		*

/krɔv-Ek-Ø/ 'COW-DIM-GEN PL'	BASE-IDENT[high]	RAISE	IO-IDENT[high]
a. krɔvek	*!		
☞ b. kruvek			*

By hypothesis, BASE-IDENT for inflected forms is a distinct constraint from whatever base–derivative faithfulness constraints may hold of derived forms. This predicts the possibility of different degrees of faithfulness for inflected *vs.* derived forms. As we saw above for Latin, inflected forms may indeed exhibit greater faithfulness than derived forms. A similar point can be made for Yiddish, in which derivationally related forms show schwa alternations: cf. [alarəm] 'alarm' ~ [alarm-ir-n] 'to alarm', [ʃirəm] 'shade' ~ [ʃirm-ə] 'screen', [varəm] 'warm' ~ [varm-əs] 'warm food'. What is not explained by this approach, however, is the cross-linguistic tendency for inflected forms to show greater uniformity than derived forms. If inflectional BASE-IDENT and base-derivative faithfulness are separate and independently re-rankable constraints, we predict that some languages may show greater uniformity in derived forms than in infected forms.

The analysis in (15) and (16) requires that the nominative singular be designated as the base, even though other inflected forms are not necessarily built compositionally from it. For the masculine diminutive [dɔwek], this coincides with the fact that nominative singular is in a substring of the remaining forms. In particular, although the nominative singular differs from the remaining infected forms in having an [e] in the diminutive suffix, its suffix is -Ø. As a result, the underlying form /dɔw-Ek-Ø/ is a phonological substring of the underlying form of inflected forms like /dɔw-Ek-a/. In many cases, it is sufficient to posit that null-affixed forms (sometimes termed *isolation forms*) serve as the base for overtly affixed inflected forms; see, e.g. Kurylowicz (1947); Kenstowicz (1996); Hayes (1999); Hall and Scott (2007).

The comparison with the Polish feminine diminutive form [krufka] shows that base forms need not always be isolation forms, however. In this noun class, there is an overt nominative singular affix /-a/ that is not contained in other case/number forms. A common intuition is that even if the feminine nominative singular is phonologically marked (in the sense of having an overt affix), it is nonetheless a plausible base form because it represents a morphologically "unmarked" category (in the sense of serving as a default or unmarked member of an opposition). Analyses that make use of this more general notion of morphosyntactic markedness are often somewhat vague as to what the criteria are for identifying the morphologically least marked member of a paradigm, but the general consensus appears to be that it is the nominative singular in a Latin or

Polish-like nominal paradigm (Kenstowicz 1996; Sturgeon 2003), and the 3rd singular in a verbal paradigm (Kuryłowicz 1947; Mańczak 1958).

The idea that the base of a paradigm is a morphologically unmarked form (null affix, or unmarked feature values) is attractive from the point of view of grounding the structure of paradigmatic correspondence in a universal, morphosyntactically motivated representation. There are cases that are difficult to reconcile with this hypothesis, however. The Latin [honor] example discussed in §1.2 is one potential counterexample, since it shows overapplication in the nominative singular on the basis of morphosyntactically more marked case forms (oblique and plural forms). The underapplication of schwa epenthesis in Yiddish noun paradigms is also a counterexample. Recall from (7b) that epenthesis may fail to apply in final rm] clusters just in case the plural has a vowel-initial suffix: [vɔram] ~ [vɔram-s] 'worm-SG/PL' (with epenthesis) *vs.* [fɔrm] ~ [fɔrmən] 'form-SG/PL' (epenthesis optionally underapplies). This case is readily accounted for if we posit faithfulness to the plural form. This is illustrated in (17) for the variant [fɔrm] 'form-SG'.

(17) *Underapplication of schwa epenthesis in Yiddish nouns*

/fɔrm-ən/ 'form-PL'	Base-Dep	*rm]	IO-Dep
☞ a. fɔrmən			
b. fɔrəmən			*

/fɔrm/ 'form-SG' Base: [fɔrmən]	Base-Dep	*rm]	IO-Dep
☞ a. fɔrm		*	
b. fɔrəm	*!		*

Under this analysis, the fact that epenthesis underapplies in noun paradigms is attributed to faithfulness to the plural, while the fact that epenthesis overapplies in verb paradigms must be attributed to faithfulness to a form in which normal application would favor epenthesis (e.g. 1st singular: Albright 2010). If this is correct, it suggests that the choice of privileged base form may differ by language and by part of speech (see also CHAPTER 102: CATEGORY-SPECIFIC EFFECTS). This conclusion naturally raises a number of questions: how do learners identify bases? Is it possible to predict which form will act as the base in a given part of speech in a given language, or must it be inferred post hoc from unexpected application of regular phonological processes? Are there limits to which form acts as the base? And if the choice of base can vary freely from language to language, why do certain forms such as the "unmarked" nominative singular and 3rd singular so often act as bases?

Albright (2002) proposes that the choice of base in a given language is not arbitrary, but follows from the distribution of contrasts within paradigms (CHAPTER 2: CONTRAST). Specifically, it is hypothesized that learners identify the form that offers the most phonological and morphological information about lexical items. For example, in Yiddish verbs, some inflectional affixes trigger neutralizing phonological processes such as regressive voicing assimilation (/red-st/ → [retst] 'speak-2SG'), degemination (/red-t/ → [ret] 'speak-3SG'; /heɪs-st/ → [heɪst] 'call-2SG') or coalescence of schwas (/blɔnkə-ən/ → [blɔnkən] 'meander-1PL') (CHAPTER 80: MERGERS AND NEUTRALIZATION). As it turns out, since the 1st singular suffix is null and Yiddish has relatively few processes that affect final codas, the 1st singular frequently preserves phonological contrasts that are neutralized elsewhere. One process that does occur word-finally (including in the 1st singular) is epenthesis in [rm] clusters, however – and as we have seen, this process overapplies in verb paradigms. For nouns, on the other hand, pluralization involves a high degree of morphological unpredictability, with several competing plural markers and irregular vowel changes to many stems. Thus, the plural often contains morphological information that is neutralized in the singular (Albright 2008b). This correlates with the fact that schwa epenthesis optionally underapplies in the singular if it does not apply in the plural.

Informativeness effects that run counter to markedness can be observed in a number of languages. In Latin, the nominative singular underwent many phonological and morphological neutralizations, including cluster simplification and morphological syncretism, which were not found in oblique forms.[4] Albright (2005) provides a quantitative comparison of neutralizations affecting Latin noun forms. This analysis reveals that the nominative singular was the least informative form, which correlates with the fact that nominative singular forms were rebuilt in Latin. An even more striking example comes from Korean verbal inflection. In a survey of dialects and acquisition studies, Kang (2006) shows that a large number of phonologically independent alternations have been eliminated across different dialects and varieties of Korean. However, all of these changes have in common the property that they extend the stem form found before a certain suffix, the informal form /-ə ~ a/. Albright and Kang (2009) show that this form is also the most informative, revealing stem-final consonant and vowel contrasts more clearly than other suffixed forms.

The typological predictions of an information-based approach are less certain. One factor that appears to encourage base status is token frequency (Kuryłowicz 1947; Mańczak 1958). Plausibly, cells in the paradigm with high-token frequency (CHAPTER 90: FREQUENCY EFFECTS) provide more information to learners, since (on average) more lexical items have been encountered in these forms. Albright (2008a) argues that attestation is by itself also an important type of information, which may bias learners to choose more frequent paradigm members as bases. This, in turn, may explain the fact that morphologically unmarked forms tend to be bases, since they often have the highest token frequency (Bybee 1985: ch. 3).

An important prediction of the base-prioritizing faithfulness account is that the choice between over- and underapplication is a straightforward consequence of whether the process applies in the base form or not. The comparison of masculine and feminine diminutives in Polish shows that even within the same language, this may have different consequences for different words. Another prediction is that the same member of the paradigm should act as basic for multiple dimensions of faithfulness. Albright (2008b) shows that for Yiddish nouns, this is true: the plural acts as a privileged base in conditioning underapplication of

[4] The importance of oblique forms in identifying phonological and inflectional properties of Latin nouns can be seen from the fact that dictionaries typically list an oblique form (the genitive singular) alongside the nominative.

/rm/-epenthesis, underapplication of final devoicing, and overapplication of open syllable lengthening. Similarly, Latin showed leveling of not only rhotacism alternations, but also vowel length and nominative singular marking (*-s* > *-is*: Kiparsky 1998; Albright 2005). Finally, the changes to Korean verb paradigms discussed by Kang (2006) show parallel changes for a large number of logically independent alternations. If this prediction proves true in general, it could provide strong support for an asymmetric approach in which paradigm uniformity extends an independently designated base form.

3.3 *Stratal and cyclic approaches*

The approaches discussed above rely on correspondence relations between related surface forms to enforce identity. An alternative approach, which denies the existence of paradigms altogether, attributes the phonological similarity of related forms to the fact that they share morphological and syntactic structure, and are thus (by hypothesis) identical at a certain stage in their derivation. For example, the framework of Lexical Phonology (Kiparsky 1982) and its successor, Stratal OT (Kiparsky 2000), assumes that phonological evaluation and affixation are interleaved, so that phonological processes may apply to inner constituents of the word prior to the addition of later affixes. Work in Lexical Phonology (LPM) has explored the implications of this approach for cyclicity effects in derivational morphology; see especially Giegerich (1999) and CHAPTER 85: CYCLICITY for overview and discussion (also CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME). Importantly, it is assumed that inflectional affixes are added in the last level of affixation, and are therefore ignored by all earlier cycles of phonological evaluation. This suggests an analysis of paradigm uniformity effects that is parallel to the stratal analysis of cyclicity effects in derivational morphology: processes apply incorrectly when phonology evaluates a morphological subconstituent that does not yet contain the relevant infectional affixes. This is sketched in (18) for the overapplication of epenthesis in Yiddish verbs.

(18) *LPM approach to overapplication of schwa epenthesis in Yiddish verbs*

a. *Stem level: Inflectional affixes not present*

/ʃturm-/	IO-MAX	*rm]	IO-DEP
a. ʃturm		*!	
☞ b. ʃturəm			*

b. *Word level: Inflectional affixes added*

/[ʃturəm]-ən/	IO-MAX	*rm]	IO-DEP
a. ʃturmən	*!		
☞ b. ʃturəmən			

Under this approach, the lack of epenthesis in paradigms of verbs such as *alarm-ir-n* 'to alarm' would be attributed to the fact that verbalizing *-ir-* is a stem-level affix, attaching to bound stems and occurring inside other affixes such as *-ist*.

(19) *LPM approach to normal application in* alarmirn

a. *Stem level: Derivational -ir- is present*

/alarm-ir/	IO-Max	*rm]	IO-Dep
☞ a. alarmir			
b. alarəmir			*!

b. *Word level: Inflectional affixes added*

/[alarmir]-ən/	IO-Max	*rm]	IO-Dep
☞ a. alarmirən			
b. alarəmirən			*!

A closely related approach relies on the syntactic mechanism of derivation by phase (Chomsky 2001) to evaluate successively larger portions of the word (Marvin 2002; Arad 2003; Piggott and Newell 2006; Marantz 2007; Skinner 2008). Under this approach, it is likewise hypothesized that words are built cyclically, and that certain syntactic heads trigger spell-out and phonological evaluation of the structure that has been built thus far. We assume that verbs like [alarmirn] 'alarm' have a structure [[[alarm]$_{\sqrt{}}$-ir]$_v$-n] and verbs like [ʃturəmən] 'storm' have a structure [[[ʃturm]$_{\sqrt{}}$-Ø]$_v$-ən], with a null verbalizing head. Under the assumption that verbalizing heads trigger spell-out (Marantz 2007) and that the "little v" head is spelled out with (or is at least visible to) its complement, the innermost spell-out domain of [alarmirn] consists of /alarm-ir/ (no epenthesis necessary), whereas the inner spell-out domain of [ʃturəmən] consists of /ʃturm-Ø/ (epenthesis expected). Thus derivations similar to those in (18) and (19) would hold in this approach as well.

Stratal and cyclic approaches evaluate morphologically complex words strictly from the inside outwards. Crucially, there is no way for affixes that are not present to influence the outcome of phonology. For this reason, effects such as the underapplication of epenthesis in Yiddish nouns are unexpected, since the outcome for singular forms like [vɔrəm] 'worm' *vs.* [fɔrm] 'form' requires reference to the shape of the plural ([vɔrəm-s] *vs.* [fɔrm-ən]). More generally, any case in which an output-output correspondence account requires reference to a base form that is not an isolation form or substring of the remaining forms poses a potential challenge to cyclic approaches. It remains a question for future research to determine whether such cases have a different synchronic status from the more common cases of "inside → out" directionality of cyclic influence.

4 Defining and constraining paradigms

Up to this point, we have been intentionally vague as to what forms count as belonging to a single paradigm, relying on an intuition notion of sets of forms that share a root, and in some cases also a set of inflectional features (e.g. imperfect indicative or present subjunctive). One possibility that cannot be immediately discarded is that output-output correspondence relations are established along many dimensions of shared inflectional features (imperfect forms, 3rd singular forms, subjunctive forms, etc.). This unstructured notion of paradigmatic relations appears to miss some general tendencies, however. In point of fact, paradigmatic similarity appears to hold much more strongly within certain sets of forms, such as the set of person/number forms in a given tense and mood. In this section, we briefly review some of the major tendencies that have been identified in the literature, and consider where these tendencies may come from.

The examples in the preceding sections show several recurring patterns. For example, person and number inflections of a verb are often constrained to resemble each other within a given tense, while alternations are tolerated across tenses – e.g. Spanish 1st singular present [ter'mino] ~ 1st singular imperfect [termi'naba]; 1st plural [termi'naban]. Although I know of no comprehensive survey of synchronic paradigmatic effects across different inflectional categories, similar tendencies can be observed in the degree of tolerance for morphologized stem changes across different categories. In a survey of 50 genetically unrelated languages, Bybee (1985) confirms that morphophonological stem changes are virtually never associated with person distinctions, and rarely with number distinctions. Tense and mood, on the other hand, are sometimes accompanied by stem changes, and aspect often is (see also Veselinova 2006 for discussion). These tendencies diagnose a paradigm structure in which certain inflectional features (aspect, and secondarily tense and mood) define rather cohesive paradigms, whereas person and number do not. We must interpret Bybee's findings cautiously, since they admit two possible explanations: perhaps sharing an aspect or tense feature is particularly important in conditioning paradigmatic cohesion, or perhaps differences in tense or aspect are preferentially marked with phonologically salient differences (Wurzel 1989). To the extent that tendencies in morphophonological stem changes are correlated with tendencies in phonological over- and underapplication, we find support for an interpretation in terms of paradigmatic cohesion.

Among nouns, it appears that the domain of phonological misapplication is more likely to be a number subparadigm (e.g. singular or plural) than a case subparadigm (e.g. all accusative forms). This appears to be mirrored by the fact that number suppletion is more common than case suppletion (though see Corbett 2007 for discussion). Similar tendencies are also found in cases of diachronic paradigm leveling.

Bybee (1985: 13) interprets these differences in terms of what she calls the *relevance* of different features to the stem. Relevance is defined as the degree to which a given inflectional category changes the meaning of the lexical root – for example, changes in valence, particularly between intransitive and transitive, tend to change the verbal action in a way that changes in person do not. Bybee argues that morphological features that are more relevant are more likely to be marked with overt morphological markers, and are more likely to be accompanied by stem changes. Restated in terms of paradigmatic identity, it appears that the less salient the meaning difference between two forms, the less likely speakers are to tolerate alternations.

Another tendency that can be observed in the examples above is that identity is more strongly enforced among some paradigms than others. For example, Spanish verbs have stress alternations within the present indicative (1sg [ter'mino] ~ 1pl [termi'namos]), but more "remote" tenses, such as the imperfect, lack alternations (1sg [termi'naba]; 1pl [termi'nabamos]). In Polish, raising alternations are observed within the case/number forms of simple nouns (8), but are suspended within the diminutive forms (9). This suggests that paradigmatic identity is not only enforced more strongly for some dimensions (e.g. person/number) than others (e.g. tense), but it is also enforced more strongly in some morphosyntactic contexts (e.g. the imperfect or the subjunctive) than others.

One attempt to derive these tendencies in a formal system is Burzio's (2005) Representational Entailments Hypothesis (see also CHAPTER 88: DERIVED ENVIRONMENT EFFECTS). Burzio proposes that the strength of the identity condition that holds between two related forms should depend on the degree to which they already have shared meaning, morphology, and phonology. According to this hypothesis, linguistic representations of different items are lined up, and the more material they share, the greater the expectation that they are alike in other respects as well. For example, suppose a given item has feature values [+F, +G, +H, +I]. This can be restated as a set of associations between co-occurring features: [+F] ⇒ [+G], [+F] ⇒ [+H], [+F] ⇒ [+I], and so on. Now suppose we are given another item with feature values [+F, +G, −H, −I]. This item shares the association of [+F] ⇒ [+G], but differs in its other associations – for example, [+F] ⇒ [+I] and [+G] ⇒ [+I] are not met in this form. Finally, compare a third item [+F, +G, +H, −I]. In this form, three entailments concerning [±I] are not met: [+F] ⇒ [+I], [+G] ⇒ [+I], [+H] ⇒ [+I]. In other words, the amount of overlap between [+F, +G, +H, +I] and [+F, +G, +H, −I] makes their difference in [±I] more salient or surprising. Burzio proposes that families of output–output faithfulness constraints are ranked to reflect such differences in overlap: OO-IDENT([±I]) (+F,+G,+H ⇒ +I) >> OO-IDENT([±I]) (+F,+G ⇒ +I). Entailments may be stated in terms of shared semantic or morphosyntactic features, or in terms of shared phonological features.

The Representational Entailments Hypothesis is useful in accounting for why some paradigms are more cohesive than others. For example, in Spanish, the imperfect is marked with an overt marker (*-ba-*) whereas the present tense has no overt tense marker. Therefore, imperfect forms share more properties in common (namely, the property of containing *-ba-*), which may in turn beget additional identity. The present subjunctive does not have an overt marker that makes subjunctive forms more similar to each other than indicative forms, but it is not unreasonable to suppose that the semantic or morphosyntactic representation of subjunctive involves more structure than the indicative does. If such explanations are on the right track, then it should be possible to correlate the degree of structural overlap between two forms and the pressure for paradigmatic identity between them. Crucially, it is possible to infer the structure of the representation of a given inflectional category through independent means (observing overt marking, finding implicational relations and default values, etc.; Bybee 1985; Harley and Ritter 2002; McGinnis 2005). Therefore, if the Representational Entailments Hypothesis is correct, it should be possible to predict the strength of paradigmatic identity effects.

5 Conclusion

Kenstowicz and Kisseberth (1977: 74) proclaimed that ". . . the notion 'paradigm' will have to be much more rigorously defined in order for the appeal to paradigm regularity to have much explanatory force." As this discussion has made clear, more than three decades later we are still in the early stages of understanding what determines the strength of paradigmatic effects, and what this might tell us about the underlying structure of correspondence among inflected forms. The growing literature on paradigm uniformity effects in the past 10 years has made progress on a number of issues, however. First, it has demonstrated that identity among inflectionally related forms is not just a diachronic phenomenon, but can be seen as a synchronic effect in the "wrong application" of productive phonological processes. Furthermore, formalized grammatical approaches to paradigm uniformity make testably different predictions about possible uniformity effects, pointing the way to those cases which deserve the closest empirical scrutiny. Finally, comparison of the cases discussed so far in the literature suggests a number of cross-linguistic trends that must be accounted for in a theory of how phonology refers to morphological structure. A deeper understanding of these tendencies will require a more comprehensive survey of synchronic paradigmatic effects, in order to understand how best to represent – and perhaps also derive – the observed tendencies concerning when paradigmatic identity is enforced.

84 Clitics

Stephen R. Anderson

1 Introduction

The notion of "clitic" derives from one of the oldest problems in the study of language: how to define the "word." Grammarians have long noted that a difficulty is posed in this area by the fact that certain elements in many languages seem to play an independent role in the grammatical structure of sentences, and thus to warrant the status of "grammatical words," but in terms of their sound structure form parts of unitary "words" (in a distinct, phonological sense) with other "grammatical words." Examples such as those in (1) from Homeric Greek are typical of the phenomenon.[1]

(1) a. hē de kai autōs **m'** aiei
she-N PTC even so me-A always
[PP ***en=*** *athanatoisi theoisi*] *neikei*
among immortal-D gods-D upbraids
even so she always upbraids me among the immortal gods
(*Iliad* 1.520, *apud* Taylor 1996: 480)

b. *theios* ***=moi*** *enupnion ēlthen Oneiros*
divine me-D dream came Oneiros
divine Oneiros came to me in a dream
(*Iliad* 2.56, *apud* Taylor 1990: 35)

In the first of these sentences (*proclitic*) **en=** is grammatically an independent preposition, but forms a word together with the following *athanatoisi* 'immortal'. In the second (*enclitic*) **=moi** is a pronominal adjunct 'to me' of the verb *ēlthen* 'came' but forms a word together with the preceding adjective *theios* 'divine'. In both cases the independent status of the pro- or enclitic seems assured by the grammar of the sentence, but the unitary status of its combination with a host is confirmed by its phonological (especially accentual) behavior. It is this conflict between two

[1] Clitics are identified in boldface type, with the symbol "=" indicating the direction of their relation to a host.

equally well-grounded notions of "word" that brought clitics to the attention of traditional grammarians, and subsequently that of linguists.

The problem as just presented is essentially a phonological one (how to get the phonology to treat two or more elements that appear distinct from the point of view of grammatical structure as one unit). The study of clitics was quickly complicated, however, by the suggestion that the same elements that displayed this anomalous phonological behavior also had specific, idiosyncratic syntactic properties. Jakob Wackernagel (1892) proposed, following Delbrück (1878), that the unstressed clitics of the oldest Indo-European languages (and thus, Proto-Indo-European) occurred systematically after the first word of the sentence, regardless of their grammatical function. This notion of a special syntax for clitics later became part of the very definition of "clitic" for some linguists, and much of the literature presumes that designating something as a clitic entails special behavior both in the phonology and in the syntax.

It is nonetheless useful to disentangle two distinct dimensions of "clitic" behavior, the phonological and the morphosyntactic, which turn out to be logically (and empirically) orthogonal (see Anderson 2005 for elaboration of this point, as well as related discussion in surveys such as that of Halpern 1998, the papers in Dixon and Aikhenvald 2002, and much other literature both traditional and modern). In the context of the present book, this chapter will focus almost exclusively on the phonological aspects of clitic behavior, and references to "clitics" will be to elements that display the relevant phonological properties (without regard to whether they display unusual syntactic distribution).

2 What is a (phonological) clitic?

As a starting point, we can ask which elements we ought to consider as clitics from such a perspective. The notion of clitic in traditional grammar is that of a "little" word, and in particular one that does not bear an independent accent but rather leans accentually on an adjacent word.[2] The proposal that clitics are always unaccented, however, is problematic.

For instance, in Modern Greek, enclitics do not usually receive stress; thus, [ˈðose] 'give!', [ˈðose=**mu**] 'give me!' with no stress on the clitic =**mu**. But when two such enclitics are attached to the same host, a stress appears on the penultimate one, as in [ˌðose=ˈ**mu=to**] 'give it to me!'.[3] This is a consequence of a general rule of Modern Greek that builds a trochaic foot over two otherwise unstressed syllables at the right edge of a word, provided the result does not involve a stress clash. Thus, when a clitic is added to antepenultimate-stressed [triaˈðafilo] 'rose', the result is [triaˌðafiˈlo=**mu**] 'my rose'. It is not the sequence of clitics *per se* that results in the penultimate stress in [ˌðose=ˈ**mu=to**], but rather the application of this rule: cf. [ˈpes=**mu=to**] 'say it to me!', with no stress on =**mu** in an otherwise identical sequence, because such a stress would clash with that on the monosyllabic stem. On the traditional understanding, the claim that =**mu** '1SG' is a clitic seems to be

[2] The word *clitic* derives from Greek *klitikos* 'leaning', from *klīnein* 'to lean'.

[3] Arvaniti (1992) provides experimental evidence that, contrary to the proposals of some previous authors, the added stress in such cases is primary with the original word stress being reduced to secondary. This result has been confirmed by the judgments of several native speakers.

compromised by the fact that it sometimes bears an accent, but we can see that this accent is due to the regular phonology of the language, and not to properties of =**mu** '1SG' itself.

Similarly, in the Papuan language Bilua (Obata 2003), stress is generally initial, but proclitic pronouns do not bear stress, as in (2a). Proclitics can also appear in constructions in which there is no adjacent stressed element, however. This occurs under two conditions: first, a vowel-final clitic does not form part of a word with a following vowel-initial stem, as in (2b); and, second, under some circumstances a cluster of clitics arises which is not associated with any non-clitic host, as in (2c). In these circumstances, the clitic receives stress if initial, as illustrated below.

(2) a. [o= ˈβouβaɛ =k =a]
3SG.MASC kill 3SG.FEM.OBJ TNS
'He killed it.'

b. ˈo ˈodiɛ =k =a]
3SG.MASC call 3SG.FEM.OBJ TNS
'He called her.'

c. ˈo =k =a ˈzari=a ˈrae=ng=o
3SG.MASC 3SG.FEM PRT want-TNS marry-2SG.OBJ-NOM
'He wants to marry you.'

Designating as "clit ics" exactly those elements that do not bear stress, then, does not appear to give us the results we desire. Instead, it is proposed in Anderson (2005) that the right way to pick out clitics phonologically is as *prosodically deficient* elements. Let us assume that full words in general have a lexical representation that organizes their phonological content into syllables, feet, and ultimately one or more *Phonological Words* (PWords; see CHAPTER 51: THE PHONOLOGICAL WORD). We can then say that a phonological form realizing some grammatical element, whose segmental content may be organized into syllables and possibly feet but which is not lexically assigned the status of a PWord, is a clitic in the desired phonological sense. This characterization is not compromised by the fact that such a clitic will typically become part of a PWord (perhaps together with other clitics, as in Modern Greek [ˌðose=ˈ**mu=t●**] or in the Bilua sentence (2c) above) as a consequence of the principles of prosodic organization of the language in question.

The property of being a clitic in this sense, then, is not necessarily a characteristic of a lexical item, but rather of a phonological form that can realize that lexical item. The same item may well have both clitic and non-clitic forms. The classic example of this is the case of the auxiliary verbs in English: many of these have both full, non-clitic forms (*is, has, had, would, will*, etc.) and clitic forms (*'s, 'd, 'll*, etc.). From the point of view of the grammar, these are essentially free variants. If a reduced (clitic) form is chosen to lexicalize the auxiliary in a given sentence, however, this may result in prosodic ill-formedness, as a consequence of the impossibility of incorporating the prosodically deficient item into the overall sound structure of the sentence in a well-formed way (see Anderson 2008 for discussion and analysis). Apart from these differential phonological effects, however, the reduced and unreduced auxiliaries are instantiations of the same grammatical element.

In order to be pronounced, such prosodically deficient material must be incorporated into the larger prosodic structure in some way: thus, the penultimate stress in Modern Greek [ˌðose='mu=to] results from incorporating both enclitics into the same phonological word as the host verb, and then building a trochaic foot over the resultant sequence of unstressed word-final syllables. The Bilua examples result from assigning PWord status to clusters of material that cannot be incorporated into any independent PWord, and then assigning initial stress to this word. It is the characterization of this sort of integration (which we will refer to as *Stray Adjunction*) that constitutes the phonology of cliticization, and this area of phonology will be central to the discussion in later sections of the present chapter.

3 How do clitics differ from affixes?

Although the characterization of clitics as prosodically deficient grammatical elements appears to capture the phonological dimension of their behavior, it does not pick them out uniquely in grammatical structure. With relatively few exceptions, the affixes found within words as formal markers of derivational and inflectional structure also lack an autonomous organization into prosodic constituents at or above the level of the PWord (see CHAPTER 104: ROOT–AFFIX ASYMMETRIES), and the question naturally arises of how clitics and affixes are to be distinguished.

The classic characterization of the issues involved is provided by the widely cited work of Zwicky and Pullum (1983), who enumerate a number of differences between clitics and affixes in defense of their analysis of English *-n't* as the realization of an inflectional category of modals and other auxiliary verbs rather than as a clitic. These include the points in (3).

(3) a. Clitics have a low degree of selection with respect to their hosts; affixes a high degree of selection.
b. Affixed words are more likely to have accidental or paradigmatic gaps than host + clitic combinations.
c. Affixed words are more likely to have idiosyncratic shapes than host + clitic combinations.
d. Affixed words are more likely to have idiosyncratic semantics than host + clitic combinations.
e. Syntactic rules can affect affixed words, but not groups of host + clitic.
f. Clitics, but not affixes, can be attached to material already containing clitics.

These points can be illustrated, following Zwicky and Pullum (1983), by the contrasts in (4) between English clitic auxiliaries (e.g. *'s* 'is, has', *'d* 'would') and the element they argue is an inflectional affix, *n't* 'NEG'.

(4) a. The clitic auxiliaries can attach to words of any class that happen to fall at the right edge of the preceding constituent; *n't* can only be added to finite forms of auxiliary and modal verbs.
b. Combinations of clitic auxiliaries with preceding material are limited only by the possibilities of the syntax; some combinations of auxiliary + *n't* do not exist (e.g. **mayn't*; in most dialects also **amn't*) while one (*ain't*) does not correspond to a specific non-negative form.

c. Combinations of host + clitic auxiliary are governed by the regular phonology of English, as seen for instance in regular plurals and past tense forms with the endings /z/ and /d/; forms such as *don't*, *won't*, *can't*, and *shan't* bear idiosyncratic relations to their non-negative counterparts.
d. Clitic auxiliaries make the same syntactic and semantic contribution to a sentence as full forms; auxiliaries in *n't* can have idiosyncratic semantics (thus, in *you mustn't go* the negation is within the scope of the modal, while in *you can't go* the modal is in the scope of negation).
e. Clitic auxiliaries do not move together with their host (thus, a question corresponding to *I think John's at the door* is *Who do you think's at the door?* and not **Who's do you think at the door?*) while the negated auxiliaries move as a unit (the question corresponding to *I haven't any more bananas* is *Haven't you any more bananas?* and not **Have youn't any more bananas?*).
f. While clitics can be added to other clitics (*I'd've done better if I could've*), *n't* cannot (thus, *I wouldn't do that if I were you* cannot be expressed as **I'dn't do that if I were you*).

Zwicky and Pullum present these differences as descriptive observations, supported by comparisons between uncontroversial instances of clitics and affixes. They can be argued to follow, however, from the proposal that clitics are introduced into syntactic structure as prosodically deficient, but morphosyntactically independent, elements, while affixed words are formed by lexical operations and appear as units in the syntax.[4] Although Zwicky and Pullum formulate some of the principles in (3) only as tendencies, the present account of the nature of clitics suggests that nearly all of them should be construed categorically.

The exception to this generally absolute nature of the differences between clitics and affixes is (3d): syntactically compositional idioms can be semantically idiosyncratic (e.g. *build castles in the air* 'make unrealistic plans or proposals'), and there is no reason to exclude host + clitic combinations from this same possibility. Indeed, many languages assign special meanings to verbs in the presence of particular clitics, such as French *il y a* 'there is' or the Italian *verbi procomplementari* studied by Russi (2008). These latter are combinations of a verb with a specific clitic or cluster of clitics, which take on a conventionalized meaning that is not compositionally related to that of the basic verb. Examples are provided in (5).

(5) a. far=la 'deceive, prevail on someone cunningly'
from *fare* 'make, do' + *la* '3sg DO'
b. voler=ne 'resent, have hard feelings for someone'
from *volere* 'want' + *ne* 'PARTITIVE'

[4] The specific framework I presume is roughly that of Anderson (1992). Within that theory, productive inflection results from the operation of Word Formation Rules that take a lexical stem and the morphosyntactic representation of a syntactic position as their input and yield inflected words as their output; while derivation and lexically idiosyncratic inflection result from Word Formation Rules that construct and relate lexical stems. The details of this position are not essential: what matters is the claim that fully inflected words, structured as PWords, appear in the prosodic structure projected from the syntax. Clitics appear in this structure either as prosodically deficient lexical items (e.g. the contracted forms of English auxiliaries: see Anderson 2008) or as "special clitics" introduced (as phrasal morphology) into that structure at a point where non-clitic material is already present, as described in Anderson 2005.

c. prender=se=la 'take offense, be upset'
from *prendere* 'take' + *si* 'REFL' + *la* '3SG DO'

The constructions in which such combinations are found are syntactically normal (e.g. *Me l'ha fatta di nuovo* 'he tricked me again'), but their interpretation cannot be directly derived from those of their parts.

The rest of the properties in (3) follow from the proposed architecture of grammar. Clitics *per se* are not selective with respect to their hosts (3a), because they are placed by principles that do not make direct reference to the host (although in the case of "special clitics," the phrasal environment for their introduction may be such that only a restricted range of hosts will be present in the appropriate position). They do not display gaps (3b), because individual host + clitic combinations are not listed as such in the lexicon and so are not subject to omission. Similarly, such combinations are not available for lexical listing of idiosyncratic form (3c). Host+ clitic combinations are not affected in a unitary way by the syntax (3e), because the fact of being a clitic entails only a phonological, not a syntactic, relation to the host.

The only way a clitic could appear "inside of" an affix (3f) would be if some special circumstances caused it to be introduced in that way as an "endoclitic." Most of the putative instances of this situation that have been adduced, such as the pronominal clitics that appear between the verbal stem and a future or conditional ending in Portuguese (e.g. *mostrár-no-los-á* 's/he will show them to us'), appear to have alternative analyses that do not involve "endocliticization" (see Anderson 2005: 152ff.).

One exception is the case of Udi as discussed by Harris (2002), which does appear to be a real example. In an Udi form like that in (6), the clitic =**ne** '3SG' comes between one affix and another.

(6) nana-n äjel-ax ak'-es=**ne**-d-e k'uʧan
mother-ERG child-DAT see-INF-3SG-CAUS-AORII puppy.ABS
'The mother showed a puppy to the child.'

In a form such as *a=**z**-q'-e* 'I received', indeed, the clitic element =**z** '1SG' appears within the monomorphemic root *aq'* 'receive'. The analysis of such cases is extremely interesting, but, as argued in Anderson (2005: 161–165), the principles involved are still consistent with the claim that clitics are added to affixed words, and not the reverse.

4 How are clitics prosodically related to their hosts?

Let us assume, then, that lexical elements appear in the input to the phonology with a certain amount of prosodic organization, and that non-clitics differ from clitics in that only the former are lexically organized into PWords. Clitics and non-clitics alike must be organized into *Phonological Phrases* (PPhrases) and perhaps higher levels of prosodic structure, although that is of less importance for present concerns. This phrasing can be regarded as being projected at least in part from syntactic structure, but the question remains of how prosodically deficient material is related to adjacent PWords within this overall organization.

The categories of prosodic structure are generally assumed to be related in a hierarchical fashion, with syllables constituting Feet, which are parts of PWords, which are in turn grouped into PPhrases, etc.

(7) *The Prosodic Hierarchy*
σ < Foot < PWord < PPhrase < Intonational Phrase . . .

A particularly restrictive view of this hierarchy known as the Strict Layering Hypothesis was defended by Nespor and Vogel (1986), for whom the relation between category types was seen as exhaustive at all levels: that is, PPhrases consisted exclusively of PWords, which in turn consisted exclusively of Feet, etc.[5] In a paper which is fundamental to the study of clitic phonology, however, Selkirk (1995), following arguments of Inkelas (1989), proposed that the principles of the Prosodic Hierarchy ought to be regarded as a set of individually ranked, violable constraints, and this view has dominated subsequent research (see CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE, CHAPTER 40: THE FOOT, CHAPTER 51: THE PHONOLOGICAL WORD, and CHAPTER 57: QUANTITY-SENSITIVITY for more discussion of the prosodic hierarchy).

Associating positions on the ordering in (7) with consecutive integers, we could express the basic nature of the Prosodic Hierarchy as involving two fundamental requirements.

(8) a. *Layeredness*
No C_i dominates a C_j, where $j > i$ (e.g. no Foot contains a PWord).

b. *Headedness* (first approximation)
Every C_i directly dominates some C_{i-1} (e.g. every PWord contains a Foot).

The Strict Layering Hypothesis can be expressed as the claim that representations also meet two other requirements.

(9) a. *Exhaustivity*
No C_i directly dominates a C_j, where $j < i-1$ (e.g. no PWord directly dominates a σ).

b. *Non-Recursivity*
No C_i directly dominates another C_i (e.g. no PWord contains another PWord; adjunction structures do not exist).

In order to maintain its logical independence from Non-Recursivity, the formulation of Headedness in (8) can be replaced by the following.

(10) *Headedness*
Every C_i directly dominates some C_j, where $j \geq i-1$.

[5] Nespor and Vogel also posited a category of *Clitic Group* between the PPhrase and the PWord. Subsequent work, such as Booij (1988) and Zec and Inkelas (1991), has generally concluded that no such distinct prosodic category need be introduced, and it is disregarded here. For some discussion, see Anderson (2005: 42ff.).

As noted already by Selkirk (1995), Layeredness and Headedness are inherent in the nature of the Prosodic Hierarchy; since these notions are in some sense definitional, they are not violable, and if construed as constraints should be treated as always undominated. Another undominated requirement, which we could call that of *Full Interpretation*, mandates that all phonological material to be pronounced be integrated into the overall prosodic structure, which means in effect that there must be a path from it to the root of the prosodic tree. It is this constraint that enforces the application of some process of Stray Adjunction in the case of material which is otherwise prosodically unaffiliated.

The requirements in (9), however, make substantive claims about the range of prosodic structures found in the languages of the world and, as such, are subject to empirical confirmation. Evidence suggests, in fact, that they are violated in some instances, and this is the basis for interpreting them not as definitional of prosodic structure, but as potentially violable constraints.

Of these the conditions in (11), formulated now as constraints, are apparently never violated and so can be regarded as undominated along with Full Interpretation.

(11) a. Layeredness
No category dominates a higher-level category.

b. Headedness
Every category directly dominates (at least) one element no more than one level below it on the hierarchy.

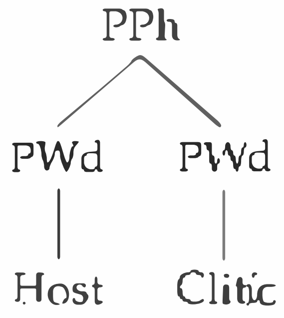
The additional conditions of the Strict Layering condition can, as we have seen, be violated. Furthermore, violation may be "local" in the sense that a language violating, say, Exhaustivity at the PPhrase level may nonetheless conform to this constraint at other levels, such as the PWord. The relevant principles thus need to be formulated as families of constraints, varying over the categories of the hierarchy as in (12).

(12) a. Exhaustivity(C_i)
Every element of category C_i is exhaustively composed of elements of category C_{i-1}.

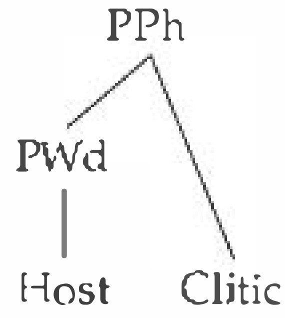
b. Non-Recursivity(C_i)
No element of category C_i directly dominates another instance of C_i.

Adherence to the Strict Layering Condition led Nespor and Vogel to require that clitics always constitute PWords in their own right, sisters of their host within a constituent of the next highest level of the hierarchy. This is somewhat problematic, given that clitics do not generally manifest the properties of independent PWords, such as autonomous stress. If we construe the conditions characterizing the Prosodic Hierarchy in (12) as constraints that can be violated under the pressure of other constraints, however, there are a variety of possible relations that might obtain between a clitic and its host, and Selkirk (1995) justifies the claim that all of these are in fact instantiated. The typology of clitic–host relations that she proposes is as in (13).

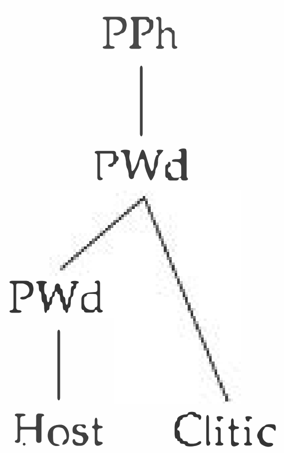
(13) a. *PWord Clitic*[6]



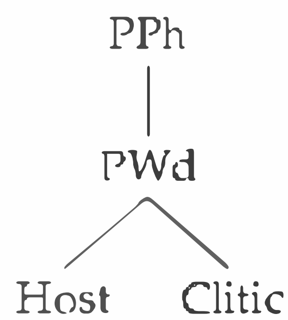
b. *Free Clitic*



c. *Affixal Clitic*



d. *Internal Clitic*



PWord clitics, of course, are structures that result when all of the constraints in (12) are satisfied, so that Strict Layering obtains. Free clitics, in contrast, result when some other constraint forces violations of Exhaustivity(PPhrase): the PPhrase thus contains a constituent lower in the hierarchy than a PWord, such as a stray syllable or foot. Affixal clitics result when Exhaustivity(PPhrase) is satisfied, but Non-recursivity(PWord) is not (and Exhaustivity(PWord) is also violated, in case the stray material constituting the clitic is a syllable and not a foot).

Internal clitics, like PWord clitics, involve no violations of any of the constraints. Differentiating these two possibilities requires us to invoke another constraint:

(14) Prosodic Faithfulness
Prosodic structure in the input should be preserved in the output.

If we assume that the prosodic structure of the host up to the level of the PWord is present in the input to that part of the phonology enforcing Stray Adjunction, we can see that this structure is preserved intact if the stray material is incorporated as a PWord clitic, but altered if it is incorporated as an internal clitic. The choice between the two, then, depends on the relative importance of Prosodic Faithfulness and some constraint disfavoring the creation of additional PWord structure (say, *Struct).

For an example of PWord clitics, we can appeal to Bilua examples such as (2b) and (2c), where other aspects of the structure prevent the incorporation of the clitic into an adjacent PWord, but the prohibition against building new PWords is not highly enough ranked to prevent a new PWord from being formed. The remaining possibilities can be demonstrated through a set of closely related systems

[6] Since clitics have been defined precisely as elements lacking PWord structure, the notion of a "PWord Clitic" may seem paradoxical. The point is that while clitics do not have such structure underlyingly, the subsequent operation of the language's broader principles of prosodic organization may give rise to such a structure, as we saw in the case of Bilua above.

analyzed elegantly by Peperkamp (1997). As reviewed below, she argues that Standard Italian post-verbal pronominal clitics have the structure of free clitics, while the corresponding elements in Neapolitan are affixal clitics and those of Lucanian are internal clitics. The three dialects provide a nice contrasting set, differing minimally in the way clitics are incorporated into prosodic structure as described in terms of varied rankings of the constraints introduced above.

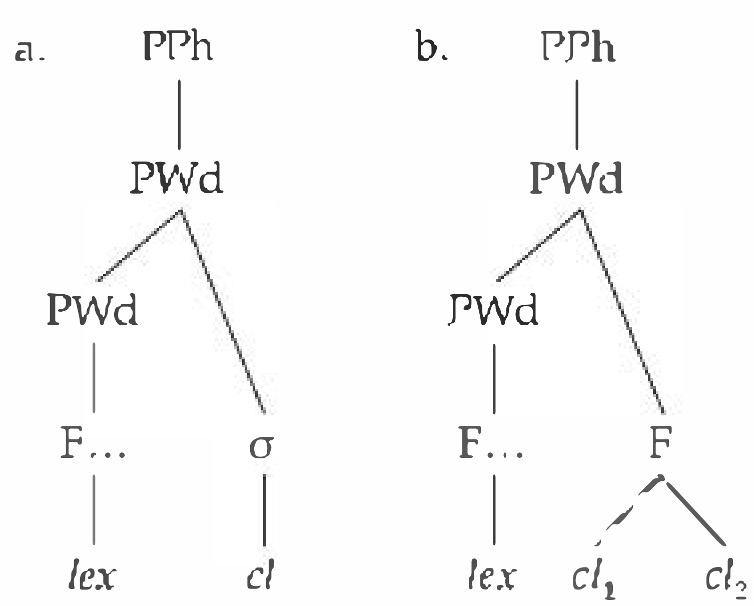
The first system to be considered is that of Neapolitan, as illustrated in (15).

(15) *Neapolitan*

imperative	*imperative* + 'it'	*imperative* + 'you' + 'it'	
'fa	'fallə	fat'tillə	'do'
'conta	'contalə	'conta'tillə	'tell'
'pettina	'pettinalə	'pettina'tillə	'comb'

I assume that PWords are built lexically over the host verbs, and then prosodically deficient clitics are added post-lexically. Note that when clitics are added, the first stress does not change except in one case ([fat'tillə]), where we can say that the new stress appearing on the clitic sequence has the effect of suppressing the original stem stress to avoid violating *Clash (which penalizes a sequence of two adjacent stresses). Peperkamp shows that we can describe this system by saying that the clitic material is adjoined to the existing prosodic word, without modifying its structure, as in (16).

(16)



A single clitic constitutes a single syllable, and not a Foot; two clitics, however, provide enough material to constitute a Foot, and thus introduce an additional stress. Peperkamp's discussion suggests that there are aspects of formal suppletion that require the treatment of the two-clitic sequence as a single unit, which is eligible to be a Foot. Alternatively, we could assume simply that the two monosyllabic units are introduced together, and subsequently organized into a Foot.

We can describe this system as follows. Full Interpretation, Headedness, and Layeredness are all undominated well-formedness conditions on the candidates that are to be compared, so they play no part in the ranking. It is also the case that prosodic structure assigned lexically is generally preserved, so Prosodic Faithfulness (14) is also ranked high.

In the case of a monosyllabic stem followed by two clitics, however, the need to avoid successive stressed syllables is more important than the preservation of input prosody, so the stress on the stem is lost as a result of the domination of Prosodic Faithfulness by another constraint (17).[7]

(17) *Clash
Sequences of two consecutive stressed syllables are disallowed.

To satisfy Full Interpretation, prosodically deficient material (i.e. the clitics) must be incorporated into the structure somewhere, and the choices are limited. Incorporation into a foot would violate well-formedness conditions on feet, as well as faithfulness to existing prosodic structure. Incorporation into the existing PWord would also violate faithfulness. Incorporation at the PPhrase level would violate Exhaustivity(PPhrase). The Affixal clitic structures that are actually found indicate that Exhaustivity(PPhrase) outranks Non-Recursivity(PWord): that is, building a recursive PWord preserves the existing prosodic structure, and avoids having lower-level constituents (syllables, feet) directly dominated by a PPhrase. The overall constraint ranking for Neapolitan is as in (18).

(18) *Clash >> Prosodic Faithfulness >> Exhaustivity(PPhrase) >> Non-Recursivity(PWord)

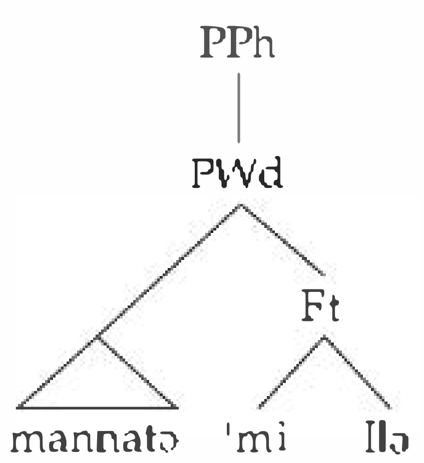
Now compare the Neapolitan approach to Stray Adjunction with that employed in another dialect, Lucanian.

(19) *Lucanian*

a.	'vinnə	'sell'	vən'nillə	'sell it'
b.	ram'millə	'give me it'	mannatə'millə	'send me it'

We see in (19a) that the addition of a clitic in this language causes stress to shift rightward.[8] Apparently, a binary trochaic foot is constructed over the last two syllables of the form, including both stem and any following clitics. The forms in (19b), with two clitics, have this foot constructed entirely over clitic material. In this language, Stray Adjunction produces Internal clitics, sacrificing Faithfulness to maintain the Strict Layering constraints. The resulting structure for a form with two clitics is as in (20).

(20)



[7] The fact that it is the first, rather than the second, of two adjacent stresses that is lost must be resolved by other aspects of the prosodic phonology of Neapolitan not considered here.

[8] Stress shift is responsible for the vowel alternation in these forms, with stressed [i] corresponding to unstressed [ə].

The constraint ranking necessary to obtain this result is (21).

(21) Non-Recursivity(PWord), Exhaustivity(PWord) >>
Prosodic Faithfulness

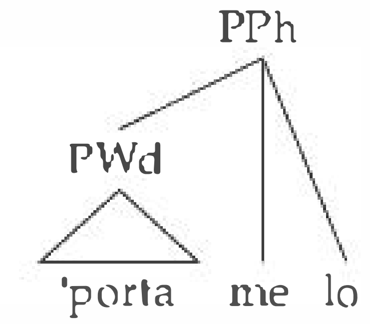
Let us finally compare the situation in (standard) Italian, illustrated in (22).

(22) *Standard Italian*

a.	'porta	'bring'	'portami	'bring me'
b.	'portamelo	'bring me it'	te'lefonamelo	'telephone it to me'

Here the addition of a clitic does not alter the lexically assigned stress, suggesting that Prosodic Faithfulness is highly ranked. Even when two clitics are added, as in (22b), the stress is not altered, and apparently no new stress is assigned even though two syllables of additional material would support the construction of a new Foot if this material were within the PWord. Apparently, then, Stray Adjunction in Standard Italian produces free clitics by attachment to the PPhrase, as in (23).

(23)



The required ranking is that in (24).

(24) Non-Recursivity, Exhaustivity(PWord), Prosodic Faithfulness >>
Exhaustivity(PPhrase)

Stray Adjunction in these three Italian dialects is thus based on different rankings of the prosodic constraints, yielding three different structural types of clitic as a reflection of these differences in their post-lexical phonology.

Peperkamp argues for the structural differences amongst Italian dialects on the basis of the distribution of stress alone, but sometimes this is insufficient to provide an unambiguous analysis. For example, in the case of a language with stress oriented to the left of the word (or simply preserved by high-ranking faithfulness constraints) and a set of unstressed enclitics, stress alone will not allow us to differentiate among the structures of free, affixal, and internal clitics. To do so, we must establish the location of PWord boundaries in the resulting form. The three possibilities can be distinguished in this way, as in (25).

(25) a. Free clitic: (. . .)host]$_{PWd}$ clitic]$_{PPh}$
b. Affixal clitic: (. . .)host]$_{PWd}$ clitic]$_{PWd}$]$_{PPh}$
c. Internal clitic: (. . .)host clitic]$_{PWd}$]$_{PPh}$

Determining which of these structures is present in a given instance is certainly not trivial, but it can often be done by looking for phonological phenomena which occur at the edges of PWords or across PWord boundaries. Revithiadou (2008) provides a detailed study of a range of dialects of Modern Greek of exactly this sort, showing that phonological regularities characteristic of prosodic boundaries identify different host–clitic relationships in different dialects. Similar arguments provided by Booij and Rubach (1987) for Polish can be interpreted as showing that proclitic prepositions in that language (e.g. *bez* 'without' in *bez namysłu* 'without thinking') are related to a following host as affixal clitics, as reviewed in Anderson (2005: 40f.).

It appears that, in general, the attachment of a clitic to a host on one side or the other can be derived from the overall prosodic organization of a language. Typically, prosodic structure above the level of the PWord is projected from the syntax, and the commonest tendency is for this structure to be respected: that is, a clitic attaches phonologically to the host (on its right or on its left) with which it is most closely affiliated grammatically. In some instances, though, this direction of attachment is directly contravened.

In Kwakw'ala, for instance, as discussed at length in Anderson (2005), DP-initial determiner clitics associate phonologically not with the following word, which is part of the same DP, but rather with the preceding word, which is not. An example is provided by the sentence in (26).

(26) jəlkʷəmas[=**ida** bəgʷanəma]$_{DP}$[=**χ-a** 'watsi]$_{DP}$[=**s-a** gʷaχt͡ɬuχʷ]$_{DP}$
cause hurt-DEM man-OBJ-DEM dog-INST-DEM stick
'The man hurt the dog with the stick.'

Here the square brackets indicate syntactic constituents, while inter-word spaces delineate PWords: thus, /bəgʷanəma[=**χ-a**/ is a single PWord, while [=**ida** bəgʷanəma]$_{DP}$ is a single DP.

This situation can be related to the fact that Kwakw'ala is a language in which virtually all morphological marking is suffixal, and thus the lexical root is always (with the exception of reduplicated forms) word initial. A preference to maintain this same situation at the level of prosodic structure can be expressed as a constraint such as (27).

(27) ALIGN(PWord, L; LexWord, L) (>> ALIGN(XP, L; PPhrase, L))

That is, it is important that the left edge of a PWord coincide with the left edge of a lexical word (and not e.g. a clitic determiner). This constraint is more highly ranked than the requirement that the left edges of syntactic phrases coincide with the left edges of PPhrases, and forces the clitics to associate anti-syntactically to their left.

The claim that the direction of attachment of clitics can be derived from the prosodic organization of the language as a whole (including constraints such as the one in (27)) is a strong one. It is at variance with proposals such as that of Klavans (1985), where it is claimed that among the dimensions defining individual clitics in a language is a parameter of direction of attachment. Subsequent research has suggested, however, that once grammatical structure and its relation to prosody are taken into account, a unitary analysis can be offered for the way clitics attach in any individual language. Counterexamples to this claim would have to involve pairs of clitics that were entirely comparable in their grammar, but where one attached to a host on its left and the other to a host on its right (under otherwise identical prosodic conditions). Such examples do not appear to exist, and it seems reasonable to propose that the direction of attachment of clitics is a function of the overall grammar of a language, rather than a property of individual clitics.

In summary, clitics can be characterized from a phonological point of view as linguistic elements lacking in prosodic structure at (or below) the level of the PWord. Linguistic units that are called "clitics" on the basis of unusual syntactic behavior may or may not be clitics in this sense: for example, Italian *loro* '3PL DAT' behaves in a way which is partially similar to the other Italian pronominal clitics, but *loro* is not prosodically deficient, and thus does not constitute a clitic from the phonological point of view. Similarly, Hungarian verbal prefixes such as *oda* in *oda-ment-em* 'I went over there' constitute PWords in their own right (as shown by stress and vowel harmony), and thus are not phonological clitics, even though they bear a special grammatical relation to an associated verb.

Material that is not fully integrated into prosodic structure (at the PWord level) in the input can be called "stray," and the phonology of cliticization is fundamentally a matter of how this stray material is incorporated into the overall prosodic structure of the sentence: how "Stray Adjunction" is enforced. The basic mechanics of this can be described by an ordering of the constraints characterizing prosodic layering with respect to one another and to other constraints within the grammar of the language in question. Arguments for this ranking can be provided either directly from properties of the resulting prosodic structure (such as the location of stress) or from other phonological phenomena that are sensitive to it.

5 How is the segmental phonology of a clitic related to that of its host?

A consequence of the grammatical architecture proposed here concerns the phonology applicable to clitic + host combinations. Since the formation of these presupposes the forms of lexical words, it would appear that in terms of classical Lexical Phonology (e.g. Kiparsky 1985; see also CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME), any adjustments to their shape must follow from principles of the post-lexical phonology, not the lexical phonology *sensu stricto*. Bermúdez-Otero and Payne (forthcoming) note this, but assert that examples exist which controvert it: cases in which host + clitic combinations are affected by rules that are lexical, not post-lexical in character.

The one such example cited by Bermúdez-Otero and Payne concerns laryngeal neutralization in Catalan. They argue, following the descriptive literature (e.g. Wheeler 2005) that voicing is neutralized in coda obstruents in this language (see CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). When these are closely followed by an onset consonant (in the same or a following word), they show the same voicing as that consonant, and it is plausible to attribute this to assimilation. Word-finally, however, coda obstruents are devoiced; and this devoicing persists even if the consonant in question is resyllabified post-lexically with a following vowel. These facts are illustrated in (28) for the stem /ʎob/ 'wolf', which ends in underlying voiced /b/.

(28)	a.	*llop*	[ʎop]	'wolf'
	b.	*llop lliure*	[ʎob.ʎiw.re]	'free wolf'
	c.	*llop trist*	[ʎop.trist]	'sad wolf'
	d.	*lloba*	[ʎo.βə]	'she-wolf'
	e.	*llop amic*	[ʎo.pə.mik]	'friendly wolf'

They suggest that there must be a "word-level" principle of laryngeal neutralization which is counterbled by post-lexical resyllabification in forms like (28e). In forms where a stem-final voiced obstruent is followed by a vowel-initial clitic, however, the pattern is subtly different: resyllabification bleeds laryngeal neutralization, as illustrated in (29) for the stem /rɛb/ 'receive'.

(29) a. *rebre* [rɛ.βrə] 'receive (INF)'
b. *rep això!* [rɛ.pə.ʃɔ] 'receive (2SG.IMP) that!'
c. *rep=ho!* [rɛ.βu] 'receive (2SG.IMP)-3SG.ACC.N!'

Why should there be a difference in voicing between the stem-final /b/ as it appears in (29b) and in (c)? Bermúdez-Otero and Payne conclude that this must be because the clitic in (29c) must already be present (and have triggered resyllabification) at the point where Laryngeal Neutralization takes place:

> These data show unequivocally that enclitic =ho belongs in the same grammatical word as the verb stem, since it causes the stem-final consonant to be syllabified as an onset already at the word level [. . .] Therefore, enclitic =ho cannot be a phrasal affix.

This conclusion does not follow, however. It results from Bermúdez-Otero and Payne's equation of "word-level" phonology with "lexical" phonology, and the assumption that the "post-lexical" phonology is monolithic. In fact, however, we can take the "word-level" character of laryngeal neutralization to refer to the PWord, not (as Bermúdez-Otero and Payne do) to the grammatical word. If we assume that post-verbal pronominal clitics in Catalan are affixal clitics, the result of stray adjunction in (29c) will be [[[rɛb]$_{PWd}$u]$_{PWd}$]$_{PPh}$. This entire construction is a PWord, and it is plausible to assume that resyllabification of this PWord yields a structure like [[rɛ]$_{PWd}$.bu]$_{PWd}$, bleeding Laryngeal Neutralization. In (29b), however, the structure is [[rɛb]$_{PWd}$[ə.ʃɔ]$_{PWd}$]$_{PPh}$. Laryngeal Neutralization, a rule whose scope is the PWord, converts this to [[rɛp]$_{PWd}$[ə.ʃɔ]$_{PWd}$]$_{PPh}$, which is subsequently resyllabified at the PPhrase level to [[rɛ]$_{PWd}$[pə.ʃɔ]$_{PWd}$]$_{PPh}$.

Resyllabification at the PPhrase level does not bleed Laryngeal Neutralization, but Resyllabification at the PWord level does. Since Bermúdez-Otero and Payne do not show that Laryngeal Neutralization has other characteristics of a "lexical" rather than "post-lexical" process (e.g. lexical exceptions), it follows only that the post-lexical phonology displays a sort of cyclic structure, with a round of phonological adjustment induced by each of the categories of the Prosodic Hierarchy, and not that clitics like Catalan =ho are not phrasal affixes. The notion that phonological regularities enforced at different levels of the Prosodic Hierarchy (such as the PWord *vs.* the PPhrase) can be at least partially distinct is a cornerstone of prosodic theory, and a basic way in which one argues that a given prosodic constituent is of one type rather than another (see Nespor and Vogel 1986).

I conclude, then, that the phonology relating clitics to their hosts is in general of the "post-lexical" type, with the specifics depending on the regularities governing various prosodic constituent types within a given language. Given the current state of instability that governs the architecture of phonological theory, with classical rule-based Lexical Phonology and its most direct constraint-based dependent, Stratal OT (Bermúdez-Otero, forthcoming), in conflict both with the "standard" monolithic model of OT and also with various alternatives such as

OT-CC (McCarthy 2007) and Optimal Interleaving (Wolf 2008), Phase-based Phonology, as represented by various papers in Grohmann (2009), and others, it is difficult to see the facts above from Catalan as decisively incompatible with the view of clitics as phonologically integrated with their hosts at the syntactic level, rather than in the lexicon.

6 Conclusion

There is very little to the phonology of clitics, then, that is unique to these elements. In terms of their representation, they have the character of being incompletely organized in prosodic terms: they are deficient in not constituting PWords, as opposed to normal lexical items. Once that is taken into account, the rest of their behavior follows from the prosodic phonology of the language. Aspects of prosodic well-formedness require that they undergo Stray Adjunction, or incorporation into adjacent prosodic units at some level, in ways that depend on the language's particular ranking of constraints governing prosodic structure. The language's "post-lexical" phonology (in some appropriate, architecture-dependent sense) then governs adjustments in the phonological shape of the resulting combination of clitic and host. Neither the prosodic organization nor the phonological adjustments involved are uniquely identified with clitics, although clitics may well provide essential clues in the determination of how the phonology (including prosody) of a language works.

A full treatment of the linguistic category of "clitics," of course, would have to deal with more than the phonological characteristics of items so designated. In particular, the principles underlying the distinctive (morpho)syntactic behavior of "Special Clitics" must be elucidated. Linguistic items that show clitic behavior in the morphosyntactic sense are usually, though not always, prosodically deficient and thus phonologically clitic as well. The analysis of this dimension of the (not entirely homogeneous) class of "clitics" would, however, take us much too far afield in the context of this *Companion*, and the interested reader can only be referred to Anderson (2005) for the development of one view.

ACKNOWLEDGMENTS

This work was supported in part by NSF award #BCS 98-76456 to Yale University. I thank two anonymous referees and the editors of the *Companion* for useful comments, and also Argyro Katsika for her assistance with the phonology of Modern Greek. None of these people is to be held accountable for my use of the information they supplied, of course.

85 Cyclicity

Ricardo Bermúdez-Otero

1 Introduction

The phonology of a natural language will often treat the same string differently according to whether it is wholly contained within a single morph, arises through a morphological operation like affixation, or straddles the edges of two adjacent grammatical words. In the generative tradition there is a widespread and long-standing consensus that such morphosyntactic conditioning effects may come about in two ways: representationally or procedurally (Scheer 2008: §3ff.; see Table 85.1). Representational morphosyntactic conditioning occurs when phonological processes are sensitive to the presence or absence of certain phonological objects – boundary symbols in *SPE*, prosodic categories in most later frameworks – which are in turn positioned by reference to the edges of morphosyntactic units. In procedural morphosyntactic conditioning, in contrast, morphosyntax directly controls the amount of structure visible during a given round of phonological computation, either by submitting to the phonology only a morphosyntactic sub-constituent of a complete linguistic expression (as in the theory of the cycle) or

Table 85.1 Two types of morphosyntactic conditioning acknowledged throughout the history of generative phonology

Theory	*Representational effects*	*Procedural effects*	*Sample reference*
SPE	boundary symbols (+, #)	the cycle	Chomsky & Halle (1968)
Lexical Phonology	prosodic units (built by rules)	the cycle (with levels)	Booij & Rubach (1984)
Stratal OT	prosodic units (controlled by Align)	the cycle (with levels)	Bermúdez-Otero & Luís (2009)
Classical OT	prosodic units (controlled by Align)	OO-correspondence	Raffelsiefen (2005)
Lateral Phonology	empty CV units	the cycle (phases)	Scheer (2008)

by allowing the phonology access to the surface representation of some morphosyntactically related expression (as in the theory of transderivational or output–output correspondence, henceforth OO-correspondence).

This chapter addresses current debates about procedural morphosyntactic conditioning in phonology, focusing in particular on the contest between the cycle and OO-correspondence (§5–§9); we shall be concerned with prosody only insofar as it raises the non-trivial problem of demarcating procedural from representational effects (§4). Much of the discussion will be taken up with three instances of morphosyntactically induced misapplication that challenge the basic premises of transderivational theories: in all three cases, the surface bases needed for an analysis relying on OO-correspondence appear to be unavailable for phonological or morphological reasons (§6–§8). As the argument unfolds, however, it will become clear that questions about morphosyntax–phonology interactions are intricately entangled with problems in every other area of phonology, notably including the theory of representations, the phonology–phonetics interface, and the balance between synchronic and diachronic explanation.

2 Two cases of cyclic misapplication in English: Post-nasal plosive deletion and Belfast dentalization

Let us begin with a well-known instance of morphologically induced overapplication. Present-day English tolerates homorganic consonant clusters consisting of a nasal followed by a non-coronal voiced plosive (i.e. [b] or [g]) only if the latter is syllabified in onset position; if the plosive would otherwise surface in the coda, it undergoes deletion (Borowsky 1993: 202).[1]

(1)	a.	*bomb*	[bɒm]	b.	*bombard*$_V$	[ˌbɒm.ˈbɑːd]
		thumb	[θʌm]		*thimble*	[ˈθɪm.bl̩]
		crumb	[kɹʌm]		*crumble*	[ˈkɹʌm.bl̩]
		long	[lɒŋ]		*elongate*$_V$	[ˈiː.lɒŋ.ˌgeɪt]

The forms in (1a) and (1b) display normal application and non-application of deletion, respectively. In (2a), however, the process overapplies: the plosives [b] and [g] fail to surface stem-finally, even though in that position they would be syllabified as onsets; cf. (2b).[2]

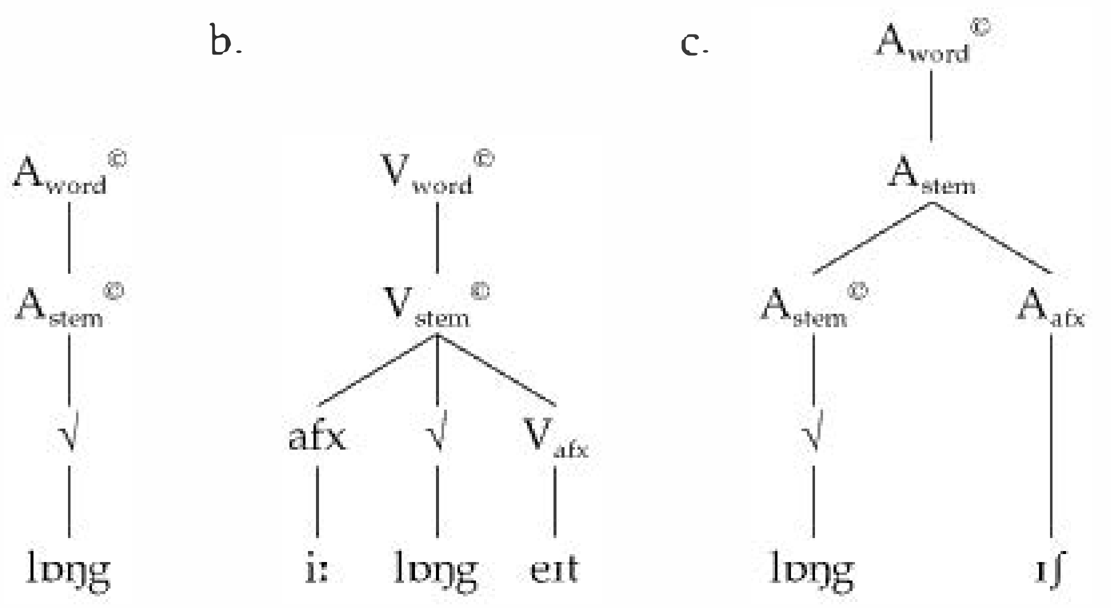
(2)	a.	*bomb-ing*	[ˈbɒ.mɪŋ]	b.	*[ˈbɒm.bɪŋ]
		thumb-ing	[ˈθʌ.mɪŋ]		*[ˈθʌm.bɪŋ]
		crumb-y	[ˈkɹʌ.mɪ]		*[ˈkɹʌm.bɪ]
		long-ish	[ˈlɒ.ŋɪʃ]		*[ˈlɒŋ.gɪʃ]

[1] All varieties of English exhibit post-nasal /b/-deletion; /g/-deletion varies across dialects.

[2] *Thumb*$_V$ and *thimble* are highly unlikely to be synchronically related, and so native speakers probably have no reason to derive the noun *thumb*$_N$ or the converted verb *thumb*$_V$ from a root /θʌmb/. If so, the gerund *thumb-ing* [ˈθʌ.mɪŋ] is in fact transparent. This does not affect our argument, however: the key point is that the grammar of English systematically disallows transparent alternations between infinitives ending in [. . . Vm] and gerunds ending in [. . . Vm.bɪŋ].

According to the theory of the phonological cycle, first formulated by Chomsky *et al.* (1956: 75), the key to such instances of morphosyntactically induced misapplication is to be found in part–whole relationships within the grammatical constituent structure of the relevant linguistic expressions. Consider, for example, the morphological structure of the adjective *long*, the verb *elongate*, and the derived adjective *longish*.

(3) a. b. c.



Let us suppose that some of the morphosyntactic constituents shown in (3) define domains for phonological computation; I shall henceforth refer to these as "cyclic nodes." Assume, at a minimum, that the set of cyclic nodes in (3) includes every stem immediately derived from a root, as well as every fully inflected, syntactically free grammatical word; these are flagged with a superscript ●. Given these premises, one obtains the following nested domain structures:

(4) a. [[lɒŋg]] b. [[iː-lɒŋg-eɪt]] c. [[lɒŋg] ɪʃ]

Now suppose that phonological computation proceeds iteratively, starting with the domains defined by the smallest, most deeply embedded cyclic nodes, and then moving to larger, less deeply embedded cyclic nodes: in other words, suppose that the computation of the phonological form of the parts precedes and feeds the computation of the phonological form of the whole.

