97 Tonogenesis

JOHN KINGSTON

1 Introduction

Tones have frequently appeared and multiplied under the influence of the laryngeal articulations of adjacent consonants (§2–§4), but much more rarely under the influence of the vowels that bear them (§6). The laryngeal articulations of following consonants readily introduce tones into previously toneless languages, but those of preceding consonants far more often split existing tones than introduce them where there were none before (§5). Opposite tones can arise from the same ostensible phonological source, apparently because the source can be pronounced so as to raise or lower F0 (§3.2.2 and §4). Finally, tone can arise from prosodic as well as segmental sources (§7). In all these sound changes, a predictable or redundant F0 difference becomes contrastive – i.e. is "phonologized" – once the contrast that introduced it neutralizes. These changes show how easily languages blur the distinction between phonetics and phonology and undermine their autonomy over time.

2 From consonants to tone

2.1 *Introduction*

The first two examples, Yabem and Korean (§2.2), show how tone can remain redundant on phonation contrasts in preceding consonants, and the next two, Kammu and Cham (§2.3), show how the contrast transfers from phonation contrasts to tone. This section closes with discussion of how redundant F0 differences are phonologized (§2.4), why voiced obstruents lower F0 (§2.5), how consonants' influence on F0 is represented phonologically (§2.6), and whether a consonant's phonological specification or its phonetic properties determine its tonogenetic effects (§2.7).

2.2 *Yabem and Korean: Contrastive phonation and redundant tone*

In Yabem, an Oceanic Austronesian language of the North Huon Gulf (Bradshaw 1979; Ross 1993), and in Korean (Jun 1996; Silva 2006; Kang and Guion 2008), tone remains redundant on phonation contrasts in preceding consonants (CHAPTER 2: CONTRAST).

2.2.1 *Yabem*

In Yabem (Ross 1993), tonogenesis is the product of tone–voicing harmony. The weak syllable of a two-syllable iambic foot acquired the tone and voicing of the strong syllable when the strong syllable began with a stop in Proto-Huon Gulf (PHG), and a strong syllable not beginning with a stop acquired the tone and voicing of the weak syllable when it began with a voiced stop in PHG,[1] as illustrated by the alternations in the three realis/irrealis verb paradigms in Table 97.1:

Table 97.1 Realis and irrealis paradigms of three Yabem verb stems. The irrealis morpheme is realized by prenasalizing the first voiced stop in the root, if it has one, but otherwise by selecting distinct allomorphs of the singular subject prefixes

	-dèŋ 'move towards'		-táŋ 'weep'		-luʔ 'vomit'	
	realis	*irrealis*	*realis*	*irrealis*	*realis*	*irrealis*
1 sg	gà-dèŋ	jà-ⁿdèŋ	ká-táŋ	já-táŋ	gà-lùʔ	já-lúʔ
2 sg	gò-dèŋ	ò-ⁿdèŋ	kó-táŋ	ó-táŋ	gò-lùʔ	ó-lúʔ
3 sg	gè-dèŋ	è-ⁿdèŋ	ké-táŋ	é-táŋ	gè-lùʔ	é-lúʔ
1 pl incl	dà-dèŋ	dà-ⁿdèŋ	tá-táŋ	tá-táŋ	tá-lúʔ	tá-lúʔ
1 pl excl, 2 pl	à-dèŋ	à-ⁿdèŋ	á-táŋ	á-táŋ	á-lúʔ	á-lúʔ
3 pl	sè-dèŋ	sè-ⁿdèŋ	sé-táŋ	sé-táŋ	sé-lúʔ	sé-lúʔ

The voiced and voiceless stems /-dèŋ/ and /-táŋ/ show the covariation of stop voicing and tone within the strong syllable of the foot. No tone is marked on /-luʔ/ 'vomit', because it varies between low when the prefix stop is voiced (after realis singular [gà-, gò-, gè-]), and high otherwise (after 1st plural inclusive [tá-] and 3rd plural [sé-] and in all irrealis forms). As this stem is high after prefixes that do not contain stops, high must be the default tone value for tone, with low occurring only when a voiced stop appears somewhere in the foot. Neither voicing nor its absence can be the default value, as alternations occur in both directions: 1st singular /gà-/ → [ká-] and 1st plural inclusive /tá-/ → [dà-]. These observations indicate that voicing is the source of low tone (as well as voicing any stop in a weak syllable's onset), and that high tone and the absence of voicing developed elsewhere.

In other examples, tone is contrastive, e.g. /áwé/ 'outside' *vs.* /àwè/ 'woman' and /óli/ 'body' *vs.* /òlì/ 'wages'. The source of the tones in these and similar

[1] Generally, Proto-Oceanic (PO) *b, *g > PHG *b, *g > Proto-North Huon Gulf (PNHG) *b, *g > Yabem /b g/ and low tone, and in some morphemes, PO *p, *k unpredictably voiced and lenited to PHG *v, *ɣ > PNHG zero reflexes in Yabem with low tone.

examples is apparently the PHG *v, *ɣ, which derive via voicing and lenition from PO **p, **k.

2.2.2 *Korean*

Following an aspirated [spread glottis] or tense [constricted glottis] stop (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION), the initial L of the accentual phrase's LHL melody found after a laryngeally unspecified lax stop is raised to H in Seoul and Chonnam Korean (Jun 1996) – elsewhere in the word, the F0 elevation is smaller and shorter lasting. Silva (2006) and Kang and Guion (2008) argue that tone is becoming contrastive after consonants that are not [constricted glottis], as the duration of aspiration in lax stops has lengthened in younger people's speech to match that of aspirated stops.

2.3 *Kammu and Cham: Contrastive tone and loss of phonation contrasts*

Kammu and Cham illustrate the transfer from phonation to tone contrasts.

2.3.1 *Kammu*

Table 97.2 shows that in two western dialects of the Mon-Khmer language, Kammu, low tones ("à") appear where syllables begin with voiced stops and sonorants in the eastern dialect and a higher tone (high "á" or rising-falling "â") where those

Table 97.2 Correspondences of tone and register in three western dialects of Kammu to the phonation contrast on initial stops (a) and sonorants (b) in the eastern dialect. Examples from Suwilai (2003). E. Kammu = Svantesson's (1989) "Southern Kammu"; the first tonal W. Kammu dialect = his "Northern Kammu"; and the register dialect of W. Kammu resembles his "Lamet"

	E. Kammu	*W. Kammu Tone 1*	*W. Kammu Tone 2*	*W. Kammu Register*	
a.	buːc	pùːc	pʰùːc	pṳːc	'rice wine'
	puːc	pûːc	púːc	pûːc	'to take off clothes'
	bok	pòk	pʰòk	po̤k	'to cut down a tree'
	pok	pók	pók	pók	'to take a bite'
	buːm	pùːm	pʰùːm	pṳːm	'to chew'
	puːm	pûːm	púːm	pûːm	'to fart'
	glaːŋ	klàːŋ	kʰlàːŋ	kla̤ːŋ	'stone'
	klaːŋ	klâːŋ	kláːŋ	klâːŋ	'eagle'
	ɟaŋ	càŋ	cʰàŋ	ca̤ŋ	'to weigh'
	caŋ	câŋ	cáŋ	câŋ	'astringent'
b.	ŋɔʔ	ŋɔ̀ʔ	ŋɔ̀ʔ	ŋɔ̤ʔ	'to fear'
	ʰŋɔʔ	ŋɔ̂ʔ	ŋɔ́ʔ	ŋɔ́ʔ	'paddy rice'
	raːŋ	ràːŋ	ràːŋ	ra̤ːŋ	'flower'
	ʰraːŋ	râːŋ	ráːŋ	ráːŋ	'tooth'
	waʔ	wàʔ	wàʔ	wa̤ʔ	'to chase'
	ʰwaʔ	wáʔ	wáʔ	wáʔ	'monkey'

syllables begin with voiceless stops and sonorants; the other western dialect shows a contrast in voice quality (also known as "register") instead (Svantesson 1989; Suwilai 2003). Whether the higher tone is high or rising–falling in the first tonal dialect depends on whether the vowel is short or long.

In both tonal dialects, voiceless sonorants have become voiced, and in the first, voiced stops have become voiceless unaspirated. These mergers *transfer* the contrast from phonation in the initial consonant to tone in the following vowel (cf. Hyman 2008 on "trans-phonologization"). In the second tonal dialect, the voiced stops of the eastern dialect have merged instead with the voiceless aspirated stops and thereby also transferred the contrast to tone. In the register dialect, a clear or tense voice quality and high tone ("ā" or "á") corresponds to voiceless initials in the non-tonal dialect, while a breathy voice quality and low pitch ("a̤") corresponds to voiced initials.[2] In this dialect, too, the contrast has been transferred completely from the initial consonant to the following vowel. Tone is rising–falling or high after [spread glottis] consonants (= voiceless aspirated stops, /s h/) and [constricted glottis] consonants (= /ʔj ʔw ɓ ɗ/ – the implosives correspond to glottalized nasals /ʔm ʔn/ in the non-tonal dialect). Surprisingly, tone is low following /ʔ/ itself.

2.3.2 *Cham*

Two Chamic languages, Eastern Cham (Phu *et al.* 1992) and Utsat (Maddieson and Pang 1993), have also developed tone from preceding consonants (see also Thurgood 1999; but cf. Brunelle 2005, for arguments that Eastern Cham is not tonal), while Western Cham has developed a register contrast instead. These developments are much like those observed in the Western Kammu dialects, except that Proto-Cham did not distinguish sonorants for phonation. Low tone emerged after voiced sonorants, unless the syllable ended in glottal stop, in which case high tone emerged.

2.4 *Exaggeration and then transfer*

In Yabem and Korean, the F0 differences remain largely predictable from the phonation differences in the consonants, yet they are exaggerated in both size and extent in both languages, so they cannot still be described as mere phonetic perturbations. The tonal Western Kammu dialects, Eastern Cham, and Utsat have taken the next step and transferred the contrast from these exaggerated but still redundant F0 differences to tone by no longer pronouncing at least some of the preceding consonants with distinct phonation. Jun (1996) shows that exaggerated F0 differences may co-exist with phonation differences, so exaggeration of one phonetic difference does not necessarily trade off at first with diminution of another,[3] but Silva (2006) and Kang and Guion (2008) show that such a trade-off may eventually occur and thereby transfer the contrast.

2 "Register" refers to breathy or lax *vs.* tense, clear or modal voice quality, low *vs.* high F0, and higher *vs.* lower vowel qualities, which may occur singly or in combination (Gregerson 1976; Huffman 1976; Thongkum 1987; Denning 1989). In many Mon-Khmer languages, the first value appears in words that began with voiced obstruents and sonorants in an earlier form of the language, while the second appears in words that began with voiceless consonants. The first values may all be concomitants of expanding the pharynx by advancing the tongue root and lowering the larynx (Lindau 1979; Edmondson and Esling 2006).

3 Phonation properties vary in their probability of occurrence, not in their value; for example, a stop may occur more or less often with aspiration but not with a greater or lesser degree.

2.5 The phonetics of low tone from voiced stops

In Yabem, Western Kammu, Eastern Cham, and Utsat, low tones developed on vowels following voiced stops and non-low tones elsewhere. These tones could have arisen from exaggerating the F0 lowering that is an automatic phonetic side-effect of an articulation whose purpose is to resolve the aerodynamic conflict between voicing and obstruency. On the one hand, producing the noise characteristic of obstruents requires that intraoral air pressure (P_o) rise, but, on the other hand, maintaining voicing requires that P_o remain enough below subglottal air pressure (P_s) that air continues to flow up through the glottis. An articulation that both maintains the pressure drop across the glottis and also lowers F0 is larynx lowering (Hombert 1978; Hombert *et al.* 1979), which slows the rise in P_o by enlarging the oral cavity (Westbury 1983) and slackens the vocal folds by tilting the cricoid cartilage forward relative to the thyroid cartilage (Honda *et al.* 1999). This slackening could be an automatic, unintended mechanical consequence of larynx lowering, because this articulation's purpose in voiced obstruents is to expand the oral cavity and keep the rise in P_o in check. Yet Honda *et al.* (1999), as well as Collier (1975), Ewan (1976), and Erickson *et al.* (1994), show that larynx lowering is also one of the maneuvers which speakers use to lower F0 deliberately. Their results suggest that larynx lowering in a voiced obstruent could also be intended to lower F0.

Why would a speaker wish to lower F0 when producing a voiced obstruent? Kingston and Diehl (1994, 1995) and Kingston *et al.* (2008) argue that a low F0 in vowels flanking a voiced stop integrates perceptually with voicing in the stop closure itself to enhance the percept of the presence of low-frequency energy in and near the stop (see also Stevens and Blumstein 1981). The percept of low-frequency energy (among other auditory qualities) rather than either voicing or low F0 individually may be what conveys that the stop is [voice]. Integration unifies the stop's phonation and the adjacent vowel's pitch phonetically, at a stage in perception between the signal's raw acoustics and the listener's recognition of the stop's value for an abstract distinctive feature [voice]. This line of reasoning suggests that the lower F0 next to voiced obstruents may be as deliberate a consequence of larynx lowering as keeping P_o from rising too fast.

This account extends naturally to the register differences that have developed from the [voice] contrast in Western Kammu, Lamet, Western Cham, and elsewhere (see also Henderson 1967, Matisoff 1973, Denning 1989, and Thurgood 2002 for recognition of this link). In breathy voice, the first harmonic is far more intense than higher harmonics compared to modal or tense voice, and in higher vowels, the first formant (F1) is lower than in lower vowels. While both differences can be interpreted as automatic concomitants of producing voicing in an adjacent stop, their exaggeration and phonologization in the development of register contrasts in these languages can equally easily be construed as an attempt to strengthen the percept of low-frequency energy next to the stop.[4]

[4] F0 is usually lower in breathy voice, as in tonal Western Kammu and Eastern Cham compared to registral Western Kammu and Western Cham. Obstruents that are sometimes described as breathy voiced also "depress" tone in many Southern Bantu languages (Rycroft 1980, 1983; Traill *et al.* 1987; Traill 1990; Cassimjee 1998; Cassimjee and Kisseberth 1998; Donnelly 2009). However, the depressors are often no longer breathy or even voiced (Schachter 1976; Traill 1990; Jessen and Roux 2002; Maddieson 2003; Strazny 2003; Downing and Gick 2005; Downing 2009), so depression has become autonomous from the original laryngeal articulation that first introduced it into the languages (Traill *et al.* 1987; Traill 1990; Maddieson 2003), like other transfers of contrast from phonation to tone.

2.6 *Stiff and slack*

Halle and Stevens (1971) propose a different unification, which substitutes features used to represent tone contrasts in vowels, [stiff] and [slack] vocal folds, for [voice] in obstruents (see also Löfqvist *et al.* 1989 for phonetic evidence, and Avery and Idsardi 2001 for a dramatic extension of Halle and Stevens's proposals). A stop specified for [slack] vocal folds would be pronounced with voicing and would lower F0 on the following vowel, while one specified for [stiff] would be pronounced without voicing and with higher F0 on the following vowel. Voicing in obstruents is thus a side-effect of the vocal folds being slack enough.

The reduction in vocal fold tension represented by [slack] both helps and hinders keeping P_o enough below P_s: slacker folds vibrate for a smaller pressure drop across the glottis than stiffer ones, but they also let a larger volume of air pass through the glottis per unit of time and thereby accelerate the rise in P_o. Speakers apparently rely instead on slowing the rise in P_o by expanding the oral cavity both actively (Bell-Berti and Hirose 1975; Westbury 1983) and passively (Ohala and Riordan 1979). Halle and Stevens's features do not therefore abstract away from the phonetic realization of the phonation and tone contrasts so much as subsume them under a single contrast, whose phonetic realization differs systematically as a function of the segment's value for other features (cf. Kingston and Diehl 1994; see also CHAPTER 17: DISTINCTIVE FEATURES).

The Korean facts show that obstruents with other phonation types than [voice] raise rather than lower F0. Jun (1996) attributes this difference to the [spread glottis] and [constricted glottis] stops also being [stiff], apparently as a byproduct of stronger thyroarytenoid (also known as vocalis) contraction compared to the lax stops – cricothyroid contraction does not differ between the three classes of stops (Hirose *et al.* 1974; Hirose *et al.* 1981). The differences in the amount and timing of thyroarytenoid contraction are intended to contribute to differences between these stops in the glottal opening's size and timing (see also Kagaya 1974) and in the [constricted glottis] stops to the firmness with which the vocal folds are pressed against one another, but they clearly affect F0 too.

2.7 *Phonetics or phonology?*

The discussion in §2.5 treats F0 lowering next to voiced obstruents as one of the intended correlates of an abstract [voice] contrast. F0 raising next to [spread glottis] and [constricted glottis] could be treated as a similarly deliberate correlate of these contrasts. Yet we have seen two clear instances of tonogenesis from phonetically predictable rather than contrastive properties, namely, predictably voiced sonorants induced a low tone in the tonal Western Kammu dialects and in Eastern Cham, and the predictably spread glottis voiceless fricative [s] induced a high tone in the tonal Western Kammu dialects. The low tone that emerged after voiced sonorants in the tonal Western Kammu dialects could be attributed to their contrasting with voiceless sonorants in their ancestor (and the Eastern Kammu dialect). However, sonorants did not contrast for [voice] in Proto-Cham, so the low tone that emerged in Eastern Cham after voiced sonorants cannot derive from a correlate of the [voice] contrast in that language. Similarly, voiceless fricatives do not contrast for [spread glottis] with voiced ones in Western Kammu. The participation of voiced sonorants and /s/ suggest that their tonogenetic effects are determined by their being pronounced with voicing or the glottis wide open (Löfqvist and Yoshioka 1980; Yoshioka *et al.* 1981) and not by their phonological specification (see also CHAPTER 8: SONORANTS).

The quandary here is this: if the F0 differences next to consonants contrasting the phonation features [voice], [spread glottis], and [constricted glottis] are the product of articulations that are controlled so as to produce those differences, why do the differences also appear next to consonants that do not contrast for any of these features? Their appearance next to this latter group of consonants suggests that they are instead automatic consequences of voicing, opening the glottis wide, etc., and that it is only the articulations which produce these properties that are controlled. Producing voicing in a sonorant, however, does not require any articulation such as larynx lowering to keep the rise in P_o in check, because no appreciable amount of air is trapped inside the oral cavity during their pronunciation. In the absence of such an articulation, F0 would also not be automatically lowered next to sonorants, however reliably voiced they would be. These facts suggest that voiced sonorants pattern with voiced obstruents because voicing makes them phonetically similar, and that F0 is deliberately lowered next to them to enhance this phonetic similarity.

The case of voiceless fricatives apparently differs: the glottis must be opened wide to provide a volume of airflow through the oral constriction downstream sufficient to produce turbulent, noisy airflow. Opening the glottis wide in voiceless aspirated stops is presumably also intended to produce turbulent, noisy airflow after the stop release, so both non-contrastive and contrastive glottal spreading have a common purpose. Even so, glottal spreading does not automatically raise F0 (Hombert *et al.* 1979; Kingston and Diehl 1994), and to do so would require deliberate stiffening of the folds next to both classes of consonants. In short, what looked like evidence that the F0 differences must be automatic turns out to be evidence that they must instead be controlled.

3 Tonogenesis from following consonants

The strikingly similar tonogenetic behavior of following consonants in Vietnamese and Chinese (§3.1) is presented first, followed by the discussion of Athabaskan (§3.2). The Athabaskan data are the first to show that opposite tones can evolve from the same ostensible phonological source (§3.2.2).

3.1 Vietnamese and Chinese

According to Haudricourt (1954b), the tone contrasts of present-day Vietnamese developed in two stages. First, a final stop induced a rising tone, a final voiceless fricative a falling tone, and a level tone developed in other syllables, which either were open or ended in a nasal (see the columns in Table 97.3). A considerable time later, each of these tones then split in two under the influence of a [voice] contrast in syllable-initial stops, with words beginning with voiced stops developing lower pitches than those beginning with voiceless ones (see the rows in Table 97.3). The resulting six-way tone contrast displayed in Table 97.3 can be observed today in the Vietnamese spoken in the northern part of Vietnam.

Thurgood (2002) argues that the tones attributed to final and initial stops in Vietnamese did not arise directly from the stops themselves but instead from differences in voice quality that perturbed F0. The distinction between a rising

Table 97.3 Tonogenesis in Vietnamese: "k" = any following stop. The italicized words are the Vietnamese names for each of the tones

		Following consonants		
		CV,CVN	CVk, CVʔ	CVs, CVh
Preceding consonants	voiceless	*pa > pa high level (*ngang*)	*pak > pak high rising (*sac*)	pas > pa high falling (*hoi*)
	voiced	*ba > pa low level (*huyen*)	*bak > pak low rising (*nang*)	bas > pa low falling (*nga*)

and a level tone initially arose from a contrast between creaky and modal voice in syllables not ending in stops or fricatives in Proto-Vietic (Diffloth 1989). Tones in syllables ending in stops subsequently merged with those arising in creaky voice syllables, because final stops were pronounced with a simultaneous glottal closure. Similarly, the subsequent tone split arose from an earlier difference between a breathy and a modal voice quality induced by preceding voiced and voiceless stops and not directly from the [voice] contrast itself. Only the falling tones that developed in syllables that ended in voiceless fricatives are attributed directly to the consonants themselves (Thurgood 2002: 336).[5]

Haudricourt (1954a), Pulleyblank (1962), Mei (1970), Baxter (1982), and Sagart (1999) propose that tones developed in much the same way in the evolution from Old Chinese (500 BCE) to Middle Chinese (500 CE). Between Old and Middle Chinese, the *ping* 'level' or A tone arose in syllables ending in vowels or sonorants, the *shang* 'rising' or B tone in syllables ending in a glottal stop, and the *qu* 'departing' or C tone in syllables originally ending in /s/, which had become /h/ by the time the tones developed. A fourth tone, *ru* 'entering' or D, arose in syllables ending in an oral stop. Between Middle Chinese and the present-day languages, these tones split into lower and higher reflexes when the voiced stops merged with the voiceless unaspirated stops. There is little disagreement about this second stage in the development of the present-day tones, but considerable controversy about the transition from Old to Middle Chinese; for alternative analyses, see Wang (1958), Benedict (1972), and Ballard (1988). Lack of space prevents me from doing more here than mention the fact of this controversy.

3.2 *Athabaskan*

The Athabaskan languages in northwestern Canada, southeastern Alaska, and the Apachean subgroup are tonal, while those in southwestern Alaska and along the Pacifiic Coast of Oregon and northern California are not (Leer 1979, 1999, 2001; Kingston 2005; Krauss 2005). Most of the latter retain a contrast between glottalic and non-glottalic stops at the ends of stems that has been replaced by tones in the tonal languages.

[5] The Tamang languages, a group of closely related Tibeto-Burman languages spoken in Nepal, synchronically illustrate the covariation of tone, voice quality, and voicing in preceding obstruents that was the hypothesized precursor to present-day Vietnamese (Mazaudon 1978, forthcoming; Mazaudon and Michaud 2008).

3.2.1 *Stem rime contents*

Three contrasts between stem-final consonants (1a–c) and two contrasts between stem nuclei (1d–e) interacted in tonogenesis:

(1) a. Glottalic *vs.* non-glottalic stops (K′ *vs.* K), sonorants (′R *vs.* R), and fricatives (′X *vs.* X)
 b. Stops *vs.* sonorants (K *vs.* R)
 c. Stops *vs.* fricatives (K *vs.* X)
 d. Full *vs.* reduced (or long *vs.* short) nuclei (VV and Vʔ *vs.* V)
 e. Full vowel nuclei ending with glottal constriction (Vʔ) *vs.* those not ending with glottal constriction (VV).

(The difference in the position of the glottalic diacritic (K′ *vs.* ′R and ′X) is explained below.)

If a stem rime lacked a coda consonant, the nucleus had to be full (VV or Vʔ), but reduced as well as full vowel nuclei occurred in rimes ending in a consonant (VC, VVC). A rime ending in a glottalic sonorant or fricative with a non-glottalic full vowel nucleus did not contrast with one with a glottalic full vowel nucleus, i.e. VV′R and VV′X = Vʔ′R and Vʔ′X. Otherwise, all possible combinations of rimes and nuclei occurred. Anticipating §3.2.2, the tones are referred to as the "marked" and "unmarked" (see also CHAPTER 4: MARKEDNESS).

When the vowel was reduced, marked tone developed in stems ending in a glottalic stop or sonorant (VK′, V′R), while unmarked tone developed in those ending in a non-glottalic stop or sonorant (VK, VR). When the vowel was full and non-glottalic, however, marked tone only developed in stems ending in glottalic sonorants (VV′R); otherwise, the unmarked tone developed (VVK′ as well as VVK, VVR). The glottalic articulation was thus lost without a trace in VVK′ stems in the tonal languages. Marked tone also developed in all stems with a glottalic full vowel (Vʔ, VʔK, VʔK′). Glottalic fricatives are derived in certain stem allomorphs by spirantizing glottalic stops (VK′ > V′X, VVK′ > VV′X), and they behave like glottalic sonorants in producing marked tone on preceding full as well as reduced vowel nuclei in the tonal languages.

Much as Thurgood (2002) did for Vietnamese (§3.1), Leer (1979, 1999) argued that marked tone did not develop directly from any glottalic articulation on a stem-final consonant; glottalic consonants instead introduced a voice quality he called "constriction" on the preceding vowel, which was subsequently replaced by the marked tone. As in the ancestor of Vietnamese, some stem nuclei already contrasted for constriction in Proto-Athabaskan, i.e. *Vʔ *vs.* *VV, and stems ending in glottalic consonants merged tonogenetically with those whose nuclei were constricted.

Kingston (1985, 1990, 2005) argues that sonorants and fricatives behaved differently from stops because they lacked a stop burst with which the laryngeal articulation could be coordinated (CHAPTER 8: SONORANTS; CHAPTER 28: THE REPRESENTATION OF FRICATIVES). The laryngeal articulation in sonorants and fricatives could therefore shift more easily to the beginning of the consonantal articulation than in a stop, where it remains bound to the release at the end of the closure. This timing difference would also explain why no contrast was possible in Proto-Athabaskan between VV and Vʔ nuclei in stems ending in glottalic sonorants or fricatives: the glottal constriction at the beginning of a sonorant or fricative consonant would coincide with that at the end of a glottalic full vowel and render VV'R and VV'X rimes indistinguishable from VʔR and VʔX rimes.

The coordination of the glottalic articulation with the release of a stop was not enough to prevent it from constricting all or most of a preceding reduced vowel, so marked tone developed in such stems, but in stems with full vowels, only a portion of the vowel would be constricted by co-articulation with the final consonant – too little for marked tone to develop on them.

3.2.2 *Opposite tones from the same source*

The marked tone differs in level between languages, for example, it is high in Chipewyan, but low in Gwich'in. Kingston (2005) argues that both high and low tones could have developed from stem-final glottalic consonants because their laryngeal articulation could have been pronounced so as to raise or lower F0. If the glottal constriction was achieved by contracting the thyroarytenoid muscle alone, then the voice quality of adjacent vowels would be creaky and F0 would be characteristically low; however, if the cricothyroid muscle was also contracted at the same time, the adjacent vowel's voice quality would instead be tense and its F0 would be characteristically high.

According to Leer (1999), the languages with the high-marked tone are found on the Canadian Cordillera's east side and those with the low-marked tone on the Cordillera's west side. Yet within each of these two geographical ranges are found closely related languages with the opposite tone, e.g. low-marked Dogrib is spoken among otherwise high-marked and closely related languages on the east side, while on the low-marked west side Northern Tutchone is high-marked next to its close relative, low-marked Southern Tutchone; and similarly Tanacross is high-marked next to its close relatives, low-marked Upper and Lower Tanana.

The glottalic *vs.* non-glottalic contrast must have been lost very early in stem-final stops in the tonal languages, as none of them retains any vestige of it in the consonants themselves. How then could these recent reversals come about? The answer probably lies in the retention of the contrast in stem-final sonorants as well as between glottalic and non-glottalic full vowels in these languages down to the present day. If the ancestor of the tonal languages originally split into a high-marked and a low-marked dialect when some of its speakers chose to pronounce all the glottalic consonants with cricothyroid as well as thyroarytenoid contraction, while others chose to do so with thyroarytenoid contraction alone, then there is no reason why speakers should have lost this freedom to choose how to pronounce glottalic consonants in the subsequent history of the family. Speakers of Dogrib, Northern Tutchone, and Tanacross could have exercised this choice quite recently in words ending in glottalic sonorants or whose nucleus was glottalic, where tone remained redundant on the laryngeal articulation of the stem-final consonant or the nucleus. The contrastive tones in what were once stop-final stems must have switched value at the same time as those in the stems where the tones were predictable. That is, all high and low tones were treated alike regardless of whether they were contrastive or redundant.

Athabaskan is by no means unique in developing the opposite tone values from ostensibly the same source. Glottal stop produced a rising tone in Vietnamese (Table 97.3) and Chinese, but a falling tone in Lhasa Tibetan (Mazaudon 1977). An [h] produced a falling tone in Vietnamese (Table 97.3), but a high tone in Utsat.

A high tone also emerged after voiceless aspirated stops, [s] and [h] in Korean, and on Punjabi vowels followed by [h] or breathy voiced stops in Middle Indic (Ohala 1973).

3.3 *Summary*

In this section, I have described how tone emerged from the laryngeal articulations of following consonants in the earliest ancestors of present-day Vietnamese, the Chinese languages and the tonal Athabaskan languages – [constricted glottis] in all three families and [spread glottis] in Vietnamese and Chinese. In more recent ancestors of present-day Vietnamese and Chinese, the [voice] contrast in preceding consonants split the tones that arose from this source. Tonogenesis in Athabaskan shows that a glottal constriction can be pronounced so as to either raise or lower F0, depending on whether the cricothyroid as well as the thyroarytenoid is contracted. Other examples show that F0 can be both raised and lowered while the glottis is constricted or spread. The next section shows that such cross-linguistic variability is pervasive. This variability is another, strong clue that the so-called "perturbations" of F0 caused by these various laryngeal articulations may instead be controlled.

4 Tone splitting in East and Southeast Asia

Examples presented in this section show that languages can differ in whether higher or lower tonal reflexes arise after [voice], [constricted glottis], or [spread glottis] consonants. This cross-linguistic variability is attributed to the freedom to raise or lower F0 next to sonorants of any phonation type.

4.1 *Two- and three-way splits and cross-linguistic variability*

Tone splitting under the influence of onset consonants is characteristic of the Sino-Tibetan, Hmong, Tai, and Kam-Sui families of languages in East and Southeast Asia. A two-way split induced by an earlier [voice] contrast in initial consonants has already been illustrated with Vietnamese; many other examples of two-way splits induced by [voice] can be found in this linguistic area (Haudricourt 1972; Matisoff 1972, 1973; Mazaudon 1977). Three-way splits (Table 97.4), in which [spread glottis] and [constricted glottis] induce distinct tones, are also not uncommon.

In Yung-chiang Kam (Table 97.4a), higher tones have evolved after [constricted glottis] than [spread glottis] consonants, while in Nakhorn Sithammarat Thai (Table 97.4b) it is the reflexes after [spread glottis] consonants that are higher. These outcomes are referred to henceforth as "Constricted High" and "Spread High" splits.

In all examples so far, reflIexes after [voice] consonants have been lower than those after other phonation types, but some languages exhibit higher reflIexes instead, when tones split both two ways (Table 97.5a) and three ways (Table 97.5b). These outcomes are "Voiced High" splits, as compared to the "Voiced Low" splits in Tables 97.3 and 97.4.

Table 97.4 Three-way tone splitting: "x > y" indicates that "x" changed into "y" in the course of the split. Labial symbols are used to represent the various phonation types. Commas separate distinct reconstructed sounds or their reflexes. Chao's 1–5 low–high pitch scale is used to represent tones here

	b m v ≠ p^h ^hm f (p) ≠ ^ʔb ^ʔm (p) voice ≠ spread ≠ constricted		A	B	C
a.	*Constricted High: Yung-chiang Kam*

	Low	b > p^h, m	31	35	11

Table 97.5 Voiced High two-way and three-way splits in Shan and Szu ta chai. Slashes indicate multiple reflexes of the same reconstructed sound

	b m v ≠ p^h ^hm f (p) ≠ ^ʔb ^ʔm (p) voice ≠ spread ≠ constricted		A	B	C	D
a.	*Two-way: Shan*					
	High	b > p, m	55	22	44	
	Low	p, ^hm > m, ^ʔb > m/w	334	11	22	
b.	*Three-way: Szu ta chai*					
	High	b > p, m	35	33	44	33
	Mid	(m)p, ^ʔm > m	33	44	13	31
	Low	p^h, mp^h > $mp^ɦ$, s > $z^ɦ$, ^hm > ^ɦm	13	34	11	11

In the face of such dramatic cross-linguistic variation, it's perhaps easy to ignore the three outcomes that are consistent across all these examples (and the many others that could be presented): (i) the reflexes that emerged after original [voice] consonants were distinct from those that emerged after consonants of other specified phonation types;[6] (ii) the reflexes that emerged after the one series of obstruents that is unspecified for phonation type, the voiceless unaspirated stops, were distinct from those that emerged after the [voice] obstruents; (iii) sonorants and obstruents of a given phonation type produce the same reflexes.

The cross-linguistic variation is limited to the differences in level between the tonal reflexes observed after consonants of each phonation type.

[6] None of the examples presented here shows comprehensively how fricatives behave in tone splits, although a hint is provided by Szu ta chai, where [s] patterns with the voiceless aspirated stops. For the purposes of tonogenesis, fricatives are analyzed as contrasting for [spread glottis] rather than [voice], with voicing differences being redundant, like sonorants. Both [f] and [^hm] are [spread glottis] and redundantly voiceless, while [v] and [m] are unspecified for [spread glottis] and redundantly voiced.

4.2 *An explanation*

The traditional explanation for the Voiced High developments has been that these languages were originally Voiced Low, in conformity with phonetic expectations, but after the initial [voice] contrast neutralized and the tone split became contrastive, the tones' values were no longer constrained phonetically, and the tones that had evolved after the original [voice] consonants exchanged values with those that evolved after consonants with other phonation types. A similar story might be devised for the Spread High *vs.* Constricted High difference: either [spread glottis] or [constricted glottis] consonants first induced higher tone reflexes in the three-way splits, and the higher reflexes later exchanged values with the lower ones.

Kingston and Solnit (1989) give three arguments against such post-merger exchange processes. First, exchange processes otherwise do not occur but would have to apply frequently in this linguistic area to this linguistic property (see also Alderete 2001 and Moreton 2004 for formal objections). Second, since it is the tone features that have developed on the vowels that apparently invert their values, inversion should apply across all proto-tones. But, once inversion occurred, the prior, uninverted stage would no longer be detectable, and there would be no way to know it had ever happened. If the mechanism that inverted tones could apply to individual proto-tones, inversion would be observable in that some proto-tones would exhibit post-inversion Voiced High reflexes, while others would retain the prior Voiced Low reflexes. However, such mixed languages do not occur (see Brown 1975 for further elaboration of this argument). Third, the difference between Spread High and Constricted High splits is observable prior to the merger of the laryngeal contrasts in the consonants, in a Spread High language in Table 97.4b, and for the Constricted High Karenic language, Pwo, in Table 97.6. If languages can differ while the tone reflexes still remain predictable from the consonants' laryngeal articulations, then there is no need to assume that one development is original and the other a later inversion. In the Voiced Low language, Shih men k'an (Hmong), and many others, consonants contrasting for [voice] remain unmerged, but I have not found any cases of a Voiced High split in which this contrast has not merged (CHAPTER 80: MERGERS AND NEUTRALIZATION).

Solnit and Kingston (1988) and Kingston and Solnit (1989) argue that the freedom to pronounce sonorants of any phonation type with a higher or lower F0 (but cf. Maddieson 1984) accounts for both Voiced High *vs.* Voiced Low and Spread High *vs.* Constricted High developments. The development of opposite tones from the same phonological sources in different Athabaskan languages was explained in §3.2.2 by appealing to the same freedom to pronounce sonorants differently

Table 97.6 Three-way Constricted High tone split in Pwo

	A	B
ʔb, p	33	41
pʰ, ʰm > m	11	41
b > pʰ, m	33	24

across languages. As in Athabaskan, once the sonorants' pronunciation and its effect on F0 had been determined in the East and Southeast Asian languages, the corresponding obstruents would be pronounced and affect F0 in the same way, even if that pronunciation would conflict with the obstruent's phonetic proclivity to perturb F0 in the opposite direction. A phonetic conflict may in fact only arise with [voice] obstruents, which lower F0, as both [spread glottis] and [constricted glottis] obstruents can be pronounced so as to raise or lower F0. Solnit and Kingston (1988) and Kingston and Solnit (1989) formalize this hypothesis by specifying first sonorants and then the corresponding obstruents for tones, using Halle and Stevens's (1971) features [stiff] and [slack], as well as for phonation type. The tone features are not substituted for [voice] in this analysis. Instead, a consonant's value for [stiff] and/or [slack] is predictable from/ redundant on its value for [voice], [spread glottis], or [constricted glottis] within a language, but not cross-linguistically.

This proposal does not account for entire language families or substantial sub-groups being either Constricted High or Spread High, while both Voiced Low and Voiced High developments are found within the same families, subgroups, and even between closely related languages. As only voiced obstruents are expected on phonetic grounds to have a consistent (lowering) effect on F0, we would expect them to constrain these changes, yet they are the most labile in tone splits.

5 Tones from preceding *vs.* following consonants: Splits *vs.* tonogenesis

Tones rarely arise *de novo* from phonation contrasts in preceding consonants, as they have done in Western Kammu dialects, Eastern Cham, Utsat, Yabem, and Korean; they are more likely to split existing tones, as they have frequently done in the Vietic, Sino-Tibetan, Hmong, Tai, and Kam-Sui families.

There is actually a paradox here. Hombert (1977) showed that the F0 perturbations induced by an initial [voice] contrast were much smaller and shorter lasting in Yoruba, where high, mid, and low tones contrast, than in English, where no contrasts between morphemes are carried by tone. The perturbations may be constrained in size and extent in Yoruba to prevent confusion of one tone with another. If the perturbations induced by initial consonants' laryngeal articulations are generally constrained in tone languages, then how could they ever bring about the splits just described? The answer must be that speakers of these languages have been sensitized to F0 differences between previously existing tones, and they would be more likely to attend to, rely on, and eventually transfer the contrast to the systematic F0 differences after preceding consonants, too, even if those differences were at first small and brief.

How, then, could tone have developed from an initial [voice] contrast in the Western Kammu dialects, Eastern Cham, or Utsat, where there was no tone before? Extensive contact with other languages whose tones have split under the influence of an initial [voice] contrast is the most likely explanation.[7] Contact

[7] Brunelle (2005) presents extensive sociolinguistic evidence that speakers of Eastern Cham did not have sufficient contact with Vietnamese, the most likely language to have provided a model for its tonogenesis.

with tone-splitting languages, however, cannot explain tonogenesis from preceding consonants in Yabem or Korean. Yabem is apparently not in contact with any other tonal languages, aside from its close relative Bukuwa. Close similarities between their tone systems indicate that tone must have developed in their immediate common ancestor, rather than Bukuwa being the source of Yabem's tones. Korean has, of course, been in prolonged contact with Chinese, but the phonologization of the F0 differences after [spread glottis] and [constricted glottis] *vs.* unspecified consonants is too recent to be explained by that contact, and too different from the tone split occasioned by the much earlier merger of the [voice] contrast in Chinese – many Chinese languages also maintain the contrast between voiceless unaspirated and aspirated stops, which is about to be transferred to a tone contrast in Korean. These languages and perhaps Eastern Cham (cf. Brunelle 2005) are at least incipient exceptions to the generalization that contrastive tone does not develop in non-tonal languages from laryngeal articulations in preceding consonants.

6 Tones from uncommon sources

While consonants have often induced or split tones on neighboring vowels, the vowels' own articulations have split tones in just two languages. The rarity of this development is surprising because F0 is higher in vowels in which the tongue is higher than in vowels in which the tongue is lower. This variation in the vowels' "intrinsic" F0 is so pervasive that it is thought to be a universal, mechanical consequence of raising the tongue, which pulls the larynx up via the hyoid bone (Ohala and Eukel 1987; Whalen and Levitt 1995; Whalen *et al.* 1999); but see Ladd and Silverman (1984), Steele (1986), and Kingston (1991, 1992) for contrary evidence. Despite these intrinsic F0 differences' ubiquity and apparently automatic character, it appears that vowel height has only split tones in the Angkuic language, U, a not-too-distant relative of the Kammu languages discussed in §2.3.1 above (Svantesson 1989), and in Lugbara, a Moru-Madi language of the Central Sudanic branch of Nilo-Saharan (Andersen 1986) – other putative cases have been argued not to be products of vowel height differences (Hombert 1978; Maddieson 1978; Schuh 1978).

6.1 *Tone from vowel height: U*

In U, the high level tone in the closely related language Hu has split: it remains high in syllables with high vowels, but became low in syllables with non-high vowels (Table 97.7a *vs.* b; forms from U's and Hu's close non-tonal relative, Lamet, are given when there is no Hu cognate showing the original vowel height).

6.2 *Tone from advanced tongue root: Lugbara*

Western Lugbara contrasts four tones: low [fì] 'it exploded', mid [fī] 'he entered', high [fí] 'intestines', and extra-high [fi̋] 'they entered'. Within a word, the vowels /ɛ ɔ/ are raised to [e o] when followed by /i/ or /u/, and /i u/ do not co-occur with /ɪ ʊ/. Andersen (1986) proposes that the language therefore distinguishes [+ATR] vowels, [i e o u], from [–ATR] vowels, [ɪ ɛ a ɔ ʊ].

Table 97.7 High tone in U where the vowel is high in Hu and/or Lamet (a) *vs.* low tone when the vowel is non-high in the related languages (b)

	U	*Hu*	*Lamet*	
a.	nchí	nsíʔ	si̯ʔ	'louse'
	si	(pa)síʔ	(pl)si̱ʔ	'rope'
	nthɨ́ɪ		ntu̯ʔ	'hole'
	thú		tu̯uʔ	'vegetable'
b.	sì	θéʔ	khe̯ʔ	'tree'
	ŋkhù	ŋkhóʔ		'rice'
	khù	sŋkhóʔ		'yesterday'

In the second syllable of disyllabic verb stems, high and extra-high tones are in complementary distribution: high tone occurs when the vowel is [−ATR], [ávɪ́] 'play' *vs.* extra-high tone when it is [+ATR] [átsi̋] 'walk'. In nouns, high tone only occurs on [−ATR] vowels, and the extra-high tone can occur on both [−ATR] and [+ATR] vowels, e.g. high [ȁrɪ́] 'blood' but *[ȁrí] and [ɔ̏tsɛ̋] 'dog' *vs.* [ɔ̏ɗɨ̋ɪ] 'thigh'. Andersen proposes that the high tone split in Western Lugbara and became high when the vowel bearing it was [−ATR] and extra-high when that vowel was [+ATR].

Higher F0 has been associated with [+ATR] in other languages (Denning 1989), so ATR differences may affect vowels' intrinsic F0 much like vowel height does, probably because [+ATR] vowels are often also somewhat higher than [−ATR] vowels.

6.3 *Why is tonogenesis from vowel height so rare?*

Tone splits from vowel height or ATR contrasts are decidedly rare. Why should a vowel's own intrinsic F0 be so unable to split its tone, while F0 perturbations brought about by neighboring consonants' laryngeal articulations can so readily do so? The most plausible answer to this question is that intrinsic F0 differences between vowels differing in height depend on the vowels being prominent (Reinholt Peterson 1978; Ladd and Silverman 1984; Steele 1986; Kingston 2007) or bearing a high(er) rather than low(er) tone (Hombert 1977; Zee 1980; Connell 2002), while the effects of consonants' laryngeal articulations on the F0 of adjacent vowels do not appear to depend on the vowels' prominence or tones. If the intrinsic F0 differences between vowels were less consistent across prosodic contexts than the F0 differences between consonants, learners would be less likely to reinterpret them as differences in tone.[8]

[8] The bias favoring the learning of modular constraints proposed by Moreton *et al.* (2008) and Moreton (2008a, 2008b) does not help here, because the constraints referring to tone and vowel height are no more a-modular than those referring to tone and consonants' laryngeal articulations.

7 From stress and intonation to tone: Tonogenesis in Germanic

Before concluding this chapter, I sketch the probable paths through which tone evolved in three North Germanic languages, Swedish, Norwegian, and Danish (Gårding 1977; Lahiri *et al.* 1999; Riad 1998, 2000, 2003), and in Central and Low Franconian (Hermans 1999; Gussenhoven 2000b; Boersma 2006; Kehrein 2007). Unlike all the other examples discussed in this chapter, the sources of tone in these languages are not the laryngeal articulations of segments, although the tones' distribution is partly regulated by or correlated with various segmental properties. The tones in these languages instead come from the F0 correlate of stress in the Scandinavian languages and from intonation in Central and Low Franconian.

7.1 North Germanic word accents

In the conservative variety of Swedish spoken in and around Stockholm, i.e. Central Standard Swedish, words contrast in whether they bear Accent 1 or Accent 2. Other dialects of Swedish, as well as Norwegian dialects, differ in whether the accents still contrast and in the timing of the F0 events that realize the accents relative to the segment strings of the words bearing them (Bruce and Gårding 1978; Bruce 1999; Gussenhoven and Bruce 1999). Despite these differences between dialects and languages, their various synchronic patterns all descend from the same reinterpretation of the F0 correlates of stress as word accents in late Proto-Nordic, between 800 and 1200 CE (Riad 1998, 2003).

On the surface, both word accents can be analyzed as a sequence of a H and L tone (Gussenhoven and Bruce 1999, among many others; see also CHAPTER 45: THE REPRESENTATION OF TONE; CHAPTER 32: THE REPRESENTATION OF INTONATION). In words bearing Accent 1, the L tone is aligned with the stressed syllable, while in words bearing Accent 2, it is the H tone that is aligned with that syllable. Thus the two word accents apparently do not contrast in the tones of which they are composed but in the alignment of those tones with respect to that word's primary stressed syllable (Bruce 1977). Phonetically, F0 is low from the beginning of the stressed vowel in words bearing Accent 1, while it starts high and falls to a low value across that syllable in words bearing Accent 2. For words bearing Accent 1, the H only appears if there is a preceding unstressed syllable. When they are the last word in a focused constituent, both Accent 1 and Accent 2 words bear a focal H tone that appears immediately after the word accent tones, and initial and final L% boundary tones appear at the beginning and end of each intonational phrase. All these tones are necessarily realized roughly a syllable later in phrases containing Accent 2 words than in those containing Accent 1 words.

Riad's (1998, 2003) phonological analysis differs from this superficial account. Rather than a contrast in the tune-to-text alignment of a HL contour that determines when the other tones of the intonational contour are realized, Accent 2 words contrast privatively in having a lexical H* aligned with their stressed syllable which is absent in Accent 1 words. Focus is still marked by an H tone, which follows the lexical H*, if any. The L that invariably precedes this H is not lexical but instead either part of focus marking, a default L, or one inserted to separate the lexical and focal Hs in Accent 2 words and satisfy the OCP. The melody of an Accent 1 word is therefore $[LH]_{Focus}$-L%, and that of an Accent 2 word H*-$[LH]_{Focus}$-L%.

The diachronic development of this phonological contrast began with a number of reducing sound changes in Proto-Nordic, particularly syncope of vowels in light (CV) syllables (sixth–ninth centuries CE), e.g. heavy–light–heavy /'doomi,jan/ > heavy–heavy */'døø,man/ 'to judge' and heavy–light /'gastiz/ > /'gæstr/ 'guest'. Stress was quantity-sensitive at this stage, and any heavy syllable would have been stressed. Syncope of medial vowels created stress clashes whenever the syllables that became adjacent as a result were both heavy. Stresses also clashed in many other words where heavy syllables abutted even prior to syncope, e.g. */'wur,ðoo/ 'words (NOM/ACC PL)'. Riad proposes that stress clash was resolved by destressing the second syllable through shortening and other changes that left the affected syllable light: */'døø,man/ > /'døø.ma/ and */'wur,ðoo/ > /'wor.ðu/.

Riad hypothesizes that high F0 was one of the phonetic correlates of stress at this time, and that this F0 peak survived destressing. Words that had undergone destressing would then have had two F0 peaks, one on the remaining primary stressed syllable and the other on the newly destressed syllable. After destressing, an F0 peak would no longer be a correlate of stress because only the first of these peaks would still be associated with a stressed syllable. Once destressing eliminated the prosodic equivalence of these two peaks, the first, the one still associated with the primary stressed syllable, was re-analyzed as a lexical H* tone. This is the path of development to present-day Accent 2 words. Words in which the primary stressed syllable was final would not have any stress clash to resolve, would not have undergone destressing, and would not ever have borne two prosodically non-equivalent F0 peaks. No re-analysis of the F0 peak on a final stressed syllable as a lexical H* would therefore take place, so what would become Accent 1 words would not acquire a specification for a lexical H*. The F0 peak on this syllable, as well as the one on the destressed syllable in Accent 2 words-to-be, would then be reinterpreted as intonational in origin, i.e. as the present-day focal H. Subsequent sound changes added syllables to words that were once monosyllabic and produced words with non-final stress and Accent 1 and thus possible contrasts with Accent 2, notably the appearance of svarabhakti vowels before syllabic sonorants, e.g. /akr/ > /aker/ 'field', /fogl/ > /fogel/ 'bird', and /sookn/ > /sokken/ 'parish', and enclisis of the definite article, e.g. **/and hinn/ 'duck the', */and-in/ > /anden/, cf. /anden/ 'the ghost', with Accent 2.

Lack of space prevents me from taking up the debates as to whether the present-day contrast between word accents is privative or equipollent, whether Accent 2 (Riad 1998, 2003) or Accent 1 (Lahiri *et al.* 2005) is synchronically marked if the contrast is privative, and whether the accents are lexically or morphologically determined in the present-day languages (see for discussion Riad 1998, 2003; Morén 2006).

7.2 Danish *stød*

Danish *stød* is phonetically a glottal stop or creaky voice that causes F0 to drop sharply at the end of the sonorant interval in a syllable bearing it. It is represented here with an apostrophe following the end of this interval. A syllable can bear *stød* if it is stressed and bimoraic (heavy), and its second mora is a vowel or a sonorant followed by another consonant. If the second mora is a sonorant consonant and word-final, then *stød* cannot occur. These conditions are referred to collectively as the "*stød* basis." Syllables bearing *stød* are typically either the sole syllable in monosyllabic words or final stressed syllables in longer words. Following Itô and Mester (1997), Riad (2000) analyses *stød* as the allophone of a general HL word contour that occurs when these conditions are met, i.e. when both tones are compressed into a single word-final stressed syllable. When the stressed syllable is non-final, the two tones can be distributed across two syllables and no *stød* occurs.

Given the constraints on its distribution, it should not be surprising that Danish *stød* corresponds to the similarly restricted Accent 1 in Swedish and Norwegian. The correspondence is not perfect, however, because the distribution of *stød* is constrained further by the *stød* basis, while Accent 1's distribution is only constrained by the original position of stress in the word. If *stød* is simply the allophone of a general HL contour that is realized under the segmental and prosodic conditions specified by the *stød* basis, then, as Riad (2000) emphasizes, these conditions only determine how that contour can be realized phonetically and do not restrict whether the underlying HL can occur, unlike the conditions on the distribution of Accent 1 in Swedish and Norwegian.

Riad (2000) proposes that *stød* developed from word accents in a North Germanic dialect quite like the Central Swedish dialect of Western Mälardalen, centered around the city of Eskilstuna, southwest of Stockholm (cf. Liberman 1982). The tones in this dialect are shifted earlier compared to Central Stockholm Swedish, such that the L% boundary tone is aligned with the stressed syllable, which crowds the tones of the focal contour earlier, too, displacing the focal L from the stressed syllable and aligning the focal H with it. A consequence of this crowding of the focal H and L% boundary tones onto the stressed syllable is that, in the appropriate pragmatic conditions, the L% boundary tone is realized as a steep drop in F0 that may end in creaky voice.

The Eskilstuna "curl" phonetically resembles Danish *stød*. However, *stød* occurs in a narrower range of contexts than curl (the *stød* basis), it is categorical in the contexts where it occurs rather than pragmatically conditioned (CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY), and word accents no longer contrast in Danish, unlike in Eskilstuna and in Western Mälardalen generally. The alignment of the L% boundary tone with the stressed syllable in the Eskilstuna-like ancestor of Danish motivated the segmental restrictions on the occurrence of *stød* that constitute its basis: the L tone needed sonorant material on which to realize itself. The shift of the focal H tone to the stressed syllable in this Eskilstuna-like ancestor would have aligned H tones with stressed syllables generally, which would lead to their re-analysis as stress correlates and the loss of any phonological distinction between the lexical H* of Accent 2 and the focal H. In words with Accent 1, nothing changes as a result of this re-analysis, but in words with Accent 2, the re-analysis of the focal H would have led speakers to hypothesize secondary stresses on the syllables bearing the focal H tone that were actually unstressed. At that point, none of the tones is lexical any longer. These sound changes effectively reverse the sequence of prosodic changes that originally created the word accents from the F0 peaks aligned with stressed syllables in late Proto-Nordic.

This analysis appears to predict, incorrectly, that *stød* should correspond to Accent 2 in addition to Accent 1. Riad (2000) points to two properties that would have blocked such correspondences. First, the restrictions imposed by the *stød* basis would block many words with Accent 2 from developing *stød*. Second, large numbers of vowel-final Danish words that correspond to Swedish or Norwegian words with Accent 2 end in schwa rather than in a full vowel, and schwa cannot bear *stød*. These characteristics jointly limit the number of possible Accent 2 words that could have met the conditions to develop *stød*.

7.3 *Scandinavian summary*

In Riad's (1998, 2003) account, word accents developed in the ancestor of Swedish and Norwegian once clash-resolving destressing of the second of two stressed syllables prosodically differentiated the H tone that remained aligned with the primary stressed syllable from that which had been aligned with the destressed syllable. The H that remained aligned was re-analyzed as a lexical H* tone, producing Accent 2. Final primary stressed syllables would not have destressed, the H tone aligned them would not have been re-analyzed as a lexical tone, and as a result Accent 1 words are not specified for tone lexically. Danish *stød* developed from word accents as a result of a shift of the L% boundary tone and the focal H tone to the stressed syllable, which led to a re-analysis of H tones as correlates of stress and the reintroduction of covert secondary stresses that reversed the sequence of sound changes that originally produced the word accents.

7.4 *Tonogenesis in Central and Low Franconian*

In Central and Low Franconian dialects, heavy, stressed syllables bear one of two tone patterns, referred to variously as "*Stosston*" or "*stoottoon*" *vs.* "*Schleifton*" or "*sleeptoon*," "*Schärfung*" *vs.* "*Trägheitakzent*," "acute" *vs.* "circumflex," and "Accent 1" *vs.* "Accent 2" (Gussenhoven 2000b; Boersma 2006; Kehrein 2007).[9] Their distribution depends on the height of the vowel in the stressed syllable of a word and the voicing of the following consonant, but neither dependency is a by-product of the effects that vowel height or voicing may have on F0. This sketch of their historical development is a synopsis of Boersma's (2006) account, broken into three stages: Old Low Franconian to Early Middle Limburgian (900–1100 CE), Early to Late Middle Limburgian (1300–1400 CE), and Late to Present-day Middle Limburgian. The first two stages are illustrated in Table 97.8:

Table 97.8 First two stages in the development of Low and Central Franconian tonogenesis. At each stage, the first row shows the underlying quantitative structure and the second row the alignment of the declarative HL melody. The interrogative LH melody would be aligned in the same fashion

	Accent 1		*Accent 2*				
stages	'sleep'	'bed'	'grape'	'walk'	'hold'	'brook'	'chest'
1	slɑ$_{\mu}$ɑ$_{\mu}$pən	bɛ$_{\mu}$d$_{\mu}$də	dru$_{\mu}$wvə	lɔ$_{\mu}$wpən	ɦɑ$_{\mu}$ldən	bɛ$_{\mu}$kə	ke$_{\mu}$stə
	slɑ́ɑ́pə̀n	bɛ́d̀də̀	drúwvə̀	lɔ́wpə̀n	ɦáldə̀n	bɛ́kə̀	késtə̀
2 OSL	slɑ$_{\mu}$ɑ$_{\mu}$pən	bɛ$_{\mu}$d$_{\mu}$də	dru$_{\mu}$u$_{\mu}$və	lɔ$_{\mu}$u$_{\mu}$pan	ɦa$_{\mu}$ldən	bɛ$_{\mu}$ɛ$_{\mu}$kə	ke$_{\mu}$stə
	slɑ́ɑ́pə̀n	bɛ́d̀də̀	drúúvə̀	lɔ́úpə̀n	ɦáldə̀n	bɛ́ɛ́kə̀	késtə̀

[9] Only the so-called "rule A" dialects are discussed. Rule B dialects reverse the assignment of accents in many, although not all, forms, but the diachronic path to reversal remains obscure.

In the first stage, a quantity contrast developed between bimoraic long non-high vowels ('sleep') and monomoraic long high vowels ('grape'), diphthongs ('walk'), and short vowel–sonorant sequences ('hold') (see also CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH; CHAPTER 57: QUANTITY-SENSITIVITY). Open and closed stressed syllables containing short vowels were also monomoraic ('brook' and 'chest', respectively), except when the following consonant was a geminate, whose first half also projected a mora ('bed'). Both tones of the declarative HL or interrogative LH focal accents could map onto the stressed syllable when its nucleus was a long non-high vowel or a short vowel followed by a geminate consonant, but only the first tone could map onto the single mora in all other stressed syllables because tones were mapped left-to-right, at most one tone to a mora, and at most one mora to a tone.

Quantity differed between high and non-high long-vowel vowels because high vowels are inherently shorter than non-high ones, prior lowering of short high vowels to a higher mid quality eliminated the quantity contrast in high vowels in Early Middle Limburgian, and the long high vowels consisted of a vocalic segment followed by a homorganic glide. They thus resembled diphthongs and short vowel–sonorant sequences structurally in consisting of a vocalic segment followed by a consonantal one. At this stage, the realization of the focal pitch accents remained entirely predictable from the quantity differences between the two kinds of stressed syllables.

Open syllable lengthening ('brook') eliminated this predictability and transferred the original quantity contrast to a pitch accent contrast in the second stage. Original long non-high vowels bore Accent 1, while the newly lengthened non-high vowels bore Accent 2. The long high vowels, diphthongs, and short vowel–sonorant sequences were necessarily reinterpreted as bimoraic after open syllable lengthening, but they, too, retained Accent 2. This accentual contrast preserved the original mapping and phonetic timing of the focal pitch accents relative to syllables of the first stage, at the expense of violating the constraint mapping just a single mora to each tone. Henceforth, F0 changed during the stressed syllable itself in Accent 1 words, while in Accent 2 words it changed between the stressed and following unstressed syllable, a difference reminiscent of the superficial timing difference between Accent 1 and Accent 2 words in Swedish and Norwegian.

In the third stage, short vowels in closed syllables that previously alternated with lengthened vowels in open syllables in nominal, verbal, and adjectival paradigms lengthened, e.g. /dak/ > /daak/ 'roof (FEM SG)', /dax/ > /daax/ 'day (MASC SG)', and /lam/ > /laam/ 'lame (SG)', by analogy with their plurals /daakə/, /daaɣə/ and /laamə/ (see also Gussenhoven 2000b). The singulars would have borne Accent 2, either because they all had short vowels previously or on analogy with their plurals, which as products of open syllable lengthening bore Accent 2 themselves.

Final schwa apocope introduced Accent 1 on words with long high vowels, diphthongs, and lengthened vowels followed by voiced consonants through a shift of the L that had been aligned with the schwa to the first syllable, e.g. /drúúvə̀/ > /drúúv̀/ > /drúùv/. Three properties made this tone's preservation and shift possible: the consonant preceding the schwa belonged to the same mora as the schwa; it therefore bore the tone mapped onto that mora; and that tone could be heard during a voiced consonant. That is, the pronunciation before apocope was [drúúʋ̀ə]. This shift produced new alternations between /lɛ́ɛ̀v/ 'live (1 SG)/ (IMP SG)' and /dáàɣ/ 'days' with Accent 1, on the one hand, and /lɛ́ɛ́vən/ 'to live' and /dááx/ 'day' with Accent 2, on the other. In the Central Franconian dialects described as undergoing Rule A, but not in those undergoing Rule A2, the extension of Accent 1 generalized to words in which the schwa did not drop, e.g. in /lɛ́ɛ̀vən/ 'to live'. Accent 1 was also retained in words with geminates when the geminate was voiced, /bɛ̀d̀də/ 'bed' > /bɛ́dd̀/ and /zóǹǹə/ 'sun' > /zóǹǹ/ (cf. /nákkə/ 'neck' > /nákk/). Later degemination produced /bɛ̂d and /zôn/, with Accent 1, *vs.* /nák/, with Accent 2. Accent 2 replaced Accent 1 when the geminate was voiceless, because the second tone of the pitch accent could not be heard during a voiceless consonant.

The development of the accentual contrast in Central and Low Franconian certainly depended on both vowel height and consonant voicing, each at a different stage in its history, but not in any way that reflected the direct influences these segmental contrasts may have on F0. Instead, it was the inherently shorter duration of high compared to non-high vowels, the absence of a quantity contrast in the high vowels, and the structural parallel between long high vowels, falling sonority diphthongs, and short vowel–sonorant sequences that determined the initial difference in the mapping of the two tones of the focal pitch accents. And it was the audibility of F0 values during voiced intervals, including those of voiced obstruents, that determined the later appearance of Accent 1 where Accent 2 might otherwise have been expected. The inception of the accentual contrast at stage 2, however, did not depend on either property, but instead on conserving the previously predictable mapping of tones to syllables after open syllable lengthening had largely eliminated the quantity contrast that previously determined that mapping.

Gussenhoven (2000b) and Kehrein (2007) present a number of additional empirical arguments for not treating the distribution of the accents as instances of tonogenesis from the intrinsic F0 differences between vowels differing in height or on vowels preceding rather than following obstruents differing voicing. First, vowel qualities changed subsequently in directions opposite to those expected from the tones they bear. Second, voiced consonants only induced Accent 1 in place of Accent 2 on high vowels in words of more than one syllable, across the board in Rule A and Rule A2 dialects following final schwa apocope, and when schwas were retained in Rule A dialects, while original monosyllables with high vowels consistently exhibit Accent 2. The presence of a following vowel should have been of no consequence if Accent 1 developed from the effect of the voicing contrast on the preceding vowel's F0. This difference is expected, however, if the voiced consonant instead preserved and made audible the tone on the second syllable. Perhaps the most compelling argument, however, is that Accent 1 and Accent 2 are only realized with a HL *vs.* sustained H melody on the stressed syllable in declaratives. In interrogatives, they are instead realized with LH *vs.* sustained L melodies. If both H and L tones can be regulated by both non-high and high vowels and by both voiced and voiceless obstruents within the same language, then the effects of vowel height and obstruent voicing differences on F0 cannot have determined the accents' distributions.

This last argument raises the question, should this accentual contrast's development be treated as an instance of tonogenesis at all? In the present-day languages, the tones themselves arise from the intonation, and there is no reason to think that they have not done so throughout the period when the accentual contrast developed. The contrast may therefore have always been in how intonational tones were aligned with the utterance's segmental material. Kehrein (2007) argues for just such a synchronic analysis in which there are no lexical tones, and a word's (original) segmental properties determine whether it projects a moraic trochee and Accent 1 alignment or a syllabic trochee and Accent 2 alignment. He also shows that phonetic evidence for a lexical tone can be hard to find in the F0 contours of present-day Central and Low Franconian words (Gussenhoven 2000a, 2000b; cf. Gussenhoven and Peters 2004).

7.5 Differences between Central and Low Franconian and Scandinavian

Boersma's analysis sharpens the synchronic and diachronic differences between the Central and Low Franconian accents and the Scandinavian accents. Even though tones are realized earlier in Accent 1 than in Accent 2 words, in both the tones remain properties of the intonation in Central and Low Franconian, while they now arise from the lexicon and/or morphology in the Scandinavian languages. Word accents developed in the Scandinavian languages as a result of clash-resolving destressing and the resulting reinterpretation of the F0 peaks that had previously been predictable correlates of stress. In Central and Low Franconian, inherent differences in duration between high and non-high vowels and differences in the audibility of F0 between voiced and voiceless targets determined instead how focal pitch accents were aligned with segments. The result in the Scandinavian languages was the development of a contrast between the presence and absence of a lexical tone, that is, true tonogenesis; but in Central and Low Franconian, the contrast was instead between prosodic structures that forced intonational tones to align differently.

8 Summary and conclusions

This chapter has reviewed the ways in which languages have acquired contrastive tone, particularly tonogenesis and tone splitting in East and Southeast Asian language families, including Sino-Tibetan, Hmong, Tai, Kam-Sui, the few tonal Mon-Khmer and Chamic languages, Athabaskan, Yabem, and Korean. The laryngeal articulations of consonants raised or lowered F0 in neighboring vowels, those effects on F0 were exaggerated, and contrast transferred from the consonants to tone once the consonants were otherwise no longer pronounced differently. Just two languages, U and Lugbara, have apparently split their tones under the influence of intrinsic F0 differences between vowels contrasting for height and ATR, respectively.

The chapter closed by discussing how the word accents developed in Swedish and Norwegian from clash-resolving destressing and the resulting re-analysis of F0 peaks as lexical and focal tones rather than as correlates of stress, how *stød* subsequently developed from these word accents in Danish when F0 peaks realigned with stressed syllables and were once again analyzable as stress correlates, and how contrasting patterns of tune–text alignment developed from original quantity contrasts and subsequent changes in quantity in Central and

Low Franconian. The Franconian case can be described as a transfer of contrast from segments to tone, but one where segmental properties affected the timing and audibility of intonational F0 targets rather than F0 values. In phonologizing a formerly predictable correlate of stress, the Scandinavian word accents also transfer a contrast: Accent 2 emerged in words in which secondary stresses were lost, to resolve stress clash *vs.* Accent 1 on words in which no stress clash occurred because the final syllable bore primary stress. Subsequent sound changes affecting Accent 1 words introduced following unstressed syllables, and words with non-final primary stress now contrast for word accent.

In Athabaskan and East and Southeast Asian languages, consonants with particular laryngeal articulations were the source of higher tones in one language and lower tones in another. This variability was attributed to the presence of contrasts for laryngeal articulations in sonorants as well as in obstruents. No phonetic constraints on laryngeal articulations in sonorants prevent them from being pronounced so as to either raise or lower F0. Individual languages, groups of languages, or whole families opt to pronounce the laryngeal articulations in sonorants one way or the other, and the obstruents with the same laryngeal articulations follow suit. Athabaskan differs from the East and Southeast Asian languages in preserving the laryngeal contrasts in sonorants and transferring them from obstruents, while it is the other way around for the East and Southeast Asian languages. As a result, particular groups of languages and individual languages in the Athabaskan family have repeatedly changed their pronunciation of the sonorants, while in East and Southeast Asian language groups are far more uniform, with the exception of the Voiced Low *vs.* Voiced High difference. These facts suggest that consonants should be specified for tone, using [stiff] and [slack] in addition to [voice], [spread glottis], and/or [constricted glottis].

This chapter does not account for tonogenesis in the many tonal Central American, African, and New Guinean languages (except Yabem). Tones have been reconstructed for the proto-languages from which the present-day Central American and African languages descend, so it has not been possible to work out how these languages became tonal. Catalogues are beginning to emerge of the types of tone languages found in New Guinea, particularly in the Trans-New Guinea stock (Donohue 1997, 2005; Ross 2005), but there the data vary too much to generalize about their historical development.

ACKNOWLEDGMENTS

I have been helped enormously in writing this chapter by Paul Boersma, Marc Brunelle, James Kirby, Wolfgang Kehrein, Tomas Riad, the editors Keren Rice and Marc van Oostendorp, two anonymous reviewers, and especially David Solnit. If its virtues are largely theirs, its errors remain mine.

98 Speech Perception and Phonology

Andrew Martin
Sharon Peperkamp

1 Introduction

The task of speech perception involves converting a continuous, information-rich waveform into a more abstract representation. This mapping process is heavily language-dependent – every language divides up acoustic space differently, and the mapping is distorted by context-dependent phonological rules. This is not an easy job, but it is made easier in two complementary respects. During the first year of life the human perceptual apparatus is gradually optimized to better perceive the distinctions that are crucial in the ambient language's phonological system while ignoring irrelevant variation, and phonological systems themselves are optimized from the perspective of human perception.

This two-way interaction, in which perception adapts to phonology and phonology to perception, has long been of interest to phonologists, but only in recent decades have the tools necessary to explore the connection between the two become available. In this chapter we provide an overview of the debates that have arisen around each issue, as well as the research that bears on each debate (see also Hume and Johnson 2001). §2 discusses how phonology influences speech perception, both in the native language (§2.1) and in non-native ones (§2.2), and how second language perception relates to loanword adaptations (§2.3). §3 addresses the question of how perception influences phonology, beginning with an overview of the relevant typological data (§3.1), and concluding with a comparison of theoretical approaches to the data (§3.2). Finally, in §4 we briefly consider the ramifications of the bidirectional nature of the phonology–perception interaction.

2 Phonological influences in speech perception

2.1 *Native language perception*

How we perceive speech in our native language has long been a topic of interest. As early as the 1930s, phonologists were interested in the role of abstract phonemes in perception (CHAPTER 11: THE PHONEME). Sapir (1933) argued that phonemes are psychologically real, in that native speakers are typically unaware of the allophones in their language. The evidence he provides comes from native speakers transcribing phonemes regardless of their phonetic realization. For instance, native speakers of Nootka fail to transcribe the phoneme /i/ as [e] when it occurs after /h/. Likewise, Swadesh (1934) observed that phonemes are the basic percepts by which native speakers perceive their language.

More recently, the psychological reality of phonemes has been investigated experimentally. For instance, Otake *et al.* (1996) used a phoneme detection task to examine the processing of the moraic nasal consonant by native speakers of Japanese.[1] In Japanese, the phonetic realization of this consonant depends upon the place of articulation of the following consonant: in the words *kanpa* 'campaign', *bando* 'band', *kenri* 'right', and *tanka* 'type of poem', it is realized as [m], [n̪], [n], and [ŋ], respectively. Otake *et al.* found that Japanese listeners respond equally fast and accurately to the four realizations when asked to detect the sound that is spelled N in *rōmaji* (the Japanese writing system that uses the Latin alphabet). Especially revealing is the lack of a difference for the bilabial realization, since in onset position the presence of [m] is contrastive (cf. *mori* 'forest' and *nori* 'type of seaweed'). Hence, Japanese listeners perceive all phonetic realizations of the moraic nasal consonant as instances of a single underlying unit.

Several other studies have shown perception differences for allophonic as opposed to phonemic contrasts (CHAPTER 2: CONTRAST) using discrimination paradigms. In these paradigms, participants are asked, for instance, to indicate whether a given stimulus is identical to another one or not, or to which of two different stimuli a third one is identical. It has thus been shown that listeners have difficulty distinguishing among allophones of the same phoneme, which are typically perceived as more similar than phones in different phonemic categories, even when acoustic distance is equated. For instance, Whalen *et al.* (1997) studied the perception of the allophonic contrast [p–pʰ] (with [p] as in *happy*), compared to that of the phonemic contrasts [b–p] and [b–pʰ]. They found that perception of the allophonic contrast was worse than that of the phonemic ones. Peperkamp *et al.* (2003) showed that, likewise, French listeners have difficulty perceiving the allophonic contrast [ʁ–χ] (both segments being realizations of the French phoneme /r/), compared to the phonemic contrast [m–n].

Of course, what is an allophonic contrast in one language can be a phonemic contrast in another language. Hence, another way of examining the effect of phonological status of a given contrast is to present it to one group of listeners for whom it is phonemic and to another group for whom it is allophonic. Such a cross-linguistic study was carried out by Kazanina *et al.* (2006). They used magneto-encephalographic (MEG) recordings to examine the perception of the contrast between [t] and [d] by native speakers of English and Korean. In English, this contrast is phonemic, whereas in Korean it is allophonic: [d] only occurs as an allophone of /t/ between two sonorant segments (CHAPTER 111: LARYNGEAL CONTRAST

[1] There is at least one earlier study on the processing of abstract phonemes: Jaeger (1980) used a conditioning as well as a concept-formation paradigm to examine whether English listeners perceive different allophones of /k/ to be part of a single category. Unfortunately, the results of these experiments were inconclusive (mainly because of lack of data).

IN KOREAN). Kazanina *et al.* revealed a mismatch negativity response (a neural marker for automatic change detection) in English but not in Korean listeners whenever a series of tokens of [ta] was interrupted by a token of [da]. In other words, Korean listeners did not detect the change from [ta] to [da], perceiving the different consonants as two instances of the same category. Similarly, using both a rating task and a discrimination task, Boomershine *et al.* (2008) found that English and Spanish speakers differ with respect to the perception of the contrasts [d–ð] and [d–ɾ]; the former is phonemic in English but allophonic in Spanish, while the reverse holds for the latter. Both groups of participants rated the contrast that is phonemic in their language as more different than the allophonic one and were better at discriminating it.

The fact that listeners have difficulty perceiving allophonic contrasts does not mean that allophones are ignored at all levels of speech processing. On the contrary, listeners appear to use their knowledge about the allophonic rules in their language for the purposes of word recognition. This was shown, for instance, by Lahiri and Marslen-Wilson (1991), who studied the processing of nasal vowels by English and Bengali listeners. In English, nasal vowels only occur as allophones of oral vowels before nasal consonants, whereas in Bengali the distinction between oral and nasal vowels is phonemic. Using a gating task, in which participants have to guess which word they hear as they listen to successively longer stretches of it, Lahiri and Marslen-Wilson found that adult native speakers of English, but not of Bengali, interpret nasality on vowels as an indication that a nasal consonant follows. That is, when listening to a word up to its nasal vowel, English speakers replied with words in which the vowel is followed by a nasal consonant. Likewise, Otake *et al.* (1996), in their study on the Japanese moraic nasal mentioned before, found that Japanese but not Dutch listeners use the phonetic identity of the moraic nasal consonant to anticipate the place of articulation of the next consonant. In particular, they had more difficulty in detecting a given consonant when it occurred after an inappropriate realization of the moraic nasal, i.e. a realization that does not share the following consonant's place of articulation; for instance, they found it hard to detect /k/ when it immediately followed a non-velar realization of the moraic nasal.

Finally, it is important to note that most of the evidence for the phoneme in perception reviewed above concerns unconscious perception processes. These processes should not be confused with (conscious) awareness. Adults who are illiterate or use a non-alphabetic writing system, as well as preliterate children, typically do not have phonemic awareness, that is, conscious knowledge about the phonemes of their language. They are thus unable to carry out metalinguistic tasks, such as deleting the first sound of a word (Liberman *et al.* 1974; Morais *et al.* 1979; Read *et al.* 1986), although they can perform such tasks with larger units such as syllables (Liberman *et al.* 1974; Morais *et al.* 1986). Importantly, the influence of the native phoneme inventory on speech perception is independent of literacy. Indeed, this influence arises very early in life, long before the question of literacy comes into play. For instance, it has been shown that, like English-speaking adults, 10- to 12-month-old English-learning infants fail to discriminate the non-phonemic contrast between [d] (as in *day*) and [d̥] (as in *stay*), whereas 6- to 8-month-olds do discriminate this contrast (Pegg and Werker 1997). Hence, during the first year of life, the capacity to discriminate non-phonemic contrasts already diminishes.

2.2 *Non-native language perception*

As shown above, our speech perception system is optimized for processing our native language. On the one hand, allophonic contrasts – which never induce differences in meaning – appear perceptually less salient than phonemic ones, even when acoustic distance is equated. On the other hand, the information provided by allophonic variation concerning neighboring segments is exploited for the purposes of word recognition. This optimization comes at a price, though, when we learn a second language later in life. Indeed, we experience difficulty perceiving non-native sounds and sound sequences, just as we find it hard to produce them.

That speech perception depends upon the phonological properties of the listener's native language was already observed in the 1930s (Polivanov 1931; Bloomfield 1933; Swadesh 1934; Trubetzkoy 1939). In the words of Trubetzkoy, the native phonology acts as a sieve during speech perception, in that non-native sounds and sound sequences are perceived as native ones, a phenomenon also called *perceptual assimilation*. Starting in the 1970s, experimental research has documented many cases of perceptual assimilation. Most of this research uses discrimination paradigms, the logic being that if a non-native sound is perceived as a native one, these two sounds are hard to distinguish; similarly, it is difficult to distinguish two non-native sounds if they are perceived as the same native one. An example of the former case is provided by German listeners, who have difficulty perceiving the contrast between the Polish phonemes /ʃ/ and /ɕ/, since they perceive non-native /ɕ/ as an instance of their native consonant /ʃ/ (Lipski and Mathiak 2007). An example of the latter is provided by what is probably the best-known instance of perceptual assimilation: Japanese listeners have difficulty perceiving the contrast between English /l/ and /ɹ/ (Goto 1971; Miyawaka *et al.* 1975). Indeed, Japanese has only one liquid consonant, /ɾ/, which acoustically falls in between [l] and [ɹ]; they thus perceive both English phonemes as instances of their native category /ɾ/ (see also CHAPTER 30: THE REPRESENTATION OF RHOTICS and CHAPTER 31: LATERAL CONSONANTS). According to the Perceptual Assimilation Model (PAM; Best *et al.* 1988; Best 1995), this English contrast is particularly difficult for Japanese listeners because [l] and [ɹ] are equally bad (or good) exemplars of Japanese /ɾ/. By contrast, the Polish contrast between /ʃ/ and /ɕ/ should cause less difficulty for German listeners, since it contrasts one good ([ʃ]) and one bad ([ɕ]) exemplar of the German category /ʃ/.

As already noted by Polivanov (1931), perceptual assimilation is not limited to segments, but also concerns suprasegmentals, syllable structure, and phonotactics. As for suprasegmentals, much research has been devoted to the perception of tones by speakers of non-tonal languages (CHAPTER 45: THE REPRESENTATION OF TONE). Kiriloff (1969) showed, for instance, that English listeners have difficulty perceiving certain lexical tones used in Mandarin. More recently, the perception of stress and length contrasts has started to be investigated. For instance, it was shown that French listeners have difficulty perceiving vowel length as well as word stress (Dupoux *et al.* 1997; Dupoux *et al.* 1999), neither of which is lexically contrastive in French. Concerning syllable structure (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE), an example is again provided by Japanese, which has a very simple syllable structure, disallowing branching onsets and allowing only for codas consisting of a moraic nasal or the first half of a geminate. Japanese listeners find it hard to distinguish between consonant clusters and the same clusters broken up by the vowel /ɯ/

(Dupoux *et al.* 1999). Hence, they perceive non-native clusters with an illusory epenthetic vowel (CHAPTER 67: VOWEL EPENTHESIS). Finally, perceptual assimilation of non-native phonotactic structure has been studied, for instance, in French listeners; they have difficulty perceiving the contrast between the word-initial clusters /tl/ and /kl/ (Hallé *et al.* 1998; Hallé and Best 2007). In French, /tl/ is not a legal onset cluster (CHAPTER 55: ONSETS), and French listeners tend to perceive it as /kl/.

Perceptual assimilation arises during very early processing stages and does not require the listener's conscious attention. This is evidenced by the fact that compared to native contrasts, non-native contrasts give rise to a reduced mismatch negativity (Näätänen *et al.* 1997); this electrophysiological response component is a neural marker of automatic change detection that arises 150 to 250 msecs after the onset of the change when a deviant stimulus interrupts a sequence of repetitive stimuli.

One caveat is in order when interpreting the results of experiments purporting to demonstrate perceptual assimilation. Specifically, it is important to use experimental designs that tap a phonological processing level, where speech is coded in an abstract, language-specific format. Indeed, if listeners are given the opportunity to perform a task using low-level acoustic response strategies, no perceptual assimilation will be observed. For instance, Dupoux *et al.* (2001) used a very robust sequence recall task that yielded a complete separation between French and Spanish listeners as far as the perception of stress is concerned (that is, even the Spanish listener who had the most difficulty with perceiving stress performed better than the best French listener). However, they showed that in the absence of phonetic variability in the stimuli, French listeners performed equally well as Spanish listeners on the very same task. Differences between phonological and acoustic perception can also be shown by transforming the speech stimuli in such a way as to make them sound like non-speech. For instance, after removal of all acoustic information except the F3 component, Japanese listeners perceived the [l–ɹ] contrast as well as native English speakers (Miyawaki *et al.* 1975).

Research with infants has shown that many aspects of the native phonology, including segments, suprasegments, syllable structure, and phonotactics, are acquired early in life; one-year-old infants thus show many of the perceptual assimilation effects that can be observed in their parents. The question as to whether perceptual assimilation can be overcome at a later age has been studied in two types of populations, i.e. bilinguals, and monolinguals who have received specific perception training. In both cases, improvement appears to be possible, with native-like performance generally remaining out of reach, though. To start with training studies, Japanese monolinguals can improve their perception of the [l–ɹ] contrast over several weeks of intensive computerized training, but their performance remains significantly below that of English monolinguals (Lively *et al.* 1993). Similar results have been reported for monolinguals who were trained to improve their perception of non-native suprasegmental contrasts (e.g. Wang *et al.* 1999).

Concerning bilinguals, we can broadly distinguish *late* bilinguals, who have started to learn a second language during or after adolescence, and *early* bilinguals, who have learned their second language during childhood. There is evidence that late bilinguals exhibit the same difficulty as monolinguals, although possibly to a lesser extent (Takagi and Mann 1995; Flege *et al.* 1997; Dupoux *et al.* 2008). For instance, Takagi and Mann (1995) found that Japanese–English bilinguals who had lived for at least 12 years in the United States did not yield the same performance as native speakers of English on the [l–ɹ] contrast; their performance was better, though, than that of Japanese monolinguals. Dupoux *et al.* (2008) found that advanced French–Spanish bilinguals were actually indistinct from French monolinguals as far as the perception of stress is concerned. However, these bilinguals had lived on average only four years in a Spanish-speaking country; the possibility that their perception of Spanish stress would improve with more exposure cannot be excluded. Perhaps more surprisingly, even early bilinguals sometimes fail to show native-like perception of their second language (Mack 1989; Pallier *et al.* 1997; Sebastián-Gallés and Soto-Faraco 1999). For instance, Pallier *et al.* (1997) tested fluent Spanish–Catalan adult bilinguals, who had started to learn Catalan before the age of six and who use Catalan on a daily basis. Spanish has only one mid front vowel, whereas Catalan has two, /e/ and /ɛ/. The early bilinguals were found to have difficulty perceiving the Catalan vowel contrast.

Three factors have been proposed that influence the strength of perceptual assimilation in bilinguals. First, in the realm of segmental perception, the Speech Learning Model (SLM) of Flege (1995) states that the greater the perceived dissimilarity of an L2 sound from the closest L1 sound, the better the L2 sound is learned, both in perception and production. Second, L2 features that play a role – even a non-contrastive one – in the native language have been argued to be less difficult than others. For instance, McAllister *et al.* (2002) compared native speakers of English and Spanish living in Stockholm. They showed that the former perceive Swedish length better than the latter. Indeed, in English, length is used allophonically, making it easier for native speakers of English to learn the Swedish length feature. Finally, the amount of usage of the native language appears to be correlated negatively with performance in the second language. That is, the less bilingual speakers use their native language, the better they perceive the sounds of their second language, possibly becoming even indistinguishable from native speakers of the latter language (Flege and MacKay 2004).

2.3 *Perception and loanword adaptations*

One area of *phonological* research in which perceptual assimilation of non-native sounds and sound sequences appears to be relevant is that of loanword adaptations. In language contact situations, words of one language that are introduced into another language will typically (though not always) be adapted to the phonological pattern of the latter. Loanword adaptations thus transform non-native segments and suprasegments, as well as phonotactic structures, into native ones (see CHAPTER 95: LOANWORD PHONOLOGY). Given the fact that words must be perceived before they can be produced, it seems necessary that loanword phonology take into account the perception of non-native words by speakers of the borrowing language.

In phonological accounts of loanword adaptations, it is generally assumed that the input to the adaptations is constituted by the surface form of the source language, and that the adaptations are computed by the phonological grammar of the borrowing language. In processing terms, this means that during perception, the phonetic form of the source words is faithfully copied onto an abstract underlying form, and that adaptations are transformations produced by the standard phonological processes in production. Some researchers explicitly argue that foreign words can indeed be perceived without distortions and that speech perception is hence irrelevant to loanword adaptations (Paradis and LaCharité 1997; Jacobs and Gussenhoven 2000; LaCharité and Paradis 2005; see also CHAPTER 76: STRUCTURE PRESERVATION: THE RESILIENCE OF DISTINCTIVE INFORMATION). They are correct in as much as – as shown in §2.2 – at some level of representation non-native contrasts are indeed discriminated (after all, such contrasts present – sometimes quite large – acoustic differences). However, whether discrimination at an acoustic level of representation suffices to faithfully import non-native forms into one's lexicon is a different question. Given the phonetic variability due to inter- and intra-speaker variation, as well as the environmental noise in which speech is embedded, it seems reasonable to expect that listeners should discriminate non-native contrasts at a more abstract level of representation in order to store them faithfully. This is where the psycholinguistic literature becomes relevant, since it is exactly at this abstract level that listeners have been shown to experience difficulty perceiving non-native contrasts.

Several researchers have argued that at least *certain* loanword adaptations take place during perception, due to difficulties with the perception of non-native sound patterns. The first explicit proposal was made by Silverman (1992), based on the adaptations of English loanwords in Cantonese. Silverman proposed a two-stage model of loanword adaptations, containing a perceptual and an operative stage. During the first stage, the surface form of the source language is mapped onto an underlying form in the borrowing language on a segment-to-segment basis. This context-free mapping involves a first part of transformations that are due to misperception of non-native segments. In particular, segments from the source language that are illegal in the borrowing language are perceived as legal ones (for instance, *bus* would be perceived as [pas], the Cantonese phoneme inventory containing /p/ and /a/, but not /b/ and /ʌ/). The perceptual level is also held responsible for the deletion of segments with a low acoustic saliency (for instance, *lift* would be perceived as [lif]). The output of the perceptual stage serves as the input to the operative stage, during which entire word forms rather than individual segments are evaluated. Adaptations take place whenever the phonological structure of the borrowing language is not respected. For instance, given that fricatives cannot occur in Cantonese syllable codas, the output [lif] of the perceptual level is transformed into [lip]. Other non-native coda consonants, as well as consonant clusters, undergo vowel epenthesis; for instance, the output [pas] of the perceptual level is transformed into [pasi].

Silverman's (1992) article, along with Yip's (1993) constraint-based reinterpretation of his model, has provided the impetus for an extensive literature on loanword adaptations, much of which is partly or wholly devoted to the issue of the role of perception (see CHAPTER 95: LOANWORD PHONOLOGY and references therein). Two questions in particular have been debated, concerning how much of loanword adaptation is due to perception, and how the role of perception is to be modeled. As to the first question, most researchers nowadays defend an intermediate position, arguing that perception does play a role in loanword adaptations, but that it cannot explain all effects. Oftentimes, arguments in favor of a perceptual account of adaptation patterns are impressionistic. For instance, word-final stop consonants are typically argued to lack acoustic saliency (especially if they are unreleased) and therefore to be prone to deletion during speech perception. Explicit reference to the psycholinguistic literature, however, has also been made. Specifically, comparing this literature to loanword data, Peperkamp and Dupoux (2003) observed a number of correspondences between adaptation patterns on the one hand and perceptual distortions of non-native phonological structure on the other hand. Some of these correspondences concern transformations applying at the level of individual segments. For instance, Japanese listeners' difficulty with the perception of the English consonants /ɹ/ and /l/ (Goto 1971) is reflected in loanwords from English, where these consonants are both adapted as /ɾ/ in Japanese (Lovins 1975). Others concern suprasegmental structure. For instance, French listeners' difficulty in perceiving stress contrasts (Dupoux *et al.* 1997) is reflected in loanwords in French, with stress being systematically word-final, regardless of the position of stress in the source word. Still others concern syllable structure. For instance, the illusory vowel that Japanese listeners perceive within consonant clusters (Dupoux *et al.* 1999) is reflected in the epenthetic vowel by which such clusters are broken up in loanwords in Japanese (Lovins 1975). This last example is especially revealing, since it contrasts with the intuition first expressed by Silverman (1992) that perception plays a role in cases of segment *deletion*, but not in those of segment *insertion*.

Speech perception experiments that specifically aim at comparing loanword data to the perception of non-native sound patterns have also been carried out (Takagi and Mann 1994; Kim and Curtis 2002; Peperkamp *et al.* 2008). For instance, Peperkamp *et al.* (2008) examined an asymmetry in French and English [n]-final loanwords in Japanese: the former but not the latter are adapted with a final epenthetic vowel (cf. [kannu] < Fr. *Cannes* [kan] and [pen] < Eng. *pen*). They showed that Japanese listeners perceive a vowel at the end of [n]-final non-words produced by French speakers but not when they are produced by English speakers. Based on these findings, they argued that the asymmetry in the loanword adaptation pattern originates in the perception of French and English words by Japanese listeners.

Concerning the question as to how the role of perception on loanword adaptations should be modeled, Silverman (1992) considered perceptually driven adaptations to be pre-grammatical, in the sense that they are computed before the phonological grammar per se comes into play. That is, they are influenced by the phonology of the native language, but not computed by the phonological grammar (see also Yip 1993; Peperkamp *et al.* 2008). Other researchers, however, have modeled perception-driven adaptations with grammatical tools, either as part of a perception grammar (Kenstowicz 2004; Boersma and Hamann 2009), or by incorporating constraints demanding perceptual similarity into the production grammar (Kang 2003; Adler 2006; Kenstowicz and Suchato 2006). The former appear to have the advantage that they can account straightforwardly for the fact that loanword adaptations sometimes conflict with native alternations.[2] For instance, in Korean, obstruents turn into nasals before nasal consonants (e.g. /kukmul/ → [kuŋmul] 'soup'), but in loanwords, obstruent + nasal sequences undergo epenthesis (e.g. [pʰikʰɨnik] < *picnic*). If loanword adaptations are computed by the phonological production grammar, this grammar thus needs to be able to distinguish between native words and loanwords; by contrast, if loanword adaptations are

[2] See Peperkamp *et al.* (2008) for an extensive list of examples, and CHAPTER 95: LOANWORD PHONOLOGY for discussion.

computed by a perception grammar, conflicts between native alternations and loan-word adaptations are a natural consequence of the fact that they are computed by distinct mechanisms, one in production and the other in perception.

3 Perceptual influences in phonology

3.1 *The influence of perception on phonology: Evidence*

Many phonological processes reduce the chances of a listener incorrectly perceiving certain sounds, particularly in contexts where they might be easily confused with other, highly similar sounds. Phonologies, in other words, appear to be optimized with respect to speech perception. In this section we survey a number of examples of this optimization; in §3.2 we discuss possible reasons for this typological bias.

In the previous section, we looked at evidence that speech perception is shaped by one's native language experience, making some distinctions easier to perceive than others. Despite the language-specific nature of perception, however, there are universal hierarchies of perceptibility imposed by the nature of the human auditory system. Some distinctions, for example those that involve greater acoustic distances, are simply more perceptible, *ceteris paribus*, than others. Although languages may differ in the phonemic contrasts they make use of, some contrasts are thus less marked than others. It is these universal differences in perceptibility that we refer to throughout this section.

As Flemming (2004) points out, perceptual markedness is best understood as a property of distinctions between sounds rather than of individual sounds themselves. Speech perception involves segmenting raw acoustic input and assigning each segment the appropriate category label. The probability that a given segment will be correctly categorized depends on what other categories it might be confused with, and where precisely the boundary between categories lies. It is thus meaningless to claim that a given sound A is difficult to perceive – it is rather the difference between two sounds A and B that is difficult to perceive. A *weak contrast* is a phonemic contrast involving two such hard-to-distinguish sounds.

The problem presented by a weak contrast can be solved in two ways: the weak contrast may be enhanced, making it easier to perceive, or it may be neutralized, making its correct perception unnecessary (Hayes and Steriade 2004). The remainder of this section discusses several examples of each type of process. We also examine the claim that perceptual similarity plays a role in processes that relate different surface forms to each other.

3.1.1 *Contrast enhancement*

Stevens *et al.* (1986) note that the distinctiveness of contrasts tends to be enhanced by the use of redundant features – high vowels, for example, are typically distinguished not only by their backness but also by rounding (CHAPTER 2: CONTRAST). This is one example of a more general tendency for languages to maximize the acoustic distance between vowels, an observation that has a long history in linguistic theory (e.g. Jakobson 1941; Wang 1971). When the vowels of a language are plotted in F1–F2 space, inventories like that in (1a) are typical, while inventories like the one in (1b) are unattested (although see Lass 1984 for a discussion of possible counterexamples).

(1) a. *Evenly spaced vowel inventory* b. *Unevenly spaced vowel inventory*

i		u				
e		o		e	ə	
	a			æ	a	ɑ

Liljencrants and Lindblom (1972) show that a simple quantitative model, which essentially maximizes the total distance[3] among a given number of points in F1–F2 space, provides a reasonably good fit to attested vowel systems (see also Lindblom 1986; Vallée 1994; Schwartz *et al.* 1997). Actual vowel inventories thus appear to be optimized in the sense that they minimize the risk of misperception by dispersing vowels as widely as possible throughout the available perceptual space.[4] Similar claims have also been made regarding consonant inventories (Padgett 2001; Padgett and Zygis 2003; Flemming 2004; Gallagher 2008).[5]

Dispersion theory, as it has come to be known, has also been used to analyze historical sound change (CHAPTER 93: SOUND CHANGE). Padgett and Zygis (2003) argue that a change in Polish in which palatalized palato-alveolar sibilants became retroflex sibilants (e.g. [ʃʲija] > [ʂija] 'neck') was motivated by the existence of an alveolo-palatal series of sibilants in Polish. Using evidence from perceptual studies, they show that alveolo-palatals are more difficult to distinguish from palato-alveolars than from retroflexes for both native Polish and English speakers. The sound change in Polish was thus perceptually optimizing in the sense that it improved the overall discriminability of sibilants.

Another case of perceptually driven contrast enhancement can be seen in the Sonority Sequencing Constraint, which requires that segments in a syllable's onset and nucleus should occur in order of increasing sonority (Sievers 1881; Jesperson 1904; Saussure 1916; Hooper 1976; Kiparsky 1981; Steriade 1982; Clements 1990; CHAPTER 49: SONORITY). Wright (2004) argues that this cross-linguistically robust generalization can be understood as a way of maximizing the perceptibility of place, manner, and voicing cues in vowels and consonants. A similar analysis is presented by Ohala and Kawasaki-Fukumori (1997), who suggest that perceptibility can also explain the low frequency of the sequences /ji/ and /wu/ in many languages, as well as the fact that the CV syllable is a more common syllable type than VC, because the cues to the place of the consonant are more robust in a transition into a following vowel than in a transition out of a preceding vowel (Fujimura *et al.* 1978).[6]

[3] Technically, their model minimizes the sum, over all possible vowel pairs, of the inverse square of the perceptual distance between each pair.

[4] Other factors, such as homophony avoidance, are presumed to regulate the number of vowels, preventing languages from adopting a single-vowel inventory, which is ideal from a purely perceptual standpoint (Flemming 2004).

[5] For more on dispersion theory, including discussion of possible formalizations, see Flemming (2002, 2004, 2005), Padgett (1997), and Ní Chiosáin and Padgett (2001).

[6] Although see Moreton *et al.* (2008) for experimental evidence of an asymmetry between CV and VC syllables that cannot be explained by this perceptual account.

A perception-based account of the Sonority Sequencing Constraint explains why sibilants, whose cues do not depend heavily on transitions into vowels, often violate the constraint. Several languages employ metathesis (CHAPTER 59: METATHESIS), whether synchronically or diachronically, in stop–sibilant clusters, converting a stop–sibilant–vowel (TSV) sequence into a sibilant–stop–vowel (STV) sequence, as in the examples from Udi in (2).

(2) *Udi metathesis* (Schultze 2002, cited in Hume 2004)

/tad-esun/	→	[tast'un]	'to give'
/t'it'-esun/	→	[t'ist'un]	'to run'
/etʃ-esun/	→	[eʃtʃ'un]	'to bring'

Metathesis of this kind, which places the stop in a position where its place cues are the strongest, is attested in Udi, Faroese, and Lithuanian (Hume 2004), while the opposite pattern (i.e. one that converts STV to TSV) is unattested (but see Blevins 2009 for a critique of this analysis).

3.1.2 *Contrast neutralization*

Perception can also shape phonologies in ways that involve the elimination of contrasts rather than their preservation (CHAPTER 80: MERGERS AND NEUTRALIZATION). One such example is the common process of nasal place assimilation, whereby nasal consonants adopt the place of articulation of the following consonant (CHAPTER 81: LOCAL ASSIMILATION). The ubiquity of this process may be related to the difficulty listeners have in determining a nasal's place of articulation when it occurs before a consonant (Fujimura *et al.* 1978; Hura *et al.* 1992; Ohala 1990; Beddor and Evans-Romaine 1992, 1995). Listeners who know that their language employs a rule of place assimilation do not need to attend to the place cues of the nasal, thus minimizing the risk of misidentification.

Another example comes from Ohala (1990), who argues that in phonological processes, or cases of historical change, in which heterorganic stop clusters become geminate stops, it is the features of the second stop in the cluster that are typically adopted by the geminate (e.g. Sanskrit *bhaktum* > Pali *bhattum*, not **bhakkum*). He explains this asymmetry as the result of the fact that cues to stop place are more salient in the transition from the stop to a following vowel than they are from a preceding vowel to the stop. The place of the second stop in the cluster is therefore more perceptible, and it is not surprising that when geminates are formed from such clusters, this place is chosen over that of the initial stop. The place contrast in stops is thus eliminated precisely where it is difficult to perceive (CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS).

Steriade (1999) shows that voicing contrasts in obstruents tend to be permitted intervocalically, where cues to voicing are strongest, and neutralized preconsonantally, where cues are weak (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). Cues to apical contrasts, such as that between [d] and [ɖ], on the other hand, follow a different pattern, being strongest after vowels and weakest after consonants. This correlates with the typology of processes that affect apicality – languages tend to eliminate such contrasts postconsonantally and preserve them post-vocalically. Place assimilation, for instance in apical consonant clusters, is overwhelmingly progressive ([ɖd] → [ɖɖ]), while major place assimilation is typically regressive ([np] → [mp]) (Steriade 2001).

3.1.3 *Similarity maximization*

A third category of perceptual effects in phonology, in addition to contrast enhancement and neutralization, could be called *similarity maximization*. Steriade (2009) observes that phonological processes tend to make changes to underlying forms that are perceptually minimal. For example, although many languages require adjacent obstruents to agree in voicing, every such language repairs disagreeing obstruent clusters through assimilation, by either voicing or devoicing one of the segments in question. No language deletes one obstruent, or inserts a vowel between the obstruents, even though both of these processes would produce a surface form that no longer violates the prohibition on voicing disagreement. Steriade argues that this is because assimilation results in a surface form that is more similar to the underlying form (or to morphologically related surface forms) than would result from deletion or epenthesis.[7] This bias toward minimal changes demonstrated in the typology of phonological processes can be thought of as optimizing, in that it increases the chances of a listener or learner correctly recognizing multiple realizations of the same morpheme in different contexts (although one must be careful to rule out alternative analyses based on ease of production, which in many cases predict the same types of changes).

Similarity maximization has also been documented extensively by Fleischhacker (2005) in two other phenomena, loanword adaptation and reduplication. Fleischhacker shows that these processes operate in ways that tend to minimize the perceptual difference between the two strings. For example, she shows that in some languages with reduplication, the reduplicant faithfully copies a consonant cluster if it consists of a sibilant and a stop (as in Gothic *ste-stald*), but not if the consonants are an obstruent and a sonorant (as in Gothic *ge-grot*), whereas the opposite pattern is not attested (CHAPTER 100: REDUPLICATION). Using evidence from perception experiments, partial rhymes in poetry (Zwicky 1976; Kawahara 2007), and imperfect puns (Zwicky and Zwicky 1986), Fleischhacker argues that this asymmetry is due to the fact that (to use the Gothic example) *ge-* and *gre-* are more perceptually similar to one another than *se-* and *ste-*.

3.2 *The influence of perception on phonology: Mechanisms*

Although there is widespread agreement that the facts of speech perception shape phonologies, there is less consensus on the causal mechanisms involved. Two types of explanation have been proposed. A *misperception* account explains perceptually optimizing processes as accidental results of language learners' confusing sounds in contexts where the cues needed to distinguish them are weak or absent (Ohala 1981, 1993; Hale and Reiss 2000; Blevins 2004, 2006, 2007). On this view, listeners' errors accumulate in the lexicon, resulting in a state in which a given process is instantiated in the data to which future generations of learners

[7] Steriade defines similarity on the basis of the perceptual confusability of two surface forms, although of course alternative definitions which take into account more abstract properties of the output are possible.

are exposed. These misperceptions could occur in a number of ways (Blevins 2004): co-articulation effects may be misinterpreted as phonological alternations (resulting in assimilation), listeners may attempt to undo a co-articulatory effect that they believe has taken place (resulting in dissimilation), or listeners may hear a range of variant pronunciations of a sound, and misidentify which is the prototypical variant.

Under a misperception account of nasal place assimilation, for example, learners would tend to misperceive [anpa] as [ampa]; once enough of these mistakes have been made, learners will posit a process of place assimilation, even if no such process was employed by the previous generation. Of course, for misperceptions to result in perceptually optimizing phonologies, confusion between sounds must be asymmetric; in the example above, listeners must mishear [np] as [mp] more often than they mishear [mp] as [np]. In an experiment carried out by Ohala (1990), English-speaking subjects did indeed misperceive heterorganic nasal–stop clusters as homorganic clusters 93 percent of the time (see Beddor and Evans-Romaine 1995 for a similar experiment with an 80 percent homorganic error rate). However, it should be noted that the fact that nasal–stop clusters in English are overwhelmingly homorganic (Hay *et al.* 2004) may have biased the subjects' perception; as discussed in §2.2, there is evidence that categorical native-language phonotactics can affect listeners' perception of ambiguous stimuli (Massaro and Cohen 1983; Moreton 1999; Moreton and Amano 1999), and it is plausible that gradient phonotactics may have a similar effect (CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY; CHAPTER 90: FREQUENCY EFFECTS). Further research is called for to identify asymmetries in misperception which are independent of language experience, and to determine the extent to which they align with the directionality of common phonological processes.

Another possible critique of this approach challenges the claim that all perceptual effects are the outcome of misperceptions. Flemming (2005) argues that misperception can only account for processes that eliminate contrasts, as in the nasal place assimilation example, and not for processes that enhance contrasts, as in the dispersion of vowel inventories. Indeed, it is hard to see at first how perceptual errors could result in making a distinction clearer. Much recent work using computational models, however, has shown that under the right conditions *self-organization* (Nicolis and Prigogine 1977) can lead to contrast enhancement even when the perception of categories is disturbed by random noise. De Boer (2001) demonstrates that a group of simulated agents which attempt to imitate each others' vowel productions evolve realistically dispersed vowel inventories over time, even in the absence of any agent-internal biases toward optimization.

In de Boer's model, an agent represents each vowel category as a cloud of tokens, representing all of the vowels heard by the agent which were classified as belonging to that category. It thus strongly resembles *exemplar theory*, the hypothesis that highly phonetically detailed tokens of sounds (or larger units such as words) are stored by listeners, and that phonological categories consist of sets of these tokens (Pierrehumbert 2001). Blevins and Wedel (2009) identify two processes that can maintain category distinctness in an exemplar model: *variant trading*, in which ambiguous exemplars (i.e. those near the border between two categories) are more likely to be misidentified than prototypical exemplars, and *variant pruning*, in which ambiguous exemplars are more likely to fail to be assigned to any category at all. Both processes have the effect of pushing categories apart, since exemplars further from the border between the categories have a higher chance of surviving (i.e. being correctly identified), and thus a greater influence over the center of the category as a whole. This work, together with other recent research using agent-based simulations (Wedel 2006, 2007; Kochetov and So 2007; Boersma and Hamann 2008; CHAPTER 6: SELF-ORGANIZATION IN PHONOLOGY), has shown that surprising and counterintuitive effects can emerge globally in a system of very simple interacting agents, and provides an important "proof of concept" for the misperception approach to perceptual effects on phonology.

An alternative to the misperception account is what we will call the *cognitive bias* approach, which sees phonological processes as being implemented *in order to* minimize the possibility of listener errors (Hayes 1999; Steriade 1999, 2001, 2009; Hayes and Steriade 2004). On this view, optimization is an explicit goal of phonological systems. A cognitive bias account would explain the ubiquity of perceptually optimized phonological processes as the result of knowledge on the part of learners which biases learning in some way. There are several ways these biases might manifest themselves. In the case of nasal place assimilation, for example, learners who know that homorganic NC clusters are "better" than heterorganic clusters, for example, might simply be unable to learn a language in which [np] is legal, but [mp] is not. Alternatively, learners may come equipped with a soft bias against the pathological heterorganic-clusters-only language – they could learn such a grammar, but only when given much more evidence than would be required to learn a homorganic-clusters-only language. If these biases are universal, then even if sound change were random and unconstrained, those languages that conform to learners' expectations would flourish at the expense of those that do not.

One way to formalize these cognitive biases is to posit optimality-theoretic (OT) markedness constraints which prohibit problematic sequences, which interact with faithfulness constraints to produce the observed typological distribution of languages (CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). Nasal place assimilation could be modeled as the effects of a constraint against heterorganic clusters and the absence of a corresponding constraint banning homorganic clusters. This type of analysis, however, would not work in other cases. How could dispersion effects be explained with constraints on output forms? In languages with one high vowel it will be central, but languages with two high vowels ban the central vowel in favor of two peripheral vowels. The grammar cannot "know" whether a front high vowel is marked or not without knowing what other vowels the language uses. The problem stems from the fact, mentioned earlier, that perceptual difficulty is a property of contrasts between sounds, not of individual sounds or sound sequences. Under standard formulations of OT (Prince and Smolensky 2004), however, phonological contrasts are emergent properties of an entire constraint ranking, and as such cannot be referred to directly by markedness constraints. Two examples of ways around this problem are represented by Flemming's (2002) *distinctiveness constraints* and Steriade's *P-map* (Steriade 2009).

Flemming (2002) solves the problem by expanding the definition of OT markedness constraints to allow them to refer to contrasts, or to entire sound inventories. These distinctiveness constraints are of two types, MAXIMIZECONTRASTS constraints, which prefer a greater number of distinct sounds, and perceptually motivated MINIMIMUMDISTANCE constraints, which ban inventories in which sounds are not sufficiently distinct. A learner equipped with these constraints will be able to posit a ranking that will generate a typical, well-dispersed vowel inventory, but no ranking will generate an unattested inventory, such as one in which there are only mid and low vowels.

Steriade's approach is to posit a "map" of perceptibility, realized as a matrix of sound pairs and contexts, with a similarity value assigned to each pair in each context. This "P-map" is essentially a representation of a speaker's knowledge of perceptual similarity (whether innate or somehow deduced by the speaker). The P-map is held to regulate rankings among faithfulness constraints, and it is these fixed rankings that result in perceptually optimizing typological biases. Recall the case discussed in §3.1.3 of voicing assimilation in obstruent clusters, which is preferred over deletion as a solution to voicing disagreement. According to Steriade, speakers faced with a cluster like /kd/ know that the difference between [k] and [g] is smaller than the difference between [k] and Ø. This translates into the fixed constraint ranking MAX-C >> IDENT[voice], with the consequence that no possible ranking will generate the unattested change /kd/ → [d].

Evaluating which of these theories is most likely to be true is made difficult by the fact that their empirical predictions largely overlap. We conclude this section by considering ways in which they may be teased apart. The first concerns parsimony. As many proponents of the misperception approach argue, if typological asymmetries can be shown to emerge without the need for a complex set of synchronic cognitive biases, then the diachronic analysis is the simplest, and should therefore be preferred. It is customary that in the absence of any empirical evidence, simpler explanations should be adopted over more complex ones, and it is surely healthy to question assumptions about the supremacy of synchronic over diachronic analyses. But ultimately, the question will be decided on empirical grounds.

A more empirical way of distinguishing the two approaches begins by independently establishing the plausibility of the mechanisms proposed by each theory. In the misperception case, this can take two forms. First, experiments can be used to determine under what conditions listeners in fact make perceptual errors, and the results can be compared to the typological facts. Several experiments (Fujimura *et al.* 1978; Ohala 1990; Hura *et al.* 1992) have shown, for example, that nasal place cues are difficult to identify before consonants, the same environment which frequently triggers nasal place assimilation. Guion (1998) shows that the sequences [ki] and [ʧi] are highly confusable when compared to similar sequences, which may explain why velar palatalization before [i] is a common process synchronically and diachronically. Kochetov and So (2007) show that the perceptibility of released stops in various environments correlates with cross-linguistic patterns of place assimilation.

Second, because misperception accounts rely on effects that emerge globally within a network of speakers and listeners, rather than inside the head of each individual, computer simulations involving multiple speakers can be used to explore how biases develop and propagate throughout a speech community. As discussed above, de Boer's (2001) work on the evolution of vowel systems falls under this heading, as does Wedel's (2006) research into the emergence and maintenance of linguistic contrasts. Boersma and Hamann (2008) show that optimally dispersed sibilant inventories can evolve over multiple generations when agents produce sounds using the same grammar used for perception. Simulations such as these do not by themselves provide direct evidence of the misperception hypothesis, but they are a crucial step in delineating the precise empirical predictions made by the theory.

Similarly, proponents of the cognitive bias model have sought to establish its plausibility by looking for evidence for these biases in domains for which diachronic explanations do not apply. Kawahara (2007) shows, for example, that the lyrics of Japanese rap songs employ a type of line-final rhyme which has no precursor in Japanese poetic tradition. Kawahara shows that the rhymes attested in a corpus of lyrics adhere to a hierarchy of perceptual similarity which plays no role in the rest of Japanese phonology, suggesting that the Japanese speakers who composed these lyrics possess a knowledge of perceptual similarity relations that is not learned.

Wilson (2006) comes to a similar conclusion using an artificial language learning experiment. He shows that English-speaking subjects who are taught a velar palatalization rule which changes /k/ to [ʧ] before [e] generalize that rule to contexts in which the vowel is [i], while subjects taught a rule that only applies before [i] do not generalize it to [e]. Wilson attributes these results to a learning bias that is motivated by the subjects' (presumably unconscious) knowledge that [ki] and [ʧi] are more perceptually similar than [ke] and [ʧe] (Guion 1998). Skoruppa *et al.* (forthcoming) also use an artificial language learning experiment to show that subjects find it easier to learn phonological rules which implement small changes.

Of course, evidence that adults use biases when faced with novel phonological situations does not itself constitute evidence that children use the same biases when acquiring their native language (CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY). The next step, for both theories, is to look for evidence that their proposed mechanisms are in fact operating in the real world of language learning and use. How often do language learners, outside of a laboratory, actually misperceive sounds, and how frequently must misperception occur in order to allow a given sound change to spread throughout a speech community? What evidence is there that children employ learning biases in the early stages of acquisition?[8] To what extent are typological patterns driven by historical forces other than sound change, for example the preferential adoption or retention of some words over others (Martin 2007)? Answering these questions would be difficult, but not impossible, and the relevant research has for the most part yet to be done. Data could come from detailed examinations of diachronic changes, either those currently in progress or those for which there is a written record, or from experiments involving numbers of interacting subjects that more closely resemble an actual language learning environment.

In a sense, both theories agree on the fact that linguistic sound systems are optimized for human perception – they disagree only on how this optimization takes place. In the misperception approach, optimization takes place globally, as the overall effect of many "innocent misapprehensions." The cognitive bias theory claims that optimization is local, occurring inside the head of each speaker. The two theories are not mutually incompatible (see Moreton 2008 for discussion). It is certainly possible that biases in diachronic change shape phonological systems, and that learners have also become biased so as to more easily learn the types of phonological patterns that they are most likely to encounter.

[8] The experimental studies in Saffran and Thiessen (2003) and Cristià and Seidl (2008) suggest that phonotactic learning in infants is indeed biased in favor of certain types of pattern.

4 Conclusion

Learning the phonology of a language involves, among other things, adjusting one's expectations in accordance with the language one has already heard. This makes the learner better able to perceive the distinctions used by her native language, albeit at the cost of a reduced ability to perceive non-native distinctions. On this view, the fact that the native phonology influences perception is not surprising – it is simply a consequence of the trade-off involved in tuning the perceptual system to expect input of a certain type. In this chapter, we surveyed evidence that the perception of phonemic and allophonic categories is biased by the phonemic categories and phonotactic restrictions of one's native language, and that these factors also influence the adaptation of words borrowed from other languages. Further research on this topic promises to give us a clearer picture of exactly which properties of the native language influence speech perception.