(5)	a. [[lɒŋg]]	b. [[iː-lɒŋg-eɪt]]	c. [[lɒŋg] ɪʃ]
inner cycle	lɒŋ	iː.lɒŋ.geɪt	lɒŋ
outer cycle	—	—	lɒ.ŋɪʃ

According to this cyclic analysis, post-nasal plosive deletion overapplies in *longish* because its conditions are met within a morphosyntactic subconstituent, the stem *long-*, which defines a cyclic domain by itself. The environment for deletion disappears in the outer cycle, as the vowel of the suffix *-ish* projects a syllable with an onset capable of sheltering the underlying /g/; but deletion has already applied in the inner cycle. The result is a counterbleeding interaction.

Observe that not all morphosyntactic constituents trigger phonological cycles. In (3b) and (4b), for example, it is absolutely crucial that roots (as opposed to stems) should not count as cyclic nodes (Kiparsky 1982: 32–33; Inkelas 1989: §3.5.5); otherwise, post-nasal plosive deletion would incorrectly overapply in *e-long-ate*.[3] A fully articulated theory of the cycle must of course specify criteria for designating particular morphosyntactic nodes as cyclic or non-cyclic. Scholars working in the tradition of Lexical Phonology (e.g. Kiparsky 1982; Hargus and Kaisse 1993) and Stratal OT (e.g. Bermúdez-Otero 1999, 2003; Kiparsky 2000) have reached a broad consensus on a number of points, sometimes strikingly at variance with phase theory in minimalist syntax (Chomsky 2001): e.g. there appear to be no cyclic nodes between the grammatical word (X^0) and the utterance (see further Scheer 2008: §740ff.). Many other issues remain open: e.g. whether or not certain affixes should be allowed to define cyclic domains by themselves (Baker 2005; see also Mohanan 1982, and cf. McCarthy 2007: 133–134).

To account for morphologically induced underapplication, the theory of the cycle needs to be supplemented with the concept of level or stratum (CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME).[4] Consider, for example, the process of dentalization found in certain varieties of English spoken in and around Belfast: the coronal non-continuants /t d n l/ have alveolar realizations unless immediately followed by /(ə)ɹ/, in which case they become dental (Harris 1985: 58, 211ff.).

(6)	a.	*train*	[t̪ɾ̥ɪən]	*drain*	[d̪ɾ̥ɪən]				
		true	[t̪ɾ̥ʉ:]	*drew*	[d̪ɾʉ:]				
	b.	*Peter*	['pit̪əʴ]	*ladder*	['lad̪əʴ]	*dinner*	['dɛ̈n̪əʴ]	*pillar*	['pɛ̈l̪əʴ]
		matter	['mat̪əʴ]	*rudder*	['ɹɔ̈d̪əʴ]	*spanner*	['spän̪əʴ]		

Dentalization underapplies when its environment is created by adding a suffix like agentive *-er* (7a) or comparative *-er* (7b) to a free stem, although it does apply normally when comparative *-er* is suffixed to a suppletive bound root (7c).

(7)	a.	*hea*[t]*er*	*loa*[d]*er*	*di*[n]*er* 'diner'	*ki*[l]*er*	
		wai[t]*er*		*ru*[n]*er*		
		shou[t]*er*				
	b.	*fa*[t]*er*	*lou*[d]*er*	*fi*[n]*er*	*coo*[l]*er*	
		la[t]*er*				
	c.	*better*	['bæt̪əʴ]	'good.COMPARATIVE'		
		cf. *better*	['bætəʴ]	'one who bets'		

Applying the same principles as in (4), we obtain cyclic domain structures like the following:

(8)	a.	[[*train*]]		b.	[[*heat*] *er*]
		[[*Peter*]]			[[*fat*] *er*]
		[[*bett-er*]] 'good.COMPARATIVE'			[[*bet*] *er*] 'one who bets'

However, it becomes immediately apparent that, if dentalization applies in every cycle, then cyclic derivation will just fail to produce the desired underapplication in (8b): dentalization will simply take place in the outer cycle.

3 For the root-based status of this form, compare verbs like *e-dulcor-ate*, *e-mancip-ate*, *e-viscer-ate*, etc., which are manifestly derived from uninflectable bound bases.

4 Some scholars pursue an alternative approach, based on Chomsky's (2001) Phase Impenetrability Condition: e.g. Marvin (2002), Scheer (2008).

Many cyclic frameworks solve this problem by asserting that phonological domains associated with morphosyntactic constituents of different kinds may be subject to different phonological generalizations: in common usage, such morphosyntactic constituents are said to "belong to different phonological levels." Theories differ as to the number of phonological levels that may be distinguished within the grammar of a single language. Lexical Phonology and Stratal OT often assume that each grammar specifies precisely three levels: the stem, word, and phrase levels. In affixal constructions, the ascription of the construction to the stem-level or word-level phonology is deemed to depend on properties both of the base (Giegerich 1999) and of the affix: the attachment of an affix to a root necessarily produces a stem-level category; the attachment of an affix to a stem may produce a stem-level or word-level category depending on the idiosyncratic affiliation of the affix (e.g. Bermúdez-Otero 2007d: 283). In constrast, full grammatical words trigger word-level cycles and complete utterances trigger phrase-level cycles.

In the case of Belfast English, one must assume that dentalization applies only within stem-level domains, and that agentive *-er* and comparative *-er* are word-level suffixes unless attached to bound roots. This yields the appropriate counterfeeding relationship between stem-level dentalization and word-level suffixation.

(9)		
	Peter	'good.COMPARATIVE'
	$_{WL}$[$_{SL}$[*Peter*]]	$_{WL}$[$_{SL}$[*bett-er*]]

	$_{WL}$[$_{SL}$[*fat*] *er*]	$_{WL}$[$_{SL}$[*bet*] *er*]
SL (dentalization on)	–	–
WL (dentalization off)	–	–

3 The Russian Doll Theorem and the life cycle of phonological processes

There is no room in this brief chapter to review all the predictions about morphosyntactically induced misapplication that follow from the theory of the cycle. It will therefore be appropriate to concentrate here on one of the most fundamental:

(10) *The Russian Doll Theorem*

Let there be the nested cyclic domains $_{\gamma}[\ldots\ _{\beta}[\ \ldots\ _{\alpha}[\ldots]\ \ldots]\ \ldots]$. If a phonological process p is opaque in β because its domain is α, then p is opaque in γ.

To my knowledge, this entailment of cyclic theory has not been formally enunciated before, probably because it has been considered so obviously true as to be entirely trivial. Later, however, we shall see that OO-correspondence is easily capable of violating the Russian Doll Theorem and captures its effects only by stipulation (§9).

The Russian Doll Theorem has the following corollary:

(11) If a phonological process exhibits cyclic misapplication within a certain phonological configuration created by affixation, then it must also exhibit cyclic misapplication if the same configuration arises by word concatenation.

This follows logically from elementary facts of morphosyntactic layering: a phonological process can cyclically misapply in the presence of an affix only if that affix is excluded from its cyclic domain, which must therefore correspond to a morphosyntactic category smaller than the grammatical word, i.e. a stem; but, by its very nature, a stem cannot straddle the edges of adjacent words. Post-nasal plosive deletion (§2) bears out this prediction: overapplication before word-level suffixes beginning with a vowel, as in *long-ish* [ˈlɒ.ŋɪʃ], entails overapplication in word-final prevocalic environments, as in *long effect* [ˌlɒ.ŋɪ.ˈfɛkt]; cf. *[ˌlɒŋ.gɪ.ˈfɛkt].

Not only does corollary (11) hold true of post-nasal plosive deletion in present-day English, but it also captures key facts in the diachronic evolution of the process. For /ŋg/ clusters, in particular, we can reconstruct the four historical stages shown in (12): Stage 0 represents the situation in Early Modern English; Stage 1 is attested in the formal, relatively conservative register of eighteenth-century orthoepist James Elphinston; Stage 2 corresponds to Elphinston's description of his own casual, more innovative register; and Stage 3 is observed in present-day RP (Garrett and Blevins 2009: 527–528). The symbol ‖ represents pause (i.e. the end of the phonological utterance).

(12)

	Stage 0	Stage 1	Stage 2	Stage 3
elongate	ŋg	ŋg	ŋg	ŋg
prolong-er	ŋg	ŋg	ŋg	ŋ
prolong it	ŋg	ŋg	ŋ	ŋ
prolong ‖	ŋg	ŋ	ŋ	ŋ

In compliance with (11), the diachronic transition from normal application (Stage 1) to word-internal overapplication (Stage 3) is effected through an intermediate phase involving overapplication at word boundaries but normal application word-internally (Stage 2).

More generally, the diachronic pathway shown in (12) provides a clear illustration of the typical life cycle of phonological processes, which stratal-cyclic frameworks capture in a particularly perspicuous way; see e.g. Bermúdez-Otero (1999: 99–103, 239–240; 2007b: 503) and McMahon (2000: ch. 4). First, phonetically driven innovations enter the grammar from below as gradient phonetic rules, which later become stabilized as categorical phonological processes applying across the board at the phrase level (Bermúdez-Otero 2007b: 505; see also CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY; CHAPTER 93: SOUND CHANGE): in (12), this is the transition from Stage 0 to Stage 1. Subsequently, analogical change causes the new phonological process to climb up to progressively higher levels, concomitantly narrowing down its domain of application (Dressler 1985: 149): in (12) we see deletion climbing up from the phrase level (Stage 1) to the word level (Stage 2), and from the word level (Stage 2) to the stem level

(Stage 3). Eventually, senescent processes typically undergo morphologization or lexicalization: see Bermúdez-Otero (2008) for incipient symptoms of this in the case of post-nasal plosive deletion.

The overall sequence of events is represented in greater detail in (13), where g̶ indicates a site of /g/-deletion.

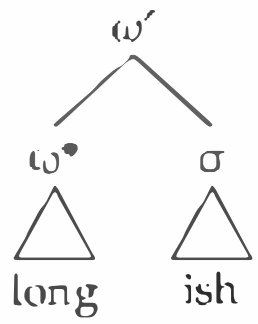
The analogical changes involved in the transitions between Stages 1 and 2 and between Stages 2 and 3 were driven by input restructuring (Bermúdez-Otero and Hogg 2003: 105ff.; Bermúdez-Otero 2006: 501ff.). At Stage 1, for example, surface $_{\text{PL}}$[pɹə.lɒŋ‖] was derived unfaithfully from word-level $_{\text{WL}}$[pɹə.lɒŋg] by a phrase-level application of deletion. By Stage 2, however, $_{\text{PL}}$[pɹə.lɒŋ‖] has been re-analyzed as derived faithfully from an identical word-level representation $_{\text{WL}}$[pɹə.lɒŋ]. This has the effect of introducing deletion into the word-level phonology, and gives rise to the innovative opaque surface form $_{\text{PL}}$[pɹə.lɒ.ŋɪt], derived from word-level $_{\text{WL}}$[pɹə.lɒŋ] $_{\text{WL}}$[ɪt]. Bermúdez-Otero (1999: 100–103, 239–240; 2003: 4ff.) outlines an approach to phonological learning that accounts straightforwardly for such patterns of recurrent input restructuring.

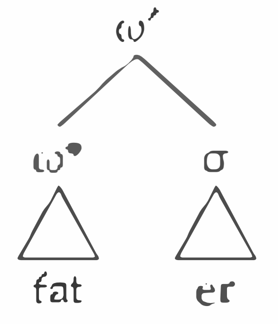
4 Cyclicity *vs.* prosody

In §2 we assumed that the morphosyntactic conditioning effects displayed by post-nasal plosive deletion and Belfast dentalization were procedural, not representational (see §1). However, several scholars have proposed that the behavior of English word-level suffixes should be explained prosodically, rather than cyclically (e.g. Szpyra 1989: 178–200; Hammond 1999: 322–329). In this approach, suffixes like agentive *-er* and adjectival *-ish* are not incorporated into the prosodic word containing the stem, but attach under a second projection of ω (CHAPTER 51: THE PHONOLOGICAL WORD):

(14) a.



b.



If this were true, then the absence of dentalization in Belfast *fatt-er* ['fatɚ], cf. *['fat̪ɚ] (§2), could be described as a case of transparent non-application, rather than as an instance of opaque underapplication: one would just need to stipulate that dentalization does not apply unless its conditions are met within the first projection of ω.

(15) $\begin{bmatrix} \text{coronal} \\ -\text{continuant} \end{bmatrix} \rightarrow$ [+distributed] / $_{\omega^*}$[. . . __ (ə)ɹ . . .]

The uncertainty whether a particular instance of morphosyntactic conditioning in phonology should be analyzed procedurally or representationally is in fact one of the most serious and recurrent obstacles faced by empirical research into the morphosyntax–phonology interface. A great deal of existing work fails to make the cut on explicit, consistent, and principled grounds (Raffelsiefen 2005: 214–215). Typically, the question cannot be settled without analyzing a very substantial fragment of the phonology of the language in question, including both morphosyntax–phonology and phonology–phonetics interactions (e.g. Bermúdez-Otero and Luís 2009).

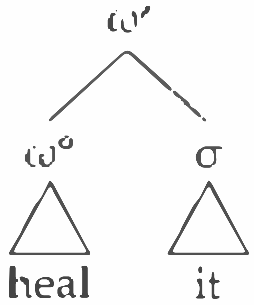
In our case, phonological variation and phonetic gradience in English provide strong evidence against the prosodifications shown in (14). Let us first consider variation. Hayes (2000: 98) shows that, in American English, the application frequency of /l/-darkening (CHAPTER 31: LATERAL CONSONANTS) follows the cline in (16):

(16) higher frequency of [ɫ] lower frequency of [ɫ]

heal ‖	>	*heal it*	>	*heal-ing*	>	*Healey*

On the basis of a comprehensive survey of English function words, however, Selkirk (1996: 204–206) shows that combinations of a verb and a weak object pronoun like *heal it* undergo affixal cliticization (CHAPTER 84: CLITICS):

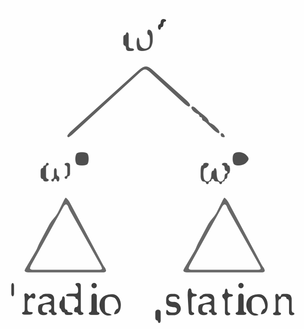
(17)



Therefore, if one adopts the approach to English word-level suffixes shown in (14), *heal-ing* will end up being prosodified in the same way as *heal it*, and so prosody will be unable to explain the fact that /l/-darkening applies with greater frequency in the latter than in the former. One would then have to fall back on a procedural (cyclic) explanation: see §9.

The argument from variable /l/-darkening suggests that the prosodification shown in (14) is descriptively insufficient (though cf. Raffelsiefen 2005: 253–256); the evidence of gradient durational effects confirms that it is incorrect. It is a well-known fact that, in English, each of the members of a transparent compound forms a prosodic word by itself:

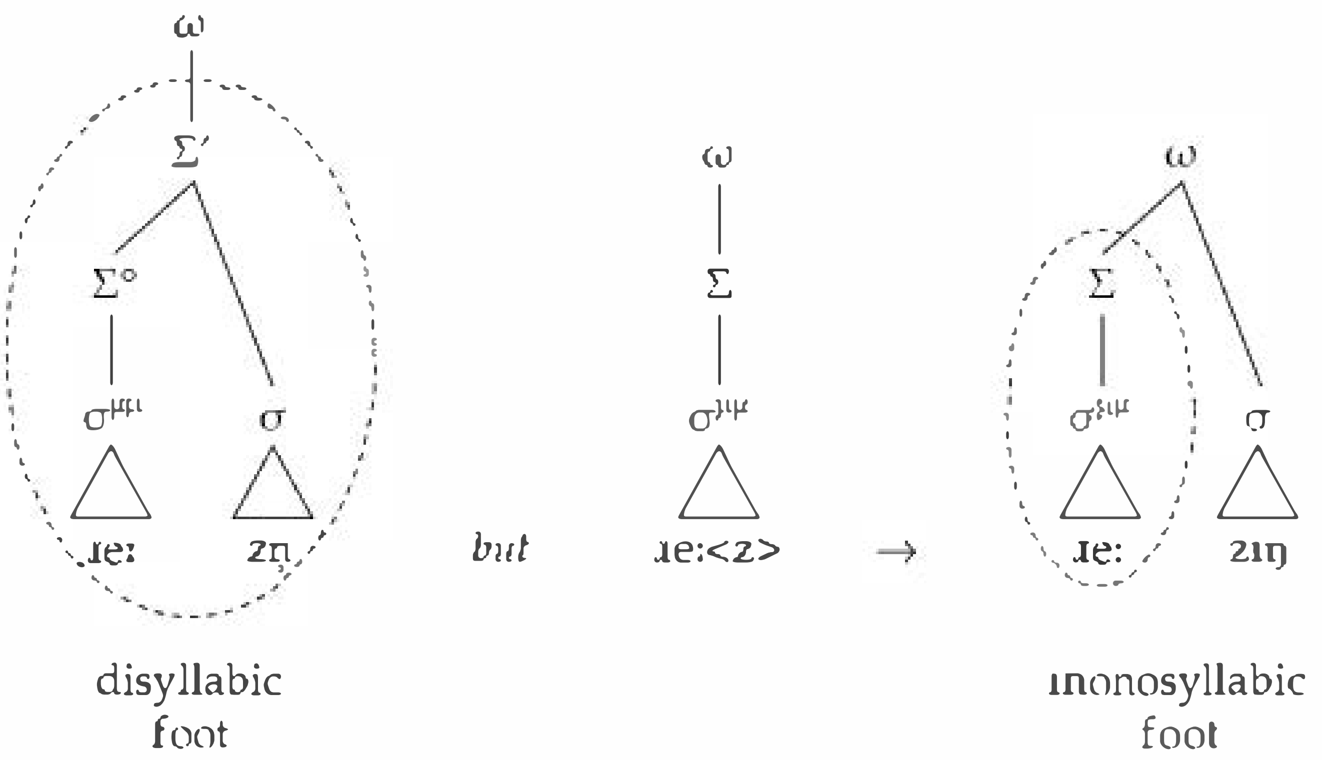
(18)



Given this fact, the approach to word-level suffixes outlined in (14) predicts that stems in word-level suffixal constructions will display the same patterns of gradient durational adjustment (resistance to polysyllabic shortening; liability to pre-boundary lengthening) as the first members of transparent compounds, since both occur in the environment $_{\omega'}[\ _{\omega^\bullet}[\ \_\_\ ]\ldots]$. This prediction proves incorrect. In an experiment with nonce words, Sproat and Fujimura (1993) found no durational effects of stem-level suffixation (e.g. ***beel**-ic*) or word-level suffixation (e.g. ***beel**-ing*) when compared with monomorphemic controls (e.g. ***Beel**ik*), whereas the first members of compounds (e.g. ***beel** equator*) were consistently lengthened; see Sproat (1993: 178). A more recent study of Scottish English has detected a very small effect of word-level suffixation: the phonetic realization of the string /ɹeːz/ appears to be slightly shorter in *raisin* ['ɹeːzn̩] than in *rais-ing* ['ɹeːzɪŋ] (Sugahara and Turk 2009). Nonetheless, this effect falls far below that of compounding: it is not statistically significant at "normal" speech rates (Sugahara and Turk 2009: 496); it manifests itself as a 6.6 percent difference (mean of 23 msecs) at "slow" speech rates; and it reaches only 9.6 percent (mean of 42 msecs) at "extra-slow" speech rates. *Pace* Sugahara and Turk (2009: 488), these findings are best understood as an effect of footing, rather than of recursive prosodic-word structure (CHAPTER 40: THE FOOT):[5]

[5] In (19a), Noun Extrametricality (Hayes 1982: 240) is implemented through the exclusion of the final syllable of the noun stem from the first foot projection (Σ•) and through its attachment under a second foot projection (Σ′) (CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY).

(19) a. *raisin* b. *raise* c. *rais-ing*



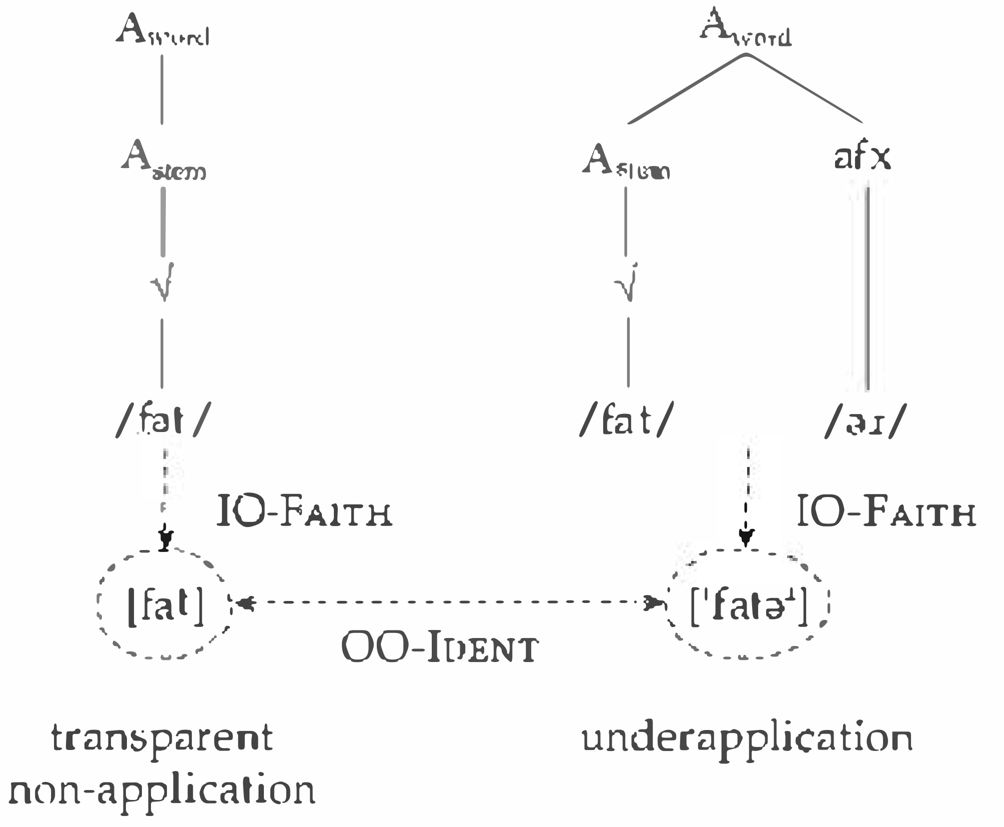
Indeed, the idea that stray syllables affiliated to word-level suffixes attach directly to ω, as in (19c), instead of being footed, makes straightforward sense of the fact that, unless autostressed, word-level suffixes are stress-neutral.

The diagnostics that we have applied so far can be used to demarcate representational morphosyntactic conditioning from procedural morphosyntactic conditioning regardless of one's particular theory of the latter. However, if one commits to a stratal-cyclic analysis of procedural morphosyntactic conditioning, then further demarcation criteria become available. One such criterion is cyclic locality: prosodic structure assigned in an early cycle can persist, and continue to affect the application of phonological processes, throughout later cycles; in contrast, the morphosyntactic structure visible during a phonological cycle ceases to be accessible in the next cycle (by "Bracket Erasure": see e.g. Orgun and Inkelas 2002: 116). Cyclic locality entails, for example, that the contrast between American English ˌ*capi*[ɾ]*a'listic* and ˌ*mili*[t]*a'ristic* must be mediated by prosody, as /t/-flapping is demonstrably phrase-level (see (36b) below) and so cannot access the internal morphological structure of words: see e.g. Davis (2005) and Bermúdez-Otero and McMahon (2006: 403–404); cf. Steriade (2000).

5 Cyclicity *vs.* OO-correspondence

Whilst phonologists generally agree that both representational and procedural morphosyntactic conditioning effects exist, as we saw in §1 and §4, there is currently no consensus on the best way to analyze procedural morphosyntactic conditioning. Within OT, the most popular alternative to the cycle is transderivational correspondence (e.g. Kenstowicz 1996; Benua 1997; Kager 1999; etc.). This theory claims that morphosyntactically induced misapplication arises when high-ranking OO-identity constraints cause a transparently derived surface property of a given expression (the "surface base") to be transmitted to the surface representation of some morphosyntactically related expression, where its presence is opaque. Thus, the underapplication of Belfast dentalization in *fatt-er* ['fatəˑ] (§2) would be analyzed as follows:

(20)



The implementation of this solution poses a number of non-trivial technical challenges, such as motivating the selection of the surface base and preventing the satisfaction of OO-identity by means of overapplication in the base (i.e. transparent /fat-əɹ/ → *['fat̪əɹ] leading to opaque /fat/ → *[fat̪]); I return to these issues in §9 below.

At this point, however, I should like to compare the core predictions of cyclicity and OO-correspondence. The comparison is in fact easy, because the two theories share a fundamental assumption:

(21) *Ultimate transparency*

If a phonological generalization *p* misapplies in the surface representation *s* of some linguistic expression, then *p* must apply transparently in some other representation *r*, with which *s* is in direct or indirect correspondence.

The theory of the cycle predicts that *p* will apply transparently in some cyclic domain defined by some morphosyntactic constituent of the expression: the output of this cycle is connected with the surface representation by relationships of input–output faithfulness. In contrast, OO-correspondence predicts that *p* will apply transparently in the surface representation of some appropriately related linguistic expression; the two surface representations are linked to each other by means of transderivational correspondence. In §6 to §8 I adduce empirical evidence supporting the first prediction and challenging the second.

6 Phonologically masked bases I: Quito Spanish /s/-voicing

Spanish has a voiceless alveolar fricative phoneme /s/. In the dialect spoken in Quito (Robinson 1979; Lipski 1989), /s/ is realized faithfully in the onset (22a), but displays contextual laryngeal allophony in the coda: coda /s/ surfaces as [s] before voiceless segments and utterance-finally (22b), and becomes [z] when followed by a voiced segment either in the same grammatical word or across a word boundary (22c).

(22)	a.	*gasa*	/gasa/	[ˈga.sa]	'gauze'
		ganso	/gaNso/	[ˈgan.so]	'gander'
		da sueño	/da sueɲo/	[ˌd̪a.ˈswe.ɲo]	'makes one sleepy'
		el sueño	/el sueɲo/	[el.ˈswe.ɲo]	'the dream'
	b.	*rasco*	/rasko/	[ˈras.ko]	'I scratch'
		gas caro	/gas kaɾo/	[ˌgas.ˈka.ɾo]	'expensive gas'
		gas ‖	/gas/	[gas ‖]	'gas'
	c.	*rasgo*	/rasgo/	[ˈraz.ɰo]	'feature'
		plasma	/plasma/	[ˈplaz.ma]	'plasma'
		gas blanco	/gas blaNko/	[ˌgaz.ˈβ̞laŋ.ko]	'white gas'
		gas noble	/gas noble/	[ˌgaz.ˈno.β̞le]	'noble gas'

Coda /s/ undergoes voicing not only before voiced obstruents, but also before sonorants: e.g. *plasma* [ˈplaz.ma], *gas noble* [ˌgaz.ˈno.β̞le]. For our purposes, the crucial fact is that voicing overapplies to word-final prevocalic /s/:

(23)	a.		*gas acre*	/gas akɾe/	[ˌga.ˈza.kɾe]	'acrid gas'
		cf.	*gasa*	/gasa/	[ˈga.sa]	'gauze'
	b.		*has ido*	/as ido/	[a.ˈzi.ð̞o]	'hast gone'
		cf.	*ha sido*	/a sido/	[a.ˈsi.ð̞o]	'hath been'

On the surface, expressions like *gas acre* [ˌga.ˈza.kre] fail to meet the conditions for /s/-voicing: in *gas acre*, [z] surfaces in a pre-sonorant environment, but not in the coda, for Spanish has a phrase-level process of resyllabification that moves word-final prevocalic consonants into the onset.[6] In this position, therefore, the transparent realization of /s/ would be voiceless: cf. *gasa* [ˈga.sa].

In a stratal-cyclic framework, the laryngeal allophony of Quito Spanish /s/ submits to the following analysis. First, the stem-level phonology allows output [s], but forbids output [z]: in an optimality-theoretic implementation, therefore, a hypothetical underlying /z/ present in the rich base would be unfaithfully mapped onto [s] in the stem-level output (see Bermúdez-Otero 2007c for an illustration of this strategy). At the word level, in turn, [s] remains unchanged if syllabified in the onset; in the coda, however, [s] loses its laryngeal node, becoming laryngeally unspecified [S]: see (24a). Finally, at the phrase level, input [s] is realized faithfully, whereas delaryngealized [S] acquires voice specifications either by leftward autosegmental spreading from an immediately following obstruent or by default: on the assumption that sonorants are not redundantly specified as [+voice] (CHAPTER 8: SONORANTS), we can just say that [S] becomes voiced before sonorants in order to satisfy a positional constraint designating [+voice] as the unmarked feature in this particular context, whereas utterance-final [S] is assigned the context-free default specification [−voice];

[6] This is confirmed, *inter alia*, by the fact that [ɾ] undergoes optional emphatic trilling in canonical coda positions, but not word-finally before a vowel (Harris 1983: 70–71): e.g. [maɾ] ~ [mar] 'sea', [ˌmaɾ.ˈne.ɰɾo] ~ [ˌmar.ˈne.ɰɾo] 'Black Sea'; but [ˌma.ɾe.ˈxe.o] 'Aegean Sea', not *[ˌma.re.ˈxe.o].

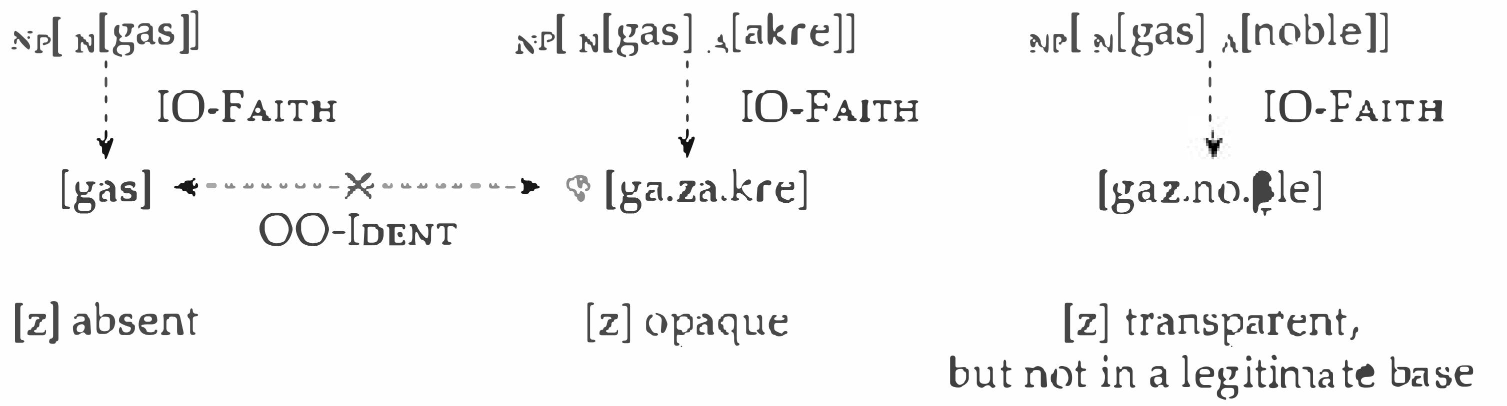
see (24b).[7] In this analysis, underlying /s/ becomes vulnerable to voicing if it finds itself in the coda in a word-level cycle and so loses its laryngeal node; the generalization is rendered opaque by phrase-level resyllabification.[8]

(24)

		$_{PL}$[$_{WL}$[gasa]]	$_{PL}$[$_{WL}$[gas] $_{WL}$[akre]]	$_{PL}$[$_{WL}$[gas]]
a.	WL (coda delaryngealization)	[ga.sa]	[gaS] [a.kre]	[gaS]
b.	PL (defaults)	[ga.sa]	[ga.za.kre]	[gas]

As stated, the facts of Quito Spanish /s/-voicing pose a challenge to OO-correspondence (Colina 2006). This theory can explain the opaque voicing of onset /s/ in *gas acre* [ˌga.ˈza.kre] only by reference to a surface base containing a transparently voiced correspondent [z] in the coda. Many such expressions are found: e.g. *gas blanco* [ˌgaz.ˈβ̞laŋ.ko], *gas noble* [ˌgaz.ˈno.β̞le]. The problem, however, is that none of them bears a non-arbitrary morphosyntactic relationship to *gas acre* [ˌga.ˈza.kre], and so none can straightforwardly qualify as its base. If surface bases are selected by the containment criterion (Benua 1997: 28–29; Kager 1999: 215ff.), the only plausible option is the citation form *gas* [gas], which consists of a subset of the morphs of *gas acre*; but this exhibits [s]. In contrast, *gas noble* [ˌgaz.ˈno.βle], which contains the desired [z], has no better claim to being the base of *gas acre* than, say, *gas caro* [ˌgas.ˈka.ɾo], again showing [s]. Within inflectional paradigms, some versions of OO-correspondence allow surface bases to be designated by arbitrary stipulation (e.g. Kenstowicz 1996: 387, 391), but this option is of no avail here, since expressions like *gas*, *gas acre*, and *gas noble* do not belong in an inflectional paradigm; see the discussion of surface base selection in CHAPTER 83: PARADIGMS.

(25)



[7] Analyzing the pre-sonorant voicing of [S] as driven by a position-sensitive default (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION; CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS), rather than by feature spreading from a following sonorant redundantly specified as [+voice], allows for a closer fit between this categorical phonological operation and the gradient phonetic processes of passive voicing on which it is grounded and from which it diachronically emerges (see below): passive voicing in environments such as that occupied by the /s/ in *plasma* involves lengthening of the voicing tail from the preceding vowel, rather than anticipation of glottal pulsing for the following sonorant (Jansen 2004).

[8] This cyclic derivation accords partly with Mascaró's (1987) reduction-and-spreading model of laryngeal phenomena, though cf. note 7. Bermúdez-Otero (2007c: §31–§34) proposes a similar account for the voicing of word-final prevocalic sibilants in Catalan (cf. Wheeler 2005: 162–164). See also Rubach (1996: 72, 82–85) on the alleged voicing of all word-final obstruents before sonorants (including vowels) in Cracow Polish, but cf. Strycharczuk (2010).

However, Colina (2009: 8–10) shows that OO-correspondence can avoid this problem by shifting part of the burden of description onto the phonetics. Colina suggests that, in Quito Spanish, delaryngealized coda [S] does not acquire categorical voice specifications during the phonological derivation either by autosegmental spreading or by default feature insertion; she claims, rather, that expressions like *gas acre* and *gas noble* merely display the effects of gradient passive voicing in phonetic implementation (Keating 1988). If Colina is right, then the surface phonological representation of *gas acre* is [ˌga.ˈSa.kɾe], with over-application of delaryngealization in the onset; but this can be analyzed without difficulty as involving OO-correspondence with the citation form *ga*[S]: cf. (25) and (26).

(26) $_{NP}$[$_{N}$[gas]] $\qquad$ $_{NP}$[$_{N}$[gas] $_{A}$[akɾe]]

$\qquad$ IO-FAITH $\qquad\qquad$ IO-FAITH

$\qquad$ [gaS] ←-------------→ ☞ [ga.Sa.kɾe]

$\qquad\qquad$ OO-IDENT

Is Colina's re-analysis correct? This question cannot be settled on a priori grounds: in particular, the fact that the environment for /s/-voicing in *gas acre* straddles a word boundary does not by itself warrant the conclusion that the process must be gradient rather than categorical (CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). Electropalatographic studies have admittedly shown that many instances of assimilatory external sandhi involve gradient co-articulation (i.e. reduction, overlap, and blending of articulatory gestures), rather than categorical assimilation (i.e. delinking and spreading of discrete phonological features): see e.g. Barry (1985), Wright and Kerswill (1989), Nolan (1992), Hardcastle (1995), and Zsiga (1995). However, there is also compelling evidence for the existence of categorical external sandhi. Holst and Nolan (1995) and Nolan *et al.* (1996) argue persuasively that at least some instances of /s#ʃ/ → [ʃː] sandhi in British English do involve discrete feature delinking and spreading; the likelihood of categorical assimilation increases in the absence of the major prosodic boundary associated with a break between clauses. Ladd and Scobbie (2003) report that, in Sardinian, total anticipatory assimilation between singletons across word boundaries yields long consonants that are phonetically equivalent to underlying geminates (CHAPTER 37: GEMINATES). Ellis and Hardcastle (2002) examined inter- and intra-speaker variation in fast-speech /n#k/ sandhi in British English, and found no fewer than four different idiolectal strategies (CHAPTER 92: VARIABILITY): (i) absence of accommodation between the two segments (in two out of ten subjects); (ii) gradient co-articulation (in two out of ten subjects); (iii) categorical assimilation (in four out of ten subjects); (iv) variation between categorical assimilation and absence of accommodation, with avoidance of co-articulation (in two out of ten subjects). Crucially, type (iv) speakers did not produce residual coronal gestures, but realized the nasal either without any tongue-tip raising at all or with full mid-sagittal linguo-alveolar closure; this behavior is inconsistent with gradient gestural reduction, but reflects the variable application of discrete feature delinking and spreading across word boundaries. Kochetov and Pouplier's (2008: 414) Korean subjects exhibited the same behavior in /t#p/ and /t#k/ sandhi. These findings clearly indicate that a process of external sandhi may apply gradiently for a speaker in some tokens, and still be categorical for other speakers, or for the same speaker in other tokens. It is therefore unsafe to relegate external sandhi to the phonetics without further argument.

Although instrumental evidence is lacking, Robinson (1979) and Lipski (1989) provide strong indirect evidence that, in many instances, word-final prevocalic /s/ does undergo categorical voicing in Quito Spanish. First, the process applies regularly in all registers independently of speech rate: it "may be frequently observed even in slow, disconnected or interrupted speech" (Lipski 1989: 53–54). Secondly, native speakers of the dialect rely on the difference between [s] and [z] to discriminate between minimal pairs like (23b): *ha sido* [a.'si.ð̞o] 'hath been' *vs.* *has ido* [a.'zi.ð̞o] 'hast gone' (Robinson 1979: 136, 140–141; Lipski 1989: 55). Thirdly, word-final /s/ voicing can be used as a turn-holding device before hesitation pauses (Robinson 1979: 141). Robinson records the following example, where he describes the realization of the /s/ of *es* as "strongly voiced":

(27) *es . . . tres . . .*
[ezːː ˈᵊtresː]
'it's . . . uh . . . three . . .' (Robinson 1979: 141)

It appears that the speaker intentionally produced a sandhi form of *es* to signal the fact that he or she had not reached the end of the utterance. Lipski (1989: 54) adduces further cases. For these reasons, Bradley and Delforge (2006: 39) conclude that the voicing of word-final prevocalic /s/ in Quito Spanish "reflects a phonological [+voice] specification," as opposed to "gradient interpolation of glottal activity through the constriction period of phonetically targetless [S]." This conclusion is incompatible with Colina's (2009) answer to the questions that Quito Spanish /s/-voicing raises for OO-correspondence.

The cyclic derivations proposed in (24) can moreover be seen as the synchronic outcome of a simple series of commonplace diachronic innovations (§3). We may assume that, in an initial round of phonologization and stabilization, the lack of robust phonetic cues for laryngeal features in codas was reinterpreted as phrase-level coda delaryngealization. Analogical change then caused this process of coda delaryngealization to percolate up to the word level. Finally, a second round of phonologization and stabilization caused the gradient passive voicing of delaryngealized sibilants in pre-sonorant contexts to be re-analyzed as a categorical phrase-level process of context-specific default feature insertion.

7 Phonologically masked bases II: English linking and intrusive *r*

Quito Spanish /s/-voicing is not an isolated case: it is not unusual for word-final prevocalic consonants to exhibit properties that are opaque in prevocalic position, but which nonetheless fail to match those of utterance-final consonants in citation forms. Linking and intrusive *r* in non-rhotic dialects of English provides another instance of this phenomenon. Again, a stratal-cyclic approach to the morphosyntax–phonology interface can easily deal with the facts, whereas OO-correspondence must shift some of the descriptive burden to a different component of the grammar: in this case, the theory of representations.

Most non-rhotic dialects of English (Wells 1982: 75–76, 218ff.) allow [ɹ] in onset positions, such as word-initially or word-medially before a stressed or unstressed vowel (28a),[9] but forbid [ɹ] in coda positions, such as word-medially or word-finally before a consonant or pause (28b). This is formalized as (28c).

(28) a. *rack* [ɹæk]
raccoon [ɹə.ˈkʰuːn]
carouse [kʰə.ˈɹaːʊz]
caramel [ˈkʰæ.ɹə.ˌmɛɫ]
b. *cart* [kʰɑːt] *[kʰɑːɹt]
car ‖ [kʰɑː‖] *[kʰɑːɹ‖]
the car came]ðə.ˌkʰɑː.ˈkʰeːɪm] *[ðə.ˌkʰɑːɹ.ˈkʰeːɪm]
c. *CODA[ɹ]
*Coda
|
ɹ

Crucially, most non-rhotic dialects tolerate [ɹ] word-finally before a vowel, whether the consonant was present etymologically ("linking *r*") or not ("intrusive *r*").

(29) a. *the car is new* [ðə.ˌkʰɑː.ɹ̞ɪz.ˈnjuː] linking *r*
b. *the spa is new* [ðə.ˌspɑː.ɹ̞ɪz.ˈnjuː] intrusive *r*

The fact that linking and intrusive *r* escapes the phonotactic ban in (28c) indicates that it surfaces in the onset (CHAPTER 55: ONSETS). In English, however, word-final prevocalic *r* (including linking and intrusive *r* in non-rhotic dialects) exhibits lenition in comparison with canonical onset *r*; the transcriptions above reflected this phenomenon by distinguishing between unlenited [ɹ] in (28a) and lenited [ɹ̞] in (29). Compared with word-initial [ɹ], word-final prevocalic [ɹ̞] displays the following properties: (i) shorter duration (Cruttenden 2001: 289; Tuinman *et al.* 2007: 1905–1906); (ii) earlier timing of the tongue-root gesture (Campbell *et al.* 2010: 62); (iii) smaller magnitude of the lip gesture (Wells 1990; Campbell *et al.* 2010: 63–64); (iv) smaller magnitude of the tongue-tip gesture (Gick 1999: 47–49; Campbell *et al.* 2010: 63–64); (v) greater magnitude of the tongue-root gesture (Campbell *et al.* 2010: 63–64); (vi) greater intensity (McCarthy 1993: 179; Tuinman *et al.* 2007: 1905–1906); and (vii) higher F3 (Hay and Maclagan 2010). Thus dialects with intrusive *r* afford minimal pairs such as the following (McCarthy 1993: 179):

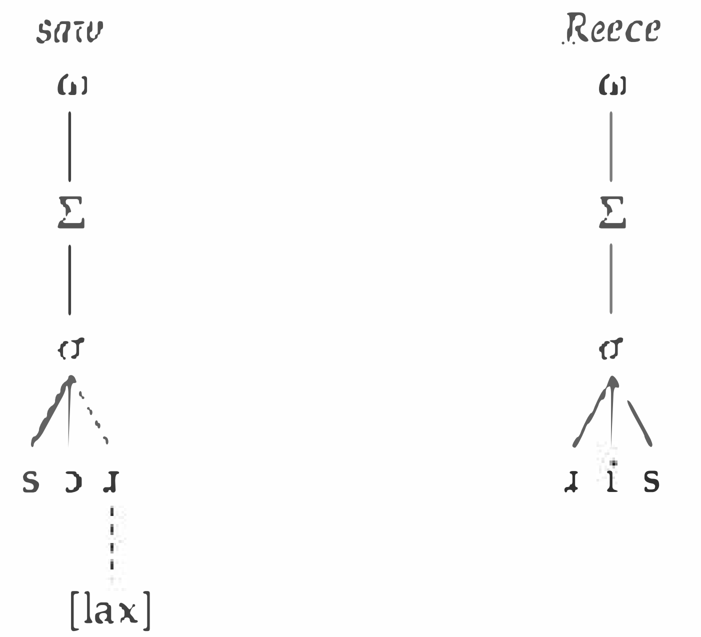
(30) a. *saw eels* [sɔː.ɹ̞iːɫz]
b. *saw reels* [sɔː.ɹiːɫz]

If, as I have suggested, linking and intrusive [ɹ̞] escapes the phonotactic restriction in (28c) because it surfaces in onset position, just like word-initial [ɹ], then the reasons why the former undergoes lenition and the latter does not are not apparent on the surface: thus *r*-lenition overapplies (CHAPTER 74: RULE ORDERING).

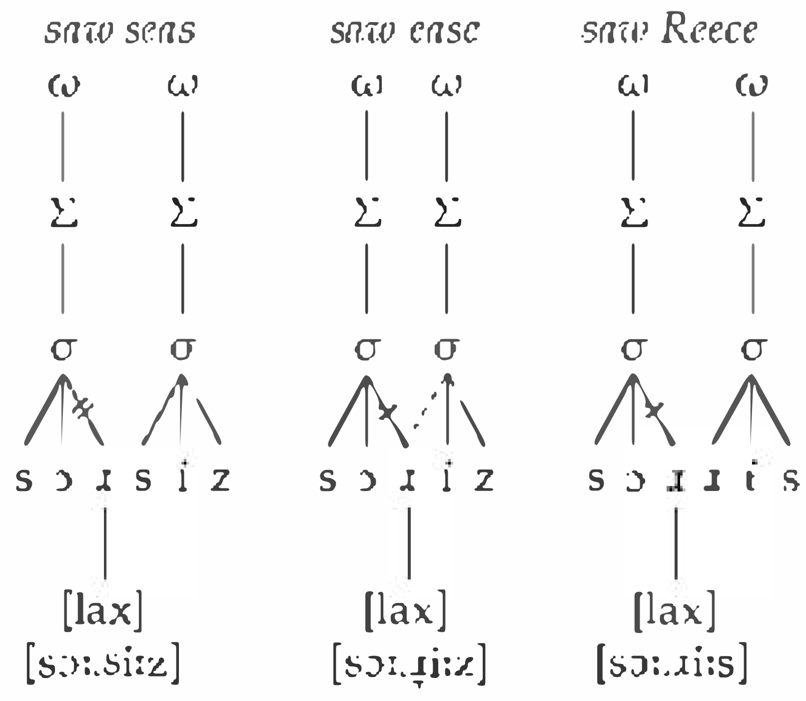
[9] Harris (2006) reports that in some Southern US dialects [ɹ] is banned outside foot-initial onsets: e.g. *ˈve~~r~~y, ˈshe~~r~~iff, ˌCa~~r~~oˈlina*.

However, this opaque pattern is easy to describe in stratal-cyclic terms (Kiparsky 1979: 437ff.; McCarthy 1991: 203–204). Intrusive *r* is inserted at the word level after ω-final non-high vowels in order to satisfy the constraint FINALC, i.e. *V]ω (McCarthy 1991: 203, 1993: 176), which outranks *CODA[ɹ] at the word level.[10] In the same cycle, the inserted *r* is targeted by coda lenition and undergoes a corresponding featural change: it acquires the feature [lax], say. At the phrase level, however, the relative ranking of FINALC and *CODA[ɹ] is reversed: in consequence, word-final *r* undergoes deletion in preconsonantal and prepausal environments, but in prevocalic position it escapes into the onset, carrying with it the feature [lax].

(31) a. *Word level:* FINALC >> *CODA[ɹ]



b. *Phrase level:* *CODA[ɹ] >> FINALC



10 The idea that *r*-intrusion is driven by FINALC receives independent support from the absence of intrusive *r* after reduced function words (which do not project an ω-node) in the non-rhotic dialect of Eastern Massachusetts (McCarthy 1991: 200ff., 1993: 173ff.). In the case of words ending with high vowels or closing diphthongs, we assume that *r*-intrusion is blocked by the final offglide, which suffices to satisfy FINALC; alternatively, FINALC can be replaced with *V$_{[-high]}$]$_{\omega}$. If *r*-intrusion applies ω-finally, then stem-level applications may be needed to generate forms like *draw*[ɹ]-*ing*, as word-level suffixes like -*ing* are incorporated into the prosodic word of the stem, and not adjoined: i.e. $_{\omega}$[*draw*] → $_{\omega}$[*drawing*], not $_{\omega}$[*draw*] → *$_{wd}$[$_{\omega}$[*draw*]*ing*]; see §4 above. If so, we may assume that listed allomorphy pre-empts stem-level *r*-intrusion in cases like *algebr*[ə] ~ *algebr*[eɪ]*ic* (McCarthy 1991: 196).

As in the case of Quito Spanish /s/-voicing (§6), this synchronic system can easily be understood as the product of a straightforward series of ordinary phonological changes:

(32)	level	processes	*manner*	*manner is*	*Anna*	*Anna is*
a.	*Initial stage*					
	WL		[mæ.nəɹ]	[mæ.nəɹ][ɪz]	[æ.nə]	[æ.nə][ɪz]
	PL		[mæ.nəɹ]	[mæ.nə.ɹɪz]	[æ.nə]	[æ.nə.ɪz]
b.	*Phonologization and stabilization (I): Lenition of* [ɹ] *in codas enters the phrase level*					
	WL		[mæ.nəɹ]	[mæ.nəɹ][ɪz]	[æ.nə]	[æ.nə][ɪz]
	PL	lenition	[mæ.nəɹ̞]	[mæ.nə.ɹɪz]	[æ.nə]	[æ.nə.ɪz]
c.	*Analogical input restructuring (I): Lenition of* [ɹ] *in codas climbs up to the word level*					
	WL	lenition	[mæ.nəɹ̞]	[mæ.nəɹ̞][ɪz]	[æ.nə]	[æ.nə][ɪz]
	PL	lenition (vacuous)	[mæ.nəɹ̞]	[mæ.nə.ɹ̞ɪz]	[æ.nə]	[æ.nə.ɪz]
d.	*Phonologization and stabilization (II): Deletion of* [ɹ̞] *in codas enters the phrase level*					
	WL	lenition	[mæ.nəɹ̞]	[mæ.nəɹ̞][ɪz]	[æ.nə]	[æ.nə][ɪz]
	PL	deletion	[mæ.nə]	[mæ.nə.ɹ̞ɪz]	[æ.nə]	[æ.nə.ɪz]
e.	*Analogical input restructuring (II): Analogical extension of word-level final* [ɹ̞]					
	WL	insertion, lenition	[mæ.nəɹ̞]	[mæ.nəɹ̞][ɪz]	[æ.nəɹ̞]	[æ.nəɹ̞][ɪz]
	PL	deletion	[mæ.nə]	[mæ.nə.ɹ̞ɪz]	[æ.nə]	[æ.nə.ɹ̞ɪz]

The path for (32e) was smoothed by a general process of schwa apocope (CHAPTER 26: SCHWA) in Middle English (Minkova 1991). As a result of this, Early Modern English had relatively few words like *Anna*, with an underlying final /ə/. Thus, the rise of phrase-level *r*-deletion in codas brought about a situation in which most tokens of preconsonantal or prepausal [ə] alternated with prevocalic [əɹ̞]. In these circumstances, learners re-analyzed phrase-level representations like [æ.nə||] as derived by *r*-deletion from word-level [æ.nəɹ̞].[11]

(33) WL [mæ.nəɹ̞] [æ.nəɹ̞]

PL [mæ.nə||] [mæ.nə.ɹ̞ɪz] → [æ.nə||] [æ.nə.ɹ̞ɪz]

In turn, this analogical extension of final [ɹ̞] across word-level outputs eventually resulted in a word-level ban of ω-final [ə], enforced where necessary by [ɹ̞]-insertion.

This stratal-cyclic account of the diachronic rise and synchronic operation of *r*-intrusion avoids many of the pitfalls incurred by its best-known competitors. Rule-inversion scenarios resulting in a phrase-level hiatus-breaking rule of [ɹ]-epenthesis in onsets (e.g. Vennemann 1972: 216; McMahon 2000: ch. 6; Bermúdez-Otero and Hogg 2003: 99ff.) do not account for the lenited realization of intrusive *r* (CHAPTER 66: LENITION). In turn, restructuring scenarios in which /ə/ is replaced

[11] In this view, the analogical extension of final [ɹ̞] across word-level outputs can only have begun after variable *r*-deletion entered the phrase level, but it may well have been in progress before the application rate of *r*-deletion approached 100 percent (see Hay and Sudbury 2005).

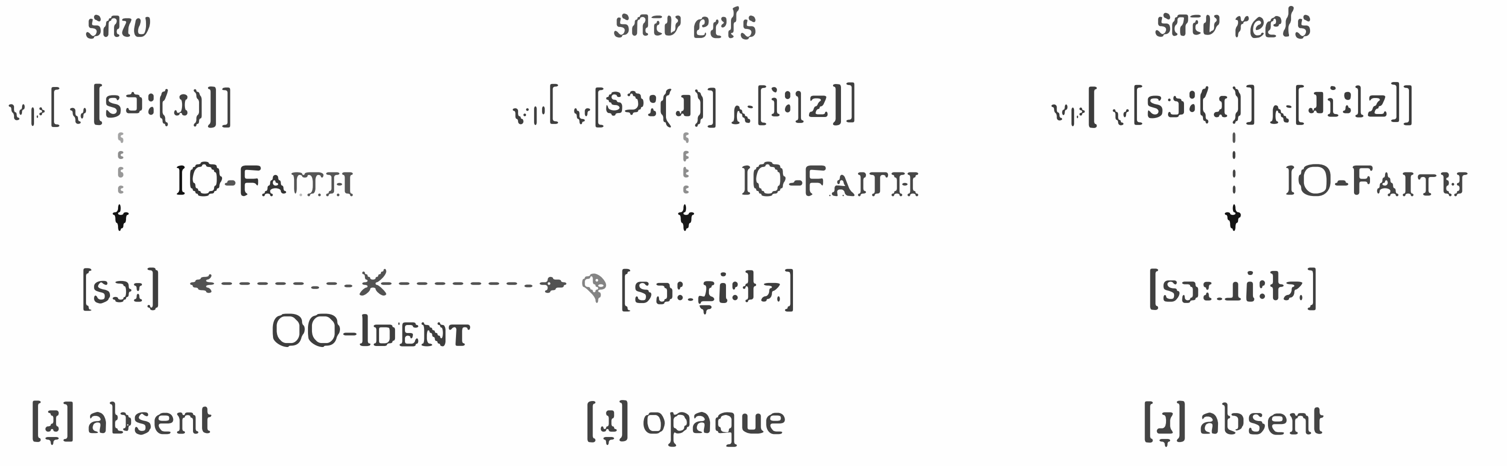
by /əɹ/ in underlying representations (e.g. Donegan 1993) fail to account for the regular and productive nature of *r*-intrusion (see the references in Heselwood 2009: 86). A regular process of [ɹ]-epenthesis in ω-final position at the word level incurs neither problem.

Furthermore, the diachronic scenario outlined in (32) accords perfectly with the normal life cycle of phonological processes (§3). Both *r*-lenition ([ɹ] → [ɹ̞]) and *r*-deletion ([ɹ̞] → Ø) first entered the categorical phonology from below, as phrase-level processes applying across the board ((32b) and (32d)). The analogical change causing lenition to climb up from the phrase to the word level (32c) proceeds by input restructuring: the lenited [ɹ̞] in surface $_{PL}$[mæ.nəɹ̞] is re-analyzed as present in the output of the word level.[12] Moreover, *r*-lenition entered the grammar earlier than *r*-deletion (as must be the case, since the former is a precondition for the latter), and so has been exposed to analogical pressures for longer: it is therefore unsurprising that *r*-lenition should be more advanced in its life cycle than *r*-deletion, the former having reached the word level, the latter remaining at the phrase level.

In this light, the synchronic markedness reversal illustrated in (31) can be seen as arising from a clash between disparate diachronic forces: the high ranking of *Coda[ɹ] at the phrase level reflects the phonologization of phonetic effects; in contrast, the high ranking of FinalC at the word level reflects the analogical restructuring of phrase-level inputs. If so, McCarthy's (1993: 181–182) complaint of arbitrariness against his own previous stratal analysis (McCarthy 1991: 203–204) arguably betrays a failure to strike a proper balance between synchronic and diachronic explanation (cf. Bermúdez-Otero 1999: 98–107).

If this account is correct, then English linking and intrusive *r* raises difficulties for OO-correspondence. The segment's lenited realization is opaque because there is no *r*-lenition in onsets. To explain the facts, OO-correspondence would need to find a surface base in which [ɹ̞] occurred transparently, i.e. in the coda. Yet this is impossible, as the defining property of non-rhotic dialects is precisely that they do not allow *r* to surface outside the onset.

(34)

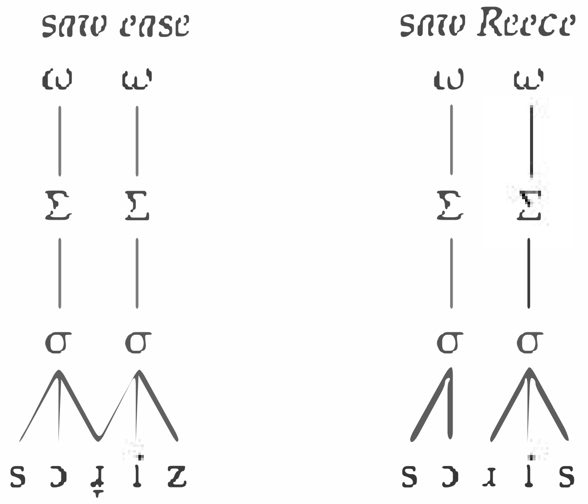


Yet, as in the case of Quito Spanish /s/-voicing, the proponents of OO-correspondence may deflect this argument by putting forward a transparent analysis of linking and intrusive [ɹ̞]. McCarthy (1993: 178–181) does so by invoking ambisyllabicity (Kahn 1976). In this approach, linking and intrusive [ɹ̞] is

12 This progression from lower to higher levels correctly predicts that, diachronically, word-internal *r*-intrusion, as in *draw-ing* (see note 10), starts later than *r*-intrusion at word boundaries, as in *draw in* (see Hay and Sudbury 2005: 816–818, 820).

permitted to surface because it has an onset attachment, but it is lenited because it has a link to the coda too: cf. (31b) and (35).

(35)



In this sense, ambisyllabicity enables McCarthy (1993: 178–181) to conflate two stages of a cyclic derivation into a single representation – at the cost of adopting a less restrictive theory of syllable structure.

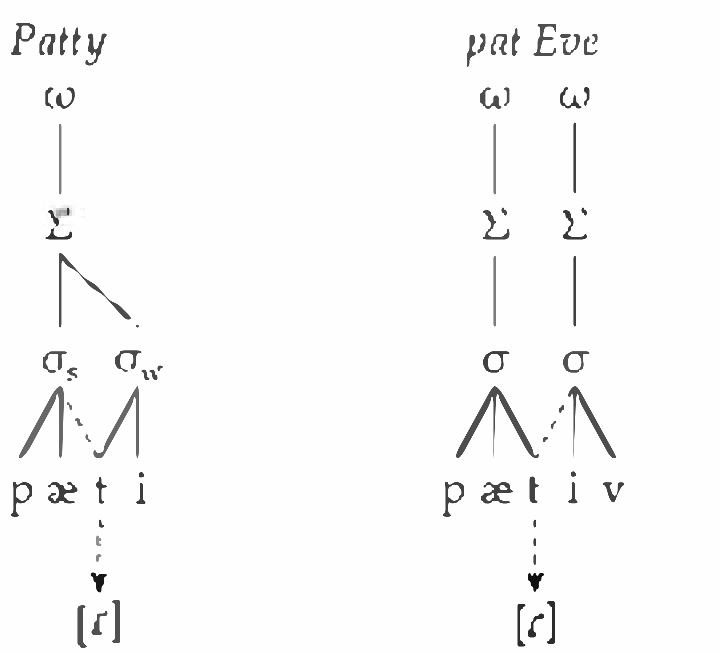
However, ambisyllabicity incurs problems of its own, and has been argued to provide an inconsistent account of English segmental allophony (e.g. Kiparsky 1979: 437ff.; Jensen 2000; Harris 2003). Bermúdez-Otero (2007a: §14–§24) notes two ambisyllabicity paradoxes. Since Kahn (1976), the standard diagnostic for ambisyllabification in English has been /t/-flapping. In most North American dialects, /t/ undergoes flapping in two environments: foot-medially between a vowel or /ɹ/ and another vowel (36a), and word-finally between a vowel or /ɹ/ and another vowel (36b).

(36) a. $_{\Sigma}[\ldots \begin{Bmatrix} \text{V} \\ \text{ɹ} \end{Bmatrix} \_\_ \text{V} \ldots]$ e.g. [ɾ] in *Patty, party, parity*

b. $\begin{Bmatrix} \text{V} \\ \text{ɹ} \end{Bmatrix} \_\_]_{\text{GWord}}\ \text{V}$ e.g. [ɾ] in *pat it, pat Eve, at it, at ease*

Since the segmental conditions in these two environments are exactly identical, formulating two separate rules of flapping would miss a generalization. Accordingly, Kahn proposed that the two environments could be unified prosodically: in (36a) /t/ becomes ambisyllabic by Coda Capture, and in (37b) /t/ becomes ambisyllabic by Onset Capture.

(37) a. *Coda Capture* b. *Onset Capture*



Thus Kahn's strategy was to use syllabification to channel the allophonic effects of both stress and word boundaries. Yet this solution does not generalize to other English consonants. Consider, for example, /l/-darkening in the Midwestern American dialect studied by Sproat and Fujimura (1993). This dialect exhibits Kahn's canonical pattern of /t/-flapping. By implication, /l/ too should display the same allophone, either clear [l] or dark [ɫ], in foot-medial intervocalic position (e.g. *Bee/l/ik*) and in word-final intervocalic position (e.g. *Bee/l/ equates*): /l/ should be ambisyllabic in the former by Coda Capture and in the latter by Onset Capture. As Sproat and Fujimura (1993: 308) themselves note in passing, however, this prediction proves false: X-ray microbeam cinematography revealed that their subjects produced clear [l], with the coronal gesture phased before the dorsal gesture, in *Bee/l/ik*, whereas they produced dark [ɫ], with the dorsal gesture phased before the coronal gesture, in *Bee/l/ equates*.

(38)	*form*	*/l/ allegedly ambisyllabic by . . .*	*/l/ allophone*	*the coronal gesture . . .*
	Beelik	Coda Capture	clear [l]	leads
	Beel equates	Onset Capture	dark [ɫ]	lags

In this dialect, therefore, Kahn's ambisyllabification rules work for /t/, but not for /l/. This is Bermúdez-Otero's (2007a) first ambisyllabicity paradox. A second paradox arises from a conflict between /t/-flapping and pre-fortis clipping (Bermúdez-Otero 2007a: §21–§24), and Kiparsky (1979: 440) observes a third paradox, further discussed by Nespor and Vogel (1986: 93–94). By casting doubt on the existence of ambisyllabicity, these paradoxes challenge McCarthy's (1993) transparent re-analysis of linking and intrusive *r* in (35).

In contrast, the English dialect described by Sproat and Fujimura poses no difficulties for a stratal-cyclic model with onset-maximal stem-level syllabification and resyllabification of prevocalic consonants in word-level and phrase-level cycles (Bermúdez-Otero 2007a: §18–§20). The right results follow from the operation of two word-level processes: one laxes /t/ in non-foot-initial position (Kiparsky 1979: 437ff.; Jensen 2000; Harris 2003); the other darkens /l/ in the coda. A full typology of English dialects supports the need to allow individual allophonic processes to target either weak positions in the syllable (i.e. the coda) or weak positions in the foot (i.e. in a trochaic system, anywhere outside foot-initial onsets). Notably, an innovative pattern of foot-based /l/-darkening (e.g. *ye[ɫ]ow*, *vi[ɫ]age*) is attested alongside the conservative syllable-based pattern: see Olive *et al.* (1993: 366) and Hayes (2000: 95–96) for American dialects, and Carter and Local (2007) for British dialects.[13]

In sum, English linking and intrusive *r* raises the same problem for OO-correspondence as Quito Spanish /s/-voicing: both are patterns of external sandhi in which word-final prevocalic consonants display opaquely derived properties that are absent from citation forms. In both cases, OO-correspondence declines responsibility for the facts, and shifts the burden of explanation either to phonetic implementation or to the theory of representations.

[13] Similarly, alongside the conservative pattern of syllable-based *r*-deletion in non-rhotic dialects, an innovative foot-based pattern has been detected in the south of the USA: see note 9 above.

8 Non-surfacing bases in non-canonical paradigms: Albanian stress

In the examples of morphosyntactically induced misapplication discussed in §6 and §7, the surface bases required by OO-correspondence are unavailable for phonological reasons: a phonological process applies normally in a non-final cycle C, but the output of C never surfaces transparently, because it is always altered by the operation of subsequent phonological processes in later cycles. However, the output of C may also fail to surface unchanged, for purely morphological reasons. This effect stands out with particular clarity in non-canonical inflectional paradigms, i.e. paradigms exhibiting phenomena such as deponency, defectiveness, suppletion, or heteroclisis (Corbett 2007). In such circumstances, the predictions of cyclicity and OO-correspondence diverge dramatically. Let two words *a* and *b* have identical syntagmatic structures in all relevant respects, but belong to paradigms with different sets of cells: one canonical, the other non-canonical. The theory of the cycle predicts that, in the phonology, *a* and *b* must exhibit the same effects of procedural morphosyntactic conditioning (§1), since the course of cyclic derivations depends on syntagmatic structure alone (Bobaljik 2008: 32; Bailyn and Nevins 2008: 242). In contrast, OO-correspondence predicts the opposite, as transderivational identity effects depend on the availability of surface bases. On the basis of evidence from Albanian, Trommer (2006, 2009) argues that the first prediction is true, the second false. In this section I briefly summarize Trommer's argument, omitting his detailed motivation of the morphological segmentations underpinning the analysis.

Trommer (2004) found that Albanian polysyllabic words bearing no overt inflection display final stress in either of two cases: (i) if the final syllable is headed by a non-mid vowel (i.e. by /i/, /u/, or /a/), as in (39a) and (39b), or (ii) if the final syllable is both headed by a full vowel (i.e. by a vowel other than /ə/) and closed by a consonant, as in (39b) and (39c)). Otherwise, stress falls on the penultima, as in (39d) and (39e).

(39)	a.	[ɟu.hɔ.'si]	'linguistics'
		[a.kə.'ku]	'here and there'
		[ɾi.'ʤa]	'prayer'
	b.	[aɾ.'mik]	'enemy'
		[ʧi.'fut]	'gipsy'
		[ɾe.zul.'tat]	'result'
	c.	[a.'det]	'habit'
		[pa.'tok]	'gander'
	d.	['ho.le]	'swing'
		['ba.bo]	'midwife'
		['hɔ.nɔ]	'moon'
	e.	['a.fəɾ]	'near'

In word-forms containing overt inflectional markers, however, stress assignment often misapplies. Consider, for example, the present indicative of a verb with a canonical paradigm (Table 85.2).

According to Trommer, metrical opacity arises as a consequence of the fact that the domain of stress assignment is the stem, not the word: stress is assigned transparently in stem-level cycles, but is rendered opaque at the word level

Table 85.2 The present indicative of the Albanian verb *formoj* 'form' (NACT denotes 'non-active')

			UR	*SR*	*opaque stress?*
ACT	SG	1	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-j]]	[for.'moj]	no
		2	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-n]]	[for.'mon]	no
		3	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-n]]	[for.'mon]	no
	PL	1	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-j] $_{\text{Affix}}$[mə]]	[for.'moj.mə]	no
		2	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-n] $_{\text{Affix}}$[ni]]	[for.'mo.ni]	yes: *[for.mo.'ni]
		3	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-j] $_{\text{Affix}}$[nə]]	[for.'moj.nə]	no
NACT	SG	1	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-j] $_{\text{Affix}}$[he-m]]	[for.'mo.hem]	yes: *[for.mo.'hem]
		2	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-j] $_{\text{Affix}}$[he-ʃ]]	[for.'mo.heʃ]	yes: *[for.mo.'heʃ]
		3	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-j] $_{\text{Affix}}$[he-t]]	[for.'mo.het]	yes: *[for.mo.'het]
	PL	1	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-j] $_{\text{Affix}}$[he-mi]]	[for.'mo.he.mi]	yes: *[for.mo.he.'mi]
		2	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-j] $_{\text{Affix}}$[he-ni]]	[for.'mo.he.ni]	yes: *[for.mo.he.'ni]
		3	$_{\text{GWord}}$[$_{\text{Stem}}$[formo-j] $_{\text{Affix}}$[he-n]]	[for.'mo.hen]	yes: *[for.mo.'hen]

by the addition of inflectional suffixes and by regular internal sandhi at the stem–suffix juncture.

(40) a. *Internal sandhi processes*
nn → n
j → Ø / __ h

b. *Sample derivations*

	$_{\text{WL}}$[$_{\text{SL}}$[formo-j]]	$_{\text{WL}}$[$_{\text{SL}}$[formo-j] $_{\text{SL}}$[he-m]]
SL (stress assignment)	[for.'moj]	[for.'moj] [hem]
WL (internal sandhi)	—	[for.'mo.hem]
	'form (ACT 1SG)'	'form (NACT 1SG)'

Let us now turn to verbs with non-canonical paradigms. The verb *pendohem* 'regret', for example, exhibits deponency: it lacks a voice alternation, and its fixed lexical meaning is expressed by a series of non-active forms (Table 85.3). Crucially, the absence of non-active forms entails that the location of stress is opaque throughout the present indicative.