We also discussed evidence of influence in the other direction, from perception to phonology. This influence operates over historical time, changing languages in the direction of eliminating difficult-to-perceive contrasts, whether by neutralizing the problematic contrasts, or by making them more distinct, ultimately resulting in a linguistic typology which appears to be perceptually optimized. Current debate on this topic is centered on the question of what drives this historical change – synchronically active learning biases, or perceptual errors on the part of language learners. Both hypotheses make strong claims regarding the fundamental structure of phonological grammars, and the results of this debate have the potential to shape the direction phonological theory will take in the coming decades.

ACKNOWLEDGMENTS

Research for this chapter was supported by the Agence Nationale de la Recherche (ANR-BLAN-0065-01) and the Centre National de la Recherche Scientifique. We are grateful to Katrin Skoruppa for comments and discussion.

99 Phonologically Conditioned Allomorph Selection

Andrew Nevins

Since Jakobson's (1948) analysis of Russian verbs as having one stem rather than two, it has been an attempt of generative phonology to minimize distinctly listed allomorphs in favor of phonological rules, some of which may be morphologically specific. Nonetheless there are certain allomorphs that cannot be derived one from the other, leading to "multiple URs" for the same morphemic category, such as the Moroccan 3rd person object clitic, which varies between the allomorphs *-h* (chosen after vowel-final stems) and *-u* (chosen after consonant-final stems), as will be discussed in §1.3 below. Such cases require distinct suppletive allomorphs, whose distribution is determined according to their phonological environments. The division of labor in dealing with allomorphy, then, is taken up both by purely phonological rules (such as those responsible for the voicing alternations of the English plural morpheme) and by morphological selection among separately listed allomorphs competing for insertion. In this chapter, we focus on the latter type of alternation between morphemes, while emphasizing that many cases of allomorphy not included in the present discussion are still best handled by phonological derivations from a single underlying form.

While a number of instances of allomorph choice depend on morphosyntactic and lexical factors (including conjugation or declension class), many cases of allomorph selection can be predicted on the basis of phonological configuration. Carstairs (1988) points out the relevance of phonological conditions on allomorph selection to morphological theory, but does not provide an implementation of how such allomorph selection should work. The tradition of analyzing allomorphy as multiple allomorphic input candidates that compete for the same morphemic realization and that are chosen among them for the output based on phonological selection begins with Mester's (1994) treatment of Latin stem augments in the perfect.[1] One of the first goals in discussing the role of phonological well-formedness in allomorph distribution is an explicit connection of these phenomena to well-established categories of phonological well-formedness

[1] However, this case will not be reviewed below, since Lapointe (1999) and Embick (2009) raise important caveats about the appropriateness of Mester's foot-based analysis for a full treatment of Latin.

based on cross-linguistic research. In this chapter I will present six different types of phonological conditions that force choice of one listed allomorph over another. I will then discuss cases which appear to be arbitrary but still reference phonological conditions, and thus require the mechanism of phonological subcategorization. Finally, I will proceed to a more general theoretical discussion about the level of phonological representation at which allomorph selection takes place, and the mechanism of choice.

1 Six phonological conditions forcing allomorph choice

I have attempted to categorize below a wide range of cases from typologically diverse languages into six basic categories of phonological markedness. As the case studies are chosen to make more general points of contact between the languages, in some cases I have chosen only the clearest examples, and direct the interested reader to the original articles for a fuller discussion of some of the complexities. The argumentation for particular analyses is necessarily abbreviated in this overview, and the reader is advised to consult the references provided for detailed argumentation in favor of certain analyses and against possible other analyses. In addition, I should mention that my choice of citations for these phenomena often reflect the most recent, or most theoretically relevant to the current discussion, rather than choosing the *locus classicus* on a particular case of allomorphy per se.

The six conditions are organized in terms of segment-level phenomena, syllable-level phenomena, and prosodic-level phenomena. I begin with segmental dissimilation, as it arises in the familiar case of English as well as many other languages, and then to segmental phonotactics. I then turn to syllable structure, whereby preference for onsetful, codaless, and less complex syllables plays a role in allomorph selection, and subsequently to morphological alignment of stems with syllables and syllabic constituents, which causes resistance to resyllabification in the relevant cases. Finally, I turn to stress-to-sonority and peak-prominence effects, which prefer sonorous stressed syllables and less sonorous unstressed syllables, and then to the optimization of foot structure.

1.1 *Segmental dissimilation*

The English Saxon genitive 's, often thought to be one of the most stoic and flexible of all inflectional markers in English, has in fact two allomorphs: 's and a zero allomorph, Ø (with devoicing and epenthesis processes well known from the plural also automatically occurring for the former, which is underlyingly /-z/; Pinker and Prince 1988). The zero allomorph is chosen when the head noun to which the genitive marker attaches contains the plural -s (Zwicky 1987; Lapointe 1996). As (1a) and (1b) show, choosing -s is ungrammatical with a pluralized head noun in -s, though not with other plural forms (1c). As (1c) shows, this is the result of a dissimilatory pressure between two *affixes* with identical segmental content: when both are [-s] (or more likely, when both are [-z]), one of them – in this case, the outermost – has to go unexpressed, but when it is part of the stem, no such constraint holds, as shown in (1d).

(1) *English possessive clitic's zero allomorphy*

a. the cats' feet are dirty ([kæts], *[kætsɪz])
b. the pigs' hooves are clean ([pɪgz], *[pɪgzɪz])
c. the oxen's hooves are dirty
d. Katz's deli (*[kæts], [kætsɪz])

Interestingly, the dissimilatory zero allomorphy of the Saxon genitive is not enforced when the pluralized noun is not the head of the entire noun phrase – in other words, when the element undergoing possessive marking is not identical to the phonological edge at which the clitic -s is placed. In such cases, some speakers (including myself) variably allow fully-fledged -s-marking even on a noun which bears the plural -s:

(2) *Zero allomorphy optional when plural is not on head noun*

a. the lady with the cats' name is Tinuviel ([kæts], [kætsɪz])
b. the man in front of the pigs's son won the competition ([pɪgz], [pɪgzɪz])

The statement of these facts requires reference to the head *vs.* non-head status of the noun phrase bearing the external marking of genitive case, and as such presents interesting challenges for fully monostratal theories of morphology–phonology interaction. Returning however to our primary concerns in (1), the choice of allomorphs and indeed the phenomenon as a whole can clearly be understood in terms of dissimilatory pressures (see CHAPTER 60: DISSIMILATION) against adjacent identity, a set of pressures we will group here under the label of the Obligatory Contour Principle (Goldsmith 1976; Yip 1988; Suzuki 1998), relativized to adjacent sibilants.

A second case of dissimilatory pressures driving allomorphy is found in the interaction between masculine gender allomorphy and plural marking in Catalan (Bonet *et al.* 2007). Like the English case discussed immediately above, it involves avoidance of adjacent sibilants. However, unlike the English case, in which -Ø is the exceptionally chosen allomorph recruited in case of potential adjacent identity, -Ø is the default allomorph in Catalan, and avoided through choice of [-u] in order to prevent adjacent identical sequences of [s], even though the regular epenthetic vowel in Catalan is [ə].

In Catalan, masculine gender on nouns can be expressed by three separate allomorphs: -Ø, the most widespread, and, according to Bonet *et al.* (2007), unmarked allomorph, is used for nouns such as (3a), which have no overt expression of masculine gender. The second-choice allomorph, [-u], is found with nouns such as (3b) and (3c), in both the singular and the plural, as a result of lexical specification to select this allomorph. Interestingly, however, there are nouns such as (3d) which clearly select the zero allomorph, as shown in the singular, but recruit the second-choice allomorph [-u] specifically in the plural, in order to avoid an otherwise adjacent-identical sequence of stridents caused by the root-final /s/ of the noun and the [s] of the plural.

(3) *Catalan theme vowel allomorphy* (Bonet *et al.* 2007)

a.	gɔt	'glass'	gɔt-s	'glasses'
b.	awt-u	'car'	awt-u-s	'cars'
c.	mos-u	'lad'	mos-u-s	'lads'
d.	gos	'dog'	gos-u-s	'dogs'

The Catalan case thus represents another instance of allomorph selection driven by the phonological pressure of dissimilation. Interestingly, as mentioned above, the choice of allomorphy is one in which an otherwise default zero allomorph is skipped over in favor of an overt allomorph, exactly the opposite of the English possessive case above. One crucial difference between the two is that the English possessive marker realized as zero occurs as the outermost suffix: avoiding identical stridents could only be resolved by jettisoning one of them. By contrast, in the Catalan case, choice of an overt masculine gender marker before the plural marker is attached involves a "prophylactic" allomorph choice, ensuring a buffer between two non-negotiably unchangeable stridents.

A third case of sibilant-OCP-driven allomorph choice, quite similar to those discussed above, is found in Hungarian (Carstairs 1988), in which the 2nd singular indefinite present indicative is normally *-as*, but is *-ol* after sibilants (and affricates whose right edge is a sibilant). In short, a number of typologically unrelated segmental dissimilatory pressures dictating allomorph choice can be found involving sibilant consonants.

While dissimilation is in general more common among consonants than among vowels (Nespor *et al.* 2003), within vowels the most common type of dissimilation is that between low vowels (Suzuki 1998). This type of pressure can be seen at work in choice of the Spanish feminine definite article, which is ordinarily *la* (4a), but which recruits the masculine allomorph *el* (4b) in the case of feminine nouns beginning with stressed *á* (Harris 1987), such as (4c). This allomorph selection to avoid the sequence *a á* is only in case of identical vowels (cf. (4d)) and in fact is only in case of stressed *á*, as can be seen in the diminutive form in (4e). In all of the examples below, stress falls on the penultimate vowel in the noun.

(4) *Spanish article allomorphy*

a.	*la mesa*	'the table (FEM)'
b.	*el libro*	'the book (MASC)'
c.	*el agua*	'the water (FEM)'
d.	*la isla*	'the island (FEM)'
e.	*la aguita*	'the water (FEM DIM)'

A similar kind of vowel dissimilation occurs with the Dutch agentive suffix, which has the allomorphs [-aar] and [-ər]. According to Smith (1976) and van Oostendorp (2009), [-ər] is the default, and [-aːr] is chosen when it follows a syllable that contains [ə], to avoid adjacent instances of schwa:

(5) *Dutch agentive suffix allomorphy*

a.	*dans*[ə]*r*	'dancer'	b.	*wand*[ə]*laar*	'walker'
	schrijv[ə]*r*	'writer'		*bewond*[ə]*raar*	'admirer'
	voorzitt[ə]*r*	'chairperson'		*tek*[ə]*naar*	'illustrator'

What is unusual about the [-aːr] allomorph is that it does not attract stress, as most other superheavy suffixes do. Van Oostendorp (2009) suggests that [-ər] is inserted first, before stress is assigned, and that after stress is assigned, [-aːr] is re-inserted as a dissimilatory repair when there are two adjacent schwas.

A third kind of dissimilatory pressure in allomorph selection is avoidance of wholesale identity between two homophonous but distinct morphemes. For example, the English demonstrative *that* and the complementizer *that* are distinct morphemes, but have identical phonologies. However, the complementizer *that* independently has a zero allomorph. Walter and Jaeger (2008), employing corpus studies, show that the incidence of complementizer *that* as opposed to its zero allomorph is much lower than otherwise expected when the distal demonstrative follows, e.g. *Among those two, I think that* <u>*that*</u> *one is better*, where the zero allomorph of the complementizer is preferred.

1.2 Segmental phonotactics

While dissimilation is one kind of segmental interaction whereby segmental similar allomorphs "repel" each other, there are kinds of segmental phenomena that involve avoiding incompatible sequences of consonant + vowel or incompatible combinations of subsegmental features. These forces, too, can drive allomorph selection, leading to avoidance of particular allomorphs when they would incur violations of combinatorial phonotactics.

In Romanian, some *k*-final nouns have an alveopalatal-final stem allomorph in the plural, while others do not (Steriade 2008), e.g. [kolak, kolaʧʲi] 'bagel (SG/PL)' *vs.* [fok, fok-uri] 'fire (SG/PL)'. Steriade (2008) shows that verbal formations based on the same root avoid the verbalizing suffix *-i* if they do not have an existing affricate-final stem allomorph available (e.g. one from the plural). Thus the denominal verb based on /fok-/ must use the suffix *-a* to avoid the consonant + vowel sequence [ki]:

(6) *Romanian availability of stem allomorphs determines denominal suffix*

singular		*plural*		*denominal verb*	
kolak	'bagel'	kolaʧ-i	'bagels'	iŋ-kolaʧʲ-i	'to roll up'
fok	'fire'	fok-uri	'fires'	in-fok-a	'to fire up'

This case is interesting because it shows that allomorph selection of an *affix* is dependent on the existence of availability of appropriate allomorphs of the *stem*, a notion that Steriade calls lexical conservatism – in other words, allomorphy is opportunistic, but it is conservative in that it depends on recruiting existing allomorphs. That is, the default verbalizing suffix (according to Steriade 2008) *-i* can only be chosen if a [k]-final stem has an independently available [ʧʲ]-final allomorph, so as to avoid the phonotactically illicit configuration of velar stop before front vowel. Otherwise, if no [ʧ]-final allomorph is available, the verbalizing suffix *-a* will be chosen.

Turning to subsegmental phonotactic restrictions, in Udihe (Bye 2008), the perfective is expressed on stems ending with [−high] vowels by laryngealizing the vowel – in this case, the allomorph is thus smaller than a full segment. However, since the language does not allow laryngealized high vowels, when the stem ends in a high vowel, there is a suffix *-ge* concatenated, instead of laryngealization:

(7) *Udihe perfective allomorphy*

a.	etetḛ	'work-PERF'	b.	dogdi-ge	'hear-PERF'
	zawa̰	'grab-PERF'		bu-ge	'give-PERF'
	olokto̰	'cook-PERF'			

In this case, therefore, a feature co-occurrence phonotactic (banning [+high] together with [+constricted glottis]) drives allomorph selection: the ordinary exponence process is overridden by a phonotactic one.

1.3 Syllable structure

Arguably some of the most widespread instances of phonologically conditioned allomorphy arise in the domain of syllable structure (see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE). When there are two or more allomorphs, the choice among them often is based on yielding a syllable structure that either avoids codas, avoids hiatus, or avoids complex codas without a sufficient sonority drop.

To illustrate this phenomenon it might be interesting to take a familiar case, the English past tense, in a slightly unfamiliar context: its use by second-language learners of English, in this case those whose native language is Brazilian Portuguese (Baptista and da Silva 2006). According to these authors (and to my own observations), speakers of Brazilian Portuguese English (henceforth BPE) choose between the allomorphs *-d* and *-ed* not based on whether the verbal stem ends in a coronal consonant, but on whether it ends in an obstruent:

(8) *BPE past tense allomorphy for obstruent-final verbs*

a.	*added*	[ædəd]	
b.	*packed*	[pækəd]	
c.	*act*	[ækt]	*[ækət]
d.	*leaned*	[ɹind]	*[ɹinəd]

As (8b) shows, in BPE the vowel-initial allomorph of the past tense suffix is extended beyond its original context and is chosen following an obstruent, in order to avoid the sonority plateau of two adjacent stops in a syllable coda. As (8c) shows, this is not a general process of epenthesis, as it occurs only in heteromorphemic contexts, and hence really is about choosing the allomorph *-ed* and not about general purpose vowel insertion. Finally, as (8d) shows, this epenthesis is sensitive to the nature of the stem-final consonant, and does not apply after sonorants. L2 phonology of this sort can be interesting, as it illustrates a case in which the distribution of allomorphs may be "opportunistically" generalized beyond their original (or historical) contexts in order to improve syllable structure.

The English indefinite article *a/an* is a case of hiatus avoidance (CHAPTER 61: HIATUS RESOLUTION), in which choosing *an* in vowel-initial contexts allows one to avoid a sequence of vowels. Stem allomorphs may also be chosen in order to avoid hiatus; Rubach and Booij (2001) cite the example of *Plato* and *hero*, which have an identical syllabic template, but which differ in their adjectival forms *Platonic* and *heroic*. In the case of *Platonic*, according to Rubach and Booij (2001), there is already an existing stem allomorph *Platon-* that can be recruited in order to avoid hiatus; in the case of *heroic*, there is not. One way of putting things is that allomorph selection is resourceful but not omnipotent: avoiding hiatus is nice when possible, and existing allomorphs can be recruited for that purpose, but wholly new stem allomorphs cannot spring into existence for this sole purpose.

Cases of phonologically conditioned allomorph selection (as opposed to general purpose epenthesis, cf. (8c), or the implausibility of lexically specific *-n-* epenthesis in *Platonic*) are clearest when the two allomorphs are quite distant from one another. In Korean, the nominative case ending is chosen according to whether the stem ends in a vowel or consonant, as shown in (9).

(9) *Korean nominative case suffix chosen based on final segment of stem* (Suh 2008)

mom-ɨ	'body-NOM'
k^ho-ka	'nose-NOM'

The vowel-initial allomorph allows for resyllabification, thus removing a coda from the representation. Both allomorphic choices result in a CV.CV profile for the suffixed stems.

The choice of phonologically unrelated allomorphs can sometimes be the result of historical divergence (CHAPTER 93: SOUND CHANGE). For example, Mascaró (2007) discusses the fact that the Moroccan Arabic object clitic used to be /-hu/, but now has developed into two distinct (and synchronically unrelatable) allomorphs, [-h], chosen after vowel-final stems (e.g. [xt^{ʕ}a-h] 'his error'), and [-u], chosen after consonant-final stems (e.g. [ktab-u] 'his book'). Each of these allomorphs is clearly chosen in order to avoid marked syllable structure: choosing the opposite contexts for these allomorphs would result in either hiatus or in a complex coda.

Somewhat similar to the BPE past tense case discussed above is the pattern of allomorphy with the Swedish definite suffix (Löfstedt 2008), in which an allomorph originally intended for one set of environments is recruited for another. The two allomorphs are [-n] and [-en]:

(10) *Swedish definite suffix allomorphy* (Löfstedt 2008)

	stem	*definite*	
a.	byː	byːn	'village'
b.	sykːel	sykːeln	'bicycle'
c.	gruːp	gruːpen	'hole'
d.	pilgrim	pilgrimen	'pilgrim'
e.	ɛlsklɪŋː	ɛlsklɪŋːen	'love (DIM)'
f.	hymːn		'hymn'

As (10a) and (10b) show, [-n] is the allomorph ordinarily chosen after sonorants, while *-en* is chosen after obstruents (10c). However, [-en] is also chosen after nasals (10d) and (10e), despite the fact that nasal + nasal sequences are tolerated tautomorphemically in Swedish (10f). This represents an emergent dispreference for sonority plateaus in codas that is blocked when possible by recruiting another allomorph (see also CHAPTER 49: SONORITY).

In French, masculine and feminine adjectives have two allomorphs, e.g. [pəti]/[pətit] 'small (MASC/FEM)'. However, the latter may also be used when preceding *masculine* adjectives if they are vowel-initial. This is a case in which hiatus resolution (or perhaps the preference for a syllable onset in the noun) recruits an adjectival allomorph of the "wrong" gender:

(11) *French adjectival allomorphy* (Tranel 1997; Perlmutter 1998; Steriade 1999)

petit canard	[pətikanar]	'small duck (MASC)'
petite bête	[pətitbɛt]	'small beast (FEM)'
petit animal	[pətitanimal]	'small animal (MASC)'

The consonant present in the feminine form is recruited wholesale for masculines simply for syllable-structure considerations. Similar patterns can be found with demonstratives (e.g. *ce* [sə], *cette* [sɛt]). While some authors treat patterns such as (11) in terms of phonological derivation (where /pətit/ is in the underlying form of both masculine and feminine, with a rule of final consonant deletion operative in the masculine), cases of wholesale suppletion, such as (12) below, clearly call out for an analysis in terms of allomorph selection, arguably driven by the same requirements of onset-furnishing as in (11) above:

(12) *French adjectival allomorphy with wholesale suppletion*

beau canard	[bokanar]	'beautiful duck (MASC)'
belle bête	[bɛlbɛt]	'beautiful beast (FEM)'
belle animal	[bɛlanimal]	'beautiful animal (MASC)'

In sum, a wide range of allomorph selection process are driven by bread-and-butter syllable structure well-formedness constraints, such as preference for onsets, dispreference for codas, and dispreference for sonority drops in codas that are not steep enough. In the next section, we will turn to a competing force in allomorph selection, where considerations of alignment of morphological and syllabic constituents may in fact create marked syllable structure.

1.4 Morphological alignment

Since at least Dressler (1977) it has been realized that there is a tendency in natural language to align morphological constituents with syllabic constituents (CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE). In fact, the tendency for C-initial allomorphs to occur after vowel-final stems and V-initial allomorphs after consonant-final stems that we have seen in the preceding section is occasionally trumped by precisely such factors, resulting in the opposite pattern. The best-known case of this is the Haitian definite article (Klein 2003), in which a C-initial suffix occurs after C-final stems and a V-initial suffix after V-final stems:

(13) *Haitian definite article allomorphy* (Klein 2003)

liv-la	'book-the'
papa-a	'father-the'

According to Klein, the default allomorph is *-a*, and *liv-la* is preferred to *li.va* because the latter would resyllabify the stem. Apparently, the morphological alignment of the right edge of the stem with the right edge of a syllable is important to maintain.

The Galician definite article (Kikuchi 2006) shows that morphological/syllabic alignment may enter into opaque interactions. The allomorphs of the definite article are *o/lo* (MASC SG), *a/la* (FEM SG), *os/los* (MASC PL), and *as/las* (FEM PL). The onsetless forms, illustrated in (14a), are the default, but following a continuant *r*, *l*, *s* in the coda of a preceding word (in combinations that are adequately close, such as infinitives or prepositions plus their complements), the liquid-initial allomorph is chosen, as shown in (14b):

(14) *Galician article allomorphy* (exemplified for feminine *a(s)* vs. *la(s)*)

a.	*a xente*	'the people'	
	as mulleres	'the women'	
	para as mulleres	'for the women'	
	sobre a xente	'about the people'	
b.	*ve-la xente*	'I saw the people'	/ver/
	'toda-las mulleres	'all the women'	/'todas/

Kikuchi (2006) proposes that, like the Haitian Creole case discussed above, the choice of an onsetless article in Galician is motivated by a preference for morphological word edges to be aligned with syllable edges. When the preceding word ends in a consonant, *ver.la* is preferred to *ve.ra*, because the latter moves the definite article *a* inside, rather than at the edge of, a syllable.

Notice that choice of the liquid-initial onset is conditioned by a preceding segment that is deleted on the surface; in other words, the allomorphic choice shows opacity (since otherwise surface ['toda] (underlying /'todas/) should pattern like *para*). The deletion at this intermediate level involves an OCP effect: *ver-la* or *todas-las* would create adjacent identical continuant consonants, which Kikuchi (2006) posits are banned across word boundaries in prosodically close domains, such as prepositions or verbs plus their complements. Hence, once the allomorph *la* is chosen, the preceding continuant deletes.

A similar case is the Korean conjunctive suffix realized as [-wa] or [-kwa] (Suh 2008). The interest of this allomorphy is the fact that within the same language, the nominative (discussed in (9)) and the conjunctive have apparently contradictory distributions.

(15) *Korean conjunctive suffix allomorphy* (Suh 2008)

kho-wa	'nose-CONJ'
mom-kwa	'body-CONJ'

According to Suh (2008), this pattern results from the need for right-alignment of the stem with the right edge of a syllable. As *mw-* is tolerated as an onset, onset maximization with *mo-mwa* would result in resyllabification of the stem *mom*, while *mom.kwa* does not. What about *mo.mi*, then, the nominative form seen above? Suh's (2008) actual constraint is about alignment with the right edge of any subsyllabic constituent. In *mo.mi* the stem-final [m] is aligned with the right edge of the onset (which is simplex), but in **mo.mwa* it is not, being blocked from the right edge of the onset by the following glide. By contrast, in *mom.kwa*, the stem-final [m] is comfortably at the right edge of the coda constituent.

Mòcheno is a German dialect spoken in the Trentino region of Italy, with two allomorphs of past participial prefix, according to Alber (forthcoming): [ga-], and a subsegmental [−voice, −cont] feature matrix. The distribution of these allomorphs depends on the initial consonant of the verb stem. With voiceless stops and supralaryngeal fricatives, the [−voice, −cont] allomorph is chosen (16a), which may result in Ø realization or affricate formation. For voiced stops and all sonorants, [ga-] is chosen (16b):

(16) *Mòcheno participial allomorphy* (Alber, forthcoming)

	stem		*participial form*
a.	tondərn	'to thunder'	tondərt
	krɐtsn	'to scratch'	krɐtst
	viern	'to conduct'	pfiert
	ʃlo:ŋ	'to beat'	ʧlo:ŋ
b.	o:tnən	'to breathe'	gao:tnt
	rɛarn	'to cry'	garɛart
	mɐxen	'to make'	gamɐxt
	bisn	'to know'	gabist
	griezən	'to greet'	gagriest

According to Alber, the principle that a stem should not be resyllabified with a prefix (i.e. that the verb stem should be aligned with its own syllable) is what drives the allomorph selection. Voiceless stops and fricatives can form a doubly linked representation with the [−voice, −cont] segment, leaving the stem at the left edge of its own syllable. The rest choose [ga-] so as not to resyllabify the stem with a preceding consonant.

1.5 *Stressedness and vowel quality*

Stressed vowels like to be more sonorous, and unstressed positions tolerate fewer vowel contrasts (Crosswhite 1998; CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE). A number of allomorph selection processes seem to be motivated by the distribution of non-peripheral vowels (i.e. mid vowels, in the cases below) in unstressed positions.

Due to the Stress-to-Weight principle, stressed syllables like to be heavy, and hence may undergo processes such as Iambic Lengthening (Hayes 1995; CHAPTER 44: THE IAMBIC–TROCHAIC LAW) and glottal stop insertion. Conversely, unstressed syllables may undergo glottal stop deletion, in order to reduce their relative prominence with respect to stressed syllables.

Somewhat like the case of the Spanish definite article allomorphy, which recruits "the wrong gender" in order to avoid hiatus of identical low vowels, an allomorphy process in Hebrew plural formation occurs that borrows the wrong gender for phonological reasons. The Hebrew feminine suffix *-ot* (17b) is exceptionally extended to masculine nouns, such as (17c) (Becker 2009), which otherwise take the masculine suffix *-im* (17a).

(17) *Hebrew plural allomorphy* (Becker 2009)

a.	'jelad	jelad-'im	'boy (MASC SG/'MASC PL)'
b.	xat'ser	xatser-'ot	'backyard (FEM SG/FEM PL)'
c.	xa'lon	xalon-'ot	'window (MASC SG/MASC PL)'

One defining feature of Hebrew plural formation is that it takes stress away from the nominal stem, and this has consequences for the marking of masculine nouns whose final vowel is [o]. Becker (2009) argues that the mid-round vowel [o] is dispreferred in unstressed syllables in Hebrew (and more generally in weak positions (Beckman 1997), but can receive support by a kind of vowel harmony that licenses it: a weak unstressed [o] can be tolerated when adjacent to a stressed [o]. For this reason, the feminine *-ot* is recruited specifically for masculine nouns of which the last syllable contains [o]. Becker (2009) shows that this allomorphic recruitment is not a historical quirk, but is actively used in novel plural formations in a wug test.

Surmiran Rumantsch verbs have two sets of stem allomorphs, chosen on the basis of stress placement. The unstressed variant is not predictable from the stressed variant, ruling this out as a case of straightforward vowel reduction. According to Anderson (2008), the alternations are not predictable, and require listing of both stem allomorphs. It is a common pattern in Romance that the infinitive, 1st plural, and 2nd plural will bear distinct allomorphs from the rest of the paradigm, as in the Italian verb conjugation for *andare* 'to go', which is wholly suppletive.

(18) *Italian present tense conjugation for* andare, *with stress marked and agreement endings separated*

	singular	*plural*
a.	*'vad-o*	*and-i'amo*
b.	*'v-ai*	*an'd-ate*
c.	*'v-a*	*'v-anno*

As in Italian, which has the longer endings for 1st plural and 2nd plural, Surmiran shows a pattern which is understandable in terms of preference for unstressed syllables to be low-sonority [i u ə] rather than [e a]. The choice of allomorphs thus aligns prosodic weakness with segmental weakness: the low-sonority stem allomorphs [ləv-] and [fit-] are chosen when stress is on the inflectional ending rather than on the root.

(19) *Surmiran stem allomorphy* (Anderson 2008)

inf	lə'var	'get up'	fit'tar	'finish'
1sg	'lev		'fet	
2sg	'levas		'fettas	
3sg	'leva		'fetta	
1pl	lə'vagn		fit'tagn	
2pl	lə'vez		fit'tez	
3pl	le'van		'fettan	

Anderson argues that these alternations do not involve unstressed vowel reduction, as the same stressed [e] corresponds to both [i] and [ə]. As no deterministic rule of reduction is at work here, this must be handled in terms of allomorph selection, in this case based on stress-to-sonority.

In a somewhat similar vein, Spanish mid vowels display an alternation whereby they diphthongize under stress. However, while certain instances of diphthongization in unstressed syllables are allowed, others are not.

(20) *Spanish mid-vowel diphthongization stem allomorphy* (Bermúdez-Otero 2009)

a. *encontrár* 'to meet'
b. *encúentro* 'a meeting'
c. *encuentrón* 'meeting (AUG)' (word-level: 'one hell of a meeting')
d. *encontrón* 'someone who bumps into others' (stem-level: deverbal)

According to Bermúdez-Otero (2009), whether or not a mid-voweled root will diphthongize or not under stress is unpredictable, and hence two stem allomorphs must be listed, e.g. /eŋkwent/ and /eŋkont/. The difference between denominal derivation in (20c) and deverbal derivation (20d) is that, while denominal derivation (e.g. diminutives, augmentatives) is word-level (within the Lexical Phonology/Stratal OT conception of levels; see also CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME), the deverbal derivation is stem-level. Given such a division, Bermúdez-Otero (2007) argues that there is a relevant stem-level constraint in Spanish that disallows unstressed dipththongs. As a result, given the deverbal derivation which places stress on the suffix, the stem allomorph /eŋkont/ will be chosen, again due to the phonological preference for stress and syllabic prominence to line up.

1.6 Foot structure

In this section we examine cases of allomorph selection which involve improving or maintaining the preferred foot structure in the language (CHAPTER 40: THE FOOT).[2] The cases are similar in spirit to the alignment of segmental prominence to stress, but often involve syllable counting in a way that requires footing in order to determine allomorph selection.

González (2005) analyzes allomorph selection in languages of the Panoan family as choosing segmental allomorphs based on foot structure. For example, the Shipibio repetitive suffix has the allomorphs [ɾiba] and [ɾibi], with the former appearing after odd numbers of syllables and the latter appearing after even numbers of syllables. Since this is a trochaic language, the effect of this allomorph choice places the vowel [a] in strong syllables and [i] in weak syllables.

(21) *Shipibio syllable-counting allomorphy:* [ɾibi] *vs.* [ɾiba] (González 2005)

a. pima 'eat-CAUS' + REPETITIVE + PAST
(pi.ma)(ɾi.bi)ki 'He made him eat it again'.
b. pi 'eat' + REPETITIVE + PAST
(pi.ɾi)(ba.ki) 'He ate it again'.

In Yaminahua, the allomorphs [tiʃo] and [toʃi], a directional perfect suffix meaning 'on arriving', are chosen on the same basis: the appearance of syllable counting, which is actually based on foot structure. Higher sonority [o] is thus lined up with the stronger half of the foot.

[2] All of the cases discussed here involve trochaic languages, which may be an accident, or may be part of a deeper generalization.

(22) *Yaminahua syllable-counting allomorphy:* [tiʃo] *vs.* [toʃi] (González (2005)

a. fiʧi 'find' + ARRIVE + PAST + PLURAL
(fi.ʧi)(to.ʃi)(afo) 'found on arriving'

b. fa 'say' + ARRIVE + yesterday
(fa.ti)(ʃo.i)(ta) 'said on arriving'

Somewhat like the cases of peak prominence discussed in §1.5 above, these cases illustrate allomorph selection based on syllable counting that makes sense once integrated with the fact that this is a trochaic language, and hence odd-numbered stems will want the more sonorous syllable to come second, while even-numbered stems will want it to come first.

Similar to the Panoan cases above is the selection of allomorphy in Estonian, where the genitive plural has two allomorphs, *-te* and *-tte*, and the partitive plural has two allomorphs, *-sit* and *-it*. When these are added to vowel-final bases, the choice of allomorph is determined by what looks like syllable count: *-it* and *-tte* are chosen with odd-numbered bases. Estonian is trochaic, and Kager (1996) argues that it is foot structure that determines the choice of allomorphy: the head of a foot should be heavy if possible (CHAPTER 57: QUANTITY-SENSITIVITY):

(23) *Estonian odd-numbered stem allomorphy:* [-tte] *and* [-it] (Kager 1996)

paraja	'suitable'	('pa.ra)(ˌjat.te)	(GEN PL)
		('pa.ra)(ˌjait)	(PART PL)

By contrast, when the stem is even-numbered, no suffixation can possibly improve the weight of the head of the foot, and so affixes which cause no resyllabification or realignment are chosen:

(24) *Estonian bisyllabic stem allomorphy:* [-te] *and* [-sit] (Kager 1996)

'visa	'tough'	'(vi.sa)te	(GEN PL)
		'(vi.sa)sit	(PART PL)

Kager (1996) argues that it is feet and not syllables that are counted, as bisyllabic bases with superheavy initial syllables group with [paraja], e.g. [aasːta-tte] 'year-GEN PL'. Hence this allomorph selection cannot be reduced to syllable counting, but must be stated in terms of heads of feet and making them heavier.

Greek is a language with mostly antepenultimate stress in trisyllabic words (Drachman *et al.* 1996). Its syllable-counting allomorphy with action nominals involves [-ma] and [-imo]. Monosyllabic stems take [-imo], thereby achieving antepenultimate stress unproblematically, whereas polysyllabic stems take [-ma], keeping the stress on the initial syllable while changing word length minimally:

(25) *Greek action nominals and syllable count* (Drachman *et al.* 1996)

'vreks-imo	'wetting'
'skupiz-ma	'sweeping'

The case above shows a kind of complementarity effect: the shorter stems take the longer allomorph and the longer stems take a shorter allomorph. A similar case can be found in Dutch, whose feet are preferably disyllabic trochees. The plural suffixes *-en* and -s are chosen in order to form trochees at the right edge.

(26) *Dutch plural allomorphy: based on trochees at right edge* (Booij 1998)

knie	*'knieën*	'knee'
bal	*'ballen*	'ball'
'natie	*'naties*	'nation'
ge'nie	*ge'nieën*	'genius'
'kanon	*'kanons*	'canon'
ka'non	*ka'nonnen*	'cannon'

Notice above that a complementarity effect obtains with monosyllables *vs.* disyllables, and also in terms of distance from the right edge: the longer *-en* is chosen when there is a shorter distance of the stress from the right edge, and the shorter -s when there is a longer distance. A similar case can be found in Spanish with the suffix that creates abstract nouns from adjectives and has two allomorphs:

(27) *Spanish* [-ez]/[-eza] *allomorphy* (Aranovich and Orgun 2006)

a.	*vil-eza*	'vileness'	b.	*rigid-ez*	'rigidity'
	nobl-eza	'nobility'		*madur-ez*	'maturity'
	trist-eza	'sadness'		*tirant-ez*	'tenseness'

According to Aranovich and Orgun (2006), there appears to be a requirement that derived nouns be larger than a foot, but not larger than necessary. This pattern also shows the complementarity effect discussed above. However, consonant-final stems appear to contradict this pattern, e.g. *gentil-eza* 'gentleness', *sutil-eza* 'subtlety'. This apparent misbehavior of allomorph selection can be resolved, however, given that Spanish vowel sequences delete heteromorphemically. With such an analysis available, the stems above are thus in fact *vilo-eza, triste-eza vs. rigido-ez, maduro-ez*, at the point before which vowel deletion applies. The more abstract underlying representation, with vowel-final stems as the conditioning environment, enables a consistent statement of allomorph selection in terms of foot structure. Aranovich and Orgun (2006) argue that allomorph selection takes place at a level of representation before vowel deletion, and that the choice is motivated by a goal of forming two perfectly binary feet at that level of representation, e.g. (vi.lo)(e.za), (ri.gi)(do.ez). This pattern thus shows allomorph selection conditioned by foot structure, but at a level removed from the surface, a point to which we will return.

2 Arbitrary cases that still reference phonology

Dealing with phonologically conditioned suppletive allomorphy, Paster (2005, 2006) proposes that certain cases of allomorphy are sensitive to phonology but do not optimize anything, and proposes instead a mechanism of subcategorization in the grammar. Based on a number of cases such as Axininca and Italian, Bye (2008) echoes this conclusion, i.e. that allomorphy is selection, and that phonological optimization is due to historical or coincidental factors. Embick (2009) endorses a similar viewpoint to these authors, eschewing a model of grammar with "global" interaction between morphology and phonology. While we will discuss their models further below, it is first worth showing a few cases of these that indeed reference phonology but in which the actual choice seems to have no phonotactic/markedness-based motivation.

Two such cases involve syllable- or mora-counting allomorphy of the type that was relevant for optimization of foot structure above, but in ways which do not seem to improve anything, and cannot be easily understood in terms of existing grammatical well-formedness constraints unless one wants to "pollute" the constraint set with a host of parochial constraints unrelated to the core intuitions of markedness. They are shown below, for Kaititj and Axininca Campa, both of which reference the phonological factor of syllable or mora count in order to determine selection of allomorphs, but choose in a way that still leaves the connection between the structural description (syllable count) and structural change (insertion of allomorph) arbitrary.

(28) *Kaititj ergative suffix allomorphy:* [-ŋ] *after bisyllabic stems,* [-l] *after trisyllabic stems* (Paster 2006)

a.	aki-ŋ	'head-ERG'	b.	aliki-l	'dog-ERG'
	iltʲi-ŋ	'hand-ERG'		aṭuji-l	'man-ERG'
	ajnpni-ŋ	'pouch-ERG'		aɣiki-l	'sun-ERG'

(29) *Axininca Campa genitive allomorphy:* [-ni] *after bimoraic stems,* [-ti] *elsewhere* (Bye 2008)

a.	no-jorʲa-ni	'my manioc worm'	b.	i-wisiro-ti	'his small toucan'
	i-çaa-ni	'his anteater'		no-jairo-ti	'my termite'
	a-sari-ni	'our macaw'		a-jaarato-ti	'our black bee'

Another case that is not obviously amenable to an optimization analysis is the plural definite article selection in Italian, which chooses [ʎi] before consonant-initial stems, but [i] before vowel-initial stems.[3] There is no obvious advantage to having [ʎi] as opposed to [i] before a vowel-initial noun.

(30) a.	*i vini*	'the wines'	b.	[ʎ]*i alberghi*	'the hotels'
	i padri	'the fathers'		[ʎ]*i inglesi*	'the Englishmen'
	i ragazzi	'the boys'		[ʎ]*i uccelli*	'the birds'

While one might imagine certain possibilities (e.g. one violation of ONSET is tolerated with vowel-initial stems, but having a vowel-initial article before it tips the scales with two violations of ONSET, perhaps due to constraint self-conjunction), these are far from obvious. Paster (2006) discusses a similar case from Jivaro, in which consonant-final stems take the suffix *-cha*, while vowel-final stems take the suffix *-cho*.

These cases clearly reference phonology, but cannot be the result of automatic grammatical choices based on well-formedness. Instead, they require a mechanism

[3] The allomorph [ʎi] is also chosen before geminate-initial and sC-cluster-initial stems. Under certain analyses (e.g. Kaye 1992), these can be reduced to the vowel-initial context. Whether or not this reduction is made does not change the point in the text about the seeming arbitrariness of the distribution of [i] *vs.* [ʎi].

called "subcategorization," which states in the lexical entry of Kaititj ergative allomorphs that /-ŋ/ is subcategorized for, or is chosen in the case of, disyllabic stems, and /-l/ in other cases:

(31) *Sample subcategorization for Kaititj ergative*

ERG ↔ /-ŋ/ in the context σσ __
ERG ↔ /-l/

Given a schema like the one above and the Elsewhere principle (see e.g. Halle 1997) for vocabulary insertion/allomorph selection, the more specific contextual specification will always block the less specific one, if met.

Although Paster (2005, 2006) and Bye (2008) argue, on grounds of parsimony, that if the language faculty needs subcategorization anyway, we need not bother with optimization at all, other authors take a stance in which the case of phonologically optimizing allomorph selection can be determined entirely by constraint satisfaction, with brute-force subcategorization arising only as a "last resort" (e.g. Lapointe 1999) for the non-optimizing cases (CHAPTER 106: EXCEPTIONALITY). Presumably such a division of labor would lead to the prediction that, as subcategorization is more costly (requiring lexical listing, whereas constraints otherwise active in universal grammar come "for free"), systems might evolve over time into becoming phonologically optimizing.

Wolf (2008) makes the interesting point that the mechanism of subcategorization is better for stating positive conditions than negative conditions. In other words, it works well for saying "choose [-ŋ] when the stem is bisyllabic," but would not work well for cases like "choose Spanish [la] when the following noun does not start with ['a]." The logic of subcategorization conditions like (31) certainly allows reference to natural classes, even those formed by negative values of features (e.g. choose English *an* before stems beginning with [-consonantal] segment), but when such specifications involve disjunctions or miss generalizations linking the structural description to the structural change (i.e. insertion of the allomorph), they become less appealing.

3 Issues for theoretical models

Having established that a great deal of allomorph selection is phonologically conditioned, important consequences arise for models of morphology–phonology interaction, whether couched in terms of constraint satisfaction as the means for choosing among allomorphs (e.g. Kager 1996; Mascaró 2007)) or subcategorization/vocabulary insertion (e.g. Halle 1997; Embick 2009). While I will not choose among these models here, I will identify two important issues for any class of models: the question of when (i.e. at what stage in a phonological computation) allomorph selection takes place, and what the mechanism of choice is.

3.1 When does allomorph selection take place?

Stratal (e.g. Bermúdez-Otero 2007), derivational (e.g. Wolf 2008), and cyclic (e.g. Embick 2009) models of grammatical computation differ from monostratal models in that the first three potentially allow multiple levels of intermediate representation, with processes like allomorph selection occurring according to the well-formedness principles of one level, but subsequently obscured by the operations of a later level. However, monostratal (or globalist) models, which allow information from various modules to be present either simultaneously or preserved across different stages of computation, have a distinguishing trait: they allow, for example, phonological processes such as allomorph selection to freely refer to syntactic boundaries and constituency. By contrast, stratal and/or cyclic models may limit such information from entering later stages of phonological computation. In the following two subsections we turn to these two issues.

3.1.1 Opacity: Allomorph selection at intermediate levels

As mentioned above in three case studies, not all allomorph selection occurs at the surface. We review the relevant facts, four of which suggest that allomorph selection occurs at an earlier level of representation (therefore requiring the interaction with tools for opacity such as rule ordering, stratal Optimality Theory or OT-CC); and one of which suggests the possibility of lexical reinsertion after certain phonological processes have applied.

Reviewing the facts in the Galician definite article case, the allomorph *la* was chosen over *a* to avoid syllabification of the definite article with a preceding onset from a different morpheme, e.g. *ver.la* 'see the' instead of *ve.ra*. However, the verb-final *r* was subsequently deleted due to an OCP effect, yielding *ve.la* (cf. *para a* 'for the', to show hiatus is clearly not at stake). Thus the phonological conditioning of allomorph selection is clearly taking place before *r*-deletion.

Similarly, in the Spanish deadjectival suffix case, the allomorph [-eza] is chosen for adjectival stems that are disyllabic as the input to this affixation, and thus *vilo, triste, gentil* all pattern the same in taking [-eza] in order to form two feet. However, the former two undergo final vowel deletion. Thus, the statement of syllable count in terms of allomorph selection is clearly taking place before vowel deletion.

Finally, in a somewhat different vein, the Dutch agentive suffix discussed above according to van Oostendorp (2009) requires selection of one allomorph, [-ɔr], before stress is assigned, as the default. However, after stress assignment has already happened, if the suffix immediately follows another syllable containing schwa, van Oostendorp (2009) proposes another cycle of allomorph selection in which [-aːr] can be chosen to resolve the schwa-based OCP.

There are two other cases I will mention here, described in Gibson (2008), which relate to allomorphs chosen after C-final and V-final stems, both of which occur derivationally prior to a process of consonant deletion. In Japanese, for example, the non-past suffix is [-u]/[-ru] and the inchoative suffix is [-oo]/[-joo]. However, [w]-final stems delete their final consonant when preceding high or mid vowels, and do so after allomorph selection. For comparison, the negative suffix [-anai]/[-nai], which does not trigger [w]-deletion, is shown.

(32) *Japanese opaque allomorphy with* [w]-*final stems*

	jom 'read'	ne 'sleep'	iw 'say'	jow 'get drunk'
non-past	jom-u	ne-ru	i-u	jo-u
inchoative	jom-oo	ne-joo	i-oo	jo-oo
negative	jom-anai	ne-nai	iw-anai	jow-anai

A very similar case occurs in Turkish, where a process of intervocalic *k*-deletion applies after C-final *vs.* V-final allomorph selection. The 3rd person possessive suffix [-i]/[-si] surfaces after C-final *vs.* V-final stems, but *k*-final nouns choose [-i], even though the conditioning stem-final consonant subsequently deletes:

(33) *Turkish opaque allomorphy with* k*-final stems*

bedel	bedel-i	'price (NOM/POSS)'
fire	fire-si	'attrition (NOM/POSS)'
bebek	bebe-i	'baby (NOM/POSS)'

In both of these cases, allomorph selection is applying to a level of representation prior to consonant deletion, which means that the optimization is on an intermediate form. If the consonant deletion processes can be assigned to different strata of phonological computation (e.g. post-lexical, or word-level), then these phenomena can be easily dealt with in Lexical Phonology or Stratal OT (CHAPTER 85: CYCLICITY; CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME).

The notion that intermediate representations are evaluated for well-formedness (i.e. a derivational model that includes negative well-formedness constraints) is entirely reasonable. It is now largely accepted that monostratalism is untenable, and also known that grammars without statements of negative constraints miss generalizations. Future models that develop a series of ordered computations with intermediate levels of representations should definitely incorporate treatment of allomorphy phenomena, particularly since they interface with interesting questions of lexical insertion (cf. Embick 2009; Wolf 2008).

3.1.2 *Reference to syntactic factors*

As mentioned above, an important issue that arises in the study of allomorphy and "where/when" it takes place is the issue of syntactic sensitivity. For example, Russian 3rd person pronouns have two allomorphs, one vowel-initial and the other containing an initial [n-], with the latter chosen after prepositions (presumably for the same reasons as the Galician case above: namely to avoid resyllabification and allow stems to begin their own syllable). Hence the pronoun [ix] is realized as [nix] when a preposition precedes, as prepositions closely prosodify with their complements in Russian (34a). However, when the pronoun is not the head of the prepositional complement, but rather a possessive modifier, no such allomorphy occurs (34b).

(34) *Russian prepositional complement allomorphy*

a. bez nix 'without them'
b. bez ix brata 'without their brother'

In fact this is the same kind of pattern we observed in the first example in this chapter: the English possessive -*s* does not display zero allomorphy when following a plural -*s* that is *not* the head of the NP. What is interesting about both of these cases is that the affected linear string is the same. Hence "syntactic brackets" must be visible. The simplest model to envision is one in which they are literally visible to morphophonological representations. However, one might also experiment with the possibility, in cyclic models, that the possessive modifier in (34) is submitted to its own closed-off morphophonological computation prior to the cycle in which the preposition is visible to its complement. In other words, the idea might be that in *bez nix*, the equivalent of [without 3PL]$_{PP}$, the preposition is visible at the moment the pronoun is spelled out; by contrast, in *bez ix brata*, the equivalent of [without [3PL brother]$_{DP}$]$_{PP}$, the pronoun is spelled out at an earlier cycle in which the preposition is not yet visible. Whether this hypothesis can be integrated with other facts about the order of spell-out in Russian prepositional complements and noun phrase structure awaits a fuller investigation.

A second case of reference to syntactic factors concerns the -s/Ø allomorphy found in dialects of Catalan, described by Bonet *et al.* (forthcoming). In these varieties, plural -s on adjectives is realized as zero between two consonants (a process which the authors argue is not due to a general process of strident deletion). However, this process can only apply prenominally:

(35) *Catalan prenominal/postnominal allomorphy*

aquelØ	bonØ	vins	blancs	dolços
those-PL	good-PL	wine-PL	white-PL	sweet-PL

The statement of these allomorphy conditions must thus take into account the hierarchical/linear position of the adjective with respect to the noun, which may be a few words away. Again, a simple model would be one in which the entire noun-phrase structure is still visible at the point of allomorph selection, and somehow the linear position with respect to the noun is relevant for -s/Ø allomorphy. An approach within a cyclic model might be one in which there is a sequenced computation in which postnominal elements do not have the same syntactic relation with the noun as prenominal elements – for example, postnominal elements being spelled out in a different cycle than the noun, and hence required to bear overt exponents of plurality. Again, while this account is potentially much more interesting (and restrictive) than a globalist model, it would require integration with independent facts about prenominal and postnominal asymmetries in the spell-out of adjectives.

In sum, much exciting work lies ahead particularly in the domain of syntactically sensitive phonologically conditioned allomorphy, as it raises important analytic challenges as to how the syntactic structure is made accessible – whether syntactic brackets are literally visible, or whether their effects arise as epiphenomenal due to the timing of spell-out.

3.2 *How are allomorphs chosen?*

Perhaps one of the most widely debated issues within the study of allomorph selection is the mechanism of choice. The existence of phonological conditioning and, in particular, phonological optimization, suggests that grammatical, rather than morpholexical, mechanisms are at work in accomplishing the selection – more specifically, that when a given allomorph is better for segmental, syllabic or prosodic structure, then the grammar will somehow "automatically" choose that allomorph without having to list these contexts in its lexical representation.

The choice of the allomorph that *does* lead to some kind of phonological optimization is relatively straightforward, particularly in models such as Optimality

Theory, or in fact any constraint-based models which encode well-formedness principles as an active grammatical force that can compel choice of one input over another. For example, a constraint such as *Coda will prevent choice of Korean [-ka] after consonant-final stems such as [mom], and will thus lead to choice of the phonologically optimizing allomorph, [-i].

However, in most of the cases described above there is one allomorph – call it "the optimizer" – chosen for particular phonotactic reasons, and another that is simply a default. For example, in the case of English *a/an* allomorphy, *a* is simply a default that does not optimize anything when it is chosen – it is only *an* that is recruited to improve phonotactics. The question thus arises why the optimizer *an* is not *always* chosen – it will provide an onset when needed for vowel-initial words that follow, and is otherwise seemingly harmless. The intuition to be captured is that the other allomorph, *a*, is the default, and is chosen "elsewhere," when providing an onset is not at stake one way or the other.

In the discussion that follows we will be concerned with a pattern as schematized in (36), (keeping in mind that in some cases *both* allomorphs are optimizers (e.g. Moroccan Arabic [-h] *vs.* [-u]), and neither is clearly a default).

(36) *Optimizer*
The allomorph chosen in order to satisfy a particular phonotactic, e.g. *an* to provide an onset, in a particular set of environments (e.g. before vowel-initial words).
Default
The allomorph chosen otherwise.

The pressing issue for models of morphology–phonology interaction thus becomes how to grammatically state that one allomorph is the *default* within different models of grammar – in other words, that it should be inserted *unless* some phonotactic pressure demands the other one. Interestingly enough, this question becomes of more relevance to precisely those models in which all the action is encoded in terms of negative constraints: how does one force the default allomorph to be used over the other one?

A number of distinct answers have been posited in the literature, and it is not yet clear which is the best. One class of proposals holds that the default is always phonologically more unmarked than the optimizer, which leads specifically to the question of context-free markedness. If the default can be shown to be generally unmarked (either in segmental or structural terms) compared with the optimizer, this approach will lead to selection of the default by unmarkedness criteria alone when phonotactic optimization with the stem + affix is not at stake.

Let us begin by considering cases such as the Djabugay genitive, in which [-ŋun] is chosen after consonant-final stems, while [-n] is chosen after vowel-final stems (a pattern which is presumably driven by avoidance of complex consonant clusters ending in [n]).

(37) *Djabugay genitive*

a. gu.lu.du-n 'dove'
b. ga.ɲal.ŋun 'goanna'

While the choice of [-ŋun] in (37b) can be understood in terms of avoidance of *[ga.ɲal.n], in order to enforce selection of default [-n] in (37a), Kager (1996) posits the constraint 'Gen=-*n*', which we can call a *violable exponence requirement constraint* (see Russell 1995 for elaboration of this type of constraint). These constraints demand a particular exponent for a particular morphological category and are thus one way of encoding the notion of a certain exponent being the default, but it might strike some as brute force to include and rank a violable constraint dedicated to every exponent in the grammar.

Along the lines of context-free unmarkedness arbitrating in favor of the default, Rubach and Booij (2001) propose that instead of stipulating that [-n] is the default in Djabugay, one should rather state that [-ŋun] is *dis*preferred, except in special cases. They appeal to segmental markedness (see CHAPTER 4: MARKEDNESS), and specifically claim that, in the absence of other competing factors, [-ŋun] will be dispreferred due to a markedness constraint against velar nasals. This formulation thus chooses the default over the optimizer when coda phonotactics are not at stake via context-free (but violable) *ŋ. This proposal is an interesting way of encoding the default selection, but it should always be kept in mind whether such constraints are consistent with the full-blown grammar of the language.

A second class of proposals involving context-free markedness in order to favor the default, applied to this same case, is an appeal to "shorter is better." For example, Wolf (2008) posits that constraints such as *Struc – which penalize structure in general, and thus prefer shorter outputs whenever possible – will lead to the preference for /n/ over /-ŋun/, or *a* over *an*, unless trumped by phonotactic factors. In cases involving complementarity of length effects, in which for example disyllabic stems take [-eza] to accomplish two full feet and all longer stems take [-ez], the default can clearly be seen to be the shorter allomorph. Appeals to *Struc, however, are not without problems, as discussed by Gouskova (2003), and further work is needed to capture the intuition that shorter is more unmarked for default allomorph selection within an implementation that does not wreak typological havoc under factorial reranking.

Not all cases of default choice seem amenable to markedness, however, particularly when inflectional, rather than derivational, morphology is involved. Bonet *et al.* (2007) and Mascaró (2007) posit pairwise preference constraints, e.g. "prefer *a* to *la*" in Haitian Creole. The more complicated use of such constraints are in cases such as the Catalan gender markers, which Bonet *et al.* posit are Ø > /u/ > /ə/ for masculine, and /ə/ > Ø for feminine. Clearly, as the relative preference for /ə/ and Ø is reversed in each gender, it is not possible to reduce these to general segmental markedness hierachies in the language. The implementation of these preference constraints involves pairwise rankings which can be used when there are more than two allomorphs, and a clear potential advantage of this implementation is that it allows *sequences* of defaults.

Stepping outside of OT models, in Distributed Morphology, e.g. Embick's (2009) model, statement of defaults is accomplished by a list of vocabulary items, which are specified for insertion in certain contexts. As schematized in (31) for subcategorization models in general, the default item is thus one with the least amount of contextual specification. Although the optimizer is often not explicitly listed as performing an optimizing function in such models, one can clearly envision a variant in which the contextual specification of vocabulary items mentions *removing* violations to phonotactic constraints. A schematic proposal along these lines for the English indefinite article appears in (38).

(38) *"Positive licensing" of non-default vocabulary item*

INDEF ↔ /æn/ if it removes a violation of ONSET
INDEF ↔ /a/

Such models can be likened to Kager's (1996) proposal, in which the default has an explicit statement "GEN=*n*," but differ in their implementation, in that the default allomorph in Distributed Morphology is precisely one about which nothing special needs to be said in the grammar.

In many cases of allomorph selection involving "recruiting" allomorphs from the "wrong" context, such as Spanish definite article allomorphy or Hebrew plural allomorphy, the default is chosen because it matches the gender features of the head noun, and that is enough to normally drive selection of *la* over *el* for feminine nouns, without need for appealing to phonological markedness in order to make *la* the default. Contextual specification – in terms of morphosyntactic features – is enough to choose the right allomorph, and this is sometimes implemented in OT with constraints referring to matching morphosyntactic features (e.g. Steriade 1999; Becker 2009). In such cases, the default allomorph is not the one that is radically underspecified, but rather the one that realizes the correct morphosyntactic features. This intuition is not straightforward to translate into vocabulary items without negative statements, but one way to accomplish it, while preserving the notion that /el/ is "recruited," is to actually view *it* as the default, used for both masculine gender and for cases where the feminine *la* fails:

(39) *"Negative licensing" of non-default vocabulary item*

DEF, +FEM ↔ /la/ if it does not create a violation of *á*-hiatus
DEF ↔ /el/

Clearly, future work will be needed in order to examine whether a true merger of the elsewhere-notion of Distributed Morphology can be made fully compatible with capturing the phonotactic generalizations that govern allomorph distribution, or whether the priority constraints of Bonet *et al.* (2007) merge more seamlessly with a grammatical treatment of phonological optimization.

4 Conclusion and outlook

Phonologically conditioned allomorph selection refers to any case in which allomorphs are chosen based on the phonology of the stem, affix, or phonological word to which they attach. We have seen that a very healthy number of these cases not only refer to phonology, but seem to involve allomorph distribution that is actively connected with improvement in (or avoidance of declination in) phonological well-formedness, at the levels of segmental, syllabic, and prosodic structure. The most active questions of debate thus revolve around whether, given that *some* allomorph selection is phonologically optimizing, this should be built into the architecture of the grammar, or whether on the contrary, given that some allomorph selection is *not* phonologically optimizing, a single mechanism that simply lists phonological environments is all that is needed. Potentially one way of resolving the question of whether allomorph selection is the result of grammatical computation, rather than morpholexical listing, would involve demonstrating infants' and adults' preferences in (artificial) language acquisition, and finding that in the face of sparse or limited background evidence, such learners demonstrate a preference for phonologically optimizing patterns of allomorph selection, before they have even had a chance to attempt or fall back on lexical listing.

Certainly one might argue that patterns of spontaneous allomorph recruitment, such as BPE speakers' use of [- əd] after all obstruent-final verbs in English, despite never having heard this in the input, reflect pure grammatical biases brought to the task of allomorph selection rather than rehearsed morpholexical listing or historical residue. Similarly, the study of Becker (2009), discussed above, demonstrates that Hebrew speakers apply phonologically conditioned allomorph selection to novel "wug" stems they have never had to inflect before.

A second issue, mentioned in the introduction, is that a great deal of allomorphy need not involve multiple URs, but rather, like the English plural alternations, can be captured entirely in terms of a single UR coupled with phonological rules. Given this division of labor between phonological derivations as one mechanism of yielding allomorphy and morphological selection as another, we may also see divergent acquisition profiles for these two.

In phonological theory, many debates that involve recurrent grammatical generalizations in some languages and exceptions to these generalizations in other languages often devolve into discussions of whether everything is the result of diachrony or not, and end up as philosophical stalemates. Certainly, while Carstairs (1990) is right in raising the point that "The existence of a phonologically conditioned alternation does not by itself prove the existence of some synchronic phonological process giving rise to it," the existence of synchronic grammatical control over allomorph selection *can* be demonstrated when it spontaneously arises in (artificial) language acquisition experiments in which the diachrony is fully controlled by the experimenter and nonetheless the learner demonstrates the emergence of a preference for phonological optimization based on sparse or insufficient evidence.

My own contention is that enough evidence is beginning to accumulate that phonologically conditioned allomorph selection *is* within the purview of the phonological grammar and not merely the lexicon, and that some of the most important questions that therefore arise involve the levels of representation at which allomorph selection occurs and the mechanism of choice, including guaranteeing the default over the optimizer in cases in which euphony is not at stake. The cases of opaque allomorph selection make clear that it needs to happen at intermediate levels of representation, but leave open many possibilities in terms of whether the right model of serial morphology–phonology interaction is stratal, cyclic, or derivational. A much harder and unresolved question is the mechanism for allomorph selection, where many theoretical alternatives are good at capturing some generalizations but in doing so may fail to capture others. A clear dichotomy in this respect is the trade-off between relying on segmental markedness to allow the default to "emerge" without explicit statement and explicit default status of an allomorph through either brute force constraints or by the Elsewhere condition.

In the above paragraphs, I have provided a critical comparison of a wide range of current options (and apologize for ones I have no doubt overlooked in such a large field of inquiry), but most importantly, I have attempted to outline new directions for synthesizing the advantageous aspects of some of these models with those of others. One of the best ways for this study to advance is by figuring out how to incorporate the seemingly incompatible but useful assumptions of one model into those of another.

ACKNOWLEDGMENTS

I am grateful to the editors and two anonymous reviews, and to Birgit Alber, Michael Becker, Ricardo Bermúdez-Otero, and Moira Yip for their comments and suggestions on an earlier draft.

100 Reduplication

Eric Raimy

1 Introduction

Reduplication is the phonological repetition of segmental material triggered by a morphological source. This definition captures the core aspects of this linguistic phenomenon and distinguishes it from other phenomena that cause the surface repetition of phonological material. This chapter provides a synthesis of questions about reduplication based on classic and contemporary models of reduplication. The most important questions about reduplication can be summarized as the *strong hypothesis for reduplication* (SHR).

(1) *The strong hypothesis for reduplication*

a. *Architectural modularity*
There is a morphology module that is distinct and prior to a phonology module. Both modules have internal structure.

b. *Bipartite reduplication*
The morphology module creates a reduplicated structure, but segmental copying occurs later in the phonology module.

c. *Identity is synchrony*
The source of identity effects in reduplicated forms is the fact that the repeated segments in the output are a single synchronous representation prior to copying. After copying has occurred, the repeated segments are distinct representations and can diverge in identity on the basis of the general application of phonological rules.

The proposed answers to these questions identified by the SHR demonstrate that reduplication informs us about grammatical architecture in general, the relation between the morphology and phonology components, and phonological identity. Two important topics in reduplication are not represented in the SHR. The first is the question of global *vs.* local computation in grammar and the second is reduplicative templates. Each of these topics will be discussed, when they are raised with respect to particular models of reduplication.

This chapter is laid out as follows. First, classic models of reduplication that help define the SHR are presented in §2. Part of the discussion of each classic model is identifying the contribution that it makes to the SHR. §3 turns to contemporary models of reduplication. Fundamental differences in contemporary models can be identified by each model's orientation to the SHR. §4 identifies open questions about reduplication that deserve attention because they raise fundamental questions about what linguistic phenomena should be treated as reduplication.

2 Classic models of reduplication

Classic models of reduplication are no longer being actively pursued. The importance of knowing about them, though, resides in the contribution that each of them made to the *strong hypothesis for reduplication.*

2.1 *Unusual phonology in reduplication*

Wilbur (1973) marks the beginning of the formal investigation of reduplication in generative grammar. Wilbur defines R_o as "the portion of the unreduplicated form . . . of which a copy is made" and states: "the part which is the copy will be referred to as . . . R_r" (1973: 7). This nomenclature also identifies, but does not name, the region of the unreduplicated base that is not part of R_o. Using this notation a reduplicated form can be delimited into sections, as in (2b, 2c). Both R_o and R_r are separated by a dash. R_o is enclosed in square brackets and R_r is underlined. Any remaining segments are part of the unreduplicated base.

(2) *VC reduplication in Chumash* (Wilbur 1973: 7)

a.	/ʔas/ + redup ($C_1V_1C_2$-V_1C_2)	ʔas-as	'chin'
b.	suffixing reduplication	ʔ-[as]-as	
c.	infixing reduplication	ʔ-as-[as]	

Wilbur notes that in cases of total reduplication when R_o and R_r are identical, it cannot be determined whether the reduplicated structure is R_o-R_r or R_r-R_o. In cases of partial reduplication, R_r can be determined by considering the unreduplicated form that consists of R_o and the rest of the base. R_r will then be the remaining segmental material that is repeated. This parsing, when applied to (2b, 2c), identifies one of the [as] sequences as R_r, but we cannot distinguish between (2b) and (2c). One way to distinguish between these options is that the placement of R_r should not alternate among prefixing/suffixing/infixing patterns, and should match the general morphological processes of the given language. For example, if a language does not have any infixes, then R_r should not be analyzed as an infix, (2c).

Wilbur (1973) demonstrates that there are non-trivial interactions between reduplication and phonological rules, because of the Chomsky and Halle (1968: 236) hypothesis that all morphological rules precede all phonological rules, reduplication being a morphological rule. Wilbur (1973) describes three different types of interactions between reduplication and phonology.

(3) *Reduplication and phonological rule interaction* (Wilbur 1973)

a. *normal application*
"Forms where R_r and R_o are not identical at the surface are the result of the normal application of any phonological rule to a form which meets its structural description." (1973: 15)

b. *failure to apply*
"those forms in which either R_o or R_r meets the structural description of a phonological rule and yet has not undergone that rule." (1973: 18)

c. *overapplication*
"Overapplication of a phonological rule refers to the fact that in many reduplicated forms, the structural change applies to a form that does not meet the structural description of the rule." (1973: 26)

The terms "normal application" and "overapplication" have been retained to this day, but "failure to apply" is now normally termed "underapplication." Only normal application is accounted for if the morphology before phonology hypothesis from Chomsky and Halle (1968) is strictly adopted. The reason for this is that, if reduplication is a morphological rule, the copying of the segments to create R_o and R_r will occur before any phonological rule has the opportunity to apply. Consequently, all phonological rules will apply after reduplication, and thus there can only be transparent application of a phonological rule.

Over- or underapplication of a phonological rule suggests that either the morphology before phonology hypothesis, (1a) of the SHR, or some aspect of the model of reduplication must be modified. The basic ordering problem at issue is that R_r must be created at some point in the derivation. Overapplication is problematic, because this situation requires ordering a phonological rule before a morphological process. If the relevant phonological environment appears in the R_o, then ordering the phonological rule prior to reduplication will solve the problem. Underapplication is a more difficult problem, because there is no way to warrant blocking the application of a rule if a relevant structural environment appears in R_o during the derivation.

Wilbur's response to over- and underapplication phenomena was to keep the morphology before phonology hypothesis intact, but to import the concept of global rules (Lakoff 1970) into phonology and propose an Identity Constraint (IC) (CHAPTER 74: RULE ORDERING).

(4) *The Identity Constraint* (Wilbur 1973: 58)

There is a tendency to preserve the identity of R_o and R_r in reduplicated forms.

The IC acts as a diacritic on a phonological rule that allows the rule to over- or underapply to ensure that R_o and R_r are identical at the surface.

Wilbur presents an example from Serrano (Hill 1967) as a case that crucially requires the IC. The important interaction is between an optional phonological rule that inserts a homorganic high vowel between a consonant and glide sequence and an adjectival reduplication rule. Hill (1967: 223) notes: "the reduplication involved in [yi'a:yi'a'n] ~ [yi'a:iyi'ai'n] 'be beautiful' (< #yə'a# 'beautiful') must be introduced *at the same time as* the rule whereby an anticipatory *i* is optionally introduced before *y*" (emphasis and transcription as in original).

(5) *Ordering in Serrano*

a.	*order 1*		b.	*order 2*	
	UR	REDUP+jəʔa+ʔn		UR	REDUP+jəʔa+ʔn
	Glide insertion	*n/a*		Reduplication	jəʔaːjəʔaʔn
	Reduplication	jəʔaːjəʔaʔn		Glide insertion	jəʔaːi̲jəʔaʔn
	Other rules	jiʔaːjiʔaʔn		Other rules	jiʔaːi̲jiʔaʔn
	SR	jiʔaːjiʔaʔn		SR	*jiʔaːi̲jiʔaʔn
				???	jiʔaːi̲jiʔai̲ʔn

(5) demonstrates that local ordering cannot derive the data from Serrano. Order 1 (5a) causes the glide insertion rule to not apply, because the rule's structural description is not met. The surface effect is equivalent to when the glide insertion rule optionally does not apply. Thus this ordering tells us nothing. Order 2 (5b) has the glide insertion rule apply after reduplication. The glide insertion rule inserts an [i] only between the R_r and R_u. The SR form in (5b) shows normal application of the glide insertion rule, but Hill does not list it as a possible form in Serrano. Neither of the possible rule orderings can produce the Serrano form, which shows overapplication of the glide insertion rule.

The key to understanding the importance of the type of pattern is Hill's insight that reduplication and the rule must apply "at the same time." Synchrony of reduplication and rule application is required because reduplication creates the environment that triggers the phonological rule. McCarthy and Prince (1995: 289) term this type of interaction *back-copying*. Back-copying interactions provide the strongest evidence for some form of global computation in phonology, such as Wilbur's IC. Wilbur's model of reduplication assumes strict local computation. This means that the rule and reduplication will each only apply once and that they must be ordered with respect to each other. (5) shows both possible orderings of the rule and reduplication; neither ordering produces the correct forms. Consequently, the data from Serrano provide strong evidence for Wilbur's IC, which explains why the glide insertion rule overapplies in (5b).

The main conclusion from Wilbur on phonology reduplication interactions is that the hypothesis that reduplication is a morphological process and all morphology precedes all phonology can be maintained if a limited amount of global computation is added to the phonological component. Global computation in the phonology is limited to the IC, which can cause phonological rules to over- or underapply to maintain identity between R_u and R_r.

2.2 *Reduplication as morphology*

Carrier (1979) is in essence a direct response to Wilbur (1973) with respect to reduplication and argues against global computation in phonology. Carrier demonstrates that global computation in phonology is not sufficient to account for reduplication patterns. Carrier (1979) points to the interaction between syncope and reduplication (presented as R2 in (6)) in Tagalog as a case where an IC approach is insufficient.

(6) *Syncope and reduplication interaction in Tagalog* (Carrier 1979: 174)

a.		/sunud-in/	b.		/sunud-in/
	Syncope	sund-in		R2	sunudsunud-in
	R2	sundinsundin		Syncope	*sunudsundin
				(overapplies)	*sundsundin

Carrier argues that only by ordering syncope before reduplication can the correct forms in Tagalog be produced. Carrier's R2 pattern of reduplication in (6) copies a foot's worth of phonological material (CHAPTER 40: THE FOOT) from the left edge of the stem. The syncope rule deletes the final vowel of a root that has been suffixed. (6a) shows that if syncope applies before reduplication, then the correct surface form is produced where the vowel of the suffix is copied. If reduplication applies before syncope, as in (6b), then there is no way to produce the correct surface form, because the vowel of the suffix is not copied. The IC can only affect whether the syncope rule over- or underapplies and cannot cause reduplication to re-copy segmental material.

Carrier develops the implications of an analysis of Tagalog where syncope precedes reduplication. She retains the strong hypothesis that all morphology precedes all phonology and argues that reduplication is the result of a [+reduplication] feature being added as part of a word formation rule. This morphological feature triggers the application of a transformational rule that causes the copying of phonological material at the end of the morphology. The bipartite nature of reduplication in Carrier's system allows for morphological rules to apply to a stem with the [+reduplication] feature prior to reduplicative copying. An immediate benefit of the bipartite hypothesis is that it predicts morphological rules can produce over- and underapplication effects, because they will necessarily be ordered before reduplicative copying.

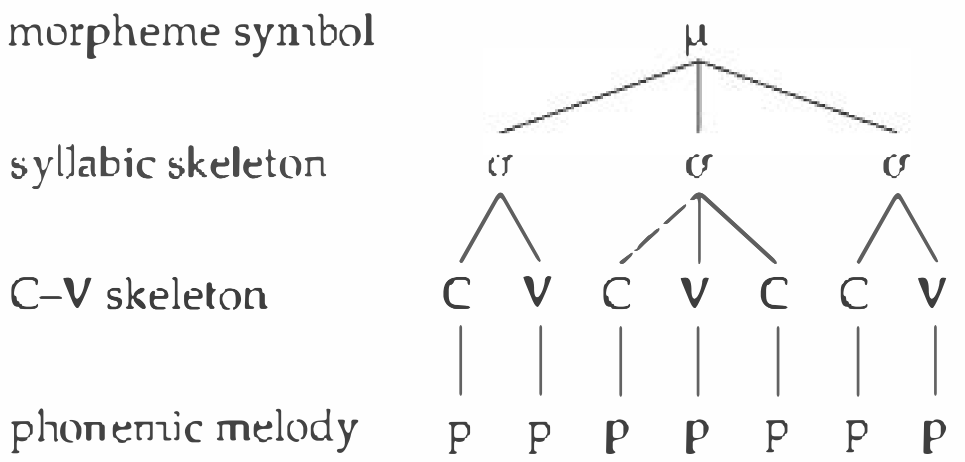
Carrier develops the bipartite hypothesis by arguing that the rules in Tagalog that show overapplication effects (e.g. syncope and nasal substitution) are morphological rules, not phonological. Carrier defines a morphological rule as one that cannot be specified in purely phonological terms. For example, syncope applies to some roots (e.g. /sunud/ → [sund-in]) but not others (e.g. /li:nis/ → [li:nis-li:nis-in]), and nasal substitution does not apply to all /ŋ/-final prefixes and obstruent-initial stems (Carrier-Duncan 1984: 274).

Carrier's contribution to our understanding of reduplication is to develop the morphological aspects of reduplication. Specifically, the hypothesis that reduplication is a bipartite process where the morphology marks a representation as reduplicated but the copying process occurs later in the derivation is extremely important. The bipartite hypothesis allows morphological rules to apply before reduplicative copying, which provides one source of explanation for over- and underapplication effects with local computation.

2.3 *Reduplication as phonology*

Marantz (1982) is a watershed for the study of reduplication. The main proposal extends ideas from McCarthy (1981) that propose prosodic morphology, (7).

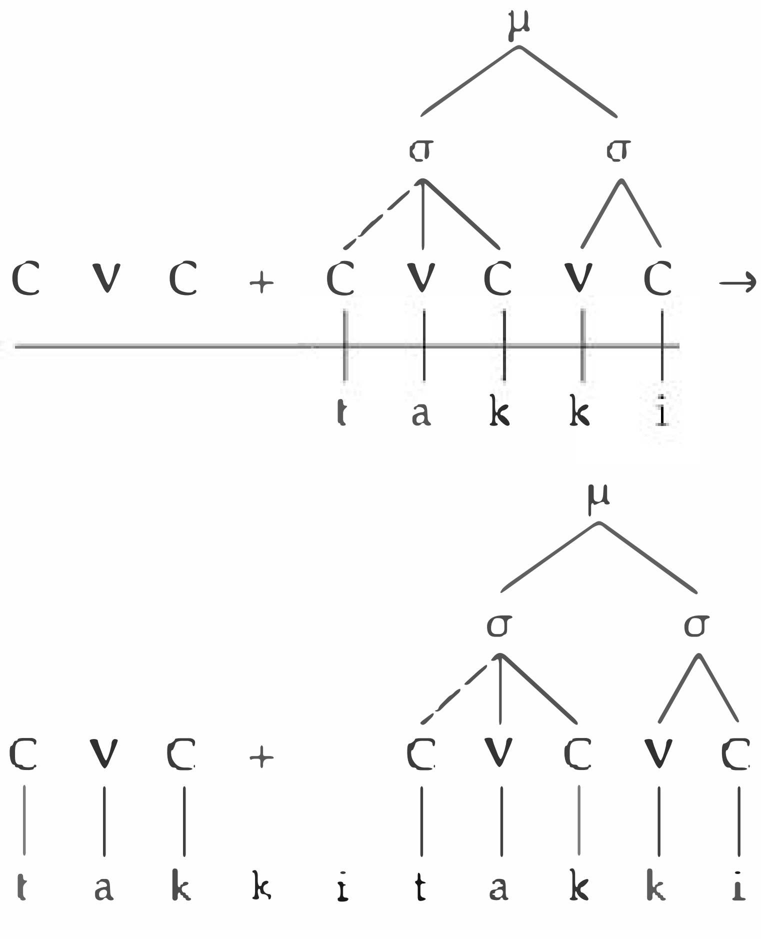
(7) *Prosodic structure of morphemes* (Marantz 1982: 454)



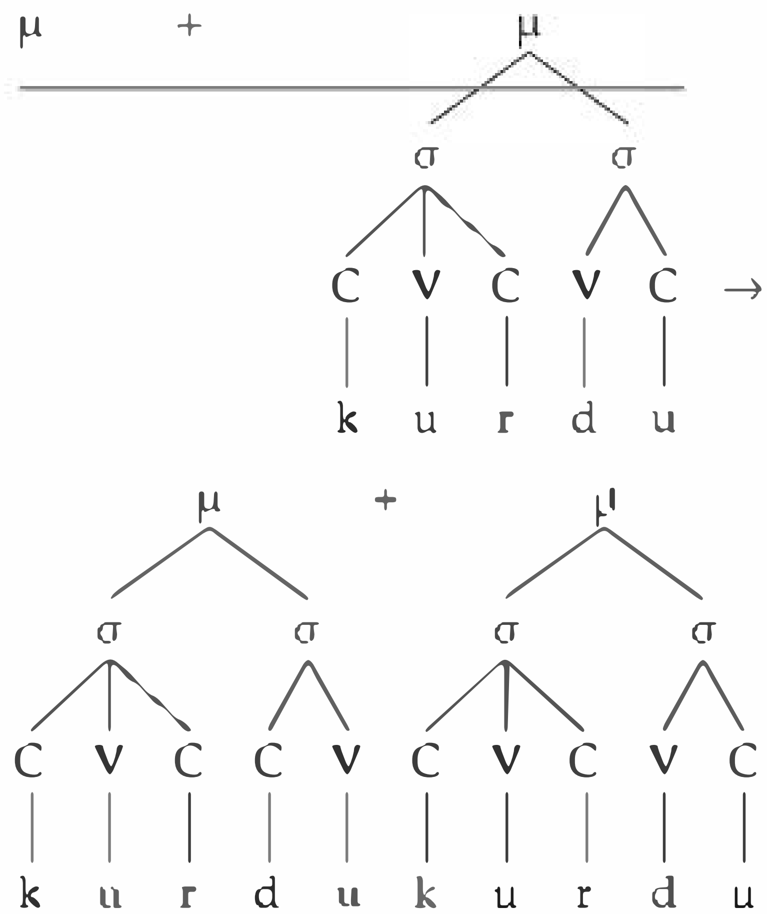
Marantz (1982) proposes that reduplicative morphemes are different from other morphemes in two ways. The first is that they are not fully specified and the second is that they trigger the copying of phonological material of the stem. The lack of specification at some level of representation allows for different patterns of reduplication to be specified by the "prosodic skeleton," which determines how much and what type of phonological material is copied. (8) presents a case of partial reduplication and total reduplication from a Marantzian perspective.

(8) *Marantzian skeletons*

a. *CVC reduplication: Agta* /takki/ → [tak-takki] (Healy 1960)



b. *total reduplication: Walpiri* /kurdu/ → [kurdu-kurdu] (Nash 1980)



Marantz focuses on expressing reduplication patterns at the C–V skeletal level due to Moravcsik's (1978: 307) observation that "reduplicated phonetic strings I found [are] invariably defined in reference to consonant–vowel sequence and absolute linear position." Moravcsik's observation suggests that all of the work being done by templates is thus at the C–V level. (8a) demonstrates the affixation of a CVC prefix that accounts for one pattern of reduplication in Agta. Total reduplication can be produced by affixing a higher level of prosodic structure, the morpheme, which will cause copying of all prosodic structure under the morpheme level, (8b). Deriving different R_r shapes from general phonological representations is a major advance in the understanding of reduplication, because questions about reduplicative templates are now questions about phonological representations and processes.

The other major insight from Marantz (1982: 436) is the proposal that reduplication is a normal affixation process. The phonology of reduplication should mirror the phonological behavior of other affixes (CHAPTER 104: ROOT–AFFIX ASYMMETRIES). By integrating reduplication into the general theories of phonology and morphology, Marantz argues that over- and underapplication effects are accounted for. One source of underapplication effects is the cyclic application of phonological rules to morpheme-internal environments (CHAPTER 85: CYCLICITY). Cyclic rules do not apply in non-derived environments (CHAPTER 88: DERIVED ENVIRONMENT EFFECTS), and if the R_r is an affix (thus a morpheme), then the effect of underapplication will be produced, because R_r will not be a derived environment. Morphological rules will also produce over- and underapplication effects, as in the Carrier bipartite hypothesis.

Marantz develops the hypothesis that phonological aspects of reduplication should be accounted for by general phonological means. Consequently, approaches to reduplication changed as phonological representations have changed. There are two important changes to phonological representations that affected the basic aspects of the Marantzian model of reduplication.

The first change is the single melody model proposed by Mester (1986) (CHAPTER 54: THE SKELETON). Note that proposals in Clements (1985) are extremely similar to Mester's, the difference being whether melodic or templatic effects are the main focus. Clements focuses on templatic effects while Mester focuses on melodic effects. Mester (1986: 172–173) proposes that reduplicative morphemes are attached to the stem in a synchronous manner. This can be viewed as an extension of autosegmental representation (Goldsmith 1976; CHAPTER 14: AUTOSEGMENTS), where different aspects of phonological representations are not linearly ordered with respect to each other. A key aspect of the synchronous nature of reduplicative template and stem is that the melodic tier is shared between them.

Mester's (1986: 190–196) single melody analysis of the interaction of the *ruki* rule (e.g. alveolars become retroflexed after /r/, /u/, /k/, or /i/) and reduplication in Sanskrit demonstrates the advances of this model (see CHAPTER 119: REDUPLICATION IN SANSKRIT). When the root /saɲʤ/ 'hang' is reduplicated and affixed with a *ruki*-triggering prefix (e.g. /ab^{h}i/), then the initial /s/ in the root /sanj/ shows overapplication of the *ruki* rule because the second retroflexed s does not occur after a segment triggering the *ruki* rule (e.g. *[ab^{h}i-ʂa-saɲʤ]). Without the *ruki*-triggering prefix, no retroflexion occurs.

(9) *Overapplication of the* ruki *rule in Sanskrit reduplication*

saɲʤ 'hang' ab^{h}i-ʂa-ʂaɲʤ 'cursed' *ab^{h}i-ʂa-saɲʤ
cf. sa-saɲʤ

(10) demonstrates the parts of a single melody analysis for these forms. (10a) presents the unaffixed root form. The prefixing CV reduplication pattern affixes a synchronous C–V skeleton to the melodic level, (10b). (10c) shows the further affixation of the prefix /ab^{h}i/ and the application of the *ruki* rule (following Mester's 1986: 192 formulation).

(10) *Single melody analysis*

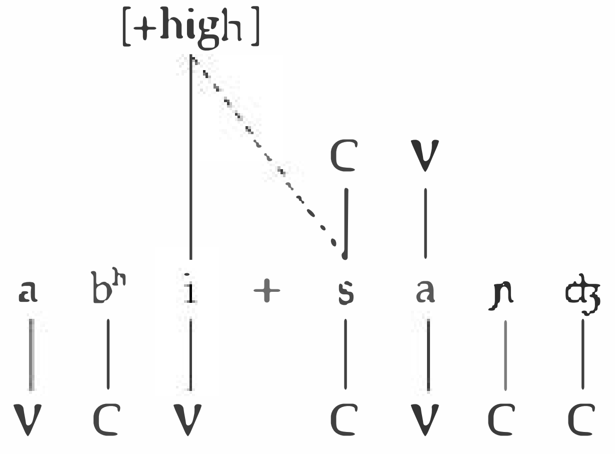
a. *root*

```
s  a  ɲ  ʤ
|  |  |  |
C  V  C  C
```

b. *root and synchronous reduplicative affix*

```
C  V
|  |
s  a  ɲ  ʤ
|  |  |  |
C  V  C  C
```

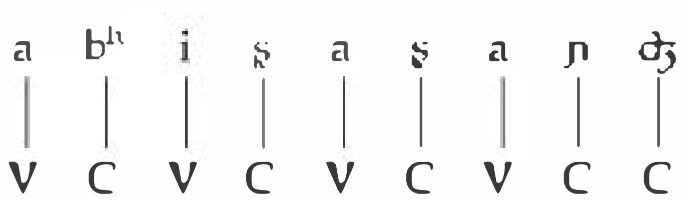
c. *prefixation and application of the* ruki *rule*



Understanding the representation in (10c) is the key to the advances from the single melody model. At this point in the derivation, there is only a single /s/ melody, which was retroflexed by the *ruki* rule. This /s/ is associated to two CV skeletons, one from the stem and one from the reduplicative morpheme. This is the strongest possible identity relationship between R_b and R_r, in that the melodic content of both is a single representation. Any melodic change to one must occur to the other. This is the source of explanation for overapplication effects in the single melody model. Any rule changing the melodic content of a synchronous representation can show overapplication effects. The single melody model also captures Carrier's insight about the bipartite nature of reduplication. The morphology builds a reduplicated structure that is later dealt with by the phonology. In this case, the structure produced by the morphology is one in which R_b and R_r are synchronous.

Non-linear representations like (10c) must be converted to a strictly linear representation. Tier Conflation (McCarthy 1986; Mester 1986: 176–177) converts (10c) into the fully linear representation in (11). Note that concatenation will create a relationship on the phonological skeleton between the /abʰi/ prefix and the reduplicated root in (10c) that is sufficient to trigger the *ruki* rule even though full linear order may not exist between the morphemes at this point in time.

(11) *Linearization as Tier Conflation*



Tier Conflation is not a reduplication-specific device, in that it is the general device to ensure that phonological representations are strictly linear, so the phonetics component can use them. McCarthy (1989) argues that planar segregation is very common in phonological representation. Consequently, a process like Tier Conflation that will provide a strict linear ordering to a representation is required in phonology and will apply to both concatenative and non-concatenative morphologies. Consequently, all phonological representations must undergo some process analogous to Tier Conflation. This is a very important observation, because it accomplishes the complete naturalization of reduplication in phonology. (See also CHAPTER 105: TIER SEGREGATION.)

The publication of Mester (1986) coincided with fundamental changes in prosodic morphology. McCarthy and Prince (1996) drastically revise the prosodic hierarchy to eliminate the CV level of representation. This change represents the debate between the x-slot and moraic theories of the syllable (see Kenstowicz 1994: 425–431; CHAPTER 54: THE SKELETON). McCarthy and Prince (1996) side with the moraic model and provide analyses of reduplicative templates and other phenomena using only legitimate prosodic categories. (12) presents the proposed prosodic categories from McCarthy and Prince (1996: 6).

(12) *Prosodic categories*

Wd	prosodic word
F	foot
σ	syllable
σ_{μ}	light (monomoraic) syllable
$\sigma_{\mu\mu}$	heavy (bimoraic) syllable
σ_{c}	core syllable

Hayes and Abad's (1989) analysis of Ilokano heavy syllable reduplication represents the fundamental arguments for the McCarthy and Prince (1996) approach to reduplicative templates.

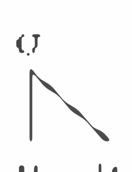
(13) *Heavy syllable reduplication for Ilokano* (Hayes and Abad 1989: 360)

a.	tra'baho	'to work'	ʔag-trab-tra'baho	'is working'
b.	'daʔit	'to sew'	ʔag-daː-'daʔit	'is sewing'
			ʔag-dad-'daʔit	
c.	'pjek	'chick'	pjeː-'pjek	'chicks'
			piː-'pjek	

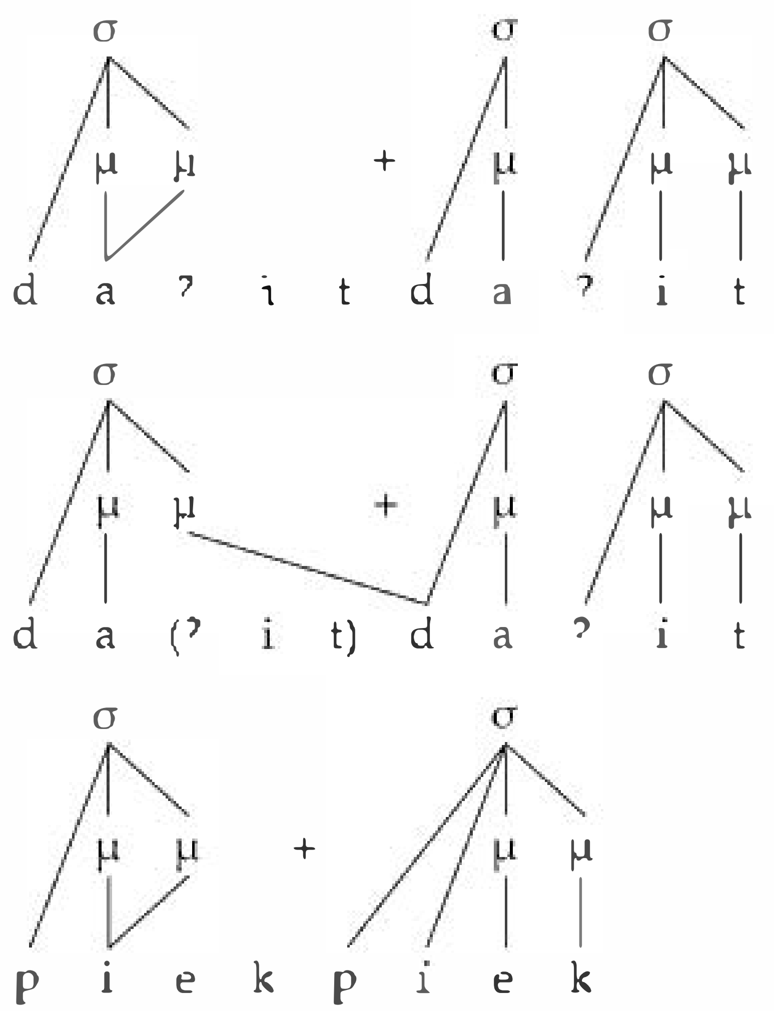
The complexity in this reduplication pattern lies in defining what satisfies the heaviness requirement. (13a) shows that a coda consonant is acceptable, and (13b, 13c) show that lengthening the first vowel copied from the R_0 also satisfies the requirement. There is variation in the forms in (13b) and (13c), though. (13b) shows dialectal variation between lengthening the vowel from R_0 and geminating the first consonant in the R_0 in order to satisfy the branching rhyme requirement. Finally, (13c) shows that a glide in an onset from R_0 can be vocalized and lengthened as a possible form of this reduplication pattern. Hayes and Abad suggest that all of these forms can be captured by specifying the reduplicative template as a bimoraic syllable.

(14) *Bimoraic syllable for Ilokano* (Hayes and Abad 1989: 360–361)

a. *heavy syllable template*



b. *examples*



[da:-daʔit]

[dad-daʔit]

[pi:-pjek]

(14) demonstrates that a single generalization at the syllable level can describe the forms that fall into the class of heavy syllable reduplication in Ilokano. All of the R_rs are a single syllable with a branching rhyme, but melodic association varies in the different forms for both phonological and morphological reasons. The variation seen in (13b) and (13c) is morphological in nature, because it cannot be predicted by phonological considerations.

Extending the original proposals from Marantz (1982) with the single melody model proposed in Mester (1986) and revisions to the prosodic hierarchy from McCarthy and Prince (1996) formalize a strong organic theory of reduplication. This theory is organic because the source of explanation for reduplication is solely from the general theory of morphology and phonology. The aspects of reduplication that make it unique are its bipartite and synchronous characteristics. Reduplication is bipartite because the morphology builds a synchronous phonological structure that is linearized later in the phonology. Reduplication is synchronous because a single phonemic melody is associated with multiple distinct prosodic structures. These two characteristics provide both morphological and phonological sources of over- and underapplication effects. Both morphological and cyclic phonological rules will apply before Tier Conflation and thus can be the source of over- and underapplication effects. Normal application effects are produced by rules that apply after Tier Conflation. Kiparsky (1986: 83) summarizes this situation as

> in principle, as strong a hypothesis as one could hope for. But our present picture of the articulation of phonology and morphology being as tentative as it is, [their proposals on morphology and cyclic phonology] are not easy to verify or falsify.

Although Kiparsky is cautionary, reduplication has been reduced to a unique synchronous representation and to the general question of what the nature of phonology and morphology is.

2.4 The full copy model

Steriade (1988) presages many of the themes dominating work on reduplication at the present time. Steriade's (1988: 146) main proposal is "that templates are not strings of concrete, fillable slots, but rather abstract conditions on prosodic weight and syllabic organization of strings." The reflex of this is the *full copy* model of reduplication, where all reduplication patterns start with R_r consisting of a complete copy of the segmental and prosodic structure of R_u and the rest of the base. Partial reduplication patterns are then produced by eliminating structure from the R_r on the basis of different prosodic parameter settings. Steriade argues that the full copy of prosodic structure remedies inadequacies in the way syllabic transfer effects are accounted for in the Marantzian model of reduplication.

Steriade's main demonstration of the full copy model involves the analysis of two reduplication patterns from Sanskrit. The intensive reduplication pattern in Sanskrit is a prefixing CVX pattern with a prespecified /a/ as the nucleus of the R_r.

(15) *Intensive reduplication in Sanskrit*

a. *Full and zero grade forms in Sanskrit* (Steriade 1988: 108)

root	*intensive full grade*	*intensive zero grade*	
svap/sup	saː-svap-	sau-sup-	'sleep'
		[sošup-]	

b. *Full copy parameter settings* (Steriade 1988: 107)

parameters
  weight parameters
    monosyllabic foot (heavy monosyllable)
  syllable markedness parameters
    obligatory onset: unmarked setting (onset is obligatory)
    complex onset: unmarked setting (onset may not be complex)
    sonorant coda: unmarked setting (coda must be a sonorant)
insertion rule
  Insert /a/ in the intensive stem
  Insertion site: first syllable, rhyme

The two intensive forms in (15a) for the root /svap/ 'sleep' provide the background on understanding how the parameters in (15b) ensure that the R_r will end up being a CVX sequence with a prespecified /a/. Note that the difference between the full grade and zero grade forms in (15a) is based on whether the vowel *a* is deleted from the root. When the *a* is deleted in the zero grade, the *v* vocalizes to *u*. The zero grade form in brackets shows the application of other rules in Sanskrit. The weight parameter is the primary source to truncate R_r to produce patterns of partial reduplication. The particular setting in (15b), monosyllabic foot, for the Sanskrit intensive pattern will ensure that the R_r has a branching rhyme. The syllable markedness parameters provide the source of other modifications to the R_r. Banning complex onsets will cause the R_r to delete segments if there is a complex onset.

The obligatory onset parameter bans the R_r from beginning with a vowel, which accounts for vowel-initial roots in Sanskrit not having a reduplicated intensive form. The sonorant coda parameter captures the observation that the R_r in intensive forms ends with either a long vowel or a sonorant consonant. Finally, there is an insertion rule that adds the prespecified /a/ vowel into the rhyme of the R_r.

(16) demonstrates how the full copy model accounts for the intensive forms for the root /svap/. To begin, the zero grade rule that deletes an unstressed /a/ in the stem occurs before full copy (Steriade 1988: 94–95) in the intensive forms. There are two distinct stems (i.e. one that has undergone zero grade formation and one that has not) to start the derivation of intensive forms.

(16) *Intensive reduplication in Sanskrit* (Steriade 1988: 109)

	full grade	*zero grade*
input	svap	sup
copy	svap-svap	sup-sup
/a/-insertion	*blocked* (OCP)	saup-sup
removal of unlicensed material		
complex onset	sap-svap	*n/a*
obstruent coda	sa-svap	sau-sup
prosodic weight		
rhyme lengthening	saː-svap	*n/a*
output	saː-svap	sau-sup

(16) requires only a few comments. The copy process takes as input the relevant full grade or zero grade form and the left copy is identified as R_r and thus subject to modification. The /a/-insertion rule applies first and is blocked if the R_r already contains an /a/ melody (as in the full grade form). Following this, the syllable markedness parameters remove any material that is not licensed. This causes the complex onset /sv/ to be simplified to /s/ and the non-sonorant /p/ to be deleted in R_r. Finally, the weight parameter ensures that R_r is a monosyllabic foot and lengthens the /a/ in the full grade form. The zero grade does not need this lengthening, because the diphthong /au/ satisfies this weight requirement.

The forms at the end of (16) are not the final output of the phonology. In particular, the output from reduplication of the zero grade /sau-svap/ must undergo the *ruki* rule to convert the /s/ following the R_r to a retroflex, and the /au/ diphthong must be converted to /o/. These additional changes produce the final form [soṣup]. The important aspect of this is that phonological processes have another chance to apply to the reduplicated form and further obscure relationships between R_r and R_o.

Steriade (1988) does not provide an exhaustive list of parameters and insertion rules for the full copy model. This is prudent, because Steriade draws the connection between modifications to R_r in the full copy model and general morphological processes found in non-reduplicative contexts. Examples of non-reduplicative truncation in Madurese and French hypocoristics and segment insertion in English strong verbs and Kaingang verbal formation are provided as examples of processes producible by similar parameters applied in a non-reduplicative context. Thus the question of what the parameters are in the full copy model is the question as to what a possible morphological or phonological rule is.

When a full copy may occur in the derivation is an important issue, because it determines what kinds of interactions between reduplication and phonological rules can occur. Steriade (1988: 141), following Kiparsky (1986), suggests that full copy will occur either at the lexical level or at the end of the cyclic level, with these levels being defined in Kiparsky's (1982) terms. Full copy in intensive reduplication in Sanskrit presumably applies at the cyclic level, which would allow zero grade formation to occur prior to reduplication, while full copy applies at the lexical level in the perfect reduplication pattern in Sanskrit, since Steriade (1988: 123–124) has the zero grade syncope rule apply after reduplication. This position basically echoes the claims about Tier Conflation in Mester (1986), with the modification that Tier Conflation can occur at different points in the derivation.

2.5 *Classic models of reduplication and the SHR*

The SHR in (1) can be seen as the result of the arc of research on reduplication spanning from Wilbur (1973) to Steriade (1988). Each of these approaches to reduplication assumes architectural modularity (1a), in that reduplication is a morphological process that interacts with phonology. Carrier (1979) introduces the bipartite (1b) aspect of reduplication, where a reduplicated structure created by the morphology is interpreted later by the phonology. The main gain here is that morphological rules can apply before reduplicative copying occurs, which is one source of over- and underapplication effects. Adoption of (1b) allows the "identity is synchrony" clause (1c) of the SHR to be adopted, providing a general understanding of the interaction between reduplication and phonological rules. Any morphological or phonological rule that is ordered before reduplicative copying occurs can produce over- and underapplication effects because R_o and R_r are a single representation at this point in time. Rules that apply after reduplicative copying occurs will produce normal application effects because at this point R_r and R_o are distinct. Although Wilbur (1973) adopted limited global computation in the Identity Constraint (4), all other classic models of reduplication favored local computation.

3 Contemporary models of reduplication

All contemporary models of reduplication are reactions to the SHR in (1). There is an interesting cyclic nature to the contemporary models, since they begin by returning to Wilbur's work on reduplication and the question of global computation in grammar.

3.1 *The parallel Correspondence Theory model*

McCarthy and Prince (1995) begin the contemporary era of work on reduplication by completely breaking away from the SHR in (1). The rejection of the SHR is based on the importance of parallel computation in reduplication. McCarthy and Prince (1995: 258) state that:

> In particular, most versions of Optimality Theory assume that constraints on all aspects of phonological structure are applied in parallel (Prince and Smolensky 1993). Inputs are mapped directly to outputs, in an essentially flat derivation.

Because a flat derivation is being assumed, the necessarily local and serial aspects of the SHR, such as separate morphology and phonology modules, the resulting bipartite nature of reduplication from these distinct modules, and the explanation of over- and underapplication effects due to the "before and after" aspects of the "identity is synchrony" hypothesis are all lost in a parallel computational model. Note that strict parallelism is not a necessary component of OT (e.g. Harmonic Serialism; McCarthy 2010), so the tenets of the SHR could be followed in OT, but McCarthy and Prince (1995) explicitly reject them.

As part of the rejection of the SHR and the adoption of global computation for reduplication, McCarthy and Prince (1995) suggest that the conclusions about reduplication should be applied to phonology in general. Correspondence Theory (CT) adopts Wilbur's IC and global computation as the core insight into reduplication and phonology. With global computation, a surface representation can be calculated from a memorized representation in a single computation, with any grammatical aspect potentially affecting the results. CT in practice eliminates all of the components of the SHR, because global computation removes the local distinctions between morphology and phonology. (17) presents the full model of reduplicative identity.

(17) *The full model of reduplicative identity* (McCarthy and Prince 1995: 273)

input	/Af_{RED} + Stem/	
IR-faithfulness	⇗ ⇅	IB-faithfulness
output	R ⇄ B	
	BR-identity	

Reduplication remains the result of the affixation of an underspecified morpheme, but the way phonological content is assigned to this affix is different. There is no copying process in CT, because a copying process operates in a computationally local way, where R_o (B in CT) can determine aspects of R_r (R in CT), but not the other way around (see McCarthy and Prince 1995: 292–294). Instead, reduplicative constructions have two direct correspondences and one indirect correspondence. The two direct correspondence relationships are BR-identity, which allows R_r and R_o to affect each other, and IR-faithfulness, which allows the input stem to influence the realization of R_r. The indirect correspondence for R_r is the general input–output faithfulness relationship between the stem and base. These relationships are all formally the same and operate in a global manner, which allows analyses of reduplicative phenomena unavailable to the classic models.

The bulk of McCarthy and Prince (1995) focuses on overapplication effects. The Malay nasal harmony example presents the strongest case for global computation in reduplication, because it is a case of back-copying.

(18) *Reduplication and vowel nasalization in Johore Malay* (Onn 1976: 180)

underlying	*stem*		*doubled stem*	
/hama/	hamə̃	'germ'	hãmə̃-hãmə̃	'germs'
/waŋi/	waŋĩ	'fragrant'	wãŋĩ-wãŋĩ	'fragrant (INTENS)'
/aŋan/	aŋãn	'reverie'	ãŋãn-ãŋãn	'ambition'
/aŋin/	aŋĩn	'wind'	ãŋĩn-ãŋĩn	'unconfirmed news'

Nasal harmony in Johore Malay operates in a left-to-right manner, as can be seen in the stem forms. The importance of the reduplicated forms is that the first vowel is nasalized even though it is not preceded by a nasal segment. Local computation has difficulties producing this effect because it would have to copy (/hame-hame/), have vowel nasalization apply (/hamẽ-hãmẽ/), and then re-copy to produce [hãmẽ-hãmẽ]. This is clearly an unattractive scenario.

McCarthy and Prince (1995: 289–294) discuss how the Johore Malay data are naturally captured in the global computation of correspondence theory. The constraints in the tableau below are straightforward (e.g. Ident-BR[nasal] is violated when R_o and R_r differ in the feature nasal, $*NV_{oral}$ is violated when a nasal segment is followed by an oral vowel or glide, $*V_{nasal}$ is violated when a vowel or glide is nasalized, and Ident-IO[nasal] is violated when the input stem and output base differ in the feature nasal).

(19) *CT analysis of Johore Malay* (McCarthy and Prince 1995: 291)

/RED-waŋi/	Ident-BR[nas]	$*NV_{oral}$	$*V_{nas}$	Ident-IO[nas]
☞ a. w̃ãŋĩ$_B$-w̃ãŋĩ$_R$			******	***
b. waŋĩ$_B$-waŋĩ$_R$		*!	**	*
c. waŋĩ$_B$-w̃ãŋĩ$_R$	**!		****	***

Given the constraint ranking in (19), (a) is the most harmonic candidate, showing a back-copying effect where the R_r provides the environment to nasalize the initial segments of the R_o and this alternation is transferred back to R_r. The global computation allows for the transfer of any alternation from the R_o to the R_r regardless of the source of the alternation, even if the cause of the alternation is R_r itself. Notice that normal application of nasal assimilation can be produced by simply ranking Ident-BR[nasal] below $*V_{nasal}$.

Adopting global computation increases the importance of generalizations on outputs, and this has resulted in further investigation of ideas about templates from Steriade (1988). *Generalized template theory* (McCarthy and Prince 1994a; Urbanczyk 2006) proposes that the particular shapes of reduplicative templates can be derived from language-specific prosodic requirements. In other words, the parameter settings from Steriade (1988) should be determined by a language's phonology and morphology instead of having to be set for each reduplicative morpheme.

Urbanczyk (2006) argues that a reduplicative template's prosodic weight can be predicted by its morphological status. Where Steriade (1988: 83) would specify a light syllable by setting a weight parameter to "unfootable," as an idiosyncratic aspect of the particular reduplicative morpheme, Urbanczyk derives the presence or lack of a coda in R_r (producing a weight contrast) from whether the reduplicative morpheme is classed as root or affix. Roots have additional faithfulness relationships (e.g. BR-Max(Rt)) that can support more marked phonological material. Affixes lack additional faithfulness pressures, and are thus subject to the effects of *the emergence of the unmarked* (TETU, McCarthy and Prince 1994b; CHAPTER 58: THE EMERGENCE OF THE UNMARKED).

(20) *Morphological status and reduplicative template shape in Lushootseed* (Urbanczyk 2006)

RED	*morphological status*	*reduplicated*
DIM	affiix	q'i-q'ix^{w}
DIST	root	saq$^{w'}$-saq$^{w'}$

(21) CV *vs.* CVC *status in* R$_r$

/DIM-q'ix^{w}/	BR-MAX(Rt)	NOCODA	BR-MAX
☞ a. q'i-q'ix^{w}		*	x^{w}
b. q'ix^{w}-q'ix^{w}		**!	

/DIST-saq$^{w'}$/	BR-MAX(Rt)	NOCODA	BR-MAX
a. sa-saq$^{w'}$	q$^{w'}$!	*	q$^{w'}$
☞ b. saq$^{w'}$-saq$^{w'}$		**	

The diminutive reduplicative morpheme in Lushootseed is an affix, while the distributive morpheme is a root, according to Urbanczyk. The constraint ranking in (21) has a root-specific BR-faithfulness constraint, BR-MAX(Rt), dominating NOCODA, which then dominates the general BR-faithfulness constraint, BR-MAX. This is a classic TETU ranking, which produces the surface effect that the DIST morpheme can contain a coda (as in [saq$^{w'}$-saq$^{w'}$]), while the DIM morpheme cannot (cf. [q'i-qix^{w}]).

(22) demonstrates how Urbanczyk derives the monosyllabicity of all R$_r$s in Lushootseed. By ranking a constraint that penalizes the number of syllables in the output (*STRUCT-σ) above both BR-faithfulness constraints, R$_r$ will be the minimal number of syllables possible (see also Spaelti 1997; Hendricks 1999). All atemplatic models assume some additional constraint that requires the reduplicative morpheme to occur in the output (see proposals by Gafos 1998).

(22) *Monosyllabic R$_r$ without a template in Lushootseed* (Urbanczyk 2006: 202)

/DIM-hiw-il/	*STRUCT-σ	BR-MAX(Rt)	BR-MAX
☞ a. 'hi-hiwil	***		wil
b. 'hiwil-hiwil	****!		

/DIST-pastəd/	*STRUCT-σ	BR-MAX(Rt)	BR-MAX
☞ a. 'pas-pastəd	***	təd	təd
b. 'pastəd-pastəd	****!		

Each of the optimal candidates in (22) has the characteristic that the R$_r$ contains as much phonological material (taking affix *vs.* root status into consideration, which determines whether a coda is in R$_r$ or not; see (21)) from R$_o$ as is needed to add only a single syllable to the output.

Although CT has had a major impact on phonology as part of the rise of Optimality Theory (Prince and Smolensky 1993), there has been little critical evaluation of whether it has furthered our understanding of reduplication. The crux of the matter is determining whether the empirical gains provided by global computation outweigh the results of the SHR in (1). While SHR models do not offer a natural account of back-copying effects, they do provide a general model of how phonology and reduplication interact. Once the point of copying in a derivation is determined for a reduplicative morpheme, there is a prediction about whether normal application for different types of rules (e.g. morphological, lexical, cyclic, etc.) should be the interaction between reduplication and phonology. Because CT abandons the modularity and local computation aspects of the SHR, it does not make any such predictions. The question that must be answered is whether a model with more empirical coverage but little predictive power is better than a model with less empirical coverage but great predictive power.

The proposals on reduplicative templates from CT are mostly extensions of Steriade (1988) because of their claimed connection to TETU effects. Urbanczyk (2006) presents the most restricted version, where prosodic principles are used to produce the reduplicative templates. Urbanczyk's proposals have not been evaluated cross-linguistically on languages with more than three reduplication patterns. Also, Haugen (2008) demonstrates the need for a syllable template to describe various reduplication patterns in Yaqui and Yapese, and work by Hendricks (1999) on bare consonant reduplication suggests that R_rs can be specified as a single segment, which conflicts with Prosodic Morphology (McCarthy and Prince 2001: 1), where reduplicative templates are to be made of authentic units of prosody (see (12)).

The role of TETU in reduplication needs to be critically evaluated, because of its widespread use as explanation in CT. Alderete *et al.* (1999) propose that fixed segmentism in any R_r has one of two sources: TETU or overwriting. The TETU analyses of Lushootseed, Nancowry, Yoruba, and Tübatulabal offered in Alderete *et al.* have all been shown to be inadequate: for Lushootseed, Fitzpatrick and Nevins (2003) demonstrate that fixed /ˈi/ in Lushootseed R_rs results from general considerations of the metrical system and has nothing to do with reduplication per se; for Nancowry, Raimy (2000a: 79–96) demonstrates that the vowel in the reduplicant is not predictable, but must be fully prespecified by the morphology; for Yoruba, Akinlabi (2004) demonstrates that the reduplicant must have a prespecified tone and that the prespecified vowel of the reduplicant is phonologically distinct from the phonetically identical epenthetic vowel derived by TETU; and for Tübatulabal, Cairns (2008) demonstrates that claimed TETU effects fall out from general phonological processes (see the original papers for the full arguments). Furthermore, the general typological claim that reduplicants/affixes will not contain any material more marked than bases/roots is questioned by the distribution of codas in Lakota (Albright 2004). These facts suggest that the Steriade (1988) position that all segmental prespecification in reduplication is carried out via insertion may be more accurate.

3.2 *Precedence-based phonology*

Raimy (2000a, 2000b) proposes that phonological representations consist of not only segments and prosodic structure but also precedence relations that encode the ordering of phonological elements (see CHAPTER 34: PRECEDENCE RELATIONS

IN PHONOLOGY). These proposals change phonological representations from (23a), where order is derived from graphemic conventions (left-to-right indicates order), to (23b), where order is directly indicated by precedence relations (indicated by '→').

(23) *Precedence in phonology*

a. kæt
b. # → k → æ → t → %

Raimy (2000a, 2000b) argues that, once precedence is encoded in representations, more complicated phonological representations can be considered and investigated. Specifically, reduplication results from a phonological representation that contains a transitive symmetrical precedence relation (i.e. a "loop").

(24) presents the unreduplicated and reduplicated forms from Johore Malay that McCarthy and Prince (1995) present as an argument against local computation in reduplication. (24a) is the memorized form for 'fragrant' and (24b) is the reduplicated version of this form.

(24) *Precedence-based reduplication*

a. # → w → a → ŋ → i → %
b. # → w → a → ŋ → i → %
c. # → w → a → ŋ → i → w → a → ŋ → i → %

The form in (24b) contains a "loop," which is the exponence of the reduplicative morpheme. Raimy reformulates the Tier Conflation of earlier bipartite proposals as serialization; see Idsardi and Raimy (forthcoming). The surface result of serialization is the repetition of segments within the loop, producing (24c) from (24b).

Although the "loops" have no privileged status (see Raimy 2009a: 187, n. 4), they are the locus of much explanation of reduplication. Raimy (2000b: 547) points out that the precedence link needed to account for reduplication in (24b) provides the exact phonological environment required to understand the interaction of reduplication and nasal harmony in Malay in a computationally local manner.

(25) *Vowel nasalization and reduplication in Malay*

a. # → w → a → ŋ → i → %
b. # → w̃ → ã → ŋ → ĩ → %
c. # → w̃ → ã → ŋ → ĩ → w̃ → ã → ŋ → ĩ → %

Non-consonantal segments in Johore Malay are nasalized if they are preceded by a [+nasal] segment, with nasalization spreading until a non-nasal consonant is reached. (25a) shows that there is a precedence relationship where /i/ precedes /w/, and this allows nasalization to spread to /w/ and consequently to /a/, producing the representation in (25b), where all of the segments are nasalized. (25c) is the serialized form where the nasalized /w̃/ and /ã/ appear in an environment that does not include a preceding nasal segment. Serialization has eliminated the environment that allowed nasal harmony to occur. This is a classic example of opacity, which is well known to occur with local computation. The conclusion of Raimy (2000a, 2000b) is that global computation is not necessary to account for back-copying or any other interaction between phonology and reduplication.

Reduplicative templates are derived from how precedence links are concatenated to a stem. Raimy (2000a, 2000b) adopts Distributed Morphology (Halle and Marantz 1994) and assumes that the phonological content of a reduplicative morpheme is simply a precedence link (or links and segmental material) that forms a loop when concatenated to the base. Precedence links that are added by the morphology are defined by *anchor points* (Raimy 2009b; see also CHAPTER 34: PRECEDENCE RELATIONS IN PHONOLOGY), which consist of a limited set of positions where links can be added. Depending on how a precedence link is concatenated to a base, segments from different parts of the base will be "in the loop" and reduplicated. Anchor points develop the idea from Moravcsik (1978: 312) that reduplication patterns can be defined in reference to positions of consonants and vowels.