This fits with the predictions of cyclicity: since the single series of forms of a deponent verb has the same syntagmatic structure as the non-active series of a canonical verb, both must display the same pattern of metrical opacity; compare (40b) and (41).

(41)

	$_{\text{WL}}$[$_{\text{SL}}$[pendo-j] $_{\text{SL}}$[he-m]]
SL (stress assignment)	[pen.'doj] [hem]
WL (internal sandhi)	[pen.'do.hem]
	'regret (1SG)'

In contrast, OO-correspondence seems unable to account for the misapplication of stress assignment in the present indicative forms of Albanian deponent verbs: there are simply no suitable surface bases with transparent stress.

Table 85.3 The present indicative of the Albanian verb *pendohem* 'regret'

			UR	*SR*	*opaque stress?*
ACT			—	—	—
NACT	SG	1	$_{\text{GWord}}$[$_{\text{Stem}}$[pendo-j] $_{\text{Affix}}$[he-m]]	[pen.'do.hem]	yes: *[pen.do.'hem]
		2	$_{\text{GWord}}$[$_{\text{Stem}}$[pendo-j] $_{\text{Affix}}$[he-ʃ]]	[pen.'do.heʃ]	yes: *[pen.do.'heʃ]
		3	$_{\text{GWord}}$[$_{\text{Stem}}$[pendo-j] $_{\text{Affix}}$[he-t]]	[pen.'do.het]	yes: *[pen.do.'het]

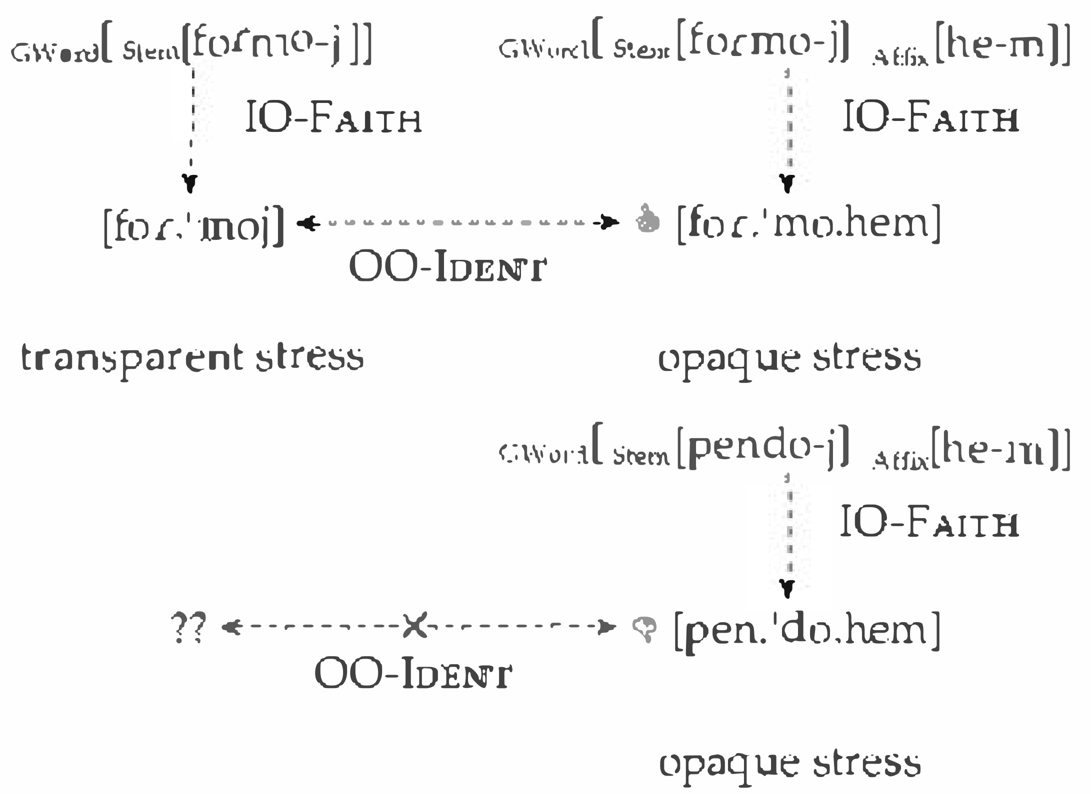
(42) a.

b.



Thus Trommer's analysis suggests that morphologically induced misapplication depends on syntagmatic structure, not on the contents of paradigms.

In the case of Quito Spanish /s/-voicing, the advocates of OO-correspondence shifted the burden of explanation to phonetics (§6); in the case of English linking and intrusive *r*, to the theory of representations (§7). A similar escape maneuver in the case of Albanian stress might conceivably appeal to morphology, e.g. by claiming that stress assignment in Albanian verbs has been partly or wholly morphologized. Whatever the merits of such an argument, OO-correspondence will remain in an anomalous position until enough languages are found in which systematic patterns of morphologically induced phonological misapplication fail to hold in defective, deponent, suppletive, and heteroclitic paradigms.

9 Further challenges to OO-correspondence

The case studies presented in §6–§8 provide the most direct challenge to the theory of OO-correspondence: in all three cases, the necessary surface bases appear to be unavailable. However, transderivational theories face other questions, briefly noted in §5: what expressions can qualify as surface bases, and how are they selected?; should OO-identity be symmetrical, base-prioritizing, or both?

(See CHAPTER 83: PARADIGMS.) Whilst these problems have attracted a great deal of attention in the literature, the fact that OO-correspondence fails to preserve much of the corroborated empirical content of cyclic theory has generally prompted less discussion. One key instance is the Russian Doll Theorem (§3).

For example, (43) reports the incidence of /l/-darkening in three English dialects where the process has not yet become foot-based (i.e. where /l/ remains light in *village*: see §7).[14] From this evidence one can reliably infer a pattern of diachronic evolution instantiating the Russian Doll Theorem: (43) is a perfect match for (12) and (13).

(43)

	RP	Am1	Am2
Healey	l	l	l
heal-ing	l	l	ɫ
heal it	l	ɫ	ɫ
heal	ɫ	ɫ	ɫ
darkening of rhymal /l/ applies at . . .	PL	WL	SL

conservative ⟶ innovative

In a transderivational analysis, however, the inevitability of the Russian Doll pattern disappears. For example, Hayes (2000: 102) proposes two separate OO-identity constraints to capture the facts in (43): Am1 shows an effect of high-ranking OO-IDENT(PHRASAL); Am2 shows effects of both OO-IDENT(PHRASAL) and OO-IDENT(MORPHOLOGICAL).

(44) a. hiːɫ ⇢ hiː.ɫɪt
OO-IDENT(PHRASAL)

b. hiːɫ ⇢ hiː.ɫɪŋ
OO-IDENT(MORPHOLOGICAL)

By factorial typology, however, these two constraints can generate an impossible dialect with [hiːɫ, hiː.ɫɪŋ, hiː.lɪt], in violation of the Russian Doll Theorem. All that is needed is a constraint hierarchy of the following type:

(45) *CODA[l] >> OO-IDENT(MORPHOLOGICAL) >> *[ɫ] >> OO-IDENT(PHRASAL)

To avoid this result, Hayes (2000: 102) resorts to stipulating an innate fixed ranking in Universal Grammar:

(46) OO-IDENT(PHRASAL) >> OO-IDENT(MORPHOLOGICAL)

The explanatory loss is plain to see: whereas (11) was a corollary, (46) is an axiom.

[14] For RP, see Cruttenden (2001: 201). The dialect I have here labeled "Am1" is the one described by Sproat and Fujimura (1993); see §7 above. For "Am2," see Olive *et al.* (1993: 212–215). The implicational relationships implicit in (43) are confirmed by the rates of variation reported by Hayes (2000: 98): see (16) above.

It thus looks as if a great deal of work remains to be done before OO-correspondence can claim to have superseded the cycle.

ACKNOWLEDGMENTS

In this chapter I have drawn on research previously presented at meetings in Groningen, Leipzig, Manchester, Rhodes, Toulouse, and Warsaw; I am grateful to the organizers and audiences on all these occasions for their comments and suggestions. I am also indebted to Sonia Colina, Andrew Nevins, Tobias Scheer, Patrycja Strycharczuk, and Jochen Trommer.

90 Frequency Effects

STEFAN A. FRISCH

1 Introduction

This chapter provides a review of evidence that occurrence frequency has an influence on phonological patterns. The examination of quantitative or statistical patterns in phonology, and grammar more generally, pre-dates the development of modern linguistic theory. For example, Zipf (1965) examined statistical properties of texts and noted a variety of effects that still have relevance in current theoretical discussions, such as the tendency for reduction of high-frequency words. Bolinger (1961) and Herdan (1962) discussed gradience and statistical distribution as a natural middle ground between the grammatical extremes of the acceptable and the unacceptable. However, given the limitations both in the understanding of language structure and in the computational resources for conducting quantitative studies, this type of research did not gain much traction in the field of linguistics more generally. With the availability of lexical and usage corpora now available, and armed with the descriptive and theoretical advances of modern linguistic theory, a variety of authors are now arguing for the influence of frequency on phonological patterns in synchronic phonology and morphophonology, phonological acquisition, and diachronic phonology. In many ways, phonology is the ideal domain in which to study the potential role of frequency effects in grammar (Herdan 1962). The set of basic phonological units (phonemes or features) is relatively limited, these units are routinely combined in a reasonably static set of fixed forms (the lexicon), and productive combinations of these units in morphology are also limited in their variety of combination by that same fixed set of units. Morphophonological changes are triggered by phonological environments defined by features (CHAPTER 17: DISTINCTIVE FEATURES) or phonemes (CHAPTER 11: THE PHONEME) and the results of the changes are within the same set of featural or phonemic varieties.

1.1 *Definition of phonology*

In this chapter, I take phonology to be any aspect of language sound structure that can vary systematically between languages or dialects. This would therefore include most of what might traditionally be called phonetics. In the debate over the phonetics–phonology interface, or lack thereof, it has been shown by the laboratory phonology enterprise over the last 20 years that phonetic patterns often vary systematically between languages (Pierrehumbert *et al.* 2000). Articulatory and co-articulatory patterns are not fully determined by physical limitations, but are instead under some degree of (usually unconscious) control in the individual (e.g. Clumeck 1976; Manuel 1990; Beddor *et al.* 2002). Similarly, phonetic perception is tuned by language experience, and not wholly determined by auditory physiology (e.g. Werker and Tees 1984; Kuhl *et al.* 1992; Best and McRoberts 2003). While expanding the domain of phonology to include physically quantitative phonetic effects also expands the potential domain of variability to be dealt with by phonological analysis, this expansion is a necessary step in developing a complete science of language sound structure. While frequency effects can be demonstrated over purely symbolic phonological patterns, expanding the study of the frequency effects on phonology to include traditionally phonetic dimensions may help to integrate synchronic phonology with sociolinguistic and diachronic studies of language sound structure, where phonetic dimensions are often relevant.

Similarly, this chapter will touch on various aspects of morphophonology, where sound patterns vary systematically in morphologically complex words. Demonstrating frequency effects in this domain supports the argument for frequency effects as part of the theory of grammar regardless of the phonetics/phonology issue. In morphophonology, the data are indisputably grammatical in nature, and some aspect of cognitive computation is required. Frequency effects in morphophonology help to show that frequency effects are not merely a residue of performance, memory, general cognition, or diachrony. To the extent that there is a phonological system distinct from other cognitive structures, a variety of evidence has been gathered in support of the use of quantitative frequency information as part of the operating parameters of grammar.

1.2 Definition of frequency

Frequency is the rate of occurrence of a phonological unit, and is unrelated to acoustic frequency. But there are still many possible frequencies, depending on what is taken to be the domain over which occurrences are counted. In studies of language using corpora of language usage, frequency is usually the frequency of occurrence in the corpus. This type of frequency is referred to as token frequency or usage frequency. In English, for example, the token frequency of the phonemes /ð/ and /v/ is relatively high, due to their presence in frequently used words like *the* and *that*, and *of* and *very*. Token frequency for words affects phonetic reduction and the resistance of lexical or morphophonological forms to diachronic change (e.g. Bybee 2002), as detailed in later sections.

Abstracting away from repeated usages of a word, phonological patterns can also be examined on the basis of the number of times the pattern is used across different words. This frequency is referred to as type frequency or lexical frequency. The type frequency of the phonemes /ð/ and /v/ in English is relatively low, as they are used in relatively few words. An example of a consonant with a high type frequency is /b/, which is the most common word onset in English. Some consonants, such as /s/ and /t/, have both high token frequency and high type frequency, being used in many words, many of which are common. Other consonants, such as /θ/ and particularly /ʒ/, have both low token frequency and low type frequency, as they are used in few words, most of which are not common. A consonant cluster with a high type frequency is /st/, which is found in many different words. The token frequency of /st/ is also high, as many of these words are commonly used. Type frequency has been shown to influence metalinguistic judgments for novel word forms (also known as non-words, e.g. Frisch *et al.* 2000), repetition accuracy for non-words (e.g. Vitevitch 2002), and the propensity for phonological or morphophonological generalization for regular or irregular forms (e.g. Bybee 1995; Pierrehumbert 2001; Albright and Hayes 2003).

A few other variants of frequency have been examined in particular cases. Transitional frequency (or transitional probability) is the frequency of one form following another in sequence. Transitional probability for intersyllabic consonant phoneme sequences has been shown to influence the parsing of non-words as simple or morphophonologically complex by adults (e.g. Hay and Baayen 2002), and repetition accuracy for subsequences within non-words in children (e.g. Munson 2001). Neighborhood density is a commonly used measure of word pattern frequency that combines the concepts of frequency and similarity (see also CHAPTER 87: NEIGHBORHOOD EFFECTS). It is typically measured as the number of words that differ from a target word by a single phoneme substitution or a limited number of phoneme substitutions, insertions or deletions (e.g. Goldinger *et al.* 1989; Frisch *et al.* 2000). High neighborhood density has been shown to inhibit word recognition (presumably through competition for lexical access; see Luce and Pisoni 1998), and to facilitate non-word repetition (presumably through activation of frequently used phoneme sequences; Vitevitch 2002).

Neighborhood density can be seen as a more specific application of the general concept of analogy between phonological words or phonological forms. Like neighborhood density, analogy combines the ideas of frequency of occurrence and similarity. Presumably the influence that a phonological pattern could have via analogy is determined in some way by the frequency of the phonological pattern and the similarity of the pattern to the target context (e.g. Bybee 1995; Davidson 2006; see also CHAPTER 83: PARADIGMS). It is also conceivable that analogy could have an influence at a variety of phonological levels, from the phonetic to the phonemic, syllabic, lexical, or morphophonological. The frequency of a phonological pattern at any of these levels may be different, and there is no reason to assume a priori that only one frequency or only one measure of frequency could be relevant.

It is the goal of this chapter to demonstrate that more than one frequency is relevant to phonology, that different frequencies are relevant to phonology in different ways, and that different levels of phonological generalization are relevant, also potentially in different ways (Bybee 2007). Overall, the theoretical position is that of the "ladder of abstractions," where phonemic categories are generalizations over phonetic patterns, sub-syllabic, and syllabic categories are generalizations over phonemic patterns, lexical and morphophonological categories are generalizations over phonemic, sub-syllabic, and syllabic patterns, and so forth (Pierrehumbert 2003; Beckman and Edwards 2010). Under this view, higher-level phonological categories emerge as systematic generalizations over lower-level categories, where the lowest-level category is physical/articulatory/acoustic experience with language. This experience is parsed into more general, abstract categories as repeated similar experiences occur. Frequency may play a role in supporting these generalizations. Token frequency creates robust, entrenched, well-defined categories through frequent exposure. Type frequency leads to grammatical generalization, as categories occur in a variety of contexts, promoting generalization and parsing of units, presumably for cognitive efficiency (Bybee 2007). Note also that this view includes frequency information as part of the grammar, and not just as a tool that can be used to analyze a lexicon or corpus for phonologically relevant patterns (e.g. as in McCarthy 1994 or Hammond 1999; see the introduction in Bod *et al.* 2003 for discussion).

2 Frequency matching in metalinguistic judgments

Evidence for the relevance of frequency in phonology is found in behavioral experiments in which the frequency or probability of phonological units in stimuli is manipulated or examined, and native-speaker judgments are consulted. It has been found that native speakers are sensitive to phonological frequency in a variety of lexical and morphophonological patterns. In the absence of traditional phonological constraints, it has been shown that baseline phonotactic probability is an influence on well-formedness judgments for novel non-words. This suggests that native speakers have encoded frequency information that is present in language data. Whether this knowledge is properly a part of their grammatical competence, as opposed to extra-linguistic information that is accessed as a part of linguistic performance, is a topic of debate. In connection with data presented in later sections that frequency has an influence over the distribution of possible forms in the language, the influence of frequency on native-speaker performance in metalinguistic experiments has been used to argue that frequency information is part of the knowledge of language sound structure that speakers have, i.e. that frequency effects are psychologically real (Frisch *et al.* 2004; Zuraw 2007).

2.1 *Novel phonotactic combinations*

Frisch *et al.* (2000) presented recordings of novel non-words to naive undergraduate listeners. These non-words were constructed by combining attested onset and rime constituents into multisyllabic non-words with no obvious phonotactic violations. The onset and rime constituents (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE) used were of relatively high or low frequency of occurrence, creating novel non-words that were relatively high or low in cumulative expected probability, but with the frequency of occurrence of any particular onset or rime constituent balanced across the experiment. Example non-words are given in (1).

(1) /sɪʃəp/
/zujɛθʊs/
/sɪrɔsɛnɔn/

Frisch *et al.* (2000) found a significant, but moderate, correlation between cumulative expected probability and native English speaker well-formedness judgments (r ~ 0.4). Well-formedness judgments were collected in two different experiments (CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY). In one experiment, speakers were asked to judge the wordlikeness of the novel non-words on a scale from 1 to 7 (1 = impossible, can't be a word of the English; 2, 3 = unlikely, doesn't sound much like a word of English; 4 = neutral, sounds somewhat like a word of English; 5, 6 = likely, sounds like it could be a word of English; 7 = definitely, sounds just like a word of English). In the other experiment, speakers were asked to judge whether a non-word was acceptable or unacceptable. In both cases, there was evidence for gradient acceptability of the novel non-words as a function of phonotactic probability (CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). For acceptability judgments, gradient acceptability was apparent when judgments of acceptability were aggregated across participants. For very low probability non-words, very few speakers judged them to be acceptable. For very high probability non-words, most speakers judged them to be acceptable. For non-words of intermediate probability, some speakers judged them to be acceptable and some did not. For wordlikeness judgments, where individual participants were able to use a gradient scale to make their judgments, the analysis of individual speaker data found significant correlations with non-word expected probability for most participants. These findings are replicated in Frisch and Brea-Spahn (2010), where the non-words were constructed slightly differently, by random combination of onset and rime constituents (screening out any categorical phonotactic violations that were created by this random process, such as the creation of a geminate across the syllable boundary; CHAPTER 37: GEMINATES).

Bailey and Hahn (2001) presented monosyllabic non-words to British English speakers in two experiments, one orthographic and the other auditory. Their non-words were selected to differ from real English words by either one or two phonemes (e.g. *drump* and *drolf*) but otherwise violated no categorical phonotactic constraints. Participants rated the novel items on a 1 to 9 wordlikeness scale. Bailey and Hahn (2001) examined a variety of predictors for judgments, focusing on probabilistic phonotactics and lexical neighborhood density. They found that each factor provided an independent influence, and thus they argued that both direct lexical information and abstract probabilistic phonotactic information are used in the wordlikeness judgment task. Frisch *et al.* (2000), in a post hoc examination of their polysyllabic non-word data, found somewhat similar results. While polysyllabic words generally have fewer lexical neighbors, the highest probability non-words did show some evidence for lexical neighborhood effects. However, a recent study by Shademan (2006) failed to replicate the lexical neighborhood effects of Bailey and Hahn (2001). Given that phonotactic probability and lexical neighborhood density are confounded with one another, it is perhaps not surprising that it has been difficult to differentiate the two and demonstrate clear influences of both in metalinguistic experiments.

Frisch *et al.* (2000) was a replication of a study by Coleman and Pierrehumbert (1997). However, the Coleman and Pierrehumbert (1997) study was less systematic in its construction of non-words, and also included non-words with phonotactic violations in onset consonant clusters. They used an acceptability judgment task, and examined aggregate acceptability across the participants in the study. Coleman and Pierrehumbert (1997) found a similar correlation between non-word expected probability and acceptability. They also found that non-words with phonotactic violations were judged as more or less acceptable depending on the frequency of the other (non-violating) constituents in the word. In other words, high frequency elsewhere in a novel non-word could mediate the detriment to well-formedness caused by a phonotactic violation. The findings of Coleman and Pierrehumbert (1997) are compatible with models of phonological grammar that use a cumulative or aggregate well-formedness in evaluating the output of the grammar, but they are difficult to capture in a model of grammar where only grammatical violations or only the greatest grammatical violation is relevant to the output.

Albright (2009) also examined well-formedness judgments for monosyllabic English non-words containing a variety of phonotactically legal and illegal sequences, with variation in frequency of the phonotactically legal sequences. Albright used a model based on transitional probability between natural classes (feature groupings; CHAPTER 17: DISTINCTIVE FEATURES) in an attempt to create a more linguistically grounded model that might extend frequency patterns in attested sequences to linguistically related unattested sequences. The goal of the model was to differentiate unattested onset clusters like /bw bn bz/ that have been shown to vary in their wordlikeness (CHAPTER 55: ONSETS). While the Albright model was successful, he also found that the transitional frequencies between natural class generalizations and the transitional frequencies between segments each contribute to predicting participant judgments, and do not overlap completely. This suggests that multiple levels of generalization may be relevant to participant performance in well-formedness judgment tasks.

Frisch and Stearns (2006) examined onset consonant clusters, presenting a variety of CC initial monosyllabic non-words auditorily to participants (cf. similar non-words presented to child participants by Scholes 1966, reported in Albright 2009). The stimuli included attested English onset clusters with varying frequency, and a few unattested clusters that might be expected to occur in English but do not, based on relatively simple phonological categorization (/sr tl dl θl/). For the attested clusters, cluster frequency was a significant predictor of well-formedness judgments. Judgments of the unattested clusters were surprisingly high, however, and some follow-up investigation has suggested that these clusters were frequently misperceived (e.g. /tl/ heard as /pl/). When orthographic supports were provided (in an unpublished replication study), well-formedness judgments for the non-attested clusters were lower, though not necessarily very different from low-frequency attested clusters such as /gw sf dw/, which might be thought of as less consistent with the overall grammar of consonant clusters in English (Hammond 1999).

2.2 *Frequency matching in morphophonology*

It has also been shown that phonological frequency influences participant behavior in metalinguistic tasks that more directly reflect linguistic productivity. For example, Ernestus and Baayen (2003) presented novel verbs to Dutch speakers and asked them to produce past-tense forms. Dutch is one of many languages with a process of word-final devoicing. Dutch verbs contain a variety of examples where stem-final obstruents alternate, as in (2) (see also CHAPTER 80: MERGERS AND NEUTRALIZATION).

(2) /vɛrʋɛit/ 'widen (3SG PRES)'
/vɛrʋɛidən/ 'widen (INF)'

There are also examples where stem-final consonants do not alternate. The standard phonological analysis is that the stem-final consonant may be voiced or voiceless, with neutralization to the voiceless consonant when the stem-final consonant is word-final (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL

NEUTRALIZATION). Ernestus and Baayen (2003) analyzed the Dutch lexicon and found that cases of alternation are not equally distributed across different natural classes of consonants. For example, stops have a very low rate of alternation, while fricatives have a higher rate of alternation. The rate of alternation also depends on place of articulation (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION). In an experiment, Ernestus and Baayen (2003) presented participants auditorily with a variety of novel verbs with potentially neutralized stem-final consonants (i.e. stimuli with voiceless final consonants), and asked participants to supply an alternative form where the underlying consonant is no longer in a neutralizing context (in this case, the past tense, which is spelled either *te* or *de* depending on the voicing of the underlying consonant). An analysis of responses found variation in the frequency with which participants guessed that the stem-final consonant had been underlyingly voiced or voiceless. The frequency distribution of responses matched the frequency distribution of alternation in the lexicon. In particular, even for consonants with a relatively low frequency of alternation, participants still occasionally guessed that there was alternation, rather than uniformly choosing the most likely result, which would be no alternation. Ernestus and Baayen (2003) attribute these frequency effects to the influence of groups of related lexical items, as in a lexical neighborhood effect.

Similar results are found in the case of Hungarian vowel harmony (with the most extensive analysis involving back vowel harmony patterns in the lexicon) and in experimental behavior (Ringen and Vago 1998; Siptár and Törkenczy 2000; Hayes and Londe 2006; Hayes *et al.* 2009; see also CHAPTER 123: HUNGARIAN VOWEL HARMONY). Hungarian back vowel harmony is sensitive to roundness for front vowels and proximity between the vowel trigger and the suffix. When a stem-final vowel is front rounded, the dative suffix takes a front vowel. When the stem-final vowel is back, the dative suffix takes a back vowel. When the stem-final vowel is front unrounded, some variation is found, depending on vowels earlier in the word. Cases where all vowels in the stem are front unrounded, or where there is a back vowel earlier in the word, can result in either back (3a) or front suffixes (3b), or in synchronic variation between these (3c) (examples from the web corpus study of Hayes and Londe 2006).

(3) a. /pɔlleːr-nɔk/ 'foreman-DAT'
 b. /mutɔgeːn-nɛk/ 'mutagen-DAT'
 c. /ɔrzeːn-nɔk/ /ɔrzeːn-nɛk/ 'arsenic-DAT'

The frequency of back vowel harmony is influenced by proximity of the triggering back vowel to the suffix. With one intervening front unrounded vowel, harmony is fairly common. With two intervening front unrounded vowels, harmony is fairly uncommon. The height of the intervening front unrounded vowel is also a factor, with /i/ more likely to be transparent (facilitating back harmony) and /e/ less likely to be transparent (blocking back harmony). Hayes and Londe (2006) found frequency matching by Hungarian participants in a pencil-and-paper experiment in which participants were asked to generate dative forms for novel Hungarian-like nouns by filling in blanks in a paragraph. This finding was replicated and extended by Hayes *et al.* (2009) in an experiment conducted via the Internet. In Hayes *et al.* (2009), frequency matching was demonstrated not only for the influences of trigger and potentially transparent vowels, but also less robustly for generalizations involving place and manner of intervening consonants and consonant clusters. Hayes *et al.* (2009) describe these as unnatural constraints, as there is no clear phonological connection between the consonant features involved and vowel backness, and suggest that there may be a bias against the learning of unnatural phonological constraints. Alternatively, the influence of these unnatural groupings may merely reflect the influence of lexical neighborhoods of related words.

Overall frequency matching was also found in a study by Zuraw (2007), in which the marginally productive process of nasal substitution in Tagalog was used in a two-part experiment. Tagalog speakers were asked to generate novel derived forms, as in Ernestus and Baayen (2003), and subsequently asked to judge the well-formedness of derived variants on a ten-point scale. A novel example from Zuraw (2007) is shown in (4).

(4) /bugnat/ 'to *bugnat*'
/mambubugnat/ '*bugnat*-er' (no nasal substitution)
/mamumugnat/ '*bugnat*-er' (nasal substitution)

Nasal substitution in Tagalog is found to varying degrees across the lexicon, and is influenced by the voicing and place of articulation of the consonant (CHAPTER 78: NASAL HARMONY). Zuraw (2007) found that speakers' use of nasal substitution and their judgments of substituted forms were influenced by voicing, but she did not find a significant effect of place of articulation. In addition, she found that the use of nasal substitution in novel forms was overall less frequent than its appearance in the lexicon, indicating that the participants in her study had a bias for the regular (non-substituted) form.

In summary, metalinguistic experiments have shown that speaker judgments of novel phonological forms can be influenced by the relative frequency of sub-syllabic constituents within the non-word, as well as by lexical patterns in the application of phonological processes. These data suggest that speakers have encoded frequency information within a variety of static phonotactic constituents as well as within the targets, results, and contexts of phonological and morphophonological processes. In other words, these data suggest that speakers have statistical knowledge of language sound structure at a variety of levels.

3 Frequency in phonotactics: OCP-Place

The previous section showed examples of the influence of phonological frequency on native speaker performance in phonological experiments. Quantitative patterns such as these have become a point of interest in the development of theories of grammar and grammar acquisition. In this section, elementary concepts are introduced, in conjunction with the application of these concepts to consonant co-occurrence data. These data have been a driving force in the development of quantitative theories of phonology.

3.1 *Base phonotactic frequency*

It has long been known that phonemes do not all occur with equal frequency (e.g. Zipf 1965; CHAPTER 11: THE PHONEME). Availability of electronic corpora in recent years has made analyzing the frequency distributions of phonemes easier, leading to comprehensive studies of a large number of languages and statistical distributions (e.g. Martindale *et al.* 1996; Tambovtsev and Martindale 2007), with substantiation of the claim that frequency differences between phonemes influence phonological processing.

Given that base phoneme frequencies may vary, the study of phonological combinations requires that these base frequency differences be taken into account (Pierrehumbert 1993, 1994). This approach was taken in a groundbreaking study by Greenberg (1950), in which the statistical combination of consonants in Arabic verbal roots was examined. Greenberg noted several series of consonants that tended not to co-occur with one another within a single root, primarily based on place of articulation. These generalizations were formalized by McCarthy (1994), using the more general Obligatory Contour Principle (OCP) applied to place of articulation features. In its simplest form, this constraint bans the co-occurrence of consonants within a root that share a place of articulation feature. It was also noted that the frequency of co-occurrence varied between places of articulation; that this variation was sensitive to manner features; and that distance between co-occurring consonants was relevant as well (Pierrehumbert 1993; McCarthy 1994; Padgett 1995). However, in a root lexicon modeling study, Frisch *et al.* (2004) found that a significant portion of consonant co-occurrence frequency across the lexicon could be predicted from base phoneme frequency alone (see also CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS).

3.2 *Phonotactic constraints and co-occurrence frequency*

In the statistical analysis of phonotactic co-occurrence, researchers typically attempt to determine whether some combination is significantly statistically underrepresented, indicating a constraint against co-occurrence (e.g. Greenberg 1950; McCarthy 1994). Presumably, statistical overrepresentation could also be found, indicating a preference for certain phonotactic combinations, such as in the co-occurrence of nasal consonants with homorganic stops in clusters. Alternatively, the rate of co-occurrence between related classes of consonants can be examined for a significant statistical variance, indicating a difference in the strength of application of a constraint between two co-occurrence classes (e.g. Frisch *et al.* 2004). These statistical approaches all use the notion that the observed frequency of a combination should be equal to the expected frequency of co-occurrence by chance (assuming independent combination of the individual units, such as phonemes, onsets, rimes, or syllables).

As a simple example, consider the following hypothetical table (see Table 90.1) of aggregated consonant co-occurrence data. The style of this example follows Wilson and Obdeyn (2009), and is similar to actual data in several studies (Padgett 1995; Frisch *et al.* 2004; Coetzee and Pater 2008). This could represent the data on consonant co-occurrence from a sample of 500 words that begin with CVC from a language, where the consonant co-occurrences have been aggregated within place of articulation classes to look for OCP-Place effects (cf. the examination of co-occurrence in 500 Italian verbs in Frisch *et al.* 2004). In this table, the number of CVC pairs with each place of articulation combination is given, and the row and column marginal totals show the base frequency of occurrence of consonants in C1 (right-hand column) or C2 (bottom row) position.

Table 90.1 Hypothetical co-occurrence data for place of articulation classes in 500 words (following Wilson and Obdeyn 2009)

	[labial]	[coronal]	[dorsal]	Mar C1
[labial]	12	83	33	128
[coronal]	104	44	70	218
[dorsal]	54	91	9	154
Mar C2	170	218	112	500

If consonants co-occurred randomly in these data, we would expect the place of articulation combinations to be evenly distributed across the different combination groups. In other words, the expected probability of combination would be equal to the marginal probability of C1 multiplied by the marginal probability of C2. The marginal probability of C1 or C2 is the ratio of the frequency of occurrence of the consonant divided by the total number of occurrences. These calculations are summarized in the following equation:

(5) $$Expected(C_1,C_2) = p(C_1) \times p(C_2) = \frac{obs(C_1)}{total(C_1)} \times \frac{obs(C_2)}{total(C_2)}$$

For the case of the [labial]–[labial] combination, for example:

(6) $$Expected([labial],[labial]) = \frac{170}{500} \times \frac{128}{500} = 0.08704$$

In a lexicon of 500 items, $0.08704 \times 500 = 43.5$ occurrences are expected. Performing this calculation for all combinations gives the following table (Table 90.2) of expected consonant co-occurrence, given random combination of C1 and C2. It's important to note that, in this view, the marginal probabilities for C1 and C2 are taken as a starting point for examining the combinations of C1 and C2.

Pierrehumbert (1993) attempted to simplify the inspection of statistical co-occurrence data such as these. She used the ratio of the observed (O) co-occurrence *vs.* the expected (E) co-occurrence to provide a single number that summarized the relative under- or overrepresentation of combinations compared to chance.

Table 90.2 Expected frequency of co-occurrence for hypothetical data in Table 90.1

	[labial]	[coronal]	[dorsal]	Mar C1
[labial]	43.5	55.8	28.7	128.0
[coronal]	74.1	95.0	48.8	218.0
[dorsal]	52.4	67.1	34.5	154.0
Mar C2	170.0	218.0	112.0	500.0

Table 90.3 Observed over expected (O/E) ratio for hypothetical data in Table 90.1

	[labial]	[coronal]	[dorsal]
[labial]	0.28	1.49	1.15
[coronal]	1.40	0.46	1.43
[dorsal]	1.03	1.36	0.26

Examining these ratios, the hypothetical data show a statistical pattern of low co-occurrence, O/E ratio less than 1, for combinations at the same place of articulation. This would be taken as evidence for the operation of a constraint against co-occurrence for homorganic consonants (i.e. OCP-Place). For co-occurrence for different places of articulation the O/E ratio is greater than 1, meaning co-occurrence is at or above the level expected by chance. This would be taken as evidence that there is no constraint against co-occurrence for consonants at different places of articulation.

Since McCarthy (1994), data such as these have been used not only to argue for the presence of a co-occurrence constraint for natural classes of phonemes, but also that there can be different degrees of constraint, or gradience, in phonotactic constraints. Quantitative differences in the frequency of occurrence of combinations (or in O/E ratios) have been used to argue that some combinations may occur, but are more or less restricted than others. In the case of OCP-Place, quantitative differences have been used to argue for stronger constraints for a variety of consonant combinations: a stronger constraint for identical consonant combinations in comparison to homorganic, but not identical, consonants (McCarthy 1994); a stronger constraint for consonants that are closer together within the root or word (Pierrehumbert 1993; Buckley 1997; Berkley 2000); a stronger constraint for consonants that share manner features or are more similar in general (McCarthy 1994; Padgett 1995; Frisch *et al.* 2004; Coetzee and Pater 2008).

As grammatical models of frequency effects have become more sophisticated, it has been suggested that quantitative O/E data for phonotactic combinations should be treated with caution. Wilson and Obdeyn (2009) demonstrate that differences in O/E such as those in Table 90.3 may arise due to a combination of constraints, without necessarily indicating a difference in the strength of a constraint. First, note that in the hypothetical data there are differences in the marginal probabilities for the different consonant places of articulation, as is common in natural data. The [coronal] class is overall more frequent both as C1 and as C2 in comparison to the [labial] and [dorsal] classes (CHAPTER 12: CORONALS). In the MaxEnt grammar model Wilson and Obdeyn (2009) use, discussed later in this section, these differences in marginal probability arise from constraints on individual consonant classes. These constraints would then interact with OCP-Place constraints for combinations of consonants.

Table 90.4 shows a set of hypothetical constraint weights for this general type of interaction model, based on the hypothetical data. The hypothetical constraint weights are given as fractions in order to more transparently reveal their impact on the frequency of occurrence of features and feature combinations, and so are

Table 90.4 Hypothetical constraint weights for a simplified interactive model of consonant phonotactics

	[labial]	[coronal]	[dorsal]	Mar C1
[labial]	0.25	1	1	0.256
[coronal]	1	0.25	1	0.436
[dorsal]	1	1	0.25	0.308
Mar C2	0.340	0.436	0.224	

not identical to the weights for a MaxEnt model of these data. These weights are most similar to the quantitative constraint values used in the Frisch *et al.* (2004) stochastic constraint model. In a MaxEnt model, the constraint weights would be inversely related to frequency and the connection from a particular weight value to frequency is less transparent. In this table, the marginal values are constraint weights for individual place of articulation features in C1 or C2 position (based directly on the marginal probabilities for simplicity of exposition), and the combination weights represent a uniform OCP-Place effect across different places of articulation. A 0.25 weight on combinations of the same feature is used in this example, providing a strong but not categorical restriction on co-occurrence. A weight of 1 is assigned to combinations for different features, suggesting these pairs are unrestricted.

From these constraint weights, it can be shown that differences in the cumulative weight for place combinations can result as a combination of the weights for marginal probabilities and the uniform OCP-Place weight for all combinations. For example, for [labial]–[labial] combinations:

(7) Weight(C1 [labial]) × Weight(C2 [labial]) × Weight(C1 [labial] & C2 [labial]) $= 0.256 \times 0.340 \times 0.25 = 0.02176$

But for [coronal]–[coronal] combinations:

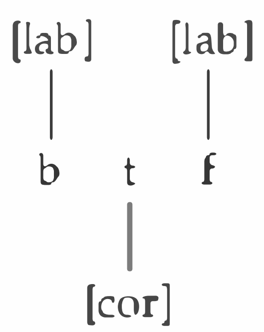
(8) Weight(C1 [coronal]) × Weight(C2 [coronal]) × Weight(C1 [coronal] & C2 [coronal]) $= 0.436 \times 0.436 \times 0.25 = 0.04752$

The ratio of the cumulative constraint weights is approximately 1 to 2, which roughly corresponds to the ratio of O/E for [labial]–[labial] *vs.* [coronal]–[coronal] combinations. Thus the same degree of direct constraint on consonant combination, interacting with positional constraints for differences in marginal consonant frequencies, produces differences in the cumulative constraint for combinations. In the Wilson and Obdeyn (2009) approach, the base phonotactic frequencies for consonant occurrence are modeled as part of the grammar, rather than taken as a starting point from which to model phonotactic combination.

3.3 *Quantitative OCP-Place effects*

A fruitful domain for the examination of frequency as a relevant dimension for phonological constraints has been the study of long-distance constraints on consonant combination, originally characterized for Arabic as an application of the Obligatory Contour Principle to place of articulation classes (McCarthy 1994). McCarthy (1988) first observed that the occurrence of Arabic verbal roots with identical consonants was restricted to forms of the type *sdd*, where C2 and C3 are identical. This pattern was analyzed using the formalism of autosegmental phonology as involving spreading from the C2 to C3 position in a root with only two consonants, e.g. *sd*, in order to fill three consonant positions in a template (CHAPTER 105: TIER SEGREGATION; CHAPTER 108: SEMITIC TEMPLATES). This analysis of the asymmetry in appearance of identical consonants in the Arabic verbal roots more or less still stands. McCarthy (1994) observed that the co-occurrence series originally presented by Greenberg (1950) could also be analyzed as an application of the OCP to place of articulation features where place of articulation features are located on distinct autosegmental tiers in feature geometry (CHAPTER 27: THE ORGANIZATION OF FEATURES). One advantage of this analysis was the ability to capture co-occurrence constraints between C1 and C3 in a three-consonant root, where the middle consonant would be invisible to the application of the constraint, due to the segregation of place features onto distinct tiers, as in (9). In this approach, two distinct OCP constraints are active in the Arabic roots, in order to prevent roots with identical C1–C2, and also to restrict roots with homorganic consonants in any position.

(9)



Frisch *et al.* (2004) argue that some type of gradient analysis of OCP-Place effects is necessary, as any set of categorical constraints on co-occurrence will either have an unacceptably large number of exceptions or fail to explain an unacceptably large number of non-occurrences. They constructed a variety of categorical OCP-Place models, based on excluding consonant pairs with different degrees of specificity of feature combination, and then counted the number of consonant pairs that occurred despite being restricted (exceptions) or did not occur relative to the expected frequency of occurrence for non-homorganic pairs (unexplained underrepresentation). Their data are presented in Table 90.5. The "enumerated pairs" model excludes only the consonant pairs that occur with zero frequency, which cannot be defined by a natural class. Previous models proposed a variety of feature combinations like the ones in this table, but cannot explain why

Table 90.5 Failure of categorical models of OCP-Place to capture exceptions or eliminate gradiently restricted pairs

Definition of classes	*Exceptions*	*Unexplained underrepresentation*
Place only	816	0
Place & [son]	123	160.8
Place & [son] & [cont]	36	312.7
Enumerated pairs	0	430.5

restricted pairs occur with such high frequency, or why unrestricted pairs occur with such low frequency, relative to the expected frequency of occurrence.

Quantitative OCP-Place type effects have been demonstrated for several languages: Arabic, Maltese, Italian, Thai (Frisch *et al.* 2004); Muna (Coetzee and Pater 2008); Shona, Wargamay (Wilson and Obdeyn 2009); Javanese (Mester 1986); Tigrinya (Buckley 1997); Russian (Padgett 1995); English, French, Latin (Berkley 2000). In all of these cases, featural similarity appears to play a role. Perhaps more importantly, there is yet to be an instance where a language is analyzed quantitatively and gradient OCP-Place effects are not found. Consonant place-based co-occurrence restrictions have been discussed for an even larger set of languages, though these have not been analyzed quantitatively from a similarity perspective (see Yip 1989, Frisch *et al.* 2004, Coetzee and Pater 2008 for references). Analogous constraints have also been investigated for laryngeal features (Steriade 1982; Itô and Mester 1986; MacEachern 1999), but these also have not yet been studied quantitatively.

3.4 *Subsidiary features and underspecification*

An interesting wrinkle to the OCP-Place constraint data for Arabic is that the constraint apparently applies more strongly within some places of articulation than others. In Arabic, for the labial, dorsal, and guttural places of articulation, co-occurrence within these places of articulation is virtually non-existent (with a few exceptions, depending exactly on how the classes are defined). Within the coronal place of articulation, however, co-occurrence can be quite frequent, particularly between obstruents and sonorants, and less so for obstruents differing on continuant, as suggested by Table 90.5. Table 90.6 shows the Arabic coronal

Table 90.6 Co-occurrence for coronal consonants in the lexicon of Arabic triconsonantal roots (totals include combinations with non-coronal consonants, which are not listed in the table)

	C2/C3

total	117	243	151	83	61	55	200	123	100	29	141	365	497	226	

co-occurrence data for individual coronal consonants in C1–C2 or C2–C3 position, from Frisch *et al.* (2004). In Table 90.6, cells showing no co-occurrence are primarily clustered near the diagonal, where identical or nearly identical consonant pairs are found.

Theoretical accounts of the OCP-Place constraint have used the difference between coronal consonants and other consonants to argue for place of articulation-specific constraints on coronals. Davis (1991), examining co-occurrence data from English, claimed that coronal place of articulation involves underspecification, with [coronal] not present in the feature representation, and so not subject to the OCP. For Arabic, there are clearly restrictions on coronals evident in Table 90.6, and so an absolute restricted/unrestricted distinction cannot be maintained on the basis of place of articulation. Quantitative accounts of place differences in the strength of OCP-Place constraints vary in their method of accounting for these differences, as detailed in the next two sections.

3.5 Similarity and OCP-Place

Pierrehumbert (1993) attempted to unify the two distinct OCP constraints, and also to capture differences in the frequency of occurrence of distinct consonant combinations at different places of articulation. She proposed that consonant combinations are restricted on the basis of their perceived similarity, where perceived similarity is influenced by two factors. One factor is the featural similarity of the consonants involved. Identical consonants would be maximally similar. Homorganic consonants that also share manner features would be highly similar. Homorganic consonants that do not share manner features would be less similar. The second factor influencing perceived similarity is distance. By her hypothesis, the similarity of consonants that are closer together in the root (C1–C2 or C2–C3) is more easily perceived than the similarity of consonants that are further apart (C1–C3). Pierrehumbert (1993) argues that perceived similarity corresponds to the frequency of co-occurrence of consonant combination, providing a unified account of variation in the strength of OCP-Place effects for different consonant combinations (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). Pierrehumbert (1993) also extended the perceived similarity account to include the influence of contrastiveness on similarity using contrastive underspecification. In this approach, places of articulation with a relatively large number of contrasts (e.g. Arabic coronals) will have relatively more features influencing similarity in comparison to places of articulation with a relatively small number of contrasts (e.g. Arabic labials). In other words, the size of the inventory at a particular place of articulation would predict how weak or strong the co-occurrence constraint is at that place.

The similarity account of OCP-Place effects in Arabic was more concretely formalized in Frisch *et al.* (2004), using a categorization function model of a gradient phonotactic constraint. In this model, similarity was related to a co-occurrence weight similar to the fractional weights used in Table 90.4. High-similarity homorganic consonants had a co-occurrence weight near zero, reflecting their near complete absence from Arabic. Non-homorganic consonants were analyzed as having no similarity and a co-occurrence weight near one. Homorganic consonants with intermediate degrees of similarity had weight values in between these extremes along a smooth curve. An example of this type of constraint is shown in Figure 90.1. The application of this type of constraint to single consonant co-occurrence pairs

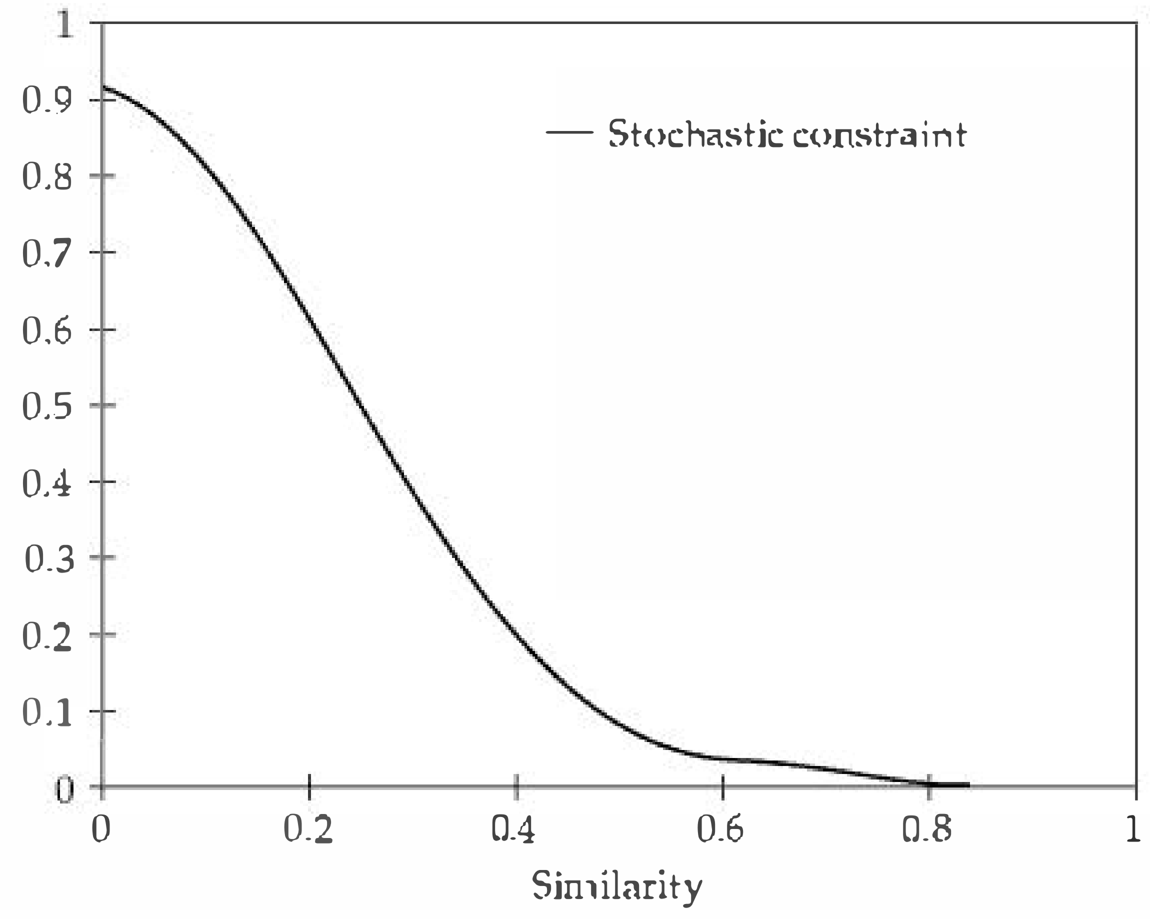

Figure 90.1 Stochastic constraint model of gradient similarity avoidance for consonant pairs in Arabic (after Frisch *et al.* 2004)

was extended in Frisch (2000) to model entire three-consonant roots by combining together constraints on C1–C2, C2–C3, and C1–C3 combinations.

3.6 *Modern interactive constraint models of OCP-Place effects*

Parallel to the development of the Pierrehumbert (1993) and Frisch *et al.* (2004) stochastic constraint model, formal phonological models of categorical constraint interaction were developed using Harmonic Grammar (Legendre *et al.* 1990; Smolensky and Legendre 2006) and Optimality Theory (Prince and Smolensky 2004). Quantitative implementations of these grammatical approaches have been applied to the OCP-Place data of Arabic and other languages. These models differ in a variety of theoretical points that are, to some extent, orthogonal to the issue of frequency effects. They will be discussed primarily from the perspective of their differences in modeling frequency effects in corpus data.

One way in which these models differ is in the degree of restriction on independent free parameters used to fit the frequency data. In Frisch *et al.* (2004), the degree of restrictiveness of consonant combination was proportional to perceived similarity, resulting in a relatively low number of free parameters. Anttila (2008a) makes a proposal most analogous to Frisch *et al.* (2004), stating that OCP-Place consonant co-occurrences can be predicted on the basis of grammatical complexity, where grammatical complexity comes from the required number of pairwise grammatical constraint rankings that are required to achieve a faithful output in an optimality-theoretic grammar. The restrictions on more specific natural classes of co-occurrence require more constraint rankings in comparison to more general natural classes of co-occurrence. For the case of Arabic coronals, for example, Anttila (2008a) presents the following constraints and rankings for representative consonant pairs:

(10) a. t-d
FAITH >> OCP-COR ∧
FAITH >> OCP-COR[−son] ∧
FAITH >> OCP-COR[−son, αcont]

b. t-s
FAITH >> OCP-COR ∧
FAITH >> OCP-COR[−son]

c. l-n
FAITH >> OCP-COR ∧
FAITH >> OCP-COR[+son]

d. t-n
FAITH >> OCP-COR

A relatively larger number of rankings must hold to allow co-occurrence to the *t-d* case (combination of coronal stops or coronal fricatives) for the input to map faithfully to the output, in comparison to the *t-n* case (combination of a coronal obstruent with a coronal sonorant). The complexity hypothesis is analogous to the account of laryngeal OCP constraints in MacEachern (1999), where the parallel between OCP constraints with multiple features and the notion of similarity due to multiple feature matches is explicitly discussed. There is an implicit hierarchy among these OCP constraints, where less specific constraint rankings can make more specific constraint rankings irrelevant. If OCP-COR >> FAITH, any coronal pair will be unable to surface faithfully, regardless of the ranking of OCP-COR[−son], for example. Since more specific feature matches for the OCP constraints means higher similarity between phonemes, the complexity hypothesis and the similarity account of the OCP make analogous predictions and are both fairly restrictive in the number of free parameters that can be used to fit the data.

Coetzee and Pater (2008) take a different approach from constraint ranking, using an accumulation of constraint violations for the same sort of constraint set as above (Anttila 2008a credits Coetzee and Pater 2008 for the constraint set that he uses). In the Coetzee and Pater (2008) approach, however, constraints are weighted relative to one another, rather than ranked relative to one another, as an application of Harmonic Grammar to the consonant co-occurrence problem. Constraints with higher weight have a greater impact on the likelihood of appearance of a form that violates that constraint. Forms that violate multiple highly weighted constraints are unlikely to appear. The most frequent forms will be those that violate the fewest and lowest-weighted constraints. In the Coetzee and Pater (2008) model, constraint weights were determined by a gradual learning acquisition algorithm, where data were presented to the learning model at rates that reflected the frequency of occurrence of forms in the lexicon. These constraint weights were then used to compute a cumulative harmony value for each type of input consonant combination that was compared to O/E values in the data for those consonant combinations. Coetzee and Pater (2008) conducted this analysis for consonant co-occurrence data from Arabic and the Austronesian language Muna. On the basis of differences in the co-occurrence patterns between these two languages, they concluded that language-specific constraint weightings are required for a relatively large number of OCP constraints, resulting in a relatively large number of free parameters. In particular, in order to account for differences between languages in the effects of subsidiary features such as [sonorant] and [continuant] for different places of articulation, Coetzee and Pater (2008) have different constraint weights for OCP-Cor[+son] and OCP-Lab[+son], for example. These differences were motivated by differences between the languages in rate of co-occurrence of consonant pairs that could not be reduced to contrastiveness, demonstrating that the proposals of Pierrehumbert (1993) and Frisch *et al.* (2004) do not generalize to Muna.

As introduced earlier, Wilson and Obdeyn (2009) attempt to account for the language-specific differences found by Coetzee and Pater (2008) with a restrictive model of constraint weighting with fewer free parameters. Wilson and Obdeyn (2009) use the MaxEnt model of Hayes and Wilson (2008). Like the Harmonic Grammar model of Coetzee and Pater (2008), the MaxEnt model uses constraint weights to predict frequency of occurrence, and gathers together cumulative violations to determine relatively high or low frequency of occurrence. Wilson and Obdeyn (2009) conclude from their modeling of Arabic and Muna, as well as data from Shona and Wargamay, that the influence of subsidiary features on consonant co-occurrence within a language can be held constant across different places of articulation, thus reducing the number of free parameters needed by the model (and consequently the number of constraints needed by the grammar). In other words, the impact of the feature [sonorant] is argued to be the same across different places of articulation within a language, though it may differ from one language to the next. Wilson and Obdeyn (2009) argue that apparent differences in the effect of subsidiary features for different places of articulation result from differences in the weights of the place features themselves. For places of articulation where the place feature weight is relatively low (e.g. [coronal] in Arabic), the effect of subsidiary features can be seen in gradient differences in frequency of co-occurrence. For places of articulation where the place feature weight is relatively high (e.g. [labial] in Arabic), co-occurrence is already at very low frequency due to the place feature, and so the effects of the subsidiary features are not visible. Wilson and Obdeyn (2009) argue that differences between their modeling results and those of Coetzee and Pater (2008) come primarily from three differences in their approach to modeling. First, the MaxEnt grammar directly determines constraint weights from frequency data, rather than learning constraint weights indirectly via a learning algorithm. Second, the success of the different models was determined by comparison directly to frequency data, rather than by comparison to O/E values: recall the discussion above on potential issues with O/E data when consonants differ in their base frequency of co-occurrence (and base frequency of occurrence is also modeled by the MaxEnt grammar). Third, the Wilson and Obdeyn (2009) modeling includes a penalty in the evaluation of model success based on the number of free parameters allowed in the model. As a result, they provide an incentive for parsimony in their model fitting. While parsimony is often implicitly part of the discussion in model comparison (e.g. Frisch *et al.* 2004; Coetzee and Pater 2008), their proposal explicitly incorporates a quantitative penalty in the numerical evaluation of a model fit for free parameters.

3.7 *Metalinguistic judgments for OCP-Place*

To test the psychological reality of the OCP-Place constraint, Frisch and Zawaydeh (2001) conducted a novel non-word study with native Arabic speakers in Jordan. Their non-words were constructed with a variety of consonant pairs along the spectrum of violations and non-violations of the OCP-Place constraint. They found that the Arabic speakers were sensitive to OCP-Place violations, including violations of the constraint by more than one consonant pair (i.e. cumulative constraint violations). Frisch and Zawaydeh (2001) also found that Arabic speakers were sensitive to different degrees of OCP-Place violation for a single consonant pair, parallel to the frequency distribution of these consonant pairs in the lexicon. Like the Coleman and Pierrehumbert (1997) data, these findings are difficult to model in a grammar that considers only a single or maximal constraint violation, and are more naturally captured by a grammatical model that considers cumulative violations in determining well-formedness. The cumulative nature of well-formedness is compatible with a grammar that includes frequency information, as the frequency of occurrence of phonological structures reflects the well-formedness of phonological forms within a language in much the same way as typological frequency reflects markedness between languages. In this way, the synchronic frequency effects seen in corpus studies of language lexicons appear to be transparently related to cross-linguistic typological patterns. Thus there is converging evidence that frequency effects at a variety of levels can contribute to our understanding of the nature of language sound structure.

4 Synchronic variation

Synchronic variation refers to cases where there are multiple alternatives for a phonological form. In general, synchronic variation is not expressed by variation between equally frequent alternatives. The cases that have been studied have shown that various phonological and morphological factors bias the output so that the frequency distribution of alternatives is unequal. In addition, there may be any number of non-phonological factors (from syntax or discourse) that influence alternatives. These types of interactions have not been studied to any great extent. Synchronic variation provides evidence that frequency information is part of the phonological knowledge possessed by speakers of a language, as the factors that condition synchronic variation are the same factors that are seen elsewhere in traditional phonological analyses. Providing a completely independent account of synchronic variation from the rest of the (non-variable) grammar seems redundant, as the same phonological factors are used in both cases. The simpler approach, then, is to begin with the same phonological building blocks for both variation and non-variation and provide a mechanism within the grammar that allows for variation to occur. Several mechanisms are discussed, in general developing from less complex to more complex alternatives. The majority of the examples use the framework of Optimality Theory, as the most recent analyses adopt constraints on possible outputs as the fundamental description of phonological patterns.

4.1 Variation as multiple optimality-theoretic grammars

One extensively studied case of synchronic variation is found in so-called *t/d*-deletion in English (e.g. Guy 1991; see also CHAPTER 92: VARIABILITY). Deletion of coda *t/d* is relatively common in English, particularly in dialects such as African American English. The deletion process is more common in consonant clusters, and depends on the following phonological context (among other factors). For example, in African American English deletion is relatively likely when the next word is consonant-initial (11a), or before a pause (11b), and least likely when the next word is vowel-initial (11c).

(11) a. *That's a fast* /fæs/ *car.*
b. *That's fast* /fæs/.
c. *That's a fast* /fæst/ *answer.*

Anttila (2007) proposes a relatively simple account of this systematic variation, using the ranking schema of Optimality Theory. In many ways, the approach is non-quantitative at its core, which makes the analysis of variation compatible with classic generative phonology, in which variation is not considered an important aspect of the theory. Using a set of basic parsing constraints, Anttila (2007) shows that any constraint ranking that allows deletion before a pause or vowel will also allow deletion before a consonant. Thus, the synchronic variation within a language is compatible with the phonological differences between languages (e.g. Davidson 2006). In order to generate variation, we can assume that speakers have multiple grammars with different constraint rankings (also called co-phonologies). If these grammars are used variably, perhaps with different rates, they can be used to model different frequencies of occurrence of *t/d*-deletion. However, the use of multiple constraint rankings does not result in a state where any pattern of variation is possible, as the set of proposed constraints does restrict the possible grammars. In the case of *t/d*-deletion, these constraints ensure that deletion before a consonant is always possible if deletion elsewhere is possible. So deletion before a consonant will always be more frequent than deletion elsewhere.

There are other factors that condition *t/d*-deletion, and their inclusion in grammar has led to more complex models of variation. For example, *t/d*-deletion is sensitive to the preceding phonological context: deletion is more likely in /st/ clusters than /ft/ clusters, more likely following obstruents than sonorants (e.g. *fast vs. pant*) and least likely after a vowel. Deletion is also more likely if *t/d* is part of the root than if *t/d* comes from suffixation, as in the past-tense morpheme (e.g. *fast vs. raced*). There are, however, confounds among the possible conditioning factors. Coetzee (2004) notes that voicing is sometimes mentioned as a conditioning factor, but that voicing is not discussed as an influence on *t/d*-deletion in many studies. However, coda clusters with /d/ are rarely found outside of cases where the /d/ is a suffix or preceded by a sonorant, so it is not clear whether voicing itself is a conditioning factor, or whether these cases of deletion are subsumed by the influence of preceding environment and morphological status. Another alternative analysis is that the effect of the manner of the preceding phoneme is actually an effect of similarity, such that deletion is more likely when *t/d* are next to a highly similar segment (i.e. obstruents are more similar to *t/d* than sonorants and vowels, and similarity also makes some predictions about place of articulation effects that appear to be correct).

4.2 Variation as unranked constraints

Anttila (2008b) takes a slightly different approach to modeling synchronic variation in Optimality Theory in a study of Finnish, in which vowel hiatus is resolved by coalescence of two distinct vowel qualities into a long vowel with a single quality. Vowel coalescence in Finnish is variable, but more common when the first vowel is a mid vowel (12a) than a high vowel (12b).

(12) a. /suomea/ ~ /suomee/ 'Finnish-PARTITIVE'
     b. /ruotsia/ ~ /ruotsii/ 'Swedish-PARTITIVE'

Assuming underlying forms with two distinct vowel qualities, Anttila (2008b) uses three distinct constraints to capture the basic patterns of possible variation: FAITH, *EA, *IA. FAITH preserves the underlying contrast, while *EA and *IA are constraints against vowel hiatus. If *EA is always higher-ranked than *IA, the height asymmetry in vowel coalescence will be preserved. In order to allow for variation, Anttila (2008b) takes some constraints to be unranked in the grammar, to be ranked only upon evaluation and determination of an output (also called floating constraints). For example, if only the universal ranking *EA >> *IA is present, then FAITH can either outrank both of these constraints, leading to no coalescence; only the *IA constraint, leading to coalescence only for /ea/; or neither constraint, leading to coalescence for both /ia/ and /ea/. Due to the asymmetry between *EA and *IA in the typological grammars, there is a predicted asymmetry in the frequency that these patterns are output at evaluation. The full analysis of Anttila (2008b) also includes morphological conditioning involving coalescence in root forms *vs.* coalescence when hiatus is created by a suffix, and also some influences of part of speech on coalescence rate, similar to the *t/d* case. This involves expanding the number of constraints used in the analysis, but the basic approach using some unranked constraints to account for variation is retained.

4.3 Variation through violation of non-crucial constraints

A third Optimality Theory-based approach to variation is presented in Coetzee (2006), where, in contrast to the two discussed above, the ranking of all phonological constraints in the grammar is maintained, but the differences in violations accrued by non-optimal candidates are relevant to frequency. Coetzee (2006) discusses Failense Portuguese, where unstressed vowels are variably deleted. This process is similar in some contexts to unstressed vowel deletion in English (e.g. deletion preceding *r/l* discussed below). It is sensitive to the quality of the unstressed vowel, and also to position within the word. Unlike English, unstressed vowel deletion can occur word-finally (e.g. *paga* /pagɐ̆/ ~ /pag/ 'she pays') and is generally more common in this position. In Coetzee's approach to modeling variability, markedness constraints that are motivated elsewhere are used. These constraints are also used to account for vowel reduction phenomena, thus adding generality to the analysis. These constraints penalize parsing vowels into unstressed syllables, roughly based on their sonority. Coetzee also includes a constraint against unstressed vowels in final position in a prosodic word as a type of markedness constraint against weak prosodic word boundaries. In classical Optimality Theory, faithfulness constraints would outrank these constraints in order for word-final unstressed vowels to appear at all.

Coetzee proposes two extensions to classical Optimality Theory to account for variability. First, non-optimal candidates are ranked relative to one another by the grammar on the basis of their non-crucial violations, so that more marked possibilities are disfavored relative to less marked possibilities overall. If these degrees of non-optimality correspond to frequencies of occurrence, then non-optimal candidates that violate the fewest number of additional constraints will be more frequent, and those which violate many additional constraints will be less frequent. Second, in order to limit the number of possible outputs and allow for categorical effects, there is a boundary in the constraint hierarchy that is a relative cut-off for frequency influences on non-optimal candidates. Constraints above this cut-off have categorical influences on the appearance of alternatives, so that relatively highly ranked constraints will limit the possible outputs qualitatively. Constraints below this cut-off will limit the possible outputs quantitatively, so that variation can be observed when only these relatively low-ranked constraints distinguish alternative outputs. This is the primary distinction between the Coetzee (2006) approach, where there is a cut-off for potential variability in the hierarchy, and the previous alternatives that generate variability with re-ranking. In a re-ranking analysis, constraints anywhere in the hierarchy can potentially be unranked and allow variation.

4.4 Variation by quantitatively ranked constraints

Boersma and Hayes (2001) present a more quantitative approach to optimality-theoretic constraint ranking, which is similar to the unranked constraints approach. In their theory, Stochastic Optimality Theory, each constraint has an associated average ranking value that represents its typical location within the constraint hierarchy. When constraint evaluation takes place to generate an output, each constraint is perturbed from its average ranking value probabilistically, so that a constraint at evaluation may be at a higher or lower point than its average location. If two constraints are relatively close together in average ranking value, it is possible that their relative position will change with respect to one another (and, if they had the exact same average ranking value, they are essentially unranked with respect to one another, and could appear in either order at evaluation). Constraints that are relatively far apart in average ranking value are very unlikely to occur in a different ranking at evaluation. In this way, Stochastic Optimality Theory can have relatively categorical constraint rankings and relatively variable constraint rankings, with the potential to fine-tune the average ranking values so that the relative ranking of two constraints at evaluation occurs with any desired frequency. With an appropriate choice of constraints, then, frequency effects can be modeled rather precisely. Criticism of Stochastic Optimality Theory has noted that it can produce no truly categorical effects, as it is always possible in any particular evaluation for the ranking value for a constraint to be very distant from its average ranking value; however, this possibility is extremely unlikely (e.g. Anttila 2008b). It has also been suggested that tuning the frequencies predicted by a grammar too closely to a corpus of data is unrealistic as a model of the knowledge of any individual speaker, as there is variation between individuals and there are extra-grammatical influences on the frequency of occurrence of variant forms. Coetzee (2006) argues that a better model of variability in grammar only provides relative frequency differences between alternatives and does not model exact frequencies of occurrence.

4.5 *Token frequency as an influence in variation*

Word token frequency has been shown to be an influence on phonetic reduction and also on the diachronic spread of sound change. Though these processes are arguably diachronic, the synchronic language learner acquires and uses a system in which there is synchronic variation. There are numerous studies documenting these types of changes (see Bybee 2000 for a review). One of the earliest studies of this type examined deletion of unstressed /ə/ preceding a sonorant /r/ or /l/. In low-frequency words, such as *artillery* and *cursory*, unstressed /ə/ is preserved (i.e. /artıləri/ not /artılri/). In high-frequency words, such as *memory*, *salary*, and *nursery*, unstressed /ə/ may be deleted or replaced with a syllabic sonorant making syllable count in these words somewhat ambiguous. Bybee (2000) argues that this variation is the result of a sound change in progress that is gradual both in its diffusion through the lexicon and in its phonetics for any particular word.

A second example of this type of reduction is *t/d*-deletion, mentioned above. The deletion of *t/d* is conditioned by a variety of social and grammatical factors (see Guy 1991). One potential grammatical factor is the distinction between function words and content words. Function words have a higher rate of *t/d*-deletion. However, function words are also highly frequent, so this potential grammatical factor is hopelessly confounded with frequency. Another potential grammatical factor is a decrease in the frequency of *t/d*-deletion when *t/d* is used as a regular past-tense marker *vs.* ordinary stem-final *t/d* in content words. Taking this factor into account, Jurafsky *et al.* (2001) show that frequency has an influence on deletion rate in content words. In a study of the phonetically transcribed Switchboard database, they found that content words with the highest frequency were twice as likely to have final *t/d*-deletion as content words with the lowest frequency. They found word frequency to be a significant factor above and beyond other potential phonological (e.g. word length) and morphophonological influences on reduction.

Bybee (2000, 2002) proposes that the other morphophonological influences on *t/d*-deletion may also reduce to frequency effects. In Bybee's model, words are represented in the lexicon in full phonetic detail, with gradient degrees of reduction being part of the idiosyncratic knowledge that individual speakers have about a word. Moreover, word usage leads to additional phonetic reduction, so that high-frequency words are more phonetically reduced than low-frequency words. As this gradual reduction proceeds to the eventual endpoint of deletion, higher-frequency words are more likely to reach this state in comparison to low-frequency words. The gradual erosion accounts for frequency effects on the reduction and deletion of unstressed /ə/ as well as *t/d*-deletion. Bybee's model also includes listing of morphologically complex forms in the lexicon, so these forms are also subject to the gradual erosion through usage that is found in simple words. Bybee claims that the supposed difference in deletion rate between morphologically complex words and simple words is actually coincidental, as morphologically complex words are more likely to contain a vowel preceding the *t/d* in comparison to simple words, and the post-vocalic environment is less favorable to *t/d*-deletion (e.g. *missed vs. said*). Finally, she notes that speech production is flexible, allowing a non-reduced form to be produced if needed. Such a form might be more likely to be used for a morphologically complex word, where the presence of a suffix conveys potentially distinctive information, in comparison to a morphologically simple word, where other parts of the word may be sufficient to indicate the lexical identity.