(26) *Reduplicative "templates" in precedence-based phonology*

a. *prefixing* CVC: *Agta* (Healy 1960: 7)

\# → l → a → b → a → n → g → % [lab-labang] 'patches'

b. *suffixing syllable: Dakota* (Sietsema 1987: 337)

Ons Ons

\# → h → ā → s → k → a → % [hāska-ska] 'are tall'

c. *discontinuous: Chukchi* (Dunn 1999: 108)

\# → w → e → n → i → % [weni-wen] 'bell (ABS SG)'

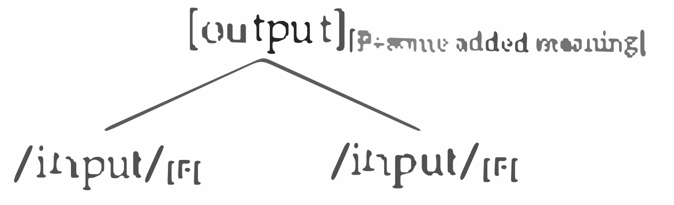
The "loop" in (26a) contains the first CVC of the stem, and these segments will be repeated when serialized. This loop can be defined by the anchor points "after the first vowel" and "first segment." Both of these anchor points are used in infixation (Yu 2007). (26b) presents a suffixing syllable pattern from Dakota that uses the anchor points "last segment" and "last onset." Finally, (26c) shows a discontinuous reduplication pattern from Chukchee that suffixes the first CVC sequence of the base. Discontinuous reduplication patterns that have the R_r separated from R_o in the surface string generally require two precedence links to be added. This pattern requires one precedence link for total reduplication (i.e. "last segment" precedes "first segment") and one precedence link to truncate the R_r to CVC (i.e. "after the first vowel" precedes %). Anchor points are not reduplication-specific, because they provide a general theory of how morphology creates concatenative (e.g. prefixation and suffixation) and non-concatenative (e.g. reduplication, infixation, truncation, root and template, etc.) phonological structures.

The proposals on precedence in phonology in Raimy (2000a, 2000b) provide a local computation solution to back-copying effects. This revitalizes the SHR in (1) as a viable model of reduplication. This makes answering the question about whether global computation in phonology is desirable or not even more important.

3.3 *Morphological Doubling Theory*

Inkelas and Zoll (2005) introduce Morphological Doubling Theory (MDT), which proposes that reduplication is the result of a purely morphological process where the output stem (which shows surface repetition of segments) results from two (or more) daughters that are featurally and semantically identical, as in (27).

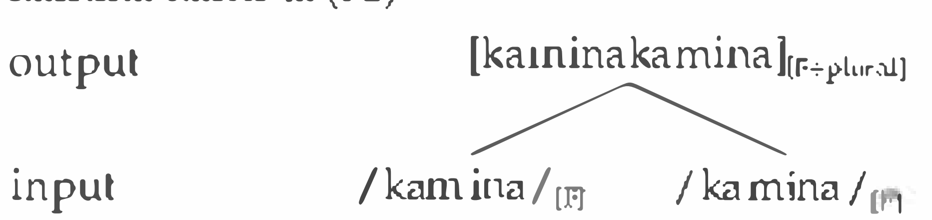
(27) *Morphological Doubling Theory* (Inkelas and Zoll 2005: 7)



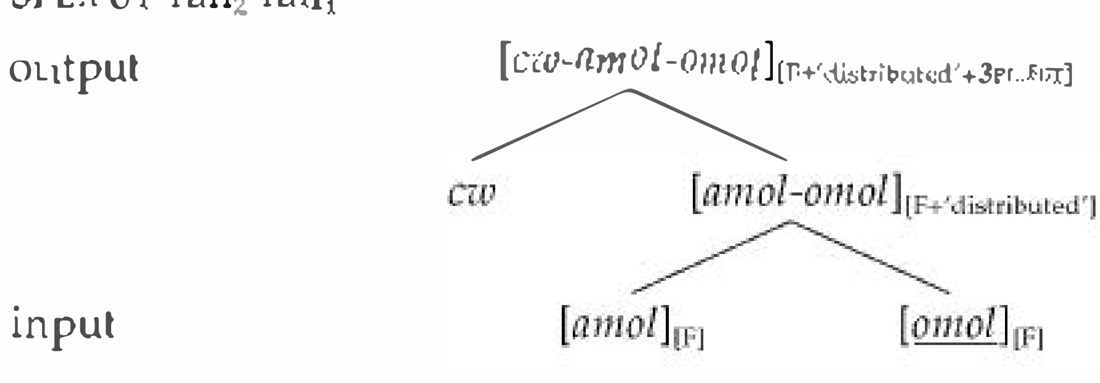
MDT denies the idea that there is phonological copying of any kind (e.g. literal derivational copying, repetition due to serialization or parallel correspondence) in reduplication. Surface repetition of segments is due to multiple independent instances of a stem. One immediate prediction that MDT makes is that total reduplication should be extremely common, since it can be produced immediately from the basic structure in (27). A more interesting prediction that MDT also makes is that a reduplication pattern can consist of two phonologically different allomorphs of a stem.

(28) *MDT basic structure examples*

a. *Warlpiri* (Inkelas and Zoll 2005: 1)
   kamina 'girl'
   kamina-kamina (PL)



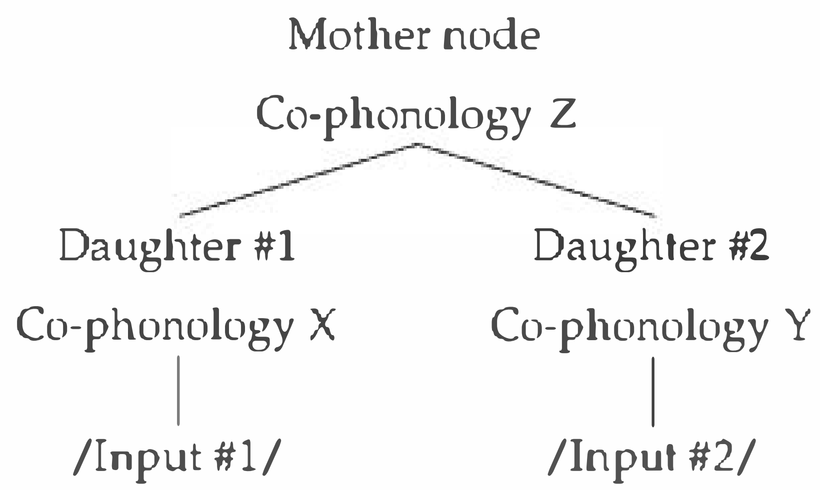
b. *Sye* (Inkelas and Zoll 2005: 54)
   cw-amol$_2$-omol$_1$ 'they will fall all over'
   3PL.FUT-fall$_2$-fall$_1$



(28a) presents an example of total reduplication from Walpiri that is produced by the basic structure of morphological doubling, where two semantically identical stems are inserted and produce total reduplication. (28b) shows that the same structure can produce patterns of reduplication where there is divergence between the two copies. Sye (Inkelas and Zoll 2005: 54, citing Crowley 1998: 79) presents a case where there is total reduplication but different allomorphs of the stem are inserted. /amol/ is what Crowley refers to as a "stem2" and /omol/ is a "stem1." Stem1 is the default form, and Inkelas and Zoll state that the stem2 form appears in a "collection of seemingly unrelated morphological environments" (2005: 52). The phonological difference between the two allomorphs leads to the surface appearance that total reduplication has not occurred.

MDT proposes that there is an analogous phonological side to the basic model in (27), where co-phonologies are associated with each node in the representation.

(29) *Co-phonologies in MDT* (Inkelas and Zoll 2005: 76)



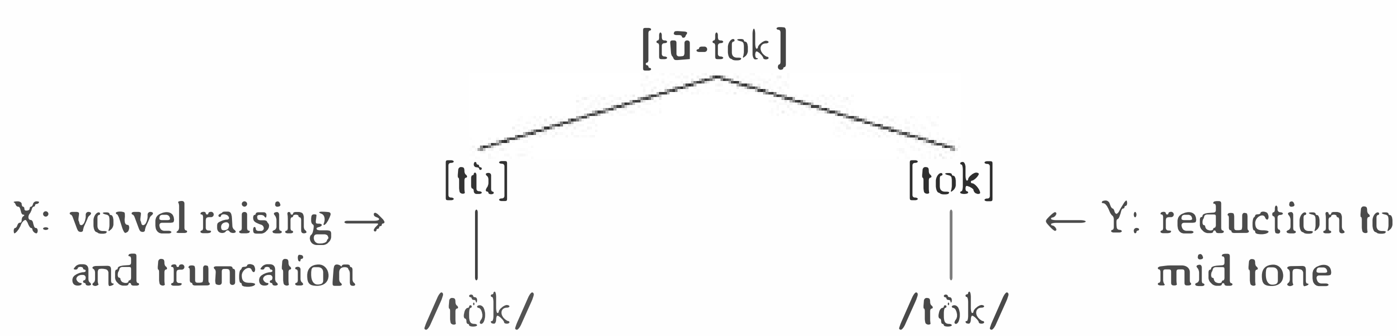
Each node in (29) has its own co-phonology associated with it. Common effects of co-phonologies are truncations that produce partial reduplication patterns. Co-phonologies X and Y will produce phonological changes that are specific to each stem. Co-phonology Z is required to produce juncture effects that hold between the stems only in reduplicative constructions.

Co-phonologies can modify both stems in different ways. Tarok presents an example of this with the reduplication pattern on monosyllabic stems.

(30) *Tarok* (Inkelas and Zoll 2005: 84)

a. ì-gìsàr ì-gìsàr-gisar 'his/her broom'
ì-tòk ì-tù-tok 'his chair'

b.



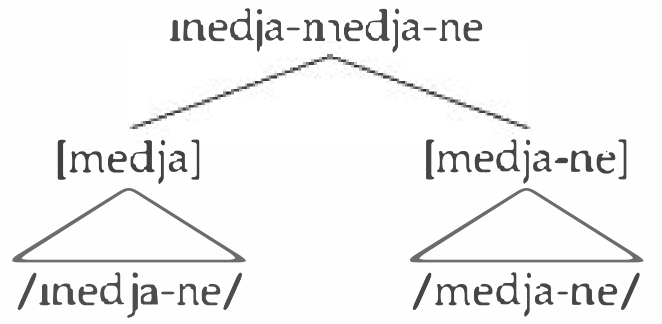
The forms in (30a) demonstrate the processes that are active in reduplicated constructions in Tarok. In all forms, the second stem (governed by co-phonology Y) has its tones reduced to mid regardless of the size of the stem. Co-phonology X must vary, depending on the size of the stem, because, if the stem is larger than a single syllable, no change to the stem occurs. However, if the stem is a single syllable, then the stem is truncated to a CV syllable and the vowel is raised. The example in (30b) lists the processes that each co-phonology is responsible for.

MDT deals with over- and underapplication of phonological processes through morphological truncation. Javanese (see Inkelas and Zoll 2005: 137 for the sources) has an /a/-raising process that interacts with reduplication in an opaque manner.

(31) *Javanese* (Inkelas and Zoll 2005: 136–138)

a. /medja/ medjɔ 'table'
medja-ne 'his/her table'
medjɔ-medjɔ 'tables'
medja-medja-ne 'his/her tables'

b. *Opacity by truncation*



(31) provides the basic template on how over- and underapplication effects are handled in MDT. The data in (31a) demonstrate that /a/ will raise to [ɔ] if it is the last vowel. Suffixation blocks the application of /a/-raising. By comparing the non-suffixed and suffixed reduplicated forms, the opaque interaction can be seen. Whether the first stem undergoes /a/-raising appears to be determined by whether or not the second stem is suffixed. MDT denies any phonological connection between the two stems, and instead proposes that the first stem is actually suffixed, (31b). The presence of the suffix on the first stem will block /a/-raising, and the co-phonology will then truncate the suffix. See Raimy (2006) for discussion of the problems MDT has with opacity in this example.

MDT is conceptually similar to Steriade (1988), in that a full copy of a level of representation is made and there is no transderivational global computation across the two copies. MDT diverges from Steriade's model, though, in disconnecting from a specific model of the phonology–morphology interaction. Co-phonologies are associated with the reduplication constructions, but MDT does not develop any relationship between co-phonologies in reduplicated and non-reduplicated constructions.

Although not working within MDT, Kiparsky (2010) develops a stratal OT model of reduplication that has the characteristics that MDT aspires to. Kiparsky argues that the phonology that an R_r undergoes is determined by the stratal level of phonology that the copy of the stem occurs at. Although there is phonological copying, there is no transderivational identity involved in reduplication, so it is very much in the MDT spirit. The analysis of Sanskrit reduplication presented by Kiparsky (2010) clearly demonstrates that the phonology that the R_r undergoes is predictable from the lexical phonology of Sanskrit.

Proposals by Inkelas and Zoll and by Kiparsky demonstrate that modified versions of the SHR can be developed in OT. These models admit some global computation, but this is limited to modules defined by morphology and phonology.

Reduplication is a bipartite process where R_r is created by the morphology and then subject to the general phonological derivation. Kiparsky differs from Inkelas and Zoll on the issue of identity as synchrony in reduplication. Kiparsky has a phonological version of this hypothesis in which both R_r and R_o are created from the same phonological representation via copying, while Inkelas and Zoll apply this hypothesis to the morphosyntactic level of representation, where R_r and R_o are created from different phonological representations that share a common morphosyntactic identity. Both models agree, though, that the wholesale move to global computation for reduplication in the CT model is unnecessary.

4 Conclusion and future questions

The SHR in (1) provides hypotheses as to how reduplication interacts with morphology and phonology and why reduplication appears to be a unique grammatical phenomenon. Contemporary models of reduplication have more or less followed the original arc of research that created the basis for the SHR. The wheel has not been reinvented by cycling through the evaluation of the parts of the SHR again. On the contrary, contemporary models of reduplication have increased the importance of the SHR, because each model raises more detailed questions about the validity of each component of the SHR.

Evaluation of the *identity is synchrony* clause in (1c) is currently underway in the guise of questioning what kinds of phonology reduplication interactions actually exist. Both Inkelas and Zoll (2005) and Kiparsky (2010) dispute the existence of back-copying. The argument is that the global computation of McCarthy and Prince (1995) and the precedence graphs of Raimy (2000a, 2000b) produce grammars that are more powerful than is necessary to account for reduplication. While the examples of back-copying discussed in the literature are few (e.g. Malay nasal spread, Chaha /x/-dissimilation), more cases do exist (e.g. Serrano). In order to further investigate whether back-copying exists, more examples should be included in the discussion. Obviously, the most fruitful way forward is to develop analyses of the following data in all contemporary models of reduplication to see where the differences in the models arise. Below are additional examples of back-copying that deserve more attention.

(32) *Abkhaz* (Bruening 1997: 325–326)

a. /bʧək/ [bə.ʧək] 'measure of weight'

b. /m/-*reduplication*
[əb.ʧək-m-əb.ʧək]
*[bə.ʧək-m-əb.ʧək]
*[bə.ʧək-m-ə.ʧək]

The Abkhaz data in (32) demonstrate that there is a phonological process that inserts an excrescent vowel between the /b/ and /ʧ/ in the unreduplicated form. When this form undergoes /m/-reduplication, the location of the excrescent vowel changes to precede the /b/ on the basis of the syllabification of the prespecified /m/. It is the syllabification of the prespecified /m/ and the /b/

of the base into a single syllable that places the excrescent schwa before the /b/. This placement of the excrescent schwa is transferred to the first copy (R_1), creating the /əb/ syllable in the reduplicated form. The excrescent schwa appears only in word-initial position, creating a VC syllable in reduplicated forms.

(33) *Korean* (Chung 1999: 177–178)

a.	/hilak/	→	[hirak]	'pleasure'
			[hi-hi-lak-lak] → [hi-hinaŋ-nak]	'rejoicing'
b.	/lwelak/	→	[nwe-rwenaŋ-nak]	'broadminded'
	/l/ → [n]		*[hi-hiraŋ-nak]	
			*[nwe-nwenaŋ-nak]	

The data from Korean in (33) show a complex pattern of normal and over-application of different realizations of the /l/. In (33a) we can see that in the non-reduplicated form the /l/ appears as [r] in an intervocalic environment. The reduplicated form in (33a) shows two interesting effects. First, the form undergoes an AABB reduplication pattern, based on an underlying compound structure to the word. The back-copying effect is present in the interaction between the /kl/ at the juncture between the two copies of the second syllable of the base, /lak/. There is a reciprocal influence on these segments, in that the /k/ preceding an /l/ causes the /k/ to nasalize to [ŋ]. This nasalization process then causes the following /l/ to nasalize to [n]. The nasalization of /l/ to [n] is then transferred to the /l/ of the first copy, [hihi-naŋ-nak], even though it does not follow a nasal segment. Adding to the complexity of these Korean data is the fact that the process that nasalizes the /k/ applies in a normal fashion, so the word-final /k/ is not nasalized. (33b) shows the same derivation for the second syllable /lak/, but the behavior of the /l/ in the first syllable /lwe/ is different. The /l/ in /lwe/ undergoes normal application of the [l ~ r ~ n] distribution, where the /l/ appears as [n] in word-initial position in the first repetition and as [r] intervocalically in the second repetition. The different behavior of the /l/s in the two different syllables creates a very complicated interaction between reduplication and phonology.

(34) *Paamese* (Russell 1997: 109–110)

/muni/	[munu-munu]	'drink'
	*[muni-muni]	
	*[munu-muni]	

The Paamese data in (34) are directly analogous to the Malay nasalization data already discussed in (18) and (25). In Paamese, an /i/ is backed to [u] if it is in non-final position. Reduplication causes the first copy of /muni/ to be in non-final position triggering the backing of /i/ to [u]. This alternation is then copied to the word-final /i/ in the second copy.

All three of these additional instances of back-copying provide examples of the exact base–reduplicant juncture effects that Inkelas and Zoll (2005) and Kiparksy (2010) deny exist. See the original sources for the full details of these examples. One should be cautious about interpreting arguments based on the validity of these data, though. MDT and Stratal OT can produce analyses of these types of data either through additional opaque copying for MDT or by positing special allomorphs in the relevant cases for Stratal OT. Consequently, the existence of back-copying effects (or not) is not as probative in distinguishing models of reduplication as McCarthy and Prince (1995), Inkelas and Zoll (2005), and Kiparsky (2010) suggest.

Another important question about reduplication is whether a repeated string of phonological segments is reduplication or repetition. Gil (2005) discusses this difference and provides examples from a naturalistic corpus of Riau Indonesian.

(35) *Repetition* vs. *reduplication in Riau Indonesian* (Gil 2005)

a. *complete arbitrary reduplication* (2005: 57)
Anton tak sini-sini a
Anton NEG RED-LOC-DEM-DEM:PROX EXCL
[commenting about his friend] 'Anton hasn't been around.'

b. *complete iconic reduplication* (2005: 54)
Naik ojek-ojek-ojek aja
go.up RED-motorbike.taxi just
[group of three persons debating whether to take a single taxi together, or separate motorbike taxis] 'Let's just ride motorbike taxis.'

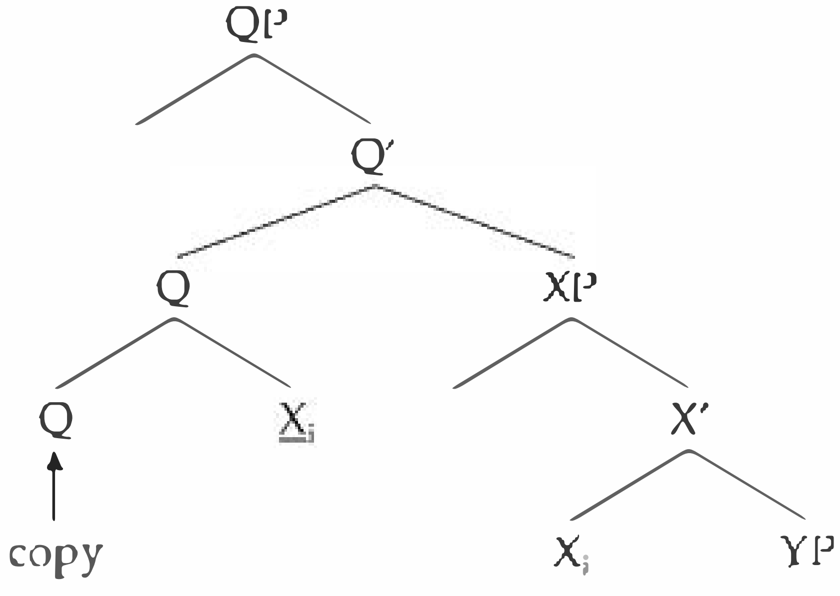
c. *ordinary language: reinforcing repetition* (2005: 43)
Masuk, masuk, masuk, masuk, ah, kelok bola
enter enter enter enter EXCL turn ball
[playing billiards on laptop computer; following the ball as it rolls] 'Go in, go in, go in, go in, damn, the ball curved.'

Gil argues that (35a) is a clear case of reduplication, because the number of repetitions is restricted to two and there is a grammatical function associated with the repetition. (35b) is iconic reduplication, where the number of repetitions of *ojek* 'motorbikes' reflects the number of motorbikes present. This is different from (35a), in that the number of repetitions is variable in (35b), while grammatically fixed in (35a). (35c) presents a case of repetition, not reduplication, because there is no grammatical function of the repetition, only a pragmatic one (i.e. it demonstrates the excitement of the player).

Travis (2003) provides a framework that can potentially distinguish between the examples in (35), on the basis of syntax. Because of the morphological aspects of reduplication, there is the potential for morphosyntactic considerations to play an important role in reduplication. (36) presents the syntax of two different types of reduplicative structures. Q represents a reduplicative morpheme, underlining indicates what syntactic constituent is the target of reduplication, and "copy" indicates where the repetition will occur. (36a) is an example from Tagalog of total reduplication (/lakad/ 'walk' → [mag-lakad-lakad] 'walk a little'), where the capitalized part indicates the R_r of the form. The head of the XP /lakad/ undergoes head movement to adjoin to Q, which is the reduplicative morpheme. Since the X is sister to the Q head, only the content of X is eligible to be copied in reduplication. The syntax of (36b) is different. The Q head copies material from the XP complement and places the copy in the spec position of the QP phrase.

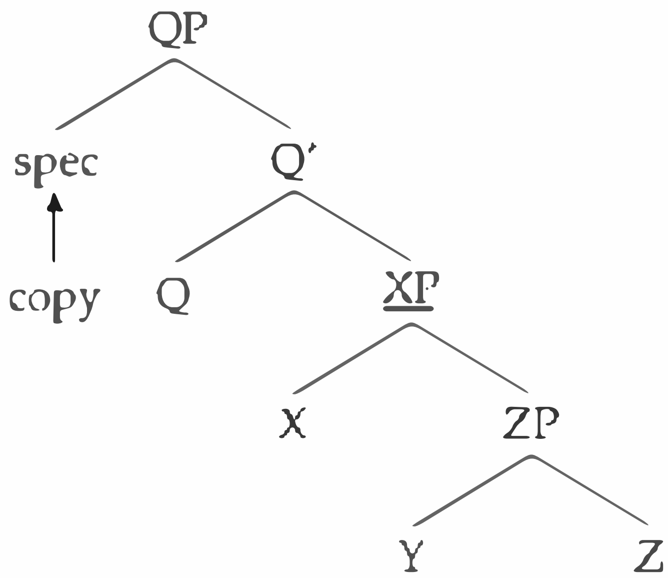
(36) *Reduplication as syntax in Tagalog* (Travis 2003: 240)

a. *phonological*



[magLAKADlakad]

b. *iterative*



CUP after cup of coffee

Travis (2003) captures two important aspects of reduplication: (morpho)syntactic representations limit the amount of phonological material that can be repeated and (morpho)syntax plays a role in determining how many repetitions occur.

Morphosyntax determines the upper bound of reduplicative copying through the sisterhood relationship in syntax. Head movement raises an X to adjoin to Q in (36a). This will limit reduplication to no larger than the phonological content of X and to one copy. X category elements are generally a "word"-sized domain, so this syntactic construction aligns closely with the familiar phonological cases of reduplication. The Q element in (36b) is sister to an XP, which allows for copying of the entire XP. Because the target of copying is an XP, more than a word can be copied in this construction. Furthermore, since the copy in this construction will appear in the spec of QP, more than one repetition can occur if multiple QPs are stacked on top of each other. This accounts for the open-ended number of reduplications in . . . *cup after cup after cup of coffee.* These are only two of the syntactic constructions for reduplication proposed by Travis (2003).

Travis's syntactic differences provide insights into distinctions among the repetition patterns discussed by Gil. (36a) is the morphosyntactic structure for common examples of reduplication such as (35a), while (36b) will account for Gil's (35b) and possibly (35c) examples. (36b) is also appropriate for phrasal reduplication examples like those in (37).

(37) *Phrasal reduplication patterns*

a. *Kannada* (Lidz 2001: 379)
nanrnu baagil-annu much-id-e giigilannu muchide anta heeLa-beeDa
I-NOM door-ACC close-PST-1SG RED that say-PROHIB
'Don't say that I closed the door or did related activities.'

b. *English* (Ghomeshi *et al.* 2004: 326)
Well, he didn't give-it-to-me–*give-it-to-me (he only lent it to me).*

Travis (2003) presents one view of syntactic aspects of reduplication; see Ghomeshi *et al.* (2004), Lidz (2001), and Idsardi and Raimy (forthcoming) for additional relevant data and different perspectives on these syntactic issues. Developing better syntactic analyses of reduplication will improve our understanding of whether there is any connection between semantics and particular reduplication patterns. If syntax plays an important role in reduplication, then there should be constraints on possible reduplication patterns and semantics pairings.

Another burgeoning question about reduplication is whether a surface repetition of segmental material is a reduplicated form or not. Buckley (1998) and Zuraw (2002) provide arguments that morphologically simplex forms can be inherently reduplicated.

(38) *Inherently reduplicated words in Manam* (Buckley 1998: 60)

a.	sa'laga	'be long'	salaga-'laga	'long (SG)'	*salaga-ga
b.	ra'gogo	'be warm'	rago'go-go	'warm'	*ragogo-gogo

Buckley (1998) argues that trimoraic forms in Manam that repeat the last two syllables, (38b) /ra'gogo/, are inherently reduplicated. One reduplication pattern in Manam is to reduplicate the final moraic foot of a form, as in (38a), /sa'laga/ → /salaga-'laga/. Forms like (38b) reduplicate only a single mora in this reduplication pattern, /ra'gogo/ → /rago'go-go/, */ragogo-'gogo/ and Buckley's idea is that if the final syllable is already reduplicated then it will "count" as bimoraic, thus producing only a single syllable for the bimoraic foot reduplication pattern.

(39) *Inherently reduplicated words in Tagalog* (Zuraw 2002: 400)

Intervocalic tapping ([ɾ] / V __ V, [d] *elsewhere*)

transparent	'duːɾi	'loathing'
overapplies	'ɾuːɾok	'acme'
underapplies	'deːde	'baby bottle'

Zuraw (2002) provides examples from Tagalog involving repetition of segmental material that violate general Tagalog phonotactic distribution of [d] and [ɾ]. Zuraw argues that these words can be understood as being inherently reduplicated. Once these forms are designated as reduplicated, their behavior follows documented phonology reduplication interactions such as over- or underapplication of a rule.

The common theme between Buckley and Zuraw's observations is that forms with surface repetition of segmental material that violate otherwise general patterns in a given language can be understood to be inherently reduplicated.

Both Buckley and Zuraw posit an "empty" RED morpheme to provide a grammatical structure to explain the over- or underapplication of some phonological process through reduplication. Fitzpatrick (2006) presents an analysis of the Manam data in the Raimy (2000a, 2000b) model of reduplication by simply allowing "loops" to be parts of an underlying representation.

To summarize this chapter, reduplication as a natural language phenomenon provides insights into grammatical architecture and the workings of grammatical modules. There is a burgeoning consensus about the general nature of reduplication, which can be summarized as the *strong hypothesis for reduplication* in (1). With Optimality Theory turning radically derivational in the form of Harmonic Serialism (McCarthy 2010), it is likely that all contemporary models of reduplication will be in line with the SHR in the near future. This does not mean that there is not disagreement about formal analyses of reduplication; thus further research into reduplication is called for. Future research should refine our understanding of architecture and computation in grammar by developing more explicit analyses of reduplication in more languages. The most difficult question that faces us about reduplication is the parceling out of explanation among potential syntactic, morphological, and phonological sources. By doing this, reduplication will further show its unique status as a natural language phenomenon that involves syntax, morphology, and phonology.

101 The Interpretation of Phonological Patterns in First Language Acquisition

Yvan Rose
Sharon Inkelas

1 Introduction

Since the seminal work of Jakobson (1941), phonological patterns observed in child language have been documented and analyzed from a number of perspectives. Throughout the relevant literature, an interesting paradox often manifests itself: while child language is generally characterized as a "simpler" version of the target language, many types of phonological patterns observed in acquisition data create challenges for theories developed to account for more "complex" adult systems. Phonologists within the generative framework have reacted to this problem in a number of ways, from tacitly or conspicuously ignoring acquisition data (e.g. Chomsky and Halle 1968: 331) to elaborating phonological models that account for phenomena observed in child phonology (e.g. Smith 1973; Bernhardt and Stemberger 1998) or, in some extreme cases, rejecting the validity of evidence from child production data for theoretical investigations of phonology (e.g. Hale and Reiss 1998). The disconnect between findings from child phonology and generalizations arising out of generative theories of grammar based on adult phonology has also been recruited in support of alternative, functionalist approaches to child phonology, including Stampe (1969) within Natural Phonology and, more recently, Vihman and Croft (2007) within Construction Grammar.

A general assumption connecting virtually all of these models is that children's phonological abilities are initially impoverished and gradually develop in the face of positive, interpretable evidence from the ambient signal. Regardless of theoretical or philosophical allegiance, researchers acknowledge that theories of linguistics should be learnable and, as such, empirically verified against language development facts. The question, then, is not about whether developmental phonology data should be considered – clearly they should – but about the way they should be incorporated into theoretical debates. As we discuss in this chapter, the main challenge lies in the interpretation of developmental patterns, given that differences between child phonology and adult phonology can be, and have been, attributed variously to perception, grammar, and production.

We begin our discussion with an overview of the types of patterns attested in the literature on phonological development. We then move on to phenomena that have featured in theoretical debates in the field, which we address in light of the main competing approaches to child language phonology. We conclude with desiderata for truly explanatory models of phonological development.

2 A brief survey of phonological patterns

This section presents a survey of the main types of segmental and prosodic patterns found in phonological development. As used here, the term "pattern" refers to any systematic difference between the actual forms produced by a child and the (adult-like) forms the child is evidently attempting. This definition is neutral as to the source of the discrepancy. For example, the child who says [tʰæt] for *cat* might be said to display a process converting target [k] to [t], with /kæt/ as his/her underlying representation; alternatively, that child might be said to have stored /tʰæt/ as his/her lexical representation, which he/she is producing accurately. Both positions, and others, have been taken in the literature.

The overview offered below builds on previous surveys by Menn (1971), Ingram (1974), Ferguson and Farwell (1975), Ingram (1989), Smit (1993), Vihman (1996), Bernhardt and Stemberger (1998), and Inkelas (2003), as well as the contributions to Kager *et al.* (2004) and to McLeod (2007). It provides only a fragmentary view of the larger picture of child phonology, because the literature has thus far been able to focus on only a relatively small number of children, and predominantly on "western" languages (cf. McLeod 2007). The possibility is high that phenomena unattested as of yet will be uncovered as research continues.

2.1 *Segmental patterns*

At the segmental level, a plethora of systematic discrepancies between child and adult pronunciations have been documented. As we can see from the list in (1), virtually all articulatory dimensions of speech are affected. For the purposes of this chapter, transcriptions between vertical bars represent adult-like, target forms. Arrows indicate correspondence between adult target forms and child productions, but should not be taken to represent generative phonological derivations; as stated above, this survey is neutral with respect to the question of the child's lexical representations (see CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION, CHAPTER 13: THE STRICTURE FEATURES, and CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION for overviews of the behavior of these features in adult languages).

(1) *Segmental patterns (non-exhaustive list)*

		Pattern	Illustration[a]		
a.	Place features	Velar fronting (to coronal)	/k/	→	[t]
		Coronal backing (to velar)	/t/	→	[k]
		Labialization	/t/	→	[p/tʷ]
		De/palatalization	/ʧ/	→	[k]
			/k/	→	[ʧ]
		Dentalization	/s/	→	[θ]
		Debuccalization	/s/	→	[h]
b.	Manner features	Gliding/rhoticization	/r/	→	[w]
			/w/	→	[r]
		Stopping/spirantization	/s/	→	[t]
			/t/	→	[s]
		De/affrication	/ʧ/	→	[t]
			/t/	→	[ʧ]
		De/nasalization	/m/	→	[b]
			/b/	→	[m]
		De/vocalization	/j/	→	[l]
			/ɫ/	→	[u]
c.	Voicing features	De/voicing	/d/	→	[t]
			/t/	→	[d]
		De/aspiration	/tʰ/	→	[t]
			/t d/	→	[tʰ]
		De/glottalization	/ʔ/	→	[k]
			/k/	→	[ˀ]

[a] These patterns and those listed in later tables are not limited to the illustrations provided. For example, fronting and backing patterns in (1a) typically target voiced as well as voiceless consonants, even though this generalization is not without exceptions (e.g. McAllister 2009).

Segmental patterns such as those in (1) are often context sensitive, varying across segmental and prosodic contexts. For example, Rose (2000) shows that French target /ʁ/ corresponds to various labial, coronal, and velar consonants in the speech of Clara, a first language learner of Québec French. The place feature that target /ʁ/ assumes in Clara's productions is harmonic with the place of articulation of other consonants present in the target form (e.g. *robe* /ʁɔb/ → [wɔb] 'robe'; *rouge* /ʁuʒ/ → [juʃ] 'red'; *carotte* /kaʁɔt/ → [ka'gɜ]/[kə'jɔːt˺] 'carrot'). Syllable context matters as well. The substitutions affect /ʁ/ in singleton onsets but not in complex onsets (e.g. *citrouille* /sitʁuj/ → [θɔ'tʁuːj] 'pumpkin'). Also, when /ʁ/ occurs in word-medial coda or word-final position in the adult target word, it undergoes deletion altogether (e.g. *ourson* /uʁsɔ̃/ → [ʊ'sɔ̃] 'teddy bear'; *renard* /ʁənaʁ/ → [lena] 'fox').[1] Although substitution patterns are often referred to outside their larger contexts (as in the list in (1), which exemplifies patterns independently of any contextualization), complex conditioning of the kind illustrated by Clara's data is actually quite typical, as other examples discussed below also demonstrate.

[1] See Rose (2000) for further discussion and analysis of these data.

2.2 *Prosodic patterns*

Systematic discrepancies between adult and child productions are also observed in the prosodic domain, i.e. syllable structure, word shape, or the location of stress or tone. A representative selection is offered in (2) (CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS, CHAPTER 67: VOWEL EPENTHESIS, and CHAPTER 36: FINAL CONSONANTS describe related phenomena in adult languages). These examples come from the general surveys cited in the introduction to §2 as well as from targeted studies of prosodic development by Spencer (1986), Fikkert (1994), Demuth (1995), Barlow (1997), Pater (1997), Ota (1999), Rose (2000), Gnanadesikan (2004), Goad and Rose (2004), and Vihman and Croft (2007), amongst others.

(2) *Common prosodic patterns (non-exhaustive list)*

		Pattern	*Illustration*	
a.	Affecting syllables	C + liquid cluster reduction	/pleɪ/	→ [peɪ]/[leɪ]
		s + C cluster reduction	/skiː/	→ [kiː]/[siː]
		Coda deletion	/kæt/	→ [kæ]
		Right-edge cluster reduction	/tɛnt/	→ [tɛn]/[tɛt]
		Consonant/glide epenthesis	/liːoʊ/	→ [liːjoʊ]
b.	Affecting word shapes	Vowel epenthesis/deletion	/bluː/	→ [bəluː]
			/əgɛn/	→ [gɛn]
		Syllable truncation	/ɛləfənt/	→ [ifənt]
		Syllable reduplication	/ɛləfənt/	→ [fæfæ]
		Stress shift	/dʒəˈɹæf/	→ [ˈdʒiːɹæf]

Similar to the segmental patterns illustrated in (1), the source of the prosodic phenomena in (2) is often open to a number of interpretations. Many of these patterns closely resemble phonological subsystems independently observed in adult languages (e.g. syllable reduplication; McCarthy and Prince 1995a), creating the temptation to analyze them as directly driven by the child's grammar. However, as we discuss further below, it is crucial that all available options be considered before any specific analysis is adopted. For example, evidence from infant speech perception shows that English-learning children tend initially to associate stressed syllables with word onsets (e.g. Jusczyk *et al.* 1999). This suggests that the apparent truncation of pretonic material in words such as *ga'zelle*, *a'bout*, and *gui'tar*, yielding productions like *zelle*, *bout*, and *tar*, may originate from a speech segmentation error that yields an incorrect lexical representation, as opposed to being the product of a grammatical rule restricting the prosodic shape of phonological productions. However, perceptual or speech segmentation errors certainly cannot be held responsible for all prosodic patterns. For example, Fikkert (1994) documents a pattern of stress shift displayed by Dutch learners who preserve both syllables of disyllabic words with final stress but systematically produce these forms with stress on the initial syllable, as exemplified in (3).

(3) *Stress overgeneralization* (data from Robin; Fikkert 1994)

gitaar	/χiːˈtaːr/	[ˈsiːtaː]	'guitar'
		[ˈsiːtau]	
giraf	/ʒiˈʀɑf/	[ˈʃiːɑf]	'giraffe'
ballon	/bɑˈlɔn/	[ˈbuːɔn]	'balloon'

Fikkert argues that these productions are conditioned by the learner's grammar, which – influenced by the predominant, trochaic, stress pattern that exists in the target language – regularizes away lexical exceptions. Fikkert's grammatical analysis is further motivated by the broad consensus that children are acutely sensitive to stress (e.g. Morgan 1996; Jusczyk 1997), a fact that argues against simple misperception of the target forms with final stress. (See Kehoe 1997, 1998 and Pater 2004 for related discussions.)

2.3 *Exotic patterns*

In addition to the two relatively clear types of patterns listed above, which have either parallels in adult language, direct phonetic motivations, or both, the literature on early phonological development contains an array of so-called "exotic" patterns, some of which are listed in (4), whose analysis defies both clean-cut classifications and, often, theoretical accounts. The term "exotic" is intended to convey that these patterns are not robustly attested in the literature on adult phonology.

(4) *Some exotic patterns*

	Pattern	*Illustration*
a.	Consonant harmony (affecting major place of articulation)[2]	/teɪbɫ/ → [beːbu]
b.	Vowel-to-consonant harmony (affecting major place of articulation)	/sxunə/ → [bunə]
c.	Long-distance consonant metathesis	/sak/ → [kas]
d.	Consonant fusion	/smouk/ → [fok]
e.	Velar fronting (across the board or in certain syllable positions)	/goʊ/ → [do]
f.	Chain shifts involving consonants	/sɪk/ → [θɪk]; /θɪk/ → [fɪk]
g.	Dummy segment or syllable insertion	/məskiːrou/ → [fi-giro]
h.	Spontaneous language games	/əlæskə/ → [ə'læskə-'bæskə][3]

As one example of an exotic type of pattern, consider the intricate yet systematic interaction between segmental and prosodic factors conditioning the productions of Marilyn, a learner of European French documented by dos Santos (2007). First, Marilyn displays syllable truncation driven by the segmental characteristics of the consonants found in the target forms: when two consonants have identical continuancy features in the target form, Marilyn produces both of these consonants, as illustrated in (5a). Conversely, in (5b), target forms that contain consonants with different continuancy features undergo truncation of the initial syllable.

[2] While consonant harmony is well attested in adult languages, it never affects major place of articulation as it does in child language (e.g. Hansson 2001; see also CHAPTER 72: CONSONANT HARMONY IN CHILD LANGUAGE; CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS).

[3] The pattern illustrated here consists of final foot reduplication combined with [b]-substitution in the foot-initial onset. Language games can take different forms across children; see Inkelas (2003) for some discussion.

(5) *Segmentally conditioned syllable truncation* (dos Santos 2007)

a. *Continuancy-harmonic onsets:*
Production of both onsets (and related syllables)

appétit	|ape'ti|	[pi'ti]	2;00.12[4]	'appetite'
biquet	|bi'kɛ|	[be'kɛ]	1;11.13	'goat'
escargot	|ɛskaʁ'go|	[ka'ko]	1;11.13	'snail'
chaussure	|ʃo'syʁ|	[ly'ly][5]	1;11.28	'shoe'

b. *Continuancy-disharmonic onsets:*
Truncation of the initial syllable

cassé	|ka'se|	['le]	1;11.13	'broken'
tennis	|te'nis|	['ni]	1;11.02	'tennis'
château	|ʃa'to|	['to]	1;11.02	'castle'
jumeaux	|ʒy'mo|	['mo]	1;11.28	'twins'

An understanding of these data immediately calls for an investigation of the child's attempts at other target word forms. In this regard, dos Santos (2007) also shows that during the same developmental period, all consonants are systematically produced when they appear in CVC forms, as we can see in (6). Interestingly, target words with continuancy-disharmonic consonants display harmony in this context, as opposed to deletion (cf. (5b)).

(6) CVC *targets: Consonant preservation and harmony* (dos Santos 2007)

bottes	|'bɔt|	['bɔt]	2;00.12	'boots'
coupe	|'kup|	['kup]	2;00.25	'cut'
passe	|'pas|	['pat]	1;11.13	'pass'
case	|'kaz|	['kak][6]	1;10.17	'box'

As we can see from these latter examples, the shapes of Marilyn's outputs are constrained by a combination of segmental and prosodic pressures, namely the types of consonants (stop *vs.* continuant) that are found in the target forms and the shape of the words in which the consonants appear (multisyllabic *vs.* CVC). Similar to Clara's data described in §2.1, the examples from Marilyn's productions illustrate how child phonological patterning often involves interactions between segmental and prosodic aspects of the developing phonological system.[7]

Partly because of their striking properties, but also because of the theoretical challenges they pose, exotic patterns like those in (4) have given rise to a rich and often contentious literature on child language development (e.g. Menn 1971; Smith 1973; Braine 1974, 1976; Ingram 1974; Ferguson and Farwell 1975; Priestly 1977; Chiat 1983, 1989; Levelt 1994; Velleman 1996; Pater 1997; Goad 2001;

[4] Here and elsewhere, ages are indicated using the Y;MM.DD format.

[5] While this example may suggest syllable reduplication, it is actually symmetrical with the other examples. Related to this is the fact that target fricatives that do not undergo deletion (or manner harmony; cf. examples in (6)) are pronounced as [l] at this stage. See dos Santos (2007) for additional discussion.

[6] The place harmony seen in this example arises through an independent process, as the child does not produce words that combine coronal and velar articulations at this stage. See dos Santos (2007) for additional discussion.

[7] For further discussion of segmental-prosodic interactions, see also contributions to Goad and Rose (2003) and to Kager *et al.* (2004), as well as Inkelas and Rose (2008) and McAllister (2009).

Gnanadesikan 2004; Menn 2004; dos Santos 2007; Vihman and Croft 2007; Fikkert and Levelt 2008; Inkelas and Rose 2008).[8] In the next section we discuss some of the fundamental questions relating to the interpretation of child phonological patterns, including exotic ones, and the formal apparatus needed to account for them. The discussion revolves around the degree of abstractness required to account for these phenomena.[9]

3 How abstract is child phonology?

The issue of abstractness in phonology has been – and continues to be – hotly debated in phonological theory, at least since Kiparsky (1968), and resides at the heart of theoretical controversy about child language development. Central questions, many of them pertaining to the degree of representational abstraction required to model children's grammars, emerge from a general lack of consensus about the phonetic or phonological level at which children operate from the onset of acquisition and throughout the developmental period. For example, phonologists often debate whether discrepancies between child and adult phonology are due to perception-based issues affecting representation, differences in grammar, or lack of motor control over production (see CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY).

While such questions are complex and cannot be resolved within the confines of this chapter, it seems clear that, just as adult phonological systems involve many different simultaneous levels of representation, children make generalizations about various kinds of representational units, depending on the types of evidence they are exposed to and able to interpret from the ambient language. Addressing this general observation, the field has gradually shifted from universalist claims about the unfolding of child phonology to a more evidence-based, individualist approach. Extreme examples of these two viewpoints can be found in Jakobson (1941) and Vihman and Croft (2007). Jakobson, on the one hand, famously argues for a maturational path of acquisition, which proceeds from one phonological feature to the next in universal fashion. On the other hand, Vihman and Croft argue that order of acquisition is determined by salient patterns in the ambient data, and can vary by individual as well as by language. A number of recent studies of infant speech perception, informed by theoretical models of categorization, have turned up support for the view that phonological structure and specificational detail emerge gradually within the lexicon. On this view, the child develops a phonetically detailed

[8] See Goad (forthcoming) for a recent summary of other theoretical issues.

[9] In this context, we must also mention the conspicuous absence of patterns affecting vowels from most discussions of phonological development (e.g. in (1)). Two main facts contribute to this asymmetry. First is a general impression, probably wrong, that children tend to produce vowels more accurately than consonants. This impression may be due in part to the lack, until very recently, of high-quality recordings, and in part to difficulties inherent to the acoustic analysis of child language vowel productions, especially with regard to place of articulation. Fortunately, the democratization of digital recording systems, the increased availability of databases documenting child language productions (especially through the Phon & PhonBank initiative; e.g. MacWhinney and Rose 2008), and the development of methods enabling less equivocal interpretations of child language speech articulations and related acoustics now offer new and exciting research possibilities. These include the consideration of potential covert contrasts and other articulatory artifacts in our characterization of phonological development (e.g. Buder 1996; Scobbie *et al.* 1996; van der Stelt *et al.* 2005; Vorperian and Kent 2007).

lexicon using inborn linguistic perceptual abilities, which are sharpened by language-specific exposure during the first year of life (see Werker and Fennell 2004 and Yoshida *et al.* 2009 for recent summaries and discussions). Pierrehumbert (2003) proposes that the phonetic detail contained in early lexical forms serves as the primary ingredient for building abstract segmental categories (see also Beckman and Pierrehumbert 2003). As Pierrehumbert (2003: 119) suggests: "the system of phonological categories includes not only segments, but also other types of discrete entities in the phonological grammar, such as tones, syllables, and metrical feet." Following similar reasoning, many acquisitionists have proposed a gradual emergence of phonological categories in the lexicon and established relationships between the emergence of these categories and phonological patterning. We return to these proposals in §5.

The issue of representational abstraction in phonological development also has implications for any theory assuming a set of universal primitives, including those based on strong interpretations of the Continuity Hypothesis, discussed in the next section.

3.1 *Child phonology and the Continuity Hypothesis*

According to the Continuity Hypothesis (e.g. Macnamara 1982; Pinker 1984), the formal properties of the grammar do not change over the course of development. The child's grammar starts with the same theoretical primitives that the adult grammar ends up with. Within the generative framework, this means that child phonology uses the same types of rules or constraints posited for adult systems. Each stage in phonological development is generally assumed to be compatible with the set of principles that regulate adult systems (e.g. Spencer 1986; Fikkert 1994; Levelt 1994; Demuth 1995; Freitas 1997; Goad 2000; Rose 2000; Goad and Rose 2004; Fikkert and Levelt 2008). The Continuity Hypothesis extends beyond grammar to lexical representations as well. For example, within feature-geometric frameworks (e.g. Sagey 1986), accounts of segmental development typically posit the emergence of feature hierarchies on the basis of phonological contrasts (e.g. Brown and Matthews 1993, 1997; Rice and Avery 1995; Dresher 2004; Fikkert 2005; see also Jakobson 1941 for an early discussion on the role of contrast in phonology). In most proposals, even the order of acquisition of the contrasts is fixed by the model, motivated by typological evidence and, at times, theory-centric learnability considerations, and thus falls under the scope of the Continuity Hypothesis. For example, the feature Coronal enjoys a special status in the literature on adult phonology, where it is often claimed to be inherently less complex than Labial or Dorsal (e.g. contributions to Paradis and Prunet 1991; cf. CHAPTER 12: CORONALS). Many acquisitionists have relied on this claim while describing phonological development (e.g. Levelt 1994) or accounting for consonant harmony patterns (e.g. Pater 1997; Fikkert and Levelt 2008; see Fikkert *et al.* 2008 for further discussion).

As the survey of exotic phonological phenomena reveals, however, child phonology sometimes requires phonological rules or constraints that are not independently motivated in adult phonological systems (e.g. Pater 1997 on child-specific constraints driving consonant harmony; see also Levelt and van Oostendorp 2007 in the context of segmental development). Similarly, lexical representations do not always conform to adult-based generalizations. For example, regarding the coronal asymmetry mentioned just above, Rose (2000: 175) points out that different children exhibit different featural behaviors in their productions, within and across target languages. Claims about the universality of phonological constructs and their emergence in acquisition are often at odds with the facts, especially when they are closely inspected.

In more functionalist approaches to phonological development, such as the constructivist approach entertained by Vihman and Croft (2007), the Continuity Hypothesis receives a different interpretation. Within Vihman and Croft's approach, there is no formal distinction between competence and performance. Language acquisition, just like its use, relies on general cognitive mechanisms operating on schematic templates, the nature of which is claimed not to change in any fundamental way over the course of one's life. (See §4.2.2 for additional discussion of Vihman and Croft's proposal.)

Whichever approach is favored, any theory of grammar is still obligated to explain why child phonology is different from adult phonology. We discuss a few of the toughest challenges in the next section.

3.2 *Some empirical challenges*

Exotic patterns or asymmetries in child phonological development, taken at face value, often suggest either rogue grammatical properties (e.g. Buckley 2003; Goad 2006) or, in some extreme cases, formal paradoxes. Such paradoxes are most evident in so-called chain shift patterns illustrated by the famous *puzzle–puddle–pickle* problem defined by Macken (1980), based on data from Amahl, an English-learning child whose productions were originally documented by Smith (1973). This chain shift takes the form of an A → B; B → C schema whereby a given phone arising from a substitution pattern may be the target of another substitution. For example, in Amahl's productions, the /z/ of *puzzle* is realized as [d] (/pʌzɫ̩/ → [pʌdɫ̩]), while /d/ itself surfaces as [g] in words like *puddle* (/pʌdɫ̩/ → [pʌgɫ̩]). Another chain shift, also found in Amahl's productions, involves the realization of word-initial /s/ as [θ] (e.g. *sick* /sɪk/ → [θɪk]), a consonant which, when present in a target form, surfaces as [f] (e.g. *thick* /θɪk/ → [fɪk]). We discuss the former chain shift in more depth in §4.[10] Such patterns are, at least in appearance, problematic for all theories of phonology in the sense that if a rule or constraint triggers the substitution of a target sound by another one, this target sound should logically be ruled out altogether from the child's output forms, at least within similar prosodic contexts.[11]

Other patterns are problematic because they contradict generalizations made from the study of adult languages. The case of positional velar fronting offers such an example. Velar fronting is a pattern whereby target velars /k g/ are fronted to coronals [t d]. Context-free (across-the-board) velar fronting can be attributed to the child's inability to either lexically represent or correctly articulate target velars. Neither of these potential analyses poses a difficult theoretical challenge beyond data interpretation per se. However, the positional version of velar fronting, whereby velars are neutralized to coronals in strong, but not in weak,

[10] Additional discussions of the latter chain shift can be found in Hale and Reiss (1998) and Rose (2009).

[11] Chain shifts do occur in adult language as well. However, they tend to involve lenition or vowel quality, not major consonantal place of articulation (see e.g. McCarthy 1999, 2008 and Mortensen 2006 for recent discussions).

prosodic environments (e.g. *go* /go/ → [do]; *bagel* /'beɪgl̩/ → ['beɪgu]), is problematic. As Inkelas and Rose (2008) point out, theories of positional asymmetries in phonology share the prediction that neutralization of segmental contrasts should occur in prosodically weak, as opposed to strong, positions, as generally happens in adult language.[12] Positional velar fronting thus contradicts the generalization that contrasts are preserved in prosodically strong positions, and challenges theories based upon that generalization.

The incidence of innovated chain shifts and apparently rogue patterns such as positional velar fronting in child phonology contradicts the view that human developing and end-state (adult) grammars share the same basic properties. Of course, we at times observe subsystems in adult grammars that exhibit phonological asymmetries or apparently odd properties. Many so-called "crazy" rules in adult language (e.g. Bach and Harms 1972) have their origins in diachronic re-analysis (e.g. rule inversion) or telescoping of sound changes. Arguably, a large proportion of these apparent rules are morphologically conditioned and can be handled via suppletive allomorphy. Opacity, which is not infrequent in adult phonology, has been analyzed synchronically by an appeal to lexical contrast preservation (Łubowicz 2003) or to abstract (underlying) properties of lexical forms, justified by semantically related morphological forms observed elsewhere in the lexicon (e.g. Kager 1999; McCarthy 1999, 2002, 2008; and Kiparsky 2000 for related discussions). Once put in their appropriate contexts, apparently rogue adult phonological subsystems can be reconciled with existing phonological theory and, in many ways, contribute to its elaboration.

In sum, morphological and lexical factors contributing to opacity and other phonological oddities in adult phonology are not directly applicable to most innovative patterns observed in child phonology. Recent literature, to which we turn next, suggests that, in addition to grammar itself, phonetic dimensions of speech perception and articulation play an important role in the exotic as well as in the ordinary, in children's phonological productions.

4 Theoretical approaches to child phonological productions

In this section, we survey a number of theoretical approaches to address empirical problems posed by child phonological productions. The sheer number of proposals available in the literature makes it impossible to provide a comprehensive survey of theoretical approaches to child language phonology. We thus restrict ourselves to contrasting representative examples of predominant approaches, and addressing related controversies. We then discuss how these approaches relate to the larger context of perceptual, lexical, and articulatory development.

[12] The extensive survey of consonantal place markedness in de Lacy (2002) upholds the generalization that contrast neutralization in prosodically weak environments – such as syllable codas or unstressed syllables – is frequent, while it is infrequent or unattested in strong positions, such as syllable onsets or stressed syllables. A noticeable counterexample to this generalization comes from Steriade (2001), who argues that "strong" must sometimes be perceptually defined; neutralization of apical and retroflex consonants, for example, can occur in word-initial onsets but not word-finally, because postvocalic position is perceptually optimal for these consonants. See also CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION.

4.1 Approaches assuming adult-like phonological representations

Since the influential study by Smith (1973), which set the tone for a vast program of research on phonological development within generative phonology and beyond, it has been largely assumed that the child's input is similar to the corresponding adult output form, as stated in (7). In analyses taking this assumption as their starting point, the child's pronounced form is generally derived from the adult form through ordered rules, parameter settings, or constraint rankings.

(7) *A "standard" assumption* (since Smith 1973)

Children's lexical representations are similar to corresponding adult phonetic forms.

This assumption is found in virtually all works couched in derivational versions of Generative Phonology, from standard *SPE* (Chomsky and Halle 1968), to autosegmental and prosodic approaches to phonology (e.g. Goldsmith 1976 and McCarthy and Prince 1995a, respectively). This assumption also holds in flavors of the non-derivational framework of Optimality Theory (henceforth OT; Prince and Smolensky 1993) that draw on formal relationships between inputs and outputs (e.g. Correspondence Theory; McCarthy and Prince 1995b). Common to these various models is the view that milestones in phonological development correspond to the relaxing of formal pressures on the child's grammar that militate against the production of complex phonological units contained in the input. For example, accounts of the acquisition of prosodic representations generally predict that children start with monosyllabic words displaying V or CV syllable structure and gradually expand the number and/or the complexity of the constituents allowed by their grammars (e.g. Spencer 1986; Fikkert 1994; Freitas 1997). The same general approach within OT is formally viewed as an initial ranking of markedness constraints over faithfulness constraints (see CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). The effect of the latter is typically evaluated against adult-like output forms, in accordance with the assumption in (7). The gradual demotion of the markedness constraints accounts for the concomitant appearance of more complex phonological structures in output forms (e.g. Demuth 1995; Barlow 1997; Pater 1997; Rose 2000; Gnanadesikan 2004).

Approaches based on the assumption in (7) raise a number of theoretical issues. Some of the most central questions can be illustrated through a consideration of Smith's (1973) and Dinnsen's (2008) analyses of opacity effects. Let us first consider a representative dataset, from Dinnsen's recent discussion of one of Smith's chain shift patterns we described in §3.2 (see CHAPTER 73: CHAIN SHIFTS).

(8) *Apparent chain shift* (as described by Dinnsen 2008; data from Smith 1973)

a. *Velarization in non-derived environments*

[pʌgl̩]	*puddle*	[æŋklaz]	*antlers*
[bɔkl̩]	*bottle*	[bʌklə]	*butlers*
[hæŋgl̩]	*handle*	[trɔglə]	*troddler*

b. *Velarization blocked in morphologically derived environments*

[kwæːtliː]	*quietly*	cf.	[kwæːt]	*quiet*
[sɔftliː]	*softly*		[sɔft]	*soft*
[haːdliː]	*hardly*		[haːd]	*hard*
[taitliː]	*tightly*		[tait]	*tight*

c. *Velarization blocked in phonologically derived environments (stopped fricatives)*

[pʌdl̩]	*puzzle*
[pɛntl̩]	*pencil*
[wɪtl̩]	*whistle*

In an analysis that reflects generative phonology of its time, Smith (1973) accounts for the set of data in (8) using a series of ordered transformational rules deriving the child outputs from their target counterparts. First, he posits two basic rules, one for velarization (R3) and one for stopping (R24).[13]

A constraint-based analysis of the same data is offered by Dinnsen (2008), who invokes Comparative Markedness (McCarthy 2002), a version of OT in which the original conception of markedness is redefined by splitting each markedness constraint into two distinct versions of itself, one that is violated by a property that is fully faithful to the input (similar to original markedness violations), the other violated by a property that is not present in the input. Dinnsen accounts for the data in (8) through a combination of input–output and output–output markedness constraints targeting sequences composed of alveolar stops and liquids. For example, the velarization pattern in (8a) and the absence thereof in (8b) are formally distinguished through an output-output constraint (OO-$_{O}$*dl), which cannot apply to monomorphemic forms that do not display alveolar–liquid sequences in the input (e.g. *quiet*).[14]

Assessing the full theoretical implications of McCarthy's (2002) theory of Comparative Markedness would go far beyond the scope of this chapter.[15] In the context of child language, the proposal relies on the OT tenets that (a) all constraints are universal and (b) phonological development can be accounted for as reranking of constraints from an initial ranking within which markedness constraints outrank faithfulness constraints (e.g. Smolensky 1996; cf. Hale and Reiss 1998). Dinnsen's (2008) account of the facts in (8) is entirely compatible with these assumptions. As he points out, the opaque chain shift in (8) is not "inferable from the primary linguistic data to which Amahl would have been exposed" (2008: 157). Amahl is nonetheless able to generate his chain shift by ranking the universal constraint penalizing "old" coronals higher than the constraint penalizing derived ones.

Both the rule-based and the constraint-based account of the chain shift in (8) are based on the key presupposition in (7) – shared by most generative approaches to acquisition – that the child's input is equivalent to the adult's output. In addition, Dinnsen's (2008) account must crucially assume that the child has access to morphological structure or, minimally, to grammatical awareness, enabling a distinction between morphologically derived *vs.* non-derived environments.

[13] In Smith's (1973) original formulation, each rule is labeled R*n*, where *n* indicates the relative order of the rule in Amahl's grammar.

[14] See Barlow (2007) for a similar approach to other cases of apparently opaque production patterns.

[15] See Hall (2006) for a discussion of Comparative Markedness in the context of adult phonology.

However, Dinnsen does not provide any independent evidence for the validity of this assumption. As discussed in the next section, alternative accounts can be formulated that do not require any such, potentially unwarranted, assumptions.

4.2 *Alternative views*

A number of challenges have been posed for the assumption in (7), which underlies the rule-based and constraint-based analyses we have just summarized. In this section we review three proposals, each of which offers its own perspective on children's inputs and, consequently, on the phonological system that governs their outputs.

4.2.1 Child phonological productions as theoretically irrelevant

One response to puzzles like the one in (8) is to deny their grammaticality, attributing them to performance factors. Focusing heavily on issues relating to speech articulation in child language, Hale and Reiss (1998) offer a rather provocative solution. Keeping with a strong version of the Continuity Hypothesis, they use a series of empirical observations to undermine the theoretical relevance of production-based studies for phonological theory. They argue that "[child language] deviations from targets are largely due to performance effects" (1998: 658), comparing child speech to "the intoxicated speech of the captain of the Exxon Valdez around the time of the accident at Prince William Sound, Alaska" (1998: 669).

Since its publication, Hale and Reiss's article has been the subject of much controversy in the literature, with the positive result of encouraging reflection on how phonological productions in child language should be approached. The general consensus that has emerged is that while there is no doubt that surface effects (intoxication, immature vocal apparatus) add noise that can obscure patterns in the data, this observation does not entail that we should throw the phonological baby out with the bathwater. The study of phonological development based on production data, if conducted in a careful manner, is worthy of empirical and theoretical investigation

4.2.2 Deriving the input from output considerations

Macken (1980), inspired by Braine's (1976) review of Smith (1973), sheds important light on differences between child and adult phonology. Macken argues that equating children's inputs to adults' outputs as per assumption (7) may give rise to misanalyses of some child-language data. She demonstrates that a reconsideration of this assumption can make child phonological systems much more transparent than they seem at first sight. In the case of the chain shift in (8), Macken argues that it is merely apparent, in that it can be decomposed into a series of simpler problems, each of which primarily involves either perception or production. According to Macken, Amahl's perception of coronal stops was influenced by the relative velarity of syllabic [ɫ] in the contexts in (8a).[16] Words like *puddle* were thus represented with a velar consonant (i.e. /g/) in Amahl's early lexicon. In (8b), the absence of a syllabic lateral after the coronal stop explains in a simple way the absence of velarization of the preceding stop, without any need to refer to

[16] This account also implies that laterals in words such as *antlers* also displayed a degree of velarity. Another potential influence in this context is the glottalization of the coronal preceding the lateral.

morphological complexity. Finally, in (8c), the consonant preceding the [ɫ] is a fricative, whose continuancy and/or stridency arguably prevented the type of velar influence that affected coronal stops in (8a). These fricatives, however, underwent stopping in onsets, a pattern widely and independently attested in the literature on child language (e.g. Ingram 1989; Bernhardt and Stemberger 1998).

In the face of this explanation of Amahl's apparently complicated production patterns, which appeals to relatively basic perception and production factors, one could be tempted to drop accounts based on grammatical processing altogether. This is in many ways the view espoused by Vihman and Croft (2007), who propose the constructivist, *Radical Templatic* model of phonology and phonological development. Within this model, the word is represented as a phonotactic template that directly encodes all melodic and prosodic characteristics of output (phonetic) forms. With regard to acquisition, Vihman and Croft's proposal can be divided into two main claims. First, phonological learning proceeds through implicit inferences based on memorized word forms:

> The child gradually develops first one or a small number of phonological templates, then a wider variety of them, while at the same time inducing a range of other phonological categories and structures from the known word shapes. (Vihman and Croft 2007: 686)

Second, template specification is constrained by the child's own productive abilities: children gradually specify their template as they discover how to reproduce the types of phonotactics that are present in their memorized target forms.

Vihman and Croft's (2007) view that the shape of children's lexical templates is governed by their own productive abilities presents, at the theoretical level, a circularity problem, in the sense that both the phenomena observed and their origins are the same. While this may be seen as a virtue in what-you-see-is-what-you-get constructivist approaches to grammar, it poses a challenge to approaches that formally separate grammatical processing from lexical representation.

Outside of theoretical considerations, it is undeniable that articulatory planning and execution are involved in speech production and, as such, may influence the learner's productions, especially at young ages. Vihman and Croft's (2007) proposal nicely highlights this fact. However, it is unclear whether all speech errors observed in child language should be related to the domain of production. For example, children are often not influenced by their own production mistakes during speech perception. This is demonstrated by Chiat (1983), who documents perceptual and productive abilities of English-learning Stephen. This child displays systematic velar fronting patterns, on the one hand, but shows, on the other, perfect discrimination abilities between alveolars and velars. Stephen's system thus illustrates the formal separation that must be made between perceptual and productive abilities. It also highlights, once again, the importance of considering the child's overall system in any investigation of developmental speech patterns.

4.2.3 Deriving outputs from statistical influences

Without addressing apparent phonological paradoxes such as the one illustrated in (8), but in a move away from intrinsic linguistic conditioning, Levelt *et al.* (2000) turn the focus to statistical pressures from the ambient language (see CHAPTER 90: FREQUENCY EFFECTS). They argue that the order of acquisition of syllable types (e.g. CV > CVC > CCV) in monolingual Dutch-learning children can be predicted through the relative frequency of occurrence of these syllable types in the ambient language. Levelt *et al.* further argue that the variability observed across groups of learners with regard to the acquisition of certain syllable types is also correlated with frequency figures from the adult language. Their argument thus highlights frequency as a potentially determining influence in child language development, an observation that matches many of the findings about infants' abilities to statistically process the ambient signal (e.g. Jusczyk 1997 for a summary).

However, further verifications of the hypothesis that frequency drives order of acquisition or the emergence of patterns of speech production in child language have yielded a series of criticisms from both empirical and theoretical perspectives (e.g. Kehoe and Lleó 2003; Demuth 2007; Edwards and Beckman 2008; Rose 2009; see also Brown 1973 for early refutations of statistical approaches). Critiques of the statistical approach generally contend that while input statistics can play a role in the emergence of phonological patterns in language development, and while it is important to look at properties of the ambient language as a whole, both linguistic and non-linguistic, frequency is only one of the several factors that can affect the developing phonological system and its outcomes in child spoken forms. Clearly, no frequency-based explanation can account for the chain shift exemplified in (8) or other patterns, such as consonant harmony or velar fronting.

4.3 *Interim discussion*

The approaches briefly addressed above far from exhaust the range of proposals available in the literature. Nonetheless, they express relatively clear views of child phonology, each of which highlights crucial areas of consideration about child phonological data. Each of these proposals, however, faces a number of relatively similar challenges, especially since they often neglect to situate the patterns observed in their larger context, that of an emerging system influenced by a variety of independent factors, whose combined effects may at times yield phonologically unexpected, yet entirely logical outcomes (Rose 2009). For example, Hale and Reiss's (1998) general argument against the validity of child language production data for theoretical investigation is based on a *prima facie* interpretation of these productions, without much consideration for the grammatical factors that may contribute to them.

While the most central object of study in both phonology and phonological development should evidently be the grammatical system, this system is connected to a series of perception- and production-related mechanisms, each of which has a potential influence on the shape of the developing lexicon and its manifestation in child speech. In light of this, we suggest that the ideal approach to phonological development should encompass all relevant considerations, a number of which are discussed in the next section.

5 Building a path between speech perception and phonological productions

During the first decade of the 21st century, some of the patterns observed in child phonological productions have been reconsidered in their larger context.

For example, thanks to recent advances in research on infant speech perception, we now know more about the shape of the emerging lexicon (e.g. Yoshida *et al.* 2009 for recent developments) and how pressures from the ambient language may impact productive abilities (e.g. Edwards *et al.* 2004). The variability observed within and across developmental paths has been assessed from learnability and grammatical perspectives (e.g. Dresher 1999 as well as contributions to Goad and Rose 2003 and to Kager *et al.* 2004). A positive result from this literature is the fact that grammatical explanations for some apparently puzzling patterns observed in children's productions now incorporate elements from both speech perception and production. In sum, the grammar no longer bears sole responsibility for differences between child and adult phonology, and child language productions can be better reconciled with phonological theories based on patterns in adult language.

5.1 *The development of lexical representations*

The question of the emergence of lexical representations and how they relate to the remainder of the phonological grammar is at the center of many current questions. A review of the recent literature on this topic reveals a promising convergence of interests between theoretical and experimental linguists and psychologists (e.g. Pater *et al.* 2004; Kager *et al.* 2007; Yoshida *et al.* 2009). Recent highlights from this literature strongly suggest that the child's early lexicon is phonetically detailed but lacks phonological sophistication. Related models of categorization also suggest that segmental and prosodic categories emerge from implicit computations of the types of phonetic distributions that appear in the early "phonetic" lexicon (e.g. Pierrehumbert 2003; Werker and Curtin 2005).

These proposals support Macken's (1980) contention that early input representations may contain artifacts of the child's misunderstanding of some of the phonotactics that exist in the adult language. Similar positions have been taken by Locke (1983), Menn (1983), Waterson (1987), Levelt (1994), and Vihman and Croft (2007), amongst others. Within the generative framework, Goad and Rose (2001, 2004) and Fikkert and Levelt (2008) establish explicit relationships between the child's developing phonological representations and the types of error patterns observed in early phonological productions. For example, Goad and Rose (2001, 2004) propose that prosodic representations gradually emerge in the lexicon through the child's implicit analysis of the distributional evidence available from the words stored within the (still developing) lexicon. While obstruent + sonorant onsets (e.g. [pr tr kr]) display clearly rising sonority profiles, this is not the case for s + consonant onsets, which show different sonority profiles, including flat (or, arguably, falling) sonority s + obstruent clusters (e.g. [sp st sk]; cf. [sl sr sw]). Goad and Rose propose that children may be temporarily misled by superficial aspects of the evidence, and thus develop early syllabic representations on the basis of sonority until the distributional facts are understood, specifically about the types of phonotactics that govern the appearance of s + consonant clusters in these languages.[17]

[17] From a broader perspective, these proposals also support the view that prosodic structure is specified in the developing lexicon (e.g. Colston 1996: 718ff. and references therein).

5.2 *The expression of phonological categories in child language*

Beyond grammatical development, the child's productions are also subject to factors pertaining to physiological growth and motor control, the effects of which must also be considered in any interpretation of child language production data.

Productive abilities figure prominently in works focusing on the transition between late babbling and early word productions. For example, Kern and Davis (2009) show that children learning different languages gradually attune their general productive abilities to the types of consonant and vowel combinations that are the most prominent in the ambient language. This literature thus emphasizes the child's progressive gain in control of his/her speech articulations. Also focusing on articulatory factors, Vihman and Croft (2007) highlight the fact that children's usage of early words and their pronounced forms are generally constrained by motor limitations that are gradually overcome during the course of development. These proposals, based on children's babbling and earliest word productions, suggest that basic biomechanical pressures that hinder early phonological production gradually give way to the types of articulations that are required to reproduce faithfully the full range of phonotactics found in the target language.

Data from slightly older learners, however, suggests that the link between lexical representations and related word productions is generally less direct. For example, in their explanation of positional velar fronting, Inkelas and Rose (2008) propose an interaction between grammatical and articulatory factors. Positional velar fronting consists of the pronunciation of velar consonants as coronal in prosodically strong positions (e.g. in word-initial or otherwise stressed onsets), but not in weak positions (e.g. non-initial onsets of unstressed syllables; codas), as exemplified in (9) (see also Chiat 1983; Stoel-Gammon 1996; McAllister 2009; see §4.2.2 above).

(9) *Positional velar fronting* (Inkelas and Rose 2008)

a. *Prosodically strong onsets*

['tʰʌp]	*cup*	1;09.23
['doː]	*go*	1;10.01
['hɛksəˌdɔn]	*hexagon*	2;02.22

b. *Prosodically weak onsets; codas*

['maɪŋki]	*monkey*	1;08.10
['bejgu]	*bagel*	1;09.23
['pædjɔk]	*padlock*	2;04.09

As already mentioned in §3.2, Inkelas and Rose (2008) point out that positional velar fronting is unexpected from a theoretical standpoint, since positional segmental neutralization in adult phonology generally occurs in prosodically weak, rather than strong, positions. In an analysis that reconciles the pattern with phonological theory, Inkelas and Rose argue that positional velar fronting derives from an interaction between the child's developing grammar and grammar-external, articulatory factors. They propose that children who display positional velar fronting are in fact attempting to produce stronger articulations in prosodically strong contexts. However, because of a combination of physiological and motor factors (proportionally larger tongue body, shorter palate, limited control of tongue articulations), the strengthening of target velars results in an articulation that extends too far forward, into the coronal area of the hard palate, yielding a fronted velar release.[18]

Inkelas and Rose's (2008) proposal potentially extends to the analysis of other apparently problematic positional substitutions. For example, in the pattern of positional stopping illustrated in (10), target fricatives undergo stopping in prosodically strong but not weak positions.

(10) *Positional stopping* (Chiat 1989; Rvachew and Andrews 2002; Marshall and Chiat 2003)

a. *Stopping in prosodically strong onsets*

[bɪˈp̱ɔ]	'before'
[ˈḏu]	'zoo'
[kəˈṯino]	'casino'

b. *No stopping in other (prosodically weak) positions*

[ˈpɜːs̱ən]	'person'
[ˈmɪs̱]	'miss'
[ˈkev̱]	'cave'

While positional stopping may suggest a fairly heavy articulatory component (strengthening of fricative articulations in prosodically strong positions), it also requires a grammatical reference to stress and word edges, in a way similar to that of positional velar fronting.

Grammatical influences, whether they relate to lexical representations or their expression in spoken forms, are also evidenced in long-distance patterns such as consonant harmony (Goad 1997, 2001; Pater 1997; Rose 2000, 2002; dos Santos 2007; Fikkert and Levelt 2008; CHAPTER 72: CONSONANT HARMONY IN CHILD LANGUAGE) and metathesis (e.g. Ingram 1974; Menn 1976; Macken 1996; Velleman 1996; Rose 2000, 2002; dos Santos 2007). For example, in cases of long-distance metathesis, consonantal place or manner features are preserved but swapped across vowels in systematic ways. This is illustrated in (11) by the productions of W, a learner of English, who produces every word-initial target fricative in word-final position (original data from Leonard and McGregor 1991, as reported by Velleman 1996).

(11) *Manner-conditioned metathesis patterns* (Leonard and McGregor 1991)

[uẕ]	'zoo'
[aɪnf̱]	'fine'
[ops̱]	'soap'
[nupis̱]	'Snoopy'
[taps̱]	'stop'

[18] Note that this analysis still applies whether the pattern is fully neutralizing or not (e.g. Edwards *et al.* 1997), as we are in both cases witnessing a difference in articulation that is prosodically driven. See also McAllister (2009) for additional arguments in favor of Inkelas and Rose's (2008) original proposal.

Systematic, word-level distributional patterns of this kind demand a grammatical analysis that transcends perceptual or articulatory factors.[19]

Finally, recent analyses of early word forms by Levelt and van Oostendorp (2007) and Fikkert and Levelt (2008) focus on the emergence of phonological features in the lexicon as well as their interaction in early word productions, which they claim to be responsible for other theoretically intriguing patterns such as consonant harmony. From a formal perspective, this research offers new and interesting ways to provide a bridge between the emergence of phonological representations and their expression in children's early productions.

6 Conclusion

Phonological patterns observed in child language offer a central source of evidence for our understanding of phonology as a grammatical system. However, careful analysis is required, as these patterns can be triggered by a number of potentially conspiring factors, be they perceptual, grammatical, or articulatory, the combination of which may elude limitations imposed by approaches that are theoretically or empirically too narrow. Recent experimental advances, combined with a growing body of scientific literature on child phonological production, show that phonological categories familiar from the literature on adult phonology cannot be taken for granted in the investigation of child language productions, especially at early stages in phonological development. Any analysis of child phonology must therefore question all properties of the child's target language that may affect development as well as consider all of the factors that might influence production throughout the relevant developmental period. This is a complicated challenge for practitioners as well as for the elaboration of theoretical models. However, theoretical simplicity cannot take precedence over the more central consideration of explanatory adequacy.

Several topics have been left aside in the above discussion, including disordered or protracted phonological systems. The characterization of these systems poses its own challenges, despite the fact that many of the patterns discussed above are also attested in clinical data (e.g. Bernhardt and Stemberger 1998 and contributions to Dinnsen and Gierut 2008). One central debate in this context pertains to whether the difference between these and typically developing child phonologies is qualitative or quantitative. While this debate lies outside the scope of this chapter, we contend that a method in which perception, grammar, and production are integrated into the explanation is the best one for all human phonological systems, no matter their characteristics or degree of development.

ACKNOWLEDGMENTS

Several aspects of our work have benefited from discussions with other scholars, especially Heather Goad, François Pellegrino, Sophie Kern, and Marilyn Vihman, as well as from

[19] One could object that [s] is hard to locate temporally in the signal and therefore is particularly prone to perceptual "migration." However, such an observation would not predict why [s] systematically goes to the end of the word, rather than to any other location within the word.

useful comments from two anonymous reviewers, to whom we are indebted. We also want to thank the *Companion*'s editors for their invitation to contribute, as well as for their feedback and support at all stages in the making of this chapter. Of course, all remaining errors or omissions are our own.

102 Category-specific Effects

Jennifer L. Smith

1 Introduction

The lexical categories *noun*, *verb*, and *adjective* are traditionally distinguished by means of distributional (syntactic) and morphological criteria. But in some languages, lexical categories also have distinct phonological behavior. This point has been discussed by Cohen (1964), Postal (1968), Kenstowicz and Kisseberth (1977), Smith (1997, 2001), Myers (2000), and Bobaljik (2008), among others. However, the cross-linguistic typology of phonological differences among lexical categories has not received much systematic investigation.

This chapter surveys category-specific phonological effects, identifying generalizations or patterns where possible. Noun/verb differences are discussed in §2, and the behavior of adjectives is examined in §3. Alternatives to allowing the phonological grammar to refer to category are discussed in §4, but none of them captures all category-specifiic effects.

2 Nouns *vs.* verbs

This section examines the basic distinction between nouns and verbs. (Adjectives, which seem to pattern as an intermediate category, are discussed in §3.)

The examples are organized according to which category shows greater phonological privilege: nouns (§2.1, §2.2), verbs (§2.3), or neither (§2.4). Here, *phonological privilege* is understood to mean the ability to support a greater array of phonological contrasts (CHAPTER 2: CONTRAST), whether this is manifested as a larger number of underlying distinctions, more variety in surface patterns, or a greater resistance to assimilation or other phonological processes (though see §2.2 for additional considerations). Within each section, examples are classified by type of phonological phenomenon. To preview the results (§2.5), noun privilege is the most common pattern, with a few cases each of verb privilege or distinct noun and verb requirements. Prosodic and suprasegmental phenomena are much more common than segmental or featural phenomena.

2.1 Phonological privilege in nouns

In the examples discussed here, nouns show greater phonological privilege than verbs. The phenomena range over suprasegmental and prosodic effects; no straightforward segmental or featural cases of noun privilege have been identified.

2.1.1 Stress, accent, and tone

In Spanish (Romance), stress location (CHAPTER 41: THE REPRESENTATION OF WORD STRESS) is contrastive for nouns but not for verbs (Harris 1983; Garrett 1996). Nouns have stress on the antepenultimate, penultimate, or final syllable; near-minimal pairs exemplifying antepenultimate and penultimate stress are shown in (1a). Verbs may appear with penultimate or final stress, but the stress location is determined by the verb's inflectional affix.

(1) *Stress location in Spanish*

a. *nouns: contrastive stress* (data from Castillo and Bond 1948; Solá 1981)

antepenultimate		*penultimate*	
['saβana]	'sheet'	[sa'βana]	'savanna'
['kaskara]	'husk'	[kas'kaða]	'waterfall'
['tortola]	'dove'	[tor'tuɣa]	'turtle'
['bispera]	'eve'	[es'pera]	'wait'

b. *verbs: stress determined by inflection* (data from Garrett 1996: 72–73)

['laβ-o]	'wash-1SG.PRES.INDIC'	[la'β-e]	'wash-1SG.PRET.INDIC'
['laβ-a]	'wash-3SG.PRES.INDIC'	[la'β-o]	'wash-3SG.PRET.INDIC'

Modern Hebrew (Semitic) has a similar pattern; nouns have stress contrasts, but verb stress is predictable (Becker 2003).[1]

A case resembling Spanish, but for pitch accent, is Tokyo Japanese (Japonic; McCawley 1968; CHAPTER 120: JAPANESE PITCH ACCENT). In nouns, accent location is contrastive. Accent, realized as a pitch fall, may appear on any syllable, and there are minimal sets among disyllabic nouns. For verbs, there is a contrast between accented and unaccented stems, but the accent location is determined by the affix category. (The principles governing verb accent location are complex; see McCawley 1968.)

(2) *Pitch-accent location in Tokyo Japanese* (data from Hirayama 1960)

a. *nouns: accent location and presence/absence both contrastive* (*-ga* marks nominative case; included to distinguish final accent from unaccented)

initial accent		*final accent*		*unaccented*	
[háʃi-ga]	'chopsticks'	[haʃí-ga]	'bridge'	[haʃi-ga]	'edge'
[káki-ga]	'oyster'	[kakí-ga]	'fence'	[kaki-ga]	'persimmon'
[kíbi-ga]	'millet'	[kibí-ga] 'sensation' ~ [kimí-ga]		[kimi-ga]	'you (INFORMAL)'

[1] See §3.2 below for further discussion of the Hebrew case, in which adjectives show a pattern intermediate between the noun and verb patterns.

b. *verbs: accent presence/absence contrastive, but location determined by affix*

accented stem		*unaccented stem*	
[kaké-ɾɯ]	'hoist-NON-PAST'	[kake-ɾɯ]	'be lacking-NON-PAST'
[káke-te]	'hoist-GERUND'	[kake-te]	'be lacking-GERUND'
[kake-nágaɾa]	'hoist-while'	[kake-nagaɾa]	'be lacking-while'

Similar patterns, in which nouns have more contrastive pitch accent choices than verbs, include other Japanese dialects (Haraguchi 1977), Proto-Korean (isolate?; Whitman 1994), Xibe (Tungusic; Kubo 2008), and Ancient Greek (Greek; Devine and Stephens 1994).

Finally, an analogous pattern can be found for tone (CHAPTER 45: THE REPRESENTATION OF TONE). In Mono (Niger-Congo, Banda; Olson 2005), nouns have lexically specified tone shapes. By contrast, verb surface tone patterns are predictable from their inflectional forms, although there is evidence from deverbal derivational forms that even verbs may have underlying tone contrasts.

(3) *Tone in Mono* (Olson 2005: 47–49, 51)

a. *nouns: any tone shape possible*

[gósá]	'type of green'	[kākó]	'leaf'	[bùdú]	'buttocks'
[zúwā]	'flour'	[lèngā]	'slit drum'	[zājā]	'anvil'
[lóbà]	'clothes'	[jāwò]	'firewood'	[gbādò]	'grub'

b. *verbs: tone determined by inflection*

Non-future:	H on first verb syllable; L on any other syllables
Future:	H on syllable preceding verb; L on all verb syllables
Imperative:	L on first verb syllable
Subjunctive:	M on first verb syllable
Stative:	Reduplicate first verb syllable; reduplicant bears HL; verb root bears L
Certainty:	Reduplicant bears HM; M on first verb-root syllable; L on any other syllables

Other languages in which nouns have more tone contrast possibilities than verbs (in complexity of underlying tone, in H tone location contrasts, or in resistance to tonal alternations) include Proto-Bantu and various modern Bantu languages (Kisseberth and Odden 2003) and Gã (Kwa; Paster 2000); see also CHAPTER 114: BANTU TONE.

2.1.2 *Prosodic shape*

In Hebrew (Semitic; Glinert 1988; Bat-El 1994), as well as in closely related Arabic (Semitic; McCarthy 2005; Ryding 2005), verbs are subject to a prosodic-shape restriction – they must fit into one of a number of disyllabic templates. Nouns may be templatic, but they need not be, particularly for loanwords (CHAPTER 95: LOANWORD PHONOLOGY). In (4), atemplatic nouns and verbs derived from those nouns are shown; regardless of the noun shape, the verbs are templatic, being disyllabic and (here) showing the /i e/ of the *piʔel* conjugation.

(4) *Prosodic shape in Hebrew* (Bat-El 1994: 577–578)

a. *nouns: not necessarily disyllabic*

[xantariʃ]	'nonsense'
[telegraf]	'telegraph'
[sinxroni]	'synchronic'
[ksilofon]	'xylophone'
[nostalgia]	'nostalgia'

b. *verbs: must fit disyllabic template*

[xintreʃ]	'talk nonsense'
[tilgref]	'telegraph'
[sinxren]	'synchronize'
[ksilfen]	'play the xylophone'
[nistelg]	'be nostalgic'

A different prosodic-shape effect is found in Mbabaram (Paman; Dixon 1991). Long vowels are relatively rare, but they are found only in nouns, never in verbs.

(5) *Long vowels in Mbabaram nouns* (Dixon 1991: 357)

a. *form with long vowel (noun)*

[guːɽ]	'nulla nulla'
[jaːɽ$^{(ə)}$]	'spear'
[ˈnɔːmbɨ]	'big red wallaroo'
[gaˈwiːr]	'tomahawk'
[namˈbuːɽ]	'big brown snake'

b. *minimally contrasting form, for comparison*

[guɽ]	'elbow'
[ja-ɽə]	'give-PAST'

2.1.3 *Absence of segmental patterns*

All the cases of noun privilege reviewed above involve a suprasegmental or prosodic contrast – tone, accent, or stress, or word shape or size. Even the vowel-length case in Mbabaram is prosodic rather than segmental, on the view that vowel length is not a segmental feature, but results from the association of one segmental melody to two timing units (Clements and Keyser 1983).

One apparent case of noun privilege that does involve segmental features is found in Nivkh (isolate). However, Shiraishi (2004) demonstrates that apparent noun/verb asymmetries in Nivkh can be analyzed in terms of base identity, since nouns can appear unaffixed in Nivkh but verbs cannot. (See §4.1 below for discussion of this point and, more generally, of the relationship between lexical category effects and the distinction between free and bound stems.)

2.2 *Phonological augmentation in nouns*

In several languages, only nouns are subject to word-minimality requirements. This might look like verb privilege, as requirements are imposed specifically on nouns. However, there is one circumstance in which phonological privilege correlates with special requirements: positional augmentation (Smith 2002), in which a privileged position is required to have some perceptually salient property.

Positional augmentation is technically a type of neutralization, because all instances of position *P* must have property *X* – but unlike other types of neutralization, it is a diagnostic for phonological strength.

Word minimality has been analyzed as a requirement for a (morphological) word to be coextensive with a prosodic word (Prince 1980; Broselow 1982; Crowhurst 1992; CHAPTER 51: THE PHONOLOGICAL WORD). Content morphemes are often subject to minimality effects in contrast to function morphemes, supporting the classification of minimality effects as positional augmentation (CHAPTER 104: ROOT–AFFIX ASYMMETRIES). Thus, the noun-specific minimality effects discussed here are compatible with the claim that nouns have greater phonological privilege than verbs.

Chuukese (Micronesian; Muller 1999) is one language in which nouns, but not verbs, are subject to a bimoraic word-size minimum. There is a general requirement, affecting both nouns and verbs, that the expected word-final mora not surface, so underlying final vowels are deleted if short and shortened if long. Crucially, when this truncation process would result in a monomoraic surface form, nouns undergo vowel lengthening. This results in a surface contrast between CVC and CV:C for verbs, but not for nouns, because potential *CVC nouns surface as CV:C.

(6) *Word-minimality in Chuukese* (final codas do not contribute weight; initial geminates do)

a. *nouns: minimally bimoraic* (Muller 1999: 395)

	UR	*Final mora loss*		
CCVC already bimoraic	/kkeji/	[kkej]	'laugh'	
	/ʧʧara/	[ʧʧar]	'starfish'	
*CVC undergoes lengthening	/fasa/	[fa:s]	'nest'	*[fas]
	/fæne/	[fæ:n]	'building'	*[fæn]

b. *verbs: no bimoraic minimum* (data from Goodenough and Sugita 1980: xiv–xv)

[fan]	'go aground'	[fa:n]	'break open'
[mær]	'move, be shifted'	[mæ:r]	'grow (plant)'

See also §4.1.2 for a discussion of Chuukese in the context of the morphological free/bound distinction and category-specific phonology.

Other languages in which nouns, but not verbs, have minimality requirements include Chukchee and Koryak (Chukotko-Kamchatkan; Krause 1979).

2.3 *Phonological privilege in verbs*

The languages in §2.1 are clearly classifiable as cases of noun privilege, since nouns allow more contrasts than verbs. Given that augmentation processes specifically target privileged positions, the cases in §2.2 are also compatible with the view that nouns are privileged compared to verbs. The languages considered in this section, however, present a different pattern; they seem to show greater phonological privilege for verbs than for nouns.

2.3.1 *Tone*

In Ewe (Kwa; Ansre 1961) nouns, the contrast between H and L tone is neutralized in syllables with voiced obstruent onsets; only L is possible in that context (CHAPTER 97: TONOGENESIS). However, verbs may have H or L tone with any onset type.

(7) *Consonant/tone co-occurrence restrictions in Ewe* (Ansre 1961: 27–28, 34–35, 39)

a. *nouns: voiced obstruent onset may not co-occur with H tone*[2]

voiceless obstruents	[ɸú]	'bone'	[ɸù]	'sea'
	[tú]	'gun'	[tè]	'yam'
sonorants	[jí]	'cutlass'	[à-jè]	'trick'
	[ŋɔ́]	'worm'	[à-ŋè]	'rubber'
voiced obstruents	(H unattested)		[βù]	'blood'
			[dà]	'snake'

b. *verbs: onsets and tones co-occur freely*

voiceless obstruents	[fá]	'is cold'	[fù]	'is white'
	[tú]	'to shut'	[tù]	'to grind'
sonorants	[jɔ́]	'to call'	[jɔ̀]	'to hurry'
	[ŋé]	'to break'	[ŋè]	'to groan'
voiced obstruents	[bú]	'to be lost'	[bù]	'to respect'
	[vó]	'to rot'	[vò]	'to be free'

Verbs thus have a greater number of surface tone contrasts than nouns.

2.3.2 *Segmental deletion?*

A small number of cases may involve verb privilege in resisting segmental deletion (CHAPTER 68: DELETION). These are unusual in two ways: noun privilege seems to be much more common than verb privilege, and category-specific phenomena tend to be suprasegmental or prosodic, rather than segmental or featural. In fact, the cases discussed here are not unambiguous examples of segmental deletion, and at least one might be re-analyzed as noun augmentation rather than verb privilege.

One apparent example of segmental deletion that affects nouns, but not verbs, is seen in Paamese (Oceanic; Crowley 1997: 243–244). Proto-Paamese */l/ was lost in northern Paamese in a variety of environments, including word-initially, but word-initial */l/ has been preserved in verbs specifically.

(8) *Loss of initial */l/ in northern Paamese does not apply to verbs* (Crowley 1997: 243–244)

a. *nouns show loss of initial */l/*

*leiai	→	[eiai]	'bush'
*la:la	→	[a:la]	'kind of bird'

b. *verbs preserve initial */l/*

*leheie	→	[lehei]	's/he pulled it'
*loho	→	[loh]	's/he ran'
*la:po	→	[la:po]	's/he fell'

Liquid onsets, being high in sonority, are marked, especially in word-initial position (Smith 2002; see also CHAPTER 49: SONORITY; CHAPTER 55: ONSETS; CHAPTER 31:

[2] Some noun examples are slightly modified from Ansre (1961). Ansre shows these L-tone examples for voiceless obstruents and sonorants with a specifier [lá], glossed 'the' ([ɸū lá] 'the sea'), in order to demonstrate that the L tone has a mid allotone when non-final. I have removed the specifier and adjusted the gloss and tone marking, because the distinction between allotones of L is not of concern here.

LATERAL CONSONANTS). Thus in Paamese we seem to have a case where a marked segment is tolerated in verbs even though it is not tolerated in nouns. If this is the correct interpretation, Paamese would be a case of greater phonological privilege for verbs. However, the avoidance of high-sonority onsets is arguably another kind of augmentation effect (Smith 2002; see also de Lacy 2001), providing a sharp sonority increase for syllables in prominent positions. Thus, a second interpretation is possible, according to which the avoidance of initial liquids in nouns is evidence for noun privilege after all. Moreover, viewing initial */l/ loss in nouns as driven by sonority (i.e. syllable structure) requirements would bring Paamese into line with the general observation that category-specific phenomena are prosodic rather than segmental.

Another example that might involve segmental deletion is Mohawk, in which, according to Postal (1968), word-final stops were lost in nouns (except reduplicating animal names), although they were retained in morphologically related verbs (CHAPTER 36: FINAL CONSONANTS). This does appear to be a phonological process affecting specifically nouns and not verbs – a case of verb privilege. However, it is unclear whether segmental deletion is the best characterization of the process. Postal's examples are compatible with the view that the driving force behind the noun deletion was word-final cluster simplification, which again is a matter of syllable structure, not segments per se.

2.4 Distinct restrictions on nouns and verbs

This section presents cases in which neither nouns nor verbs appear to have a greater array of phonological contrasts; both categories are subject to some phonotactic requirement. However, the requirements that hold of nouns and those that hold of verbs are distinct.

2.4.1 *Stress assignment*

In Lenakel (Oceanic; Lynch 1975, 1978), primary stress is always penultimate, but secondary stress assignment is different for nouns and verbs. In nouns, secondary stresses are assigned on alternating syllables *leftward* from the primary stress, and initial syllables might not bear stress. In verbs, the initial syllable always bears a secondary stress (unless the second syllable has primary stress), and additional secondary stresses are assigned on alternating syllables *rightward* from the initial syllable, subject to the condition that no secondary stress immediately precedes the primary stress.

(9) *Stress assignment in Lenakel* (Lynch 1978: 19)

a. *nouns: secondary stress assigned leftward from primary stress syllable*

/kamatoa/	[ˌka.ma.'do.a]	'kind of taro'
/nimʷakilakil/	[nɨ.ˌmʷɒ.gə.'la.gəl]	'beach'
/tupʷalukaluk/	[tu.ˌbʷɒ.lu.'ga.lukʰ]	'lungs'

b. *verbs: secondary stress assigned rightward from initial syllable*

/r-ɨm-olkeikei/	[ˌri.mɔl.'gɛj.gɛj]	'he liked it'
/n-ɨm-ar-olkeikei/	[ˌnɨ.ma.rɔl.'gɛj.gɛj]	'you-PL liked it'
/n-ɨm-am-ar-olkeikei/	[ˌnɨ.ma.ˌma.rɔl.'gɛj.gɛj]	'you-PL were liking it'
/t-n-ak-am-ar-olkeikei/	[ˌtɨ.na.ˌga.ma.rɔl.'gɛj.gɛj]	'you-PL will be liking it'

A similar, although less straightforward, case is English (Germanic; Kelly 1988; see also Chomsky and Halle 1968), which has a preference (not a requirement) for initial/trochaic stress in disyllabic nouns *vs.* final/iambic stress in disyllabic verbs. See §4.3 below.

2.4.2 *Tonal patterns*

In Lamang (Chadic; Wolff 1983), both nouns and verbs have predictable tone, but different factors determine the surface tones in each case (10). Noun tones are determined by the onset consonant, interacting with phrase-level and assimilatory effects. The basic pattern is that tone is low when the onset is a voiced obstruent (as for nouns in Ewe; see §2.3.1), and tone is high[3] when the onset is a sonorant, a voiceless obstruent, or one of [ɓ] or [ɗ], which Wolff (1983: 28) describes as "laryngealized" but "only . . . incidentally 'implosive' on some occasions." Verb tones, on the other hand, are entirely determined by inflectional category, except for two exceptional verb roots that pattern like nouns.

(10) *Predictable tone patterns in Lamang* (Wolff 1983: 67–68, 77)

a. *nouns: L after voiced obstruent, H otherwise*

voiced obstruents (L)		*voiceless obstruents (H)*		*sonorants (H)*	
[ɣ̱ʷà]	'mountain'	[ɬ̱á]	'cow'	[éw̱é]	'mouth'
[ḏẕə̀v̱ò]	'hand'	[úṯáḵá]	'country'	[ɪhkíḻí]	'rat (sp.)'

b. *verbs: tone determined by inflectional category*

[kə̀lì]	'I take (CONT)'	[kə́lí]	'I take (DUR CONT)'
[kàkə̀lì]	'I have begun to take (PERF II)'	[kákə́lí]	'I have taken (PERF I)'
[kə̀làjò]	'that I take (SUBJ I)'	[kə̀láјó]	'I took (AORIST)'

Lamang is typologically unusual, in that, unlike nouns and verbs, function morphemes do have contrastive tones (Wolff 1983: 74). It is more common typologically for lexical morphemes to have greater freedom in phonological contrast than function morphemes have (McCarthy and Prince 1995: §6.2; Beckman 1999; CHAPTER 104: ROOT–AFFIX ASYMMETRIES). Lamang ideophones, which Wolff calls "expressives," also have contrastive tones.

2.4.3 *Prosodic shape*

Finally, there are some languages in which prosodic-shape restrictions are found for both nouns and verbs, but the restrictions are different for the two categories.

One example, discussed by McCarthy (2005), is Classical Arabic (Semitic; CHAPTER 108: SEMITIC TEMPLATES). As mentioned in §2.1.2, all verbs in Arabic are templatic; most nouns are templatic as well. McCarthy (2005) shows that different restrictions on template shape hold for nouns and for verbs. Noun templates may only begin with one consonant, but verb templates may begin with either one or two consonants. On the other hand, verb templates must end with CVC, but noun templates may end with CVC, CV:C, or CVCC.

[3] In some cases a preceding low tone causes this potential high tone to assimilate and become low (Wolff 1983: 67). In addition, there are certain phrase-level dissimilatory effects, as well as an "accent" that may boost tone on the antepenultimate syllable of the phrase. For a summary of predictable tone effects in nouns, see Wolff (1983: 72).

(11) *Template shape in Arabic* (McCarthy 2005: 178, 209)

a. *noun templates: no initial* CC; *may end with* CVC, CV:C *or* CVCC

Triliteral	*Quadriliteral*
CV CVC	CVC CVC
CV: CVC

CV CVC	CVC CVC	CV: CVC
CCV CVC	CCVC CVC	CCV: CVC

Another language in which prosodic-shape requirements affect nouns and verbs differently is Itelmen (Bobaljik 1998, 2008). In nouns, a "resonant" consonant (sonorants and [z]) must be adjacent to a vowel; otherwise, a preceding schwa is epenthesized. Nouns consequently show schwa–zero alternations, since the environment for epenthesis is met in some morphological forms but not in others (CHAPTER 26: SCHWA; CHAPTER 67: VOWEL EPENTHESIS). In verbs, resonants likewise never violate this restriction, but there are no schwa–zero alternations. According to Bobaljik's interpretation, schwa epenthesis overapplies in verbs, in that it applies to *all* forms of a verb if its environment is met in *some* form.

(12) *Schwa epenthesis in Itelmen* (Bobaljik 2008: 44)

a. *nouns: epenthesis and alternations*

[ɬxəm]	'sable-SG'	[ɬxm-en']	'sable-PL'
[spəl]	'wind-DIRECT'	[spl-ank]	'wind-LOCATIVE'
[ʷtχəz-xʔal]	'road-ABLATIVE'	[ʷtχz-enk]	'road-LOCATIVE'

b. *verbs: no alternations; overapplication of epenthesis*

[t-zəl-ʧen]	'I gave it.'	[zəl-en]	'You gave it.'	*[zlen]
[t-ɬəm-ʧen']	'I killed them.'	[q-ɬəm-in]	'Kill it!'	*[qɬmin]
[spəl-qzu-in]	'It was windy.'	[spəl-in]	'It was windy.'	*[splin]

The Itelmen pattern involves a prosodic-shape requirement that affects both nouns and verbs: a syllabification restriction on resonants. However, nouns may show morphological alternations with respect to the schwa epenthesis, whereas verbs may not. Bobaljik's (1998, 2008) formal analysis of this pattern has epenthesis apply cyclically in verbs but non-cyclically in nouns; it is therefore only verbs that undergo epenthesis in cases where subsequent affixation would potentially bleed that process. On this approach, it is not immediately clear whether nouns or verbs should be seen to have greater phonological privilege, since both are subject to an epenthesis process. (On the other hand, if the avoidance of alternation is seen as an additional requirement that holds of verbs only, then Itelmen could be a case of noun privilege, as in §2.1.)

Both Classical Arabic and Itelmen have featured in discussions of base identity as an alternative to category-specific phonology; see §4.1.2 below.

2.4.4 Absence of patterns involving segmental contrasts

As with the examples of noun privilege discussed in §2.1 and §2.2, the languages with distinct predictable patterns for nouns and verbs seem to involve exclusively suprasegmental and prosodic properties such as stress, tone, and syllable structure. One language that has been said to have different segmental inventories in nouns and verbs is Michif (Bakker 1997). However, this difference would probably not strictly speaking be a lexical category effect, as Michif is a mixed language in which nouns and verbs tend to derive from distinct source languages, Canadian French (Romance) and Plains Cree (Algonquian) respectively. Furthermore, Rosen (2007) argues that French/Cree stratification is not synchronically relevant for Michif phonology.

2.5 *Summary: Survey of category-specific effects*

The category-specific effects reviewed in §2, involving differences in phonological behavior between nouns and verbs, are summarized in Table 102.1.

Noun privilege (plus noun augmentation, which is arguably related to noun privilege) appears to be the most common pattern, with fewer cases of verb privilege and distinct predictable patterns for nouns and verbs. Nearly all of these examples of category-specific phonological behavior involve either suprasegmental properties like stress, accent, and tone, or else prosodic shape (word-minimality, word or syllable shape, or vowel length). The only cases possibly involving segmental phenomena that have emerged in this survey are the two examples of diachronic segment deletion specific to nouns, and, as noted in §2.3.2, these may be reinterpretable as prosodic effects as well.

Table 102.1 Noun/verb differences in phonological behavior

Language	*Phenomenon*	*N/V pattern*
Spanish Hebrew Japanese Proto-Korean Xibe Ancient Greek Mono Proto-Bantu Hebrew Mbabaram	stress stress accent accent accent accent tone tone prosodic shape prosodic shape	N privilege
Chuukese Chukchee, Koryak	prosodic shape prosodic shape	N augmentation
Paamese	diachronic segment deletion(?)	V privilege?/N augmentation?
Ewe Mohawk	tone diachronic segment deletion(?)	V privilege
Lenakel Lamang Arabic Itelmen	stress tone prosodic shape prosodic shape	distinct but predictable

3 Adjectives

Adjectives are in a sense intermediate between nouns and verbs morphosyntactically, and their phonological behavior reflects this. In some languages, adjectives fall together either with nouns or with verbs in terms of their phonology, and the grouping they form often correlates with the nature of adjectival inflectional morphology in the language (§3.1). In other languages, adjectives have "partial privilege" – they lie between nouns and verbs on a continuum of phonological behavior (§3.2).

3.1 *Adjectives as a subcase of nouns or verbs*

In a language with category-specific phonological patterns, adjectives often pattern with either nouns or verbs in a way that mirrors their categories of inflection (see Table 102.2).

When adjectives inflect for N-type morphological categories such as person, gender, number, or case – as in Spanish, Mono, Mbabaram, and Hebrew, Table 102.2(a) – they tend to pattern phonologically with nouns. Analogously, when adjectives inflect for V-type categories such as tense, mood, or aspect – as in Japanese and Ewe, Table 102.2(b) – they tend to pattern phonologically with verbs.

The languages in Table 102.2(c) present additional complications, however. In Hebrew, adjectives inflect for nominal categories, but their behavior with respect to stress is actually intermediate between that of nouns and verbs. Mandarin (Sino-Tibetan) is a language that does not have much of an inflectional system at all, but here again, adjectives show a pattern that is distinct from both nouns and verbs. These two cases are discussed in §3.2, along with an additional case, Finnish (Finnic), which shows distinct behavior between nouns and adjectives even when they bear the *same* inflectional morphemes. Finally, Lenakel (see §2.4.1 above) appears to show a tight correlation between inflectional morphology and category-specific phonology; this language is discussed further in §4.2 below.

Table 102.2 Adjective behavior and inflection type

Language	*Phenomenon*	*N/V pattern*	*Adjective behavior*	*Adjective inflection*
a. Adjectives pattern with nouns				
Spanish Mono Mbabaram Hebrew	stress tone prosodic shape prosodic shape	N privilege	same as N	N-type
b. Adjectives pattern with verbs				
Japanese Ewe	accent tone	N privilege V privilege	same as V	V-type
c. Pattern is more complicated				
Hebrew Mandarin Lenakel	stress reduplication stress	N privilege distinct distinct	N > A > V distinct depends on role?	N-type isolating language depends on role?

3.2 *Adjectives as an intermediate category*

Many languages show adjectives patterning together with either nouns or verbs, but Hebrew stress, Mandarin reduplication, and Finnish mutation and deletion are phonological phenomena in which adjectives have their own specific pattern. These cases nevertheless suggest that, even when adjectives show distinct behavior, they fall at a point intermediate between nouns and verbs with respect to phonological privilege.

Becker (2003) discusses stress in Hebrew, in which nouns, adjectives, and verbs all show distinct behavior. The default is "mobile" stress, in which stress is attracted to the right edge of the word: mobile stress falls on the final syllable of an unaffixed form, or on the rightmost suffix. All verbs have mobile stress. Adjectives and nouns differ from verbs; they have a phonological contrast between mobile stress and "fixed" stress, a pattern in which stress remains on a particular syllable of the base. But there is a further difference between adjectives and nouns. When adjectives have fixed stress, it always falls on the root-final syllable, whereas the location of fixed stress is contrastive for nouns.

(13) *Stress contrasts in Hebrew* (Becker 2003: 1–2)

a. *nouns: location of fixed stress is contrastive*

mobile stress			
[dik'duk]	'grammar-SG'	[dikduk-'im]	'grammar-PL'
fixed stress			
['kopirajter]	'copywriter-SG'	['kopirajter-im]	'copywriter-PL'
[dik'tator]	'dictator-SG'	[dik'tator-im]	'dictator-PL'
['tut]	'strawberry-SG'	['tut-im]	'strawberry-PL'

b. *adjectives: fixed stress is always root-final*

mobile stress			
['tov]	'good-SG'	[tov-'im]	'good-PL'
fixed stress			
[mal'jan]	'rich-SG'	[mal'jan-im]	'rich-PL'
[fono'log-i]	'phonological-SG'	[fono'log-i-im]	'phonological-PL'

c. *verbs: always mobile stress*

[ʃa'mar]	'keep-SG'	[ʃamr-'u]	'keep-PL'
[biz'bez]	'spend-SG'	[bizbez-'u]	'spend-PL'

As Becker (2003) observes, this means that adjectives have greater phonological freedom than verbs, but not as much as nouns.

In Mandarin, nouns, adjectives, and verbs show distinct behavior in reduplication (Feng 2003; see also CHAPTER 100: REDUPLICATION). Disyllabic (AB) adjectives reduplicate as AABB, while disyllabic verbs reduplicate as ABAB. (Disyllabic nouns do not reduplicate, although monosyllabic nouns do.) Some adjective or verb bases reduplicate both ways, in which case the AABB form is an adjective, and the ABAB form is a verb.

(14) *Reduplication in Mandarin* (Feng 2003: 2)[4]

a. *adjectives:* AB → AABB

[kán.tɕîŋ]	'clean'	[kán.kán.tɕîŋ.tɕîŋ]	'clean (intensified)'
[mʲǐŋ.pǎi]	'clear'	[mʲǐŋ.mʲǐŋ.pǎi.pǎi]	'clear (intensified)'

b. *verbs:* AB → ABAB

[tɕʰîŋ.ʈʂʷû]	'celebrate'	[tɕʰîŋ.ʈʂʷû.tɕʰîŋ.ʈʂʷû]	'celebrate a little'
[tǎ.sàw]	'clean up'	[tǎ.sàw.tǎ.sàw]	'clean up a little'

c. *shape of reduplicated form determines category*

adjective base	[kāw.ɕîŋ]	'happy'
AABB = adjective	[káw.kǎw.ɕîŋ.ɕîŋ]	'happy (intensified)'
ABAB = verb	[káw.ɕîŋ.káw.ɕîŋ]	'have some fun'
verb base	[ʈʂǐ.tʲɛ̀n]	'suggest'
AABB = adjective	[ʈʂǐ.ʈʂǐ.tʲɛ̀n.tʲɛ̀n]	'critical, bossy'
ABAB = verb	[ʈʂǐ.tʲɛ̀n.ʈʂǐ.tʲɛ̀n]	'comment here and there'

Feng (2003: 7) presents evidence from third-tone sandhi alternations (CHAPTER 107: CHINESE TONE SANDHI) that the morphosyntactic bracketing in the two cases is distinct; namely [A[AB]B] (adjectives) but [AB][AB] (verbs). She sees this as driving the difference between adjective and verb reduplication; for verbs, it is more important for the edges of morphosyntactic constituents to align with the edges of prosodic constituents (on the assumption that all four-syllable reduplicated forms have the prosodic constituency (σσ)(σσ)), whereas, for adjectives, it is more important that the linear sequence AB from the base form not be disrupted. The different structures and their differing priorities are shown in (15).

(15) *Morphosyntactic and prosodic constituents in Mandarin reduplication*

verbs

		A	B	A	B
Morphosyntactic	[		][		]
Prosodic	(		)(		)

Edges match; linear sequence of base not respected

adjectives

		A		A	B		B
Morphosyntactic	[		[			]	]
Prosodic	(			)(			)

Edges do not match; linear sequence of base respected

Mandarin differs from Hebrew because it is not entirely clear in Mandarin whether it is adjectives or verbs that should be seen as having greater phonological privilege; each category has a predictable reduplication type, even though they differ. However, adjectives do set a higher priority for maintaining the linear sequence of the base. From the viewpoint of Optimality Theory (Prince and Smolensky 2004), under Correspondence Theory (McCarthy and Prince 1995), this

[4] Mandarin tone marks are given in accordance with IPA usage, rather than the pinyin transcriptions used by Feng (2003).

suggests higher-ranking faithfulness for adjectives than for verbs, and therefore greater phonological privilege for adjectives.[5]

Finally, Anttila (2002) discusses a category-specific effect in Finnish involving two different phonological alternations: under certain morphological and phonological conditions, a stem-final /a/ either deletes or changes to /o/ (mutates), when the plural morpheme /-i-/ is added. An examination of a corpus of Finnish shows that, in the absence of phonological factors leading to a preference for one strategy or the other (e.g. a tendency to avoid mutation after labial consonants), the mutation option is preferred by nouns and the deletion option is preferred by adjectives. This difference is seen even when nouns and adjectives are inflected with identical affixes.

(16) *Deletion* vs. *mutation in Finnish* (Anttila 2002: 13)

a. *nouns: prefer mutation*

/kihara-i-ssa/	'curl-PL-INESS'	→	[kiharo̱-i-ssa]
/korea-i-ssa/	'Korea-PL-INESS'	→	[koreo̱-i-ssa]

b. *adjectives: prefer deletion*

/kihara-i-ssa/	'curly-PL-INESS'	→	[kiharØ-i-ssa]
/korea-i-ssa/	'beautiful-PL-INESS'	→	[koreØ-i-ssa]

Again, it is somewhat difficult to interpret this pattern in terms of relative phonological privilege, because both mutation and deletion involve a phonological process. However, mutation, the pattern favored by nouns, does preserve all input segments (even though certain feature values are changed), so it is not out of the question to view the correlation between mutation for nouns and deletion for adjectives as a consequence of greater noun privilege.

3.3 Adjective patterns as scale conflation

The examples in §3.1 and §3.2 all appear to be compatible with one of the following scales:[6] adjectives fall together with nouns, fall together with verbs, or exhibit a degree of privilege intermediate between that for nouns and verbs.

(17) *Scales of phonological privilege by lexical category*

a. {N, A} > V
b. N > {A, V}
c. N > A > V

[5] Another interesting point related to lexical categories in Mandarin reduplication is that AB verbs actually reduplicate as ABAB only if both the A and the B morphemes are verbal; V + object (N) forms reduplicate as AAB (Feng 2003: 3).

[6] The scales in (17) assume a more basic scale N > V, with greater phonological privilege for nouns than for verbs. As noted in §2.5 above, cases that seem to show greater privilege for verbs than for nouns appear to be few in number and exceptional in pattern; in particular, two out of three of the cases may involve segmental phonology, which category-specific patterns generally do not. Further investigation is needed to determine whether the scale of privilege N > V is truly a typological (near-)universal, but the intermediate behavior of adjectives reviewed in this section could be seen as additional support for this view.

This pattern resembles *markedness conflation* (de Lacy 2004), in which there is a universal markedness scale X > Y > Z, but on a language-specific basis adjacent levels of the scale can be conflated and pattern as a single class with respect to that markedness dimension (CHAPTER 4: MARKEDNESS; CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). So, positing a universal scale of phonological privilege for lexical categories, as in (17c), is compatible with the existence of languages that conflate the middle category, A, with N (17a) or V (17b).

4 Attempting non-phonological explanations

The discussion so far has focused on demonstrating that there exist languages with category-specific phonological effects. However, important questions remain. Does the phonological grammar actually need to refer to lexical categories? Or can all category-specific effects be reduced to epiphenomena, simple outcomes of the interaction between phonology and other modules of the grammar such as morphology or syntax? Finally, to the extent that there are category-specific effects in phonology, does this require reference to the same lexical category labels used by the morphosyntax, or should it instead be handled in the same way as cases of exceptional phonological behavior by arbitrary classes of morphemes?