5 Summary

A review of the evidence for occurrence frequency having an influence on phonological and morphophonological patterns finds support for frequency as an influence on language sound structure at a variety of levels in a variety of ways. Corpus studies based on the dictionary as a model of the mental lexicon have found systematic variation in phonotactic type frequency that influence native-speaker judgments in novel non-word processing tasks. Corpus studies of spoken language corpora have found that speech production is influenced by type and token frequency that can also be observed in novel word production experiments. Theoretical models of frequency effects in grammar are being developed, and this is an area of growing research interest in phonology and other areas of grammar (e.g. Bod *et al.* 2003). Combined with laboratory research techniques, these models provide new opportunities to understand language sound structure in the grammar, as well as in language use.

In the view presented in this chapter, language sound structure is built up from language use, starting with the phonetic level. Phonemic categories are generalizations over phonetic patterns; sub-syllabic and syllabic categories are generalizations over phonemic patterns; and lexical and morphophonological categories are generalizations over phonemic, sub-syllabic, and syllabic patterns. Basic abstractions at each level (e.g. segments at the phonemic level) provide material for abstraction and generalization at higher levels. As models and theories of language sound structure bridge the gap between abstract symbolic knowledge representations and actual occurrence in language use, they also provide new opportunities to integrate the study of phonology with the study of phonetics, sociolinguistics, and psycholinguistics. In these other domains, frequency effects are well-known and well-documented. Advances in theoretical phonology to model frequency effects may also be useful to researchers in these fields, allowing them to model their data with more sophisticated phonological representations (Dell 2000). This potential for interdisciplinary exploitation of probabilistic models of phonology is likely to make for the most robust models of phonological phenomena that provide a real understanding of how language sound structure is represented in the mind/brain.

91 Vowel Harmony: Opaque and Transparent Vowels

Adamantios I. Gafos
Amanda Dye

1 Introduction

In linguistic theory, there is a tension between two core aims of the field: theoretical parsimony and empirical coverage of the remarkable diversity and specificity seen in linguistic data. Vowel harmony, and more specifically the two phenomena of transparency and opacity in vowel harmony that concern us in this chapter, provide prime examples of phonological research concerned with resolving this tension.[1] Recent findings and promising new theoretical ideas on transparency and opacity indicate that our understanding of these phenomena is at a critical stage. The crucial future step will be the integration of the new data patterns with insights from theoretical analyses. This will require an improved understanding of the phonetic basis of vowel harmony, of the nature and origin of the grammatical forces governing transparency and opacity, and finally of the organizational principles governing the resolution of these forces within and across languages.

2 Definitions and exemplification of the basic patterns

Vowel harmony is a regularity found in many languages requiring vowels in certain grammatical domains to agree in terms of specific phonological features. For example, the vowels of Hungarian can be divided into two subsets, the "front" vowels /i iː e eː ø øː y yː/ and the "back" vowels /u uː o oː ɔ ɑː/ (Vago 1980a; van der Hulst 1985; Siptár and Törkenczy 2000; see also CHAPTER 123: HUNGARIAN VOWEL HARMONY). In terms of phonological features, the vowels in the "front" set share the feature [−back] and those in the "back" set share the feature [+back]. The existence of vowel harmony is most readily observed in

[1] For excellent reviews of vowel harmony, see van der Hulst and van der Weijer (1995) and Archangeli and Pulleyblank (2007). See Gordon (2006) for a short article on the phonetics of transparency in vowel harmony. At an introductory level, a cogent discussion of different proposals on vowel harmony can be found in Kenstowicz (1994). For recent dissertation-length treatments of vowel harmony, see Baković (2000), Krämer (2003), and Przezdziecki (2005).

suffix vowel alternations where the [±back] quality of the suffix vowel is determined by the [±back] quality of the stem vowel. For example, as shown in (1), the dative suffix alternates between two forms, one with the front vowel /e/ and another with the back vowel /a/, as a function of the stem vowel: *ház-nak* 'house-DAT', *város-nak* 'city-DAT', but *kéz-nek* 'hand-DAT', *öröm-nek* 'joy-DAT' (in Hungarian orthography, the acute accent denotes a long vowel, the umlaut denotes a front round vowel, and the double acute indicates a long front round vowel). In such combinations of stems and suffixes, then, the suffixes adjust or harmonize to the [±back] "harmonic feature" of the stem vowels. Because it determines the suffix form, the stem vowel is called the trigger and the suffix vowel is called the target of the harmony pattern.

(1) *Regular vowel harmony*

a. *stem vowels are front* ([−back])

vidék-től	[videːktøːl]	'country-ABL'
öröm-nek	[ørømnɛk]	'joy-DAT'
hegedű-nél	[hɛgɛdyːneːl]	'violin-ADESS'
víz-ben	[viːzbɛn]	'water-INESS'

b. *stem vowels are back* ([+back])

város-tól	[vaːroʃtoːl]	'town-ABL'
mókus-nak	[moːkuʃnɔk]	'squirrel-DAT'
harang-nál	[hɔrɔŋgnaːl]	'bell-ADESS'
ház-ban	[haːzbɔn]	'house-INESS'

A central aim in phonological theory has been to characterize the range and possible forms of such systematic sound patterns in different languages (Chomsky and Halle 1968). A particularly fruitful research strategy in this regard has been to explore the *phonetic basis* of sound patterns, i.e. the extent to which such patterns can be seen as adaptations to biological constraints on speech production and perception (Lindblom 1983; cf. Anderson 1981). For vowel harmony, it has been proposed that a natural basis for it can be traced to the low-level phonetic influences among vowels in consecutive syllables (Fowler 1983; Ohala 1994a, 1994b; Beddor *et al.* 2002; Przezdziecki 2005). The crucial fact is that vowels exert influences on neighboring vowels across intervening consonants, the so-called *V-to-V co-articulation* (Öhman 1966). Acoustically, this means that in a V_1CV_2 sequence, V_2's formant values are influenced by the identity of V_1 and vice versa. Articulatorily, the basis of this phenomenon is well understood. Vowels are produced by movements of the tongue body and the jaw, with relatively slow changes in the global shape of the vocal tract, because of the larger mass involved. In the case of a V_1CV_2 sequence, while the consonantal constriction is localized at some area in the vocal tract, the free part of the tongue is allowed to assume different shapes and thus move in a "smooth transition" (Öhman 1966) from the shape of the first to the shape of the second vowel. Vowels, in other words, provide a continuous articulatory substrate on which consonants are superimposed. V-to-V co-articulation is a direct consequence of this articulatory continuity. This phonetic effect can develop, via processes of phonologization, into vowel harmony (Przezdziecki 2005).

However, within the attested range of phonological vowel harmony patterns there exist phenomena that are systematic, yet unexpected given the phonetic grounding sketched above. Specifically in Hungarian, but also in other languages with vowel harmony, we find as well a set of "neutral" vowels, which do not undergo harmony. Neutral vowels come in two species: transparent and opaque. The best known property of transparent vowels is that they may intervene between the trigger and the target vowel even when they bear the opposite value for the harmonizing feature. The examples in (2) show that the first stem vowel dictates the backness value for the suffix vowel across the intervening transparent vowels *í* [iː], *i* [i], and *é* [eː]. In (2a), stems with initial front vowels followed by a transparent vowel select front suffixes. In (2b), however, the initial stem vowel and the suffix vowel are back, despite the front quality of the intervening transparent vowel. Hence the initial and suffix vowels seem to establish a harmony relationship across both consonants and transparent vowels.

(2) *Transparent vowels: Agreement across the medial vowel*

a.	*first stem vowel is front*		
	emír-nek	[ɛmiːrnɛk]	'emir-DAT'
	zefír-ből	[zɛfiːrbøːl]	'zephyr-ELAT'
	bili-vel	[bilivɛl]	'pot-INSTR'
	művész-nek	[myːveːsnɛk]	'artist-DAT'
b.	*first stem vowel is back*		
	papír-nak	[pɔpiːrnɔk]	'paper-DAT'
	zafír-ból	[zɔfiːrboːl]	'sapphire-ELAT'
	buli-val	[bulivɔl]	'party-INSTR'
	kávé-nak	[kaːveːnɔk]	'coffee-DAT'

The other species of neutral vowels, opaque vowels, block harmony by overriding the expected consequences of another potential trigger in the phonological form. For example, whereas the front unround Hungarian vowels are transparent, front round vowels in Hungarian and other palatal vowel harmony systems are opaque, e.g. *papír-nak* 'paper-DAT' *vs. parfüm-nek* 'perfume-DAT'. In the latter form, the front round *ü* [y] initiates its own harmony domain, imposing a [−back] specification on its following suffix. Thus, [y] is opaque but [iː] is transparent.

Whereas the existence of opaque vowels is consistent with the generally accepted idea that the phonetic basis of vowel harmony inheres in V-to-V co-articulation effects, transparent vowels pose a challenge to that idea. Consider, for example, the difference in the suffix vowels between words like *papír-nak* and *zefír-nek*. The backness of the suffix in *papír-nak* must be linked to the backness of the stem-initial vowel. However, it is not clear how this can be achieved through the acoustic consequences of V-to-V co-articulation, given that the stem-initial and suffix vowels are not adjacent. Although long-distance co-articulation across schwa has been found in English (Magen 1997), studies also show that [iː] is resistant to co-articulation from the preceding vowel(s) in terms of perception (e.g. Magen 1984 for Japanese; Farnetani *et al.* 1985 for Italian; Recasens 1987 for Spanish and Catalan). As we will see in §3, because of this long-distance character, transparency has been a recalcitrant problem in theoretical treatments of the phenomenon.

A notable generalization in "palatal" vowel harmony systems is the existence of a relation between vowel height and transparency. In Hungarian, stems in which a back vowel is followed by [ɛ] are commonly described as "vacillating," because they allow both front and back suffixes (Vago 1980a).[2] Hence, stems such as *hotel* vacillate: *hotel-nak/nek* 'hotel-DAT'; but stems such as *papír* do not, *papir-nak*, **papír-nek*. Thus, the generalization is that the lower and more retracted [ɛ] is phonologically less transparent than the higher and more front [i] (see Beňuš 2005 for the first characterizations of these vowels based on ultrasound and electromagnetic articulometry data). A similar generalization is true for other palatal vowel harmony systems (L. B. Anderson 1980; Beňuš 2005). As far as we know, the opposite generalization, that lower vowels are more transparent than higher vowels, is not attested.

Another notable generalization concerns the relationship between suffix choice and the number of transparent vowels in stems: stems where a back vowel is followed by two transparent vowels are more likely to vacillate or take front suffixes than stems where a back vowel is followed by only one transparent vowel. For example, *mam-i* and *mam-csi* (both 'mother-DIM') select back suffixes: *mami-nak*, *mamcsi-nak* 'mother-DIM-DAT'. However, when the two diminutive suffixes are combined in *mamicsi*, both front and back suffixes are acceptable: *mamicsi-nak/nek* 'mother-DAT' (Farkas and Beddor 1987; Ringen and Kontra 1989; Beňuš 2005; Hayes and Londe 2006). Beňuš (2005), highlighting this aspect of the Hungarian data, concludes that transparency is not a categorical property of vowels but it is determined contextually. The same vowel can be transparent in one context (e.g. *mamcsi-nak*) but opaque in another (e.g. *mamicsi-nek*).

Our examples of transparency and opacity so far come from a so-called *"palatal" vowel harmony* system where, following standard description, the phonological feature exhibiting harmonic behavior is [±back]. Transparency and opacity can be instantiated regardless of the vowel feature exhibiting harmony. In what follows, we exemplify the other major classes of harmony: "tongue root" harmony, "rounding" harmony, and "height" harmony.

2.1 "Tongue root" harmony

In languages described as having "tongue root" harmony, vowels harmonize for features that correspond to the position of the tongue root or pharyngeal expansion/compression. In these languages, following common phonological description, vowels may be "advanced," i.e. articulated with the tongue root in an advanced position, or "retracted," i.e. articulated with a non-advanced or retracted tongue root. The relevant phonological dimension of distinction, it has been proposed, is [±ATR] (originally from Halle and Stevens 1969) with advanced vowels sharing [+ATR] and retracted vowels [−ATR]. This has come to be the standard way of describing the phonetic basis and the phonological feature in question. But work by Lindau (1978), using radiographic and acoustic data, and by Tiede (1996), using MRI data, indicates that the relevant difference is in terms of pharyngeal expansion *vs.* compression, which can be achieved in different ways, one of which is by positioning the tongue root in the way implicated by [±ATR]. At a first approximation, however, we can talk about patterns of transparency and opacity in "tongue root" harmony without being precise about the phonetic dimensions involved.

[2] This statement is a first approximation to a set of complex data patterns. Farkas and Beddor (1987), Kaun (1995), Beňuš (2005), Beňuš and Gafos (2007), and Hayes and Londe (2006) provide details, data, and relevant discussion on this height–transparency link in Hungarian.

Our first example of "tongue root" harmony comes from Akan (Ladefoged 1964; Schachter and Fromkin 1968; Lindau 1978; Dolphyne 1988). The Akan verb /di/ 'to eat', which contains a [+ATR] vowel, imposes that value on a personal pronoun prefix, so that we get forms such as [mi-di] 'I eat' and [wu-di] 'you eat'. By contrast, the verb /dɪ/ 'to be called' imposes its [−ATR] value to its prefix, so that the same prefixes surface as [mɪ-dɪ] 'I am called' and [wʊ-dɪ] 'you are called'.

In Akan, both high and mid vowels are subject to harmony, but in other "tongue root" harmony languages the vowels that alternate comprise a more restricted set. Thus, in Wolof, only the mid vowels /e ɛ o ɔ/ alternate in harmony; for example, the past tense suffix appears as [-ɔɔn] with a [−ATR] stem, as in [rɛɛr-ɔɔn] 'had dinner', and as [-oon] with a [+ATR] stem, as in [reer-oon] 'was lost'.

In Wolof, the high vowels are neutral (Archangeli and Pulleyblank 1994). In particular, high vowels in Wolof are transparent to vowel harmony.[3] In (3), the initial stem vowels determine the [ATR] values of the suffix vowels across the medial transparent vowels. In (3a), stems with initial [+ATR] vowels take [+ATR] suffixes. In these cases the intervening high vowel has the same [ATR] value as the initial vowel, but in (3b) the opposite is true. In the forms on the right, stems with [−ATR] vowels take [−ATR] suffixes, despite the fact that the intervening high vowel has the opposite feature value for ATR.

(3) *Transparent vowels in Wolof* (Archangeli and Pulleyblank 1994)

a.	toxi-leen	'go and smoke'	b.	tɛkki-lɛɛn	'untie!'
	gəstu-leen	'do research!'		mɔytu-lɛɛn	'avoid!'
	təriji-leen	'go sleep!'		sɔppiwu-lɛɛn	'you have not changed'
	seenu-woon	'tried to spot'		tɛɛru-wɔɔn	'welcomed'

Like high vowels, low vowels may also be neutral. In Pulaar, for instance, low vowels are opaque to vowel harmony. Pulaar shows regressive harmony of mid vowels, such that the [ATR] value of suffixes migrates to stems, as in [peetʃ-i] / [pɛɛtʃ-ɔn] 'crack-PL/DIM PL', where the plural suffix /-i/ causes the stem to surface with a [+ATR] vowel, while the diminutive plural suffix /-ɔn/ imposes its [−ATR] value on the stem. The behavior of the opaque low vowel /a/ is exemplified in (4).

(4) *Opaque low vowels in Pulaar* (Archangeli and Pulleyblank 1994)

bɔɔt-aa-ri	*boot-aa-ri	'dinner'
pɔɔf-aa-li	*poof-aa-li	'breaths'
nɔdd-aa-l	*nodd-aa-li	'call'
ᵑgɔr-aa-gu	*ᵑgor-aa-gu	'courage'

In (4), the [+ATR] value of the rightmost suffix cannot spread to the low vowel /a/, which surfaces as [−ATR] everywhere in Pulaar. The low vowel not only does not accept the feature value of the suffix to its right, it also blocks vowel harmony from propagating to the stem to its left. The vowel starts its own harmonic

[3] High-vowel-initial roots are always harmonic (for [+ATR]) in Wolof, but this is the only circumstance in which high vowels trigger harmony.

domain, as shown by the starred examples; when a stem appears to the left of /a/, it cannot contain a [+ATR] vowel.

Archangeli and Pulleyblank (1994) discuss plausible phonetic bases for the behavior of high vowels in languages like Wolof and low vowels in languages like Pulaar. Tongue body raising, which is required for [+high] vowels, and tongue root advancement, which is required for [+ATR] vowels, are compatible gestures (CHAPTER 21: VOWEL HEIGHT). Both serve to lower F1, producing the percept of a higher vowel. In the same way, lowering of the tongue body (for [+low] vowels) and retracting the tongue root are compatible, and in concert they help create a perceptually lower vowel by producing a higher F1. Tongue body raising/tongue root retraction and tongue body lowering/tongue root advancement, however, can be said to constitute pairs of incompatible gestures, because one member of each pair serves to counteract the acoustic effect of the other. This phonetic basis provides plausible reasons for the lack of [+high, −ATR] vowels contrasting with transparent vowels in Wolof, and [+low, +ATR] vowels contrasting with the opaque vowels in Pulaar. Further, Archangeli and Pulleyblank (1994) propose that such lack of contrast (CHAPTER 2: CONTRAST) may underlie the neutrality of these vowels. As is often the case with phonetic motivations for phonological patterns (Anderson 1981), identifying plausible phonetic grounds for neutrality does not fully explain the behavior of neutral vowels in these harmony systems. The fundamental question is: what principles determine when a vowel is transparent or opaque? Consider the case of Wolof, in which high vowels are transparent to vowel harmony, but where, in some circumstances, the low vowel may be opaque.[4] There exist plausible phonetic grounds for saying that both [+high, −ATR] and [+low, +ATR] vowels are marked. But it remains unclear how exactly these similar markedness considerations are translated into the different phonological behavior that these vowels seem to exhibit. The reader is referred to Archangeli and Pulleyblank (1994), who discuss cases of cross-linguistically variable behavior of [+high, −ATR] and [+low, +ATR] vowels.

We can highlight the issue of how deterministic phonetic forces may be of phonological behavior when we also consider that what appears to be the same vowel may be transparent in some languages but opaque in others. For example, in Pulaar, as described above, and in Tangale (Jungraithmayr 1971; Kidda 1985; van der Hulst and van de Weijer 1995) the low vowel /a/ is opaque, whereas in Kinande (Schlindwein 1987; Steriade 1987; Cole and Kisseberth 1994; Mutaka 1994) /a/ has traditionally been analyzed as transparent to vowel harmony. Predicting the transparency *vs.* opacity of /a/ in these languages cannot be reduced to a question of phonological contrast, since /a/ has no phonological [+ATR] counterpart in any of the relevant languages. On the surface, then, the cross-linguistically variable behavior of neutral /a/ seems to present a puzzle. However, recent articulatory work (Beňuš 2005; Gick *et al.* 2006) suggests that the real question may not be one of opacity *vs.* transparency, but rather of opacity *vs.* participation in harmony: experimental data show that /a/ in Kinande is affected by vowel harmony. It should be noted that, like low vowels, neutral high vowels show cross-linguistically variable behavior in ATR harmony. For instance, high vowels are transparent to

[4] The long low vowel /aː/ is always opaque in Wolof, but short /a/ usually participates in vowel harmony. There are exceptions to the behavior of short /a/, however, in which it is also opaque. See Archangeli and Pulleyblank (1994) for a thorough discussion.

harmony in Wolof, as discussed above, but are opaque in Yoruba (Archangeli and Pulleyblank 1994; see Pulleyblank 1996 for discussion).

2.2 *"Rounding" harmony*

In various languages, including those of the Turkic, Mongolian, and Tungusic families, as well as Yawelmani (now called Yokumne), an American Indian language of California, vowels harmonize for lip posture (CHAPTER 19: VOWEL PLACE). As we remarked in the case of "tongue root" harmony, the phonetic basis of the harmonizing "rounding" feature is a separate, non-trivial issue (see Goldstein 1991). With this in mind, we will follow standard descriptions in saying that the feature showing harmony in these languages is [±round]. In Turkish "rounding" harmony, both high and non-high vowels can trigger rounding harmony, but only high vowels are eligible as targets. The 1st person singular possessive suffix, for example, alternates depending on the value of the stem for the feature [round], as *ip-im* 'my rope' *vs.* *süt-üm* 'my milk'. See CHAPTER 118: TURKISH VOWEL HARMONY for extensive discussion.

A well-known case of transparency in rounding harmony is observed in Khalkha Mongolian. In (5a) we see the [+round] feature of the stem propagating across /i/ to the (rightmost) suffix vowel (data from Svantesson *et al.* 2005). The examples in (5b) show that these suffix vowels surface as [−round] when the initial stem vowel is [−round].

(5) *Transparent* [i] *in the rounding harmony of Khalkha Mongolian*

a.	poor-ig-o	'kidney-ACC-RFL'	b.	piir-ig-e	'brush-ACC-RFL'
	xɔɔʤ-ig-ɔ	'food-ACC-RFL'		teeʤ-ig-e	'gown-ACC-RFL'
	ɔʤʲi-ʤɔ	'to squint-DPST'		tʰɛ.xʲi-ʤa	'to be bent-DPST'

Previous theoretical discussions of Mongolian rounding harmony (S. R. Anderson 1980; Steriade 1995) have considered the transparency of /i/ to be problematic. As we discuss in the following section, a popular account of transparency in vowel harmony maintains that the harmonizing feature, in the present case [+round], is first transmitted to all vowels in the word. For example, in [poor-ig-o], according to this account, the transparent vowel /i/ would be assigned the feature [+round]. This is a standard way to express formally the intuition that the rounding of the suffix vowel in [poor-ig-o] is due to the rounding of the first stem vowel, while respecting one of the fundamental phonological principles that such dependencies among vowels in words are local and hence rounding must propagate also to the intervening /i/. As a result of this step, however, the intermediate representation obtained is [poor-yg-o], where /i/ has changed to /y/. In order to derive the correct surface form, this intermediate form would need to be repaired via a rule like /y/ → [i]. However, such a rule would not be tenable in the case of Mongolian, because /y/ is thought to be a phoneme of the language, and there is no principled way to distinguish derived [y] from underlying /y/ in the application of such rules. But acoustic data from Rialland and Redouanne (1984), as well as from Svantesson *et al.* (2005), show that the phoneme notated with /y/ in past analyses is not a front vowel. Therefore, /i/ and /y/ are not phonemically contrastive in this language. Rather, the data show that the purported [y] is a back vowel. In light of the phonetic evidence, then, this case of transparency is not unique as it was thought to be. As we have seen in the cases of transparency in "palatal" and "tongue root" harmony systems reviewed so far, the transparent vowels do not contrast with respect to the harmonizing feature, e.g. /i/ in Hungarian does not have a back counterpart, /i/ in Wolof does not have a [–ATR] counterpart, and /a/ in Kinande does not have a [+ATR] counterpart.

2.3 *"Height" harmony*

In phonological terms, "height" harmony systems require uniformity across vowels in terms of the phonological feature [±high] (CHAPTER 21: VOWEL HEIGHT). Some instances of what have been called "height" harmony systems have been an issue of discussion in connection with "tongue root" harmony. This issue arises because tongue body vertical position, an undisputed correlate of phonological height, and pharyngeal size have very similar effects in the frequency of the first formant – see Lindau (1978) for a particularly clear illustration of this from Akan. As an expected consequence, then, in some harmony systems, such as that of Kinande, the harmonic classes seem to differ according to vowel height as well as tongue root position. Clements (1990, 1991) proposes an account for such systems in terms of an "aperture" theory of vowel height. In his theory, the harmonic classes are distinguished on the basis of their value for the feature [open], used to implement height distinctions. More recent discussion of the same issue, "tongue root" *vs.* "height" harmony, can be found in the instrumental studies of Gick *et al.* (2006) and Kenstowicz (2009), who provide converging evidence in favor of the "tongue root" interpretation for the Kinande vowel harmony system.

In part because of this issue, the "height" harmony systems in dialects of Italian (CHAPTER 110: METAPHONY IN ROMANCE) have not received an interpretation in terms of "tongue root" harmony and thus can be considered as good representatives of "height" harmony (see van der Hulst and van de Weijer 1995 for further relevant discussion of the "tongue root" *vs.* "height" harmony issue). This position must be qualified as tentative. The phonetic bases of the distinctions implicated in the Italian vowel harmony systems have not been the subject of systematic studies.

3 Previous accounts

Transparency and opacity have provided persistent challenges to phonological theory. A fundamental understanding of these phenomena implicates long-standing phonological issues: the range of possible rules or constraints (CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS), the nature of representations (CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS; CHAPTER 19: VOWEL PLACE; CHAPTER 21: VOWEL HEIGHT; CHAPTER 27: THE ORGANIZATION OF FEATURES), the central issue of locality (CHAPTER 81: LOCAL ASSIMILATION), markedness (CHAPTER 4: MARKEDNESS), and the phonetic bases of phonological patterning. In this section, we review various analyses of transparency and opacity. Our aim is to highlight the central issues and the key insights, and to point out the areas where improvements can be expected.

The first generative account of vowel harmony is considered to be Lightner (1965). Lightner promoted the intuition that stems in vowel harmony languages are marked for a value of the feature exhibiting harmony. In this "root-marker" approach, the Akan stem for 'pierce' [fiti] would be marked for the feature [+ATR] and 'show' [cɪrɛ] would be marked for [−ATR] (data from the Asante dialect of Akan; Clements 1985). This feature is then realized on all vowels of the stem and on harmonizing affixes that may appear in combination with the stem. Representative derivations of [o-fiti-i] 'he pierced it' and [ɔ-cɪrɛ-ɪ] 'he showed it' are given in (6). The intuition that the harmonizing feature is a property of the stem or, more precisely, that it is not a property of any particular segment in the stem invited attempts to treat vowel harmony in ways parallel to contemporary proposals on the treatment of tonal phenomena (Goldsmith 1976). In the domain of tone and around the same time in the development of phonological theory, substantial attention was devoted to data where tonal melodies on a tier independent from that of the segmental sequence are associated to the segmental sequence via general principles of association. Spreading, specifically, is the operation that adds association lines between, say, a single low or "L" tonal specification and each vowel in the stem. The same formal mechanism of spreading could then be applied to vowel harmony (Clements 1976). The main intuition of the "root-marker" approach, feature sharing among multiple vowels in stems or in stem plus affix combinations, could thus be expressed via this independently motivated formal mechanism of spreading. Employing the same formal mechanisms for such disparate phenomena as tone, vowel harmony, and non-concatenative morphology provided the main momentum for the appeal of the autosegmental approach.

(6) *Analysis of ATR harmony in Akan*

a. o-fiti-i → o-fiti-i

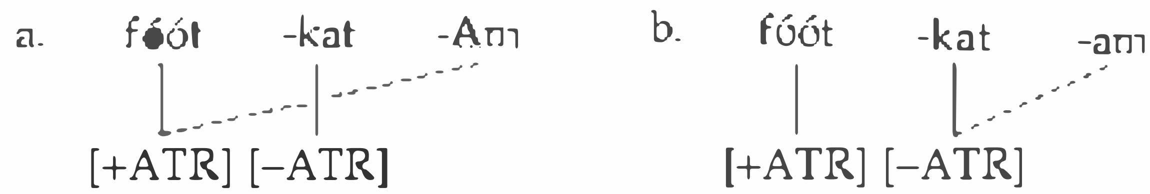
[+ATR] [+ATR]

b. ɔ-cɪrɛ-ɪ → ɔ-cɪrɛ-ɪ

[−ATR] [−ATR]

An immediate consequence of pursuing such an approach to vowel harmony is that the behavior of opaque vowels seems to follow from independently motivated constraints on autosegmental representations. For instance, in Clements (1976, 1980, 1985), opaque vowels are specified with their values for the harmonic feature, so that such a pre-existing association on an opaque vowel blocks spreading from the stem beyond the opaque vowel. The blocking is due to the well-known constraint against crossing association lines. To make this concrete, recall that in Wolof /a/ is in some cases opaque to [ATR] harmony and, in those cases, the vowel surfaces as [−ATR]. For instance, when the suffix [kat] intervenes between a stem and another suffix, it blocks harmony from a [+ATR] stem to the following suffix. In (7), we show how this fact follows from autosegmental principles. The feature specification of the stem vowel cannot spread to the suffix, as shown by the dashed line in (7a), because it would result in line crossing; 'A' denotes a low vowel unspecified for the value of [ATR]. The only allowable result is (7b), where the [−ATR] specification of [kat] spreads to the following suffix. In different words, opacity is seen here as a reflex of the fundamental phonological principle of locality. The final suffix receives its featural specification from its closest eligible donor, its preceding vowel, not from the first stem vowel, which is further away.

(7)



Unlike opacity, transparency has proved to be a recalcitrant problem for phonologists throughout the past approximately fifty-year period of theoretical developments. In autosegmental approaches, the behavior of transparent vowels was not as directly derivable from general principles of representations as was the case with opaque vowels.[5] Consider, for example, the Hungarian diminutives of the proper names *Erzsébet* and *Klára*, *Erzsi* [ers-i] and *Klári* [klaːr-i]. When the diminutives are further combined with the endearment suffix [-kɔ/-kɛ], the result is [ers-i-kɛ] *vs.* [klaːr-i-kɔ]. How is the backness of the suffix transmitted to the suffix vowel? Clements (1976) proposes that, in a first step, the feature [+back] spreads to all vowels of the stem–suffix–suffix combination, including the medial [i]. This step expresses the intuition, by means of spreading, that the suffix is back because the stem vowel is back. But it also results in a representation where [+back] is linked to the medial high, unround vowel. Hungarian lacks such non-low, unround, back vowels. In Clements's (1976) analysis, then, this intermediate representation is corrected by linking [−back] to that vowel. This latter step is conceptually equivalent to the absolute neutralization rules of rule-based analyses, as in Vago (1976, 1980a). Its technical implementation in autosegmental accounts, however, effectively deconstructs the result of the first spreading step to a representation where each vowel has its own separate specification of backness (S. R. Anderson 1980, in a critique of such approaches to vowel harmony, calls this the "mitosis" step; Kenstowicz 1994 brings out independent issues with such manipulations on autosegmental representations). Kiparsky (1981), Clements and Sezer (1982), and Ringen (1988) propose variants of this basic analysis that proceed to either parameterize the harmonic feature-bearing units or keep the features at a different plane from that in which vowel harmony applies (or keep the features at a different tier, as in those accounts that hold the relevant featural specifications of transparent vowels "locked in" the so-called segmental core). The effect of such elaborations is that, in languages with transparent vowels the spreading envisioned in the first step of Clements's (1976) analysis above would not link to these vowels at all. The "correction" step could thus be avoided. Representative works pursuing this perspective are Kiparsky (1981), Goldsmith (1985), Steriade (1987), and Ringen (1988); for critical reviews, see Kenstowicz (1994: 357–359), Farkas and Beddor (1987), and Steriade (1995: 135ff.).

The issue of transparent vowels first participating in harmony and then being readjusted in some way persists across different phonological theories. Thus,

[5] Rule-based accounts of transparency either write in the rule the optional transparent material that can intervene between trigger and target (Ringen 1975: 24) or apply the rule of vowel harmony to all vowels in the stem. In the latter case, the representations are then adjusted so that transparent vowels end up with the expected values for the harmonizing feature (via neutralization rules, as in Vago 1980a).

in Ringen and Vago's (1998) Optimality Theory (OT) analysis of Hungarian, both the representations and the constraints encode a distinction between transparent and all other vowels. On the side of representations, the transparent vowel in e.g. [klaːr-i-ka] is assumed to be unspecified for backness. In Ringen and Vago's (1998) analysis, this assumption crucially enters into the evaluation of the constraint, ensuring that the harmonizing feature links throughout every vowel in the word. That constraint is defined in such a way that it is not violated by the presence of a transparent vowel placed between two back vowels (see e.g. Ringen and Vago 1998: tableau (12)). On the side of the constraints, the distinction between transparent and non-transparent vowel is encoded in the constraint set used in Ringen and Vago (1998) (see e.g. the definition of their constraint in (5b)). Baković and Wilson (2000) and Ní Chiosáin and Padgett (2001) are two later approaches illustrating the same issue. The technical details among the different accounts are of course rather different, but the problem of transparency has remained a persistent challenge.

In early OT (Prince and Smolensky 1993) accounts of vowel harmony, the key notion of spreading is inherited from autosegmental approaches. The formal implementation of spreading pursued an extension of the constraint schema known as ALIGN (McCarthy and Prince 1993). ALIGN constraints were originally used for aligning morpheme edges with prosodic domain edges. For feature spreading, as in vowel harmony, alignment constraints require the alignment of harmonizing features with selected edges of domains. Apart from this, however, within the scope of early OT (Prince and Smolensky 1993) applications, attempts to address the transparency challenge were less reliant on representational assumptions. Thus Smolensky (1993), in his treatment of transparency in Finnish harmony, proposes that the reason for the transparency of [i] is that the feature combination that would result from imposing [+back] on [i] is marked – his constraint *[+B/I]. This constraint is ranked higher than *EMBEDDED, which penalizes embedded feature domains. Then, if ALIGN[+back] is ranked higher than the constraint against *EMBEDDED domains, this results in transparency (the other ranking results in opacity; see Kirchner 1993, Akinlabi 1994, Pulleyblank 1996, Cole and Kisseberth 1995, and Ringen and Vago 1998 for related analyses and discussion). This solution, then, excludes transparent vowels from the domain harmony. But because these vowels intervene between two vowels that agree in terms of the harmonizing feature, this analysis forces the conclusion that harmony can be non-local. Arguably, on both formal theoretical and typological grounds (McCarthy 1989; Clements and Hume 1995; Gafos 1999; Ní Chiosáin and Padgett 2001), this conclusion is considered unwarranted. Subsequent accounts of vowel harmony in OT, discussed below, make efforts to maintain locality in vowel harmony while accounting for opacity and transparency.

In one such account, Kiparsky and Pajusalu (2003) construct a typology of vowel harmony, with a special focus on neutral vowels. In Kiparsky and Pajusalu's system, the presence of vowel harmony is a consequence of a high-ranked constraint AGREE[F], where F is the harmonizing feature; thus, AGREE[ATR] for "tongue root" vowel harmony languages or AGREE[back] for "palatal" vowel harmony languages, and so on. The constraint is formulated in (8) in a way that maintains strict locality – evaluating a candidate with respect to this constraint never requires comparing segments that are not adjacent in the articulatory domain (Gafos 1999; Baković 2000: 4).

(8) AGREE[back]

Articulatorily adjacent vowels must have the same specification for the feature [back].

In addition to AGREE constraints, the Kiparsky and Pajusalu system works with two more types of constraints: markedness constraints such as "front vowels must be non-low and unrounded (*ä, *ö, *ü)," which oppose harmony, and positional faithfulness constraints such as IDENT-FOOT$_1$, which forces faithfulness to an initial foot, and IDENT-STEM. Kiparsky and Pajusalu (2003) use the latter constraints to account for "derived environment" asymmetries in harmonic patterning. Specifically, such domain-specific constraints can capture the pattern that harmony may be stricter in derived environments (CHAPTER 88: DERIVED ENVIRONMENT EFFECTS) than within a morpheme, and stricter in non-initial feet than in the more salient and thus phonologically privileged initial foot. This is formally implemented using the concept of constraint conjunction. In OT, Smolensky (1993, 1995, 1997) has argued that two constraint violations are worse when they occur locally than when they occur non-locally (CHAPTER 62: CONSTRAINT CONJUNCTION). This idea appears to be useful in capturing patterns of optimization in a wide range of cases (see Smolensky 1993, 1995, 1997, on segmental markedness, sonority profiles, and vowel harmony, respectively; Alderete 1997 and Itô and Mester 1998 on dissimilation; Gafos and Lombardi 1999 on consonant transparency; among others). To express this property of constraint violation, Smolensky proposed that the constraint component of OT includes "an operation in UG [Universal Grammar] by which two constraints governing substructures of a given local domain are conjoined into a higher ranked constraint" (Smolensky 1993). This operation, called Local Conjunction, is defined in (9).

(9) *The Local Conjunction of* $_1$ *and* $_2$ *in domain* D

$_1$ &$_l$ $_2$ is violated when there is some domain of type D in which both $_1$ and $_2$ are violated. Universally, $_1$ &$_l$ $_2$ >> $_1$, $_2$.

One use of constraint conjunction in the Kiparsky and Pajusalu (2003) system concerns patterns of stem-internal harmony. Thus, in Finnish, front and back vowels contrast in the second syllable of a stem, *sinä* 'you' *vs.* *kina* 'squabble', *riittä* 'suffice' *vs.* *viitta* 'cloak'. But beyond the first foot this potential for contrast disappears: *kipinä* 'spark', **kipina*. Furthermore, in morphologically complex contexts or "derived environments" such as stem–suffix combinations, the harmonic forces are stronger than within stems: thus, *viit-tä* 'five-ABESS', **viit-ta*. To account for this patterning, a constraint conjoining the individual IDENT-FOOT$_1$[back] and IDENT-STEM[back] constraints is employed.

(10) *Locally conjoined constraint*

IDENT-FOOT$_1$[back] & IDENT-STEM[back]: an [αback] input segment in the first foot of a stem cannot have a [$-\alpha$back] output correspondent.

As a consequence of this constraint, AGREE violations are allowed within morphological or prosodically privileged domains such as the stem or the first foot. In (11) this is formally expressed by the ranking IDENT-FOOT$_1$[back] & IDENT-STEM[back] >> AGREE[back].

(11) *Agreement violations admitted within the privileged domain of the stem/first foot*

	IDENT-FT$_1$[bk] & IDENT-STEM[bk]	AGREE[bk]
☞ a. ([viita])$_{Ft}$		*
b. ([viitä])$_{Ft}$	*!	

Since stems impose their backness value as in *viit-tä*, we must also posit the ranking AGREE[back] >> *ä, *ö, *ü. For *viit-tä*, the conjoined constraint is silent, since the suffix vowel is foot-initial but not stem-internal. But in Uyghur, when the neutral vowel is the only vowel in the stem, the suffix is back: [[i] a], *[[i] ä], where brackets indicate morphological constituency. This difference between Finnish and Uyghur in the way sole transparent vowels combine with suffixes is strikingly simple, and Kiparsky and Pajusalu (2003) propose a formal analysis that seems correct. In Finnish, the ranking is AGREE[back] >> *ä, resulting in transparent vowels imposing their frontness on suffixes despite the markedness of low front vowels: [[i] ä], *[[i] a]. In Uyghur, *ä >> AGREE[back], resulting in transparent vowels failing to impose their frontness on suffixes: *[[i] ä], [[i] a].

When in the context following a back vowel, however, Finnish and Uyghur exhibit the same pattern, namely [[a i] a], *[[a i] ä]. This is the case of transparency, to which we turn next. To account for transparency, Kiparsky and Pajusalu (2003) build parsimoniously on the ideas used in capturing the stem-internal *vs.* derived environment effects described above. As discussed, stem-internally in Finnish, some disharmony is allowed, but [ä a] sequences are not permitted. The key insight here from Kiparsky and Pajusalu (2003) is that harmony violations with marked vowels are avoided, or in other words "disharmony with marked vowels is both worse than disharmony alone, and worse than markedness alone" (Kiparsky and Pajusalu 2003: 8). Formally, this insight enters the grammar as another locally conjoined constraint, shown in (12). As a direct effect of this constraint, *[a ä] is excluded because [ä] is marked and the sequence is disharmonic, but [i a] is admitted because the sequence is disharmonic but none of the vowels is marked.

(12) *Generalized Marked Harmony*

AGREE[back] & *ä, *ö, *ü

This key intuition, capturing such facts about stem-internal harmonic patterning, can be extended to account for transparency. Specifically, as shown in (13), the ranking Generalized Marked Harmony >> AGREE[back] results in transparency. Given /a i – ä/ as input, and comparing candidates [[a i] ä] and [[a i] a], the former candidate incurs a violation of Generalized Marked Harmony: the first two vowels in this string disagree in terms of the harmonic feature, and the last vowel is marked with respect to that feature. The other candidate, [[a i] a], does not violate Generalized Marked Harmony, because it does not contain a marked vowel, though it does incur two violations of AGREE[back].[6] This is the ranking accounting for the case of transparency in Finnish and Uyghur.

[6] This use of constraint conjunction does away with the domain specification in the original definition of conjoined constraints (see (10)), in that evaluation of the conjoined constraint pools violations of the individual constraints irrespective of their locus in the form being evaluated; hence the "generalized" in the constraint reference.

(13) *Transparency*

/a i - ä /	Agree[bk] & *ä,*ö,*ü	Agree[bk]
a. [[a i] ä]	*!	*
☞ b. [[a i] a]		**

In this approach, then, the backness of the suffix vowel is related to the backness of the first stem vowel in a novel way. The reason why markedness in the suffix is a decisive factor is that the first two vowels, [a i], disagree. Since the second vowel is a neutral vowel (hence, front), disagreement implies that the first vowel must be back. Constraint conjunction imposes in this indirect way the same value of backness between the first and the third vowel.

Flipping the ranking of the constraints needed to get transparency results in opacity. That is, with the opposite ranking, Agree[back] >> Agree[back] & *ä, *ö, *ü, and for input /a i – ä /, Agree[back] decides in favor of the opaque candidate [[a i] ä]. This is the pattern observed, for example, in Eastern Khanty. However, note that, in the ranking necessary to express opacity, Agree[back] >> Agree[back] & *ä, *ö, *ü, the conjoined constraint is outranked by one of its constituent constraints. This is generally ruled out in OT (see Kager 1999: 393).

(14) *Opacity*

/a i - ä /	Agree[bk]	Agree[bk] & *ä,*ö,*ü
☞ a. [[a i] ä]	*	*
b. [[a i] a]	**!	

It is a notable corollary of the Kiparsky and Pajusalu (2003) system that back vowels in "palatal" harmony languages are opaque rather than transparent. That is, in the system entertained here, [[ä o] ä] is harmonically bound by [[ä o] a]. The sequence [[ä o] a] violates Generalized Marked Harmony (12) once and Agree[back] once. The sequence [[ä o] ä] violates Generalized Marked Harmony twice and Agree[back] twice. Thus, regardless of the ranking between the two constraints, Generalized Marked Harmony and Agree[back], [ä o ä] is less harmonic than [ä o a]. This is a remarkable result, following from two "first principles" in the Kiparsky and Pajusalu system: markedness and agreement.

We now return to the Hungarian facts, to work out the implications of transparency and opacity being present in the same system. To account for transparency, we must posit the ranking Agree[back] & *e >> Agree[back] (henceforth, when referring to Hungarian forms, the symbol for the low front vowel will be "e" in place of Kiparsky and Pajusalu's "ä" symbol). The candidate illustrating opacity, [[a i] e], violates the conjoined constraint Agree[back] & *e, *ö, *ü, because "e" is marked for the harmonizing feature [back] and [i] is disharmonic for [back]. This entails the desired harmonic ordering, that is, [[a i] e] (opacity) < [[a i] a] (transparency).

(15)

	AGREE[bk] & *e,*ö,*ü	AGREE[bk]
☞ a. [[a i] a]		**
b. [[a i] e]	*!	*

In this formal system, then, markedness as embodied by the *e constraint plays a crucial role in deriving transparency. However, Hungarian presents a problem here. The vowel *é* [eː] is a mid vowel, whereas *e* is a low or at least lower vowel, typically transcribed as [ɛ] (Siptár and Törkenczy 2000: 385, 426). This is the standard phonological classification. Furthermore, ultrasound imaging data show a rather clear difference in tongue height between the group [iː i eː] and [ɛ]. The latter vowel shows a much lower and more retracted tongue body posture than the other vowels. In Hungarian, there are suffixes with front non-low surface alternants such as the adessive [-neːl]/[-naːl]. The markedness constraint "front vowels must be non-low and unrounded (*e, *ö, *ü)" would not be violated by the vowel in [-neːl]. The conjoined constraint Generalized Marked Harmony would therefore also not be violated in [[a i] eː], and the decision is made by the other constraint AGREE[back], which declares [[a i] eː] > [[a i] aː]. This is the wrong outcome. In Hungarian, the choice between [-neːl], [-naːl] is made in the same way as for other suffixes such as the dative [-nɛk], [-nɔk].

Furthermore, unlike Finnish and Turkish, Hungarian admits disharmonic stems with marked vowels such as [fotel] 'armchair' and [farmer] 'jeans'. Hungarian also has back-initial stems followed by front round vowels as in *sofőr* 'driver', *parfüm* 'perfume', and *kosztüm* 'costume'. These words are relatively recent loans (Kertész 2003: 67), perhaps belonging to a lexical "periphery" in the sense of Itô and Mester (1995). Nevertheless, in their harmonic behavior they are completely regular. To account for the opacity pattern exhibited in these stems, the ranking schema must be AGREE[back] >> Generalized Marked Harmony. But recall that the transparency pattern required Generalized Marked Harmony >> AGREE[back]. The relevant datum is sequences of the [[a y] e] profile, the opaque candidate, *vs.* [[a y] a], the transparent candidate (see (16)). The crucial decision rests on how AGREE[back] & *e, *ö, *ü is evaluated. In [[a y] e], [a y] disagree and e is marked. This is the same profile of violations for the transparent winner [[a i] a] discussed above, and implies at least one violation of AGREE[back] & *e, *ö, *ü. Furthermore, the subsequence [a y] may also be considered to violate AGREE[back] & *e, *ö, *ü exactly as assumed for the stem-internal [ä a] sequences in Finnish above: [a y] disagree and [y] is marked. If two violations of AGREE[back] & *e, *ö, *ü are assigned, then [[a y] a] is the predicted winner. If only one violation of AGREE[back] & *e, *ö, *ü is assigned, then [[a y] e] is the correctly predicted winner.

(16)

	AGREE[bk] & *e,*ö,*ü	AGREE[bk]
a. [[a y] a]	*	**
b. [[a y] e]	*(*?)	*

In this system, it is conceivable to split the conjoined constraint into two separate ones: AGREE[back] & *e and AGREE[back] & *y. This permits more freedom in differentially weighing violations of the corresponding constraints, as shown in (17). But in this case, this change does not help, since to account for transparency we must posit AGREE[back] & *e as the highest-ranked constraint. This constraint is violated by the attested output [[a y] e], which is thus predicted to be sub-optimal.

(17) *Splitting the conjoined constraint*

	AGREE[bk] & *e	AGREE[bk]	AGREE[bk] & *y
☞ a. [[a y] ə]		**	*
b. [[a y] e]	*!	*	*

The challenges reviewed so far derive from a single formal property of the analysis: the rankings of constraints needed to account for transparency and opacity are different. There is no hard evidence a priori that this must be true of any system that aims at capturing both transparency and opacity. After all, focusing on palatal vowel harmony systems and without loss of generalization, within any given language, the transparent vowel is different from the opaque one, e.g. [i] is transparent and [y] is opaque in Hungarian/Finnish. An alternative approach to transparency and opacity could capitalize on inherent properties of the vowels in question while leaving the general schema of grammatical forces the same.

The need for different grammar rankings for transparency and opacity can be traced to a crucial assumption. That assumption is that transparent vowels categorically do not partake in agreement, as required by harmony. In other words, (all) transparent vowels categorically disagree with their adjacent vowels. A diametrically opposed perspective is to abandon this key assumption of disagreement and devise a system admitting differential agreement relations between vowels – that is, not simply agree *vs.* disagree, but a spectrum of agreement qualities tailored to the specific combination of vowels involved in the relation for which agreement is assessed. Beňuš (2005) develops this approach on the basis of a rigorous experimental study of Hungarian transparent vowels. The general schema governing both transparency and opacity in Beňuš's account is expressed by a single ranking: PERCEPTUAL FAITHFULNESS >> AGREEMENT >> ARTICULATORY FAITHFULNESS. The broad correspondence between the constraints in this ranking and those discussed so far is as follows. AGREEMENT corresponds to AGREE[back], requiring overlapping vowels to agree as much as possible in constriction location. Its opposing but lower-ranked constraint is ARTICULATORY FAITHFULNESS. This corresponds to IDENT[back] of previous accounts. The ranking AGREEMENT >> ARTICULATORY FAITHFULNESS expresses the simple fact that the language exhibits vowel harmony. The dominating PERCEPTUAL FAITHFULNESS restricts the harmonic agreement forces to degrees of agreement that leave the perceptual identity of the vowels in question unchanged. The closest parallel to PERCEPTUAL FAITHFULNESS in contemporary OT accounts is Baković and Wilson's (2000) similarity scale – in that analysis, transparent vowels are by-products of an optimization starting with the full assimilation candidate and changing that to a less marked candidate, while maintaining similarity with the full assimilation candidate. Overall, then, the main idea in Beňuš's proposal is that vowel harmony is driven by articulatory agreement between overlapping vowel gestures and that this agreement is constrained perceptually. In an A–I sequence, where "A" represents any back vowel and "I" any front vowel, vowels differ with respect to their potential for agreement: following any given back vowel, a high front vowel like /i/ is most retractable, a mid front vowel like /e/ is somewhat retractable, and the high front round /y/ is minimally retractable. Articulatory–perceptual quantal relations are crucial in determining the degree to which a vowel can be retracted without losing its perceptual identity. For transparent vowels, such as the [i] in the sequence [[a i] V_{suffix}], articulatory agreement with the preceding back vowel can be substantial without changing the perceptual identity of the [i]. In turn, the degree of articulatory backing induced on the transparent vowel by agreement with its preceding back vowel is sufficient to trigger a back suffix, hence [[a i] a]. For opaque vowels, the ranking of constraints remains the same. The difference in behavior between opaque and transparent vowels derives from the quantal characteristics of the different vowels. In [[a y] V_{suffix}], the front round vowel cannot be retracted to the same degree as the vowel [i] without losing its perceptual identity as a front vowel. The limited potential of agreement with a back vowel for [y] results in less articulatory backing on the [y], which in turn results in the selection of a front suffix, hence [[a y] e]. In other words, the high ranking of PERCEPTUAL FAITHFULNESS prevents establishing articulatory agreement to a degree that would induce a back suffix alternant just when the front vowel is [y].

The typological implications of the phonetically informed approach pursued in Beňuš (2005) have yet to be pursued systematically. That approach crucially relies on rigorous phonetic records. There is a great disparity between the range of languages whose vowel harmony patterns have been described or even analyzed in the theoretical literature and those for which we have systematic phonetic investigations for the same or even a subset of the same data. Apart from Beňuš's studies on Hungarian and some more recent data on transparency from Kinande, to be discussed in the next section, there are no other studies we are aware of that have systematically examined transparency and opacity patterns in vowel harmony using rigorous experimental methods. It would not be an exaggeration to state that we have only recently begun to register the phonetic record for transparency and opacity using rigorous (i.e. non-impressionistic) data registration methods.

Thus two key insights have emerged. In the typological study of Kiparsky and Pajusalu (2003), markedness and its prioritization with other generally accepted grammar principles such as AGREE go a long way in capturing essential distinctions between the different languages reviewed in that study. The other idea, from Beňuš's (2005) experimentally based work, is that considerations of the relation between articulation and acoustics play a crucial role in transparency and opacity. It seems that a combination of the two insights, supported by a parallel pursuit of theoretical and experimental work, would provide a solid basis for gaining a better understanding of the phenomena at hand.

4 Phonetic bases

Understanding the phonetic bases of opacity and transparency must begin with an understanding of the phonetic bases of vowel harmony in general. Since Gay (1977, 1978), it has been known that a non-contiguous sequence of identical vowels such as [u–u] in *kutup* is produced by speakers of English with a discontinuity in both the articulatory and the electromyographic measures of lip rounding. For example, in the electromyographic signal there is a trough coincident with the production of the intervening consonant. The cessation of muscle activity during the consonant is consistent with the hypothesis that the linguistic representation underlying the production of lip rounding schedules the rounding of the two identical vowels as two independent events, $[u]_{Round}C[u]_{Round}$ (C is a variable for any permissible intervocalic consonant or consonant cluster). A number of other studies have documented the same trough pattern in the production of non-contiguous identical vowels in Spanish, French (Perkell 1986), and Swedish (McAllister 1978; Engstrand 1981). In contrast to these cases, Boyce (1988, 1990) found in Turkish a plateau of continuous activity for /uCu/ utterances both in muscle excitation patterns (of the orbicularis oris) and in lower lip protrusion kinematics. This pattern of results, the English trough *vs.* the Turkish plateau, seems to reflect the fact that Turkish but not English has vowel (rounding) harmony. Furthermore, the linguistic representation underlying the production of lip rounding in Turkish is consistent with a central idea of autosegmental theory, namely that assimilation and harmony involve representations in which a single instance of the assimilating or harmonizing property extends over a domain encompassing all segments required to agree on that property. Thus, in Turkish, the rounding property of the two vowels would extend over a domain encompassing both vowels in /uCu/ (Clements 1976; Kiparsky 1981; Goldsmith 1985), and this is what gives rise to the plateau seen in Boyce's study. Open issues do remain, however, with establishing a link between linguistic representation and the experimental record here with some degree of confidence (Gafos and Goldstein, forthcoming).

The picture becomes more complex when we consider the facts of transparency. As we have seen, many languages with harmony include vowels that can intervene between the trigger and the target of vowel harmony even when they bear the opposite value for the harmonizing feature. In Hungarian, *papír* selects [+back] suffixes, such as *nak* 'DAT', *húz* 'ALL', *tól* 'ABL', *ban* 'INESS', in agreement with the [+back] value of the initial stem vowel and despite the intervening [−back] value of /iː/. At the heart of the problem that transparent vowels pose for the phonetic basis of vowel harmony is an assumption about their representation. The assumption is that the phonological category of a transparent vowel is invariant across different contexts and irrelevant to the quality of the suffix following the transparent vowel. In an impressionistic sense, the transparent vowels in words like *buli-nak* 'party-DAT', *híd-nak* 'bridge-DAT', and *mamicsi-nak* 'mother-DIM-DAT' are not perceptually different from those in *bili-nek* 'pot-DAT' and *víz-nek* 'water-DAT'. Hence, they are assumed to be invariant across these different contexts. However, it is well known that, for vowels, a relatively stable acoustic output can be produced using multiple articulatory strategies and constriction locations. Stevens (1972, 1989) promotes the idea that the relation between acoustic and articulatory dimensions of phonetic form displays discontinuous characteristics. In "stable" regions of an abstract articulatory–acoustic space, change along an articulatory dimension does not result in significant change in acoustics. In "unstable" regions, however, comparable articulatory change can cause significant difference in acoustics. Stevens argued that Universal Grammar utilizes the presence of such discontinuities in the dual articulatory–acoustic phonetic substance to encode

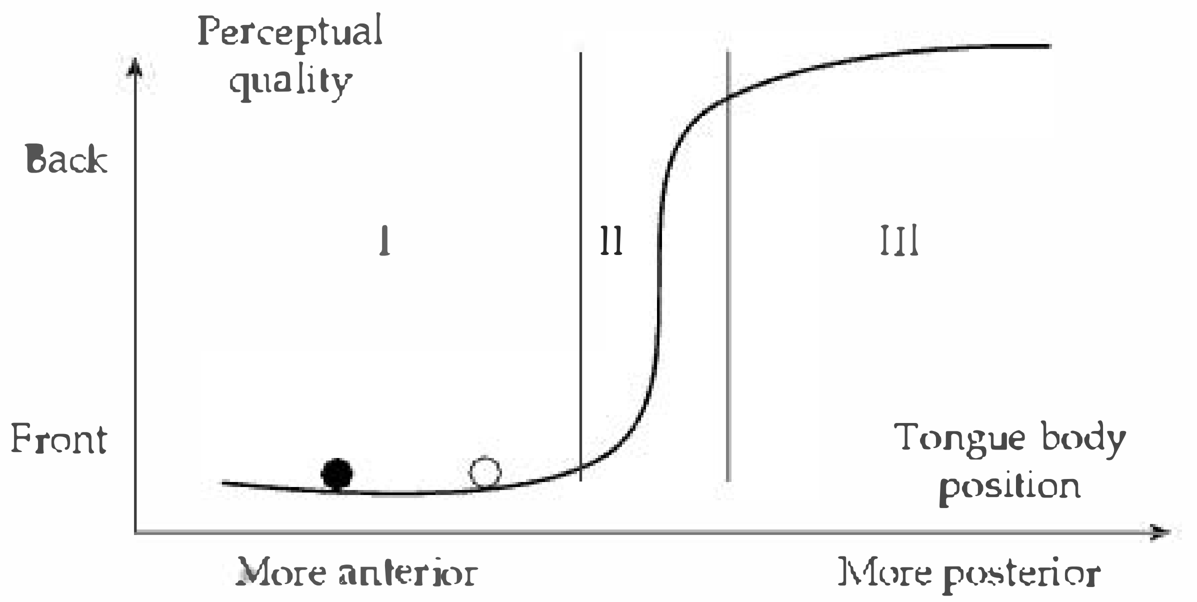


Figure 91.1 Non-linearity in front non-low unround vowels. Tongue body retraction is shown as the difference between the x-coordinates of the two circles, while the minimal perceptual effect of this retraction is shown on the y-axis

contrasts in phonological systems. Moreover, the presence of such regions, according to Stevens, explains why the abundance of co-articulation in natural speech does not hinder perception.

A group of sounds with well-documented discontinuities in the relation between articulation and acoustics is that of the non-low front unround vowels. Calculations using both simple tubes (Stevens 1989) and natural human vocal tract profiles (Wood 1979) show that the acoustic outputs for non-low front vowels are insensitive to a limited amount of variation in the horizontal position of the tongue body. For example, the vowel [i] may be articulatorily retracted to some degree without losing its perceptual identity. The central result is illustrated in Figure 91.1. The S-like curve divides the abstract phonetic space into the stable Regions I and III and the unstable Region II. The horizontal coordinate of the ball sitting on the curve represents the locus of a palatal constriction formed by the tongue body articulator. The black circle corresponds to a tongue body position with the palatal constriction of a prototypically front vowel. The slightly retracted tongue body position illustrated with the white circle falls in the stable region of perceptual stability; a vowel with this constriction location is still considered a front vowel.

We stress that the foundational results of Stevens and Wood above are not about a specific language. Rather, they characterize properties of articulatory–acoustic relations for specific sets of vowels, the non-low front unround vowels, language-independently. These are precisely the transparent vowels of palatal vowel harmony systems like Hungarian and Finnish.

The articulatory–acoustic relations reviewed above provide a plausible phonetic basis for transparency: transparent vowels in palatal vowel harmony are those vowels that can be articulatorily retracted to a certain degree, but maintain their perceptual quality of being front. This hypothesis has been pursued in studies of Hungarian transparent vowels [iː], [i], and [eː] using a combination of electromagnetic articulometry and ultrasound (Beňuš 2005: ch. 4). In these studies, one set of stimuli consisted of word pairs where transparent vowels occur in stems triggering front or back suffixes. In the first set, all words were trisyllabic, e.g. *zefír-ben* 'zephyr'-INESS *vs.* *zafír-ban* 'sapphire'-INESS. Such pairs permitted comparisons of the tongue posture for /iː/ in the two vowel harmony contexts, front and back. The second set of stimuli consisted of monosyllabic words. For example, /eː/ in *szél* 'wind' was compared to /eː/ in *cél* 'aim'. The forms *szél*, *cél* correspond to the nominative case of the respective nouns, where there is no overt suffix. When these stems appear with overt suffixes, *szél* triggers a front suffix while *cél* triggers a back suffix: *szél-nek* 'wind-DAT' *vs.* *cél-nak* 'aim-DAT'. Once again, such pairs permit comparisons of the tongue posture for /eː/ in the two vowel harmony contexts, front and back. However, they differ from pairs like *zefír vs. zafír* in one crucial respect. For *zefír vs. zafír*, the difference in suffix choice, front for *zefír vs.* back for *zafír*, is typically ascribed to the presence of a front *vs.* back stem-initial vowel. In the *szél vs. cél* pairs of stimuli, if systematic subcategorical differences are found in the transparent vowels, then the source of these differences cannot be ascribed to another vowel within the same stem. The results were, first, that transparent vowels in back harmony contexts show a less advanced (more retracted) tongue body posture than phonemically identical vowels in front harmony contexts: e.g. [i] in *buli-val* is less advanced than [i] in *bili-vel*. Second, transparent vowels in monosyllabic stems selecting back suffixes are also less advanced than phonemically identical vowels in stems selecting front suffixes: e.g. [iː] in *ír*, taking back suffixes, compared to [iː] of *hír*, taking front suffixes, is less advanced when these stems are produced in bare form (no suffixes). Because these monosyllabic stimuli were presented in isolation, the observed sub-phonemic differences cannot be attributed to contextual co-articulation. These differences must be part of the speakers' knowledge of these stems.

To review, then, the main result of the above experiments is that the harmonic type of a stem is realized as a sub-phonemic difference in the tongue body position of transparent vowels. Transparent vowels in the front-selecting stems are produced with the tongue body more advanced than the phonemically identical vowels that occur in back-selecting stems. The non-linearity in the articulatory–acoustic relations in these vowels provides a way to understand why the articulatory differences revealed in these experiments cause minimal differences in the acoustic output of these vowels. In turn, we can then understand why in impressionistic transcriptions these vowels are denoted with a phonemically invariant category, even though there are systematic articulatory differences.

The hypothesis that transparency has a basis in non-linearities between articulation and acoustics can be extended to at least two other cases of transparency in harmony. In ATR harmony, we discussed articulatory and perceptual factors contributing to limited contrast potential in the class of vowels commonly exhibiting transparency in these harmony systems. As noted, in Kinande "tongue root" harmony, articulatory, and acoustic data also indicate that the low vowel /a/ is an integral part of the harmony domain (Gick *et al.* 2006; Kenstowicz 2009). In the case of Mongolian, where [i ɪ] are transparent to the spreading of rounding, we see no principled reason why the same hypothesis would not be applicable. If the phonetics of "rounding" is pursued with some care (Disner 1983; Goldstein 1991), lip posture can be hypothesized to spread through the intervening [i] without a substantial effect on its acoustics. Overall, then, the plausible hypothesis is that transparency is not failure to participate in harmony but failure to produce salient acoustic consequences of harmony on a specific class on segments. Kaun (1995: 142) expresses a similar intuition, that for transparent vowels their "occurrence does not constitute a substantial interruption of the signal associated with the extended feature."

The hypothesis grounding transparency in articulatory–acoustic relations may also allow us to understand why certain vowels exhibit transparency, but other similar vowels exhibit opacity. To illustrate this, consider that one important generalization in the phonological patterning of transparency in "palatal" harmony systems concerns front round vowels. Phonologically, front round vowels do not behave transparently. In Hungarian, for example, front round vowels in stem-final position are followed by front suffixes, irrespective of the quality of the preceding vowels (*parfüm-nek*, **parfüm-nak* 'perfume-DAT', *tök-nek*, **tök-nak* 'pumpkin-DAT'). In contrast, front unround vowels can be followed by front or back suffixes. Whence the difference in harmonic patterning between [y] and [i]? The two vowels are very similar in terms of their lingual articulation (Beňuš *et al.* 2003; Beňuš 2005: ch. 4). The only remaining source of difference between [y] and [i] is their rounding. Both Wood (1986) and Stevens (1989) show that rounding in front vowels significantly affects their quantal properties. In front round vowels the degree of perceptually tolerated tongue body retraction is more limited than for unround vowels. The reason for this is the difference in the effective position of the constriction relative to the length of the vocal tract. Lip rounding, as for [y], increases the length of the vocal tract. This effectively advances the stable region in which horizontal articulatory perturbations have minimal acoustic effects (Beňuš 2005: §4.6.2). As a result, the potential degree of tongue body retraction for [y] is minimal as compared to [i]. There is therefore a plausible phonetic basis for the horizontal tongue body position for [y] to be more constrained than that of [i] in the context of adjacent back vowels. Hence, the binary (phonological) choice in suffix form correlates with differences in the quantal characteristics of stem-final vowels: front vowels for which some articulatory retraction is perceptually tolerated are followed by either front or back suffixes, whereas front vowels for which comparable retraction is not tolerated are followed by front suffixes only.

To summarize, the evidence reviewed indicates that a plausible phonetic basis for transparency and opacity can be formulated by reference to the link between articulation and acoustics.

5 Prospects

We have reviewed theoretical and experimental work on transparent and opaque vowels in vowel harmony. Here we highlight some directions for future work.

Just as in other areas of phonological patterning, our understanding of transparency and opacity has been increasingly informed by the availability of new experimental methods. Yet much remains to be done on the experimental side. The main aim should be gaining a more rigorous empirical foundation. Phonological theorizing has relied heavily on impressionistic descriptions of data. In the few cases where harmony data have been examined with experimental methods (Rialland and Redouanne 1984; Beňuš 2005; Svantesson *et al.* 2005; Gick *et al.* 2006; Kenstowicz 2009), the results provide new information that in turn requires revision of past theoretical analyses or inspires new ones.

Closely related to the aim of gaining a better grip on the data is research on perception. The experimental findings from Hungarian and Kinande reviewed above show that transparent vowels have two variants, depending on the harmonic type in which they appear. For example, the Hungarian vowels [iː i eː] show a more advanced variant in the front harmony type words and a less advanced one in the back harmony type words. Yet the phonological literature and impressionistic intuitions of Hungarian native speakers suggest that the two variants are non-contrastive. Ultimately, then, connected to this line of research must be perception experiments, testing the ability of listeners to differentiate transparent vowels embedded in different harmonic contexts.

On the side of theory, in turn, insights from theoretical analyses should be integrated with the new data patterns. Another way to express this is to say that high-level phonological theory should make predictions about results that could be obtained in future experiments (CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY). It is this integration between theory and rigorous data that seems to us most likely to lead to a deeper understanding of the phenomena at hand.

92 Variability

Gregory R. Guy

1 Introduction

Variability is a term used in phonology with several meanings. One common meaning is sociolinguistic diversity: speakers of different social backgrounds speak differently, and all speakers vary in speech style and register. Thus in New York City, as Labov (1966) famously demonstrates, a consonantal articulation of coda /r/ is preferred by higher status speakers, and by all speakers in their more careful styles, while a vocalized or deleted realization is preferred by lower status speakers and in casual styles.

Another sense refers to acoustic and articulatory diversity: English voiced stops can be articulated with voice onset times ranging from negative values to +10 msecs, with a mode around +5 msecs, while their voiceless counterparts typically show VOTs from +20 to +90 msecs. Successive articulations by the same speaker under the same conditions are not identical, but wander around these ranges. Vowels are similarly variable in realization. As Peterson and Barney (1952) showed, a vowel cannot be defined as an articulatory point, or as a particular acoustic realization, but rather as a region in articulatory and acoustic space; a series of measurements of a speaker saying a given vowel will show considerable scatter in this range, and sometimes items that fall outside it.

A third sense of variability addresses simple optionality: phonological characteristics or processes that may or may not occur in certain circumstances. Thus English voiceless stops in final position may be aspirated or not, although those in initial position show aspiration systematically. Hence we can describe aspiration as obligatory in initial position, but optional or variable in final position.

But, despite this range of meanings, variability is simple to define: in its broadest sense it is the inverse of generality. A phonological generalization is a statement about a sound system that is true everywhere, in every relevant occurrence; when some statement is not true everywhere, we encounter a case of variability. A phonological phenomenon that occurs in some, but not all, of its possible instances is not fully general; it is in some respect variable in occurrence (sometimes it happens, and sometimes it doesn't) or in realization (sometimes it happens one way, and sometimes another).

Variability as lack-of-generality is therefore a chronic problem for linguistic analysis. Generalizations are, of course, privileged in linguistics. Linguists are trained to seek generalizations; indeed, we see regularly recurring structures as a defining property of language, and the absence of all regularity as the defining property of noise (i.e. non-language). Consequently, phonology has repeatedly addressed issues associated with defining the frontiers of generality and the treatment of partial generality.

Limits on generality. The search for ever broader and deeper generalizations has been a prominent theme in the history of linguistics. The broadest generalizations about sound systems are phonological universals: statements that are true of all utterances in all languages. A truly universal property cannot be absent or contradicted in some language or some speakers, cannot have lexical exceptions, and must be apparent in 100 percent of cases. Hence a context-free universal can be characterized as in (1):

(1) *Maximum generality: Phonological universals*

For all human speakers (of all languages),
in all linguistic contexts,
in all lexical items,
x is always true.

Any phonological generalization that cannot satisfy all the quantifiers in (1) is less than universal. But this is true of most of phonology; although universals have important status, most work in phonology deals with generalizations that are limited in some respect, for example to a particular language or particular context. Hence, in a sense, most of phonology deals with variability, with partial generalizations that leave a region of variation where non-conforming realizations occur. The phonologist who pursues generality and regularity is therefore always confronted with the task of identifying the limits on the generalization, and the alternatives that occur beyond those limits. This is the problem of variability.

The problem can be approached in terms of the various quantifiers in (1). These are of two types: the "all" quantifiers, which deal with issues of scope, and the "always" quantifier, which addresses prevalence. When these are less than universal, they delineate the several problems of variability. First is social scope: generalizations that are true of only some human speakers (some language, speech community, or ethnic or other social group) constitute cases of social variation. Second is contextual scope: many generalizations are context-sensitive, i.e. valid only for items in a particular structural position. But the definitions of contexts, and indeed of what may count as a relevant context, are substantive theoretical and empirical questions. Various forms for the interaction between context and item have been proposed: a context may be seen as having a categorical effect, a gradient effect, or some other non-categorical outcome. And third is the problem of lexical scope: do phonological processes apply to all relevant words (all that have a given phonological structure in the right context)? Or do some words of the appropriate phonological shape nevertheless fail to conform to an applicable generalization by virtue of their lexical identity? If phonological statements are limited in their applicability to subsets of the lexicon, leaving words or sets of words in which different conditions prevail, we confront problems of lexical variability.

Orthogonal to the problems of scope is the problem of variable prevalence – does a given state of affairs always prevail, or is it encountered only some of the time? Although some theoretical approaches treat this as a scope problem, for example by seeking to define a narrow social or contextual domain in which prevalence is categorical, the logical problem of prevalence exists nonetheless: if all relevant dimensions of scope are held constant, is a given phonological generalization valid for all successive occurrences of relevant forms? If we listen to the same speakers producing the same words in the same contexts, do we always hear the same productions, or do they vary? Does a given process apply 100 percent of the time in the relevant domains, or less than 100 percent? And how does phonology cope with the two scenarios – how does it model categorical prevalence, and how does it account for variable prevalence?

In what follows we consider in turn each of these potential limitations on generality – each of these types of variability. We begin with the question of prevalence.

2 The quantitative limits of generality: Variable prevalence

A linguistic universal has universal prevalence: it always occurs wherever possible. We can describe a phonological generalization that is always true as categorical or obligatory. But how does phonology treat a state of affairs with less than universal prevalence – a generalization that is not categorically true, or a process that is not obligatory? This question lies at the core of what many linguists consider variability.

To illustrate this issue, consider common alternations, found in a number of languages, between presence and absence of coda consonants (CHAPTER 68: DELETION). In natural speech in English, words containing final coronal stops, such as *best*, *old*, are often articulated without those stops (cf. *bes' friend*, *ol' man*). In colloquial Caribbean Spanish and Brazilian Portuguese, syllable- and word-final /s/ is similarly variable in realization: *estamos*, *menos* are often articulated as *etamo*, *meno*. Such facts can be accounted for by phonological deletion processes, which are plausibly motivated by markedness considerations that are likely universal: simpler codas are universally less marked than more complex ones. But in the cases cited, the prevalence of these deletion processes is less than categorical. Not all utterances of eligible words undergo deletion.

These are not questions of scope. The alternations are not restricted to particular words. Although social groups vary in deletion rates, these societies are not composed of some groups or individuals who always delete and others who never do (Guy 1980, 1981). And although these processes show contextual conditioning – for example, all three languages delete more before consonants than before vowels – the contexts do not define domains in which deletion always applies or never applies. No matter how we slice up the data in terms of scope, we always encounter both deleted and non-deleted forms. Hence, the prevalence of these phenomena is less than "always." How does phonology deal with such cases? Or indeed, is phonology responsible for such facts at all?

A phonological state of affairs that does not always prevail needs some statement of limitations on its prevalence. This can be done with quantitative vagueness, by replacing the "always" quantifier in (1) with non-universal quantifiers like "sometimes" or "optionally," or with existential quantifiers like "may occur." Or, a more precise quantification can be used, specifying some frequency or probability of occurrence (CHAPTER 90: FREQUENCY EFFECTS). Thus the prevalence clause on generality can be restated as (2a) or (2b):

(2) *Quantifying prevalence*

a. *Optional generalization*
. . . x is optionally true.

b. *Probabilistic generalization*
. . . x is true with probability p.

As we shall see, these choices are the subject of considerable theoretical debate. Some schools of thought strenuously argue that grammar has nothing to say about frequency or quantification, and consequently deny that statements like (2b) are permissible in formal phonology. Other frameworks embrace to a greater or lesser extent the quantification implied by (2b), seeking to account for variable prevalence by grammatical means. Let us consider the range of arguments bearing on variable prevalence.

The preference for categorical prevalence. Since so much linguistic analysis is inductive, it is unsurprising to observe a long, articulate tradition in linguistic theory of preferring generalizations that are categorical, i.e. true of 100 percent of relevant cases. Generalizations that are not fully general are often treated as valueless. The typical heuristic in linguistic analysis is to hypothesize a generalization, and, if counterexamples are discovered, to seek a reformulation of the generalization that either properly excludes the counterexamples, or accounts for them in another way, perhaps as a consequence of some other generalization (see also CHAPTER 106: EXCEPTIONALITY).

The historical prototype for this heuristic is Verner's (1877) refinement of Grimm's Law, which describes the sound changes characteristic of the Germanic languages. In the early nineteenth century Grimm and others discovered a set of common correspondences between the obstruents of the Germanic branch and those of other Indo-European languages (Rask 1818; Grimm 1819). Among these was the correspondence between Proto-Indo-European voiceless stops and Germanic voiceless fricatives (thus Latin *ped, tres, cornu vs.* English *foot, three, horn*). But there were also many recognized exceptions to these correspondences, so they appeared to fall well short of being categorical "laws." Thus in many words PIE voiceless stops end up as voiced stops or fricatives in Germanic (cf. Old English *fæder, hundred* vs. Latin *pater, centum*). Based on the data known to early nineteenth-century linguists, the Germanic sound-shift might more accurately have been described as a variable process with several outcomes, among which one particular set (those known as Grimm's Law) were quantitatively prominent.

In 1877, this picture was dramatically altered when Karl Verner published a paper showing that one large class of exceptions was regularly conditioned by the position of the word-stress in PIE: the regular fricative outcome for voiceless stops occurs only in initial and post-tonic positions, while the exceptional voiced outcome occurs elsewhere. This discovery removed many counterexamples to Grimm's Law, reducing the domain of apparent variability, and greatly increasing the prevalence of the Grimm's Law generalizations. This allowed the conjecture that a correct definition of contexts would yield two categorical generalizations – two separate conditioned sound changes, each of which *always* occurred in its appropriate context. This conjecture received explicit formulation as the Neogrammarian hypothesis: sound change is "exceptionless," admitting no variation (Osthoff and Brugmann 1878). By this hypothesis, any variability in the data was spurious, deriving from alternate sources such as borrowing, neologism, or dialect mixture, or from an inaccurate statement of the context of the change, calling for a Verner-like amendment of the generalization.

With the emergence of modern linguistics since Saussure (1916), the idea of exceptionlessness became dominant in synchronic phonology: generalizations should be categorical. If a generalization is nearly categorical, the analyst should seek to make it categorical by redefining the context or by explaining the exceptions. Variability, in the sense of a phonological state of affairs for which no redefinition of context yields categorical prevalence, is considered an unhappy outcome by many schools of phonological theory, including structuralism, generative phonology and its various developments, and mainstream Optimality Theory, and it receives little theoretical attention in these frameworks, being tolerated only where empirically necessary.

Optionality. Despite this widespread theoretical preference for categorical statements, the task of accounting for a body of data has always led linguists to the necessity of non-categorical descriptive statements. In American structuralism, this necessity was formally treated in phonemic theory in terms of "free variation" (Swadesh 1934; Hockett 1942). Thus, to account for variable realizations of final voiceless stops in English, a structuralist analysis would present a list of possible allophones in this position which included the aspirated and unaspirated variants. Declaring that these allophones occurred in free variation was equivalent to a statement that their occurrence was random, not subject to further principled (i.e. structural or contextual) analysis. Such an account therefore adopted the strategy of (2a), declaring only that these alternatives all occurred with limited prevalence, but making no attempt to quantify their respective frequencies.

In rule-based generative frameworks, the equivalent mechanism is the "optional" rule: a rule which may apply, generating its output, or fail to apply, which leaves its input to surface unaltered (Chomsky and Halle 1968). Thus the English voiceless stop alternations could be modeled in generative phonology with an optional rule that rewrites the feature matrix of a voiceless stop to include aspiration in final position. When it applies, aspirated forms are generated, but when it optionally fails to apply, an unaspirated realization is generated. Again, this reflects the (2a) approach to variable prevalence, stating only that it exists, without further quantification.

Variable prevalence in OT. The treatment of variability-as-optionality has survived the transition from rule-based to constraint-based models. In constraint-based phonology, optionality can be captured with variable or incompletely specified constraint rankings (Anttila 1997). In Optimality Theory, a fixed constraint ranking is expected to yield a unique outcome for every evaluated form. This is the ranking equivalent of "obligatory" rules: if constraint A outranks constraint B, and the requirements of A and B conflict in some situation, candidate forms must obligatorily satisfy A over B in order to be selected. In most circumstances, the conjunction of the ranked demands of a set of constraints will rule out all but a unique candidate, excluding the possibility of variation.

But Optimality Theory also allows for the existence of a great variety of rank orders, and makes extensive explanatory use of ranking differences. Although OT postulates a universal constraint set, it captures phonological differences between languages by differing constraint rankings. Similarly, dialect differences, and, by extension, all sorts of sociolinguistic differences between individuals, class and ethnic groups, even speech styles and registers, can be modeled as differences in constraint rankings. The theory also models change across time as changes in the rank order of the constraint set. Since different orders generate different outcomes, variable orders within a given grammar will generate variable outcomes, and variable prevalence of any given outcome.

To illustrate, consider the English case mentioned above, final coronal stop deletion (CSD), where alternations like *best* ~ *bes'*, *old* ~ *ol'* occur. To simplify for illustrative purposes, we might model this alternation in OT with two constraints, one that disfavors complex codas (*ComplexCoda), and a generalized faithfulness constraint stating that underlying segments should be realized on the surface (Faith). An OT grammar with these two constraints will generate full forms (*best*, *old*) if Faith is ranked higher, but will generate deleted forms (*bes'*, *ol'*) if *ComplexCoda has the higher ranking. Consequently, if these constraints are variably ranked, the grammar generates both forms in variation. Variable (or underspecified) constraint ranking is thus the OT equivalent of the optional rule.

Competence and performance. All the above accounts – structuralist, generative, and optimality-theoretic – treat variable prevalence in terms of optionality, as in (2a), while eschewing the quantification in (2b). In these schools of thought, the "optionality" approach is considered empirically adequate. For the structuralists, it was typically adequate to account for all the structural patterns in a corpus; hence, a list of options was sufficient. An adequate generative grammar, according to Chomsky (1965), must be able to generate all and only the possible grammatical utterances of a language (or, more properly, of an idealized homogeneous idiolect), and this criterion is largely maintained in OT. In all these frameworks the theory and grammar are responsible only for accounting for the *existence* of a possible form, but not for a more precise account of its likelihood or frequency of occurrence.

The formal models we have considered – the sequence of frameworks that runs from Saussure through the structuralists and generativists to OT – thus say nothing about whether a form is common or rare, preferred or exceptional. In fact, they mostly define such facts as lying outside the purview of grammar and formal linguistics. The limited empirical responsibility of the grammar is seen as a theoretical necessity in these models, as a consequence of a set of assumptions about the organization of language. They claim a fundamental distinction between the system of language (which defines grammaticality, possible structures, etc.), and the usage of that system and the utterances it generates. Linguistic theory, and the grammars that encapsulate linguistic knowledge, are concerned with the former, termed *langue*, competence, or i-language, according to the terminology of the day. The usage speakers make of the system, their productions and utterances, is treated as a separate phenomenon, termed *parole*, performance, or e-language. Performance and production are argued to bear an uncertain relationship to the system, subject to non-linguistic constraints such as errors, interruptions, or memory lapses. And the system says nothing about prevalence. Grammars are postulated to be essentially non-quantitative; in one formulation, "grammars can't count." Properly speaking, such models are weakly quantified: the grammar permits the specification of at most three levels of quantification: "always" (anything obligatory), "never" (anything the grammar doesn't generate), and "sometimes" (anything optional or occurring in free variation). But any more quantitative detail than this is, by definition, a consequence of usage, and hence need not and cannot be modeled by the grammar. Statement (2a) is a possible element of competence, but (2b) is, by this definition, a statement about performance.

The position just described lies on one side of a major fault-line in phonological thought. On the other side lie several theoretical frameworks that take a more expanded view of the empirical responsibilities of grammar, and a different view of the capabilities of grammar. As we see in the next section, these frameworks undertake to quantify prevalence, and admit statements like (2b) as elements of grammar.

Quantified prevalence. Opposed to the models just described are theories in which phonological analysis explicitly engages with the quantitative facts of variable prevalence. Some examples of these are the "quantitative paradigm" arising from sociolinguistic research (exemplified by the variable rule model; Labov 1969; Cedergren and Sankoff 1974), the variable OT models associated with scholars such as Anttila (1997, 2009) and Nagy and Reynolds (1997), the Stochastic OT model (Boersma and Hayes 2001), and "usage-based" models such as Exemplar Theory (Bybee 2001; Pierrehumbert 2001, 2006). The point of departure for these frameworks lies in the empirical evidence demonstrating that many variants have distinctive quantitative tendencies: some forms are recognizably rare, while others are common, frequent, even highly preferred. For example, in American English, final voiceless stops are rarely aspirated, while in other dialects, such as Irish English, aspiration is common (Kirke 2005). Speakers appear to be aware of these quantitative facts in the sense that they faithfully reproduce the aspiration rates typical of their speech communities, and are capable of recognizing speech that shows a different rate as distinctive.

Empirical studies of variation massively document the systematic nature of such quantitative patterns (Labov 1966, 1969; Cedergren 1973; Poplack 1979; Guy 1981). Every language has phonological variables that systematically occur at certain frequencies. This is the quantitative form of structure, and the quantified models we will consider seek to account for this structure. The typical kinds of patterning and systematicity are illustrated in Table 92.1. These data are drawn from a study of CSD in early New Zealand English (conducted by the author with Jen Hay and Abby Walker using the ONZE corpus; cf. Guy *et al.* 2008; Hay *et al.* 2008). As many studies have demonstrated, coronal stop deletion rates are sensitive to following context, here classified as consonants, glides, vowels, or zero (i.e. utterance-final position). The study sample included speakers from several national backgrounds; the table separates those with Scottish backgrounds, English backgrounds, and mixed backgrounds (including Scottish, English, and/or Australian parents and settlement histories).

These data show several highly regular patterns. First, they are not random. Randomness does occur in linguistic production: some phonetic variability in articulation, such as the scatter observed in vowel articulations, is a consequence of random variability in physical gestures; random ordering of constraints is postulated to be a basic feature of the selection mechanism in variable and

Table 92.1 Probabilities of coronal stop deletion in Early New Zealand English, by following context and national background of speakers

	__C	__G	__V	__Ø
Scots	0.84	0.57	0.22	0.12
English	0.77	0.59	0.29	0.18
mixed	0.77	0.71	0.32	0.15
mean	0.793	0.620	0.275	0.151
range	±0.047	±0.09	±0.055	±0.031

Stochastic OT models. But random is not the same as non-categorical (CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). The statistical meaning of randomness is that all possible outcomes are equally likely: when there are two alternants, each should occur 50 percent of the time, like coin flips. Since the possibilities in this case are deletion or non-deletion, a grammar that randomly generated forms would yield deletion probabilities of 0.5. Second, the results show a systematic effect of following context: consonantal contexts promote deletion (glides somewhat less than obstruents), while vowels disfavor deletion and null contexts are associated with the least deletion of all. Third, these contextual effects are regularly observed in all the speaker groups. The rank order of favorability to deletion is C > G > V > Ø for all three groups, and the actual numerical values for each context fall into non-overlapping ranges, tightly clustered around a mean. Each of these speaker groups, of course, constitutes an independent experiment, being made up of separate individuals who had little or no lifetime contact with the other speakers. If they were behaving randomly, it would be essentially impossible for them to converge on common values.

Such findings, echoed repeatedly in studies of variation, are a principal motive for the quantified models considered here. Given quantitative properties of language that are non-random, systematic, and linguistically conditioned, these theories all seek to account for them by grammatical means, which implies statements of prevalence along the lines of (2b). However, the various quantified theories differ substantially in their assumptions and formal models; in the rest of this section we consider the principal models in turn.

Variable rule model. The earliest formally quantified approach was the "variable rule" model (VR), developed by Labov (1969) and Cedergren and Sankoff (1974). This model was conceived as a straightforward extension of generative grammar, in which the rules are all quantified by probability of occurrence. "Obligatory" rules receive the same quantitative treatment as in conventional models: they have a probability of 1. But the distinctiveness of VR lies in the treatment of "optional" processes, here termed variable processes: for these, the probability can be any real number between 0 and 1. This permits a VR model to make specific quantitative predictions for any phonological variable. The values in Table 92.1 are taken from such an analysis, in which the likelihood of deletion was related to following context; VR incorporates a treatment of contextual constraints on a process. Context-sensitivity is of course an essential feature of an adequate account of variability, just as it is essential for adequate accounts of invariant outcomes, as we saw in the Germanic sound-shift case. Contextual limits on generality are discussed further in §4, below.

The probabilistic quantification of VR illustrated in Table 92.1 lends the model all the interpretive significance of real numbers. First, different numbers mean differing effects. A model that only defines options could only say that deletion is optional in all four contexts, but a quantitative model shows relationships of more and less: in this case, that consonants and glides favor deletion most, followed by vowels and then by zero. Second, difference is scalar, distinguishing proximal values from distant values; here following glides are closer in effect to consonants than they are to vowels: comparing means for C (0.793), G (0.620), and V (0.275), the distance from G to C (0.173) is just half of the distance from G to V (0.345). Third, the model is quantitatively comparable and falsifiable: we compared across the speaker groups and found that they all had similar values for these contexts. We could look at other speakers to see if they have similar values, or look at lexical or morphological subsets of the data to see if the context effects remain constant. If they do not, we might explore other predictors of these differences. Finally, precise quantification lets us use the standard apparatus of statistics: tests of significance, central tendencies, dispersion, etc. For example, the values reported in Table 92.1 are significant predictors at the 0.05 level or better.

An important characteristic of VR is that it uses a multivariate analysis to partial out the effects of various predictors or contexts. This has an important practical consequence: it controls for differing distributions of the data across the independent variables. In CSD, for example, the morphology of a word has a substantial effect on deletion rates: past tense forms like *missed, packed* are deleted less than monomorphemes like *mist, pact*. This factor was controlled for in the analysis shown in Table 92.1. But an analysis that failed to do this could yield numbers like those in Table 92.1 purely as an epiphenomenon. Thus if most of the words with following vowels happened to be verbs (in phrases like *messed up, baked it*), while most words with following consonants were monomorphemes (in phrases like *best friend, old man*), a univariate analysis would be open to doubt: do monomorphemes have high deletion rates because they usually occur before consonants, or do following consonants show high deletion because they are most often preceded by monomorphemes? Multivariate analysis, used in VR (and in Exemplar Theory studies; Jannedy and Hay 2006), routinely controls for such problems.

As noted above, the "variable rule" model was originally designed for a rule-based grammar, but it is not wedded to such a formalism. The conceptual framework of VR treats linguistic production as set of choices in which each alternative is associated with a probability. The model is agnostic with respect to whether those choices are modeled as rules, constraint orders, branching graphs (as in systemic functional grammar, cf. Halliday 1985), selections among allophonic inventories (CHAPTER 11: THE PHONEME), or other formal devices.

Stochastic OT. A prominent quantified model in a constraint-based framework is Stochastic Optimality Theory (Boersma and Hayes 2001). As we have noted, conventional OT can generate optional outcomes by means of variable constraint ordering, but says nothing about relative frequencies of particular constraint orders, nor about relative frequencies of occurrence of alternative outputs. This arises from the fact that constraint ranking in conventional OT is purely ordinal:

one can say that A outranks B, but not by how much. There is no concept of A being slightly higher than B, or a lot higher. Stochastic OT adds the concept of proximity. Ranking values in Stochastic OT are real numbers, not sequential positions – values like 92.7, 94, and 101.3, not A >> B >> C. An analogy can be drawn with the results of a horse race: conventional OT tells us which horse finished first, second, third, etc., but doesn't say if the first place finisher won by a nose or a mile. Stochastic OT, however, metaphorically gives the finishing times, from which we can deduce whether A beat B by a tenth of a second, or by several minutes. This concept of proximity is then translated into a likelihood of ranking orders being reversed: if the race is re-run with a certain amount of randomness affecting the outcomes, horses or constraints that are separated by very little might well end up in a reverse order, but a horse that trails by a mile is unlikely to ever make up the distance and come out ahead.

Formally, Stochastic OT postulates that each constraint varies randomly within a probability envelope around its central ranking value whenever it is called upon to evaluate a form; at some points in this range it may outrank other nearby constraints, but at other points it will fall below them in ranking value. By suitably adjusting the ranking values of constraints, this model can match frequency distributions observed in natural data. In the English CSD example, a speaker who deletes 50 percent of the time gets equal ranking values for the markedness constraint (*ComplexCoda) and the faithfulness constraint (Faith), so their order of dominance is completely random. But a speaker who deletes at a low rate like 10 percent would have a ranking value for Faith that is appreciably higher than the value for *ComplexCoda, and the distance between them is such that their probability envelopes overlap in just 10 percent of their total area, representing the region in which the markedness constraint prevails, selecting for deletion.

Variable OT. An interesting variant of Optimality Theory that generates quantitative predictions without an explicit quantitative apparatus within the grammar is found in the works of scholars such as Anttila (1997, 2007) and Nagy (1996; see also Nagy and Reynolds 1997). These approaches treat quantitative patterning in the data as a structural consequence of variable constraint ordering. As noted above, two randomly ordered constraints would, in the long run, occur in the order A >> B at 50 percent of the time, and B >> A the remaining 50 percent. If these orders select different candidate outputs, a random model predicts the two variant realizations should occur in a 50 : 50 ratio. Anttila, Nagy, and their associates have extended this simple observation to larger sets of randomly or partially ordered constraints, sometimes with remarkable results.

The basic device of these approaches depends on the identification of a number of interacting constraints which, if randomly ordered, would generate the appropriate proportions of observed variants. These proportions depend crucially on the number of relevant constraints. Two constraints have just two possible orders, but the number of possible orders (O) increases as the factorial of the number (n) of constraints ($O = n!$). Thus three constraints have six possible orders (ABC, ACB, BAC, BCA, CAB, CBA), four constraints have 24 possible orders, and so on. If these orders occur at random, the variants they select should occur in the ratios of the number of orders that select them.

This can be illustrated with an extension of our simplified example for CSD. If, in addition to the Faith and *ComplexCoda constraints, the more general markedness constraint NoCoda (disfavoring all coda consonants) were included in the variably ordered set, there would be six possible orders, of which only two – those with Faith highest ranked – would select an undeleted form like *best* or *old*. Hence such a system would generate full forms one-third of the time, and deleted forms two-thirds.

The works mentioned above differ in the details of the model. Anttila mostly relies on fully random subsets of constraints, as in the example just presented, while Nagy and Reynolds work with orders that are fixed for some constraints while others "float" within a certain range. This is illustrated in their study of variable word-truncation in Faetar (a Franco-Provençal language in Southern Italy). A word like *brokele* 'fork' has alternate realizations ['brokələ] ~ ['brokl̩] ~ ['brokə] ~ [brok] (plus a few other rarer forms not considered here). Nagy and Reynolds treat this variation as a consequence of variable ordering of the floating constraint Align-PrWd with respect to the members of a specified set of constraints; the ones relevant to this word are the ranked set *Coda >> Parse >> {HNuc, *Schwa} (HNuc = HarmonicNucleus, disfavoring syllabic consonants). When Align-PrWd (which aligns the right edges of the stressed syllable and the prosodic word) is highest ranked, the form [brok] is selected, because the post-tonic syllables in the other alternatives violate Align-PrWd. When Align-PrWd ranks below *Coda, either ['brokl̩] or ['brokə] is selected; the choice between these two depends on the relative order of HNuc and *Schwa (disfavoring reduced vowels), which are variably ordered with respect to each other. Finally, when Align-PrWd falls below Parse (which requires segments in the input to be maintained on the surface), the full form ['brokələ] surfaces.

Counting up all possible tableaux resulting from the variable orders of the constraints they consider, Nagy and Reynolds find 28 possible orders, of which 16 (57 percent) select ['brokələ], 6 (21 percent) select ['brok], while ['brokə] and ['brokl̩] are selected by 3 tableaux (11 percent) apiece. These are the percentages that Nagy and Reynolds's model predicts should be observed in actual data, assuming they have correctly identified the right constraints and orderings. Table 92.2 shows that the data they observed match these predictions fairly closely.

As in this example, variable OT studies have successfully modeled the empirical distribution of phonological variants in several cases (e.g. Anttila 1997, 2009 on case inflections and vocalic phonotactics in Finnish). But the strict linkage they require between number of varying constraints and predicted frequencies of prevalence raises questions about their general applicability. As we shall see, social variability commonly involves differences in prevalence: class

Table 92.2 Variable OT model of word-truncation in Faetar (from Nagy and Reynolds 1997)

variants	*% predicted*	*% observed*
'bro.kə.lə	57	55
'bro.ka	11	15
'bro.kl̩	11	14
'brok	21	10

differences, gender differences, even stylistic differences in the same individual are typically realized as higher or lower overall rates of use of some form. For example, for the English (*-ing*) variable, seen in alternations like *running/runnin'*, higher rates of the velar variant (*-ing*) are found in more careful speech styles and in higher status speakers and females. But studies rarely report any differences in constraints among these social groups. To generate quantitative differences, variable OT models would require different sets of variably ranked constraints for women and men, for different social classes, and even for a speaker's casual and careful speech styles. Nagy and Reynolds suggest that this is true for some of their speakers:

> women, particularly younger women [favor] full forms of the words. For those speakers, ALIGN-PRWD floats at the lower end of its domain, below PARSE, so that the optimal candidate more frequently has all its segments surface . . . In the grammar of the males and oldest women . . . ALIGN-PRWD has a greater tendency to float at the higher end of its domain, above PARSE. (1997: 47)

But such results are atypical in the sociolinguistic literature on variation; indeed, the empirical evidence suggests that speakers in a community tend to share important grammatical properties like constraint rankings (cf. Labov 1969; Guy 1980).

Exemplar Theory. The usage-based models that have achieved prominence in recent years begin with a very different set of assumptions about mental representations and grammatical processes (Johnson 1997; Bybee 2001, 2002; Pierrehumbert 2001, 2006; Hay and Sudbury 2005; see also CHAPTER 1: UNDERLYING REPRESENTATIONS). Instead of the conventional abstract mental representations of words and speech sounds, these approaches postulate that lexical and phonological units are stored in the mind as concrete memories ("exemplars") of the tokens that a speaker has previously encountered. This set of memories is potentially vast – in principle, the exemplar set for a given word may include all the utterances of that word that one has heard in one's lifetime.

Consequently, variability is directly represented in memory. If a speaker has heard a sound or a word pronounced in variant forms, those exemplars are available. Hence the exemplar set provides each speaker with direct knowledge of variation, of the quantitative ratios at which each variant occurs, and of the contextual facts about which contexts favor or disfavor a variant. Each speaker therefore "knows" precisely the values of parameters like those in (2b), quantifying prevalence. (They also know all the details of scope – social, contextual, and lexical, but these are treated in subsequent sections.)

This knowledge is used in production: when speakers compose utterances, they select production targets from the relevant exemplar clouds. Since these targets vary in the same proportions that the speaker has encountered in the input, the speaker faithfully reproduces this variability in production (subject to limitations by certain other factors discussed in §5). Given so rich a set of mental representations, Exemplar Theory relies very little on the abstract processes that are so prominent in other schools of phonology. Indeed, some versions of the theory deny that such processes exist. Consequently, this framework is little concerned with many of the theoretical debates we have mentioned, such as the domain of linguistic description, competence *vs.* performance, etc.

3 The social limits of generality: Sociolinguistic variation

The most obvious limitation on generality in phonology is that so many phonological phenomena are language-specific. Most of the phonology of Chinese has little resemblance to a phonological account of English, Arabic, or Seneca. The features that differ among these languages are thus, in effect, variable elements of universal grammar: different languages vary in terms of whether they have lexical tone, triliteral roots, nasal vowels, and voicing contrasts in the stops. Linguists often take it for granted that the domain of phonological analysis and generalization is a language, but a moment's reflection shows that there are substantive issues at stake here. A "language" is not necessarily a well-defined domain of description. Some things commonly considered languages, like English and Arabic, clearly encompass a wide range of dialects, social varieties, registers, and speech styles, and the differences between any two language varieties can occupy any point on a continuum from near-identity to complete disparity. Some varieties commonly treated as different languages, like Serbian and Croatian, occupy very similar points on such a continuum. Hence phonology faces a systematic issue of how to define the social limits of a generalization. The universal statement must be modified as follows:

(3) *Quantifying social scope*

For speakers in some social domain *i* . . .

(At this level of abstraction we leave open the question of whether the domain *i* defines a language, dialect, speech community, idiolect, speech style, social class, ethnic group, etc., but we return to this matter below.)

This issue has often gone unaddressed by phonologists. When a phonological analysis refers to the social limits of its range of applicability, these are often vaguely defined or deliberately restricted. Some approaches that are commonly encountered are: (i) informal definition of the social domain, using popular labels for languages ("The sound pattern of English"), localities or dialects ("Juchitán Zapotec") or social identities ("upper middle class white speech"); (ii) description of a defined social set ("my informants," "my idiolect"); (iii) definition by linguistic means, such as shared intuitions (speakers who judge a given form to be grammatical). This approach is of course tautological – the grammar accounts for the speakers who use the grammar.

Such approaches leave open questions. Vague definitions make it difficult to identify which speakers are included or excluded; narrowly restricted ones leave it unclear what relevance the analysis has for speakers outside the limits (How might your idiolect differ from mine? How representative of a broader social universe are the speakers who were studied, or who shared a given intuition?) Of course, in some theoretical schools these are not considered linguistic questions. Vague or narrow social scopes may serve a theoretical end: they externalize diversity, facilitating a more homogeneous description.

These issues reflect an unresolved theoretical debate about the domain of linguistic description. In the generative tradition, this domain is narrowly focused on the concept of a mental grammar containing the knowledge required to produce grammatical utterances. Each speaker possesses such a mental grammar, acquired through the interaction between innate capacities (the language faculty or universal grammar) and individual experience. Since the experiences of each individual are unique, it follows that each individual can potentially possess a unique grammar. In this tradition, the scope of a grammar is the speech of the individual who possesses it, the "idiolect." Social variability is therefore extragrammatical, reflecting only the variability between individuals in linguistic experience. The theory and methods of linguistics per se have little to say about sociolinguistic variation.

The principal alternative to the idiolect treats language as a social construct, with an existence independent of any given individual; indeed, the knowledge of the language that exists in a community of speakers is more comprehensive and arguably more systematic than the partial subset available to a single individual (Labov 1966). Linguistic description therefore takes some larger social entity as its object: a language, dialect, or speech community. Some level of social variability therefore lies within the domain of the grammar of the speech community; indeed, some knowledge of social variation in the community is possessed by each individual, and utilized in commonplace linguistic activities such as accommodation to context and interlocutors.

This social focus has deep roots in linguistic theory. Saussure sees linguistics as principally the science of *langue* – an object that characterizes the systematic and general properties of a language as a whole, rather than of *parole* – in which individual and idiosyncratic properties are located. Similarly, the methodological strictures of American structuralism typically define the appropriate domain of linguistic description as a corpus of observations, which could as easily be drawn from a speech community as from a single informant. Since the 1960s this position has been especially associated with sociolinguistic research (see for example, the discussion of "communicative competence" in Hymes 1972). It is from this tradition that most of what is known about social variability has emerged. Two important theoretical issues arise from this work: the nature of linguistic similarity and difference, and the content of grammar.

A central finding of the research on social variability in phonology is what Weinreich *et al.* (1968) term "orderly heterogeneity": social diversity in language use is neither random nor highly idiosyncratic; rather, it shows great consistency and order. The simplest summary of this orderliness is that social proximity correlates with linguistic similarity: you talk like the people you talk to.

The theoretical problem this presents for phonology is to define what it means for the usage of one speaker to be "like" another. Formal phonology has a good account of identity and non-identity; having the "same" grammar means being identical in all respects, while any differences in what speakers accept as grammatical means that they are "not the same" in grammar. But the theory lacks an account of linguistic similarity. My phonology is nearly identical to my brother's, very similar to those of the friends I grew up with, broadly like other speakers of American English whose ethnic and social backgrounds are comparable to my own, quite different from but recognizably related to that of speakers of Australian English, and drastically different from that of a speaker of Vietnamese. How does phonology capture this scale?

Finally, studies of social variability in language shed important light on the content of grammar – what level of diversity is one grammar capable of modeling?

Table 92.3 Overall rates of coronal stop deletion in early New Zealand English, by national background of speakers

	Probability of deletion
Scots	0.18
English	0.33
mixed	0.22

It seems uncontroversial that Kimbundu and Portuguese should be modeled by two different grammars, and that bilingual Angolans who speak both are therefore possessed of two mental grammars. But what about stylistic variation in one language in an individual: does the switch from a casual style, chatting with one's friends in a bar, to careful style, being interviewed for a job, involve different grammars, or modest adjustments to some stylistic parameters within a single grammar?

Research on social variability in language has yielded some answers to these questions. Consider for example the above-mentioned study of final coronal stop deletion in early New Zealand English. As noted, this corpus includes speakers from several national backgrounds. Table 92.1 showed the three nationality groups had very similar effects of following context on deletion. But other aspects of their usage were not so similar.

The first is difference in prevalence: the groups deleted at different rates. Table 92.3 shows overall rates of deletion by nationality. The differences among the groups are significant. The English delete the most, Scots the least, and the mixed group falls in between.

These results lead to an immediate conclusion: prevalence and constraint effects are independent and orthogonal. The nationality groups are significantly different in prevalence of deletion, but nearly identical in following context effects. This is a result that shows up repeatedly in studies of social variation. For example, speakers of different social classes in a speech community may have markedly different levels of prevalence of a socially significant variant, but show the same constraints: thus Labov's (1966) New Yorkers varied wildly in rates of rhotic articulations, but all produced more /r/ in final than in internal position. And speakers vary their styles by adjusting prevalence, using more or less of prestige variants, but without changing constraint effects.

This leaves the question of whether and when contextual effects can differ. In the New Zealand study, the nationality groups showed some differences with respect to several other linguistic contexts, as can be seen in Table 92.4.

Beside following context, all three groups showed a significant effect of morphology, but only two showed an effect of whether the target stop was /t/ or /d/, a different two showed a lexical frequency effect, and only one showed a preceding context effect.

These results demonstrate that different speech communities often differ in constraint effects. A variety of research results show the same finding: the following zero effect on CSD, although constant for the three national groups in Table 92.1,

Table 92.4 Significant constraints on coronal stop deletion in early New Zealand English, by national background of speakers

	Following context	*Morphology*	/t/ vs. /d/	*Lexical frequency*	*Preceding context*
Scots	✓	✓	✓		✓
English	✓	✓	✓	✓	
mixed	✓	✓		✓	

differs significantly in many speech communities (Guy 1980); the contexts for tensing of /æ/ vary substantially in American English dialects (Labov *et al.* 2006; Labov 2007); the contexts affecting subject pronoun expression vary among Spanish dialects (Cameron 1993; Otheguy *et al.* 2007); metrical constraints on Portuguese /-s/ deletion vary among speech communities in Brazil (Guy 2002). However, these and other studies show that, within speech communities, speakers are mostly similar or identical in contextual effects.

Such findings provide an answer to the question posed above about the content of grammar. Grammatical similarity is measured by shared constraints, not by prevalence; within a grammar, prevalence may vary, but not contextual constraints. Speakers within a speech community share a grammar; therefore, stylistic and social class differences in a community consist of differences in prevalence, but not in constraints. Differences in constraint effects imply different grammars, and different speech communities.

What are the implications for phonological theory? The unquantified models considered above, such as generative phonology and conventional OT, do not engage with such facts. Among the quantified models, these results are naturally accommodated in the VR model, which makes a basic distinction between contextual constraints and prevalence, expressed by an overall probability associated with each rule or grammatical choice-point. They are also easily modeled in Exemplar Theory, since all relevant data on both prevalence and context are stored in each speaker's memory to guide their production; indeed, Foulkes and Docherty (2006) argue that an exemplar account "offers the most productive means of modeling sociophonetic variation." But such results are awkward for OT-based models, because they lack an independent representation of prevalence.

This difficulty can be illustrated with the data on overall prevalence in Table 92.3. In a variable OT model like Anttila's (1997), the differences in deletion rates between the three NZ speaker groups can be modeled only by postulating different sets of variably ordered constraints. The 0.33 deletion probability for the English group could be generated by three constraints (P, Q, R) that select for deletion only when P is ranked highest. But to approximate the deletion rate of 0.22 for the mixed nationality group would require adding an additional constraint S to the variably ordered mix, which also prevents deletion if it outranks P. Then the model predicts deletion in the 25 percent of cases in which P was highest ranked of these four. And modeling the 0.18 rate for the Scots group would require still another mix of five or six constraints. This approach thus implies substantively different grammars for any differences in surface ratios, making no distinction between constant grammar and varying prevalence. A Stochastic OT model has a somewhat easier time, since it can predict different prevalence levels in a constant set of constraints, by varying the distances among them on the ranking scale. But how does Stochastic OT model different prevalence for speech styles or social classes in a community where everybody has the same constraint effects? It is a complex, perhaps impossible, mathematical task to generate constant constraint effects like those illustrated in Table 92.1, while simultaneously generating differences in overall prevalence, like those in Table 92.3, simply by sliding the same constraints up or down the ranking value scale.

4 The contextual limits of generality: Context-sensitivity and variability

Phonological theory commonly makes a distinction between statements, processes, properties, etc. that are context-free ("all syllables have a nucleus") and context-sensitive ("English vowels are ordinarily oral, but may be nasalized before a nasal consonant"). In the latter case, context-sensitive operations involve variability: English vowels vary in their realization on the nasal–oral dimension. This implies that the scope of many generalizations must be defined in some statement such as (4):

(4) *Quantifying contextual scope*

. . . in some linguistic context *j* . . .

It is an interesting fact about the discipline that such limitations on contextual scope are a routine part of phonological analysis, while limitations on social or lexical scope are less often examined and are typically seen as problematic. In fact, phonological theory doesn't even consider contextual limitations as variability, provided prevalence is categorical within the context. Following the Grimm/Verner example, a clearly defined contextual scope in which a unique outcome occurs is not a violation of exceptionlessness. The analytical heuristic that seeks to partial out variable outcomes to categorical contexts holds a privileged status in the conceptual armory of phonology. Nevertheless, context-sensitivity raises several issues associated with variability.

As we have seen, contexts are often associated not with categorical prevalence, but with probabilistic effects. Often a linguistic context favors one outcome without precluding others. This is clear in Table 92.1: each following context has a distinct quantitative effect on CSD, but none categorically demands or prohibits deletion.

Importantly, the following segment effects in Table 92.1 have a phonological explanation consistent with a broad spectrum of work on phonotactics and syllable structure. The words that undergo this deletion process end in consonant clusters: . . . CC#. When they occur in running speech with a following word, sequences like . . . CCC . . . (e.g. *west side*), . . . CCG . . . (*west wing*) and . . . CCV . . . (*west end*) result. Universal principles of markedness, sonority sequencing, etc. all agree that CCC is more marked and less acceptable than CCV (CHAPTER 49: SONORITY; CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS). OT constraints like NoCoda, *ComplexCoda, and Onset are designed to capture such generalizations. Sometimes these principles have categorical effect: many languages prohibit CCC sequences completely. The quantitative findings in English reflect the same principles, but with probabilistic effect.

Such results, echoed in numerous studies of variation, have been termed "stochastic generalizations" (Bresnan *et al.* 2001; Clark 2005): generalizations that are categorically true in one language but are probabilistic constraints in another language or social variety. This constitutes crucial evidence against the more extreme theoretical positions favoring categorical prevalence discussed in §2, such as denying the validity of non-categorical generalizations, and exiling all quantitative facts to the grammatically irrelevant terrain of usage and performance. If phonotactic markedness is a continuum (CHAPTER 4: MARKEDNESS), generating categorical effects in some social or contextual domains and probabilistic effects in others, phonological theory should treat it as an integrated phenomenon.

These results also shed light on another area of variability mentioned in the introduction: phonetic gradience. The intermediate effect of following glides in Table 92.1 (promoting deletion more than vowels but less than consonants) reflects an intermediate status for glides on phonetic/phonological scales. Many phonologists treat this as a sonority scale: glides are more sonorous than obstruents but less sonorous than vowels (CHAPTER 15: GLIDES; CHAPTER 49: SONORITY). Syllable structure and the markedness of consonantal sequences also depend on sonority sequencing: for example, many languages prohibit obstruent-obstruent sequences (CC) but permit obstruent–glide sequences (GC or CG). Viewed in this light, the results of Table 92.1 reflect gradient sonority effects: deletion is inversely correlated with sonority of following context. Phonetic properties thus parallel the quantitative behavior of generalizations: in some social and linguistic domains they are involved in discrete (categorical) phenomena, but in other domains they have probabilistic effects. (For an insightful discussion of gradient variability in an OT framework, see Anttila 2008.)

Finally, as seen in §3, context is also a defining element of linguistic similarity: differences in contextual effects define a difference in grammar, while differences in overall prevalence do not. Members of a speech community converge to a remarkable degree on the contextual limits of phonological generalizations, whether categorical or probabilistic, while they vary considerably in prevalence. Collectively, these results suggest that the typical heuristic of seeking linguistic structure by pursuing Neogrammarianesque categorical contexts is misguided, if the analyst ignores the possibility that such types of contextual conditioning are just one point on a continuum. Context is indeed a fundamental element of linguistic structure, but it includes probabilistic as well as categorical conditioning.

5 The lexical limits on generality: Lexical exceptions

The lexical scope of phonological generalizations has been a recurring topic of debate for over a century. The central question is lexical variability in phonology: does a statement or process apply to all relevant lexical items, or are there words that exceptionally fail to show some generalization (CHAPTER 106: EXCEPTIONALITY)? If so, how does the theory account for lexical limits on generality? A generalization that varies across the lexicon, applying to some words, but not all, requires a specification of lexical scope, as in (5):

(5) *Quantifying lexical scope*

. . . in some lexical domain *k* . . .

The debate over the lexical limits of phonology first achieves prominence in the nineteenth century, in connection with the emergence of the Neogrammarians. The Neogrammarian hypothesis specifically asserts lexical universality of phonological change: "exceptionlessness" means no lexical exceptions to a generalization (Osthoff and Brugmann 1878). In fact, the Neogrammarians propose a phonemic model that rules out lexical variability (Paul 1880): words are constituted as sequences of phoneme-like units; phonologically, they have no independent existence apart from the string of phones of which they are composed. Sound change operates on these phones, so when one of them changes, all words containing them necessarily change as well.

At the same time an anti-Neogrammarian critique emerged, arguing that the historical record actually does show lexical variability (Schuchardt 1885). One slogan for this position was "each word has its own history" – a position that affirms lexical variability as forcefully as the Neogrammarians denied it. In the twentieth century, this position re-emerged under the label "lexical diffusion," in work by Wang and his associates (Wang 1969, 1997; Chen and Wang 1975). These scholars argued against the "lexically abrupt" application of phonological change (i.e. categorical processes applying to all relevant words simultaneously), and in favor of a "lexically gradual" model of phonological process, which spreads across the lexicon word by word, in a manner reminiscent of analogical change (see also CHAPTER 93: SOUND CHANGE).

The focus on synchronic phonology in linguistics after Saussure continued to confront lexical generality. As we have noted, the dominant formal theories emphasized the pursuit of invariant generalizations, and largely assumed, with the Neogrammarians, that words are merely assemblages of the phonological units (such as phonemes, feature arrays, autosegments) on which phonological processes operate. Hence these theories give short shrift to lexical limits on generality other than those that can be given a segmental, prosodic, or morphological formulation. They assume that phonological statements normally apply without lexical limits.

But synchronic phonology has witnessed the reappearance of theories that give primacy to the word, and envisage significant lexical variability. Thus Exemplar Theory argues that the word is the primary unit that speakers recognize, remember, and manipulate, and, indeed, that speakers rely on their massive inventories of remembered auditory images (exemplars) of words they have heard as their primary mental database for most of phonology. Phonemes, features, and the like are emergent abstractions or generalizations across those exemplars, rather than primary units of perception and production. For some versions of the theory, abstract phonological operations do not exist; all of phonology is reduced to "phonetic" processes (neuromechanical events such as gestural overlap, gestural weakening, etc.) and "generalizations" that function more like analogies than like phonological operations.

Such a model consequently assumes that lexical variability is a normal state of affairs. Each word has its own phonological identity, and the mental representation of a word, since it incorporates a broad array of remembered exemplars, necessarily includes all the variability that a speaker has encountered hearing people say that word. The theory permits, even predicts, that any statement that might be made about the phonology of a language might have to be lexically qualified word-by-word across the vocabulary.

Empirical evidence. The issues in this debate are partly empirical. Do we observe lexical limitations on phonology? In the historical record, there are quite a few cases that suggest lexical exceptionality. For example, Latin onset clusters containing /l/ changed in several directions in Old Portuguese (Williams 1938; CHAPTER 30: THE REPRESENTATION OF RHOTICS; CHAPTER 31: LATERAL CONSONANTS). Sometimes /l/ becomes /r/, thus *branco, praia, praça, fraco, cravo, regra* (compare cognates in Spanish, which lacks this change: *blanco, playa, plaza, flaco, clavo, regla*). Other words show the entire cluster changing to the palatal fricative /ʃ/: *clavem* > *chave, plenum* > *cheio, flammam* > *chama*. And in numerous cases Portuguese retains the historical /l/: *flor, flamengo, claro, classe, planta*. There are no obvious contexts that predict one or the other outcome, nor do the usual Neogrammarian tactics for resolving lexical effects appear to offer solutions: the exceptional cases do not obviously arise from dialect borrowing, paradigm leveling, neologisms or classicisms, etc. But it should be emphasized that history records many cases where Neogrammarian regularity does prevail. The Grimm's Law changes in Germanic included a shift from IE voiced aspirates ([bh dh gh]) to Germanic simple voiced stops ([b d g]). This change left no lexical residue whatsoever in the Germanic languages, no words that retain a voiced aspirate. Similarly the loss of the voiced velar fricative in Middle English left behind not a single lexical item in which it was preserved, despite the fact that this sound continues to be spelled in English orthography as <gh>, in words like *cough, though, night*. The empirical evidence thus indicates that both patterns occur, although the literature suggests there are far more cases of regular sound change than of lexical diffusion.

In synchronic phonology the situation is similar: the literature attests many processes that apply without lexical limitations, but a substantial number of cases have been reported showing lexical limits; some of these involve just a few words that are exceptions to a general pattern, while others define substantial subsets of the lexicon that show distinctive phonology, such as the Chinese-origin loanwords in Japanese (CHAPTER 95: LOANWORD PHONOLOGY). These cases of lexical variability have attracted considerable attention in phonological theory.

Theoretical solutions. For a survey of theoretical thought on lexical exceptionality, readers are referred to CHAPTER 106: EXCEPTIONALITY. The principal approaches fall into two camps: lexical strategies, which represent exceptionality in the lexical entries, and phonological strategies, which use the phonological apparatus (features, rules, constraints, etc.) to generate distinctive outcomes for exceptional words. Although these are sometimes treated as technical questions about the workings of a theory, they actually raise substantive questions about the workings of the human mind. The lexical approach – encoding exceptionality in underlying representations – effectively assumes that speakers use minimalist, local, memory-based strategies: they simply remember that a word is anomalous. But the phonological approach implies that speakers strive to extract maximum generalities, and are willing to rejig the whole system if there are any efficiencies to be gained. These are matters worthy of direct investigation.

Lexical frequency. The emergence of Exemplar Theory has brought forward additional questions about lexical variability, and stimulated a range of research

Table 92.5 Lexical frequency effect on coronal stop deletion in early New Zealand English

	Log lexical frequency		
	0	1	2
English	0.42	0.50	0.58
mixed	0.41	0.49	0.56

that has revealed important evidence bearing on lexical variability. Since Exemplar Theory postulates that speakers retain a rich set of memories of utterances of words, they have available a great deal of evidence on which to base their linguistic behavior that other theories ignore. One prominent prediction of the theory is that phonological processes should be sensitive to lexical frequency – how often a speaker encounters a word (CHAPTER 90: FREQUENCY EFFECTS). The exemplar set obviously contains frequency information: frequent words have more exemplars. Scholars in this framework have argued that lenition processes should correlate directly with lexical frequency, because lenition is an articulatory process favored by repetition. This prediction has been confirmed in a range of research in the ET framework. For example, in the New Zealand study previously cited, significant frequency effects were found for CSD (Guy *et al.* 2008). Some relevant findings appear in Table 92.5.

For both groups shown, increasing lexical frequency (measured here by the logarithm of the number of occurrences of the item in the ONZE database) is associated with increasing rates of deletion, consistent with the predictions of Bybee (2001, 2002). Although this effect is treated discretely here, by dividing the frequency range into blocks, Guy *et al.* (2008) demonstrate a continuous correlation.

Lexical frequency effects have been investigated in a variety of studies in usage-based models and elsewhere (e.g. Phillips 1984). Many find significant effects, but the evidence is mixed: some studies show no frequency effects (e.g. the Scots nationality group in the NZ study showed no frequency effect). But the theoretical implications of frequency are extensive. Such facts are difficult to accommodate in any model that assumes economical (i.e. impoverished) lexical representation – in other words, in most theoretical currents from the Neogrammarians to Optimality Theory. Traditional abstract lexical representations provide no place to record how often and in what form the word has been heard, activated, or articulated. If the lexical frequency of items turns out to regularly affect their phonological treatment, richer representations that can incorporate frequency information will be required.

6 Conclusions

One historical task of phonology reflects the perceptual task that hearers face when listening to a speech signal: the signal contains many components, from which the meaningful elements need to be extracted, and the noise and other non-linguistic elements removed. Consequently, phonologists have sought to maximize generality and predictability, to find constancies and regularities, to tell the signal from the noise. Variability in its various forms presents a challenge to this undertaking – irregularities and limitations on generality. Not unreasonably, one response to variability has therefore been to exclude or minimize it, to treat it as part of the noise.

But in taking this approach, phonology runs the risk of reifying the task as the object. Since our method involves seeking generalities, we risk assuming that generalities are all there is to be sought, that phonology is exceptionless, always regular, invariant. This is a perilous course: if we predefine what we seek, we may not be able to find anything else. If we look only for forests, we may not see the trees. A careful scrutiny of the empirical evidence shows that language does contain "irregularities" that are not noise, variability that is generated by and part of the linguistic system. All the schools of thought we have considered recognize this at some level, at least by acknowledging optionality and contextual variability, and some level of lexical variability. Some schools additionally seek to model social variability and quantitative aspects of variable prevalence. A comprehensive account, which departs from the ideal generality – the phonological universal – in each relevant dimension, will have the following form:

(6) *Quantified generality*

For speakers in some social domain i,
in some linguistic context j,
in some lexical domain k,
x is true with a probability p.

The evidence so far available further suggests that the value of p will be some function of i, j, and k. Phonology has made great progress on the task of seeking maximal generality, even universals. It is now beginning to confront the task of exploring the limits of generality, and the linguistic uses of variability.

93 Sound Change

José Ignacio Hualde

1 Sound change and synchronic phonology

This being a chapter on sound change in a series of volumes primarily concerned with synchronic phonology, it seems appropriate to begin by stating the relationship between synchronic and diachronic phonology that will be assumed here. As is well known, for the Neogrammarians a scientific investigation of language could only be undertaken from a historical perspective (Paul 1880). More recently some scholars of phonology have expressed somewhat similar views (see Good 2008a: 11–15 for discussion). Thus Blevins (2004) has argued that historical explanations must be given priority in accounts of synchronic phonological patterns. One of Blevins's main points, also expressed by other authors (e.g. Bybee 2008), is that the phonetic naturalness of phonological patterns is a consequence of their origin in common mechanisms of sound change.

The view that typological tendencies observable in synchronic sound patterns and (morpho)phonological alternations follow primarily from the relative frequency of different sound changes and paths of development (so that "naturalness" resides in diachrony) is not universally held. The alternative is that (in addition) there are principles of UG that dictate the shape of synchronic "phonological grammars." Kiparsky (2008: 52) proposes "a principled separation between true universals, which constrain both synchronic grammars and language change, and typological generalizations, which are the results of typical paths of change." In this view, "true universals" are due to UG.

I believe that, regardless of one's opinion on this matter, the study of synchronic sound patterns should not be reduced to an account of their historical evolution. There is more to synchronic phonology than accounting for the relative frequency or rarity of patterns and alternations. Synchronic and diachronic phonology have different goals. The goal of the diachronic analysis of a phonological pattern is to discover how it developed through time. A synchronic analysis of the same phenomenon, on the other hand, may be concerned with providing a succinct and precise statement of the facts and/or with modeling speakers' knowledge of the phenomenon in question.

Consider, for example, /e/-epenthesis before word-initial consonant clusters starting with /s-/ in Spanish (CHAPTER 67: VOWEL EPENTHESIS). Spanish, unlike

English, French, or Italian, lacks sC- clusters. In the adaptation of borrowings an initial /e/ is automatically inserted, as in *eslogan* 'slogan', *estrés* 'stress', etc. This insertion phenomenon is obligatory, and also pervasive in the second-language pronunciation of native speakers of Spanish. Spanish speakers are typically unaware that there can be a difference between [sC-] and [esC-]. A synchronic phonological account would presumably explain these facts by making reference to the syllable structure of the language.

When we consider the historical origin of the phenomenon, it turns out that this is a very old process in Romance, which originally had a much wider dialectal distribution (see Sampson 2010). Under one hypothesis, a short /i/ was initially inserted when a word starting with sC- was preceded by a consonant-final word, i.e. / C# __ sC, a context where epenthesis is still found in formal or conservative styles in Italian, as in *scritto* 'written' but *per iscritto* 'in writing', *strada* 'road', *in istrada* 'on the road'. In Old French, the context for vowel insertion was expanded and an epenthetical vowel is found both after a consonant and after pause, but not after a vowel: *espose* 'wife' ~ *ta spose* 'your wife', *espée* 'sword' ~ *la spée* 'the sword' (Price 1984). In both Gallo-Romance and Ibero-Romance, epenthesis with these words was then generalized to all contexts, as we can see by comparing the following examples in Latin, Italian, French, and Spanish, among many others that could be given (in French syllable-final /s/ was later lost: sC > esC > ehC > eC).

(1)	*Latin*	*Italian*	*French*	*Spanish*	
	SCRIPTUM	*scritto*	*écrit*	*escrito*	'written'
	SCHOLA	*scola*	*école*	*escuela*	'school'
	STATUM	*stato*	*été*	*estado*	'been'
	STUDIĀRE	*studiare*	*étudier*	*estudiar*	'study'
	SPONSA	*sposa*	*épouse*	*esposa*	'wife'
	SPATHA	*spada*	*épée*	*espada*	'sword'

In Spanish, as mentioned, the rule has remained fully productive as a phonotactic constraint on pronunciation up to the present day. In French, on the other hand, this rule lost its vitality at some point in its history, after which the language started accepting unmodified sC- words, as shown by the fact that we find words like *style*, *spatule*, etc. (cf. Sp. *estilo*, *espátula*). A diachronic analysis would need to account for all these facts: what is the source of the inserted vowel? How did the process become generalized from the phrasal C# __ sC- context to the lexical __ sC- context in Gallo- and Ibero-Romance? How was the insertion rule lost in Gallo-Romance after centuries of productivity? Why didn't the same thing happen in Ibero-Romance? These questions are different from those that arise in a synchronic analysis of present-day Spanish or French phonology.

Frequently, an adequate account of a synchronic alternation or sound pattern may need to differ substantially from its diachronic explanation. It is perhaps useful to briefly make the point that synchronic and diachronic phonology do not need to provide converging accounts. Knowing how an alternation came about does not necessarily tell us how it should be analyzed synchronically. There is, in fact, evidence that speakers sometimes interpret the facts in a way that is not consistent with their diachronic origin. Let us consider an example.

Regular plural formation in English involves a phonologically conditioned alternation (CHAPTER 99: PHONOLOGICALLY CONDITIONED ALLOMORPH SELECTION) among three allomorphs, /-əz/, /-z/, and /-s/. Diachronically, this allomorphy was brought about by a process of vowel deletion, followed by voice assimilation in resulting clusters of obstruents. Comparison of modern English *stone/stones* with Old English *stān* (NOM/ACC SG), *stānas* (NOM/ACC PL) shows us that, historically, a vowel has been lost in the plural form *stones*: Old English /sta:nas/ > Middle English /stɔ:nəz/ > Modern English /sto:nz/. The vowel was not deleted when the stem ended in a strident fricative or affricate, so as to avoid a cluster of strident consonants, as in *churches, kisses*. Historically, then, the ending /-əz/ is primary. It does not follow from this, however, that, from a synchronic point of view, /-əz/, as in *churches* and *kisses*, is the most basic plural allomorph and that a synchronic process of vowel deletion, mirroring the historical sound change, should be postulated to account for *stones* or *cats*. Depending on the analyst's theoretical persuasion, the choice of synchronic analysis may be based on psycholinguistic evidence such as "wug" tests (Berko 1958; CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY), simplicity of the statements, or other criteria. In this case, perhaps the most adequate account of the morphophonological alternation that we find in regular English plurals would posit /-z/, as in *stones*, as the most basic allomorph, and would derive /-əz/ as in *churches, kisses* by an epenthesis rule and /-s/ as in *cats* by a voice assimilation rule or constraint (tautosyllabic clusters of obstruents always agree in voice in English).

A well-known phenomenon, which English plural allomorphy exemplifies in part, is rule inversion (Vennemann 1972). This is the case where a synchronic rule takes the opposite direction from the sound change that caused the alternation. That is, a sound change of the type $x > y$ in context z is phonologized as a synchronic alternation best captured as $y \rightarrow x$ in other contexts.

In Basque, for instance, in the compositional form of a set of nouns a final vowel is deleted and, if the preceding consonant is *-r*, it is changed to *-l*, as schematized in (2a) and exemplified in (2b).[1]

(2) -r/-l *alternation in Basque*

a. *-r*V → *-l* in compositional forms

b.

basic forms		*compounds*	
gari	'wheat'	*gal-buru*	'head of wheat'
atari	'doorway'	*atal-zain*	'doorman'
euskara	'Basque language'	*euskal-dun*	'Basque speaker'
abere	'cattle'	*abel-gorri*	'free-roaming cattle'
merkatari	'merchant'	*merkatal-*	'commercial'

Since this rule is fairly productive, and can be applied to new formations, we may speculate that from knowledge of pairs like those in (2b), Basque speakers can extract something like the rule in (2a).

If we now consider the diachronic origin of the alternation, it turns out that it is to be found in a sound change in the opposite direction. We can see this from

[1] This Basque alternation is also discussed in Hualde (1991: 84) and is used to exemplify rule inversion in Trask (1996).

the treatment of early borrowings from Latin. Borrowings such as *zeru* 'sky' < Lat. CAELU(M), *gura* 'desire' < Lat. GULA, *goru* 'distaff' < Lat. COLU(M), etc. show a change from intervocalic *-l-* to *-r-*. It seems reasonable to assume that the same process affected the native lexicon at the time. The original form of, for instance, 'wheat' may have been **gali*, which became *gari* by rhotacism. In compositional forms intervocalic rhotacism was bled by the deletion of the final vowel (CHAPTER 74: RULE ORDERING). The original lateral of **gali* was thus preserved stem-finally in the compositional form *gal-*. This resulted in pairs with a basic form in *-r*V and a compositional form in *-l* (e.g. *gari* ~ *gal-* 'wheat'), which created a pattern for analogical formations. The compositional form *abel-* in (2b), for instance, is the result of such an analogy, since the source of Basque *abere* 'cattle' is Lat. HABĒRE. In other words, to repeat, the sound change *-l-* > *-r-* (**gali* > *gari*) has given rise to a synchronic rule *-r*V → *-l* (2a) (*gari* → *gal-* in compounds).

To give another example, Stockwell and Minkova (2001: 125) analyze the alternation in cases like English *table* ~ *tabulate*, *single* ~ *singular*, etc., as instances of synchronic "*u*-epenthesis," although from a historical point of view what we have is vowel deletion (in the evolution from Latin to French): Lat. TABULA > Fr. *table*.

The accumulation of sound changes can also give rise to synchronic alternations that lack any phonetic motivation, as in the alternation in English *critic* ~ *criticize*, where /k/ is replaced by /s/ before a low vowel (on this general topic, see Anderson 1981). Such cases of "telescoping" may be capturable by means of more or less natural synchronic rules by positing derivations with a series of intermediate stages, as in classical generative models. Consider for instance the examples in (3) for Ondarroa Basque:

(3) *Ondarroa Basque*

uninflected	*absolutive* sg	
gixon	*gixona*	'man'
sagar	*sagarra*	'apple'
neska	*neski*	'girl'
alaba	*alabi*	'daughter'

As the first two examples in (3) show, the absolutive singular form is normally created by adding the suffix /-a/. In words whose stem ends in /-a/, however, this vowel is replaced by /-i/. This is the result of the accumulation of four distinct sound changes affecting the sequence /a–a/ in this inflectional context: *neskaa* > *neskea* > *neskia* > *neskie* > *neski* 'the girl'. All the intermediate forms are attested in other Basque dialects. In a generative analysis it would be possible to formulate a series of ordered natural synchronic rules that mirror the (necessarily ordered) sound changes that we have illustrated (see Hualde 1991). In a less abstract analysis, different processes could be postulated to account for the pairings of uninflected and singular forms, depending on the last segment of the stem, without synchronically deriving *neski* from /neska + a/ (see Hualde 1999). Knowledge of the historical evolution does not determine the choice of synchronic analysis.

To summarize this section, synchronic and diachronic phonological analysis have different goals. Furthermore, since synchronic phonological patterns may reflect their history only in an indirect way, knowledge of how a given pattern originated does not necessarily provide information on the best synchronic analysis of the facts. The choice of synchronic analysis will depend in part on the analyst's criteria for selecting among competing accounts. A phonologist's goal may be, for instance, to provide an accurate and elegant description of the sound patterns of a given language; or it may be to discover what generalizations regarding the sound structure of the language its speakers actually make, as revealed by psycholinguistic experimentation, and perhaps by modeling them.[2] The diachronic origin of the phonological facts is not directly relevant for either of these purposes.

Sound changes have an effect on the synchronic "phonological grammar" of a language when they give rise to (morpho)phonological alternations or to new phonotactic constraints. But the same type of change that creates robust patterns of alternations in one language may not create any alternations in another language, depending on the structure of the lexicon of the language in question. In the rest of this chapter we will be concerned exclusively with changes in pronunciation, either complete or in progress, but will leave the synchronic phonological analysis of the facts aside for the most part. The issues to be addressed have been topics of debate for many decades, some since the origins of our discipline. Some of these issues will be presented here in a somewhat different light than they are in other contemporary discussions.

2 Phonemes or words as objects of phonological change

A classic but still current debate in diachronic phonology concerns the question of whether sound change affects phonemes (CHAPTER 11: THE PHONEME) in specific phonetic environments, without regard to lexical identity or, alternatively, whether sound change affects words, so that different words will undergo sound changes at different speeds. In recent years, some authors have defended the view that phonetic change always operates on words and that more frequent words will change more rapidly than less frequent ones (CHAPTER 90: FREQUENCY EFFECTS). The possibility (or necessity) of "word-specific phonetics" would appear to follow from the architecture of exemplar models of lexical encoding. Different words will be used in different contexts and with different frequencies, and their reduction patterns will be part of their mental representation (see Pierrehumbert 2002; Bybee 2003).

On the other hand, Labov (1981, 1994, 2006, 2007) has argued that, even though some changes do show lexical effects, the various vowel shifts currently taking place in North American English dialects are affecting all instances of the respective phoneme in the relevant phonological contexts in the same manner and simultaneously, regardless of whether the words containing them are frequent or infrequent. Whatever pronunciation a given speaker has for the vowel of high-frequency *pin* will also be his/her pronunciation of the vowel in the first syllable of low-frequency *pinafore*.

[2] See Hayes *et al.* (2009) for a recent application of the "wug" test methodology, with computational modelling of the results.

This debate goes back to the original formulation of the notion of sound change by the Neogrammarians.[3] The Neogrammarians distinguished two types of process, "(regular) sound change" *stricto sensu* and "analogy" (see Kiparsky 2003 for discussion). Regular sound change is claimed to be phonetically gradual and lexically abrupt. It is lexically abrupt because all words containing the same sound in the relevant phonetic environment are affected in the same manner and simultaneously (see, for instance, Paul 1889: 58–59). Analogical change, on the other hand, is lexically gradual and phonetically abrupt. For instance, pre-Latin **honōsis* 'honor (GEN SG)', **flōsis* 'flower (GEN SG)' became Latin *honōris, flōris* by a regular sound change that, by hypothesis, simultaneously affected all instances of intervocalic /s/, gradually modifying their articulation, s > z > r / V __ V (with phonetically intermediate realizations). Later on, -*s* also became -*r* in the nominative singular of some words, where it was word-final and therefore not in the context of the sound change, as in *honos* > *honor*. The latter was an analogical change that abruptly replaced a phoneme with another phoneme under the influence of other words in the inflectional paradigm. This analogical phenomenon is lexically gradual, because only some words were affected. For instance, *flōs* 'flower (NOM SG)' did not undergo the change (or not until much later).

(4)	Stage I		Stage II (s > *r* / V __ V)		Stage III	
	honos	**honōsis*	*honos*	*honōris*	*honor*	*honōris* (by analogy)
	flōs	**flōsis*	*flōs*	*flōris*	*flōs*	*flōris*

The distinct operation of regular (Neogrammarian) sound change and analogy can also be observed in phonological change in progress. As mentioned above, Labov has claimed that changes like those involved in the Northern Cities Vowel Shift operate with Neogrammarian regularity.[4] On the other hand, the shortening (or laxing) of long /u:/ to /ʊ/ is spreading throughout the lexicon, so that a given speaker may pronounce *roof* with a short vowel and *proof* with a long one. Gradual lexical diffusion involves the abrupt replacement of one phoneme with another. The spread to a new word may be due to analogy with similarly sounding words: e.g. if a speaker knows that *roof* can be either /ru:f/ or /rʊf/, s/he may also start accepting and producing both pronunciations for *proof*, by analogy.

In one type of process, "regular sound change," the change affects sounds or phonemes. In the other type, "analogy," the objects are words (see Labov 1981 for discussion). Another way to interpret this dichotomy is that "regular sound change" and "analogy" differ in the structural level at which they apply. "Regular sound change" operates at the level of meaningless sound units, phonemes and allophones, and it is thus purely conditioned by mechanical, physical aspects of speech. "Analogy," on the other hand, takes into account meaningful sound units, morphemes and words, and may thus be conditioned by both physical and mental aspects.

[3] For an overview of the development of Neogrammarian thinking, see Pedersen (1931). An early dissenting voice was Schuchardt (1885).

[4] The Northern Cities Vowel Shift involves a number of changes affecting different stressed vowels at different stages. First /æ/ rises and diphthongizes; then /a/ and /ɔ/ front; finally, /ɪ/ lowers, /ɛ/ lowers and retracts, and /ʌ/ retracts (Labov 1994: 195).

A third logical possibility is that sound change may be both lexically and phonetically gradual. In this view, the objects of sound change are always words, which undergo gradual, essentially reductive, change (see e.g. Bybee 2008).

It could obviously be the case that different types of sound changes show different paths of development and that only some types of sound changes show Neogrammarian regularity, but what the "words as objects of phonological change" hypothesis denies is that sound change ever operates as the Neogrammarians envisioned. Under this hypothesis it should be the case that those sound changes that have been claimed to operate with Neogrammarian regularity, affecting all lexical items with the relevant phonological environment simultaneously and at the same rate, actually show lexical effects when more carefully examined. This remains to be proven (see Dinkin 2008).

It is useful to make a distinction between reductive and non-reductive sound changes, since they appear to differ in fundamental ways regarding both their origin and their spread (Phillips 1984). Reductive sound changes are those that have their origin in the reduction of magnitude and temporal overlap of articulatory gestures, as typically found in relaxed styles and especially in less informative parts of utterances (see Browman and Goldstein 1991; also CHAPTER 79: REDUCTION).

Not all sound changes appear to be reductive (although most of them certainly are).[5] It should be noted that vowel shifts, on whose evidence Labov has relied to maintain the validity of the Neogrammarian hypothesis, are rather special types of sound changes. Whereas the most frequent sound changes involve reduction of segments in prosodically weak positions, the vowel shifts that Labov has studied target (prosodically strong) stressed vowels. There is no a priori reason to expect that lexical frequency or lexical identity should play the same role in reductive and non-reductive sound changes.

In the next sections we will consider the phonetic and phonological nature of reductive sound change, before turning to the less common non-reductive sound changes. Regarding regularity, the specific view that will be presented here is that many sound changes, including regular reductive phenomena with a well-understood mechanical origin, start as across-the-board phonetically gradual processes, as the Neogrammarians claimed, but involve the operation of something very close to analogy at some point in their phonologization. In other words, regular change initially affects sounds in specific phonetic contexts, but, at a later stage, the sound change is lexicalized. This happens when sounds are phonologically recategorized. The observation that word and morpheme boundaries may condition phonological processes by either preventing their application or allowing a less restricted application than within single morphological domains is relevant for establishing this point. The distinction between regular sound change and analogy may not be as straightforward as the Neogrammarians envisioned.