This section considers the distinction between morphologically free and bound forms (§4.1), the relationship between nominal or verbal inflection and category-specific behavior (§4.2), prosodic structure (§4.3), and morpheme-specific effects (§4.4). While some of these factors are relevant some of the time, not all cases of category-specific phonology can be re-analyzed in these terms.

4.1 *Free vs. bound*

As seen in Table 102.3, there is often overlap between the lexical categories in a language with phonological privilege, and the lexical categories in that language that occur as free forms (without obligatory overt inflection). Indeed, some of the apparent category-specific effects discussed in the literature have been shown either to reduce directly to the free/bound distinction, or to exhibit base-identity effects that can be formally modeled with reference to the free/bound distinction. Examples of each type are reviewed in §4.1.1.

As shown in Table 102.4, however, some cases of category-specific phonological patterns cannot be directly equated with the distinction between free and bound forms. These are discussed in §4.1.2.

Table 102.3 Phonological privilege matches free/bound distinction

Language	*Phenomenon*	*N/A/V privilege*	*Free/bound*
Japanese	accent	N > A, V	N free | A, V bound
Mono	tone	N, A > V	N, A free | V bound
Mbabaram	prosodic shape	N, A > V	N, A free (absolutive case) | V bound
Lenakel	stress	N, (A) ≠ (A), V	N free | A by function | V bound

Table 102.4 No exact match between phonological privilege and free/bound distinction

Language	*Phenomenon*	*N/A/V privilege*	*Free/bound*
Spanish	stress	N, A > V	N, A free or bound | V bound
Chuukese	prosodic shape	N > V	both N, V free (modulo truncation)
Mandarin	reduplication	N ≠ A ≠ V	N, A, V can all be free
Hebrew	prosodic shape stress	N, A > V N > A > V	N, A free or bound | V bound

4.1.1 *Category-specific effects that reduce to free/bound effects*

It has been argued that some apparent category-specific effects reduce to the distinction between free and bound forms, either directly, as for word-minimality requirements, or indirectly, as for base-identity effects.

In Chuukese (§2.2; see also §4.1.2), minimality requirements truly differentiate between nouns and verbs. However, some cases of apparent category-specific minimality are actually due to the free/bound distinction: if the minimality requirement holds at the level of the word, and (by definition) only free forms can constitute words on their own, then only free forms show minimality effects.

For example, consider Mono (Niger-Congo, Banda). Olson (2005: 75, 79) observes that there are no monosyllabic surface forms of nouns (or adjectives), and proposes a process of Subminimal Root Augmentation (SRA), which epenthesizes a copy vowel into an underlyingly monosyllabic noun: /CV_1/ → [V_1CV_1]. However, Olson (2005: 82) explicitly notes that SRA does not apply to verbs, because verbs must appear with some inflectional affix, so they never happen to be monosyllabic on the surface even if they have a subminimal root. Moreover, Olson (2005: 89, 94) shows that even /CV/ nouns fail to undergo SRA if they bear a plural affix or form part of a compound. In short, there is no need for a category-specific analysis of minimality in Mono. It is simply the case that *words* must be disyllabic; for unrelated reasons, only nouns and adjectives may surface unaffixed, so only they are ever in danger of violating the category-free requirement on word size.

There is another, more abstract way in which the free/bound distinction potentially has implications for privilege in maintaining phonological contrast. In some languages, morphologically complex forms show base-identity effects – phonological similarity to some aspect of their morphological base forms. This has been modeled as phonological cyclicity, or in terms of constraints that enforce faithfulness to morphologically related base forms (e.g. Kiparsky 1982, 2000; Kenstowicz 1996; Benua 2000; CHAPTER 83: PARADIGMS; CHAPTER 85: CYCLICITY). Schematically, suppose that a language has a base form /X/ and a complex form /X + Y/. In the absence of base-identity effects, the phonological grammar simply applies to the segments in /X + Y/ as they appear there. But, if there is a base-identity effect, then some similarity requirement holds between the surface form of [X + Y] and the surface form of its base [X], giving rise to a property of [X + Y] that would not be expected if this form were simply subject to the phonological grammar of the language on its own.

Base-identity effects are relevant in the context of the free/bound distinction because if a root /X/ never appears unaffixed, as *[X], then the non-existent surface form *[X] will never influence the phonology of the morphologically complex /X + Y/. If nouns and verbs differ precisely in this way, such that [N] is a possible surface form but [V] is not, this could potentially lead to differences in the phonology between [N + affix] and [V + affix] forms: [N + affix] forms might show base-identity effects that [V + affix] forms do not show. Such a pattern would not require crucial use of category-specific phonology, however, because the fundamental distinction would instead be that between free and bound forms.

Precisely this argument has been made by Shiraishi (2004) for Nivkh (isolate), in which noun phonology and verb phonology differ in several ways, involving segmental effects (which, as noted above, are rare among category-specific phonological phenomena). Nivkh has a four-way contrast among obstruents: stops and fricatives contrast with each other, and, furthermore, aspirated stops and voiceless fricatives (the "fortis" obstruents) contrast with plain stops and voiced fricatives (the "lenis" obstruents).

(18) *Nivkh obstruent inventory* (Shiraishi 2004: §2.1)[7]

	fortis					lenis				
stops	pʰ	tʰ	cʰ	kʰ	qʰ	p	t	c	k	q
fricatives	f	ř	s	x	χ	v	r	z	ɣ	ʁ

Although these sounds are all contrastive, there are contexts in which neutralization processes override these contrasts (CHAPTER 80: MERGERS AND NEUTRALIZATION). One such case involves the neutralization of the stop–fricative contrast in non-phrase-initial position in a morphologically derived environment (CHAPTER 88: DERIVED ENVIRONMENT EFFECTS): following a vowel, glide, or stop, obstruents surface as fricatives, but following a nasal or fricative, obstruents surface as stops (Shiraishi 2004: §2.1).

An apparent difference between categories appears in a systematic exception to this stop/fricative pattern. Nouns resist changing stem-initial fricatives into stops when a pre-stem morpheme is added. The requirements of morphologically derived environment and non-phrase-initial position are met, but the underlying fricatives still surface as fricatives.

(19) *Hardening in Nivkh* (Shiraishi 2004: §2.1–2)

a. *nouns: resist hardening*

[tʰulv vo]	*[tʰulv bo]	'winter + village'
[cʰŋər vox]	*[cʰŋər box]	'grass + hill'
[təf řə]	*[təf tʰə]	'house + door'
[tʰeŋ vaqi]	*[tʰeŋ baqi]	'coal + box'

b. *verbs: undergo hardening*

[cʰxəf qʰa-]	(< /χa-/)	'bear + shoot'
[cus tʰa-]	(< /řa-/)	'meat + bake'
[tux ke-]	(< /xe-/)	'axe + take'
[pʰnənx təu-]	(< /rəu-/)	'one's sister + teach'

[7] Shiraishi (2004: §2.1) describes /c cʰ/ as (pre-)palatals that are inconsistently characterized in the literature as plosives or affricates. He notes that /r/ and its (partially) devoiced counterpart /ř/ pattern phonologically with fricatives.

Shiraishi argues that the important difference here is that noun stems can appear in isolation, but verb stems require affixation. Thus, only nouns are potentially subject to base-identity effects. In Shiraishi's (2004: §2.4) analysis, the fricative status of the initial consonant in a derived form must match that of its underived base, and this identity requirement takes priority over the usual process of hardening. For verbs, which have no base to enforce identity, hardening applies unimpeded. No reference to lexical category is needed to account for the noun/verb asymmetry. Shiraishi also presents a similar analysis for a second segmental phonology difference between lexical categories in Nivkh, a process of stem-final fricative voicing under suffixation from which nouns are, again, exceptionally exempt.

Base-identity accounts of category-specific patterns have also been developed by Kenstowicz (1996) for cluster simplification in Korean and by Cable (2005) for schwa epenthesis in Itelmen. However, Bobaljik (2008) argues that base identity is not the right way to approach Itelmen; see the discussion in §4.1.2 below. (See also Albright 2008 and Albright and Kang 2008 for a different view of "base" for Korean nouns and verbs.)

Thus, for languages where a phonological difference between nouns and verbs aligns with the distinction between free and bound roots, it is possible that base identity could be invoked instead of category-specific phonological processes. This is a particularly attractive approach to Nivkh, where the phenomenon involved (segmental alternation) is not one that typically participates in category-specific effects. For a case like Mono, where lexical category is empirically less successful than the free/bound distinction for characterizing the environment where the phonological process applies, it is even more clear that appealing to lexical categories is undesirable. However, for the other languages listed in Table 102.3 above, either a base-identity account or a category-specific account appears to be feasible; the choice may come down to theory-internal considerations.

In any case, the free/bound distinction cannot be the source of all category-specific effects. Some languages show category-specific phonology that cannot be handled in terms of differences between morphologically free and bound forms. Examples are discussed in the following section.

4.1.2 *Mismatches with the free/bound distinction*

The difference between free and bound roots is not always consistent with phonological differences between nouns and verbs. This is true when both nouns and verbs are bound, and when both nouns and verbs are free – or, more generally, when some free forms have more phonological privilege than others.

Spanish (§2.1.1) provides evidence that lexical category differences in phonology are possible even among bound roots. It is true that verbs are always bound, while nouns and adjectives need not be. Crucially, however, the lexically contrastive antepenultimate stress pattern occurs even on noun and adjective stems that consist of a bound root and a (productive) gender suffix.

(20) *Spanish bound roots with antepenultimate stress* (data from Castillo and Bond 1948; Solá 1981)

		masculine	*feminine*	
a.	*nouns*	[ˈnawfraɣ-o]	[ˈnawfraɣ-a]	'shipwrecked person'
		[ˈbiɣam-o]	[ˈbiɣam-a]	'bigamist'

b.	*adjectives*	['loβreɣ-o]	['loβreɣ-a]	'murky, dismal'
		['prosper-o]	['prosper-a]	'prosperous'
		[me'toðik-o]	[me'toðik-a]	'methodic'
		['benet-o]	['benet-a]	'Venetian'
		[su'perflu-o]	[su'perflu-a]	'superfluous'
		[pur'pure-o]	[pur'pure-a]	'purple'
		[simul'tane-o]	[simul'tane-a]	'simultaneous'

If noun- or adjective-specific contrast in Spanish were dependent on nouns and adjectives being able to appear as unaffixed forms, these antepenultimate examples would not be possible.

Chuukese (§2.2) provides further evidence that category-specific effects are not always due to the free/bound distinction. In this language, both nouns and verbs may appear unaffixed,[8] and yet only nouns are subject to a minimality requirement. Similarly, Mandarin (§3.2) shows a three-way difference between nouns, adjectives, and verbs in reduplication patterns, but this is a language with essentially no inflectional morphology at all.

An interesting case is the category-specific nature of stress in Hebrew (discussed in §3.2). Both nouns and adjectives may be atemplatic, i.e. morphologically free, but verbs may not. Arguably, status as an atemplatic form is precisely what correlates with the capability for a noun or adjective to take the fixed stress pattern (Becker 2003), because even nouns and adjectives predictably have mobile stress if they are templatic. However, the free/bound distinction cannot account for the further difference between free nouns, in which the location of fixed stress is phonologically contrastive, and free adjectives, in which fixed stress always falls on the root-final syllable.

As noted in §2.4.3, McCarthy (2005) describes a noun/verb difference in template shape in Classical Arabic. McCarthy analyzes this pattern using Optimal Paradigms Theory, a variation on the base-identity approach (§4.1.1), in which similarity is enforced among members of a paradigm even in the absence of a free-standing base form. Bobaljik (2008) calls into question whether McCarthy's approach fully accounts for the Arabic pattern, noting, for example, that it predicts contrasts between noun and verb stem shapes that should be able to emerge under derivation, even if not within inflectional paradigms (see Bobaljik 2008: §3.2.2 for detailed discussion). Regardless of the success of a (quasi-)base-identity approach to template shape, however, it is important to note that McCarthy's analysis, which replaces reference to lexical category with reference to facts about affix shape and template shape, does not address *all* category-specific effects in Arabic. As seen in §2.1.2, the fact remains that nouns may be templatic or atemplatic, but verbs must be templatic. In other words, Arabic nouns still allow a greater degree of phonological contrast in their prosodic shape than verbs do, in a way that stands outside the template system and therefore cannot be derived from the differences between affix inventories for templatic nouns and verbs.

Finally, Bobaljik (2008), discussing Itelmen (described in §2.4.3 above), argues specifically against the attempt to recast all category-specific effects in terms of

[8] As seen in §2.2, both categories are also subject to a final-mora truncation process, so roots do not in fact surface unaltered. However, this process does not distinguish between nouns and verbs, so it cannot be the source of the category-specific phonological difference.

base identity. He shows that some verbs are derived from "category-neutral" roots, which can also be nouns and therefore have a free base form. Nevertheless, these verbs still follow the general verb pattern of schwa epenthesis. This is similar to Chuukese, where verbs are no less free than nouns, but nouns are phonologically privileged. Conversely, some Itelmen nouns have obligatory singular inflection and are therefore not free, but they nevertheless follow the noun pattern of schwa epenthesis. This is similar to Spanish, where nouns and adjectives have greater phonological freedom even when bound. As Bobaljik argues, these two types of mismatch between noun/verb and free/bound show that, in Itelmen, lexical category predicts phonological patterning more accurately than the free/bound distinction does.

In summary, the fact that nouns often appear phonologically privileged as compared to verbs may well be related at some fundamental level to the fact that nouns are cross-linguistically more likely to be free forms. However, attempts to relate these two asymmetries directly, in frameworks that make crucial use of the bound/free distinction to invoke the existence of a morphological base form that accounts for special aspects of noun phonology – or even frameworks that simply make use of differences in the inventories of inflectional morphemes for the two categories to account for phonological differences – are unable to capture the full range of category-specific phonological effects.

4.2 *Inflectional morphology*

As noted in §3, whether adjectives pattern phonologically with nouns or verbs shows a striking correlation with whether adjectives inflect for nominal or verbal categories. A particularly interesting case is Lenakel (see §2.4.1), where adjectives take verbal inflection when they are predicates, but not when they modify nouns (Lynch 1975, 1978). The presence or absence of verbal morphology on adjectives probably determines whether they take on the stress pattern of nouns or that of verbs (John Lynch, personal communication).

Nonetheless, this *correlation* between inflection type and category-specific phonology is not an *explanation*. For example, in Spanish or Mono, it is true that verb stress or tone is entirely determined by the inflectional paradigm (§2.1.1). However, the fact that verbs take inflectional suffixes does not preclude the logical possibility that verb roots might have underlying stress or tone contrasts (which might emerge in some particular inflectional form). That this is often not the case requires explanation; apparently, the phonological grammar does need to enforce the lack of contrast in verbs as a property separate from the fact that individual verbal inflectional morphemes happen to assign stress or tone.

Furthermore, languages like Mandarin, Hebrew, and Finnish (see §3.2) show that adjectives sometimes behave differently from both nouns and verbs – even if they have N-type inflection, as in Hebrew and Finnish.

4.3 *Prosodic structure*

Some apparent category-specific effects can be attributed to prosodic structure. For example, in Digo (Narrow Bantu; Kisseberth 1984), tones originating with the verb may end up on a following noun. However, Kisseberth shows that this is caused by phrase-level tonal phonology; verb tones surface on syllables within the noun because tone-assignment rules refer to the right edges of phonological phrases (CHAPTER 50: TONAL ALIGNMENT).

Kelly (1988) argues that the different stress preferences for disyllabic nouns and verbs in English (§2.4.1) originate in their syntactic and prosodic contexts; nouns prefer initial stress because they are typically preceded by an unstressed determiner, and sequential alternation between stressed and unstressed syllables is desirable. Verbs occur in a distinct syntactic and prosodic context, so they prefer final stress.

While explanations based on prosodic structure may cover some apparent cases of category-specific behavior, however, this approach cannot handle all the diverse cases discussed in §2 and §3.

4.4 *Morpheme-specific effects*

Whether or not they have category-specific phonology, languages generally have morphemes or morpheme classes that exhibit exceptional behavior (Saciuk 1969; see also the discussion in CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE). So, are category-specific effects meaningfully distinct from morpheme-specific effects? Is there a qualitative difference between assigning certain morphemes a phonology-relevant feature named "[−native]" and assigning certain morphemes a phonology-relevant feature named "[+noun]"? While "[−native]" and "[+noun]" might participate formally in the phonological grammar in much the same way, there are arguably important differences between the two. First, lexical categories do, obviously, have significance outside the phonology. If items of the same morphosyntactic category also pattern together phonologically, then allowing the phonology to use the morphosyntactic label captures a generalization that would be missed if an arbitrary, phonology-specific feature were invoked instead. Second, to the extent that the privilege scale N > A > V (§2, §3) is a linguistic (near-)universal, using the morphosyntactic category labels to demarcate phonologically relevant classes predicts their relative ability to support phonological contrast in a way that using arbitrary phonological labels does not.

4.5 *Summary: Alternatives to category-specific phonology*

While there are instances of category-specific behavior that may be accounted for by morphological, prosodic, or other factors, there remains a core of cases that do appear to require reference to lexical category within the phonology.

5 Conclusions

In this examination of category-specific phonological phenomena, a number of patterns have emerged. Many, although perhaps not all, cases are consistent with a universal scale of phonological privilege, N > A > V. Furthermore, the overwhelming majority of cases involve prosodic and suprasegmental phenomena rather than segmental or featural phenomena. Finally, there appear to be correlations between phonological behavior and type of inflection, seen especially in the case of adjectives. However, purely morphological or prosodic factors do not provide adequate accounts for all instances of category-specific phenomena, indicating that the phonological grammar must be able to refer to lexical categories.

In addition to phonology, there are other ways in which lexical categories show differences beyond morphosyntax, especially in child language acquisition and in psycholinguistics; for recent reviews, see e.g. Ogura *et al.* (2006) or D'Odorico and Fasolo (2007) for acquisition, and Rapp and Caramazza (2002) or Mätzig *et al.* (2009) for psycholinguistic evidence from aphasic speakers. Perhaps future research will uncover ways in which category-specific phonology is related to other sources of differentiated behavior among words of different categories.

The full array of facts about category-specific phonology – including the intermediate status of adjectives; the fact that nouns are more likely to be phonologically privileged than verbs, but in some languages both nouns and verbs are subject to equally predictable but nevertheless distinct requirements; and the fact that category-specific phonological differences often parallel, but do not fully match, other differences between categories, such as free-morpheme status – has not yet been captured by any single theoretical approach, including noun faithfulness (Smith 1997, 2001) and the various implementations of base identity or paradigm uniformity (e.g. Shiraishi 2004; McCarthy 2005; Cable 2005; Bobaljik 2008). An intriguing challenge remains for phonological theory.

103 Phonological Sensitivity to Morphological Structure

Jochen Trommer

1 Introduction

Virtually all areas of phonology show extensive sensitivity to morphological structure. Many segmental and tonal processes are restricted to apply only across morpheme boundaries (or only morpheme-internally). Computation of stress typically reflects morphological constituency, and phonotactic generalizations often seem to be restricted to a subset of the morphological material of a given language (e.g. affixes). Thus one of the central questions research on the morphology–phonology interface addresses is what types and amount of morphological structure phonology can access and what consequences this has for phonological processes.

The chapter is structured as follows: in §2, I will introduce the different types of sensitivity which phonology shows to morphological structure. §3 summarizes different ways of reflecting these types of sensitivity in the architecture of the morphology–phonology interface, and §4 discusses possible restrictions on phonological sensitivity to morphology.

2 Types of phonological sensitivity to morphological structure

2.1 *Sensitivity to the presence of a morpheme or morpheme type*

Probably the simplest type of sensitivity phonology can show to morphological structure is the capacity to detect the presence of a morpheme, i.e. to determine for a specific piece of phonological structure which specific morpheme (if any) it belongs to, and which morphological type the morpheme is (noun or verb, root or affix, etc.)

A number of phonological processes are simply sensitive to whether segmental material is part of a morpheme or not. For example, Mohawk (Michelson 1989; Piggott 1998) and Selayarese (Mithun and Basri 1986; Piggott 2001) stress the penultimate syllable of a word if the last syllable contains a vowel with morphological affiliation (1a), whereas stress appears on the antepenultimate if the vowel heading the final or penultimate syllable is not part of a morpheme, i.e. it is epenthetic; see CHAPTER 67: VOWEL EPENTHESIS and (1b) (Selayarese examples from Mithun and Basri 1986: 240; Mohawk examples from Michelson 1989: 41, 44, epenthetic vowels are underlined):[1]

(1)	a.	*Mohawk*	/k-atir-ut-haʔ/ 1SG-ACT-pull-HABIT	[kati'ruthaʔ]	'I pull it'
		Selayarese	/sahala/	[sa'ha:la]	'sea cucumber'
	b.	*Mohawk*	/ʌ-k-r-ʌʔ/ FUT-1SG AGT-fill into-PUNCT	['ʌkerʌʔ]	'I will put it into a container'
		Selayarese	/sahal/	['sa:hala]	'profit'

A typical locus of phonological sensitivity to morpheme type is segmental inventories which are different for different types of morphemes. Thus German inflectional affixes only contain coronal or nasal consonants and the reduced vowel /ə/, whereas lexical roots and derivational affixes also employ labial and dorsal consonants and 23 different vowels. Under the assumption that this asymmetry follows from phonological rules or constraints (e.g. morpheme structure constraints or OT-markedness constraints, cf. CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS), the phonology must minimally "know" which segments belong to inflectional affixes and which do not, to impose the appropriate restrictions on specific morphemes.

Sensitivity to morpheme type is also pervasively attested in effects on prosody and word-minimality. For example, German inflectional affixes can never be stressed, whereas lexical roots have obligatory stress. In the same vein, lexical roots in German have the minimal size of a bimoraic syllable (Golston and Wiese 1998), whereas inflectional affixes consist of light syllables or single consonants/consonant clusters.

A typical case where sensitivity to morpheme type shows up in an alternation context are harmony processes based on an asymmetry between roots and affixes (CHAPTER 104: ROOT–AFFIX ASYMMETRIES). Thus in Wolof, a Niger-Congo language of the Atlantic sub-branch, root and affix vowels agree in the feature [ATR], where the underlying [ATR] feature of roots is systematically retained whereas affix vowels adjust to the root (Pulleyblank 1996: 314–315):

(2)	+ATR		−ATR	
	gən-e	'be better in'	xam-ɛ	'know in'
	re:r-e	'be lost in'	dɛm-ɛ	'go with'
	do:r-e	'hit with'	xɔl-ɛ	'look with'

A standard optimality-theoretic interpretation of these data is that they exhibit positional faithfulness, i.e. faithfulness constraints referring to segments which are part of a root (or root-initial) are ranked higher than faithfulness constraints

[1] Under a derivational account, it could be argued for Mohawk and Selayarese that stress assignment is simply ordered before vowel epenthesis. See Alderete (1999) for detailed arguments that rule ordering accounts for stress–epenthesis interactions of this type are generally problematic.

for affix vowels or general faithfulness constraints (Beckman 1998; McCarthy and Prince 1995). But, whatever the specific implementation is, if the intuition is right that root vowels act differently from phonologically identical affix vowels, then the phonology must be able to access the information as to which vowel belongs to a root and which one to an affix.

An obvious question is to which properties of morphemes phonology can be sensitive. It is well established that phonology tends to reflect the affix/root distinction. A related relevant distinction is that between lexical words and function words (Selkirk 1995). Languages often also treat prefixes and suffixes differently for prosodic restrictions and segmental processes (see Hyman 2008, and references cited there). CHAPTER 102: CATEGORY-SPECIFIC EFFECTS shows that many languages also differentiate phonologically between nouns and verbs. Phonological distinctions often also refer to etymological strata (Itô and Mester 1999; CHAPTER 95: LOANWORD PHONOLOGY) or to arbitrary lexical or exceptional classes (CHAPTER 106: EXCEPTIONALITY). Thus in Finnish, root-final /a/ before suffixal /i/ is raised to [o] in specific roots (3a), while it is deleted with other roots (3b), even though the roots do not differ in any crucial phonological aspect; (3c) is an example of a third class of roots, which sometimes show deletion and sometimes raising (Pater 2009: 9, based on Anttila 2002):

(3)	a.	/tavara-i-ssa/	[tavaroissa]	'thing (PL INESS)'
	b.	/jumala-i-ssa/	[jumalissa]	'God (PL INESS)'
	c.	/itara-i-ssa/	[itaroissa] ~ [itarissa]	'stingy (PL INESS)'

2.2 Sensitivity to morpheme boundaries

Sensitivity to morpheme boundaries can be illustrated with *s*-dissimilation in Swabian German. In Swabian, the contrast between /s/ and /ʃ/ (4a) is neutralized to [ʃ] before all instances of /t/ and /p/ (4b) (Hall and Scott 2007: 154):[2]

(4)		*Standard German*	*Swabian*	
a.	*Saal*	[za:l]	[sa:l]	'hall'
	Schale	[ʃa:lə]	[ʃa:l]	'bowl'
	Bus	[bʊs]	[bʊs]	'bus'
	Rausch	[rauʃ]	[rɔuʃ]	'intoxication'
b.	*Speize*	[ʃpaizə]	[ʃpais]	'food'
	Haspel	[haspə]	[haʃpəl]	'hasp'
	Post	[pɔst]	[pɔʃt]	'mail'
	Fenster	[fɛnstɐ]	[fɛnʃtɐ]	'window'

However, if there is a morpheme boundary between underlying /s/ and /t p/ (or /b/) the process is blocked (Hall and Scott 2007: 158):

[2] As shown by the first example in (4a), the /s/~/z/ contrast of Standard German is neutralized to /s/ in Swabian. Standard German also exhibits s-dissimilation, but only word-initially (cf. the first example in (4b)).

(5)

	Swabian	
Kinder-Brei	[kendlesbrəi]	'pap'
miss-trauen	[mistrəuə]	'mistrust'
pass-t	[past]	'fit-3SG'
ge-wuss-t	[gvist]	'KNOW-PAST PART'

S-dissimilation is an instance of what Wolf (2008) calls a *non-derived environment* effect: a specific process only applies if the trigger and the target of the process are not separated by a morpheme boundary. The opposite type of restriction also occurs for specific processes in so-called *derived-environment effects* (or *non-derived environment blocking*: Kiparsky 1993; CHAPTER 88: DERIVED ENVIRONMENT EFFECTS). Thus in Finnish assibilation, /t/ is fricativized to [s] before /i/ (6a, 6c), but only if there is a morpheme boundary between /t/ and /i/ (6b, 6c) (Kiparsky 1973, 1993):[3]

(6)

a.	/halut-i/	[halusi]	'want-PAST'
b.	/koti/	[koti]	'home'
c.	/tilat-i/	[tilasi]	'order-PAST'

Morpheme boundaries also play a role in syllabification and processes which are sensitive to syllabification (cf. e.g. Nespor and Vogel 1986; Booij 1995; Raffelsiefen 2005; and the contributions in Hall and Kleinhenz 1999). Thus Kager (1999: 136) argues that Diola-Fogny shows a preference for aligning the left edge of a morpheme with the left edge of a syllable, which accounts for the fact that the language deletes morpheme-final, not morpheme-initial consonants to avoid a syllable-final stop (underlying /let-ku-jaw/ gives [le.ku.jaw], not *[let.ku.jaw] or *[le.tu.jaw]).[4]

It is important to distinguish sensitivity to boundaries from sensitivity to boundary symbols, a theoretical device which plays a crucial role in early rule-based phonology. Thus in Chomsky and Halle (1968; *SPE*) it is assumed that the agentive suffix *-er* in *singer* (/sıng#ər/ → [sıŋər]) is separated from its base by a different boundary symbol from the one separating comparative *-er* from its base in *longer* (/lɔng+ər/ → [lɔŋgər]), accounting for the fact that deletion of stem-final /g/ is obligatory before agentive, but not before comparative *-er*. Different types of morphemes are separated by different types of boundary symbols even though the morphological boundary is in both cases a morpheme boundary. However, this type of boundary sensitivity can in most cases be reconstructed as a combination of sensitivity to morpheme type and sensitivity to morpheme boundaries. Thus we might say that *g*-deletion in English is blocked by a morpheme boundary involving the lexical class of morphemes instantiated by comparative *-er* (so-called level 1 affixes), but not if the morpheme boundary is adjacent to a level 2 affix.[5] More generally, sensitivity to morpheme boundaries might be understood as a special case of sensitivity to

[3] See Wolf (2008) for a derivational view on non-derived environment blocking which does not explicitly refer to boundaries, and a discussion of cases of non-derived environment blocking which might not be reduced to sensitivity for morpheme boundaries.

[4] See McCarthy (2008) for a recent analysis of Diola which does not refer to morphological structure, and for references to other analyses of the same data.

[5] Boundary symbols will be discussed in more detail in §2.2.

morphemes. Thus with respect to Finnish assibilation, the statements in (7a) and (7b) are equivalent:[6]

(7) a. Assibilation happens only if /t/ and /i/ are separated by a morpheme boundary.
b. Assibilation happens only if /t/ and /i/ are part of different morphemes.

2.3 *Sensitivity to the morphological function of a morpheme*

2.3.1 *Heads* vs. *non-heads*

Revithiadou (1999: 5) argues that the selection of lexical stress in lexical accent systems such as Russian (8) is determined by the morphological head of the construction. Thus in (8a) the head is the lexical root, not the inflectional affix, therefore the underlying stress of the root survives; in (8b) the head is the derivational suffix, therefore affixal stress survives:

(8)	a.	/ʧ'eʧ'e'vits-'a/	ʧeʧe'vits-a	'lentil-NOM SG'
	b.	/'gorl-'ast-'a/	gorl-'ast-a	'loud-mouthed-NOM SG-FEM'

2.3.2 *Adjuncts* vs. *complements*

Bachrach and Wagner (2007) argue that phonological processes might be sensitive to the distinction between affixes which are morphosyntactically heads and those which are morphosyntactically adjuncts (see also Newell 2005 for a similar analysis of bracketing paradoxes). Their crucial empirical observation is that diminutive affixes behave phonologically differently from other affixes in Brazilian Portuguese (see also Vigário 2003 for the same observation). For example, whereas all derivational suffixes attract stress, nasalization of stressed vowels before nasal consonants is lost with other suffixes (9a), but not with diminutive suffixes (9b).

(9)	a.	'*f*[ã]*ma*	'fame'	*f*[a]'*moso*	'famous'
	b.	'*k*[ã]*ma*	'bed'	*k*[ã]'*miña*	'small bed'
				ˌ*k*[ã]*ma*'*ziña*	'small bed'

Bachrach and Wagner (2007) relate the different behavior of diminutive affixes to the fact that they behave morphologically as adjuncts – evidenced, for example, by the fact that they don't change part of speech or gender of the base to which they attach – while other derivational affixes are heads taking their bases as complements. On the assumption that adjuncts are assigned stress independently from the constituents they select, they argue that bases maintain independent main stress with diminutives, which is only changed by late phonological processes. Hence base vowels are stressed at the relevant phonological level and are not denasalized.

[6] The idea that morphological affiliation replaces morpheme boundaries is originally due to McCarthy (1979). See van Oostendorp (2007) for a theory of derived environment effects which is based on this intuition.

2.4 *Sensitivity to stems*

Any discussion of stems faces the problem that the literature invokes very different notions of "stem." One usage of this term is that every morphologically complex structure containing a lexical root morpheme is a stem (Downing 2006). I will call this the *morphological stem*. Thus in the word form *naturalists* we might isolate the morphological stems *nature, natural, and naturalist*. Under a second reading, "stem" is intended as a constituent which contains a root and all derivational affixes of a word form, hence in *naturalists* only *naturalist* would count as a stem. I will call this type of stem *derivational stem*. A third reading of "stem" is often found in phonological work where stem is a designated morphological stem which is relevant to the phonology. Thus in Stratal OT (Bermúdez-Otero, forthcoming), it is assumed that every stem headed by a level 1 affix and not selected by a level 1 affix forms a phonological stem, which is an arbitrary choice from the point of view of the morphology. I will call this type of stem the *phonological stem* (see §3.2 for more discussion).

For all three types of stems it has been argued that they are relevant for phonology. This is most obvious for the phonological stem. Thus, in English, many processes, such as nasal place assimilation, stress assignment, and trisyllabic laxing, take place in the phonological stem as defined above. Downing (2006) argues that in many languages morphological stems have to obey prosodic minimality requirements not applying to non-complex words. Thus German infinitives (e.g. /geː-ə-n/ 'to go', with epenthetic schwa) must be at least bisyllabic, whereas bare verb roots and other roots (e.g. the imperative /geː/ 'go!' and the numeral /tseːn/ 'ten') can be monosyllabic.[7] In Albanian, the relevant domain of word stress is the morphological stem (Trommer 2008b; see §2.5 for examples), and Hyman (2008) shows that in many Bantu languages processes of vowel, consonant, and tone harmony apply to the morphological stem as well as prosodic restrictions on minimal or maximal size.

However for most cases, diagnosing sensitivity to stems is conceptually problematic, because the phonological sensitivity to stems is by no means unambiguous. Thus most of the effects discussed in Downing (2006) as evidence for the morphological stem are construction-specific. For example, the bisyllabicity requirement for German infinitives does not extend to other inflected forms such as the 3rd singular (e.g. /geː-t/ '(s/he) goes'), which also has an overt affix.

Once this is taken into account, cases like this might be reduced to affixation of prosodic material. Thus the restriction on the German infinitive could be derived by a bisyllabic foot template which is part of the infinitive suffix. Reference to the morphological or the phonological stem can often be replaced by reference to morpheme type. Thus, in a canonical Bantu language, it is tantamount to claiming that a specific phonological process applies only to derivational suffixes and to stating that it is restricted to a stem constituent.

Data which exhibit relatively clear-cut evidence for the phonological sensitivity to stem-like constituents seem to be restricted to the boundaries of morphology, to cases of non-concatenative morphology, and to specific cases of opacity

[7] There are only two high-frequency German verbs which have a monosyllabic infinitive, /tuːn/ 'to do' and /zaɪn/ 'to be' (Neef 1996: 135). The claim that schwa in German is in general epenthetic is defended in detail in Wiese (1996).

discussed in detail in §2.5. An example of the first type is stress assignment in English compounds. Consider for example the compounds in (10) (see also CHAPTER 116: SENTENTIAL PROMINENCE IN ENGLISH):

(10) a. [[*blackboard*]$_N$ *eraser*]$_N$
b. [*linguistics* [*language requirement*]$_N$]$_N$

In (10a), the first two nouns form the simple compound *blackboard*, which is in turn part of the complex compound *blackboard eraser*. Main stress is on the first word; secondary stress on the third. In (10b), the second and third nouns form an internal compound, and as a consequence main stress is on the second noun and secondary stress on the first one. To compute English compound stress clearly requires access to the bracketing of stem constituents, but compounding is notorious for being a boundary case between morphology and syntax.

A case of non-concatenative morphology/phonology in which bracketing seems to be crucially visible in the phonology is the tonal behavior of affixes in Hausa (Inkelas 1998). Hausa has two types of affixes: recessive (or tone-integrating) affixes add their underlying tone melody to the tone melody of the base to which they attach (11a), whereas dominant affixes replace the tone of the base by their own melody (11b) (all data originally from Newman 1986, 2000):

(11) a. *Recessive affix* (Inkelas 1998: 127)

ba-goobir	+	-ii	→	bagoobirii
L L H		H		L L HH
'from-Gobir'		ethonym		'a Gobir man'
ba-zamfara	+	-ii	→	bazamfarii
L L L L		H		L L L H
'from-Zamfara'		ethonym		'a Zamfara man'

b. *Dominant affix* (Inkelas 1998: 127)

ba-katsina	+	-ee	→	bakatsinee
L L HL		HL		HH H L
'from-Katsina'		ethonym		'a Katsina man'
ba-zamfara	+	-ee	→	bazamfaree
L L L L		HL		HH H L
'from-Zamfara'		ethonym		'a Zamfara man'

Crucially, the domain of tone integration or replacement is delimited by morphological bracketing, as is obvious from the examples in (12). In both forms, the dominant suffix /-ii/ imposes its tone pattern LH on the constituent [karanta + -ii], and the recessive prefix /ma-/ "adds" an additional initial H tone, resulting in the output form shown in (12a). In (12b), this form is embedded inside a further dominant affix, /-ijaa/, whose tone melody HLH overwrites everything in its scope. Thus both forms contain a final dominant affix, but in (12b) this is the outermost affix of the construction, whereas it is embedded inside of a (recessive) prefix in (12a). As a consequence, the final affix in (12b) replaces the tone patterns of the entire word, whereas it doesn't affect the prefix in (12a), which shows that it is not the phonologically linear position of a dominant affix that determines the extension domain of its tonal melody, but its hierarchical position in morphological structure (Inkelas 1998: 130):

(12)	a.	[ma- [karanta + -ii]]	→	makarancii	
		H HL H LH		H L L H	
		NML 'read' -AGENT		'reader (MASC)'	
	b.	[[ma- [karanta + -ii]] -ijaa]	→	makaranciijaa	
		H HL H LH HLH		H H H L H	
		NML 'read' -AGENT		'reader (FEM)'	

The degree to which phonological sensitivity to stems is a necessary assumption is thus a delicate question.

2.5 *Sensitivity to paradigmatic structure*

All types of sensitivity we have discussed so far refer to the syntagmatic structure of morphological expressions. An alternative way to approach morphology (and phonological sensitivity to morphology) is by paradigmatic relations between words and word forms (CHAPTER 83: PARADIGMS). Thus sensitivity to paradigmatic structure gives us a different view on the type of data already discussed rather than a new range of phenomena. For example, Hall and Scott (2007) assume that the restriction of Swabian s-dissimilation to monomorphemic contexts is due to the faithfulness of inflected forms to their paradigmatic bases: in an inflected form such as /griəs-t/ 's/he greets', /s/ is not dissimilated to /ʃ/, because this would disrupt featural identity to the base form /griəs/ 'I greet', which doesn't have /ʃ/, due to the absence of a following /t/. For words such as /poʃt/ 'post', s-dissimilation is also triggered in the base and therefore found in the whole inflectional paradigm, and for an inflectional suffix such as /-st/ there is no base form, so it freely undergoes dissimilation in a form as /doːf-ʃt/ 'most stupid'.

Like s-dissimilation, most phenomena which can be described as morpheme boundary effects are cases of opacity where processes are simply blocked in the absence or presence of boundaries ("underapplication"). In contrast, the paradigmatic view also extends to cases of opacity where a process applies even though the appropriate context is not present in the word form itself, but only in a paradigmatically related form ("overapplication"). For example, in Albanian, uninflected words ending in a mid-vowel have stress on the penultimate syllable (e.g. *'ba.bo* 'midwife'), whereas words ending in a closed syllable or non-mid vowels have final stress (e.g. *pa.'tok* 'gander' and *ash'tu* 'thus'). Crucially, inflected forms maintain the stress of their base word. Thus the definite form of *pa.'tok*, *pa.'to.ku*, has stress on the final syllable of the stem even though this syllable is open in the actual form, and the word ends in a high vowel. A paradigmatic account can capture facts like this by assuming that inflected forms must be faithful in their stress position to their bases (Trommer 2008b).

A type of sensitivity to morphology which seems to be systematically beyond the reach of a paradigmatic approach is that of derived environment effects such as Finnish assibilation discussed in §2.2. The restriction of a process to occurring across a morpheme boundary obviously doesn't serve the purpose of making the derived form more similar to its base. Even under the assumption that the derived environment effect is made in some way possible by the fact that the derived form gets more dissimilar from its base (see Kenstowicz 2005 for cases of effects which are triggered by the requirement to make paradigmatically related form less similar), this would not account for the fact that this effect does only

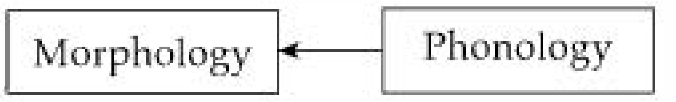

Figure 103.1 Sensitivity to morphology in a modular architecture

occur locally, at the morpheme boundary (recall that underlying /tilat-i/ becomes [tilas-i], not [silas-i] or [silat-i]).[8]

3 Sensitivity to morphology and the structure of the morphology–phonology interface

Considering the data discussed in §2, it is clear that many phonological processes reflect morphological structure. However, the idea that morphology as a whole communicates information to phonology as a whole is only one type of approach to morphologically conditioned phonology presupposing a modular architecture which cleanly separates morphology and phonology, as is schematically shown in Figure 103.1.

Under this approach, the nature and extent of sensitivity to morphology is fully determined by the single interface that the two modules phonology and morphology use to communicate. The nature of this interface will be discussed further in §3.3. Alternatives to this architecture are discussed in §3.2.

3.1 Fine-grained sensitivity to morphology in Optimality Theory

A much less clear-cut picture of the morphology–phonology interface is standard in most versions of Optimality Theory, where different constraint types have different amounts of access to morphological structure. Thus it is often implicitly assumed that standard markedness constraints are incapable of accessing any morphological information, while alignment constraints can access the position of morphological boundaries, and positional faithfulness constraints are sensitive to information on boundaries and affiliation of segments to morphological constituents, but only if these are prominent in some well-defined way (e.g. roots but not affixes). This amounts to an architecture where phonological constraint types have different access paths to morphological structure, as illustrated in Figure 103.2.

In fact, most proponents of OT go even further, denying that phonology and morphology are different modules, such that phonological and morphological constraints directly interact, and phonological constraints can enforce violations of morphological constraints (see e.g. Golston 1995; Wolf 2008). The question of whether abandoning morphophonological modularity in this way is empirically and conceptually justified goes beyond the topic of this chapter; but, also under a non-modular and fully parallel architecture, the access of phonological

[8] A paradigmatic account might be invoked to account for cases of derived environment effects which are non-local (Burzio 2000); see §4.2 for discussion.

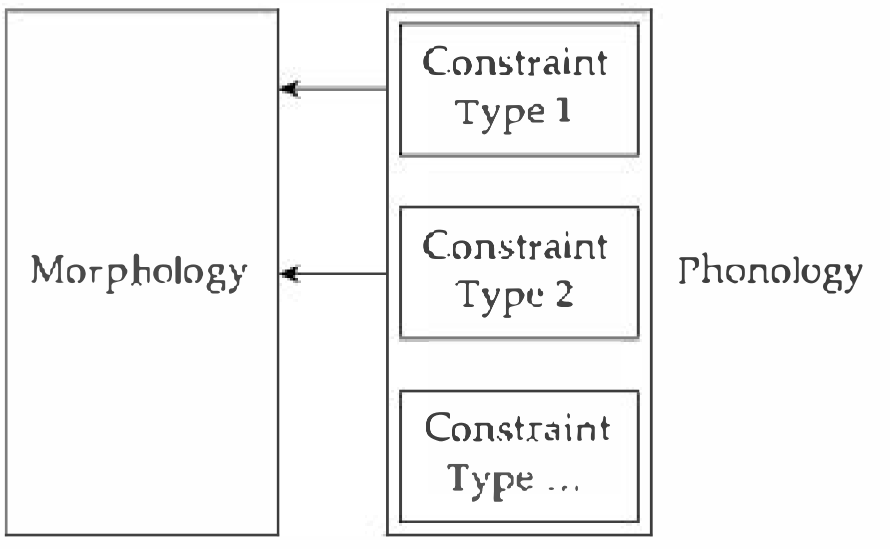

Figure 103.2 Sensitivity to morphology in OT

constraints to morphological structure follows the same principles as depicted in Figure 103.2. Note also that a strictly modular architecture of morphology–phonology interaction might be emulated by restrictions on specific constraint types. Thus Bermúdez-Otero (forthcoming) argues that the only phonological constraints which can access morphological information are alignment constraints for prosodic categories, whereas other constraints can only refer to prosodic categories. This reconstructs a derivational modular system, where prosodic categories serve as the interface between morphology and phonology.

3.2 *Sensitivity to morphology vs. external control: Co-phonologies and cyclicity*

An even more radical alternative approach to phonological processes which are sensitive to morphological structure is to assume that morphology governs phonology in a way which mirrors its own structure-building processes. In effect, phonology reflects morphological structure, but, without phonological rules or constraints having access to morphological information, phonology undergoes external control. Hence no morphological structure is accessed by the phonology. This approach is sketched schematically in Figure 103.3.

It is not the goal of this chapter to discuss arguments for this or for the sensitivity-based architecture, since they are partially equivalent, and many of the differences discussed in the literature depend on orthogonal assumptions which

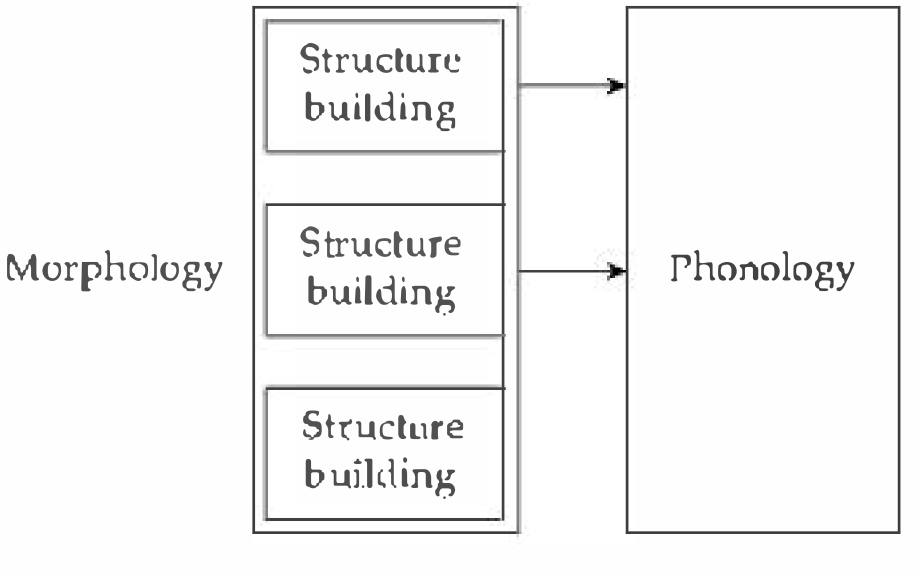

Figure 103.3 External control of phonology by morphology

advocates of these architectures make.[9] Moreover, the external-control approach and the sensitivity approach can be combined in a fruitful way. Here I will discuss some of the most important features of the external-control approach to morphophonology, but take a mostly sensitivity-based perspective in the rest of the chapter, keeping an eye on the alternative or complementary role external control might play.

A theory which consequently applies the idea of external morphological control to morphologically sensitive phonology is sign-based phonology and morphology (Orgun 1996; Inkelas and Zoll 2005). As an illustration, consider a case of exceptional phonology in Turkish, where velar stops are deleted intervocalically in the affixation of the dative suffix to a nominal stem, but not in the affixation of an aorist suffix to a verbal stem:

(13) a. *Dative suffix: Velar deletion*

nominative	*dative*	
bebek	bebe-e	'baby'
inek	ine-e	'cow'

b. *Aorist suffix: No velar deletion*

past	*aorist*	
gerek-ti	gerek-ir	'be necessary'
bırak-tı	bırak-ır	'leave'

A possible interpretation in terms of sensitivity to morphology would be that phonology is sensitive to the presence of the exceptional dative suffix. In the system of Pater (2009), this might take the form of a lexically indexed constraint, i.e. a phonological constraint which is by definition restricted to an arbitrary set of morphemes ***M***, or, put slightly differently, which only induces constraint violations for phonological structure that overlaps with phonological material of a morpheme in ***M***. For the case at hand we might assume a constraint *VKV$_{Dat}$, which doesn't allow /k/ in the context of a preceding and a following vowel, and is morphologically indexed for (restricted to) the dative morpheme. Since the phonological configuration inducing a constraint violation of *VKV$_{Dat}$ overlaps with an exponent of dative in (14), /k/ is deleted, whereas no constraint violation obtains in the absence of the dative, therefore the /k/ in (15) is protected by MAX-C:

(14) *Dative: By indexed constraints*

inek-e	*VKV$_{Dat}$	MAX-C
☞ a. ine-e		*
b. inek-e	*!	

[9] For example, it is often claimed that an important difference between the co-phonology approach (an external control approach) and the indexed constraint approach is that the former, but not the latter, can capture "markedness" reversals. However, as shown in detail in Inkelas and Zoll (2007), both frameworks can incorporate the disputed assumption (or refrain from doing so) with equal ease.

(15) *Aorist: By indexed constraints*

gerek-ir	$*VKV_{Dat}$	MAX-C
a. gere-ir		*!
☞ b. gerek-ir		

The principal idea of the sign-based approach is that different constructions such as dative and aorist forms simply invoke different phonologies. Thus the dative construction has *VKV ranked above MAX-C, resulting in intervocalic /k/-deletion (16), while the ranking of the aorist construction is the opposite, leading to maintenance of /k/ (17):

(16) *Dative: Co-phonology* Φ_1

inek-e	*VKV	MAX-C
☞ a. ine-e		*
b. inek-e	*!	

(17) *Aorist: Co-phonology* Φ_2

gerek-ir	MAX-C	*VKV
a. gere-ir	*!	
☞ b. gerek-ir		*

Crucially, the phonology in this system doesn't have direct access to morphological information. The constraints in (16) and (17) do not "know" by themselves that specific structures involve a dative or aorist affix. Instead, the morphology chooses the right phonology for specific contexts. This is achieved by an architecture of morphology where every construction is a hierarchical structure which fixes the phonology of the entire structure as a function of its substructures: thus the dative construction (18a) has the phonology which results from applying the ranking Φ_1 to the concatenation of the base noun and the dative suffix, while the aorist construction has the phonology resulting from applying Φ_2 to the concatenation of the base verb and the aorist suffix (18b):

(18) a. *Dative construction*

[Syntax = Dative N
  Phonology = $\Phi_1(P_x, /\text{-E}/)$]

[Syntax = N
  Phonology = P_x]   [/-E/]

b. *Aorist construction*

[Syntax = Aorist V
  Phonology = $\Phi_2(P_x, /\text{-r}/)$]

[Syntax = V
  Phonology = P_x]   [/-r/]

Co-phonologies and indexed constraints seem to be largely equivalent, but there are important differences in the specific implementations of locality restrictions on morphological accessibility which will be discussed in §4.2. Moreover, co-phonologies allow an alternative approach to opacity which largely obviates the use of paradigmatic constraints. Thus the fact that Albanian inflected word forms inherit stress from their base forms (e.g. the definite form *pa.'to.ku* from the indefinite form *pa.'tok* 'gander'; see §2.5) can be derived by assigning weight-sensitive co-phonologies to bare roots and derivational affixes, and co-phonologies which are faithful to their input stress to inflectional affixes (Trommer 2008b). Since the phonology of a complex expression is computed as a function of the phonology of the base, this effectively preserves base stress.

A different approach, where morphological structure is also reflected by different co-phonologies, is found in Stratal Optimality Theory (Kiparsky 2000; Bermúdez-Otero, forthcoming) and its predecessor Lexical Phonology (Kiparsky 1982; Mohanan 1986). In Stratal Optimality Theory, not every morphological construction has a specific co-phonology, but co-phonologies are attached to stems, words (and, going beyond morphology, to phrases). For example, in a word with a stem-level affix (*-ous*) and two word-level affixes (*-ness* and *-less*) such as *glori-ous-ness-less*, the stem *glori-ous* is evaluated by the stem-level phonology, and *glori-ous-ness-less* (the concatenation of the resulting stem with *-less* and *-ness*) by the word-level phonology (see also CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME).

Triggering of phonology by morphology and sensitivity to morphological information by phonology are not necessarily mutually exclusive options Thus proponents of Stratal Optimality Theory usually assume that there is some form of sensitivity to morphology in the form of the prosodic hierarchy (cf. §3.3). Stratal Optimality Theory might therefore be called a hybrid model of the morphology–phonology interface, because it integrates sensitivity and triggering. This hybridity is reminiscent of the architecture assumed in *SPE*, where phonology reflects syntax not only by the virtue of boundary symbols, but also through the cycle, a mechanism which subjects morphosyntactic chunks of increasing size to the same battery of phonological rules. Scheer (2009) also adopts a very similar architecture, where the use of boundary symbols (cf. §3.3) is supported by a version of the cycle in the form of recent phase theory (Chomsky 2001; see also CHAPTER 85: CYCLICITY).

3.3 *Dialects of phonology–morphology communication*

As pointed out by Scheer (2008), the situation of phonology–morphosyntax interactions is similar to the communication of speakers speaking different languages: morphology might communicate to phonology via morphological vocabulary, via phonological vocabulary, or via an interlanguage, i.e. a vocabulary which is neither proper to phonology nor to morphology. In this subsection I will discuss these different possibilities.

3.3.1 *Phonology and morphology speaking an interlanguage*

Probably the most influential approach to phonological sensitivity to morphology in the last decades is the idea that communication between phonology and morphology is based on an interlanguage which conveys morphological information to the phonology module. The classical version of this approach is proposed in *SPE*, where the interlanguage consists of boundary symbols such as the weak boundary "+" and the strong boundary "#." These symbols are inserted after the completion of morphosyntax, mirroring the hierarchical structure of syntax. Thus + is roughly speaking inserted at morpheme boundaries, and # at word boundaries, subject to further readjustment rules, and then interpreted in the phonology by phonological rules. Word-final devoicing in German can be captured by the rule [–son] → [–voice] / __ #. It is important to note that something like # is not really a syntactic symbol (although it is derived by reference to syntactic structure), since no syntactic rules refer to it or build structures containing it. While the positions of # assumed for English correspond roughly to pre-theoretic intuitions about English word boundaries, it doesn't correspond to morphosyntactic word boundaries in *SPE*, since *SPE* is a purely syntactic theory of morphosyntax, where words do not have any theoretical status at all. Word-like boundaries are only introduced to communicate with phonology; # is not a phonological symbol either, because it doesn't undergo phonological rules and is not present in the output of phonology to phonetics. Its only function is the communication between morphosyntax and phonology.

A slightly different interlanguage approach has been developed in Prosodic Phonology, in the form of prosodic constituents such as the prosodic word and the clitic group (Nespor and Vogel 1986; CHAPTER 51: THE PHONOLOGICAL WORD; CHAPTER 84: CLITICS).[10] Whereas the lower-level units (e.g. the syllable, the mora, and the foot) of Prosodic Phonology can be seen as purely phonological entities which aren't necessarily linked to morphosyntax, the prosodic word and clitic group seem to serve similar duties to the boundary symbols of *SPE*. Here is a classic example for the working of prosodic words. In Hungarian, backness vowel harmony applies to suffixes attached to lexical roots (hence across a root–suffix boundary) (19a), but not to prefixes (19b) or across compounds (19c) (CHAPTER 123: HUNGARIAN VOWEL HARMONY):

(19)	a.	*mos-at*	wash-CAUS	'make wash'
		küld-et	send-CAUS	'make send'
	b.	*oda-menni*	there-go	'to go there'
		be-utazni	in-commute	'to commute in'
	c.	*Buda-Pest*		'Budapest'
		könyv-tár	book-collection	'library'

The prosodic word-based analysis of Nespor and Vogel (1986: 121–122) assumes that prosodic words in Hungarian are built as follows:

(20) a. The domain of the prosodic word consists of a stem and any linearly adjacent string of suffixes.
b. Any unattached element forms a prosodic word on its own.

As a consequence, suffixes form a prosodic word together with the preceding root ($[mos\text{-}at]_{PW}$), two roots in a compound form different prosodic words ($[Buda]_{PW}$ $[Pest]_{PW}$), and prefixes form separate prosodic words, since they are stranded ($[oda]_{PW}$ $[menni]_{PW}$). On the assumption that vowel harmony in Hungarian cannot cross prosodic word boundaries, the distribution of vowel harmony follows. The major argument for the prosodic word is that the phonology instantiates domains which do not correspond to any morphosyntactic domain. Thus *Budapest-ben*

[10] The discussion of the Prosodic Hierarchy in this section follows closely the insights of Scheer (2008).

'in Budapest' has the morphological bracketing [[*Buda Pest*] *ben*] and the prosodic bracketing $[Buda]_{PW}$ $[Pest\text{-}ben]_{PW}$, where $[Pest\text{-}ben]_{PW}$ is a prosodic word which is not isomorphic with a morphological constituent.[11] However, the overall function of prosodic words is still to make morphological boundaries visible to phonology. Thus, in the analysis of Nespor and Vogel, (21a) and (21b) are equivalent:

(21) a. Vowel harmony cannot cross a prosodic word boundary.
b. Vowel harmony cannot cross left edges of words or root morphemes.