In principle, the same stages that I am proposing for lenitions would apply to fortitions, although the types of words that would lead in the change at the stage of phonological recategorization would be expected to be different. In this

5 The hypothesis that sound change (when properly defined) is always reductive is put forward in Mowrey and Pagliuca (1995). I do not believe this hypothesis can be maintained, but sound changes that have their origin in articulatory reductions are clearly much more frequent than all other sound changes.

view, the lack of lexical effects in the Northern Cities Vowel Shifts (if Labov is correct) would follow from the fact that there has not been actual phonological recategorization, in spite of changes in vowel quality. At the phonological level there has not yet been a change.

3 The phonetic seeds of reductive sound change

It is fairly well established that common processes such as lenition (CHAPTER 66: LENITION) and assimilation (CHAPTER 81: LOCAL ASSIMILATION) have their ultimate origin in the reduction and co-articulation that we find in casual speech, as opposed to more careful styles. Articulatory phonology provides an explicit model of these phenomena as arising from synchronic variation; in particular, from undershooting and overlap of targets (Browman and Goldstein 1990, 1991 and other work by these authors; see also CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS). In this framework, segmental weakening, including deletion and assimilation, are shown to be the consequence of the online reduction in magnitude and overlap of articulatory gestures. For instance, the reduction in the magnitude of the gesture of the active articulator needed to produce complete occlusion, under time pressure or in relaxed speech, would result in an approximant realization. Assimilation between adjacent targets may likewise result from overlap and reduction of gestures under temporal compression.

In addition to weakenings and assimilations, quite a few other phenomena that are traditionally given very different labels can also result from gesture retiming and reduction. An example would be consonant epenthesis in sonorant-obstruent groups, as in Eng. *som*[p]*thing*, *el*[t]*se*, Lat. TENERA > **tenra* > Fr. *tendre*, etc. In the last example, for instance, the epenthesis is the result of a retiming of the closure of the velic-nasal port with respect to the oral gestures: the cessation of airflow through the nasal cavity while the apico-alveolar contact of /n/ is still maintained will result in the production of a segment identifiable as /d/.

Beddor (2009) shows that American English speakers perceive pronunciations such as [bɛnt] and [bɛ̃t] as being equivalent, the crucial thing being the duration of the nasal gesture, rather than its specific alignment with respect to the dorsal gesture of the vowel and the apical closing gesture at the end of the word. This equivalence could lead to the development of nasal vowels by the progressive favoring of the latter gestural alignment in this context.

Another common diachronic change, word-final devoicing (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION), which at first glance appears very different from lenition and assimilation, can also be understood in reductive terms. Hock (1991: 239–241) argues that word-final devoicing has its origin in prepausal devoicing and is a sort of assimilation (to silence), in spite of the apparent differences.

At least some types of metathesis (CHAPTER 59: METATHESIS) may also be understood as originating in gestural co-articulation. Metathesis would arise from the reinterpretation or resegmentation on the part of listeners of an ambiguous or indeterminate signal created by gestural co-articulation (Blevins and Garrett 1998; Hume 2004). To give an example from sound change in progress, whereas many Spanish dialects have aspiration of /s/ in syllable-final position, a recent development in Andalusian Spanish is the postaspiration of stops following an etymological /s/: *pasta* [pasta] > [pahta] > [patʰa] 'paste'. Torreira (2007) shows that this development, which mirrors historical metathesis in other languages, can be modeled as a re-adjustment in the timing of laryngeal and oral gestures.

Even some dissimilations (CHAPTER 60: DISSIMILATION) may be attributed to gestural mistiming/retiming, to the extent that they involve the coordination of "stretched-out" gestures with other gestures (see Ohala 1993).

It is thus clear that unintended online retiming and reduction of gestures, which are pervasive in unmonitored speech styles, may produce new articulations, as casual speech variants. These online reductions may mirror many of the most common changes that we can observe when we study the history of languages.

An understanding of these phenomena, however, is not sufficient to explain sound change. Casual speech phenomena need to be conventionalized and phonological recategorization must take place for sound change to occur.

4 Conventionalization and recategorization

Sound change involves both phonetics and phonology. It seems fair to say that the phonetic mechanisms that give rise to different reductive sound changes, which we have just briefly considered in the previous section, are better understood than the psychological and social processes that lead to their conventionalization in specific environments and to the recategorization of sounds.

Ohala (1993, 2003) has argued that the operation of sound change requires a mistake on the part of listeners, who misinterpret the sound signal as something different from what the speaker had intended (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). For instance, the unintended voicing of /p/ between vowels, due to temporal reduction of the labial gesture and incomplete abduction of the vocal folds, is reinterpreted by listeners as intended /b/. As Ohala (2003) points out, however, the ambiguity of speech signals and the consequent potential for errors of interpretation is a pervasive phenomenon. To continue with our example, examination of acoustic records shows that sporadic voicing of intervocalic stops is found in many languages without leading to recategorization or even to the conventionalization of allophonic rules. One would expect sound change to operate at a much higher rate than it actually does if ambiguity systematically led to errors in perception and sound categorization. There must be factors that slow down the progress of sound change.

What may explain the relatively slow pace of sound change is that, at the phonological level, two things need to happen for /p/ to become /b/, as in, for instance, Lat. SAPĚRE > Port. *saber* 'to know', Lat. LUPU(M) > Port. *lobo* 'wolf', etc. First, at some point in time, [b] must become a conventionalized realization of the phoneme /p/ in intervocalic position. At a later point, [b] must be reinterpreted as /b/, a different phoneme, so that perhaps [p] is no longer an option in words that used to have that sound:

(5) *Sound change* p > b

a. Phonetic change	[p]	> [b] / V __ V	/apa/ [apa] > /apa/ [aba]
b. Phonological change (recategorization)	/p/ [b] > /b/ [b]		/apa/ [aba] > /aba/ [aba]

In fact, since [b] is only one of several ways in which [p] may be reduced in this context, the other common one being its reduction to a voiceless bilabial fricative or approximant, a prior phenomenon must be the conventionalization of the reduction process. That is, before recategorization takes place, a specific way of reducing targets must have already been conventionalized in the language. This may involve a choice among competing reductive mechanisms. For instance, in our example, among the various ways to reduce /p/ between vowels, its voicing to [b] may be chosen. Conventionalization of the phonetics involves the recognition of a distinct and acceptable articulatory target, first as an optional allophone and later perhaps as the normal realization of the phoneme in a given context; for example the recognition of [b] as an acceptable allophone of /p/ in intervocalic position.

Phonological recategorization consists of the recognition of a different phonological category. To continue with our example, recategorization takes place when [b] is no longer an allophone of /p/ but rather something different, /b/.

In Portuguese and the other Western Romance languages, Latin word-internal intervocalic /p t k/ were recategorized as /b d g/, becoming identified with the original voiced plosives in other contexts. Thus, for instance, the intervocalic consonant of LUPU(M) 'wolf' > *lobo* was at some point no longer identified with the initial consonant of PORTA 'door', but was now a member of the same phoneme as the initial consonant of BUCCA 'cheek' (> 'mouth').

(6) *Recategorization in Western Romance*

Latin		*Portuguese*	
/p/	PORTA	/p/	*porta*
/p/	LUPU	/b/	*lobo*
/b/	BUCCA	/b/	*boca*

In our example, there has been recategorization because *[lopo] is no longer a possible pronunciation for Portuguese /lobo/ (whereas in Italian dialects with optional voicing of intervocalic stops, completely voiceless realizations are still found; Cravens 2002). I would thus like to suggest that, in the case of reductive sound changes, phonological recategorization is typically preceded by a conventionalization of a specific reductive process. In our example, *p* > *b*, we would have the three stages in (7):

(7) *Stages in sound change* p > b / V __ V

a. *Online gestural reduction*
   Variable voicing and/or incomplete labial closure in casual speech
   /lopo/ [lopo] ~ [lop̬o] ~ [lobo] ~ [loβo] ~ [loɸo]
b. *Conventionalization of phonetics*
   Voicing becomes the conventionalized casual speech variant
   /lopo/ [lobo]
c. *Phonological recategorization*
   Realizations are no longer attributed to underlying /p/
   /lobo/ [lobo]

Conventionalization affects the phonetic realization of phonemes in specific contexts and it is thus lexically abrupt. Recategorization, on the other hand, may occur in a word-by-word fashion. Its subsequent spread across the lexicon may again produce regularity. Whereas recategorization of intervocalic /p t k/ operated quite regularly in word-internal position in Western Romance (but see §6 below for the word-initial position), in Italian it is a lexically very irregular process; compare, for instance, Lat. STRĀTA > Ital. *strada* 'road' and Lat. CANTĀTA > Ital. *cantata* 'sung (FEM SG)' (see Cravens 2006).

To give another example, in present-day Spanish, the voiced obstruents /b d g/ are systematically realized as the approximants [β ð ɣ], with a variable degree of constriction, intervocalically and in some postconsonantal contexts, without regard to lexical identity. This is a fully conventionalized allophonic process. The recategorization of the weakest degree of lenition, which involves the deletion of the segment, on the other hand, is operating in a lexically conditioned manner. Some words have acquired two distinct pronunciations, with and without an intervocalic consonant, but most have not; e.g. *lado* 'side', with two categorically distinct pronunciations (/lado/ [laðo] and /lao/), *recado* 'errand' (/r:ekado/ [r:ekaðo] and /r:ekao/) *vs. enfado* 'anger' (only /enfado/ [eɱfaðo], not */enfao/), *invado* 'I invade' (only /inbado/ [imbaðo], not */inbao/).

Browman and Goldstein (1991) point out that the change from Lat. HABĒRE to It. *avere*, Fr. *avoir* involves a reduction in degree of constriction, from stop to fricative. This is the phonetic aspect. But we also need to explain the conventionalization of this reduction whereby intervocalic [b] came to be regularly pronounced as [v] and subsequently recategorized as /v/, but only in word-internal position.

This sound change is slightly more complex than the voicing of intervocalic /p t k/ in Western Romance. We may note that from the reduction of [b] we would not directly expect a labio-dental fricative [v], but rather an approximant [β] (see Lavoie 2000: 163–164): HABĒRE [abe:re] > [aβe:re]. There is some evidence that this was in fact the initial result. The eventual outcome [v] may have been due in part to merger between intervocalic realizations of /b/ and the original phoneme /w/, as in LAVĀRE [lawa:re] 'to wash'. In all Romance languages there was a merger between -B- [β] and -V- [w]. The result of this merger is eventually [v] in most of the Romance area (Herman 2000: 39). We may assume that first [w] became a labio-dental [v], a relatively common sound change, and that this was followed by the merger between -B- [β] and -V- [v]. We will come back to the restriction of the merger to the word-internal position.

To give another example, long-distance dissimilation, as in Grassman's Law in Sanskrit and Ancient Greek, may have its roots in listeners' "hypercorrection," as claimed by Ohala (1993): in domains containing more than one segment bearing a certain "stretched-out" feature, the listener attributes all the effect to one of the segments. In order for something like Grassman's Law to arise, however, the phenomenon must be conventionalized. "Hypercorrection" does not determine directionality in the dissimilation. It could in principle result in asystematic assignment of the marked feature to only the first potential feature-bearing segment in one word and to only the last one in another. What we find in Grassman's Law is that the last aspiration is systematically retained: $C^h \ldots C^h > C \ldots C^h$ (also in Basque, e.g. *hil* 'dead' + *herri* 'town' > *ilherri* 'cemetery'; Michelena 1985: 211–212). In Quechua, under the hypothesis that present-day Aymara represents the older situation (which is not undisputed; see Landerman 1994), we find the opposite: only the first instance of glottalization or aspiration is retained, cf. Aymara *t'ant'a* 'bread', Quechua *t'anta* 'bread'.

In this section, I have made the point that an important aspect of sound change, beyond its phonetic origins, is phonologization/recategorization. I have suggested that this process may involve the conventionalization of (across-the-board, optional) phonetically conditioned processes followed by (lexically gradual) recategorization.

5 How does recategorization happen in sound change?

As mentioned, in Ohala's model (1993, 2003), sound change takes place when unintended articulatory reductions are reinterpreted by listeners as new intended targets. Intended or underlying forms are subject to online reductions, and, eventually, these online reductions become lexicalized, i.e. intended or underlying. This recategorization, in Ohala's model of sound change, involves a "mistake" on the part of the listener.

For instance, Nolan (1992) demonstrates that coronal assimilation in English, as in *red car*, is a gradual process that allows for a continuum of reduction of the alveolar gesture (CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). In his response to this paper, Ohala (1992) points out that, even if this is the case, there could be instances where the assimilation is categorical, phonologized, intended as such. In his words, "there may be a huge gap between the faintest version of an alveolar stop in *red car* and the fully assimilated form [rɛgkɑː]" (Ohala 1992: 286). The point is that for sound change to take place, the products of online phonetic reductions must become lexicalized as categorically different. The question is how and when this lexicalization takes place. How can we know whether a given token of complete assimilation was intended as such, and whether it is not just an extreme instance within a continuum of reduced articulations? In the case of coronal assimilation in English, besides the gradual reduction and co-articulation that Nolan documents, could it be that some speakers already optionally have a different target gestural score to produce these sequences, which does not involve an apical gesture? In any event, coronal assimilation appears to be a conventionalized process in English, to the extent that this is something that affects specific sequences in a specific way in this particular language. The phonetic gradual process is a conventionalized phenomenon of English which may apply in a Neogrammarian fashion, without regard to the identity of the lexical items involved. On the other hand, phonological recategorization as something different from the historical sequence may operate on an item-by-item basis, showing frequency effects.

The traditional demonstration that re-analysis has taken place is provided by the occurrence of the new target in contexts beyond the one where it arose. For instance, we can be sure that listeners have interpreted the acoustically overlapped /t/ in *perfec(t) memory* (to use one of Browman and Goldstein's 1990 examples) as being intentionally absent when, as speakers, they start producing sequences such as *perfe*[k] *art*, where the absence of the word-final [t] cannot be attributed to acoustic masking. In the case of word-internal segments, however, this evidence may not be available, as the phonetic context is constant.

Recategorization clearly takes place earlier than has sometimes been assumed. Janda (2003) discusses Twaddell's explanation of the phonologization of umlaut. As Janda points out, at the time it was proposed, Twaddell's account was seen as real progress. Essentially the idea is the following. Umlaut was a predictable allophonic process as long as the triggering high front vowel was present (Stage I in (8a); I illustrate with a familiar pre-English example). At this stage [y] would be a predictable allophone of the phoneme /u/ in the environment of a following /i/. We may postulate the synchronic rule in (8b) to capture the distribution of allophones. Later, the reduction of final unstressed /i/ to schwa made the presence of [y] unpredictable from the context, thus triggering its categorization as an independent phoneme (Stage II):

(8) *Umlaut*

a. Stage I / Stage II
/mu:si/ [my:si] > [my:sə] /my:sə/ 'mice'

b. /u:/ → [y:] / __ (C) i

Janda (2003), following several other critics of Twaddell's analysis, calls our attention to a conceptual problem with this account. If umlaut was a predictable effect at Stage I, triggered by the phonological environment, it should have gone away once the conditioning factor disappeared. That is, if the synchronic allophonic rule was as in (8b), the centralization of the conditioning final vowel should have resulted in [my:si] changing to *[mu:sə]. That is, once the final vowel could no longer condition its fronting, the phoneme /u/ should surface as [u]. The conclusion that Janda draws is that the umlauted [y] vowel became a distinct phoneme while the original conditioning environment was still present. Whether or not we want to use the term "phoneme" in this sense (CHAPTER 11: THE PHONEME), the lesson clearly is that [y] was an intended, conventionalized target, part of the gestural score of the word (in Articulatory Phonology terms) at some historical point when final /i/ was also part of the gestural score.

If phonologization must precede loss of the conditioning environment, the question is, then, what causes it. Janda makes the reasonable assumption that when two allophones are phonetically distinct enough they will be learned as distinct categories, even if they are in complementary distribution (for discussion see also Kiparsky 1995: 656–657). It is unclear, however, how one can determine the relevant degree of dissimilarity that would warrant independent phonemic categorization (although this could, in theory, be empirically investigated through psycholinguistic experimentation). We must also ask the question of how the fronting of /u/, caused by co-articulation, was exaggerated to the point that speakers of the language reinterpreted it as a different target. One possibility is that this was an abrupt change: at some point, Old English listeners reinterpreted very co-articulated, fronted productions of /u/ as a distinct target /y/, maybe on a word-by-word basis. In principle, Ohala's listener-induced abrupt recategorization seems more compatible with changes that show lexical diffusion or are sensitive to the presence of morpheme or word boundaries than with sound changes that apply across the board. Umlaut and vowel harmony rules are typically limited to (prosodic) word domains and tend to have exceptions and/or be limited to certain morphological contexts. Co-articulation of the type that may give rise to umlaut has been observed across words sequences (Cole *et al.* 2010). If this co-articulation is not phonologized (as vowel assimilation) across word boundaries (e.g. hypothetical *bl*/u/ *boat vs. bl*/y/ *sea*), it must be because analogical pressure among tokens of the same word prevents this from happening.

To give another example, consider the difference in the duration of vowels preceding voiced and voiceless coda consonants in present-day American English. This difference goes considerably beyond what may be expected from merely phonetic co-articulatory effects and is sufficiently salient to serve as a cue for the voicing of the following consonant (Peterson and Lehiste 1960; Rafael 1972; Rafael *et al.* 1975). Final obstruents in English show a tendency to devoice (Flege and Brown 1982; Smith 1997). We may thus envision a future scenario where word-final devoicing of obstruents becomes an obligatory rule of English, as has happened in German (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). It would not be surprising in this hypothetical scenario if pairs such as *bet* and *bed* were still distinguished by the duration of the vowel: /bɛt/ *vs.* /bɛːt/. In this scenario, final devoicing would have caused the phonologization of a formerly predictable difference in vowel duration, as has happened, for instance, in Friulian (Vanelli 1979). Arguably, however, this vowel duration contrast has already been phonologized in present-day English. That is why we wouldn't expect it to disappear by the systematic devoicing of word-final obstruents. On the other hand, to the extent that vowels preceding both voiced and voiceless obstruents are still treated in a similar manner in phenomena such as the various vowel shifts that are taking place in English, it must be concluded that speakers still categorize over both contexts. What appears to be needed to understand sound change is a richer theory of categorization than is traditionally assumed (see e.g. Hualde 2004 and Ladd 2006 for proposals). Unlike the example that we considered above, umlaut in German and in Old English, which is restricted to certain morphological contexts (Janda 1998), durational differences in English vowels conditioned by the phonological voicing of a following consonant apply without exception. Vowel duration has been conventionalized, but no phonemic recategorization has occurred.

6 Word boundary effects

Unless word boundaries can be demonstrated to have phonetic correlates in the language, they should be irrelevant for "regular sound change." For instance in Spanish, /b d g/ are spirantized both within words and across word boundaries, e.g. *Maria bebe agua* [maɾiaβeβeaɣwa] 'Maria drinks water'. The spirantization of /b/ in Amharic is similarly an across-the-board phenomenon: [bet] 'house', [kaβet] 'from the house'. In some historical lenitions, however, we observe that rephonologization is restricted to the word domain.

In the Western Romance voicing of intervocalic stops, which we mentioned in the preceding section, only word-internal intervocalic instances of /p t k/ were recategorized as /b d g/; e.g. Lat. LATU(M) > Sp./Port. *lado* 'side' *vs.* Lat. ILLA TERRA > Sp. *la tierra*, Port. *a terra* 'the land'. On the other hand, outside of the Western Romance area, in central and southern Italian dialects, in Corsican and Sardinian, the voicing of these segments has an allophonic or optional character and applies both inside words and across word-boundaries, e.g. Lat. LATU(M) > Sard. [laðu], Lat. TERRA > Sard. [tɛrːa] 'land', Lat. IPSA TERRA > Sard. [saðɛrːa] 'the land' (Jones 1997: 377). As Weinrich (1958) pointed out, the area where Lat. /p t k/ underwent systematic recategorization coincides with those languages where the voicing is restricted to the word-internal domain. The question that arises is how to account for this difference in the domain of application of the sound change.

Examination of synchronic variation and possible sound change in progress appears to show that at the initial stages intervocalic lenition applies across the board. In some Spanish dialects, for instance, we are witnessing an incipient "second round" of lenition of intervocalic /p t k/. In a recent study, Hualde *et al.* (2010) found about 30 percent of partially or completely voiced tokens of intervocalic /p t k/ in a sample of spontaneous speech. Other studies have found roughly comparable percentages, sometimes higher, depending on the specific dialect, the speaking style, and the speaker (Machuca Ayuso 1997; Lewis 2001). Leniting voicing is found both word-internally and across word boundaries.

Both the state of affairs in other areas, such as Sardinia and southern and central Italian areas with "phonetic" voicing, and the examination of the incipient second round of voicing witnessed in some Spanish dialects lead us to the conclusion that voicing must initially also have operated across word boundaries in Western Romance (as Weinrich 1958, Hall 1964, and Cravens 2002 also conclude). As voicing became obligatory and categorical, it became restricted to the word-internal context. The elimination of voicing across word boundaries must be attributed to the operation of analogy among tokens of the same word in different syntactic contexts. In a phrase like ILLA TERRA > hypothetical Western Romance [latɛrːa] ~ [ladɛrːa] 'the land', the voiceless realization would eventually prevail under the influence of phrase-initial and postconsonantal tokens of the word /tɛrːa/, including contexts of word-initial gemination (from consonant assimilation): AD TERRĀ > [atːɛrːa] 'to land'. Sporadically, however, we find generalization of the voiced variant instead, as in Lat. COLAPHUS > Sp. *golpe* 'strike'.

We find the same restriction to the word-internal context in Browman and Goldstein's (1991) example of lenition as reduction in constriction degree: Lat. HABĒRE > It. *avere*. Whereas Latin word-internal intervocalic B and V have merged in all the Romance languages, the intervocalic [b] of, for instance, ILLA BUCCA did not become [v] in It. *la bocca* [labokːa] 'the mouth', Fr. *la bouche*.

As mentioned above, Latin -B- /-b-/ and -V- /-w-/ have merged in all Romance languages. In French, Italian, and standard Portuguese, the modern result is /v/:

(9)

	Italian	*French*	*Portuguese*	
HABĒRE	*avere*	*avoir*	*haver*	'have'
DEBĒRE	*dovere*	*devoir*	*dever*	'must'
LAVĀRE	*lavare*	*laver*	*lavar*	'wash'

In word-initial position on the other hand, these languages preserve an etymological contrast between /v/ and /b/:[6]

(10)

	Italian	*French*	*Portuguese*	
BUCCA	*bocca*	*bouche*	*boca*	'mouth'
BONA	*buona*	*bonne*	*boa*	'good (FEM SG)'
VACCA	*vacca*	*vache*	*vaca*	'cow'
VŌCE	*voce*	*voix*	*voz*	'voice'
VŌS	*voi*	*vous*	*vos*	'you (PL)'

[6] In Old Castilian Spanish the contrast may have been between /β/ and /b/. This contrast was subsequently lost, in post-medieval times, through the lenition of /b/.

As mentioned in the previous section, in these Romance evolutions, the first relevant change is the lenition of Latin intervocalic /b/, which subsequently results in its merger with /w/.[7] Again, the merger would also be expected to affect word-initial B- and V- when intervocalic; that is, ILLA BUCCA, for instance, should have undergone lenition to [ilːaβukːa], and its B should have acquired the same articulation as the V in ILLA VACCA [ilːavakːa] when the contrast between the medial labials of HABĒRE [aβeːre] > [aveːre] and LAVĒRE [lawaːre] > [lavaːre] was lost:

(11) *Hypothesized evolution of intervocalic* -B- *and* -V-

HABĒRE	>	aβere	>	avere
LAVĀRE	>	lavare	>	lavare
BUCCA	>	bukːa	>	bukːa
ILLA BUCCA	>	ilːa βukːa	>	ilːa vukːa
VACCA	>	vakːa	>	vakːa
ILLA VACCA	>	ilːa vakːa	>	ilːa vakːa

At the last stage represented in (11), the phonemes /b/ and /v/ are in contrast in word-initial position only if not intervocalic (e.g. after pause or consonant). There is no phonemic contrast in intervocalic position, either word-internally or phrase-internally. The result is that words that have different initial consonants in some contexts do not in other contexts.

No Romance language has preserved the situation depicted in (11). We may conclude that languages like Italian, French, and Portuguese have analogically re-established the contrast between /v-/ and /b-/ also after a vowel, so that a given word either begins with [v-] or with [b-] in all phrasal contexts (Weinrich 1958).

The frequent cases of confusion between initial *b*- and *v*- in old texts from central Italy and even in graffiti from Pompei (see Tekavčić 1972: 142–144) provide quite strong evidence for the hypothesis that the phonemic contrast was indeed analogically re-established in word-initial postvocalic position, after a period where the two phonemes were contextually neutralized, as proposed by Weinrich (1958).

In the Romance lenition processes that we have just considered, a sound change was prevented from operating across word boundaries as it became phonologized. In other cases, the opposite seems to have happened, with extension of the process to further contexts across word boundaries.

Although in American English the flap /ɾ/ originally arose from the weakening of /t/ and /d/ in certain contexts, it is now, arguably, a distinct articulatory target (CHAPTER 113: FLAPPING IN AMERICAN ENGLISH). Speakers show awareness of its existence as a different sound. A word like *better*, for instance, has a flap in its normal pronunciation in the relevant dialects, but speakers may replace it with /t/ for stylistic purposes. Flaps are found both word-internally and word-finally. All words ending in /t/ in their citation form can be pronounced

[7] Whereas we cannot be sure when /b/ started to admit approximant realizations or even when these approximant realizations of intervocalic /b/ became the usual articulatory target, we know that -B- /b/ merged with -V- /w/ by the first century of our era. This is because around this time the graphemes B and V start getting confused (Weinrich 1958: 87; Allen 1978: 41).

with /ɾ/ before a vowel in the next word, as in *but again, at all, forget about, eat oats*. Interestingly, the phonetic conditions for the occurrence of the flap are different word-internally and across word boundaries, as shown by the impossibility of flapping in *atoll* and its possibility in *at all*. Inside words, the segment must be preceded by the stress and followed by an unstressed vowel. Across word boundaries, however, flapping is not conditioned by stress and may occur immediately before a stressed vowel, as in *ate apples*; this is also the case in a compound such as *whatever* (cf. *potato*).

Given the importance of word stress in English as a conditioning factor in reductive processes, I assume that the more restrictive phonetic conditioning that is still found word-internally was the original one and that, across word-boundaries, the change was generalized to all prevocalic contexts, not only unstressed ones.

Flapping is a conventionalized reduction of /t/, since it is only one of the possible phonetic reductions that it may undergo. Other possibilities, all of them found in the same contexts in other English dialects, are the replacement of [t] with a glottal stop, its affrication to [ts], and its spirantization to [θ]. It seems reasonable to assume that after [ɾ] was conventionalized as a replacement for [t] before unstressed vowels it was analogically extended to the context before stressed vowels when word-final.

Bybee (2000, 2003) discusses a similar example, the extension of the aspiration of /s/ in Spanish dialects from the preconsonantal context, where it is found word-internally, as in *este* [ehte] 'this (MASC SG)', to the prevocalic context, where one may have aspiration across word boundaries in the relevant dialects, as in *los animales* [lohanimale] 'the animals'. In Bybee's account, the extension of aspiration to the intervocalic context across word boundaries involves a sort of analogy. In a first stage of development, the plural masculine article *los*, to give an example, would have aspirated realizations in phrases such as *los toros* 'the bulls', where the final /s/ is preconsonantal, but not in *los animales* 'the animals', where it is prevocalic and, thus, not in the context of aspiration. The fact that s#C is more common than s#V (i.e. there are more consonant-initial than vowel-initial words) implies that at this hypothetical stage [loh] ~ [los] would be more frequent than invariant [los], and the alternation would subsequently be extended from the more frequent to the less frequent context. Bybee shows that the distribution of aspiration in several Spanish dialects is consistent with this hypothesis. In the view that I am defending in this chapter, it is at this second stage where we are more likely to find lexical effects. An example would be intervocalic word-internal aspiration in *nosotros* /nos + otros/ [nohotro] 'we', where a morphological boundary is discernible (cf. *los otros* [lohotro] 'the others') *vs.* e.g. word-internal *ositos* [osito], **[ohito] 'little bears', in the relevant dialects. This is similar to flapping in *whatever*, as we saw above.

The phonologization of phrase-final devoicing at the word level provides another example of analogical extension. As mentioned above, a reasonable hypothesis is that word-final obstruent devoicing, as we find in German, starts out as phrase-final devoicing and then is extended to the word domain (Hock 1991: 80). The phonetic causes of phrase-final devoicing are reasonably clear, as this is in fact a phenomenon that is easily observable in many languages, affecting all kinds of word-final segments, not only obstruents. This phonetic effect may at some point become conventionalized for phrase-final obstruents. After that, it may be analogically generalized to the word-domain, so that alternations of the type -p## ~ -b#V are eliminated by extension of the word variant ending in a voiceless consonant.

7 Non-reductive sound change

As mentioned in §2, the main evidence that Labov adduces in favor of the Neogrammarian orthodoxy comes from the study of vowel shift in progress. These vowel shifts in English crucially differ from reductive processes in that they affect segments in prominent positions, i.e. stressed syllables. In fact, Labov points out that one finds more advanced vowel tokens in the direction of the shift in syllables with primary stress than in syllables with secondary stress, vowels in words with emphatic stress being especially advanced along the path of the vowel shift (Labov 1994: 122–123, 173, 195). This is quite different from reduction processes, where we expect to find the least reduced tokens under emphatic stress.

The changes involved in vowel shifts are essentially the same types of processes as other changes targeting stressed vowels, both conditioned (umlaut/metaphony) and unconditioned, including diphthongization, mora dissimilation within diphthongs and rising of (tense/long) vowels. In at least some of these changes it is clear that the added duration of vowels in certain positions led to their recategorization. Thus, in Spanish, the phonologically short mid vowels of Latin, which had acquired a more open quality /ɛ ɔ/, gave rise to rising diphthongs when lengthened under stress. In French they diphthongized in the same manner, but only in syllables that were stressed and open, cf. Lat. PEDE(M) > Sp. *pie*, Fr. *pied* 'foot' *vs.* Lat. PERDIT > Sp. *pierde*, Fr. *perd* 's/he loses'. The long mid vowels of Latin also diphthongized in French, in this case producing falling diphthongs, but again only in stressed open syllables, where the extra length would presumably favor the perception of a difference in quality between the beginning and the end of the nucleus. In this case, further developments show the sort of mora differentiation that we find in some of the vowels involved in the English vowel shifts; cf. Lat. TĒLA > [tei̯lə] > [təi̯lə] > [toi̯lə] > [twel] > [twal] *toile* 'cloth'. Notice that under the hypothesis that greater stress causes greater vowel duration and longer vowels are more likely to be recategorized as diphthongs (and diphthongs as containing a more extreme change), if anything, we would, expect the least frequent words to lead these changes, since they would be more likely to receive phrasal stress.

Besides changes targeting stressed vowels, the most obvious examples of non-reductive changes are consonant fortitions. Whereas experimental work has pointed out the existence of domain-initial strengthening (Fougeron and Keating 1997; Cho and Keating 2009), its phonologization as word-initial fortition is a rare phenomenon. When they happen, these changes for the most part seem to have non-phonetic, analogical origins. For instance, the strengthening of word-initial /r/, /l/, and /n/ in different Ibero-Romance languages, where they give the same result as word-internal geminates (Lat. ROSA > Sp. [rːosa], Lat. LŪNA > Cat. *[lːuna] > *lluna* [ʎuna] 'moon', Lat. NŪBES > Leonese [ɲuβes] 'clouds'), is most likely an extension from contexts where a word-initial geminate arose from consonant assimilation (AD LŪNA > [alːuna]; see Cravens 2002). To the extent that these changes are correctly analyzed as purely analogical, they operate on words, and we may expect lexical effects.

The fortition of word- and syllable-initial glides, as repeatedly found in the history of the Romance languages (e.g. Lat. IOCĀRE > It. *giocare*, Fr. *jouer*, Sp. *jugar* 'to play'; Sp. *huevo* [weβo] ~ [gweβo]; also in Basque **e-an* > *jan* [ɟan] ~ [ʤan] ~ [ʒan] ~ [ʃan] ~ [xan] 'to eat') remains ill understood. In the several successive processes of syllable-initial palatal glide fortition in the history of Spanish (and also of Basque), the recategorization of the palatal glide shows lexical effects, e.g. IAM > Sp. *ya* 'already' *vs.* IAM MAGIS > OSp. /ʒamas/ > Sp. *jamás* /xa'mas/ 'never'; Argentinian Sp. *yerba* /ʒerba/ *(mate)* 'maté leaves' *vs.* *hierba* /ierba/ 'grass', etc. The hypothesis would be that fortition of glides starts in prosodically strong phrase-initial contexts, and is later phonologized as a word-initial phenomenon, which may then spread to word-internal syllable-initial contexts.[8] On the other hand, the fortition that we observe in examples such as Lat. VACCA [wak:a] > OSp. [βaka] > Sp. *vaca* [baka] 'cow' is the indirect (analogical) result of the weakening of intervocalic /b/ at two distinct stages in the history of the language.

8 Summary

This chapter has focused to a large extent on the classic issue of the regularity of sound change (i.e. the Neogrammarian hypothesis) which, in the context of recent debate, may be termed the question of whether there are sound changes that operate purely on phonemes in specific phonological contexts, without regard to the lexical identity of the words containing them. I have proposed that in many common sound changes we should distinguish two stages. The first stage is the conventionalization of a phonetic process. Conventionalized phonetic processes operate without regard to lexical identity. At a second stage, there may be phonological recategorization, which will tend to operate on a word-by-word basis. The spreading throughout the lexicon of this recategorization (by analogy) will produce the effect of regularity. Phenomena such as word boundary effects may be an effect of analogical spreading.

We have studied reductive and non-reductive sound changes separately, since their paths of development can be reasonably expected to be different. Whereas significant progress has been made in our understanding of the phonetic origin of reductive sound changes, non-reductive changes, including those affecting stressed vowels and consonant and glide fortition, are less well understood.

ACKNOWLEDGMENTS

I am grateful to Jennifer Cole, the anonymous reviewers, and the editors for their valuable comments.

[8] Another ill-understood phenomenon is the gemination of consonants before glides, as found in Italian, cf. *avete* 'you (PL) have' *vs.* *abbiamo* /ab:jamo/ 'we have', Lat. AQUA > It. *acqua* /ak:wa/ 'water', etc.

94 Lexical Phonology and the Lexical Syndrome

Ellen M. Kaisse
April McMahon

1 Introduction

The theory of Lexical Phonology and Morphology (LPM) deals with the place of phonology within the larger grammar. It has much to say about the relation between morphology and phonology, and also provides a model for the integration of phonology with the material provided by syntax and the phrasing derived from syntax. It is also a theory of phonological typology, assigning one set of characteristics to processes that apply only within words (the lexical phonology) and another, complementary set to processes that apply within or between words (the post-lexical phonology). The theory was first developed in the early 1980s by Kiparsky (1982) and his colleagues and students (especially Mohanan 1982, 1986) at MIT. It rapidly attracted a great deal of interest among phonologists because of the new tools it supplied for attacking recalcitrant problems, the set of intriguing questions it allowed a researcher to ask about any phenomenon, and the organic way it grew out of many of the major trends in phonology and morphology that had occupied linguists since the publication of Chomsky and Halle (1968). LPM was the basis for much of the synchronic and diachronic work, both descriptive and theoretical, that went on in phonology for a decade or more following its birth. Classical LPM was probably also the last model of phonology–morphology interaction to enjoy a wide consensus (Noyer 2004). LPM remains influential today, in its legacy of ways of thinking about phonology and in new instantiations that marry it with Optimality Theory (Orgun 1996; Kiparsky 2000; Rubach 2000; Bermúdez-Otero, forthcoming; among many others). As is often the case with valuable but complex and inevitably imperfect theories, LPM did not simply collapse under its own weight. Rather, interest largely moved elsewhere. Starting in the early 1990s, many phonologists turned away from rules and derivations to Optimality Theory (OT). Until recently, most versions of OT have involved only one evaluative step – potential output candidates are evaluated simultaneously for their satisfaction of ranked constraints. The result of the large-scale turn to OT was that most people stopped writing about and within LPM before consensus had been reached on what to do about the difficulties that had been encountered within it. It is certainly true that there was not much from Kiparsky's (1982) proposals that did not have some qualifications, exceptions, or caveats attached by the mid-1990s, but this is not, as we reconstruct it, the main reason one no longer hears so much about LPM. On the contrary, many phonologists continued to recognize advantages to the theory and to adopt pieces of its legacy.

We will not be able to give a full introduction to LPM in this chapter, though we will certainly review some of its major features. For more detailed background, the original source, Kiparsky (1982), is invaluable. Kaisse and Shaw (1985) and Kenstowicz (1994: ch. 5) also provide introductions to the original model. Kaisse and Hargus (1993) summarize developments which the theory underwent in the decade after its first appearance, including those contained in the volume to which it is an introduction, Hargus and Kaisse (1993).

Lexical Phonology and Morphology's contributions center around two major areas: the segregation of characteristics typical of lexical *vs.* post-lexical rules, sometimes called the *lexical syndrome*, and the interaction of morphology and phonology, including affix ordering, stratal organization, and cyclicity. We will begin this chapter with a review of the characteristics that together made up the lexical syndrome and a discussion of how each of these has been modified or discarded in the light of empirical challenges. The succeeding section deals with the interaction of morphology and phonology in LPM, the difficulties which much of the original proposal has encountered, and alternatives that have been offered. The final section discusses the lasting influence of LPM and some of the directions it has taken in more recent years.

2 The lexical syndrome and its complications

Classical Lexical Phonology (Kiparsky 1982, 1983) proposes that a cluster of properties characterizes lexical rules, while a different, complementary cluster is found in post-lexical rules. The properties that have been used most often as diagnostics and which have attracted attention in subsequent literature are the following:

(1) a. Lexical rules are word-bounded. They find their target and structural description within the same word and do not apply between words. This is the easiest diagnostic to apply, and is often used as the starting point from which other characteristics are then predicted.

b. Lexical rules are cyclic. They have access to the internal morphological structure of a word and may apply more than once, first to the most deeply nested constituents, then again as more morphological material is brought into consideration (see also CHAPTER 85: CYCLICITY).

c. Lexical rules are subject to non-derived environment blocking. They apply to strings derived by the concatenation of morphemes or to strings derived by previous applications of phonological rules, but they do not apply within a single, underived morpheme (see also CHAPTER 88: DERIVED ENVIRONMENT EFFECTS).

d. Lexical rules are structure preserving. They are restricted to producing segments that are found in the underlying inventory of the language. Allophonic variants are not produced by lexical rules. However, lexical rules may assign structure not present underlyingly, in the form of tonal associations, metrical feet, and syllable structure (see also CHAPTER 76: STRUCTURE PRESERVATION: THE RESILIENCE OF DISTINCTIVE INFORMATION).

e. Lexical rules apply categorically, rather than gradiently. As a corollary of structure preservation, they do not produce partially assimilated sounds, and they do not apply more robustly to segments nearer to the trigger of the change (see also CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY).
f. Lexical rules may have exceptions (see also CHAPTER 106: EXCEPTIONALITY).
g. Lexical rules are subject to lexical diffusion (Kiparsky 1988). In diachronic sound changes, they apply to more and more individual lexical items over time (see also CHAPTER 93: SOUND CHANGE).

Post-lexical rules have radically opposed characteristics:

(2) a. They apply between as well as within words.
b. They apply once, non-cyclically, across the board, independent of morphological or syntactic structure.
c. As a corollary to (b), they are not subject to non-derived environment blocking.
d. They need not be structure preserving. They may produce allophones not present in the underlying segment inventory.
e. They may apply gradiently, producing partially assimilated segments or applying more robustly to segments temporally closer to the trigger.
f. They do not have exceptions.
g. In diachronic change, they apply in the fashion predicted by Neogrammarian views of sound change. Every string that meets their description undergoes the change, with no lexical conditioning. The changes can be small, allophonic, and non-neutralizing.

These characteristics were posited within an organization of grammar approximately like that in Figure 94.1. The stem level is so called because it contains affixes that can attach to bound bases (stems) that cannot appear unaffixed, while the word level deals in the formation of words from other words.

To illustrate how these segregated lists of characteristics play out, consider the simplified example of Trochaic Shortening *vs.* North American Flapping employed in Kaisse and Shaw (1985). (For a more nuanced and current discussion of the

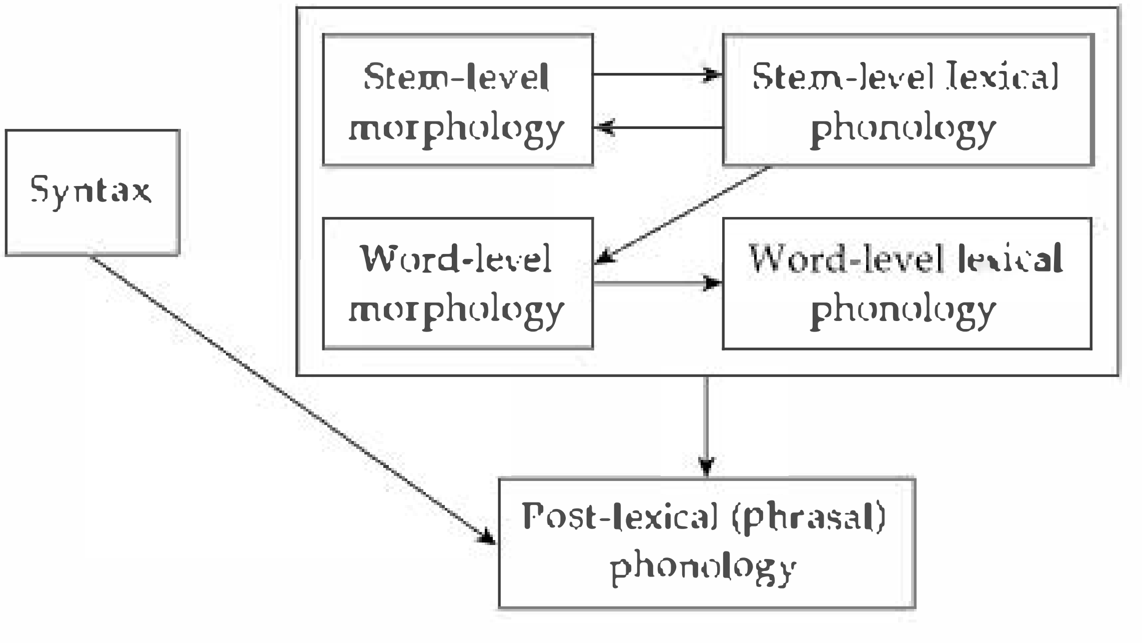

Figure 94.1 The organization of the grammar in LPM

theoretical implications and analysis of Flapping, see CHAPTER 113: FLAPPING IN AMERICAN ENGLISH and Bermúdez-Otero 2007b.) Flapping converts an underlying coronal stop to [ɾ] when it is intervocalic (roughly speaking) and ambisyllabic (Kahn 1976.) The rule can make up its intervocalic environment with vowels from the same word, or the second vowel can come from a following vowel-initial word. The word-internal environment can come from a single morpheme (*ci*[ɾ]*y*), from the combination of a stem plus stem-level suffix (*fa*[ɾ]+*al*), or from a word plus a word-level suffix (*chocola*[ɾ]-*y*, *edi*[ɾ]*ed*). The between-word environment is insensitive to the part of speech of either word and to their syntactic relationship, though phrasing into independent prosodic groups, which interferes with ambisyllabicity, does block Flapping (compare *It's the close*[ɾ] *Annette cares about* with *It's the close*[t], *Annette insisted*). The fact that Flapping can apply between words is the prime diagnostic for its being post-lexical. We have just seen its insensitivity to morphological or syntactic structure. It is also non-cyclic. A word like *atomic* does not contain a flap even though the word from which it is derived, *atom*, does. Continuing down the list, words like *city* and *butter*, where the coronal stop is frozen in an intervocalic environment within a single morpheme, show that Flapping is not subject to non-derived environment blocking. The segment [ɾ] is not part of the underlying inventory of English; the coronal tap or flap is not well distributed, but occurs only where the environment of Flapping is found. We are not aware of studies that show Flapping to be gradient, though this is certainly true of the distribution of aspirated and plain stops in English, to which Flapping is related – stops which are initial in large prosodic categories are more aspirated than those which are initial in internal syllables. However, Flapping is extremely common but nonetheless variable, in that the likelihood of its application is partly dependent on register and rate of speaking (see Patterson and Connine 2001, who find that American English Flapping is almost categorical in its application). And while Flapping is not completely obligatory, it does not have lexical exceptions – any word of English can undergo it if the phonological and stylistic prerequisites are present.

Compare the behavior of Trochaic Shortening, the rule responsible for alternations like that in *sane* ~ *sanity*, *meter* ~ *metric*(*al*), and *nation* ~ *national*. The rule shortens a vowel followed by an unstressed syllable – i.e. it shortens the stressed syllable of a trochaic foot. (The rule is often called Trisyllabic Shortening, because English has final extrametricality, placing the stressed syllable of many trochees three syllables from the end of the word; see CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY; CHAPTER 44: THE IAMBIC–TROCHAIC LAW.) Trochaic Shortening cannot make up its structural description out of adjacent words – the vowel of *sane* in the phrase *sane as a judge* must be long even though the prosodic phrasing can place its vowel before a string of unstressed syllables. Going down our list, we see that Trochaic Shortening is sensitive to the type of affix added: word-level affixes do not trigger shortening, as shown by *nationhood* or *metering*. The rule is also cyclic, since once the vowel in *metric* is shortened, it persists as short in derived words even when the stress falls on the vowel immediately after, as in *metrician*. As for non-derived environment blocking, Kiparsky (1982) makes the point that English contains many long vowels in the Trochaic Shortening environment, but almost all are found within a single morpheme (synchronically speaking), such as *nightingale* or *Rotenberg*. Thus Trochaic Shortening is blocked in non-derived environments. Trochaic Shortening is structure preserving, since all the shortened vowels are phonemes of English. It is non-gradient. And it has exceptions, such as the long vowels in *notional* and *obesity*.

Optimality-theoretic work has tried to deal with many of the phenomena of the lexical syndrome, but for the most part in piecemeal fashion, rather than as following from a particular organization of the grammar. One finds many publications framed in OT which aim to explain apparent cyclicity effects (Kenstowicz 1995; Benua 1997; Kiparsky 2000; Pater 2000; and many others); work by Łubowicz (2002) and Wolf (2008) attempts to recapture non-derived environment effects within OT; Steriade (1999), Burzio (2002), Raffelsiefen (2004), and Bermúdez-Otero and McMahon (2006), among others, have advanced explanations for why word-level morphology seems to have so little effect on phonology. And this piecemeal treatment may exist with good reason. We will shortly look into how the features of the lexical syndrome have fared since they were first proposed and will discover that the connections between strata and features are not nearly as tight as the original LPM theory proposed.

But before we get to the complications, let us first consider how the philosophical outlook imposed by the LPM model influenced the way in which phonologists worked. There are some key, if non-architectural, features that strongly affected the research strategies of those who considered themselves practitioners and which continue to affect the expectations we have of a phonological description to this day:

(a) LPM encourages interest in processes which are not exceptionless, transparent, or expressible in maximally general and elegant statements. Interest was directed equally to processes with exceptions and oddities either in the environment or in the list of items applied to, and researchers tried to understand the difference between these and the maximally general and transparent type of process. The concept of opacity, long of interest to Kiparsky, gained a new dimension, since lexical rules are often opaque, while post-lexical rules typically are not. And since morphology can make a phonological rule opaque by being invisible to that rule at the stratum in which it applies, or by allowing a phonological rule to apply before a new morphological process destroys the environment, understanding the interaction of phonology with morphology can lend insight into some of the sources of opacity (CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE).

(b) LPM encourages investigations of interactions between phonology and other aspects of the grammar, notably phonetics and syntax at the "bottom end" in the post-lexical component, and morphology and the lexicon at the "top end." The observation that post-lexical rules can be gradient was influential in the great expansion of our understanding of the relation between phonetics and phonology in the last two decades and in the realization that phonetics is a language-specific, rule-governed domain closely related to the phonology of the language.

(c) LPM encourages investigations of diachronic change. LPM provided a new architecture which made sense of the way sound changes progressed over time and thus aided in resolving the so-called "Neogrammarian controversy" (Kiparsky 1988). If there were lexical and post-lexical rules, and more than one level in the lexicon, and each was characterized by different properties, rules could apply differently throughout their history. A rule could start post-lexically and be very close to the phonetics, transparent and phonetically conditioned, applying everywhere that its context arose. Later it could come to apply lexically, be influenced by the morphology, gain lexical exceptions, and in time become more and more opaque. Eventually, it could become a matter for learning rather than online application, and color or alter underlying representations, while no longer existing as a rule per se. Given that Trochaic Shortening occurs in almost all dialects of English while Flapping is geographically restricted, it seems likely that Trochaic Shortening is an older rule and has moved deep into the lexicon – indeed perhaps it is no longer an online rule at all – while Flapping is still showing the post-lexical characteristics of its initial entry into the language.

We shall return in more detail to each of these points in §4. One moral to draw is that, even though the lexical syndrome is not as strong as it first appeared, the sorts of questions that the segregated lists of traits made one ask about a phonological process were valuable research tools. It is important to know whether a process has exceptions, applies only in derived environments, shows cyclic characteristics, refers to morphological structure, is bounded with the word, creates novel segments, and so forth. And it may still be the case that one can make a better-than-chance prediction of how these traits are going to be distributed on the basis of the theory of LPM. Our suspicion is that the lexical syndrome is like so many other things once thought to be universal but now realized to be violable – it is not an utterly exceptionless principle, but an insight into the unmarked state of affairs in phonologies. It is worth remembering that it took over a decade for research within the LPM model to come up with the list of exceptional phenomena we present below, and that some are single instances of problematic cases in the face of dozens of attested cases of the predicted behavior. These problematic cases were not easy to come by because, in fact, the predictions of the model were much more often right than not.

Where do we stand with respect to the health of the lexical syndrome? In the first two columns of Table 94.1, we repeat a list of the characteristics that make up the lexical syndrome (including for completeness a few of the less influential ones we did not mention above), adapted from Kaisse and Hargus (1993: 16–17). Where the characteristic was not part of the early and generally accepted LPM canon (Kiparsky 1982, 1985; Mohanan 1982, 1986), we give a source. The last two columns give a quick summary and citation of works that raised problems with each putative characteristic. Most of these difficulties are summarized in Kaisse and Hargus (1993), and the details can be found in papers from their volume or other sources in the table, so we will only outline their content here. What we see in general is a gradual and traceable retreat from some of the formal features of LPM. For instance, structure preservation is at best a feature of stem-level rules, more likely not predictable from stratum. By the time we reach OT, the question of structure preservation becomes unaskable, since Richness of the Base precludes any characterization of the underlying segment inventory of a language. Cyclicity also stops being a feature of all lexical rules, and becomes a feature only of some, again perhaps those of level I. Even cyclicity of the stem level becomes a non-issue in the most recent work of Bermúdez-Otero and McMahon (2006) or Collie (2008), being replaced with a type of lexical listing called "fake cyclicity," which we discuss below. And, of course, rules become non-standard currency as we shift toward OT and constraints.

Table 94.1 Characteristics of the lexical syndrome

	Lexical	*Post-lexical*	*Problems*	*Reference*
a.	Word-bounded	Not word-bounded	Apparent post-lexical rules with exceptions may be precompiled in lexicon; lexical rules may access output of syntax	Hayes (1990); Odden (1993)
b.	Access only to word-internal structure assigned at same level	Access to phrase structure only	Some post-lexical rules like English /l/-velarization need access to word-internal morphology	Sproat (1993); Bermúdez-Otero (2007b)
c.	Cyclic	Apply once	Stem level only; word level not cyclic; no true cycle in stem level, rather lexical listing and faithfulness	Borowsky (1993); Bermúdez-Otero & McMahon (2006); Collie (2008)
d.	Apply in derived environments	Apply across the board	Non-Derived Environment Blocking more likely associated with obligatory neutralization rules	Kiparsky (1993); Wolf (2008)
e.	Structure-preserving	Not necessarily structure-preserving	Word-level rules not structure-preserving; P1 rules often structure-preserving; post-lexical rules may differ w.r.t. structure-preservation. Sound changes may introduce non-structure-preserving segments at stem level	Harris (1989); Kaisse (1990); Borowsky (1993); Hyman (1993); Bermúdez-Otero & McMahon (2006)
f.	May have exceptions	Automatic	P1 rules like the English Rhythm Rule have exceptions	Kaisse (1990)
g.	Not transferred to a second language (Rubach 1984)	Transferable to L2		
h.	Output subject to lexical diffusion (Kiparsky 1988)	Change via Neogrammarian sound change		Calabrese (2009)
i.	Apply categorically	May have gradient outputs	Raises issues relevant to the link between gradience and phonetic implementation	

Of these characteristics, some were not really counterexemplified or rejected by the authors cited – rather they were refined or altered in interesting ways. For instance, Borowsky (1993) (row (c) in Table 94.1) did not reject the idea that lexical rules are cyclic. Rather, she claimed that cyclicity should be limited to the stem level, while both the word and the phrasal level are non-cyclic. She also followed Kiparsky (1985) in suggesting that structure preservation turns off at the stem level, so that word-level rules can create allophones (CHAPTER 11: THE PHONEME). And finally, in the most radical of her proposals, she argued that many word-level rules show a syndrome all their own. They are non-cyclic, do not obey the strict cycle condition (and thus can apply within a single morpheme), apply between stems and level I suffixes, but are unable to see word-level affixes. Finally, they do not apply between words, so that they cannot be phrase level. One of her more familiar examples uses Harris's (1989) Belfast Dentalization, a process where coronal consonants are realized as dentals before [r] or [ər]. The process is not structure preserving, as it produces dentals which alternate in variable fashion with alveolars and are not separate phonemes. These dentals, however, are only produced morpheme-internally (*butter*) or before [(ə)r] introduced by a stem-level suffix (*elementary*). The rule does not apply between an alveolar and an [r] in a word-level suffix (*fitter*), nor in the next word (*foot rest*), the latter fact indicating that Dentalization cannot be post-lexical. For Borowsky, Belfast Dentalization is a word-level rule that cannot see word-level morphology. It shows its word-level nature by applying in non-derived environments (*butter*) and by producing the novel dental segments. Because of work like Kiparsky and Borowsky cited here, Ricardo Bermúdez-Otero (personal communication) suggests that it is more sensible to talk about a stem syndrome than a lexical syndrome.

Such examples point to the difficulties the theory begins to encounter once the boundaries between lexical and post-lexical characteristics begin to break down. Is the non-structure-preserving nature of Dentalization enough to categorize it as a word-level rule (Borowsky), or is its inability to apply before word-level affixes enough to categorize it as stem level, requiring the rejection of structure preservation as criterial of the stem level? The latter is the tack taken by Bermúdez-Otero and McMahon (2006), who go on to argue that the whole notion of structure preservation was never well defined and that we are well rid of it within any theory that adopts Richness of the Base.

Another example of refinement rather than rejection is Kaisse (1990). Kaisse did not deny that the original class of post-lexical rules referred to by Kiparsky and Mohanan is exceptionless, i.e. that there are no listed lexical items that fail to undergo them. Rather, it drew attention to a different sort of syntax-sensitive post-lexical rule which was, in its own way, cyclic, exception-bearing, and subject to the lexical syndrome. One of Kaisse's examples is the Rhythm Rule of English, the process which repels clashing pitch accents in phrases like *ˌthirteen ˈpeople*. The rule is clearly post-lexical, as the stresses in the independent words *thirˈteen* and *ˈpeople* show. Yet it has many individual lexical exceptions in the forms of words that will not retract their accents in clash: *inˈtense*, *oˈbese*, and many other words do not participate in the Rhythm Rule. Kaisse attempted to divide post-lexical rules into two strata, the first of which (P1) contained more grammaticalized rules like the Rhythm Rule, while the second (P2) was the home of the classical post-lexical rule. Hayes (1990) was an alternative proposal for dealing with non-word-bounded rules that exhibited some of the characteristics of lexical rules, again with the intention of supporting the general notion of a lexical rule syndrome.

On the other hand, Kiparsky's (1993) attack on the Strict Cycle Condition (which he terms "Non-Derived Environment Blocking"; NDEB) as a characteristic of only lexical rules is quite devastating, and leads us to conclude that we still have not really understood this phenomenon, which has vexed phonologists since Kiparsky discovered it in the early 1970s. Perhaps the best-known example of NDEB, first introduced by Kiparsky (1973), is assibilation in Finnish. The rule turns /t/ to [s] before [i] either across morpheme boundaries (/tilat+i/ → [tilasi] 'ordered') or when the [i] is derived by another phonological rule, such as raising of final /e/ to [i] /vete/ → veti → [vesi] 'water (NOM SG)'. It is blocked within a morpheme, such as [tila] 'order'. This example is already problematical, Kiparsky (1993) argues, since assibilation is fed by the word-level rule of raising and thus must itself be word level. NDEB had otherwise been thought to affect only cyclic processes, and cyclic processes are supposedly restricted to the stem level. Even worse, Kiparsky shows that the Vedic Sanskrit rule that retroflexes /s/ after /r/, /u/, /k/, and /i/ shows strong NDEB effects, but applies between words. Kiparsky concludes that NDEB is not a property of any particular level – it does not lend support to the idea of a lexical syndrome. Most recently, Wolf (2008) has argued that NDEB effects are best modeled in an optimality-theoretic model with candidate chains that permits the interleaving of phonological and morphological operations.

Hyman's (1993) discovery of two tone rules in Dagbani, which are both post-lexical and have the same domain of application, yet which differ in whether they are structure preserving – in this case, in whether they are or are not permitted to create a contour tone – seems to us to be a clear demonstration that structure preservation cannot be absolutely predicted on the basis of the component in which a rule applies. But this is one of those cases which were so difficult to find; it took a decade of research within the model to uncover a counterexample of this type. Hyman's example could simply be taken as evidence that structure preservation, though generally predictable on the basis of a process's domain, may sometimes need to be stipulated. Note also that the claim of LPM was that lexical (in particular, stem-level) rules could not create novel segments and structures. The claim was never that post-lexical rules could *not*, accidentally, happen to create structures that obeyed structure preservation. Hyman's example is therefore more a counterexample to Kaisse's (1990) claim that structure preservation is to be found in syntax-sensitive (P1) rules and not in across-the-board (P2) rules.

Odden's (1993) discovery of a demonstrably lexical glide formation rule in Matumbi that must have access to the syntactic structure and phonological characteristics of surrounding words is highly problematical for the general organization of phonology proposed within LPM. But the case is extremely unusual and complex; again, it is not the sort of thing phonologists run into more than once or twice in a career.

Cyclicity has perhaps received the most attention from later theoreticians and is the subject of a full chapter in this *Companion* (CHAPTER 85: CYCLICITY). Within monostratal Optimality Theory, cyclic application has been rejected in favor of various sorts of output–output faithfulness constraints, paradigm uniformity constraints, or constraints favoring "uniform exponence," where the allomorphs of a morpheme differ as little as possible. And, as mentioned earlier, even within contemporary stratal theories, some authors deny even that level I shows true cyclic derivations. Rather, the concept of fake cyclicity (see Collie 2008 for a review) ensures that all stem-level outputs are listed in long-term memory rather than derived online. Stem-level phonological generalizations simply express typical but not exceptionless static relations between a base and its derivative. Collie argues that this is the only way to handle the fact that the preservation of relative prominence under embedding in English is gradient and less likely to occur the more frequent the derivative is in relation to its base. So for instance, the prominence-preserving position of pre-tonic stress in *E,liza'bethan* is a consequence of faithfulness to the listed form *E'lizabeth*. The variable lack of faithfulness between the possible pronunciation *,antici'pation* (with secondary stress on the first rather than the second syllable) and the related form *an'ticipate* results from the possibility that *anticipation* is accessed whole rather than decomposed into component morphemes and derived via cyclic application of stress. We will again encounter this relationship between the frequency of a derived word and the likelihood that it is accessed whole rather than having its affixes stripped off when we discuss affix ordering in the next section.

3 The interaction of morphology and phonology in LPM

We think it is safe to say that the morphological side of the LPM model was always weaker than the phonological side. One of the most attractive, if doomed, features of the LPM model was an attempt to unify apparent generalizations about the phonology of cohering (also known as stem level, level I, or +-boundary) affixes, their morphological behavior (especially their triggering of cyclic rule application), and their linear order. Such affixes were opposed to the non-cohering (word level, level II, or #-boundary) affixes. Unfortunately, the strong position adopted by LPM has turned out to be readily falsifiable. LPM adopts and elaborates the level ordering (or "affix ordering") hypothesis of Siegel (1979). This hypothesis, first made on the basis of English, claims that cohering affixes will occur close to the root, while non-cohering affixes will always occur outside the cohering ones. In other words, level I affixes cannot attach to a word to which a level II affix has already been attached. Thus, according to Siegel, Kiparsky (1982), and other LPM work, the non-existence of words like **happi#ness+al* or **sing#er+ous* comes from the fact that they contain a word formed with a non-cohering affix (*#ness*, *#er*) to which a cohering affix (*+al*, *+ous*) has been affixed. Affix ordering permits words like *person+al+ity*, since both *+al* and *+ity* are level I suffixes. The word *danger+ous#ness* is also fine, since it contains a level I suffix followed by a level II suffix. And some words with strings of level II suffixes are also fine: *seam#less#ly*, *seam#less#ness*. The correlation with phonology is that all the affixes starting from the stem outward to the first non-cohering affix should form part of the visible input to level I lexical phonological rules, while all of the affixes starting from the first non-cohering affix outward will not be the trigger or target of any such rule, and will only undergo post-lexical rules.

Table 94.2 shows the workings of the lexical module as it was devised for English, modified slightly from the diagram found in Kiparsky (1982: 133). The double-headed arrow symbolizes the potential passing of forms back and forth from the morphology to the phonology as more morphemes are added.

Table 94.2 The lexical module for English

	Morphology		*Phonology*
Level I (stem level)	+-boundary inflection and derivation, zero derivation of nouns from verbs	⇔	stress rules, trochaic shortening, velar softening, sonorant syllabification, etc.
Level II (word level)	#-boundary derivation and compounding, zero derivation of verbs from nouns, most inflection		compound stress

In this model, morphological operations occur one affix at a time. Each time an affix is added at level I, the form is passed to the level I phonology, which applies to the string as it is currently concatenated. The form is then passed back to the morphology at that same level, over to the phonology again, and so on until all level I affixes for that word are added. Cyclic application (Chomsky and Halle 1968) results from this interleaving of phonological and morphological operations at level I. Then the form passes on to level II. In English, it appears that all the cyclic phonological rules apply at level I. To illustrate the segregation of morphological operations into levels and the concomitant applicability of certain phonological rules only to strings created at that level, consider a point about the zero derivation of nouns from verbs *vs.* that of verbs from nouns made in Kiparsky (1982). When nouns are derived from verbs with final stress, they often preserve final stress as a secondary prominence but add a penultimate, primary stress, as befits a noun. Thus we find noun/verb pairs such as *'con,vict* from *con'vict*, and *'tor,ment* from *,tor'ment*. In a derivational theory such as LPM, one would say that nouns are zero-derived from verbs at level I, and are thus subject to another cycle of the stress rules after that affixation occurs. However, Kiparsky argues, the zero derivation of verbs from nouns takes place at level II. Since the stress rules of English do not apply at level II, the stress does not change in denominal verbs like *to 'pattern* (**to ,pat'tern*), even though primary verbs ending in two consonants receive final stress. Thus we could say that deverbal -∅ is a level I suffix while denominal -∅ is level II.[1]

But the affix ordering hypothesis makes incorrect predictions, certainly for English. Problems with the level ordering of affixes had been recognized as early as Aronoff (1976). Best known from the beginning were cases where affix ordering proves to be too strong a theory, ruling out combinations that actually occur, such as *#ment+al* (*governmental*) and *#iz+ation* (*neutralization*). The suffixes *-ment* and *-ize* are stress-neutral, and hence non-cohering, as witnessed by forms like *'government*, with stress in the same position as its source verb and no stress on its heavy penult, and *'marginalize*, with stress four syllables from the end of the word. But *-al* and *-ation* are stress affecting, and hence cohering. Bracketing paradoxes like *un#grammatical+ity*, *re#organiz+ation*, and many others have demonstrated that the affix ordering hypothesis undergenerates. For instance,

[1] Kiparsky (1983) modified this analysis on the basis of a wider dataset, making it more complex in the process; we use the possibly oversimplified version for illustration.

in *ungrammaticality*, level I *-ity* should attach before level II *un-*, and yet *un-* attaches to adjectives (like *grammatical*) and not to nouns.

Equally telling is Fabb's (1988) demonstration that the affix ordering hypothesis is too weak and overgenerates. Fabb notes that affix ordering restrictions account for only a small percentage of the sequences of affixes that don't occur in English. He lists 43 common affixes in English. If there were no stratal affix ordering, we might expect around 600 grammatical combinations of these affixes by simply making sure that affixes that select for a particular part of speech are combined only with that part of speech, and that the particular stress requirements of the affixes like deverbal *-al* are met. With affix ordering, we can pare the expected number down to 459 combinations. But English words actually contain only about 50 pairs of suffixes. The main reason is that 28 of the common suffixes never combine with another suffix. Six suffixes combine with only one suffix; for instance *-ic* only attaches to unsuffixed stems or words (*comic*, *metallic*) or to the suffix *-ist* (*modernistic*). Six other suffixes are semi-productive: noun-selecting *-al*, for instance, combines with three cohering and non-cohering affixes *-ion*, *-ment*, and *-or*. Only *-able*, deverbal *-er*, and *-ness* show no selectional restrictions beyond part of speech.

Plag (1996, 1999) shows that even Fabb's restrictions are inadequate. First, Fabb's treatment gives no obvious reasons why suffixes should fall into the combinatorial classes they do. And critically, there are more restrictions on the combinations of English suffixes than are covered by Fabb's observations. These restrictions extend to non-cohering suffixes as well. Plag demonstrates that semantic, phonological, morphological, and syntactic selectional restrictions must be stated on individual suffixes' combinations with stems and other affixes. Once these are stated, both level ordering and Fabb-style lists of combinatorial restrictions become superfluous. Consider for instance the verb-forming suffix *-en*. It can only attach to monosyllabic bases, as in *blacken* vs. **maroonen*. It immediately follows that *-en* will fall into the class of affixes that cannot attach to another affix, since an affixed base would already have at least two syllables. Its behavior is thus explained without additional need for level order or lists of what suffixes it can combine with. Additional insights can chip away further at the otherwise unexplained list of suffixes which cannot attach outside of any suffix. For instance, that list contains five deverbal noun-forming suffixes: *-age*, *-al*, *-ance*, *-ment*, and *-y*. If these were to attach to already suffixed words, they would have to attach to words ending in one of the verb-forming suffixes of English, namely *-ate*, *-ify*, *-ize*, and the already accounted for *-en*. But affixation onto these first three suffixes is "base-driven" in Plag's terminology: *-ify* requires the suffix-particular allomorph *-ication* (as in *classification*), *-ize* requires *-ation*, and *-ate* requires *-ion*. These very specific base-driven requirements again make superfluous any statements about the affixes that cannot attach to other affixes, let alone the stratal membership of those affixes.

Hay (2002) and Hay and Plag (2004) take one further step in the advancement of our understanding of what controls affix ordering. They criticize Plag's earlier work because of a certain residual arbitrariness. Are there not any underlying principles behind the individual suffix- and base-driven restrictions that he notes? For this they utilize Hay's Complexity-based Ordering, which states that affixes that are easily parsed out of derived words must occur outside affixes that are not easily parsed. The likelihood of a derived word being accessed as one unit or instead parsed into base and affix depends on the relative frequency of the whole word to its parts. For instance, *government* is more likely to be left unparsed into component parts than is *discernment*, because *government* is more frequent than *govern*, while *discern* is more frequent than *discernment*. Therefore there is nothing wrong with a formation like *governmental*, while *discernmental* is ill formed. This is because *-ment* is not easily parsed out of *government* and so can be followed by *-al*. But *-ment* is easily parsed out of *discernment* so it cannot be followed by *-al*.

The inevitable conclusion from the combined work of Aronoff, Fabb, Plag, and Hay is that the affix ordering hypothesis must be rejected, at least for English,[2] and with it, that part of LPM that rests upon it.

A strong trend in the mid-1980s to early 1990s was the attempt to replace phonology's direct access to morphological structure with access to prosodic structure based on morphology but not identical to it. Inkelas (1993) and Booij and Lieber (1993) argue that it is possible to maintain a version of LPM, substituting prosodic groupings that need not be isomorphic with morphology. For instance, in Korean (Kang 1992) and Polish (Booij and Rubach 1984) prefixes are independent morphological words. In Polish, no lexical phonological rules apply between prefix and stem, there is always a syllable boundary in that position, and the rules of Lowering and Vowel Deletion cannot be made to operate properly unless prefixes are treated as words. Truckenbrodt's work on the phonology–syntax interface (2002, 2007) is a logical outgrowth of the Inkelas (1993) and Booij and Lieber (1993) approaches, and shows how the variable phrasing of words into post-lexical prosodic groupings can be achieved using the tools of Optimality Theory. As with morphology, a strict translation of syntactic structure into phonological structure does not seem to be adequate.

In contrast to their rejection of the affix ordering hypothesis, both Fabb (1988) and Aronoff and Sridhar (1987) continued to believe in another tenet of level ordering, namely that the word boundary and morpheme boundary affixes could be sorted into two coherent groups on the basis of their phonological behavior, just as had been claimed in Chomsky and Halle (1968) and in LPM. The +-boundary suffixes were available to rules of stress assignment – both those assigning stress and those choosing which of these would be the primary stress; they were available for syllabification so that the vowel-initial ones could bleed Sonorant Syllabification (*hinder*, *hinder#ing*, but *hindrance*); and their content was visible to Trochaic Shortening. We are not aware of many discussions that place this claim under the scrutiny that the affix ordering hypothesis has received. And indeed, a recent instrumental study by Sugahara and Turk (2009) continues to assume this segregation, working upon prosodic structure rather than directly on morphological structure. Sugahara and Turk find support for a distinction among affix types. Their study investigated whether differences in word-internal morphology is reflected in durational differences of monomorphemic stems, stems before level I suffixes and stems before level II suffixes in Scottish English. They hypothesize that the base to which a level II suffix is attached must be a prosodic word and thus will be temporally longer than a level I base. In slow speech, they found stem-final rhymes followed by level II suffixes were longer

[2] We do not know if arguments like Fabb's go through for languages with highly productive agglutinative suffixation, such as Turkish.

than corresponding strings in monomorphemic words, and even longer than stem-final rhymes followed by level I suffixes. Their results are consistent with a model where stems preceding level II suffixes are mapped onto prosodic words. Of course, given the exigencies of a rigorous experimental setting, Sugahara and Turk were only able to test a small subset of affixes. To represent level II, they used only the inflectional suffixes -s, past tense *-ed*, and *-ing*. Level I was represented by *-ance*, *-ence*, *-ent*, and adjective-forming *-al*. Thus their results will need to be extended to many more affixes before it can be concluded that there are coherent sets of level I and of level II affixes in English.

The question is how far one should go between holding out for two well-segregated groups of affixes, and losing the generalizations and possible predictions that follow from some such grouping (albeit with exceptions). Raffelsiefen (2004), for instance, allows each affix to invoke its own constraint ranking, so that every affix is in effect its own class. Note, however, that this work does not necessarily cast doubt on the lexical syndrome, because it is not concerned with operations within the syntax, only within the morphology–phonology nexus.

4 The lasting legacy of lexicalism

In the first section of this chapter, we suggested that LPM had not been entirely disproved or abandoned, but on the contrary that many of its earlier adherents continue to recognize its advantages and achievements. However, rather than remaining as part of a single, self-contained theoretical approach, these positive aspects of LPM have typically become integrated into newer models, or have led to innovative ways of addressing phonological problems. This final section addresses the legacy of LPM in more detail; in particular, we have chosen to focus on its contributions to the understanding of phonological change, opacity, and the phonetics–phonology interface. We will also illustrate the operation of a version of Optimality Theory that incorporates levels, showing how it draws on aspects of LPM to handle some forms of opacity which otherwise create difficulties for OT.

4.1 Diachrony

While standard generative phonology did invoke an interaction between sound changes and phonological rules, this was not especially well motivated, and was difficult to integrate with the architecture of the model. While there was a mechanism for introducing new rules into the grammar through "rule addition" (King 1969), rules could only be added at the bottom of the list of ordered rules, and there was no clear way of allowing those then to percolate up into the grammar and hence alter the underlying representation. In turn, this led to the notorious difficulty that the order of rule applications tended to reflect the order of operation of sound changes, and hence to recapitulate history; this was one of the more powerful factors influencing the abstractness of underlying representations, or at least enabling them to be particularly abstract, and hence not a reason for recommending the model.

The stratal architecture of LPM and the properties of the lexical syndrome solve both these problems. For one thing (as argued by McMahon 2000), it is simply not possible both to adhere to the tenets of LPM and to construct maximally abstract representations and strings of rules recapitulating history. Instead, we must accept that the form of a sound change and of the phonological rule that derives from it may be radically different. McMahon (2000) suggests that the historical Great Vowel Shift, for instance, has been restructured into two modern English phonological rules, one for lax vowels and one for tense ones, both fed by a set of independently motivated tensing and laxing rules, and hence applying in derived environments only. Of course, it is an open question whether or not one might wish to maintain the existence of a rule or process or constraint to generate alternations which might equally well be lexically stored; the point is that if we are to do so, we cannot maintain that underlying forms are unchanged since Chaucer, and that the shape of a sound change precisely dictates the form of its derived and productive phonological rule.

Moreover, once LPM allowed phonologists to depart from the assumptions of identity between sound changes and phonological rules, and of the essentially static nature of underlying representations, there was a welcome freedom to explore the ways in which sound changes could in fact enter the grammar and continue to develop through time. Labov (1981), while strictly speaking pre-dating LPM, introduces the idea of two sorts of phonological rules, mapping on to two types of sound changes, which respectively follow Neogrammarian principles and spread gradually through lexical diffusion. Kiparsky (1988) and Harris (1989) develop this theme, making explicit the relationship between Neogrammarian changes and post-lexical phonological rules, and between lexically diffusing changes and lexical rules. However, Harris also develops the argument further, arguing that post-lexical rules may become lexical over time. Harris (1989) focuses on /æ/-tensing, which in a range of varieties of English gives a lax vowel in *tap, bath, manner, ladder*, but a tense one, albeit variably realized, in *pass, path, man, manning, man hours*. However, while /æ/-tensing applies before anterior nasals and anterior voiceless fricatives in Philadelphia, it also applies before voiced stops in New York, and additionally before /l/ and voiced fricatives in Belfast. Harris traces this phonological process to an earlier, automatic, phonetic change, operating in a hierarchy of environments which have been phonologized differently in different dialects. It is also clearly now a lexical rule, being lexically selective and sensitive to morphological information. This analysis, supported for example by McMahon's (2000) parallel account of the development of the Scottish Vowel Length Rule through phonologization of the familiar low-level English lengthening process before voiced consonants, establishes that post-lexical rules may begin to diffuse, and may then progressively acquire more properties of the lexical syndrome. In due course, as rules percolate up through the lexicon from level II to level I and become increasingly idiosyncratic, they may cease to be productive altogether, instead triggering changes in the underlying representations, which themselves become more dynamic and changeable, and hence also less abstract.

There are two important consequences of the dynamic architecture of LPM, and crucially the lexical syndrome. First, it sharpens the focus on different dialects, which become important repositories of data on intermediate stages in the cycle from sound change to post-lexical rule to lexical rule to lexical restructuring. Furthermore, it legitimates a new interest in sound change and in how changes become rules, which has had a wider impact on linguistics. In theoretical terms, this development raises the question of whether it is the job of a formal linguistic theory to explain or account for change, and to what extent that should be the case (see McMahon 2003, 2007; Bermúdez-Otero 2007a). If we are to evaluate linguistic models partly on the basis that good ones ought to allow us to model a trajectory from change to synchronic process, this raises questions both about the nature of change and about the nature of theory, and understandably these continue to be controversial issues. For example, Hale (2007) explicitly excludes these longer-term trajectories of change from the purview of formal linguistics, which is taken to be concerned only with the modeling of intergenerational changes in the grammar. On the other hand, modeling change has been taken very seriously in Optimality Theory, which also has a relevant mechanism in the shape of constraint reordering, and which in its stratal form shares architectural characteristics with LPM. It is interesting to note that the papers in Holt (2003), which despite the title are really almost all about phonology, quite often refer to LPM as well as to OT.

4.2 *Phonetics and phonology*

While the distinction between the lexicon and the post-lexicon is vitally important in modeling the two types of sound change originally envisaged by Labov (1981), and the possible diachronic transition between them, the bipartite structure of LPM also reconceptualizes the interplay between phonetics and phonology. McMahon *et al.* (1994) argue for a gestural model, as in Articulatory Phonology (Browman and Goldstein 1992; see also CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS), which allows straightforward and perhaps explanatory modeling of phonetic processes and phonetically induced sound changes. They propose that this gestural account should be integrated into LPM, allowing different constraints to operate on the manipulation of gestures in the lexical component, and hence allowing some less restricted phonological processes than would otherwise be compatible with a gestural model. There is interesting support for this conclusion from studies of connected speech processes, where Holst and Nolan (1995) and Nolan *et al.* (1996), for instance, argue that not all such processes can be modeled simply as gestural overlap. However, this does not mean that lexical processes are phonological while post-lexical ones are phonetic; instead, it arguably begins to break down the distinction between phonetics and phonology, reintroducing the important category of language-specific phonetic processes, which form an important bridge between universal phonetics and language-specific phonology.

Again, this shift toward a more dynamic interaction between phonetics and phonology has two important consequences, this time partly methodological. If processes which might once have been relegated to phonetics are increasingly seen as language-specific and phonological, then methods previously restricted to phonetic investigation become extendable to the exploration of phonological issues. It might not be too far-fetched to see this as a contributory motivation (though obviously not the only one) for the establishment of laboratory phonology. Secondly, and again looking forward to the development of Optimality Theory, there is considerable ongoing debate about whether constraints are all, or should all be, essentially phonetically grounded. Flemming (2001, 2004) proposes a unified theory of phonetics and phonology, in which constraints are functionally motivated; this links the current section to the previous one, as it introduces a further option for explanation of changes and of their offspring, synchronic phonological consequences, this time in the form of constraints. Overall, this work causes us to re-evaluate the relationship between phonetics and phonology, or even to ask whether there is a distinction, and reintroduces concepts of gradience discussed far earlier by Kiparsky, for instance. Although the overall framework has moved on, and these discussions are no longer held within LPM as such, we again contend that the structure of LPM, and the dynamic possibilities it opened up, have enabled and encouraged such questions to be asked, and have sharpened our expectations of phonological (and phonetic) theory.

4.3 Stratal Optimality Theory

In this section so far, we have focused on aspects of LPM which do not translate directly into most current phonological models, though they have profoundly influenced the ways phonologists do their work and the expectations they have of their models and tools. However, there is one case in which direct structural influence from LPM feeds a current debate within Optimality Theory. In the last decade or so, several proposals have been offered for a theory of LPM-OT (Kiparsky 2000), Derivational OT (Rubach 2000), and Stratal OT (Bermúdez-Otero, forthcoming). While they may differ in their details, these theories have in common the adoption of the independent stem, word, and phrase levels of LPM. Otherwise they adopt most of the architecture of Optimality Theory – most notably, ranked violable constraints rather than language-specific ordered rules. The main justifications for a stratal OT are its ability to deal with opacity and cyclicity, and its adoption of the division of levels, which has found much support across languages and analytic frameworks. Proponents argue that a theory with the limited derivational capacity of levels is able to handle the very kinds of opacity that are attested, while opacity has been of persistent difficulty for purely parallel versions of Optimality Theory. (Capturing the lexical syndrome has not been a particular goal of these stratal OTs.) The reader is directed to McCarthy (2007) and references therein for discussion of how to describe opaque processes within OT. Generally, those OT theorists who support fully parallel evaluation argue that not all opacity can be described using strata, certainly not if the analysis is limited to strata that are independently motivated by the morphology.

A simple example from a dialect of Spanish will illustrate how stratal organization can be used to treat a certain kind of opacity and to capture a cyclic effect. Kaisse (2009) discusses a process in Spanish that is responsible for the realization of underlying /s/ as [h] in codas. In the Rio Negro dialect of Argentina, this process, known as "Aspiration," is transparent within morphemes and between morphemes, but it overapplies when one word ends in an underlying /s/ and the next word begins with a vowel.

(3)	/kas+a/	[ka.sa]	house+FEM SG	'house'
	/kasp+a/	[kah.pa]	dandruff+ FEM SG	'dandruff'
	/des+krem+ad+a/	[deh.kre.ma.ða]	NEG+cream+PPL+ FEM SG	'non-fat'
	/des+arm+ar/	[de.sar.mar]	NEG+arm+INF	'to disarm'
	/los##oxo+s/	[lo.ho.xoh]	the (MASC PL) eye+MASC PL	'the eyes'

In parallel OT, the opaque form [lo.ho.xoh] contains a gratuitous faithfulness violation, the first [h], which is not in a coda yet not faithful to the underlying /s/. The solution in a derivational framework would simply be that there is a cycle, with Aspiration following syllabification at the stem and word level but preceding (re)syllabification at the phrase level.

Kaisse shows that this example does not yield easily to a Sympathy analysis (the solution to most opacity in OT at the time the paper was written, in the early 2000s). However, independently motivated lexical *vs.* phrasal strata provide a limited type of serial derivation, which allows the output of the lexical stratum to form the input to the phrase level. We first derive [de.sar.mar],[3] [loh], and [o.xoh] as outputs of the word-level evaluation, shown in the first tableau in (4). The second tableau then shows how these outputs become the new inputs to the phrase level.

(4) *Word-level derivational OT tableau*

/des+armar/	Onset	*s]$_{CODA}$	Anchor(Rt,σ,L)	Ident(pl)
a. des.ar.mar	*!	*		
☞ b. de.sar.mar			*	
c. deh.ar.mar	*!			*
d. de.har.mar			*	*!

/los/	Onset	*s]$_{CODA}$	Anchor(Rt,σ,L)	Ident(pl)
a. los		*!		
☞ b. loh				*

/oxos/	Onset	*s]$_{CODA}$	Anchor(Rt,σ,L)	Ident(pl)
a. o.xos	*	*!		
☞ b. o.xoh	*			*

At the phrasal level, the outputs [loh] and [o.xoh] are strung together, and it becomes possible to fulfill the onset constraint by violating Anchor(Rt), the constraint which favors a coincidence of syllable boundaries with the edges of morphemes. The opacity emerges naturally from the tableau, because the input form for *los* already has /h/. There is no gratuitous faithfulness violation, as there was in the parallel OT derivation.

[3] Spanish prefixes, like those of Korean and Polish discussed in §3, act in some ways like independent words, with their consonants initially syllabifying into codas regardless of the identity of the following root-initial segment. Harris and Kaisse (1999) present derivational analyses of Rio Negro Argentinian Spanish that show that this separate syllabification occurs early, at the stem level, and is overridden by resyllabification between prefix and vowel-initial stem at the word level. Aspiration in Rio Negro is not a stem-level process – it turns on at the word level. Therefore, the /s/ in *desarmar* does not aspirate in Rio Negro.

(5) *Phrase-level derivational OT tableau*[4]

/loh##o.xoh/	Onset	*s]$_{\text{CODA}}$	Anchor(Rt,σ,L)	Ident(pl)
a. loh.o.xoh	*!			
☞ b. lo.ho.xoh			*	
c. los.o.xoh	*!	*		*
d. lo.so.xoh			*	*!

5 Conclusion

We have shown in this chapter that elements of Lexical Phonology and Morphology were either overstated or disproved by later data, and that not all aspects of the model can or should be integrated into later frameworks. Nonetheless, the perennial LPM concerns with the interaction of phonology with morphology and syntax, and with the concepts of opacity and cyclicity, may be recast in optimality-theoretic terms in current stratal, LPM-OT analyses. Much more importantly, the empirical phenomena which LPM highlighted and legitimized continue to form a central part of the debate.

95 Loanword Phonology

YOONJUNG KANG

1 Introduction

"Loanwords" are words borrowed from one language to another. These borrowed words usually undergo "adaptation" processes to conform to the structural constraints of the borrowing language phonology. Such adaptation affects all facets of phonological structure, reflecting the segmental, phonotactic, suprasegmental, and morphophonological restrictions of the borrowing language. The patterns that emerge in loanword adaptation often reveal aspects of native speakers' knowledge that are not necessarily obvious in data of the native language and, as a result, loanword data can inform our analysis of the native phonology (Hyman 1970; Holden 1976; Ahn and Iverson 2004; Kawahara 2008; Wetzels 2009; Chang, forthcoming, among others). In this respect, loanword adaptation can be considered a real-life *Wug test* (Berko 1958) which can enable us to probe into the grammatical knowledge of speakers in ways that native data alone cannot. Conversely, however, such emergent patterns in loanword adaptation present a learnability puzzle (cf. Broselow 2009): if a loanword pattern is underdetermined by the native phonology, where does the pattern come from? Also, what type of representation does the adaptation process refer to as it searches for licit forms in the borrowing language that most closely match the foreign language input? Is it an abstract phonological representation, a detailed phonetic representation, or a combination of the two? Are there any universal preferences for certain types of repair over others (e.g. epenthesis over deletion, or retention of a vocalic feature over a consonantal feature)? These are some of the major recurring questions in recent studies in loanword phonology and we will address them in this chapter.

This chapter is organized as follows. §2 examines various types of emergent patterns in loanword adaptation which pose a potential learnability puzzle, as well as examining proposed explanations for such emergent patterns. §3 provides a survey of instances of segmental adaptation and the levels of representation they refer to. §4 examines phonotactic adaptations.[1]

[1] There is a growing body of research on suprasegmental adaptation, which is not dealt with in this chapter due to limitations of space. Readers should refer to Y. Kang (2010) for a recent review of this topic.

2 Emergent patterns in loanwords

Research on loanword phonology intensified with the advent of constraint-based models of phonology, such as the theory of Constraints and Repair Strategies (Paradis 1988) and Optimality Theory (Prince and Smolensky 1993) in particular, largely due to their use of output constraints which could motivate the adaptation process even when particular processes themselves had no precedents in the native phonology (Yip 1993; Paradis and LaCharité 1997; Broselow 1999; Jacobs and Gussenhoven 2000). In addition, the principle of *Richness of the Base* in Optimality Theory naturally allows for, and perhaps even requires, an analysis of novel input forms which are not attested in native learning data (cf. Smolensky 1996), making the theory more amenable to the study of loanword adaptation phenomena. However, it has also been noted that constraint-based models only resolve one aspect of the puzzle (i.e. why an adaptation takes place at all), while leaving many other questions unanswered (Golston and Yang 2001; Peperkamp 2005; Broselow 2009). The puzzling emergent patterns in loanword adaptation identified in the literature can be classified into five categories.

1. THE TOO-MANY-SOLUTIONS PROBLEM: The *too-many-solutions* problem (Steriade 2001), or *differential faithfulness* (Broselow 2009), refers to how, given an offending structure in the foreign input, there is almost always more than one logically possible repair strategy, yet adaptation often converges on a specific strategy even when speakers have no apparent evidence for that process in their native language. For example, Hawaiian does not have a voiced stop /b/, and thus, as it is unattested in native phonology by definition, there is no direct evidence from the native phonology as to how such an illicit segment should be repaired. Yet English /b/ is systematically adapted as /p/ (*boulder* → [polu'ka:]) and not /m/, /w/, or any other segment of the Hawaiian inventory (Adler 2006). Similarly, a repair for a phonotactic constraint violation presents a wide range of logically possible choices. For example, when an onset cluster (C_1C_2V) is borrowed into a language which bans complex onsets, the structural requirements of the native language can be satisfied by the deletion of a consonant (> C_2V or C_1V), an option found in French loanwords in Vietnamese (*crème* → [kem]), or by the epenthesis of a vowel in front of the cluster (> vC_1C_2V) or inside the cluster (> C_1vC_2V). The epenthesis repair is found in Japanese (*Christmas* → [kurisumasu]) and Hawaiian (*Christmas* → [kalikimaki]), among other languages, and these examples also illustrate some of the different possibilities in the quality of the epenthetic vowel (Broselow 2006). How, given all these options, do adapters converge on a specific repair strategy?
2. DIVERGENT REPAIR: Even more puzzling is the fact that the repair chosen sometimes seems to contradict the native repair strategy – a situation referred to as *divergent repair* by Kenstowicz (2005) and as *ranking reversal* by Broselow (2009; see also CHAPTER 70: CONSPIRACIES). For example, Thai requires the final syllable of a word to be heavy. This requirement is satisfied by glottal stop insertion in native words, as in /pʰrá/ → [pʰráʔ] 'monk', but by vowel lengthening in English loans, as in *coma* → [kʰō:mā̂:]. In native Korean, a restriction against a sequence of an obstruent + nasal is repaired by nasalization, as

in /kuk-mul/ [kuŋmul] 'soup', but epenthesis is the dominant repair option employed for English loanwords, as in *picnic* → [pʰikʰɨnik] (see Peperkamp *et al.* 2008: 156 for more examples of divergent repairs).

3. Unnecessary repair: Moreover, there are cases where adaptation takes place even when there is no apparent illicit structure in need of repair – a situation referred to as *unnecessary repair* by Peperkamp (2005). For example, Korean allows voiceless stops in coda position, but English voiceless stops are variably adapted with vowel epenthesis, as in *cut* → [kʰʌtʰɨ] ~ [kʰʌt] (Y. Kang 2003). Also, an English cluster of a coronal stop + [w] is adapted with epenthesis in Korean (*twin* → [tʰɨwin], *[tʰwin]) (H. Kang 2006), even though such clusters are allowed in Korean. In Hmong, /ʒ/ in French loanwords is adapted as /j/, despite the fact that /ʒ/ is a phoneme in Hmong (/ʒo.zɛf/ *Joseph* → /jɔ̀.sè/, */ʒɔ̀.sè/) (Golston and Yang 2001). Also, in French loanwords in Japanese and Korean, an epenthetic vowel is added "unnecessarily" following word-final nasals (French [kan] *Cannes* → Japanese [kannu], *[kan] (Shinohara 1997; Peperkamp *et al.* 2008); French [kom] *comme* → Korean [k'omɨ], *[k'om] (H. Kang 1996)).
4. Differential importation: Yet another type of puzzling emergent pattern is *differential importation*. Importation refers to a situation where a structure not attested in native phonology is exceptionally allowed in loanwords. While such importation in and of itself is not a problem from a learnability perspective, the fact that only certain structures, but not others, are imported requires an explanation (Holden 1976; Itô and Mester 1995; 1999, 2001; Davidson and Noyer 1997; Broselow 2009). Given foreign input with two types of novel structures which are both equally unattested in the native data, why is one structure readily allowed into the language but not the other? For example, in Hawaiian, the fully nativized form of the English word *truck* is [kə'lakə]. Also possible is a "less Hawaiian" variant [tə'lakə], where English /t/ remains unadapted. But the variant *['krakə], where the complex onset is retained, but /t/ is adapted as /k/, is judged to be impossible (Adler 2006). In other words, the restriction against /t/ is more easily relaxed than the restriction against an onset cluster. In Russian, the requirement that only palatalized consonants occur before /e/ is often violated in adaptation, but the process of reducing unstressed /o/ and /e/ is more likely to be upheld (Holden 1976).
5. Retreat to the unmarked: While importation is a situation where native constraints are relaxed in the loanwords, allowing a wider range of output structure in the loanword stratum than in the native stratum, we also find the opposite situation, i.e. that loanwords conform to *stricter* structural requirements than the native phonology, such that the foreign input is transformed to an unmarked form, even when there is a seemingly more faithful licit form available in the language. Kenstowicz (2005) refers to such cases as *retreat to the unmarked*. Pitch accent assignment in Japanese and Korean exhibits an emergence of a default accent assignment pattern – the most general pattern being to accent the penultimate syllable in Kyungsang Korean (Kenstowicz and Sohn 2001; Lee 2009) and the antepenultimate mora or syllable in Tokyo Japanese (Shinohara 2000; Kubozono 2006). Similarly, tone assignment in loanwords in White Hmong (Golston and Yang 2001), Thai (Kenstowicz and Suchato 2006), Tibetan (Hsieh and Kenstowicz 2008), Taiwanese (Hsieh 2006), Mandarin (Wu 2006), and Vietnamese (Barker 1969) is based on the segmental

composition of the input. The "retreat to the unmarked" is also found in the segmental domain. In Hungarian, word-final voiceless obstruents in monosyllabic loanwords are geminated, in an apparent requirement for syllables to be heavy (e.g. *shock* → [sokk], *[sok]), but "Hungarian does not have a requirement for syllables to be heavy" and this is a case of "a peripheral stratum of the lexicon introducing a requirement which is not a part of the core-stratum" (Kertész 2003).[2] In Thai, English word-initial voiceless stops are generally adapted as aspirated stops, retaining the aspiration of the input (e.g. English [pʰ]*in* → Thai [pʰin], [tʰ]*eam* → [tʰiːm], [kʰ]*one* → [kʰoːn]). The only exceptions are when there is an unaspirated stop in the same word, as in [pʰ]*eg* → [pek], *[pʰek], and [kʰ]*ook* → [kuk], *[kʰuk], indicating a preference for a non-aspiration harmony – a generalization not present in the native phonology (Kenstowicz and Suchato 2006). The retreat to the unmarked in many of these cases is particularly puzzling, because there is no clear evidence for the "unmarked" status of the resulting structure in the native data.

We now turn to explanations for emergent patterns in loanword phonology in the literature, which can be grouped into five broad categories, which are not necessarily mutually exclusive.[3]

1. Native phonology: The first possibility is that the adaptation pattern is indeed a reflection of language-specific facts of the native phonology – the loanword pattern only appears to be novel. For example, it has been proposed that in segmental adaptation, the choice regarding which feature to preserve and which feature to sacrifice is informed by the status of the features in the native phonology (Hancin-Bhatt 1994; Clements 2001; Herd 2005, among others; see §3.1 for further discussion). Rose and Demuth (2006) propose that the choice of the epenthetic vowel quality in English and Afrikaans loanwords in Sesotho is predictable from the contrastive feature specifications of the native phonology. The native phonology generalizations that affect loanwords can also take the form of covert statistical generalizations. Zuraw (2000) demonstrates that the variable application of nasal substitution in loanwords in Tagalog is a direct reflection of statistical tendencies in the native lexicon. It has also been argued that the default accentuation in loanwords in Tokyo Japanese has a direct correlate in native phonology as a covert default in the lexicon as a whole (Kubozono 2006). Luke and Lau (2008) show that in recent English loans in Cantonese, verbs are generally truncated to become monosyllabic,

[2] Consonant gemination in loanwords is a widespread phenomenon, found in Japanese (Katayama 1998; Shinohara 2004; Kato 2006; Kubozono *et al.* 2008), Italian (Repetti 1993, 2006, 2009), Finnish (Karvonen 2005), Maltese and Egyptian Arabic (Hafez 1996), and Kannada (Sridhar 1990). While some writers analyze gemination in loanwords as the emergence of the unmarked (Repetti 1993; Shinohara 2004; Kubozono *et al.* 2008, among others), others argue that the gemination is motivated by the preservation of the input structure and does not necessarily result in less markedness of the output (Kato 2006; Repetti 2006). Repetti (2006), in fact, refers to the gemination in loanwords in Italian as a case of the emergence of "marked" structures. Under these alternative interpretations, consonant gemination can be categorized as a case of (seemingly) unnecessary repair ((3) above), rather than a retreat to the unmarked.

[3] Another possibility not listed here is to posit a separate set of principles or constraints governing loanword adaptation (Paradis and LaCharité 1997). Such approaches may be considered a type of UG approach if we assume that UG contains a separate set of principles for loan adaptation.

whereas nouns tend to be bisyllabic, and this pattern conforms to lexical statistics in native words. Walter (2006) argues that gender assignment in Arabic loanwords in Spanish also mirrors phonological generalizations and statistical tendencies in the native lexicon.

2. Default setting of UG: However, many emergent patterns in loanwords still elude explanations based on covert generalizations in native phonology. Some attribute these emergent patterns to default settings of Universal Grammar. Default accentuation in Northern Kyungsang Korean exhibits a case of this retreat to the unmarked – a pattern which does not appear otherwise to be motivated in the native phonology and which must thus be attributed to UG (Kenstowicz and Sohn 2001). Uffmann (2006) resorts to a universal markedness hierarchy to account for the epenthetic vowel quality in loanwords in Shona, Sranan, Samoan, and Kinyarwanda. In their influential work on the lexical stratification of Japanese, Itô and Mester (1995, 1999, 2001) argue that the differential importation of foreign features in loanwords reveals covert constraint rankings from the initial state of UG that lie latent in the native phonology (also see Shinohara 2000, 2004).[4] Similarly, Davidson *et al.* (2004) argue that the differing rates in the correct L2 production of foreign clusters reveal a covert ranking in the initial state of UG. Analyses that resort to the universal hierarchy of perceptual similarity (*P-map*) to account for adaptation patterns can also be grouped into this category (Fleischhacker 2005; Shinohara 2006; Kawahara 2008). We will return to this P-map-based approach below.
3. Adaptation as perception: The next possibility is that a seemingly puzzling adaptation in fact takes place during the perception of foreign input and not in the computation of the production grammar (Silverman 1992; Peperkamp and Dupoux 2003; Peperkamp *et al.* 2008; Boersma and Hamann 2009; Calabrese 2009). Based on findings that the perception of foreign sounds is constrained by the segmental and structural constraints of the native language (Massaro and Cohen 1983; Werker and Tees 1984; Dupoux *et al.* 1997; Dupoux *et al.* 1999), it is argued that most, if not all, of the adaptation in fact takes place during the perception of foreign input. This approach breaks away from the assumption that the input to the production grammar in loanword adaptation faithfully retains the phonetic and/or phonological structure of the source language input (cf. Jacobs and Gussenhoven 2000; LaCharité and Paradis 2005). This view provides a solution to many puzzling adaptations, such as *unnecessary repair* or *divergent repair*, where the adaptation pattern seems to contradict the production grammar of the borrowing language.[5]

   While some propose that perceptual adaptation is one of many steps in adaptation (e.g. Silverman 1992; Kenstowicz 2003; Broselow 2009), others propose that "*all* loanword adaptations are phonetically minimal transformations that

[4] Crawford (2007, 2008) argues that the different degree of nativization is grammar-external (i.e. the apparent differential adaptation is a reflection of differing transmissibility of foreign features as they spread from bilingual to monolingual populations). Davidson (2007) also shows how foreign structures can initially be introduced by bilingual speakers and evolve further during transmission to the monolingual population.

[5] Under this view, the burden of explanation for the adaptation pattern is passed on to the perception module and the question of learnability is still not fully resolved – i.e. why is the novel foreign input perceived the way it is? Some cases of perceptual adaptation have a comparable precedent in the native language, but not all do.

apply during speech perception" [emphasis original] (Peperkamp 2005; see also Peperkamp *et al.* 2008 and Boersma and Hamann 2009).[6] Peperkamp *et al.* (2008: 132) state:

> [D]ue to the automatic character of perceptual assimilation and the primacy of perception over production, [our psycholinguistic model] only allows for a limited number of loanword adaptations that are not due to distortions during speech perception.

Boersma and Hamann (2009) take the strict view that perception is largely bound by native output constraints, so that a structure that violates native constraints cannot be perceived faithfully. Peperkamp *et al.* (2008), on the other hand, allow for the possibility that foreign structures may be correctly perceived, leading to importation rather than adaptation. Overall, this approach makes the strong empirical prediction that adaptation is tightly correlated with perception. See CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY for further discussion.

4. PERCEPTUAL SIMILARITY: Steriade (2001) proposes that speakers possess knowledge of perceptual similarity between strings of sounds (the P-map), which is utilized in loanword adaptation (see Yip 2002, 2006; Y. Kang 2003; Kenstowicz 2003, 2007; Fleischhacker 2005; Kawahara 2006; Miao 2006; Shinohara 2006; Y. Kang *et al.* 2008, among others, for the application of P-map constraints to loanword adaptation).[7] The perceptual similarity approach, similar to the adaptation-as-perception approach, places an emphasis on perceptual factors and phonetic details in accounting for adaptation patterns. However, the former differs from the latter in that perceptual factors are incorporated into grammatical constraints which can be ranked with respect to other grammatical constraints. As a result, the P-map dictates that the repair be as perceptually minimal as possible, but does not necessarily dictate whether adaptation has to actually take place; this is determined by the relative ranking of P-map-based faithfulness constraints with respect to native structural constraints (Steriade 2007). In other words, this approach allows for the possibility that foreign input is faithfully perceived, yet can nevertheless be adapted to adhere to native phonotactic constraints. For example, Kabak and Idsardi (2007) examined Korean speakers' perception of English consonant clusters that violate phonotactic restrictions in Korean and found that some clusters that undergo adaptation in loanwords, such as [gm] and [km], were correctly perceived as distinct from their counterparts with an epenthetic vowel, i.e. [gɯm] and [kɯm] respectively. This contrasts with the adaptation-as-perception view, where the connection between perception and adaptation is much tighter. Yip (2002: 10) notes:

> [R]eference to perceptual salience within the phonology proper resolves the paradox that quite subtle non-native distinctions are clearly perceived, but nonetheless less salient segments are more likely to be sacrificed than highly salient ones.

[6] Peperkamp (2005) and Peperkamp *et al.* (2008) acknowledge the possibility that some adaptation processes may be due to non-perception-related factors (e.g. cases of "retreat to the unmarked").

[7] The knowledge of the P-map is largely universal, and therefore this approach can be categorized under the UG approach. However, Steriade (2001: 243) also leaves open the possibility that the specifics of the P-map can differ according to language-specific experiences, and Y. Kang (2003), for example, employs the P-map model, but assumes that some aspects of the P-map can be language-specific.

A strict interpretation of the P-map, as presented in Steriade (2009), predicts a strong correspondence between native repair and loan repair, since the P-map hierarchy affects both native and loanword phonology. However, cases of divergent repair, discussed above, contradict this strict interpretation. Y. Kang (2003), Kenstowicz (2005), and Yip (2006), on the other hand, propose loanword-specific mapping constraints, variously named Be Similar, Match, Mimic, or output–output faithfulness constraints, which are distinct from native input–output constraints (see chapter 63: markedness and faithfulness constraints). These constraints require preservation of the source language information, and – depending on the relative ranking of these constraints with respect to native markedness and faithfulness constraints – importation (F_{loan} >> M >> F_{native}), retreat to the unmarked (F_{native} >> M >> $F_{foreign}$), or divergent repair ($F1_{loan}$ >> $F2_{loan}$, while $F2_{native}$ >> $F1_{native}$) can occur (Kenstowicz 2005).

Yip (2006) also notes that adaptation by perception alone is too deterministic to account for the range of variation attested in data. For example, a single language, such as Mandarin, can show different adaptation strategies for illicit codas in English loanwords, namely epenthesis in Mainland Mandarin (*Friedman* → [fu.li.tə.man]) and deletion in Taiwanese Mandarin (*Friedman* → [fu.li.man]). Similarly, Adler (2006) reports variation between deletion and epenthesis in English loanwords in Hawaiian. In such cases, perception underdetermines adaptation and the ranking of grammatical constraints determines the final outcome. Broselow (2009) and Peperkamp *et al.* (2008), concerned with the unconstrained nature of these loanword-specific mapping constraints which can be freely ranked across languages, argue that adaptation is actually much more constrained by perceptual factors than is predicted by loanword-specific faithfulness constraints.

5. Grammar-external factors: Finally, it has been proposed that sociolinguistic or grammar-external factors affect the pattern of (non-)adaptation, especially where aspects of loanword phonology are underdetermined by grammatical factors. First of all, the rate of importation has been shown to positively correlate with the level of bilingualism in the community (Haugen 1950; Paradis and LaCharité 1997, 2008, 2009; Heffernan 2007; Friesner 2009a). The level of bilingualism has also been argued to determine the mode of adaptation: the higher the level of bilingualism, the more likely the adaptation will refer to phonological representations over phonetic representations of the input language (Heffernan 2007).[8] The channel of borrowing (i.e. spoken *vs.* written) and the related influence of orthography have also been proposed to affect the adaptation pattern (Dohlus 2005; Smith 2006; Vendelin and Peperkamp 2006; Detey and Nespoulous 2008; Friesner 2009a). It is also proposed that adapters look to orthography, especially when other factors underdetermine the adaptation pattern and the adapters are uncertain about the "correct" pattern (Y. Kang 2009). For example, in 1930s Korean, non-preconsonantal /s/ in English loanwords was variably adapted as lax /s/ or tense /s'/, the latter written as geminate <ss> in Korean orthography. Whether the English /s/ was written with a single or double <s> had a significant effect on the choice between the two adaptation patterns.

[8] See Paradis and LaCharité (2008, 2009) for arguments against this view that the mode of adaptation is dependent on the level of bilingualism.

3 Segmental adaptation

When the foreign input contains a non-native segment, the segment is replaced with the "closest" sound in the native language. The main problem here is how to define the "closest" sound. For example, when a front rounded vowel ([−back, +round]) is borrowed into a language that lacks such vowels, the vowel undergoes transformation. The French high rounded vowel [y] is adapted as [u] in White Hmong (Golston and Yang 2001), preserving the rounding feature of the input, as [i] in Mauritian Creole (Jacobs and Gussenhoven 2000), Fula, Kinyawaranda, and Lingala (Paradis 2006), preserving the backness feature of the input, and variably as [u] or [i] in Moroccan Arabic (Paradis 2006) and Egyptian Arabic (Hafez 1996). The same vowel is adapted as [ju] in Japanese (Dohlus 2005), preserving both the backness and rounding features of the input segment, but creating a bisegmental structure. Such diverse substitution indicates that there is no universal metric of similarity that all languages follow in segmental adaptation. How then is similarity determined in segmental adaptation? A related key issue in the literature on loanword phonology, and segmental adaptation in particular, is the level of representation that the similarity calculation refers to. This question can be examined in two parts: the nature of the *borrowing* language representation (§3.1) and the nature of the *input* language representation (§3.2).

3.1 *Borrowing language representation*

As for the level of representation of the *native* language which acts as a sieve for the foreign language input, it has been hypothesized that phonological features in the input form that are underlyingly contrastive in the native phonology are preferentially preserved over features that are redundant and non-contrastive in the native phonology (Clements 2001; Herd 2005; Dresher 2009, among others). For example, in all Indo-Aryan languages that maintain a contrast between dental and retroflex stops, English alveolar stops ([+anterior, −distributed]) are consistently adapted as retroflex stops ([−anterior, −distributed]), rather than as dental stops ([+anterior, +distributed]) (Lehiste 1988; Arsenault 2009). For example, English *taxi* and *soda* are adapted as /ʈæksi/ and /soɖa/, respectively, in Hindi. The observed adaptation preserves the [−distributed] feature of the English input while sacrificing the [+anterior] feature. Arsenault (2009) proposes that this is due to the fact that [distributed] is a phonologically active feature in these host languages and [anterior] is not.

Similarly, Clements (2001) discusses the adaptation of English consonants to Hawaiian and proposes that substitution preserves the contrastive feature specification of the native language, which is determined by the composition of the native inventory, as well as a universal hierarchy of feature accessibility. Herd (2005) applies Clements's (2001) model to the adaptation of English consonants in other Polynesian languages. For example, both Hawaiian and New Zealand Maori lack sibilants, and English sibilants /s z ʃ ʒ/ are adapted to /h/ in New Zealand Maori, but the same English sibilants map to /k/ in Hawaiian, despite the fact that both /k/ and /h/ are available in both languages.[9] According to Herd

[9] Adler's (2006) elicitation data, however, show that sibilants are variably adapted as /k/, /h/, or null (i.e. are deleted) in Hawaiian.

(2005), the crucial difference between Hawaiian and New Zealand Maori is that in Hawaiian /h/ contrasts with /ʔ/ and, as a result, /h/ is contrastively specified for [+spread glottis], thereby creating a mismatch with English sibilants, while in New Zealand Maori /h/ does not contrast with another glottal sound and therefore is unspecified for [+spread]. At the same time, in New Zealand Maori, /t/ and /k/ contrast and /k/ is contrastively specified for [Dorsal], which creates a mismatch with English sibilants. Similarly, Hancin-Bhatt (1994) and Brown (2000) claim that features that play a higher contrastive function in the L1 are more likely to be preserved in the modification of foreign sounds in L2 production.

An alternative view is that phonetically salient input characteristics are preferentially preserved over less salient characteristics and that the abstract phonological status of those characteristics – i.e. whether they are underlyingly contrastive or not – is not particularly relevant (Brannen 2002; Hsieh and Kenstowicz 2008; Lin 2008; Hsieh *et al.* 2009; Steriade 2009). Given that phonologically contrastive features tend to be phonetically salient and that there is also a degree of indeterminacy in phonological analyses of contrastiveness, the two views often converge on the same predictions, but not always (see Y. Kang 2008a for more discussion on this issue).

For example, Brannen (2002) proposes that the English interdental fricative /θ/ is adapted differently in European French and Quebec French, mapping to /s/ in European French and to /t/ in Quebec French. The crucial difference between the two dialects is that in European French the coronal fricative /s/ has a dental place of articulation, while in Quebec French /s/ is alveolar, a phonetic detail that is not contrastive in either of the dialects. On the basis of these findings, Brannen (2002) argues that adaptation is sensitive to non-contrastive, but phonetically salient, features, such as stridency and minor place of articulation features. The adaptation of English vowels in Mandarin (Lin 2008) is another case where non-contrastive features of the borrowing language are preferentially preserved at the cost of contrastive features. In Mandarin non-high vowels, height is contrastive but backness is not – it is predictable from the context (Duanmu 2000). If the phonological status of these features directly influences the segmental adaptation, we would expect height to be preserved and backness to be sacrificed when the input vowel has to be modified due to phonotactic or semantic restrictions. However, contrary to this prediction, Lin's (2008) survey finds that when English vowels are adapted in Mandarin, vowel height is routinely altered, but backness is fairly consistently preserved (on the relation between backness and vowel height see also CHAPTER 21: VOWEL HEIGHT). A similar tendency is also found in English loanwords in Cantonese (Yip 2002).

Proponents of perceptual similarity assume that there is a quasi-universal hierarchy of featural salience such that "certain features are inherently more salient than others" (Brannen 2002). For example, Steriade (2009) states that "stricture differences ([sonorant], [continuant], [consonantal]) play the major role in generating dissimilarity judgments, in contrast to voicing and place."[10] This hierarchy is compatible with the adaptation pattern found in Selayarese (Broselow 1999) and

[10] Clements's feature hierarchy (2001: 80, repeated below) also predicts quasi-universal tendencies in selective feature preservation, although in his model, only features that are contrastive in the native language are relevant in loanword adaptation: [coronal] > [sonorant] > [labial] > [dorsal] > [strident] > [nasal] > [posterior] > [lateral] > [voice].

Mandarin (Miao 2006). In Selayarese, the coda position is restricted to glottal stops and velar nasals, and potential violations of the coda restriction in loanwords from Bahasa Indonesian are repaired by changes in place of articulation, but never by changes in nasality or continuancy. Also, in a comprehensive examination of segmental adaptation in English, German and Italian loanwords in Mandarin, Miao (2006) concludes that segmental adaptation obeys the following hierarchy: IDENT(Manner) >> IDENT(Major Place) >> IDENT(Place) >> IDENT (Voice/Aspiration). Brannen (2002), on the other hand, provides a slightly different hierarchy to account for the adaptation of English dental fricative in various languages: Turbulence (strident/mellow) > Major Articulators (Labial /Coronal) > Airflow (stop/continuant) and Location (Lip/Dental/Alveolar) > Minor Articulators (Laminal/Apical). It remains to be seen to what extent the claim of universal hierarchy holds true, either as an absolute principle or as a general tendency, in view of the full body of data.

Finally, the adaptation-as-perception view claims that segmental adaptation is also a result of L1 speech perception applied to the foreign acoustic input (Silverman 1992; H. Kim 2008, 2009; Peperkamp *et al.* 2008; Boersma and Hamann 2009). H. Kim (2008, 2009) proposes that segmental adaptation is due to L1 feature-driven perception. Foreign input is mapped to a phonological category via perceptual mapping of the acoustic signal to relevant featural representations. The concept of "feature" in her model is somewhat more abstract than what is assumed in the other studies discussed above. For example, a [tense] feature can be signaled by a combination of acoustic correlates, such as duration and pitch of the adjacent vowel, and the same feature can be signaled by different combinations of acoustic correlates depending on the context within which it occurs.

As mentioned above, the adaptation-as-perception view predicts a very strong correlation between perception and adaptation. The strongest view, where all foreign segments are obligatorily transformed to native sounds (Silverman 1992; Boersma and Hamann 2009, among others) has difficulty accounting for how some foreign contrasts can be easily perceived (Best 1994), and some foreign segments are adopted without adaptation (i.e. imported). Also, the view that all adaptation occurs during perception is unable to explain cases where adapters can perceive the foreign contrast but nevertheless adapt it to a native segment. Also, there are cases where the perception results do not match the adaptation results. For example, Brannen (2002) shows that [f] is the segment that is most likely to be confused with [θ] by French speakers, yet [t] or [s] is the consonant of choice in the adaptation of English [θ].

3.2 *Input language representation*

With respect to the input to the adaptation process, some argue that the input is the phonological representation of the source language, devoid of redundant phonetic details (Paradis and LaCharité 1997; Shinohara 2004; LaCharité and Paradis 2005). This view, referred to here as the "phonological input" view, predicts uniform adaptation of a source language phoneme across different contexts (i.e. phonemic uniformity). Others assume that the input is the acoustic representation of the source language, including all subphonemic phonetic details of the source language sounds (Silverman 1992; Yip 1993; Peperkamp 2005; Iverson and Lee 2006; Peperkamp *et al.* 2008). The latter view, referred to here as the "phonetic input" view, predicts that a given phoneme of the source language can be adapted differently in different segmental contexts depending on its surface phonetic characteristics in the input language.

Empirical research accumulated over the years, however, shows that adaptations of both types are amply attested. The range of possibilities is well illustrated by the different adaptation of English voiceless stops in languages with aspiration contrasts in voiceless stops. English voiceless stops vary in aspiration depending on the context. The "phonological input" view predicts that the adaptation should be uniform, regardless of position, barring modifications due to phonotactic restrictions. The "phonetic input" view, on the other hand, predicts adaptation to aspirated and unaspirated stops, depending on the allophonic realization of the English input stops. An example of adaptation based on "phonological input" is found in Korean, where English voiceless stops are consistently adapted as aspirated, even in contexts where the English input is unaspirated, as in [tʰ]*oy* *s*[t]*ory* → [tʰoi sitʰori].[11] Examples of adaptation based on "phonetic input" are found in Cantonese (Silverman 1992; Yip 1993) and Thai (Kenstowicz and Suchato 2006). In Thai, English voiceless stops are adapted as aspirated in word-initial position, but as unaspirated following /s/. In word-medial position and elsewhere, the adaptation varies between aspirated and unaspirated stops, with the aspirated adaptation being more likely in pretonic position.

Burmese and Mandarin present a mixed picture. In Burmese, voiceless stops are adapted as unaspirated voiceless stops in most contexts, as in *Poland* → [pou.lã], except in English word-initial TR sequences, where the stop is adapted as aspirated, as in *cream* → [kʰə.jĩ] (Chang 2009). In Mandarin, the majority pattern is to adapt English voiceless stops as aspirated stops regardless of the input aspiration as in [pʰ]*izza* → [pʰitsa] ~ [pʰisa] and *hi*[p]*ies* → [sipʰiʂ] (Paradis and Tremblay 2009). However, the aspirated adaptation is proportionately much more likely to occur when the English input stop is aspirated (88.8 percent) than when it is unaspirated (78.8 percent), indicating some influence of the phonetic information.

Additional examples of segmental mapping based on phonological *vs.* phonetic input found in the literature are listed in (1).

(1) a. *Phonetic input*

Thai: English /v/ is mapped to /w/ in the onset and to /p/ in the coda (Kenstowicz and Suchato 2006).

Jahai: Malay /k/ is generally adapted as /k/, but as /ʔ/ word-finally, reflecting the allophonic realization of /k/ in the Malay input (Burenhult 2001).

Fon: French /r/ is mapped to /xl/ word-initially, to /l/ in non-initial prevocalic position, and is deleted in preconsonantal or word-final position (Gbéto 2000, as discussed in Kenstowicz 2003).

Korean: English /s/ is adapted as /s'/ in prevocalic or word-final position and as /s/ elsewhere (S. Kim and Curtis 2002; Ahn and Iverson 2004; Davis and Cho 2006; Y. Kang 2008c).

1930s Korean: English voiced stops /b d g/ are mapped to tense stops /p' t' k'/ word-initially and as lax stops /p t k/ elsewhere (Y. Kang 2008b).

[11] See Oh (2004) and Kenstowicz (2005) for alternative analyses.

Yanbian Korean: Mandarin unaspirated voiceless stops/affricates /p t k ts tɕ tʂ/ are mapped to tense stops/affricates /p' t' k' c'/ word-initially, but to lax stops/affricates /p t k c / elsewhere (Ito and Kenstowicz 2009).

Korean: Japanese voiceless stops are adapted as lax stops word-initially, but as lax or tense stops in word-medial position, depending on the place of articulation (Ito *et al.* 2006).

Hawaiian: English /t d/ is mapped to /k/ in general but the adaptation varies between /k/ and /ʔ/ word-finally (Adler 2006).

Palauan: Palauan lacks /g/ as a phoneme. Japanese /g/ is adapted as /k/ word-initially but as /ŋ/ word-medially, reflecting the allophonic variation of Japanese /g/ (Takahashi 2006).

b. *Phonological input*

Thai: English voiced stops are adapted as voiced word-initially, where they are significantly devoiced, and hence voiceless adaptation may be expected under the phonetic adaptation view (Kenstowicz and Suchato 2006).

Korean: English non-morphemic /z/ is consistently adapted as /c/, even in contexts where /z/ is significantly devoiced and is better matched by /s/ or /s'/ (Y. Kang 2009).

See LaCharité and Paradis (2005) for more examples.

The empirical evidence overwhelmingly suggests that loanword adaptation is not completely based on phonetic or phonological representation; rather, both types of adaptations are attested, oftentimes within a single contact situation, leading many to conclude that the adaptation process can refer to both phonological and phonetic (as well as morphological,[12] semantic, and orthographic) details of the source language (Y. Kang 2003, 2009; Adler 2006; Kenstowicz and Suchato 2006; Smith 2006; Friesner 2009a, 2009b; Chang, forthcoming, among others).

It seems reasonable to assume that adapters have some knowledge of the input language phonology, which is accessible in adaptation – contra the view that the input to adaptation is an unstructured acoustic signal (Silverman 1992). At the same time, simply the fact they know phonology does not mean that it is the only aspect they pay attention to (Y. Kang 2008a; Chang, forthcoming) – contra Paradis and LaCharité (2009). From this perspective, a more appropriate question is not whether loanword adaptation is phonological or phonetic, but rather what factors make one type of adaptation more likely than the other. For example, aspects of the contact situation, such as the level of bilingualism or the spoken *vs.* written channel of borrowing, have been proposed as factors that help shape the adaptation pattern (Dohlus 2005; Rose and Demuth 2006; Smith 2006; Heffernan 2007; Y. Kang 2008c, 2009).

4 Phonotactic adaptation

I now turn to adaptation due to phonotactic restrictions. Here again, we are faced with the "too-many-solutions" problem and many seemingly puzzling emergent adaptation patterns. In §4.1, I will examine the claim that epenthesis is the generally

[12] See Repetti (2006, 2009), Y. Kang (2009), and Friesner (2009b) for discussion on the role of morphological information in the input language in adaptation.

preferred adaptation over deletion (Paradis and LaCharité 1997; Shinohara 2006). In §4.2, I will examine co-occurrence restrictions where the adaptation forces the preservation of certain features over others.

4.1 Epenthesis vs. deletion

Paradis and LaCharité (1997) propose the *Preservation Principle*, which dictates that the input material be preserved as much as possible, unless the cost of preservation is too extreme (see also CHAPTER 76: STRUCTURE PRESERVATION and CHAPTER 67: VOWEL EPENTHESIS). In other words, epenthesis should generally be preferred over deletion. In this section, I will provide a survey of word-initial and word-final cluster adaptations to examine whether epenthesis is indeed the preferred option overall.

4.1.1 Word-initial clusters

As for word-initial onset clusters, a survey of available cases indeed shows that epenthesis is the predominant choice of repair. Epenthesis-only adaptation is found in Burmese (Chang, forthcoming), Egyptian Arabic (Hafez 1996), Farsi (Shademan 2003), Fijian (Schütz 1978), Fula (Paradis and LaCharité 1997), Hindi (Singh 1985), Huave (Davidson and Noyer 1996), Inuktitut (Pollard 2008), Japanese (Katayama 1998),[13] Kikuyu (Mwihaki 2001), Korean (H. Kang 1996, among others), Samoan (Cain 1986), Sesotho (Rose and Demuth 2006), and Shona (Uffmann 2006), among others. For example, Inuktitut does not allow consonant clusters, and onset clusters are repaired by epenthesis as in *(Santa) Claus* → [kalasi] and *Scotia* → [sikusa] (Pollard 2008).

There are many fewer languages that only employ a deletion strategy in word-initial clusters and many of them are creole languages where only /s/ + stop clusters are repaired (see also CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS). In the English-based creole Sranan, /s/-nasal clusters are retained without adaptation, as in *smoke* → [smoko], but /s/-stop clusters are repaired by /s/-deletion: *speak* → [piki] (Alber and Plag 2001). A similar pattern is found in Dutch-based Negerhollands (e.g. *stop* → [tɔp] ~ [stop]; Sabino 1990, cited in Alber and Plag 2001), English-based Krio (e.g. *spoon* → [pun]) and Guyana (e.g. *story* → [tɔri]; Tinelli 1981, cited in Fleischhacker 2005), and an older stage of English-based Belizean Creole (e.g. *skirt* → [koːti]; Greene 1999, cited in Fleischhacker 2005). The only non-creole language where deletion repair is reported to the exclusion of epenthesis for word-initial clusters is Finnish, where all consonants, except for the one immediately preceding the vowel, are deleted (e.g. Swedish *strand* → [ranta] 'shore', Russian *gramatika* → [raːmattu] 'bible'). English loans found in "Finglish" (Finnish as spoken by the Finns who migrated to America) also employ the deletion strategy, as in *street* → [riːti] ~ [triːti] and *blanket* → [lɛnketti] ~ [plɛnketti] (Karttunen 1977). However, in most deletion-only cases, importation of clusters is the prevalent option along with deletion.[14]

[13] According to Smith (2006), deletion repair is marginally found even in word-initial clusters in Japanese, but these forms exist as a part of doublets with a variant with epenthesis.

[14] As Fleischhacker (2005) points out, the deletion of /s/ is potentially problematic for theories of loanword adaptation that appeal to perceptual factors (i.e. the adaptation-as-perception view and the perceptual similarity view), since /s/ is arguably one of the most salient consonants and is argued to be preferentially preserved in most other contexts (cf. Steriade 2001; Shinohara 2006).

Several languages use a deletion strategy in combination with epenthesis word-initially. Polynesian languages that lack /s/ in their inventory delete /s/ in /s/-initial clusters while all other clusters are repaired by epenthesis. Examples include Maori (*frock* → [poraka], *Scotsman* → [koːtimana]; Harlow 2004; Herd 2005) and Tahitian (*president* → [peretiteni], *stocking* → [totini]; Geraghty and Tent 2004a; Herd 2005). In Hawaiian, initial clusters are generally adapted with epenthesis, as in *blessing* → [pele'kine], but for /s/-initial clusters, there is variation between epenthesis and /s/-deletion, as in *speak* → [kə'pikə] ~ ['pikə] (Adler 2006). Adler (2006) attributes the Hawaiian pattern to the fact that /s/ is not a segment of Hawaiian and retaining it requires additional steps of repair in violation of the Threshold Principle of Paradis and LaCharité (1997). However, note that this explanation does not extend to the deletion of /s/ in the creole languages discussed above. For example, in Sranan, the language not only has /s/, but it preferentially preserves /s/ in non-initial position, as in *sister* → [sisa], *[sita], *haste* → [hesi], *[heti] (Alber and Plag 2001).

Other languages that show a combination of deletion and epenthesis strategies preferentially preserve /s/-initial clusters, while obstruent + liquid clusters may be simplified via deletion of C2 (liquid) (cf. Fleischhacker 2005). In Cantonese, deletion and epenthesis repairs are both attested, and the variation is conditioned by the bisyllabic word requirement, as shown in *freezer* → [fiisa] *vs. cream* → [kejlim] (Silverman 1992; Yip 1993). Interestingly, it is only the obstruent + liquid clusters that allow deletion (of the liquid); /s/-initial clusters undergo epenthesis rather than deletion. Mandarin shows a similar asymmetry between cluster types (Miao 2006). Vietnamese is another case where the repair varies between deletion and epenthesis for obstruent + liquid clusters (French *gramme* → [gam] ~ [garam]) (Barker 1969; Andrea Hoa Pham, personal communication).

In Thai, /s/-initial clusters are adapted with epenthesis (*style* → [sataːj]), but obstruent + liquid clusters are often adapted with deletion of the liquid (*plastic* → [pattik]) (Gandour 1979).[15] A similar asymmetry is found in Contemporary Saramaccan (Aceto 1996, cited in Fleischhacker 2005).

Finally, in Telugu, the repair varies between epenthesis and deletion, regardless of the type of cluster, and deletion targets a liquid in obstruent + liquid clusters (*glass* → [gasu] ~ [galasu]) and /s/ in /s/-initial clusters (*station* → [teʃənu] ~ [isteʃənu]) (Broselow 1992, cited in Fleischhacker 2005). Languages that employ deletion repair in word-initial clusters are summarized in Table 100.1.

4.1.2 Word-final coda consonants and clusters

Compared to word-initial position, repairs for coda clusters (e.g. NoCoda or CodaCondition violation) in word-final position are more variable and it is not clear whether epenthesis is cross-linguistically the preferred strategy over deletion in this position (see also chapter 36: final consonants). Examples of languages that choose epenthesis as the repair of choice for word-final coda restrictions include Japanese (Katayama 1998), Kikuyu (Mwihaki 2001), Korean (H. Kang 1996), and Sesotho (Rose and Demuth 2006). On the other hand, there are languages that systematically choose deletion for repair, such as Vietnamese (Barker 1969), Burmese (Chang 2009), Thai (Kenstowicz and Suchato 2006), and White Hmong (Colston

[15] Kenstowicz and Suchato (2006) report that obstruent + liquid clusters are allowed in Thai and therefore remain unadapted.

Table 100.1 Languages that show deletion repair in word-initial clusters

	/s/-C	*Obstruent + Liquid*	*Languages*
Deletion only	**/s/-deletion** ~ importation	*n/a*	Sranan, Negerhollands, Krio, Guyanese Creole, Belizean Creole
	C1 deletion ~ importation	**C1 deletion** ~ importation	(older) Swedish, Russian, and English loans in Finnish
Epenthesis and deletion	**/s/-deletion** ~ epenthesis	Epenthesis (CC > CvC)	Hawaiian, Maori, Tahitian
	Epenthesis (sC > svC)	Epenthesis ~ **C2 deletion**	Cantonese, Mandarin, Vietnamese
	Epenthesis (sC > svC)	Importation ~ **C2 deletion**	Contemporary Sarammacan, Thai
	Epenthesis (sC > vsC) ~ **/s/-deletion**	Epenthesis (CC > CvC) ~ **C2 deletion**	Telugu

and Yang 2001).[16] Some examples from White Hmong include *cake* → [kʰê] and French *Adam* [adam] → [ʔàdà]. Notable is the fact that all languages listed above that choose deletion repair in coda position have a strong preference for monosyllabic morphemes. But note that even these languages do not systematically prefer deletion for onset clusters. For example, Burmese chooses epenthesis for word-initial clusters but debuccalization and deletion for word-final clusters, as in *Christ* → [kʰə.ɾɪʔ] (Chang 2009).

Yet another group of languages show both epenthesis and deletion depending on the segmental composition of the offending structure. These languages include Cantonese (Silverman 1992), Fijian (Schütz 2004; Shinohara 2006; Kenstowicz 2007), Hawaiian (Adler 2006), Inuktitut (Pollard 2008), Hawaiian Japanese (Higa 1970; Smith 2006), Mandarin (Miao 2006), Maori (Harlow 2004), Marshallese (Shinohara 2006), and Yoruba (Shinohara 2006). Examples from Fijian, *east* → [ˈisi], *wolf* → [ˌoˈliva], illustrate the variability of repair patterns.

The question then is what factors contribute to the choice between epenthesis and deletion in coda position. The P-map theory proposes that, all things being equal, consonants with more salient perceptual cues are more likely to be retained than those with less salient cues (Steriade 2009; see Shinohara (2006) and Fleischhacker (2005) in particular for the application of the P-map theory for variable deletion in onset and coda clusters, respectively. See also Miao (2006) for a detailed examination of onset and coda repair patterns for different segmental types in Mandarin).

[16] Golston and Yang (2001) state that "syllable-final consonants are categorically deleted in White Hmong." While the majority of relevant data available in Golston and Yang (2001) indeed show deletion of word-final coda consonants, there are some exceptional forms showing final epenthesis (French [lyk] *Luke* → [lɨ.kà]).

As for grammar-external factors, Smith (2006) demonstrates that English loanwords in Japanese are systematically adapted with epenthesis in the homeland variety, with deletion attested only sporadically, but deletion is much more prevalent in Hawaiian Japanese. She attributes the difference to the different channel of borrowing: the homeland variety is more influenced by the written input and is thus more likely to preserve the input material, while the Hawaiian variety is more influenced by the aural input and is more prone to perceptual adaptation. Miao (2006) proposes a similar explanation to account for why coda deletion is much more frequent in English loanwords than in German loanwords in Mandarin.[17]

The choice in the specific location and the quality of the epenthetic segment also often lacks a straightforward precedent in native phonology (see Fleischhacker 2005 for a P-map-based account of the location of the epenthetic vowel in word-initial clusters). Different strategies for determining the quality of the epenthetic segment include default insertion, vowel harmony, and consonantal assimilation (cf. de Lacy 2006; Uffmann 2006). The specific patterns of vowel epenthesis have been examined in detail in various languages, e.g. Farsi (Shademan 2003), Fijian (Kenstowicz 2007), Hindi (Singh 1985), Inuktitut (Pollard 2008), Kikuyu (Mwihaki 2001), Korean (Oh 1992; Heo 2006; K. Kim 2009), Mandarin (Miao 2006), Cook Island Maori (Kitto and de Lacy 1999), Samoan (Uffmann 2006), Sesotho (Rose and Demuth 2006), Selayarese (Broselow 1999), Shona (Uffmann 2006), Sranan (Uffmann 2006), and Yoruba (Pulleyblank 1988, Akinlabi 1993). Here again, explanations proposed for the choice of epenthetic vowel and its location are very diverse, from the spreading of (contrastively marked) features determined by native phonology (Akinlabi 1993; Pollard 2008; K. Kim 2009) to the emergence of the unmarked (Lombardi 2002; Uffmann 2006), perceptual similarity (Y. Kang 2003; Kenstowicz 2007; Steriade 2008), and epenthesis by misperception (Dupoux *et al.* 1999; Kabak and Idsardi 2007). See CHAPTER 67: VOWEL EPENTHESIS.[18]

4.2 *Co-occurrence restrictions*

Languages may also impose restrictions on possible combinations of vowels and consonants, and such restrictions can induce adaptation of the foreign input. Again, we are faced with the too-many-solutions problem. In the case of segmental adaptation discussed in §3, the features that compete for preservation are all consonantal features or all vocalic features, but in the case of sequential co-occurrence restrictions, vocalic and consonantal features are pitted against each other. Here I will discuss a few such examples.

In Inuktitut, vowels are allophonically retracted next to a uvular consonant, as in /tiriganniq/ [tiriganniq] 'fox' and /pirurtuq/ [pirurtoq] 'fruits' (Denis and Pollard 2008). Therefore, on the surface, a sequence of a retracted vowel and a

[17] Miao (2006) also notes that loans used in commercial brand names are more likely to show deletion than other loans.

[18] Consonantal epenthesis is also a common repair for a vowel-initial word or vowel hiatus in languages that require onsets. Examples of consonantal epenthesis in loanwords are found in Egyptian Arabic (Hafez 1996), Burmese (Chang, forthcoming), Jahai (Burenhult 2001), and White Hmong (Golston and Yang 2001), among others.

non-uvular consonant cannot occur. Thus, when the English input contains illicit sequences such as /ɪk/, there are at least two logically possible repairs to bring the foreign input in line with native phonotactics: change the vowel quality to [ik] or change the place of articulation of the dorsal consonant to [ɪq]. Actual data suggest that the consonantal place remains stable; the vowel quality changes, as in *six* → [siksi], *[sɪqsi] (based on Pollard 2008). This seems like a case of straightforward maintenance of contrastive features of the native language, since in Inuktitut, the distinction between tense and lax vowel is allophonic, but the contrast between velar and uvular places of articulation is phonemic.

French and Spanish loanwords in Moroccan Arabic, on the other hand, show the opposite pattern (Kenstowicz and Louriz 2009). In Moroccan Arabic, the vowels /i a u/ are allophonically lowered and/or retracted to [e ɑ o] when adjacent to emphatic (= pharyngealized) consonants, as in [sif] 'sword' *vs.* [sˤef] 'summer'. In other words, the contrastive distinction in Moroccan Arabic is the emphatic *vs.* non-emphatic distinction in consonants, whereas the vowel-quality difference is an allophonic property. In actual adaptations, mid vowels of French and Spanish are adapted as their corresponding mid vowels in Moroccan Arabic, but with an emphatic version of the adjacent consonants, as in French *taupe* [top] → Moroccan Arabic [tˤobˤbˤ-ɑ] 'rat (FEM)', retaining the allophonic distinction of the native language over a contrastive distinction. The adaptation of the English sequences [ɑn] and [æŋ] in Mandarin, as examined by Hsieh *et al.* (2009), presents a similar pattern. In Mandarin, the backness of a low vowel is predictable from the context; specifically, it is front before /n/, but is back before /ŋ/, a restriction referred to as "rhyme harmony" by Duanmu (2000). English, on the other hand, allows the free combination of low vowels and nasal codas, including [ɑn] and [æŋ], which violates the phonotactic constraints of Mandarin. Surprisingly, in loanword adaptation, the backness of the vowel is preferentially preserved over the place of articulation of the nasal consonants ([ɑn] → [ɑŋ], [æŋ] → [an]), despite the fact that the place feature of a nasal consonant is contrastive and the backness of a low vowel is not in Mandarin. Some representative examples are *monsoon* [mɑnsun] → *mang.xun* [maŋ.ɕyn] and *bank* [bæŋk] → *ban.ke* [pan.kʰɤ]. They attribute this pattern to the perceptual saliency of vowel place contrasts over that of consonantal nasal place contrasts, which are known to be perceptually not very salient (Jun 2004; Steriade 2009).

While the place feature of a consonant seems vulnerable in the Mandarin and the Moroccan Arabic examples, consonantal manner features such as [nasal] seem to be more stable than vowel features. Burmese (Chang 2009) provides a relevant example. In Burmese, only glottal stops are allowed in coda position and coda nasals are adapted as nasalization on the preceding vowel, as in *champagne* → [ʃȁpḗĩ]. However, not all Burmese vowels have a nasalized counterpart. When English words contain a vowel that lacks a nasal counterpart in Burmese, such as [ɛ ɔ i u], followed by a nasal coda, further adaptation is necessary. In such cases, the vowel quality is changed to allow nasalization, rather than failing to preserve nasality, as shown in *November* → [noʊ̀vȉbà], *[noʊ̀vɛ̀bà]. This indicates that preservation of the input nasality takes precedence over preservation of the input vowel quality. However, the limited number of cases examined in the literature does not allow us to conjecture on any cross-linguistic generalizations.

5 Conclusion

The study of loanwords has played an important role in the development of phonological theories in recent years, and loanword phonology presents a rich empirical ground for examining many topical questions in the field of phonology. The issues that the study of loanwords bears upon, directly or indirectly, include the role of output constraints *vs.* processes, the phonetics–phonology interface (more specifically, the role of perceptual factors in shaping phonological patterns), the role of native phonological contrasts in phonological processes, the productivity of stochastic generalizations, and the role of innate *vs.* acquired knowledge.

At the same time, loanword adaptation is conditioned by many extragrammatical factors, such as the role of orthography, the channel of borrowing, the degree of bilingualism, etc. The diverse nature of the contact situation poses an interesting challenge and yet also presents a natural locus of interface between theoretical phonology and sociolinguistics. It has been pointed out that some of the disagreements in the debate on the nature of loanword phonology stem from differing assumptions on what is classified as a loanword (cf. Rose and Demuth 2006); some linguists focus on online adaptations (by monolinguals or bilinguals), while others focus on established loanwords that are sanctioned by norms of the community. While these two endpoints likely exhibit slightly different patterns of adaptation and varying degrees of variability, we expect the two to be related in a systematic way – the output of the initial online adaptation serves as the input for a successive chain of speakers in the rest of the community, eventually leading to the establishment of norms. Some researchers are already addressing the question of how loanwords are transformed over time, in order to provide a more comprehensive and dynamic picture of loanword phonology (Poplack and Sankoff 1984; Crawford 2007, 2008; Davidson 2007; Y. Kang 2008b; Y. Kang *et al.* 2008; Friesner 2009a).

ACKNOWLEDGMENTS

I would like to thank Michael Kenstowicz, Sharon Peperkamp, and Andrea Hoa Pham, as well as the editors and two anonymous reviewers, for their helpful comments and suggestions.

6 Self-organization in Phonology

Andrew Wedel

Structure can arise in a system in many different ways. Self-organization is one general mechanism for structure formation which has relatively recently been explored as a possible contributor to patterns found in language. The aims of this chapter are: (i) to provide an overview of self-organization as a general mechanism for structure formation; (ii) to describe some of the ways that self-organizational processes can interact with other familiar mechanisms for structure formation; and (iii) to review selected work done to date which argues that particular phonological phenomena may arise through the contribution of self-organizational mechanisms.

Self-organization has been argued to play a role in a wide variety of phonological phenomena, from the development of a phonological grammar in acquisition through the systemic grammatical changes that occur in language over many generations. A central mechanism in self-organization is feedback, in which the properties of a current state of a system are dependent in some way on those of a preceding state. When such states are linked in a temporal chain, structure can develop in ways that cannot be described in terms of a single set of causal steps. Arguments that phonological patterns can emerge in this way are not new: Lindblom *et al.* (1984) for example argued that phonological inventories are shaped by interactions between phonological categories, mediated by constraints on effort and perceptibility rather than through, for example, innate constraints on features and their combinations (see CHAPTER 17: DISTINCTIVE FEATURES). In the last decade, however, the scope of self-organization-based accounts has rapidly widened to include phonological acquisition, evolution of complex grammatical patterns (CHAPTER 101: THE INTERPRETATION OF PHONOLOGICAL PATTERNS IN FIRST LANGUAGE ACQUISITION), evolution and maintenance of phonological contrast (CHAPTER 2: CONTRAST), grammatical "conspiracies" (CHAPTER 70: CONSPIRACIES), and many other phenomena. A representative set of these accounts will be discussed in detail below in §3, but it will be helpful to begin with a general introduction to key concepts in self-organization as a general structure formation mechanism. Supplementary simulations illustrating these concepts are included in the online version of this chapter.

1 Self-organization as a pathway to structure

"Self-organization" is not a concept with crisp edges. Instead, it is a big-tent term covering the many ways structure can form in *non-linear, dissipative* systems (Kauffman 1995; Ball 1999; Camazine *et al.* 2001; Heylighen 2001). Non-linear systems are those in which the properties of the system as a whole cannot be understood in terms of the properties of individual system elements, in other words, those in which new properties emerge through interaction. Cooked egg white is a familiar example of a non-linear system. Egg white consists primarily of the protein albumin, and prior to cooking the globular albumin molecules slide past one another easily, producing a translucent semi-liquid. When the temperature is raised beyond a certain point, the albumin protein chains unfold and stick to each other, creating a large, highly interlocked structure that is opaque and stiff. These properties of cooked egg white cannot be understood in terms of the summed properties of individual unfolded albumin molecules, but from their interaction as they stick together. Likewise, many features of language are dependent on the interaction of elements at some lower level of description for their existence, most obviously in that language change arises through language use and transmission across generations.

Dissipative systems are those in which a given state or structure is maintained through a constant flux of energy or matter. As a consequence, an account of a structure within a dissipative system includes time at some level. A ripple in a creek provides a familiar example of a higher order structure produced through a flux at a lower level of description. At one level of description, a ripple is an independent element of a creek that can interact with other elements at that level, such as a floating leaf or another ripple. At a lower level of description, it is a vast and constantly changing set of water molecules interacting with each other and the creek bed as they move. If the flow of water stops, the ripple disappears. Any given language is dissipative in the sense that it is instantiated through usage and transmission, just as a ripple is instantiated through flow. As we will see in the examples below in §3, self-organizational accounts of structure formation in language depend on cycles of use and/or acquisition.

Structure arises in non-linear, dissipative systems when many similar elements or events interact over time to produce persistent changes at some higher level of organization. Typically, structure formation in self-organizing systems is the result of positive and negative feedback loops engendered by the interaction of system elements with each other or with the environment. Positive feedback (also sometimes referred to as autocatalysis) arises when a given event makes a similar event more likely in the future. An example is the population growth that occurs when individuals have offspring at greater than the replacement rate. In this case, the birth of each additional individual makes a subsequent birth more likely. Positive feedback promotes change and can result in runaway processes. As an example of a potentially central role of positive feedback in language, I have argued that positive feedback in the form of similarity bias in production and perception may drive the development of coherent grammatical patterns despite storage of low-level phonotactic detail in the lexicon (CHAPTER 1: UNDERLYING REPRESENTATIONS), which should otherwise promote lexical idiosyncrasy (Wedel 2007).

Negative feedback arises when an event makes a similar event less likely in the future, as when a growing population outstrips its supply of resources. In this case, each additional birth *lowers* the probability of a subsequent birth through increased competition. Negative feedback promotes stability. Both positive and negative feedback represent types of non-linearity, because the description of patterns resulting from feedback must make reference to interactions between system elements. Self-organization often occurs in systems through positive feedback between system-internal elements that is prevented from snowballing beyond a certain point by negative feedback. Examples of this sort include population growth limited by finite resources, thunderstorm structure in which a growing updraft is constrained by a resulting downdraft, and economic bubbles, burst by the collapse of credit. In §3, we will see several examples of the ways negative feedback may inhibit loss of phonemic contrast over the course of language change (CHAPTER 93: SOUND CHANGE).

Self-organized systems frequently exhibit *emergence*. Emergence in this context refers to the generation of a higher order structure that interacts meaningfully with other structures of the system at this level of description. Our earlier example of a ripple in a stream serves as a familiar instance of emergence: the influence of a ripple on other system elements (a leaf, another ripple) is most usefully described in terms of our understanding of the behavior of ripples, rather than our understanding of water molecules. Likewise in language, for example, many phonological patterns can be described in terms of the interaction of (possibly conflicting) phonotactic generalizations or constraints. In models in which phonotactic generalizations are derived over the course of acquisition and usage from the lexical items that instantiate them, these generalizations are emergent (see e.g. Blevins 2004; Wedel 2006; Mielke 2008).

Finally, self-organized systems frequently exhibit phase transitions between semi-stable states defined by *attractors*. An attractor is a system state (or set of states) that nearby states tend to evolve toward. A simple visual metaphor for a system with multiple attractors is a surface with multiple basins. If a ball is placed somewhere on this surface, it will tend to roll to the bottom of whatever basin it happens to be in. Phase transitions correspond to the transition from one basin of attraction to another and are accompanied by a shift in the behavior of a system. In our visual analogy, if we begin to shake the surface, the ball will begin to bounce around within its basin and may eventually by chance roll up and over into a new basin, where it remains until it again rolls up and over into a new basin. Within the domain of morphology, local similarity bias in the form of analogical extension has been argued to create attractors that influence the course of morphological change over time (see e.g. Hock 2003; Garrett 2008). Likewise, pockets of formally similar irregulars ("gangs") have been shown to be more likely to recruit new members than formally isolated irregulars (Bybee and Moder 1983; Stemberger and MacWhinney 1988). Under this general model, coherent generalizations over forms act as emergent attractors. These patterns of similarity-based extension and, plausibly, resistance to extension are consistent with a model in which local similarity effects play a significant role in the formation of larger-scale morphological regularities. For a detailed implementation of this type of model simulating the evolution of past tense forms in Old English, see Hare and Elman (1995). In a similar fashion, I have argued that similarity biases at the level of sound categories may underlie the development of regular patterns in phonology (Wedel 2007), as well as the outcome of conflicts between phonological and morphological regularities (Wedel 2009); (see also CHAPTER 87: NEIGHBORHOOD EFFECTS).

"The Game of Life" (J. H. Conway, reported in Gardner 1970) provides a simple example of a deterministic, self-organized system that exhibits all these properties (examples of The Game of Life can be found on the web; see also the online version of this chapter). The Game of Life is a simple cellular automaton that occupies an infinite, two-dimensional orthogonal grid, the cells of which can be either "alive" or "dead." There are three simple rules governing cell birth and death, each of which makes reference to a cell's eight immediate neighbors: (i) if a living cell has fewer than two living neighbors, it dies; (ii) if a living cell has more than three living neighbors, it dies; (iii) if a dead cell has exactly three living neighbors, it becomes alive.

The grid is initialized with some seed pattern of living cells, and then left to evolve according to these three rules. Some seed patterns result in uninteresting outcomes: if the distribution of living cells is too sparse, all cells quickly die; conversely, some seed patterns are stable and do not change even though the rules continue to be applied. (Four cells arranged in a square is one example of such a stationary pattern.) Other seed patterns produce oscillating structures or structures that move in a consistent direction across the grid. "Gosper's Glider Gun" is a particularly beautiful example of the complexity that can arise through the interaction of these simple rules over time. (A movie of Gosper's Glider Gun can be found on the web or in the online version of this chapter.)

The Game of Life exhibits many of the typical features of self-organizing systems. Structure formation depends on the interaction between elements (it is non-linear) and the application of cell birth and death rules over time (it is dissipative). It also requires the interaction of context-dependent positive and negative feedback processes: depending on the local context, the birth of a cell can cause the birth of additional cells in the next round or it can cause death. As in many self-organizing systems, structure arises in The Game of Life through positive feedback that is held in check by negative feedback. Finally, this system exhibits emergence, in which distinct groupings of living cells function as units with predictable behavior. In Gosper's Glider Gun, for example, two large groupings of cells bounce off of stationary square groupings at the edges of the system, and then bounce off of each other. In the process of bouncing off of each other, they create small self-contained "gliders" that embark on an infinite journey away from the center.

2 Self-organization in interaction with other influences on structure

Self-organization does not operate in a vacuum. It contributes structure in a context supplied by the system and its environment, and the properties of the system that support and direct the emergence of new structure can have any source, including innate pre-specification. For example, features of the environment can supply negative feedback or serve as templates that give initial direction to self-organized structure. In The Game of Life, self-organized structure formation is dependent on the properties of the environment (the orthogonal grid), and on the predetermined character of interactions between cells. The structures that develop are also critically dependent on the initial seed pattern of living and dead cells which serves as an organizing template.

From a design point of view, self-organization is a powerful tool: if the details of a complex structure can be constructed through emergence instead of direct specification by some other means, it can be encoded considerably more compactly than otherwise possible (Gell-Mann 1992). For example, the specification of Gosper's Glider Gun requires only a description of the environment, the rules for cell birth and death, and the initial seed pattern. Further, different complex structures can be created by minimal changes to this description, such as the properties of the environment, the seed pattern, or the rules for cell birth and death.

Similarly, many biological structures are thought to emerge from self-organizational pathways which are given shape and direction by innately specified contexts. For example, the spots and stripes that are found throughout the animal kingdom have been proposed to emerge through a single basic system with slight variations involving the competition between diffusing activator and inhibitor molecules in an animal's skin. (This model was originally proposed by Alan Turing in 1950; for discussion see Ball 1999: ch. 4.) Different shapes and patterns of coat markings can be produced simply by changing the relative diffusion speeds of the activator and inhibitor, or by changing the shapes of the underlying pigment-producing cells. This is a much more informationally compact way to produce a complex coat pattern than, for example, specifying the state of each and every individual pigment-producing cell. Furthermore, patterns that arise through self-organizational pathways are often very robust to perturbation, because of the role that attractors play in the evolution of the system. Chain shifts are possible linguistic examples of the ability of self-organized patterns to survive perturbation, i.e. to persist despite change at some other level in the system (discussed in §3.6 below; see also Gordon 2002; Wedel 2006; Ettlinger 2007). For an overview of some of the many biological patterns that are thought to arise through self-organization, including examples of the interaction between self-organizational pathways and other mechanisms, see Camazine *et al.* (2001).

There are many resources available on the web to learn more about self-organization and related concepts. Excellent published resources include Kauffman (1995), Ball (1999), Camazine *et al.* (2001), and Heylighen (2001).

3 Self-organization as a pathway for structure formation in language

Much recent work approaches language as a complex adaptive system in which grammatical patterns are emergent properties resulting from the repeated interaction of the many different elements that make up a larger language system: innate and acquired biases; forms at multiple levels of representation; interacting spheres of use; sociolinguistic networks; and chains of acquisition and transmission over longer time-scales. For representative examples, see Haspelmath (1999); Nettle (1999); Plaut and Kello (1999); de Boer (2000); Browman and Goldstein (2000); Croft (2000); Lindblom (2000); Bybee (2001); Kirby (1999); Oudeyer (2002); Bod *et al.* (2003); Blevins (2004); Wedel (2007); Boersma and Hamann (2008); Kirby *et al.* (2008); Mielke (2008); Blevins and Wedel (2009).

A priori, there are at least two plausible reasons to think that self-organizational pathways may contribute to some of the patterns we find in language. The first is simply that at many levels and time-scales, language provides the necessary conditions to support spontaneous emergence of patterns through self-organizational pathways (see e.g. Lindblom *et al.* 1984; Ohala 1989; Lindblom 1992; Keller 1994; Labov 1994; Cziko 1995; Dennet 1995; Elman 1995; Deacon 1997; Cooper 1999; Hurford 1999; Steels 2000; Bybee 2001; Blevins 2004; MacWhinney 2006; Pisoni and Levi 2007; Beckner *et al.* 2009; and many others). Language involves the repeated interaction of many similar elements, in similar ways, at many levels of description and time-scales. Variation and bias in language acquisition and use provide many potential feedback pathways. Basic language-external constraints, from articulatory and perceptual factors through general categorization mechanisms to cross-culturally common salience relationships, all provide structures and templates that could give common shape to self-organized patterns. Because structure tends to emerge spontaneously under these conditions, it would be surprising if self-organizational pathways do not contribute to the formation of some of the many observed patterns in language, whether language-particular or crosslinguistically frequent. Put another way, if we found that self-organizational mechanisms played no role in the emergence of any observed language patterns, our burden would be to explain why not.

The second, perhaps less compelling reason derives from design principles. As briefly reviewed above, the specification of a complex pattern can be much more compact and the resulting structure more robust to perturbation when created through self-organizational pathways. To the extent that the language faculty has evolved under functional constraints for use and that grammars continue to do so diachronically, self-organization represents a powerful mechanism for structure in the "blind watchmaker's toolbox" (Dawkins 1986).

3.1 *Self-organization in phonology*

Explorations of self-organizational accounts for linguistic patterns can be understood in terms of the general scientific goal of explaining more with less. Just as a good Optimality Theory (Prince and Smolensky 1993) account attempts to explain new patterns through rankings of existing constraints, an account of linguistic patterns making use of a self-organizational pathway attempts to explain a complex pattern through the interaction of simpler independent mechanisms. Often, authors of these accounts argue that a linguistic pattern emerges through the interaction of domain-general factors rather than through innate grammatical mechanisms, but it is worth emphasizing that this is not a necessary feature of a self-organizational account. Just as a self-organized biological pattern may arise from innately specified processes, a self-organized linguistic pattern could arise from simpler language-specific structures. Some models have been framed in these terms under the rubric of "biolinguistics"; see e.g. Medeiros (2008).

Many self-organizational accounts make use of computational simulation, either as an existence proof that a given structure can arise through interactions between some defined set of system properties, and/or as a supporting illustration for verbal or analytic arguments. Simulation is particularly useful in this context, because self-organization proceeds through chains of circular causation progressively building structure over time. As a consequence, verbal descriptions of proposed self-organizational processes are often hard to assess critically. More importantly, interacting feedback loops are notorious for producing counter-intuitive results, so a computational implementation of a model provides both an important research tool for a theorist and a demonstration for a reader that the model operates as expected (Peck 2004). The following is a brief survey of several phenomena in phonology that have been proposed to arise in part through self-organizational pathways. This is of course just a sample of the many insightful self-organization-based models of phonological phenomena, and interested readers are encouraged to explore the literature further.

3.2 *Early phonological acquisition*

In early phonological acquisition (CHAPTER 101: THE INTERPRETATION OF PHONOLOGICAL PATTERNS IN FIRST LANGUAGE ACQUISITION), initial relatively accurate word imitation is followed by a period of less accurate, but more systematic productions (Ferguson and Farwell 1975, reviewed in Vihman *et al.* 2009). This is reminiscent of the U-shaped learning curve of irregular morphological forms in which irregulars are initially reproduced faithfully, followed by a period of over-regularization, followed in turn by increasingly accurate production. Further, while these production patterns are consistent for a given child, they differ across children, suggesting that the pathway to phonological competence is not prespecified at this level (Beckman and Edwards 2000; Vihman and Croft 2007; Vihman *et al.* 2009). Vihman *et al.* (2009) propose that this phenomenon can be explained in a model based on the ability of infants to acquire individual word gestalts, combined with an ability to generalize over those gestalts through feedback from their own production (see also Pierrehumbert 2003 for related discussion). Under this model, an infant's set of practiced babbles provide the seed patterns for initial generalizations over learned word gestalts. Feedback between these initial generalizations and word productions allows the infant to develop practiced sub-lexical "templates" (see also Fikkert 2007; Fikkert and Levelt 2008). The substitution of these generalized phonological "templates" in place of gestalts accounts for the period of poorer production accuracy in matching the adult pronunciation of given words, yet greater precision between individual utterances. Accuracy subsequently improves as the myriad interactions with caregivers further shape the trajectory of learning. Vihman *et al.* argue that a self-organizing, feedback-driven model of this kind is particularly well suited to explain both the highly individual initial production templates observed in children, and their subsequent convergence on a community standard of pronunciation.

3.3 *Conspiracies in historical phonology*

Conspiracies, in which a seemingly disparate set of processes all result in a common pattern, are widespread in phonology (Kisseberth 1970; CHAPTER 70: CONSPIRACIES). Blust identifies many different types of diachronic change in Austronesian languages that conspire to create a disyllabic word, in many cases restoring a historical disyllable that had lost or gained a syllable through other changes (Blust 2007). In the history of Javanese, for example, reduplication, epenthesis, deletion, and loss of a morpheme boundary have been favored if the product of change is a disyllabic word. Blust suggests that conspiracies arise when a pattern in a language becomes particularly salient, leading it to function as a "linguistic attractor" in language change (Cooper 1999). Within variationist approaches to language change (e.g. Ohala 1989; Labov 1994; Bybee 2001; Blevins 2004; and many others; see also CHAPTER 92: VARIABILITY), a salient pattern can influence the course of language change by biasing categorization (cf. the notion of "Change" in Evolutionary Phonology; Blevins 2004), and/or by biasing the range of variation in production. (For a simulation of pattern feedback in production biasing language change, see Wedel 2007.) In this context, Blust notes that disyllables have been reported to make up 94 percent of the set of content words in proto-Austronesian, and that in many modern Austronesian languages the disyllable remains the dominant word type.

A wide range of evidence is consistent with the hypothesis that such linguistic attractors bias individual behavior and thereby influence the course of language change. Many studies have shown that variation in linguistic behavior is biased toward previous experience: both grammaticality judgments (e.g. Albright 2002; Krott *et al.* 2002; Pierrehumbert 2006a) and production variation/errors (e.g. Bybee and Moder 1983; Dell *et al.* 2000; Vitevitch and Sommers 2003; Gonnerman *et al.* 2007; and many more) are biased by similarity and by pattern type-frequency at a wide range of representational levels (for reviews on various of these topics, see Bybee 2001; Ernestus and Baayen 2003; Bybee and McClelland 2005; Pierrehumbert 2006b; Baayen 2007; Pisoni and Levi 2007). Patterns of simulated language change in simple model systems (Wedel 2007, 2009) are also consistent with this notion: when production and perception errors by simulated agents are biased toward previous perception and production experience, change is strongly influenced by pre-existing patterns in the system. Further evidence concerning the influence of attractors in language change could be sought using iterated artificial language learning and transmission paradigms of the sort pioneered by Kirby *et al.* (2008). Finally, it is worth noting that within models such as Evolutionary Phonology, synchronic alternation patterns are created through diachronic change rather than through mechanisms localized within a single individual's language faculty (see Blevins 2004: ch. 3 for a review of earlier theories of this type). Under this model, this account of diachronic conspiracies provides the basis for an account of synchronic conspiracies as well.

3.4 *Actuation vs. propagation of change*

A significant question in historical linguistics is how an initially isolated change can survive and propagate throughout a community, given that language learners tend to converge on a common community standard. To the extent that this is the case, isolated variants should never be able to gain a foothold in a speech community, because every learner is exposed to many speakers (see Keller 1994: 99 and Nettle 1999 for discussion). In a foundational paper, Nettle (1999) uses a well-articulated simulation to explore factors that are required to allow randomly occurring variants to become established, assuming the existence of a stratified social structure. He finds that given reasonable assumptions (i.e. that *ceteris paribus*, learners tend to adopt the local majority pattern), random variation in acquisition is not sufficient to induce a population-wide transition from one pattern to another without being so pervasive as to obliterate any coherent pattern at all. He then shows that when significant prestige inequities are introduced in which a small number of individuals serve disproportionately as acquisition models, a novel variant can survive if it spreads in the population sufficiently to support itself through positive feedback. When a small number of individuals exert strongly disproportionate influence, the *effective population size* is small, allowing random events a greater chance of influencing the trajectory of change (see the literature on genetic drift in biological populations, e.g. the introductory article by Kliman *et al.* 2008). However, it is clear that functional articulatory and perceptual factors influence the course of change as well; otherwise, we should observe as many diachronic changes that are phonetically unnatural as those that are natural. Nettle explores the influence of functional biases in his model, and concludes that in order to enforce change alone, functional biases have to be sufficiently strong so that anti-functional patterns should never occur. Since this is not the case, Nettle argues that social factors are a critical engine of change, but that the rate of actuation and the efficiency of propagation must also be biased by functional factors that influence ease of production, perception, and acquisition.

3.5 Emergence of phonemes and inventory structure

Vowel inventories appear to be constructed to optimize perceptual contrast between neighboring vowels, given extant articulatory constraints (Liljencrants and Lindblom 1972). How does this apparent optimization come about? In an early self-organizational approach to this problem using a perception/production feedback loop, de Boer (2000) proposed that structure in vowel inventories emerges through interaction of language users under perceptual and production constraints, assuming a tendency for language users to imitate each other (see Browman and Goldstein 2000 for an abstractly similar self-organizational account couched within Articulatory Phonology; also CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS). To test and illustrate this idea, de Boer constructed a simulation in which a group of agents can produce, perceive, and remember vowel pronunciations in the form of prototypes. (Agents are entities within a simulation that can change independently, here representing individual language users.) Within the simulation, agents speak and imitate each other, modifying their vowel categories in response to how successful their imitations are. In each round, a random pair of agents is chosen from the larger set of agents to act as speaker and hearer. The speaker articulates a randomly chosen vowel from memory with some random error; if it has no vowels in memory, it produces a random vowel within the available articulatory space. The hearer compares the formant values of the vowel to prototypes it has in memory and chooses the closest one. If it has no vowels in memory, it creates a similar vowel and calculates its associated articulatory parameters. The listener then repeats the matched prototype vowel for the speaker, who checks to see how close it was to the originally produced vowel. If the vowel is judged to be the same, the speaker agent gives the listener feedback that its imitation was successful. In that case, the listener shifts the parameters of its matching prototype closer to the vowel that it heard from the speaker. If the imitation was not successful, the listener checks its memory to find out how often that prototype has given rise to successful imitations. If it has been mostly unsuccessful, it moves that prototype closer to the sound it heard, just as in a successful imitation. If it has been mostly successful before, it may be that the speaker has an additional prototype vowel in that region of vowel space, and so the listener creates a new prototype to match approximately what it heard. Several additional processes come into play in this simulation: (i) if a vowel prototype is infrequently matched to a perceived vowel, it is discarded; (ii) if two vowel prototypes are too close together, they are merged; and (iii) new vowels are introduced by speakers at a low frequency (CHAPTER 90: FREQUENCY EFFECTS).

This simulation employs a number of features that may not correspond directly to actual features of language use (e.g. direct feedback on imitative success; the operative mechanisms of category loss and merger), but that is not its primary point. These mechanisms simply allow vowel inventories in individual agents to change over time in response to constraints on the differentiation of vowels that are perceived in individual usage events. De Boer shows that, given these constraints, populations of agents starting with empty vowel inventories develop jointly held phonetically natural vowel inventories. He concludes from this that the typological generalizations over vowel inventories found in natural language may arise through articulatory and perceptual constraints in usage rather than some more direct, innate specification. Coherent structure is primarily driven by positive feedback in this system, which comes in two forms: modification of prototypes toward perceived vowels, and merger of prototypes that get too close. These encourage the development of coherent vowel categories shared across the set of agents. Because vowels that are too perceptually confusable tend to be merged, the set of surviving vowels tends toward a perceptually "optimal" arrangement.

Oudeyer (2002, 2006) has used an abstractly similar, more physiologically grounded model of a perception/production feedback loop to argue that positive feedback inherent in processing can create categorial distinctions in the absence of any functional pressure. Research in response biases of cortical fields of neurons shows that their output is well predicted by the aggregate response of the entire field, rather than by the output of the most highly activated neuron. From the set of activities of all neurons, it has been found that one can predict the perceived stimulus or motor output by computing the population vector over the field, namely, the sum of all preferred outputs of the set of neurons multiplied by their activities (Georgeopoulos *et al.* 1986; for an account of the perceptual magnet effect (Kuhl 1991) based in this phenomenon, see Guenther and Gjaja 1996). The important feature of the population vector for our purposes is that it is shifted toward the center of the local distribution of outputs relative to the most highly activated neuron. Given a close mapping between perception and production (Oudeyer 2002; Fowler and Balantucci 2005), this property of cortical fields should produce positive feedback promoting the coalescence of perceptual-motor categories into well-defined distributions over many cycles of use.

In Oudeyer's (2002) model, linked motor and perceptual cortical fields are initially populated with randomly tuned neurons, such that there are no distinct coherent sound categories. Over the course of the simulation, randomly chosen production stimuli are produced by the motor field and processed by the perceptual field. In processing, each neuron in the perceptual field is activated by the production stimulus under the control of a Gaussian tuning factor responsive to the degree of match between the stimulus and a neuron's preferred vector. The preferred vectors of all neurons that have been activated to some degree by the stimulus are then shifted toward that of the maximally active neuron, producing a reversion to the local mean. This update function acts to incrementally consolidate the vectors exhibited by the neural map, influenced by random peaks in the distribution of stimuli produced early in the simulation. The perceptual and motor fields are linked by an update function that shifts vectors in the motor field in parallel to those in the perceptual field, closing the perception/production feedback loop. The resulting positive feedback between perception and production allows a rapid collapse of the originally random distribution of vectors in the sensory map into a small number of coherent sound-motor categories. Oudeyer interprets this feature of his model to suggest that native features of our neurological production and perception apparatus may be designed to develop categories of a particular granularity, and that this feature may play a role in the development of phoneme inventories.

3.6 *Merger* vs. *contrast maintenance*

When one sound category becomes more similar to another over the course of sound change, one possible outcome is category merger, as has occurred between /ɑ/ and /ɔ/ in western dialects of North American English (CHAPTER 80: MERGERS AND NEUTRALIZATION). Often however, the set of categories translates through phonetic space in a "chain shift," such that the system of contrasts is maintained even though the specific phonetic correlates of each category change (see Gordon 2002 for a review). A number of feedback-based models have been recently proposed that provide accounts for the mechanisms of both merger and/or shift and make predictions about the conditions under which either may occur. To understand these models, it will be helpful to review briefly the role of experienced phonetic variation in production and perception. A wide variety of experimental evidence indicates that individual percepts can leave detailed, long-lived traces in memory, and that these memory "exemplars" influence future perception and production behavior (for reviews, see Tenpenny 1995; Johnson 1997; also Pierrehumbert 2006b and the papers in Gahl and Yu 2006). The influence of perception on production (Goldinger 2000; Nielsen 2007) creates the possibility of a perception/production feedback loop in which the effect of biases anywhere in the cycle can potentially build up over time to shift behavior within a single generation. Pierrehumbert used an exemplar-based model of this loop to explore the consequences of feedback for merger between perceptually adjacent phonological categories (2001, 2002). In this model, categories consist of an abstract label and a set of stored perceptual exemplars that have been mapped to that category, where each exemplar is associated with an activation level that decays exponentially over time. No proposed mechanism in this particular model requires transmission between distinct agents, so as a simplification the simulation architecture uses a single category system in conversation with itself. Production proceeds by probabilistically choosing an exemplar in relation to activation level, averaging all the exemplar values within a set window around the chosen exemplar in proportion to their activations and then adding a small amount of normally distributed noise to that average. Averaging within a window around a single exemplar creates a reversion to the mean of the local distribution, just as the use of the population vector does in Oudeyer's simulation described above. Adding noise to production outputs keeps the distribution from collapsing to a single point through the effect of averaging and allows the system to evolve over time. To decide what label the new output should be categorized under, the summed activation level of exemplars within a set window around the output value is calculated for each label. The percept is then stored as a new exemplar under the category label with the highest score.

Pierrehumbert showed that, given this architecture, if two categories drift close enough such that they begin to compete for percepts along their mutual boundary, the category with greater overall exemplar activation tends to eventually absorb the less active category. This occurs through positive feedback between current activation and the ability to compete for percepts. All else being equal, an ambiguous percept is more likely to be mapped to a more active category than a less active category, which only results in the active category becoming yet more active with respect to the less active category. This snowballing feedback results in more and more percepts being mapped to the more active category, until the activation of the other category eventually falls low enough that it effectively no longer exists and is absorbed into the more frequent category. An example that can be modeled this way is the above mentioned merger of /ɔ/ with the more frequent /ɑ/ in western dialects of American English.

In all of the work reviewed above, local, similarity-based positive feedback drives coalescence of system elements into categorial groupings. In none of these accounts, however, is there any repulsive force that would prevent the steady merger of categories over time as they eventually drift into one another. As a consequence, the maintenance of multiple categories over the course of language change in these models would require either regular generation of new distinctions as in the de Boer (2000) model above or some mechanism to favor preservation of at least some existing contrasts. Boersma and Hamann (2008) approach the problem of contrast maintenance between existing sound categories through a constraint-based model that makes use of categorization accuracy on the part of a language learner. As a demonstration of their model, Boersma and Hamann simulate the evolution of category label/contents mappings within a unidimensional space. To concretize the model, they use the spectral frequency range of sibilants in human languages as the perceptual space. (In the following brief discussion of their model, I use an /s/ + /ʃ/ two-sibilant system as a running example, although more or fewer categories are possible.) The architecture of the model is vertical, in which a naive agent learns to associate part of the spectral frequency range with /s/ and another part with /ʃ/ by hearing examples from a teaching agent with feedback. After this learning phase, the agent becomes a teacher and produces examples of /s/ and /ʃ/ to a new learner agent, and so on. For the purposes of the argument, Boersma and Hamann assume that learning agents have acquired sound category labels from word patterns prior to the beginning of the simulation. As a result, learners know at the start how many sibilant categories their language has, but are not yet sure where their distributions lie within the frequency continuum. In addition, learners have the ability to learn an association between a given spectral frequency and /s/ or to /ʃ/ by constructing a ranking among optimality-theoretic constraints banning the mapping of a particular frequency to a particular category label (Boersma 1997). The architecture of the perception grammar incorporates both frequency of presentation and categorization accuracy, with the result that the grammar is maximally "certain" about mappings for sibilant frequencies that are further apart relative to those frequencies that were most often heard. Because subsequent production is based on sampling from the learned perception grammar rather than from the distribution of actually learned examples, an agent's production favors a distribution of sibilants that is slightly better separated than that which she heard herself. This creates a positive feedback loop that promotes increasing contrast between categories over many teacher/learner cycles. However, agents' productions are also influenced by ranked articulatory constraints that have the effect of biasing productions toward the center of the frequency continuum. Boersma and Hamann show that under the balancing influence of positive feedback via the perception grammar and negative feedback from articulatory constraints, categories evolve as well-spaced distributions with a joint center of gravity at the midpoint of the continuum.

The Boersma and Hamann model relies on error feedback from the lexicon within the learner to drive contrast maintenance. Another model for contrast maintenance has been proposed that operates in situations in which there is an *absence* of error feedback (Wedel 2004; Blevins and Wedel 2009; see also Ettlinger 2007). The relevant absence of error feedback in this model occurs when an ambiguous pronunciation is not rescued by an external context to determine its intended category mapping. As an example of external disambiguation, words like "too" and "two" in English are rarely confused by listeners, because they are used in distinct sentential and semantic contexts. In contrast, because of their semantic similarity, words within morphological paradigms are often distinguished in context primarily by their phonetic differences. For example, utterances like *I cook chicken well* and *I cooked chicken well* could be used in very similar contexts, in which case the tense of the verb *cook* is conveyed almost entirely by the audible presence or absence of the past tense [-t].

A hypothesis introduced in Wedel (2004) and explored more deeply in Blevins and Wedel (2009) is that this effectively greater "functional load" of word-internal phonetic information within paradigms may account for anti-homophony effects in paradigms. "Anti-homophony" refers to the failure of otherwise regular sound changes to occur in words when that change would render them homophonous with another word (see Blevins and Wedel 2009 for a review and examples). As in the Pierrehumbert (2001, 2002) model of category merger reviewed above, this model rests on evidence that category behavior is updated by experience: if a pronunciation is ambiguous in context, a hearer may map it to a category that the speaker did not intend, resulting in the effective trading of a variant between the two categories at their boundary. It is this "variant trading" between perceptually adjacent categories that drives the behavior of the model by preserving a crisp boundary between adjacent categories (see Blevins and Wedel 2009 for more discussion).

4 Looking forward

Our ability to build theories is limited by the knowledge that we already have. Whether or not any of the current self-organization-based accounts in phonology are "right," they are valuable in expanding our understanding of pattern formation mechanisms. Self-organization is ubiquitous in physical, biological, and cultural systems, and given that language provides the conditions for self-organization many times over, linguists should anticipate finding it as a contributing mechanism in this domain as well. Just as with any other type of account, however, showing that a particular structure could arise through self-organization does not mean that it does so. A hypothesis stands or falls on the empirical success of its predictions. Arguments from first principles about, for example, whether phonological patterns are more likely to derive from a language-specific cognitive faculty or a more general set of factors are less valuable than well-constructed tests of model predictions. Fortunately, a wide variety of techniques and approaches are now available for testing hypotheses, from the ever-growing array of psycholinguistic techniques through corpus studies and artificial language-learning paradigms.

Self-organizational models for structure formation make use of previously identified cognitive, articulatory, perceptual, or social factors as contributing building blocks. In turn, these models make further predictions about those factors, or may predict some yet undescribed phenomenon. For example, self-organizing models of phonological change through usage require a production/perception feedback loop that can drive small, but persistent and generalizable changes in post-acquisition phonological categories (e.g. Bybee 2001; Pierrehumbert 2001, 2002; Wedel 2007; Mielke 2008). Although more work needs to be done to establish their generality, results from a variety of psycholinguistic studies are consistent with this prediction (e.g. Goldinger 2000; Kraljic and Samuel 2006; Nielsen 2007). Likewise, each of the other models reviewed above makes new predictions that can be tested empirically. As phonologists bootstrap back and forth between model building and simulation on the one hand and empirical methods on the other, the field should gain a steadily better sense of whether and how self-organizational mechanisms contribute to the wide variety of phenomena that we study.

96 Experimental Approaches in Theoretical Phonology

SHIGETO KAWAHARA

1 Introduction

This chapter provides an overview of how experimental work has informed phonological theories, and vice versa. This chapter starts with a historical overview; when phonology was being established as its own area of research, there was a sharp division between phonetics and phonology. This division was called into question, and issues concerning the phonetics–phonology interface are currently being extensively pursued by an approach that is now known as "laboratory phonology." After this historical overview, I discuss in some detail how phonetic experiments and phonological theories have informed each other.

1.1 *The tension between phonetics and phonology*

When phonology was being established as its own area of research, it was often assumed that phonology and phonetics were independent of one another. For example, Trubetzkoy (1939: 11) stated:

> The speech sounds . . . possess a large number of acoustic and articulatory properties. All of these are important for the phonetician since it is possible to answer correctly the question of how a specific sound is produced only if all of these properties are taken into consideration. Yet most of these properties are quite unimportant for the phonologist.

We still sometimes witness a sharp divide between phonetics and phonology in the current literature: some claim that phonology is an abstract, substance-free computational system, which should be separated out from phonetics: "patterns of phonetic substance are not relevant to phonological theory strictly defined" (Hale and Reiss 2000: 158; see Blaho 2008 for a recent review of this position). There has been an uneasiness about integrating phonetics into phonological studies, because of a belief that the phonetic module belongs to performance and the phonological module belongs to competence; i.e. phonetics does not belong to grammar per se (see e.g. Blaho 2008: 2). An assumption behind this claim is that phonetics involves automatic, universal mechanisms.

However, contrary to the view that phonetics consists of universal implementation rules, experiments have shown that phonetics is neither automatic nor universal; i.e. speakers control their phonetic behaviors, and cross-linguistic variation exists in the realm of phonetics (Keating 1985, 1988a; Kingston and Diehl 1994; see also §2.3.1 for more discussion). In this sense, any adequate model of grammar must integrate phonetics as a part of its model.

Phoneticians also responded to the thesis that we can and should study phonology without considering the phonetic mechanisms behind phonology (see Lindblom 1962, Ohala 1990b, and Diehl 1991 for general discussions).[1] Perhaps the best-known advocate of the objection is Ohala (1990b, among many other references). His general point is that many phonological patterns can be explained in terms of articulatory and perceptual factors, and therefore purely phonological explanations without considering phonetic substances can be arbitrary, circular, and post hoc. For example, many languages lack voiced stops in their inventory, a situation for which we could propose a redundancy rule [−son, −cont] → [−voice], as in *SPE* (Chomsky and Halle 1968), or a constraint *[−son, −cont, +voice], but these approaches miss the aerodynamic reason behind the dispreference for voiced stops. In order for speakers to maintain voicing, intraoral air pressure must be lower than subglottal air pressure, but the airflow required for voicing increases intraoral air pressure when the airway is significantly occluded. The increase in intraoral air pressure in turn makes it difficult to satisfy the aerodynamic condition. For this reason, it takes additional articulatory effort – e.g. larynx lowering, tongue advancement, etc. – to keep the intraoral air pressure sufficiently low to maintain voicing during stop closure (Jaeger 1978; Westbury 1979; Ohala 1983).

In addition to this kind of articulatory difficulty, perceptual factors demonstrably affect phonological patterns as well. For example, non-low back vowels are usually rounded, so that we could postulate a redundancy rule [−low, +back] → [+round] or a constraint *[−low, +back, −round], but again these explanations miss the generalization that rounding, by enlarging a resonance cavity, enhances the F2 difference between back and front vowels (Stevens *et al.* 1986; Diehl and Kluender 1989; Diehl 1991).

Finally, psycholinguistic factors also seem to play an important role in shaping phonological patterns. For instance, word-initial segments provide important cues for word recognition (Nooteboom 1981; Hawkins and Cutler 1988). Speakers thus seem to disfavor making phonological changes in word-initial positions, because such changes would result in difficulty in word recognition (Beckman 1997; Kawahara and Shinohara 2010).

In summary, there seem to be phonetic and/or psycholinguistic reasons behind many, if not all, phonological patterns. Therefore, according to Ohala, purging phonetic and psycholinguistic factors from phonological theory is misguided.

1.2 Current situation

Thus, on the one hand, there has been some reluctance to incorporate phonetic (and psycholinguistic) factors into phonological explanations. On the other hand, phonetics does seem to offer some insights into phonological patterns. For this

[1] The tension between phonetics and phonology existed before the inception of generative phonology (Chomsky and Halle 1968). See Ohala (1990b, 1999) for reviews of the history.

(and perhaps other) reason(s), there has been some unfortunate intellectual tension between phonetics and phonology, which Ohala describes as a "turf war" (1990b: 168), where people from each discipline felt that they had to delineate and defend their own territory.[2]

The situation, however, has been changing, as we witness the rise of a general approach which has come to be known as "laboratory phonology" (see Cohn 2010 for sociological aspects of the development of laboratory phonology in the field of general linguistics). The following quote from Beckman and Kingston (1990: 5) succinctly summarizes the spirit of this approach:

> We believe that the time has come to undo the assumed division of labor between phonologists and other speech scientists; we believe this division of labor creates a harmful illusion that we can compartmentalize phonological facts from phonetic facts. At the very least, we maintain that the endeavor of modeling the grammar and the physics of speech can only benefit from explicit argument on this point.

As the following discussion shows in more detail, many experimental studies have contributed to theoretical debates. The rest of the discussion proceeds as follows. In §2, I discuss how experimental approaches have informed phonological theories. In §3, I reverse direction and discuss cases in which theories have informed experiments. Although I try to be comprehensive in my review, there is necessarily a limit. For further examples and discussion, readers are referred to contributions in the *Laboratory Phonology* series (Kingston and Beckman 1990 *et seq.*), as well as in other volumes and papers devoted to this and other related issues (Ohala 1986b; Ohala and Jaeger 1986; Diehl 1991; Hayes *et al.* 2004; Kingston 2007; Solé *et al.* 2007; Coetzee *et al.* 2009).

2 How experiments have informed theory

2.1 *Beyond introspection-based data*

In generative linguistics, native speakers' intuition – or introspection – is the primary source of data, because "the set of grammatical sentences cannot be identified with any particular corpus of utterances obtained by the linguist in his field work" (Chomsky 1957: 15). Since generative phonology aims to study competence, i.e. what speakers know about their language, rather than performance, i.e. how speakers use the language, the only way to assess competence, it was believed, was introspection (though see Schütze 1996 for a critical discussion). Contrary to this research tradition, phonetic and psycholinguistic experiments have offered important insights into knowledge of grammar.

2.1.1 *Wug tests*

The first good example of experiments that have complemented the introspection-based approach is a wug test. In wug tests, named after an experiment by Berko (1958), native speakers are asked to pronounce novel words. Berko tested

[2] An anonymous reviewer points out that there may also be "punting," when people say that some other subfield is responsible for a phenomenon that they cannot account for.

whether English-speaking children acquire a rule of voicing assimilation in the English plural and other suffixes, and found that, given a nonce word like *wug*, most children pluralize it as *wug*[z], not as **wug*[s], showing that English-speaking children know that the plural suffix and the stem-final consonant must agree in voicing. In this way, the wug test has been used as a litmus test for the productivity of a phonological generalization. Recent years have witnessed a renewed interest in wug tests, which has provided some important insights into phonological knowledge, as summarized in (1).

(1) a. A standard assumption in generative phonology is that speakers assign a simple dichotomous grammatical/ungrammatical judgment to linguistic structures. In other words, speakers should treat all attested structures as equally good, and all ungrammatical structures as equally bad. However, several wug tests revealed that speakers can distinguish the relative grammaticality of two (un)grammatical structures (Shinohara 2004; Zuraw 2007).

b. More generally, the results of wug tests often show stochastic, rather than dichotomous, patterns (Albright and Hayes 2003; Hayes and Londe 2006).

c. Some experiments have shown that the probability of speakers applying a certain phonological process in a wug test reflects the frequency of the items that undergo that phonological process in their language (Bybee 1999; Zuraw 2000; Albright and Hayes 2003; Ernestus and Baayen 2003; Hayes and Londe 2006; Hayes *et al.* 2009; CHAPTER 90: FREQUENCY EFFECTS).

d. In some experiments, speakers either fail to replicate some statistical patterns in the lexicon (Becker *et al.* 2008) or at least show bias against reproducing some arbitrary, though statistically significant, patterns in the lexicon (Hayes *et al.* 2009).

e. Some phonological patterns are not productive (at least under a wug test), which leads to the suspicion that they are not a part of the speakers' grammar. Patterns whose productivity wug tests have failed to reveal include English velar softening (Ohala 1974; though see Pierrehumbert 2006), Japanese verb conjugations (Vance 1987: ch. 12) and Polish raising (Sanders 2001). See also Zimmer (1969) for a test of morpheme structure conditions in Turkish.

2.1.2 *Well-formedness judgment studies*

Another type of experiment which complements generative phonology's introspection-based approach is well-formedness judgment experiments. In these experiments, native speakers are asked to judge the naturalness of particular words or phonological processes (they can also take the form of word-likeliness judgments). These experiments, like wug tests, reveal, for example, that speakers can distinguish the relative grammaticality of two (un)grammatical structures (Pertz and Bever 1975; Coetzee 2008) and show that grammatical patterns exhibit a stochastic, rather than a simple dichotomous grammatical/ungrammatical, distinction (Hayes 2000; Albright and Hayes 2003; Fanselow *et al.* 2006). Well-formedness judgments are also known to reflect the frequency of the target items (e.g. Frisch *et al.* 2000; see also CHAPTER 90: FREQUENCY EFFECTS).

2.2 *Addressing the quality of phonological data*

2.2.1 *Re-evaluating phonological data*

Experiments have also re-evaluated what is phonological and what is not. Phonetic experiments have shown that many textbook examples of "phonological patterns" do not involve categorical changes but instead involve gradient changes, suggesting that they might be phonetic processes (CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). For example, English was thought to have a vowel nasalization rule before a nasal consonant, as in [bĩn] *bean* and [dĩn] *dean* (Fromkin and Rodman 1998: 280–281). Cohn (1993), however, based on an instrumental study measuring patterns of nasal airflow, showed that English nasalization differs from contrastive nasalization in French in that, the closer to the nasal consonant, the more nasal airflow was detected within a nasalized vowel. English nasalization is therefore gradient rather than categorical, in the sense that it does not alter the whole segment but instead the degree of nasalization changes within a segment. For this reason, Cohn concluded that English nasalization belongs to phonetics. Many other examples of phonological patterns have been argued to show similar gradient properties, which I list in (2):[3]

(2)
- a. Arabic tongue backing (emphasis) spreading (Keating 1990 and references cited therein; see also CHAPTER 25: PHARYNGEALS)
- b. English /l/-velarization in the coda (Sproat and Fujimura 1993)
- c. English flapping (Fox and Terbeek 1977; de Jong 1998; CHAPTER 113: FLAPPING IN AMERICAN ENGLISH)
- d. English phrasal nasal assimilation (Nolan 1992; Gow 2002; but cf. Ellis and Hardcastle 2002)
- e. English phrasal palatalization (Zsiga 1995)
- f. English and French schwa deletion (Fougeron and Steriade 1997; Davidson 2006b; CHAPTER 68: DELETION)
- g. Japanese tonal spreading in unaccented words (Pierrehumbert and Beckman 1988)
- h. Russian vowel reduction in second pre-tonic syllable (Barnes 2002; but cf. Padgett and Tabain 2005; CHAPTER 79: REDUCTION)

The abundance of such examples led Hayes to state "I occasionally wondered, 'Where is the normal phonology that I was trained to study?'" (1995: 68).

The list in (2) shows that many patterns that were believed to be phonological have turned out to be phonetic. A more complex example comes from the domain of intonation. In Japanese and many other languages, the height of tones generally declines toward the end of an utterance. The question arose whether this pattern of declination is due to phonetics or phonology. One could posit that

[3] Davidson (2006a) demonstrates that a "schwa" inserted in English speakers' production of non-native clusters differs from a lexical schwa. She argues that this "schwa" results from gestural mis-coordination, and hence differs from phonological epenthesis (see also Hall 2006 for related cross-linguistic phenomena). However, within the framework of Articulatory Phonology (Browman and Goldstein 1986), she also proposes that gestural mis-coordination arises in the phonological component, rather than in the phonetic component.

this declination is phonetic (Fujisaki and Sudo 1971; see Poser 1984: 200 for more references); for example, subglottal air pressure decreases towards the end of an utterance, and the height of tones naturally drops. On the other hand, McCawley (1968) proposes a phonological rule in Japanese that changes a high tone to a mid tone after another high tone within a phrase. It turns out that it would be most fruitful to approach intonation from both perspectives. Poser (1984) argues that Japanese has both local lowering of H after another H(L), which seems phonological, and gradient, steady declination throughout the utterance, which is phonetic.[4] Beckman and Pierrehumbert argue that a similar hybrid approach accounts for the complex pattern of intonation in both English and Japanese (Beckman and Pierrehumbert 1986; Pierrehumbert and Beckman 1988).

In addition to helping us to decide whether patterns under discussion are phonological or phonetic, some studies have called into question the existence of some phonological patterns per se. Based on the traditional description of Tswana, Hyman (2001) discusses a case of post-nasal devoicing, but Gouskova *et al.* (2006) argue, on the basis of a production experiment, that Tswana may not have a process of post-nasal devoicing after all. A later study, however, suggests that some, though not all, speakers do show evidence of post-nasal devoicing (Coetzee *et al.* 2007). A general lesson we can draw from this series of studies is that careful instrumental experiments help us to establish whether phonological patterns under discussion really exist.

2.2.2 *Incomplete neutralization*

While it is standardly assumed that phonological processes involve categorical changes (see §2.2.1 and §2.3.2), some experiments have called this assumption into question. Port and O'Dell (1985) report a production experiment on German where they found some acoustic differences between underlying voiceless stops and "voiceless" stops that are underlyingly voiced but devoiced by coda devoicing (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). They found appreciable differences between these two categories in terms of preceding vowel duration, closure voicing duration, closure duration, and aspiration duration. Further, they demonstrated that listeners can detect the differences between the two categories at more than chance frequency. They argue that coda devoicing in German is therefore incomplete.

Subsequent studies have found other cases of incomplete neutralization in many languages, including Cantonese (Yu 2007), Catalan (Dinnsen and Charles-Luce 1984), Dutch (Ernestus and Baayen 2006, 2007; Warner *et al.* 2006), English (Fourakis and Port 1986; Ohala 1986a), Japanese (Mori 2002), Lebanese Arabic (Gouskova and Hall 2009), Polish (Slowiaczek and Dinnsen 1985; Slowiaczek and Szymanska 1989) and Russian (Chen 1970; Dmitrieva 2005; Padgett and Tabain 2005); see also CHAPTER 80: MERGERS AND NEUTRALIZATION. Some studies have argued, however, that these experimental results are largely or entirely due to extra-grammatical factors such as speakers' familiarity with English, orthographic influences, and hyperarticulation in a laboratory setting (Fourakis and Iverson 1984; Jassem and Richter 1989; Warner *et al.* 2006). The status of incomplete neutralization is much debated in the literature (see Warner *et al.* 2004; Port and Leary 2005 for reviews), but these

[4] Downstep may apply iteratively (Poser 1984; Kubozono 1988), resulting in quasi-gradient behavior. See §2.2.1 and §2.3.2 for the categorical nature of phonological patterns.

experiments at least show that we need to be careful when talking about the categoricality of phonological changes.[5] See §2.3.2 for more on the discussion on the categorical nature of phonological alternations.

2.3 *Bearing on the architecture of the grammar*

Not only have experiments served to evaluate the quality of phonological data, some phonetic studies have provided important insights into the general architecture of the grammar.[6]

2.3.1 Against universal phonetics

In *SPE*, the output of phonology was considered to be "the phonetic transcription" (*SPE*: 293), which lacked "properties of the signal that are supplied by universal rules" (*SPE*: 235). Keating (1985, 1988a) characterizes this view as phonetics involving universal, automatic rules (see also Kingston and Diehl 1994: §1.2). Phonetic studies soon showed that this view is too simplistic. For example, Chen (1970) compared durations of vowels before voiced consonants and those before voiceless consonants in seven languages (English, French, Russian, Korean, German, Spanish, and Norwegian), and showed that different languages show different degrees of lengthening before voiced consonants. Keating (1979) (reported in Keating 1985) followed up on this result, and showed that neither Czech nor Polish shows a reliable effect of voicing on preceding vowel duration. It therefore seems that the degree of lengthening before voiced consonants is language-specific. Similarly, an acoustic experiment by Port *et al.* (1980) showed that in Japanese vowel durations are heavily affected by the duration of adjacent consonants, but in Arabic such patterns are not evident, concluding that rhythmic compensation is not universal. These examples show that phonetic implementation is neither automatic nor universal. See Port and Leary (2005) for recent summaries of language-specific phonetic patterns.

2.3.2 The phonetics–phonology divide

As briefly discussed in §2.2.1, many experiments have identified a crucial difference between phonetics and phonology: phonological patterns involve complete categorical changes, whereas phonetics yields gradient outcomes (Keating 1990; Cohn 1993, 2006; Zsiga 1995; Tsuchida 1997; Barnes 2002). Experimental results played an essential role in establishing this difference. For instance, an electropalatographic study by Zsiga (1995) showed that English possesses two kinds of palatalization: complete palatalization, which we find in a morphophonological process, as in *press* [prɛs] *vs. pressure* [prɛʃər], and gradient palatalization, which we find across a word boundary, as in *miss you* [mɪʃju]. Zsiga found that the

[5] Some phonologists admit that some phonological changes are incomplete and propose a model of phonology that handles incomplete neutralization (van Oostendorp 2008; Gouskova and Hall 2009). Others consider the results of neutralization as lacking phonological/phonetic specifications (Steriade 1995, 1997), following the theory of phonetic underspecification (Keating 1988b; also Hsu 1996, cited in Steriade 1995, 1997). Yet others consider these incomplete neutralization patterns to be implemented in the phonetic component (Fourakis and Port 1986).

[6] Another topic that would fit in this subsection is the search for the phonetic basis of distinctive features. Due to space limitations, I cannot provide comprehensive discussion. See Kingston (2007) for a summary.

former [ʃ] is [ʃ] throughout its constriction, whereas the latter [ʃ] starts like an [s] and ends like an [ʃ]. An explanation we can give is that the former process involves a categorical phonological change, whereas the latter process is a gradient phonetic gestural overlap.

Pycha (2009) demonstrated another difference: comparing phonological lengthening (i.e. gemination) and phonetic lengthening at phrase edges in Hungarian, she found that phonological lengthening always targets the closure phase of affricates, whereas phonetic phrase edge lengthening affects portions that are adjacent to the boundaries. In this way, experiments have identified characteristics of phonetics that distinguish it from phonology. See Keating (1996: 263) for constellations of other properties that distinguish phonetics and phonology. See also Anderson (1981) for a general discussion of the phonetics–phonology divide.

2.3.3 *The phonetics–morphology interface?*

As exemplified by the two palatalization processes in English, morphophonological processes tend to involve categorical changes, whereas phonetic processes yield gradient outputs. A general assumption in generative studies is thus that phonology can be sensitive to morphology, but phonetics is not. The inaccessibility of morphological structures to phonetics was assumed in Chomsky and Halle (1968), where morphological boundaries are erased at the end of each transformational cycle (*SPE*: 15). The Bracket Erasure Convention in Lexical Phonology (Kiparsky 1982) also removes morphological boundaries after each level of derivation (CHAPTER 85: CYCLICITY). As a result, word-internal structures are inaccessible to later post-lexical rules or phonetics.

As an illustration, take the case of minimal word requirements. Many languages require (lexical) words to be of a certain minimal length, and this requirement is expressed in terms of abstract prosodic units (McCarthy and Prince 1986), but not in terms of raw phonetic duration (Cohn 1998). For example, even though English tense [i] is shorter than lax [æ] in raw duration ([i] = 100 milliseconds; [æ] = 123 milliseconds, according to Strange *et al.* 2004), [pi] is well formed, but [pæ] is not. Therefore, the minimal word requirement operates on abstract phonological units rather than on raw phonetic duration. This sort of requirement can be sensitive to morphological information. For example, in Yoruba, only nouns are required to be maximally disyllabic (Pulleyblank 1988: 250, fn. 24). On the other hand, no known languages seem to vary raw phonetic durations depending on morphological categories. Phonological requirements, therefore, may refer to morphological information whereas phonetic implementation cannot.[7] This thesis has been taken for granted and rarely questioned or addressed in the phonological literature.

However, Cho (2001) directly addressed this issue using EMA (electromagnetic articulography), and found that, in Korean, gestural timing is more variable across a morpheme boundary than within a morpheme, and also more variable across a non-lexicalized compound boundary than across a lexicalized compound boundary. Also, Sproat and Fujimura (1993) used X-ray microbeam technology and compared the amount of dorsal retraction of English coda [l] at various boundaries,

7 In turn, morphological processes can be sensitive to phonological information (i.e. phonologically conditioned allomorphy; see McCarthy 2002: 183 for references), but do not seem to be controlled by phonetic information (though see Bybee 1999 for a case of a morphological pattern that manipulates a non-contrastive feature).

including Level I and Level II boundaries, and found a difference between these two contexts. These experimental findings suggest that morphological boundaries may be visible to phonetic implementation rules.[8]

Another debate was initiated by Steriade (2000), who challenges the immunity of phonetics to morphological information. She argues that there are cases of phonetic analogy, a requirement that paradigmatically related words be phonetically similar. For example, derived words are required to be identical in raw phonetic duration to their corresponding bases. This phonetic analogy is proposed to explain why flapping applies in words like *capi*[ɾ]*alistic* (cf. *capi*[ɾ]*al*), whereas it fails to apply in words like *militaristic* (cf. *mili*[t]*ary*) with a similar stress pattern: the applicability of flapping in derived words depends on whether flapping is possible in the base words. However, Riehl (2003) found in a production experiment that the transfer of flapping from a base form to related words was not robustly observed. On the basis of an acoustic study, Riehl also challenged the assumption that the distinction between [t] and [ɾ] is made solely in terms of constriction duration (see Fox and Terbeek 1977 and de Jong 1998 for the phonetics of flapping; also CHAPTER 113: FLAPPING IN AMERICAN ENGLISH).

In relation to incomplete neutralization discussed in §2.2.2, Ernestus and Baayen (2006, 2007) argue for another case of morphological influence on phonetics. They found that there is slight voicing left in "devoiced" final consonants, and argue that this voicing is due to the activation of morphologically related words with a voiced consonant (CHAPTER 83: PARADIGMS). In summary, whether phonetics has access to morphological information or not is still under debate; experiments will be able to contribute much to this debate (see Bybee 1999, Barnes and Kavitskaya 2003, Davis 2005, Cohn 2006, and Yu 2007 for further discussion on the phonetics–morphology interaction and phonetic analogy).

2.4 *Arguments for and against the psychological reality of grammar*

Not only have experiments addressed what grammar should look like, they have also examined whether grammar is psychologically real in speakers' minds. Many experiments have addressed the question of whether the rules, constraints, and structures that linguists posit are psycholinguistically real or are merely theoretical devices that help us explain the linguistic patterns (Zimmer 1969; Ohala 1974, 1986a; Cena 1978; McCawley 1986). A general concern behind this work is that the psychological reality of a grammatical postulate has sometimes been confused with the analytical success of that postulate. As McCawley (1986: 28) puts it, "Chomsky's [(1986)] policy that the subject matter of linguistics is psychological in nature does not provide any reason for assuming that the purported facts that linguists have hitherto adduced as evidence for or against particular analyses are psychological in nature, nor even that they are strictly speaking facts." Psychological reality of phonological data should not be taken for granted, and must be explicitly tested. Some wug tests in fact revealed that some phonological patterns are not reflected in speakers' behaviors (see (1e)).

[8] A question that remains with respect to these results is whether the differences could be attributed to differences in the presence of prosodic boundaries like foot boundaries or prosodic words, which the phonetics is presumably able to see.

Recent development of experimental techniques has allowed us to address the question of psychological reality from a different perspective. In particular, a number of perception experiments showed that phonological constraints affect speech perception – given ambiguous acoustic signals, speakers are biased against categorizing the stimuli as those not allowed by their phonological grammar (Massaro and Cohen 1983; Pitt 1998; Dupoux *et al.* 1999; Moreton 2002; Berent *et al.* 2007; Coetzee 2008). A classic work by Massaro and Cohen took advantage of word-initial phonotactic restrictions in English, where only [ɹ] is allowed after [t], only [l] is allowed after [s], and both are allowed after [p]. They created a continuum from [ɹ] to [l] by varying F3 and presented the continuum in these contexts, and found that speakers judge tokens as [ɹ] most frequently after [t], less frequently after [p], and least frequently after [s]. These results showed that phonotactic restrictions in speakers' grammars affect how they categorize the speech signals.

Extending this work, some studies showed that some particular phonological hypotheses are psychologically real. For example, in Japanese, only foreign words, but not native or Sino-Japanese words, allow word-final long [aa] and singleton [p] (Itô and Mester 1995). Moreton and Amano (1999) showed that once listeners hear [p] in the stimuli, cueing foreignness of the stimuli, they are more likely to judge the word-final [a] as long [aa]. Gelbart and Kawahara (2007) extended this result and showed that, as long as real foreign words are presented, a similar bias towards allowing word-final long [aa] perceptually is observed, even in the absence of phonological cues to the lexical affiliation. See Gelbart (2005) for similar results from other languages.

On a slightly different line of research, acoustic studies have provided evidence for particular prosodic structures (Maddieson 1993; Broselow *et al.* 1997; Frazier 2006) or tonal representations (Morén and Zsiga 2006). Broselow *et al.* (1997) show that language-particular prosodic structures, each motivated in terms of stress placement, are manifested in different phonetic implementation patterns. Yet another line of research argues for the psychological reality of underspecification (Archangeli 1988). For example, a priming study by Lahiri and Reetz (2002) shows that labial and dorsal signals can activate coronal input. They argue that, assuming coronals are underspecified in the mental lexicon, all labial, coronal, and dorsal consonants can be matched up with underlying coronals (see also Lahiri and Marslen-Wilson 1991; CHAPTER 12: CORONALS). These studies aim to show that theoretical devices that have been proposed, such as lexical stratification, prosodic structure, or underspecification, may not merely be abstract theoretical constructs, but may be psychologically real, influencing our speech behaviors (see Goldrick, forthcoming, for discussion).

2.5 *Sources of phonological patterns*

Finally, many experiments have addressed the issue of sources of phonological patterns. This tradition has been most rigorously pursued by Ohala (e.g. 1983, 1990b), but has been taken up by many other researchers. For example, in many languages [kʲ] (or [k] before front vowels) changes diachronically into [ʧ]. The ubiquity of this sound change (and its synchronic correspondence) may be attributed to the acoustic affinity between [kʲ] and [ʧ] (Ohala 1989; Guion 1998; Chang *et al.* 2001; Wilson 2006). Raising of F2 via palatalization makes [k] sound similar to palatal consonants, and a long period of aspiration of dorsal [k] makes it sound similar to an affricate. A perception experiment by Guion (1998) demonstrated in fact that listeners often misperceive [kʲ] as [tʃ], showing that the sound change [kʲ] → [tʃ] may be due to acoustic similarity. Furthermore, Chang *et al.* (2001) point out that the directionality of the [kʲ] → [tʃ] change is rarely if ever reversed, and demonstrate experimentally that listeners may perceive [kʲ] as [tʃ], but not vice versa.

Another example is provided by the fact that in many languages a vowel must be long after a glide. Traditionally, this restriction has been analyzed as a case of compensatory lengthening: the first vowel in vowel sequences obtains a mora by a universal convention, loses its mora when it becomes a glide, with the floating mora being reassociated with the following vowel, resulting in a long vowel (Hayes 1989; see also CHAPTER 64: COMPENSATORY LENGTHENING). Myers and Hansen (2005) offer an alternative explanation: given a sequence of two vocoids, the boundary between them is blurry, and listeners may misattribute the gradient transition to the second vowel. The misattribution would result in a percept of long second vowels. Their perception experiments supported their hypothesis: the longer the transition duration, the more likely listeners judge the second vowel to be long (CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH).

The list of other experiments which have searched for the basis of phonological patterns would include, but is not limited to, the following: Kohler 1990; Ohala 1990a; Hura *et al.* 1992; Kawasaki-Fukumori 1992; Huang 2001; Hume and Johnson 2001; Barnes 2002; Mielke 2003; Kawahara 2006; Kochetov 2006; Myers and Hansen 2007) as well as those discussed in §3.1. See also Blevins (2004) and Ohala's other work (e.g. Ohala and Lorentz 1977; Ohala 1981, 1983) for further cases of phonetic origins of phonological patterns.

3 Experiments informed by phonology

So far I have been focusing on how experiments have informed phonological theories. However, the communication is by no means one-way. So we now turn our attention to how phonological observations and theories helped us design phonetic experiments and led to important discoveries.

3.1 Experiments motivated by phonological observations

As discussed in §2.5, many experiments have attempted to make sense of why certain phonological patterns occur. Put in a different perspective, this tradition has allowed us to reveal aspects of our phonetic systems by addressing why phonology works in the way that it does. To illustrate this point with another example, an influential tradition of this line of research is that of Adaptive Dispersion Theory, initiated by Lindblom and his colleagues (Liljencrants and Lindblom 1972; Lindblom 1986; Diehl *et al.* 2004) and pursued in a number of studies (e.g. Flemming 1995; Boersma 1998; Padgett 2002). This theory sets out to address why languages have the sets of vowels that they have. For example, languages that have three contrastive vowels usually have [a i u] rather than, say, [ə i ʌ], and languages that have five contrastive vowels have [a i u ɛ ɔ] rather than [ə ɨ ʌ ɤ ɪ]. The general idea is that speakers keep contrasting elements maximally (Liljencrants and Lindblom 1972) – or sufficiently (Lindblom 1986) – distinct from one another; this thesis has received support from experimental work (Engstrand and Krull 1994; Padgett 2002), as well as from corpus-based cross-linguistic analyses (Kingston 2007; see also CHAPTER 2: CONTRAST). This research tradition shows that an attempt to explain phonological patterns provides important insights into our speech behaviors. In this sense, taken together with the discussion in §2.5, phonological observations and phonetic experiments inform one another.

3.2 *Experiments motivated by phonological theories*

Not only can phonological observations lead to interesting phonetic hypotheses and experiments, specific phonological hypotheses can sometimes provide a guideline for where to look in experimental work. For example, in traditional analyses of Japanese intonation (Beckman and Pierrehumbert 1986; Pierrehumbert and Beckman 1988; Venditti 2005), Japanese was not thought to have an Intonational Phrase. Selkirk (2005), however, on the basis of cross-linguistic patterning, proposes a general theory of syntax–phonology mapping where clause edges should generally correspond to Intonational Phrase edges. Guided by this theory, Kawahara and Shinya (2008) investigate the intonational properties of clause edges in Japanese and find evidence for Intonational Phrase edges. In particular, they find that the left edges of clauses show larger initial rises and stronger pitch reset compared to VP edges, and clauses are also characterized by final lowering of tones, final creakiness and pause at their right edges. This work shows that theories can provide a guideline as to what to look for in phonetic studies.

Another example comes from articulatory studies on transparent segments in harmony contexts (Gick *et al.* 2006; Beňuš and Gafos 2007; Walker *et al.* 2008; CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS). Several authors have proposed that autosegmental spreading is strictly local and can never skip a segment (Ní Chiosáin and Padgett 1997; Gafos 1998; Walker 1998). Transparent segments in harmony patterns pose a problem for this theory because it looks as though these segments are "skipped." Recent articulatory studies have shown, however, that "transparent" segments also undergo harmony (e.g. tongue body backing in back vowel harmony in Hungarian and the tip blade gesture in Kinyarwanda consonant harmony), without causing much perceptual effect. This outcome is as predicted by strict locality, because transparent segments, too, undergo harmony phonologically. Again, the theory of strict locality has led to experiments that reveal a non-trivial aspect of transparent segments in harmony contexts. See Hayes (1999) for related discussion on theory-driven experiments.

3.3 *Testing specific phonological hypotheses and beyond*

Specific phonological hypotheses can motivate specific hypothesis testing, which has often resulted in further insights into the intricacy of the phonetics–phonology interface. To take one example, Steriade (1997, 2009) proposes that the less perceptible a phonological contrast is (in a particular context), the more likely it is to be neutralized. Some work has shown that at least some contrasts that are likely to be neutralized are indeed less perceptible than non-neutralizing contrasts (Kawahara 2006; Kochetov 2006; CHAPTER 80: MERGERS AND NEUTRALIZATION). Kochetov (2006) showed further, however, that not all differences in phonetic perceptibility are reflected in phonological patterns. Once again, Steriade's specific hypothesis about the interaction between phonetic perceptibility and phonological patterns motivated experimental testing, which revealed the complex interaction between phonetics and phonology.

To take another example, many languages require that lexical words be minimally bimoraic or bisyllabic (§2.3.3). Japanese, however, allows monomoraic lexical words, and Mori (2002) tested whether Japanese does indeed violate the minimality requirement. She found that, when monomoraic words are pronounced without a case particle, they undergo lengthening, while longer words do not show such lengthening. In this sense, Japanese does satisfy the minimal word requirement. However, she further found that lengthened monomoraic roots are not as long as bimoraic roots, instantiating a case of incomplete neutralization (§2.2.2).

To summarize, these experiments show that specific phonological hypotheses can inform experiments, which often in turn provide insight into the complex interaction between phonetics and phonology. The list of theories that have motivated specific experimentation includes the sonority sequencing principle (Broselow and Finer 1991), Optimality Theory's (Prince and Smolensky 1993) transitivity of constraints (Guest *et al.* 2000), the Emergence of the Unmarked (Broselow *et al.* 1998), and positional faithfulness theory (Kawahara and Shinohara 2010).

4 Summary

Phonetic and psycholinguistic experiments have contributed much to the development of phonological theories, and they will continue to do so. In (3) and (4) I summarize how experiments have informed phonological theories and vice versa.

(3) *How experiments inform theory*

a. Provide data beyond those available through introspection.
b. Re-examine the quality of phonological data.
c. Address questions about the architecture of the grammar.
d. Show and examine the psychological reality of the grammar.
e. Find the sources of phonological patterns.

(4) *How phonology informs experiments*

a. Helps to find restrictions on – and the nature of – speech through phonological patterns.
b. Provides a guide as to where and what to look for in phonetic experiments.
c. Motivates specific hypothesis testing.

ACKNOWLEDGMENTS

Thanks to the audiences at Kyoto University, members at Kyushu University, especially Toshio Matsuura, and my students in my graduate seminar in Spring 2009 and the graduate phonetics class in Spring 2010 at Rutgers University, especially Aaron Braver, Will Bennett, and Jimmy Bruno. Particular thanks are due to Osamu Fujimura, Beth Hume, Michael Kenstowicz, Marc van Oostendorp, Jaye Padgett, and two anonymous reviewers for their comments on earlier versions of this chapter, although they are not responsible for remaining errors. The preparation of this chapter was partially supported by a Research Council Grant from Rutgers University.