In general in the prosodic word literature, prosodic word boundaries correspond to morpheme boundaries, in contrast to syllables and feet (cf. the monomorphemic name of the Hungarian town *Debrecen*, which is parsed as $[De.bre]_{Ft}$*.cen*). Just like the boundary symbols of *SPE*, prosodic words are created by the morpho-syntax to communicate with phonology, and just like boundary symbols, the only motivation of prosodic words in the phonology is to trigger or block phonological processes at specific boundaries.[12] Note also that although prosodic words are formally quite distinct from boundary symbols – prosodic words are constituents in a hierarchical tree, not symbols which are linearized in the same way as segments – phonological processes refer to them in much the same way as to boundary symbols. Thus Nespor and Vogel suggest (following Selkirk 1980) that prosodic word-related phonological rules all belong to a small set of formats which refer only to the boundaries of prosodic words. In fact Neeleman and van de Koot (2006) show that the tree representations of Nespor and Vogel (1986) can be translated without any loss of information in a system where all parts of the Prosodic Hierarchy are boundary symbols.

The interlanguage approach is also used to encode information on single morphemes. Thus *SPE* uses boundary symbols to mark exceptional morphemes. For Nespor and Vogel (1986: 140), specific affixes are marked by a diacritic, which has the effect that they form independent prosodic words. On the assumption that prosodic words can be recursive, they can also directly encode more complex bracketing patterns (see Peperkamp 1997).

3.3.2 *Morphology speaking phonology*

A system where morphology communicates with phonology in the vocabulary of phonology, called "Direct Interface," is developed in Scheer (2008). Scheer assumes that the only information morphosyntax can transmit to phonology consists of phonological symbols such as the phonological timing elements C and V. More specifically, morphosyntactic boundaries can be encoded at the output of morphosyntax by inserting specific phonological material between morphemes

11 As rightly pointed out by one of the reviewers, there are no detailed arguments for the assumed morphological structure for many cases where non-isomorphism between morphology and phonology is claimed. Thus it is quite possible that the morphological structure of *Budapestben* is actually [*Buda*-[*Pest-ben*]], since the semantic scope of *-ben* 'in' is in any case larger than the morphological base to which it attaches (its scope is over the entire DP, including determiners and modifiers).

12 This is not strictly true in theories where the prosodic word is an inextricable part of the representation for word stress, but Nespor and Vogel assume that word stress is implemented by the metrical grid, not the prosodic word, and is in principle independent of the prosodic word. Note also that the domain of stress in Hungarian is bigger than the domain for vowel harmony since it comprises compounds and clitics (Vogel 1988).

or by restricted types of manipulation of phonological segments at morpheme edges. For example, it is assumed that many languages insert the sequence CV (an unassociated C timing slot and an unassociated V timing slot) to mark the left edge of morphosyntactic words. In the version of Government Phonology assumed by Scheer, an unassociated V slot is only possible if the next V slot to its right is associated to a phonetically visible vowel: C-t V-a and C-t V-Ø C-r V-a are fine, but C-t V-Ø C-k V-Ø C-r V-a is ruled out because the initial V-Ø is followed by another V-Ø, which accounts for the absence of triconsonantal word-initial clusters.

Obligatory addition of unassociated CV at the left word edge now leads to an additional empty nucleus, which cannot be licensed. Hence something like #tr is systematically impossible in a language of this type, because it would be represented as C-Ø V-Ø C-t V-Ø C-r V-a. Crucially, Direct Interface works very much like *SPE*: CV elements inserted at boundaries are boundary symbols in the sense that they correspond to the edges of morphosyntactic constituents, but are not present themselves in the syntax. The crucial difference is that CV slots (and other boundary markers assumed in Direct Interface) are part of the independently motivated vocabulary of the assumed phonological formalism. They occur both in lexical representations of single morphemes and in the output of phonology, with well-defined consequences.

In a Direct Interface approach, information on specific morpheme types must also be encoded by phonological vocabulary. Thus apparent exceptionality can be implemented by assuming different phonological representations for exceptional and regular items. For example, Inkelas and Cho (1993) argue that exceptions to final devoicing in Turkish (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION) are due to the fact that "regularly" devoicing obstruents are underlyingly underspecified for voicing, whereas exceptionally non-devoicing obstruents are underlyingly voiced (and consistently voiceless obstruents underlyingly voiceless). On the other hand it is hard to imagine how a Direct Interface approach would handle sensitivity to complex bracketing as in the cyclic computation of compound stress (cf. §2.4), and in fact Scheer (2009) assumes that effects of this type are due to external control, much as in *SPE*.

3.3.3 *Phonology speaking morphology*

In most varieties of Optimality Theory, phonological constraints have direct access to morphological structure. Hence phonological constraints can access morphological structure without an interlanguage being invoked or morphosyntax bothering about translating boundaries into phonological vocabulary.[13]

4 Restrictions on phonological sensitivity to morphology

Approaches to phonological sensitivity for morphology are inherently theories of non-sensitivity. In other words, they try to impose interesting and general restrictions on the amount of morphological structure which can be accessed by

[13] Approaches where phonology has direct access to morphosyntactic boundaries have also been advocated by Odden (1990) and Kaisse (1990).

phonological mechanisms. These restrictions are generally of two different types: restrictions on the types of accessible information (e.g. specific boundaries, but not others), and restrictions on the locality of accessibility (e.g. the identity of a specific morpheme might be accessible for a process which applies to sounds which are exponents of this morphemes, but not to other sounds). I will discuss the first type of restriction in §4.1, and the second one in §4.2. In §4.3, I will discuss the most prominent restriction on sensitivity to morphology which has been proposed in the literature, "indirect reference," which basically claims that the communication between morphology and phonology is achieved by an interlanguage or by phonological vocabulary in a modular architecture. I will argue that indirect reference is not by itself an interesting restriction, but only in as far as it predicts that sensitivity to morphology works in a consistent way for all types of phonological processes.

4.1 *Restrictions on the type of accessible morphology: Impoverishment*

Most approaches to the morphology–phonology interface propose explicitly or implicitly that phonological sensitivity to morphology is restricted as to which types of morphological properties are accessible to phonology. For example, specific types of morphemes or morpheme boundaries might be visible to phonology, whereas other types are not. Procedurally, this type of restriction can be interpreted as a kind of impoverishment process: a part of the structure built by morphology is deleted before the phonology has the chance to interpret it.[14]

A simple example is the version of Positional Faithfulness Theory in Beckman (1998) applied to morphological categories, where there are special faithfulness constraints for prominent categories, but not for non-prominent categories, e.g. there is a constraint Ident-σ_1 protecting sounds in root-initial syllables, but no corresponding constraint for affixes. Affix segments are only protected by a general version of Ident, which extends to all segments. Under this approach, phonology (at least for faithfulness constraints) cannot directly access whether a segment belongs to an affix. A related restriction which has been proposed in the OT literature is the claim that only faithfulness constraints can be indexed for morphological categories, which predicts that morphology cannot trigger markedness reversals (cf. Itô and Mester 1999 and Alderete 2001, but see Inkelas and Zoll 2007, Pater 2009, and Bermúdez-Otero, forthcoming, for critical discussion).

Under a modular architecture, a substantive restriction on the types of brackets which can be accessed is introduced by Kaye (1995). Kaye argues that only analytic morpheme boundaries (level 2 boundaries) are visible to phonology, while synthetic boundaries (level 1 boundaries) are systematically invisible. A similar claim is implicit in Prosodic Phonology. Thus Nespor and Vogel's analysis for Hungarian makes root–suffix boundaries virtually invisible to the phonology, since they do not correspond to prosodic word boundaries (nor to any other prosodic boundaries, except by accidental correspondence to foot and syllable boundaries).

Finally, impoverishment also plays an important role in external-control models of sensitivity to morphology. Thus, in Stratal OT, constraint evaluation takes place – apart from applying to words – in phonological stems. For example,

14 The label "impoverishment" in this context is due to Bermúdez-Otero (forthcoming).

Bermúdez-Otero (forthcoming) shows that in Spanish the (partially lexically controlled) process of stressed stem vowel diphthongization applies to stems, since it is bled by stem-level affixation of (stress-shifting) *-(r)al*, but not at the word level, since the affixation of the word-level affix *-on* doesn't affect diphthongization, even though it also leads to stress shift:

(22)	a.	*cuerpón*	[kwer.'pon]	'big body (N); of large and robust build (A/N)'
		cf. *cuerpo*	['kwer.po]	'body (N)'
		corporal	[kor.po.'ɾal]	'bodily, corporal (A)'
	b.	*huevón*	[we.'βon]	'big egg (N); stupid, plucky, lazy (A/N)'
		cf. *huevo*	['we.βo]	'egg (N); (colloq.) testicle (N)'
		oval	[o'.βal]	'oval (A)'

A second process found in some varieties of Spanish illustrates phonological evaluation at the word level. *n* becomes a placeless nasal ([N]) in coda position, which is maintained under resyllabification across word boundaries, but is bled by resyllabification triggered by the augmentative word-level affix *-azo*:

(23)	*huevón*	[we.'βoN]	'big egg (N); stupid, plucky, lazy (A/N)'
	huevon-azo	[we.βo.'na.θo]	'big *huevón*'
	huevón imbécil	[we.'βo.Nim.'be.θil]	'stupid *huevón*'

The crucial argument of Bermúdez-Otero is now that, in the morphological structure [[[*huev*]-*on*]-*azo*], the constituent [[*huev*]-*on*] does not trigger evaluation by the phonology, which is evident from the fact that the *n* does not undergo debuccalization. Crucially, "stem" in Stratal Optimality Theory is a phonological stem (cf. §2.2), not a genuinely morphological constituent (thus stem is not a label in the morphological representation), but a specific sub-word constituent selected by the morphology–phonology interface as visible for phonological evaluation, which effectively makes all other sub-word constituents invisible to the phonological evaluation algorithm.

4.2 Restrictions on the locality of sensitivity to morphology

Since most types of sensitivity to morphology can at least partially be reduced to sensitivity to morphemes (cf. §2), the discussion here will be restricted to the locality for phonological sensitivity to specific morpheme types. Sensitivity to morpheme type is usually quite local, which can be best illustrated by positional faithfulness effects. Recall the vowel harmony data from (2), where the special protection to underlying [ATR] values "imported" by root morphemes into the phonological representations of words is radically local in the sense that it only applies to segments which are part of the very same root. If it were otherwise (if the high-ranked faithfulness attributed to the root extended to the whole word containing a root), the relevant asymmetry between roots and affixes would disappear, since affix segments should be just as faithful to their underlying ATR values as root segments.

In the literature one finds three major proposals for relevant locality domains in phonological sensitivity to morphology.[15] First, locality of morphological sensitivity might be subject to phonological locality. This type of locality follows directly from the architecture of the grammar in approaches where all communication between phonology and morphology is carried out by boundary symbols of the interlanguage (*SPE*) or of the phonological (Direct Interface) type. For example, since boundary symbols are treated as phonological units, they should only be able to have an impact on dissimilation or assimilation processes if they intervene between trigger and target, simply because this is the only position where other phonological units could influence (dis-)harmony.

A second proposal implicit in much of the OT literature is that the locality of morphological sensitivity is restricted to exponence of morphemes. I will call this type of locality *morpheme-based locality*. Thus the schema of positional faithfulness constraints is defined in such a way that only segments which are in a prominent position enjoy special protection. For positional root faithfulness this means root consonants, hence sensitivity to morphology in this case is restricted to the phonemes which are exponents of a given morpheme. For markedness constraints which are sensitive to morpheme type we might assume a similar locality convention as in (24):

(24) $*X_L$

Assign a violation mark to any instance of X that contains only phonological exponents of morphemes specified as L.

Thus, if *NÇ (Pater 1999), a constraint which penalizes sequences of a nasal and a following voiceless obstruent (NÇ), were restricted to root segments it would be violated by a word form where both the nasal and the voiceless stops are part of a root (or of different roots), but not if at least one of these segments would be affiliated to an affix (thus it would be violated by *mp* in *imperial*, but not in *im-polite*).

Pater (2009) argues that the convention in (24) is likely to be too restrictive. For example, in the case of velar deletion discussed in §3.2, $*X_L$ corresponds to $*VKV_{Dat}$. However, this constraint is obviously relevant as soon as one of the segments (the final vowel) is part of the dative affix. Pater (2009) himself proposes that morphologically indexed phonological constraints are applied in such a way that they count constraint violations if the locus of the constraint violation just overlaps with some exponent of the morpheme:

(25) $*X_L$

Assign a violation mark to any instance of X that contains a phonological exponent of a morpheme specified as L.

[15] One prominent proposal on locality of morphological sensitivity which I do not discuss here is Bracket Erasure, a key assumption of Lexical Phonology (Kiparsky 1982; Mohanan 1986), which requires that at the end of a phonological cycle all hierarchical structure internal to the cycle is erased. This derives, for example, the important generalization that phrase-level processes do not have access to the internal morphological structure of words (Bermúdez-Otero, forthcoming). However, Inkelas and Zoll (2007) show that bracket erasure which requires locality with respect to phonological stems follows a fortiori in a system which requires locality with respect to morphological stems (see also Bermúdez-Otero, forthcoming). The latter is discussed in detail below.

A third proposal for the locality domain of morphological sensitivity is made in sign-based morphology and phonology (Inkelas and Zoll 2005), where all sensitivity to morphological structure is restricted to "constructions," which roughly translates to the notion of morphological stem defined in §2.4. I will call this type of locality stem-based locality. Although morpheme-based and stem-based locality are advocated as alternative approaches to the same problem, they are conceptually not mutually exclusive, and hence an argument for one of these locality domains does not necessarily mean that the other one is wrong.

Evidence for morpheme-based locality comes from cases of sensitivity to exceptional morphemes or to boundaries. Thus Assamese has regressive iterative [ATR] vowel harmony (26a) (Mahanta 2007), where [ɑ] is generally opaque to harmony (26b) (Mahanta 2008: 166):

(26)	a.	[b^{h}ɛkola]	'frog'	+	[i]	[b^{h}ekuli]	'frog (DIM)'
		[k^{h}ɔrɔs]	'spend'	+	[i]	[k^{h}orosi]	'prodigal'
	b.	[kɔpɑh]	'cotton'			[kɔpɑhi]	'made of cotton'
		[zɔkɑr]	'shale'			[zɔkɑri]	'shake (INF)'

However, before the affixes [-ijɑ] and [-uwɑ], [ɑ] exceptionally undergoes [ATR] harmony ([-ijɑ] derives adjectives; [-uwɑ] is a causative suffix):

(27)	[sɑl]	'roof'	[solijɑ]	'equipped with aroof'
	[mɑr]	'beat (VB)'	[moruwɑ]	'beat (CAUS)'

The crucial observation is now that exceptionality only affects an [ɑ] if it immediately precedes the [+ATR] vowel of [-ijɑ/-uwɑ], but not if it is separated from the suffix by other vowels, as shown in (28). This follows from the formulation of morphemic locality if exceptional vowel harmony is triggered by the constraint *[−ATR][+ATR] indexed to [-ijɑ/-uwɑ]:

(28)	[pɑtɔl]	'light'	[pɑtolijɑ]	'lightly'
	[ɑdhɑ]	'half'	[ɑdhoruwɑ]	'halved'

Sensitivity to boundaries is implicitly local in a way which is very similar to sensitivity to exceptional morphemes. Thus in a derived environment effect such as Finnish assibilation (cf. §2.2), a boundary triggers (or allows an otherwise not found) process, but only if the trigger and the target of the process are adjacent to the boundary, not by virtue of being part of the same word as the relevant boundary. Thus underlying /tilat-i/ becomes [tilas-i] in the output, not [si-las-i]. This follows under the assumption that boundary sensitivity is actually a subtype of morpheme sensitivity (cf. §2.2). Thus, if Finnish assibilation is interpreted as spreading of a [+continuant] feature from /i/ to a preceding /t/, its restriction to derived environments could be captured in the theory of van Oostendorp (2007) by the constraint ALTERNATION, which bans derived association of features to tautomorphemic segments (Wolf 2008: 329), as would be the case for the two initial segments of /tilat-i/ (see also Pater 2006 for a related implementation of locality in derived environment effects).

Evidence for stem-based locality comes from cases like the Hausa data discussed in §2.4, where exceptional deletion of tone affects the complement of dominant affixes (i.e. the base to which the affix attaches), but not of affixes attached outside of dominant affixes. Hausa also provides a problem for morpheme-based locality, because it affects not only tones phonologically adjacent to the dominant affixes, but all tones in the complement of the affix. This is structurally similar to cases of long-distance derived-environment effects. For example, Catalan does generally not allow the dental fricative [θ]. However, in Spanish loanwords [θ] is possible, indicating that loanwords are exceptional phonologically and introduce sensitivity to morpheme type (CHAPTER 95: LOANWORD PHONOLOGY). If a loanword containing [θ] undergoes derivation by a Catalan affix, the whole word becomes subject to the ban on [θ], and instances of [θ] are turned into [s], which is a licit sound of Catalan. This effect of affixation is phonologically non-local, since it also applies to cases of [θ] which are not adjacent to the triggering affix (Mascaró 2003):

(29)	a.	*Zamora*	(place name)	/θəmorə/	→	[θə'morə]
	b.	*Zamorá*	'pertaining to Zamora'	/θəmorə-'a/	→	[səmu'ra]

Cases like the one in (29) seem to be fatal for morpheme-based locality, since the initial /θ/ in /θəmorə-'a/ does not even overlap with the affix *-á*. For example the application of a constraint *θ indexed for *-á* to stem-initial /θ/ in (29b) satisfies neither the locality convention in (24) nor the relaxed version in (25). There is a simple solution, which has been proposed in different places in the literature (Kiparsky 1993; Bonet 2004; Wolf 2008). If the phonology is not sensitive to the exceptionality of roots, but of stems (or words), exceptionality of a morpheme must be inherited by the stem/root which contains it by feature percolation (CHAPTER 106: EXCEPTIONALITY). In a derived form, where the derivational affix is the head, not the exceptional root, percolation of exceptionality fails, the stem or word is not marked as exceptional, and the entire form is subject to the native phonology. A problem for this escape hatch for morpheme-based locality is that it automatically provides a loophole which allows violations of stem-based locality: if exceptionality features can be percolated upwards, they can spread far beyond the stem which contains a specific affix. A potential problem for stem-based locality is described in detail in Pater (2009) for two homophonous affixes *-wa* in Yine. Suffixes in Yine generally trigger syncope in vowel-final bases (e.g. /heta+ja/ → [hetja] 'see there'). Whereas $-wa_1$ exceptionally fails both to trigger syncope for material it selects and to undergo it if selected by another affix (e.g. /heta+wa+lu/ → [hetawalu] 'going to see him yet'), $-wa_2$ fails to trigger syncope, but undergoes it (/meji+wa+lu/ → [mejiwlu] 'celebration'). As Pater points out, neither the local tree headed by $-wa_{1/2}$ nor the local tree headed by an affix outside them can provide the adequate locality domain for capturing the difference between $-wa_1$ and $-wa_2$. But, as admitted by Pater, the Yine data could also be captured by an analysis which grounds the different behavior of affixes in different underlying phonological representations, and which is thus in accordance with the Direct Interface approach and phonological locality. Note, however, that the data showing non-local effects of the Hausa and Catalan type are also crucially problematic for phonological locality, i.e. the assumption that the only access phonology has to morphology is by the way of phonological material.

4.3 *Indirect reference and consistency of sensitivity*

Indirect reference is a grammatical meta-principle which requires that phonological rules or constraints are not allowed direct access to morphological or syntactic information (Inkelas 1990: 47; Bermúdez-Otero, forthcoming). However, indirect reference does not by itself imply substantial empirical restrictions on the amount of sensitivity to morphology. Thus a great number of morphological categories might be translated into a rich system of prosodic categories (see e.g. Inkelas 1990 and Downing 2006 for well-articulated inventories of morphologically motivated prosodic categories), satisfying indirect reference, but allowing detailed access to morphological information. On the other hand, we might imagine a system where phonology has direct access to morphological structures, but only to a very restricted subset, since access is restricted by general interpretability conditions or a kind of impoverishment filter which removes specific aspects of morphological structure from the information communicated to phonology. In principle the relevant restrictions are the substantial restrictions on phonology–morphology interaction, not the language which phonology and morphology use to achieve communication.

However, indirect reference – at least in a modular architecture – predicts an interesting generalization, which I will call "Consistency of Sensitivity": different phonological processes are expected to have in principle the same access to morphological structure as other processes. Take again as an illustration Hungarian vowel harmony to which root-suffix boundaries are invisible but prefix–root boundaries are visible. Under Consistency of Sensitivity we might expect that other phonological processes in the language work in the same way, i.e. they respect prefix–root boundaries in some way, but disrespect root-suffix boundaries. Nespor and Vogel argue that this holds true for Hungarian, as illustrated by processes of palatalization (Nespor and Vogel 1986: 123–124) and ellipsis (Trommer 2008a). This follows under a restrictive version of the interlanguage approach. On the assumption that no other prosodic constituent of Hungarian has edges which systematically correspond to root–suffix boundaries, it is predicted that these boundaries are generally invisible throughout the language.[16] Consistency of Sensitivity follows directly not only in interlanguage approaches, but also in theories where morphosyntax translates boundaries into phonological structure – since phonology does not have direct access to morphosyntax, but only to the phonological elements generated by morphosyntax, all processes can access morphological structure to the same extent, and more generally in a modular architecture where phonology and morphology communicate through a unique interface.[17]

Hence, if Consistency of Sensitivity is an empirically valid prediction cross-linguistically, it provides an important argument against the direct access of

[16] Of course there might be a language where prosodic words are constructed in a different way, such that the claim is that Consistency of Sensitivity holds for single languages. However, depending on the details of the theory, it might also make predictions about morphological boundaries which are universally invisible.

[17] A modular architecture where phonology has access to a restricted subset of morphological vocabulary might work in such a way that specific types of morphological structure are systematically deleted before morphological information is transmitted to phonology. For example, specific features of morphemes or boundaries might be deleted.

phonology to morphological structure. Unfortunately, there are few empirical studies which attempt to test this prediction. Nespor and Vogel (1986) provide a number of nice examples for languages which show Consistency of Sensitivity, but many of their examples are empirically flawed, since crucial data are not taken into account.[18] Moreover, citing cases which confirm a given hypothesis is not instructive as long as it is not shown in a systematic way (e.g. by the evaluation of a typologically balanced sample of languages) that there are no counterexamples – or at least significantly fewer languages with counterexamples. In fact, Bickel *et al.* (2010) discuss a number of languages which have different word-like prosodic domains which differ from each other for different phonological processes, providing explicit counterevidence to Consistency of Sensitivity.[19] Thus it is fair to say that it is unclear at the moment whether Consistency of Sensitivity is a valid empirical generalization.

5 Summary

We have identified three basic types of sensitivity of phonology to morphological structure (sensitivity to the presence and type of morphemes, sensitivity to morpheme boundaries, and sensitivity to stems), and three basic approaches to model it (external control, paradigmatic relations, and intermodular communication), but the central question which formal and substantive restrictions constrain possible cases of such sensitivity of remains a major topic for future research.

104 Root–Affix Asymmetries

SUZANNE URBANCZYK

1 Introduction

When taking stock of the phonological patterns found in the languages of the world, some patterns can be allocated to roots, some to affixes, and even more to when roots combine with affixes. As Jakobson (1965: 29) observed, "... roots as lexical and affixes as inflectional morphemes ..." show asymmetric patterning, such that affixes "... illustrate a selected use of phonemes and their combinations." For example, in Semitic languages pharyngeal consonants (CHAPTER 25: PHARYNGEALS) are found in roots, but not in affixes (McCarthy and Prince 1995), and in many languages ejectives are only found in roots (Rose and Walker 2004; Bybee 2005). Examples from Classical Arabic (Semitic; McCarthy 2005) and Lushootseed (Salish; Bates *et al.* 1994) illustrate these patterns in (1) below.

(1) *Root–affix segmental qualities*

		roots		*affixes*	
a.	*Arabic*	faʕal	'do (PERF)'	-tu	(1SG COM, PERF)
		ħmarar	'redden'	na-	(3PL COM, IMP INDIC)
		dħaraʒa	'to roll (CONJ I)'	-aj	(DUAL, GEN/ACC)
b.	*Lushootseed*	q'axʷ-	'to freeze'	-alap	'you (PL)'
		k'ʷas-	'to roast'	-icid	'you (SG)'
		gəq'-	'to open something'	-txʷ	'CAUSATIVE'

In terms of combinations of sounds, in Sanskrit roots can have complex onsets (CHAPTER 55: ONSETS), while affixes cannot (Steriade 1988; no glosses given for affixes).

(2) *Sanskrit prosodic structure*

roots		*affixes*
krand	'cry out'	-ur
dwis	'hate'	-ta
djaut	'shine'	-ita

In terms of assimilatory processes, many languages exhibit what is referred to as "root-controlled" vowel harmony. In Turkish, a suffix vowel agrees in backness and rounding with a preceding root vowel, as can be seen in the plural words in (3a) below (CHAPTER 118: TURKISH VOWEL HARMONY). And in English, when the productive form of the plural /-z/ is suffixed to roots, the affix consonant, not the root consonant, becomes voiceless (though there are some exceptions, like *leaves, wives*, and *clothes*).

(3) *Root–affix alternation asymmetries*

		singular	*plural*		
a.	*Turkish*	dev	devler	'giant'	
		cɑn	cɑnlɑr	'soul'	
		ip	ipler	'rope'	
		son	sonlɑr	'end'	
b.	*English*	kɪt	kɪts	'kit'	*[kɪdz]
		tɑp	tɑps	'top'	*[tɑbz]
		dɑg	dɑgz	'dog'	*[dɑks]

This cursory view of root–affix asymmetries belies a more complex situation in which general trends interact with other factors. The aim of this chapter is twofold. The first is to tease apart some of these factors by presenting a survey of a range of root–affix asymmetries to determine the scope and kinds of asymmetries found in the phonological patterns of languages. The second is to present various theoretical approaches, with a brief discussion of how the predictions match the patterns found. In doing so, criteria for establishing what are authentic *root–affix asymmetries* (RAAs) will be provided, while also identifying what could be alternative explanations for the patterns when relevant. For instance, with the Turkish example, one could reasonably ask whether the pattern of vowel harmony is specifically due to the root maintaining the contrast at the expense of the suffix, or whether it is due to directionality, i.e. progressive assimilation. A striking finding in reviewing the literature on RAAs is that authentic cases of RAA reversals (affix dominance) seem to share a common property, that of being dominant–recessive systems. The two areas reported to have affix dominance are morphological accent and vowel harmony. Finally, the preferences found are part of a larger trend where certain prominent positions are known to exhibit more contrasts and resist changes (Trubetzkoy 1939; Steriade 1995; Beckman 1999).

A number of secondary themes have arisen from compiling this research. The first relates to methodological considerations when investigating root–affix asymmetries, discussed in §2. A second theme that has emerged relates to the mapping of form and function, with homophony avoidance or effective contrast (Ussishkin 2006) playing a potential role. This relates to contrasts in the following way. It is common to find far more roots in a language than affixes, due to the larger number of meanings expressed in roots – typically an open class of morphemes. If a language is to have roots that are not homophonous, it is necessary to draw upon a wider set of contrasts, delving into more marked segmentism. This brings the study of root–affix asymmetries full circle with Jakobson's (1965) work, which also examines the relation of form and meaning. Finally, this study touches on the topic of understanding what a root is, as well as morphemes more generally. In cases where the morphology is not strictly concatenative, it is not a straightforward matter to identify root and affix.

After a discussion of methodological considerations, the paper outlines some of the basic patterns found, which can be grouped into two broad categories: the expression of contrasts, and the preservation of contrasts. The expression of contrasts will be the focus in §3, along with some discussion of whether or not markedness, complexity, or grammaticization plays a role in the patterns. The trend to preserve contrasts in roots at the expense of alternations in an affix will be addressed next in §4, under the label root–affix alternation asymmetries. After surveying the types of patterns found, a review of several theoretical approaches is presented (§5). Finally, because one characteristic of roots *vs.* affixes relates to the types of meanings conveyed by each, a section on form–function mappings will delve into more morphological domains of investigation (§6), including non-concatenative morphology, the role that the number of affixes a language has plays in its phonological system, morphologically conditioned alternations, and a brief overview of research on how morphological processing favors roots.

2 Methodological considerations

In terms of methodological considerations, issues that arise in identifying asymmetries, and identifying roots and affixes, will be discussed. This is followed by a brief discussion of the scope and limitations of the current study.

2.1 *Identifying asymmetries*

The first point to consider in undertaking a study of RAAs is determining what an asymmetry is. Two situations can be identified: a complement set relation and a subset relation. In the former, an asymmetrical pattern would have the following distribution, where two domains have entirely different patterns. The two basic domains are root and affix, and the two parameters of investigation are contrasts (represented below by letters {a, b, c, d}), and alternations (represented below with a function sign and subscripts to indicate different alternations $\{f_1, f_2, f_3, f_4\}$).

(4) *Root–affix asymmetry: Complement sets*

	Contrasts	Alternations
Root	{a, b}	$\{f_1, f_2\}$
Affix	{c, d}	$\{f_3, f_4\}$

As illustrated with shading in one set *vs.* another, the asymmetry shows a complementarity of patterning. What is found in roots is not found in affixes and vice versa; there is no overlap at all in terms of the contrasts or the types of alternations found. No examples of this type of RAA have been found. But this is not surprising, because the general trend in language patterning is one of subset relations. Nonetheless it is important to point this out as a potential, logically plausible asymmetry, as it is relevant in the discussion of the types of predictions made by different theoretical models.

The more usual type of asymmetry in language, such as found in research on language universals (Greenberg 1966), is that of a subset relation. For any two domains, what is found in one domain is a subset of what is found in the other domain. With two domains and two parameters, and two possible values for each parameter, the actual number of possibilities is eight (2^3), as illustrated below.

(5)	*root*	*affix*	
a.	*segmental inventory*		
	{a}	{a}	same segmental inventory
	{a}	{a, b}	root is a subset of affix inventory
	{a, b}	{a}	affix is a subset of root inventory
	{a, b}	{a, b}	same segmental inventory
b.	*alternations*		
	$\{f_1\}$	$\{f_1\}$	same alternations
	$\{f_1\}$	$\{f_1, f_2\}$	root alternations are a subset of affix alternations
	$\{f_1, f_2\}$	$\{f_1\}$	affix alternations are a subset of root alternations
	$\{f_1, f_2\}$	$\{f_1, f_2\}$	same alternations

If we eliminate the systems that do not show root–affix asymmetries, that leaves us with four possible systems of root–affix subset type asymmetries: affixes have a subset of the contrasts found with roots, roots have a subset of the contrasts found with affixes, affix alternations are a subset of root alternations, and root alternations are a subset of affix alternations. If the only principle of RAAs is that of a subset relation, then all four systems are expected to occur in the languages of the world.

In terms of the types of asymmetries investigated, as noted above, the basic patterns include contrasts and alternations. Contrasts are somewhat static, while alternations are not.[1] Alternations are very common in phonological systems, and issues arise as to what sorts of alternations to investigate. For example, in some languages there can be a set of morphemes that induce alternations only to the base, such as with English apophony found in the pair *sing vs. sang*. Do we include morphophonologically triggered alternations in understanding phonological patterning, or not? I have left discussion of these out of the section on alternations, because of the morphological conditioning.

2.2 *Identifying roots and affixes*

Several issues arise in identifying roots and affixes. When examining morphologically related words, one can see that there are core elements of form and function that are shared between them. For example, in the Halkomelem examples below, the words in (6a) and (6b) have the meaning of 'to sew', an example of what Jakobson referred to as a lexical morpheme. The second member is inflected for progressive aspect, referring to how the activity is unfolding. The words in (6a) are intransitive, while those in (6b) and (6c) are transitive.

[1] As will be discussed below, in vowel harmony systems there is some interaction between these two dimensions.

(6) *Halkomelem* (Central Salish; Suttles 2004)

	perfective		*progressive*	
a.	'pet'$^{\theta}$	'sew'	'pepət'$^{\theta}$	'sewing'
b.	'pet'$^{\theta}$ət	'sew it'	'pepət'$^{\theta}$ət	'sewing it'
c.	'qamət	'bend it'	'qaqəm'ət	'bending it'

In terms of identifying the parts of the word, one would say that the form associated with the core lexical meaning 'sew' is the root in (6a) and (6b). In the first column the form associated with the meaning 'to sew' is ['pet'$^{\theta}$], while in the second column it is [pət'$^{\theta}$], with the root changing to schwa because of a regular process of unstressed vowel reduction. In terms of the other meanings expressed above, there is a transitiving suffix [-ət]. Looking at the words in (6) above, standard linguistic analysis would identify the roots as /pet'$^{\theta}$/ 'to sew' and /qam/ 'to bend', and the transitivizing suffix as /-ət/. Issues arise, however, in identifying the progressive "affix" in the second column. One exponent of *progressive* can be described as a C_1V_1- reduplicant (see CHAPTER 100: REDUPLICATION), which is formed with segments from the root. Another exponent is glottalization of the sonorant consonant in the root in (6c). What then is the affix here? As this simple example demonstrates, the issue of identifying roots and affixes in languages depends on the type of morphological operations that are used to create words. It is much more straightforward with concatenative morphology than with non-concatenative morphology (see CHAPTER 105: TIER SEGREGATION and CHAPTER 108: SEMITIC TEMPLATES on various issues related to tier segregation and non-concatenative morphology). As a result, this study will treat these types of morphological systems differently, presenting the bulk of generalizations regarding root–affix asymmetries in concatenative systems first, followed by a brief examination of non-concatenative systems.

A second set of issues arises when one considers content words *vs.* function words (lexical *vs.* inflectional, in Jakobson's terms). The issue relates to whether function words pattern with roots or affixes. For example, Willerman's (1994) cross-linguistic study of pronouns found that they have less complex segments (CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION) than content words, suggesting that function words pattern with affixes in this regard. Studies by Casali (1997) on vowel hiatus (CHAPTER 61: HIATUS RESOLUTION) and Alderete (2003) on Navajo have also found that function words (and functional categories) pattern with affixes in terms of being the locus of an alternation, while content words are similar to roots in terms of retaining contrasts and resisting alternations. Both types of RAA are therefore attested with function words. In terms of specific types of roots, different lexical classes of content words have also shown asymmetrical patterns along these same lines (see CHAPTER 102: CATEGORY-SPECIFIC EFFECTS).

Finally, there are many languages in which affixes can have a lexical type of meaning as well as a grammatical type of meaning. For example, in Salish languages there is a class of lexical suffixes that illustrates semantic, phonological, and syntactic properties of roots, and researchers on this topic have proposed that they are bound roots (Blake 1998; Urbanczyk 2001; Wiltschko 2005). Thus we can see that being bound is not a sufficient condition for being an affix. Many languages have obligatory bound roots, and many have free roots, and so it seems likely that a language can have both. Similarly, Alderete (2003) has found that the disjunct domain of prefixes patterns with the stems in Navajo in terms of having more lexical meanings, more marked phonological structure, and resisting alternations. A cursory examination of a language may fail to note these subtle patterns, so care must be taken in understanding how to categorize affixes, as they could be bound roots.

To summarize, the term root will be used as a convenient if not entirely accurate label for those parts of words that have lexical meaning, whether that be obligatorily bound or potentially free. Likewise, affixes will be understood as that portion of the word that has a more grammatical or morphosyntactic meaning associated with it, whether it be bound or not.

2.3 Summary and limitations

The limitations of this study extend to the body of data that was compiled in order to determine the range and types of root–affix asymmetries attested in the languages of the world and to issues discussed above in terms of analyzing words into roots and affixes.

Two types of research have been surveyed: research that is focused on root–affix asymmetries, such as Noske (2000), Alderete (2003), and Bybee (2005), and research that is broadly typologically based, such as Casali (1997), Hansson (2001), and Rose and Walker (2004). In surveying the research, I first attempted to find as comprehensive information on contrasts as possible, and Bybee (2005) was taken as a representative study. To find comprehensive information on alternations, I surveyed typological studies that focused on particular phonological processes, like morphological accent (Alderete 2001c) and lenition (Kirchner 1998). It is hoped that the examination of a range of different types has yielded an adequate sampling. A balance of studies was also hoped for in terms of detailed examination of a single language (Noske 2000; Alderete 2003) and broader surveys (Bybee 2005). It should be pointed out that a survey of the research shows that the broader typological studies have limitations that are not found with the detailed studies.

A further limitation on the examination of affixes is that no systematic comparison of affix type was attempted. Thus there was no specific examination of how prefixes, suffixes, and infixes could differ from each other. It should be pointed out that there may be significant differences between prefixes and suffixes, because the beginnings of words often show different phonological patterning than the ends of words and there are some well-known prefix–suffix asymmetries.

As was discussed above, the types of root–affix asymmetries that are possible fall into several categories of complement sets, and four different subset possibilities. If root–affix asymmetries are entirely unconstrained, then we expect to find an approximately equal number of each type of asymmetry. However, as will be discussed below, two types of subset root–affix asymmetry have been found much more frequently than any others: affix segment inventory is a subset of those found in roots (as pointed out by Jakobson), and affixes illustrate more alternations than roots. The reverse patterns – more contrasts in affixes and more alternations in roots – are not as robust. The following sections outline these findings for root–affix contrasts (§3) and for alternation asymmetries (§4).

3 Root–affix contrasts

As a means of investigating contrast asymmetries, this section deals with segmental contrasts and morpheme shapes.

3.1 *Segmental contrasts*

As Jakobson's observation reveals, contrasts found in affixes can be a subset of those found in roots. Bybee (2005) investigates this observation, by asking the following questions: how robust are the findings, and what are some hypotheses that account for the findings? In doing so, Bybee provides a comprehensive examination and discussion of segmental asymmetries, as found in a variety of typologically unrelated languages. As pointed out above, all segments found in affixes were a subset of those found in the language as a whole, although fewer than one quarter of the languages in her study illustrated restrictions that could be considered natural classes. The discussion of these restrictions is organized according to features classes, starting with place of articulation. The section ends by outlining some of the hypotheses put forward by Bybee in accounting for the patterns.

There are a number of well-known place markedness hierarchies, whereby sounds like coronals and glottals are considered less marked (CHAPTER 12: CORONALS; CHAPTER 4: MARKEDNESS; CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION), while complex sounds like pharyngeals and uvulars are considered marked (see de Lacy 2006 on markedness hierarchies; CHAPTER 25: PHARYNGEALS on pharyngeals). In terms of coronal unmarkedness, while Bybee (2005: 183) reports that "there is no particular evidence for the favoring of coronal consonants in affixes," Alderete (2003) observes that only coronal consonants are found in conjunct prefixes in Navajo. A difference between Bybee's and Alderete's statistical methods should be touched on at this point. Bybee was interested in determining the likelihood of specific segments occurring in affixes *vs.* roots, so just one instance of a segment in one affix is sufficient to include it as occurring in affixes. However, Alderete's study is based on frequency of occurrence. He found that some affix-class morphemes include non-coronals, but the presence of them is not statistically significant compared to other affixes in Navajo. Bybee (2005: 183) also observes that systematic exclusions of "place of articulation are rare if both obstruents and nasal consonants are taken into account," noting that labials are the ones most commonly excluded. She reports that, while they occur in roots in Abipon, Kanuri, and Tohono O'odam, alveo-palatal affricates are excluded from affixes; and in Shuswap, uvulars are excluded from affixes, even though they are found in roots. And in English, while roots have the entire range of contrasts, inflectional affixes have only coronal consonants, with the notable exception of *-ing*.

In terms of laryngeal features, the strongest tendency in Bybee's study relates to the absence of glottalization (both ejectives and implosives) in affixes. This finding is also supported in research elsewhere. In Cuzco Quechua, roots can have ejectives and plain and aspirated plosives, while affixes only have plain plosives (Parker and Weber 1996). In Amharic and Salish languages, ejectives appear only in roots, and never in affixes (Urbanczyk 2001; Usshkin 2006). The restriction is quite striking also when combined with Rose and Walker's (2004) finding that instances of consonant glottal harmony (CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS) are only found within roots, not between roots and affixes. In terms of other laryngeal contrasts, out of the core set of languages Bybee examined, only Dakota and Tojolabal have affixes that ban voiced obstruents in affixes, though the former permits voiceless aspirated stops in affixes. It is interesting to note that the majority of languages in Bybee's corpus do not show any symmetrical patterning with respect to voicing or aspiration. For example, Kanuri has [b t k g] in affixes, but not [p d]. Bybee examined seven other languages to confirm that the restriction of glottalization on affixes is robust. Interestingly, of this set of supplementary languages, Kanakura and Tigre also banned voiced obstruents from affixes and Krongo banned implosives.

In addition to the points above regarding alveo-palatal affricate and nasal/place restrictions, not much is known about manner contrast RAAs. An interesting pattern is found in Chaha, in which laterals appear only in loanwords and affixes, never in roots (see work by Banksira, cited in Golston 1996). In reviewing Bybee's appendices, one can see that there are many languages which restrict laterals in affixes (Maidu, Tojolabal, Kanuri, Baluchi, and others).

In terms of asymmetric vowel contrasts, languages were found to exclude long vowels (Kui, Kanakuru, Krongo), nasalized vowels (Ngambay, Slave), front rounded vowels (Guaymí), and non-peripheral vowels (Buriat, Krongo) from affixes, even though they are found in roots.

In terms of understanding the patterns of root–affix segmental asymmetries, Bybee outlines several approaches one can take: markedness, complexity, and grammaticization. The first two share the property that the restrictions found with affixes are related to being less marked or less complex (see CHAPTER 4: MARKEDNESS). Bybee (2005) points out that, without a suitable theory of markedness, it is difficult to assess whether affixes are truly less marked than roots. Having found only six languages which show classes of restrictions from affixes, Bybee proposes that neither markedness nor complexity offers a satisfactory account of the range of patterns found. Instead, she proposes that grammaticization is the cause of the asymmetry. Under this view, affixes are reduced forms of lexical morphemes, which start off with the full inventory of sounds. As morphemes are grammaticized, they tend to become reduced phonologically, thus eliminating some of the more complex articulations. The randomness of some affix segments is thus a reflection of the randomness of the earlier form of the morpheme or root, and is not the result of synchronic alternations to eliminate marked structure.

Bybee considers a very early conception of markedness, as presented in *SPE* (Chomsky and Halle 1968), alongside Willerman's (1994) proposed "complexity" metric, finding the latter to offer a more satisfactory explanation of some of the patterns found in her survey than markedness theory. However, there are two aspects of markedness constraints that make them well suited for understanding some of the patterns that Bybee found. First, markedness constraints can either be context-free or context-sensitive. Thus it is not the case that segments are simply indicated as marked or unmarked, as in *SPE*; context is crucial. Secondly, for some researchers markedness constraints can be grounded in the sense that there is often a phonetic explanation for why segments or segmental sequences are less common (Archangeli and Pulleyblank 1994; cf. de Lacy 2006 for a different view).

Let us take an example from Bybee (2005), presented to illustrate randomness. The consonants not found in affixes are indicated in parentheses, including [p g].

(7) *Consonant inventory of Tohono O'odham* (Bybee 2005: 178)[2]

(p)	t		(ʧ)	k	ʔ
b	d	ɖ	(ʤ)	(g)	
			(s)	ʂ	h
m	n		ɲ		
(w)	r (l)		j		

Given a rudimentary view of markedness, where voiced obstruents are more marked than voiceless (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION), the pattern above does indeed seem to be arbitrary: voiceless bilabial stops and voiced velar stops do not form a natural class. However, if one takes a phonetically grounded view of markedness, then we can consider the phonetic conditions under which voicing occurs. Whether or not the vocal folds "vibrate" has an aerodynamic underpinning, and the pattern of contrasts in Tohono O'odham appears to be a case of more natural (unmarked) segments emerging in affixes. The explanation is as follows. For voicing to occur at all, the vocal folds must be closed, and the air pressure above the glottis must be lower than the subglottal air pressure (Kingston and Diehl 1994). By Boyle's Law, the higher air pressure below the glottis will force the vocal folds open, causing periodic pulses (vocal fold vibration) to occur. With oral stops, air cannot leave the vocal tract during the closure phase. Because the total volume of air is held constant for stops, there is an interaction between the place of articulation (related to volume of air above the glottis) and the effort needed to maintain voicing. When a stop consonant is made closer to the front of the mouth, as with bilabial place, the volume of air is larger above the glottis and less effort is needed to maintain voicing than when a stop consonant is made closer to the glottis, as with velar place. Therefore, the more natural stops are voiced bilabial – more volume of air above the glottis facilitates voicing – and voiceless velar – less volume of air above the glottis inhibits voicing. The marked stops [p g] are missing from affixes. Because this explanation is based on a principle of aerodynamics, and there is only one feature involved in the contrast – [voice] – it is a good case in which we can separate complexity from phonetic markedness. A complexity approach cannot address why [voice] would be present with [labial] but not [dorsal].

Recall that for vowel contrasts, length, nasalization, and other features were excluded from affixes. If one views complexity as correlated with the number of features or structures present (μ, [nasal]), then this seems to support a complexity approach. However, when we consider languages with front rounded vowels, the issue is not as clear. If a language has [−back, −round] and [+back, +round] vowels, there is no a priori reason to assume that [−back, +round] is more complex than [+back, −round].[3]

[2] I represent the inventory following Saxton (1963), but with IPA symbols.

[3] This discussion is somewhat simplistic, as a full analysis would also need to consider whether features are binary or unary, and whether they are fully specified or not, as in research on underspecification theory (see CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION).

3.2 *Root–affix shapes*

In many languages, affix morphemes have simple onsets, though complex and simplex onsets are widely attested in roots (Sanskrit, Tibetan). I have found no examples where only affixes have complex onsets while roots have simplex onsets. Once again this is an instance of affixes having a subset of the patterns found in roots.

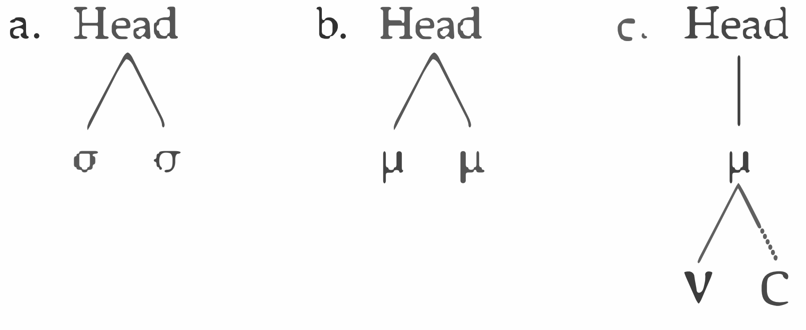
A growing body of research indicates that roots have a special status in terms of their shape. In particular, Downing (2006) has argued extensively that roots, being heads of words, demand more complexity to their shape.

(8) HEADSBRANCH (Downing 2006: 122, adapted from Dresher and van der Hulst 1998)

Lexical heads (roots) must prosodically branch.

The representations in (9) all satisfy HEADSBRANCH.

(9)



Downing also proposes that roots, being monomorphemic heads, are predicted to be monosyllabic and to optimally satisfy branching by matching (9b) or (9c). Monosyllabicity follows from the MORPHEME–SYLLABLECORRELATION constraint, in which "each morpheme contains exactly one syllable" (Downing 2006: 120, adapted from Russell 1997: 121). The representation in (9a) would be ruled out in many languages if MORPHEME–SYLLABLECORRELATION is active. Downing's approach can account for different sizes of morphemes, but it is not clear how to extend this to syllable onset complexity. While one can view complex onsets as having branching structure, there doesn't seem to be evidence for a constraint that *requires* root syllables to have branching onsets.

A second type of asymmetry in morpheme shapes is related to a type of conspiracy in ensuring well-formed syllable structure over the word as a whole. In Salish and Bantu languages, the canonical root shape is CVC, though other root shapes exist, such as CVCC, CVCVC, etc. In these languages suffixes frequently have a -VC shape, so there is an asymmetry whereby roots are consonant-initial and suffixes are vowel-initial. When one considers that affixes by their very nature never occur in isolation, and that syllabification occurs to produce well-formed syllables, the end result is that no further codas are added to a word. So the addition of vowel-initial affixes to consonant-final roots seems to conspire to keep the number of codas the same. The following is a schema from a Salish type language to illustrate this (cf. (6a) *vs.* (6b) above).

(10)		UR		SR	
	a.	/CVC/	→	[CVC]	(1 coda)
	b.	/CVC + VC/	→	[CV.CVC]	(1 coda)

Finally, one might wonder about whether or not to include morphological accent in the section on contrasts. I have opted to include them in the section on alternations because the determination of whether a morpheme is accented or unaccented, and of how morphemes interact with each other, is a type of alteration.

In terms of morpheme shape, it is difficult to tease apart markedness from complexity. Clearly, complex onsets branch, which correlates with complex structure. However, it is not clear how that differs from our conceptions of syllable markedness.

4 Root–affix alternation asymmetries

In terms of investigating root–affix alternation asymmetries, the following processes have been examined: vowel harmony, consonant harmony, vowel elision, lenition, nasal place assimilation, voicing assimilation, and morphological accent systems. Vowel harmony seems to have special properties, which are related to how affixes are specified; this is the area where the most root–affix reversals have been pointed out in the theoretical literature (Baković 2000; Noske 2000; Pensalfini 2002; Ussishkin 2006). Therefore more space is dedicated to discussing this process than others. One preliminary finding of this survey is that there appear to be some processes that are more likely to be sensitive to the root–affix distinction than others. For example, I haven't found examples where nasal place assimilation, voicing assimilation, or lenition occur in affixes, but not in roots. If these types of processes occur at all, then they seem to occur across the board.

4.1 Vowel harmony

Vowel harmony is a process whereby the vowels within a particular domain (typically a phonological word) agree in their values of some (rarely all) vocalic features (see CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY). There are two types of vowel harmony systems in the languages of the world: root- (or stem-) controlled and dominant–recessive systems (Baković 2000). An illustrative example of root-controlled harmony can be found in Akan (Niger-Congo), which has both prefixes and suffixes (Clements 1980). Following standard format, the affix vowels which are able to harmonize are indicated in capital letters in the input (indicating that they lack the harmonizing feature); the root is indicated with √.[4] As can be seen, both prefix and suffix vowels agree in [ATR] with the neighboring root vowel.

(11) *Akan* [ATR] *harmony* (Clements 1980, as cited in Baković 2000)

a. /E + √bu + O/ → [ebuo] 'nest' [+ATR] root
CLASS + nest + SFX

b. /E + √bʊ + O/ → [ɛbʊɔ] 'stone' [–ATR] root
CLASS + stone + SFX

[4] Based on the hypothesis that vowel features are only fully specified in roots, one could also argue that this is a case where roots show more contrasts than vowels.

c. /O + bE + √tu + I/ → [obetui] 'he came and dug (it)' [+ATR] root
3SG + come + dig + PAST

d. /O + bE + √tu + I/ → [ɔbɛtʊɪ] 'he came and threw (it)' [−ATR] root
3SG + come + throw + PAST

With dominant–recessive systems, a dominant vocalic feature is realized, regardless of whether it is in the root or affix. Furthermore, if it is present in both root and affix, then the affix feature prevails.[5]

A case of affix dominance is identified by Noske (2000), who proposes that Turkana (Eastern Nilotic) is an example of a language in which some suffixes trigger [ATR] harmony in the root. The relevant data are presented below. Observe in (12) that the root vowel is [−ATR]. However, when some suffixes are added with a [+ATR] vowel, then the root vowel alternates.

(12) *Turkana* (Noske 2000)

unsuffixed root		*suffixed root*	
a-k-dɔk	'to climb'	e-dok-eːn-e	's/he always climbs'
		e-dok-e	'way of climbing'
a-k-ɪmʊj	'to eat'	a-k-imuj-eːn	'to eat regularly'
		e-k-imuj-e	'way of eating'
a-dɛm-ar	'to take away'	e-dem-eːn-e	's/he always takes'
		e-dem-e	'way of taking'

The examples below crucially illustrate that the suffix's harmonizing feature can be [−ATR] as well as [+ATR].

(13) *Non-alternating* [−ATR] *suffixes in Turkana: Roots become* [−ATR]

unsuffixed root		*suffixed root*	
a-ki-lep	'to milk'	a-lɛp-ɔr	'to milk out'
a-ki-gol	'to close'	a-gɔl-ɔr	'to close out'
a-ki-bon	'to return'	a-bɔn-ɔr	'to return to a place'
a-ki-rem	'to spear'	ɛ-rɛm-ɛ-rɛ	'(why) is it speared?'
a-ki-mor	'to insult'	ɛ-mɔr-ɛ-rɛ	'(why) is he insulted?'

In trying to understand this system as a whole, it is important to compare the root vowels that enter into the harmony system with the affix vowels that participate in the [ATR] harmony. In doing so, we can see that the pattern of suffix-controlled harmony differs in a crucial way from root-controlled harmony. While the suffixes that undergo harmony can be triggered by both high and mid vowels (low vowels do not participate in harmony), only mid vowels on roots will agree with the [ATR] value of the suffix, as the following examples illustrate.

[5] Hansson (2001) observes that the majority, if not all, of the dominant–recessive harmony systems involve tongue root features [ATR] or [RTR].

(14) *High vowels are not affected* (Noske 2000: 78)

a.	a-bu-ɛt	'swelling (SG)'
	a-tub-ɛt	'judgment (SG)'
	a-tiŋ-ɛt	'handle (SG)'
b.	a-duŋ-ɔr	'to cut open'
	a-rɪp-ɔr	'to skim off'
	a-buk-ɔr	'to pour out'

This suggests that Turkana is actually a case of root alternations being a subset of affix alternations. Note that the set of vowels that participate in vowel harmony in the root is a subset of those that undergo harmony in the affix.

(15) *Summary of Turkana vowel harmony*

a. *Root-controlled*
Mid and high affix vowels alternate.

b. *Affix-controlled*
Mid root vowels alternate.

Secondly, there are several different types of suffix in Turkana: those in which the vowel freely participates in [ATR] harmony, and those in which it does not, so the set of affixes that trigger harmony is a subset of the affixes as a whole. To be a case of a true reversal, or even a complement set asymmetry, the alternation is expected only in the root, or the affix alternations should be a subset of the root alternations. These observations lead us to determine that the pattern found in Turkana is not an authentic instance in which the affix has more alternations than the root, but rather a specific type of RAA involving a dominant–recessive distinction with a specific, small set of affixes.[6]

4.2 Consonant harmony

While vowel harmony systems illustrate root control and affix dominance, only root control is found with consonant harmony systems (Hansson 2001). There are many instances in which affix consonants assimilate to root consonants in terms of place, manner, and voicing. Much rarer are cases of consonant harmony, whereby affix consonants assimilate entirely to the features of root consonants in the word. See also work on long-distance consonant assimilation by Rose and Walker (2004).

4.3 Other assimilations

Finally, we will make a quick examination of other types of assimilation. Vowels can assimilate to consonants in terms of manner of articulation – becoming nasalized vowels – and changes in vowel height. In many Salish languages, vowels lower in the context of a uvular consonant, which has a low tongue body. This

[6] Baković (2000) analyzes the Turkana system as a dominant-recessive harmony system, invoking the cycle to derive the correct harmony patterns. He also needs to refer to high-ranking specific suffix faithfulness constraints. Cf. Noske (2000).

process is almost universal in those languages that have uvular place of articulation. As far as I am aware, there are no languages in which the assimilation occurs with affix vowels but not roots; nor with root vowels but not affix vowels. In all the cases that I am aware of vowel lowering happens across the board.

In terms of consonants assimilating to vowels, some common processes include lenition (CHAPTER 66: LENITION) and palatalization (CHAPTER 71: PALATALIZATION). In a typological survey of lenition patterns, based on over 200 languages, Kirchner (1998) does not identify any root–affix asymmetries, though he does observe that lenition can be blocked in two environments: word-initially, and in the onset of a stressed syllable. These are two prominent positions identified by Beckman (1999) in her Positional Faithfulness model of phonological asymmetries (to be discussed further below).

Finally, some processes seem to be quite ubiquitous, applying freely anywhere within a word. Nasal place assimilation is an example. In this instance the nasal is almost universally the target of the assimilation rather than the following stop articulation. However, when nasal–stop sequences result in coalescence, whereby the output is a single nasal consonant that has the same place of articulation as the stop, Pater (1999) has found that coalescence does not always occur with root-initial segments. The failure of nasals to assimilate to the place of articulation of a following consonant can also be found in English with the prefix *un-*, which is external to the prosodic word.

4.4 Deletions

Deletions can affect both consonants and vowels (CHAPTER 68: DELETION). Let us start with vowel elision and the typological survey reported on in Casali (1997), based on 68 Niger-Congo languages and 19 other languages. The effects of vowel elision can be seen when morphemes or words combine. Casali observes that while it is widely claimed that V_1 elides universally in V_1–V_2 sequences, cases in which V_2 elides form a natural grouping in terms of belonging to a non-prominent position (see also CHAPTER 61: HIATUS RESOLUTION). The following summarizes the relevant findings presented in Casali (1997). It is important to point out that the summary below combines all findings; thus it represents the universal preference for V_1 to elide, as well as the preference for affixes and/or function words (FunctWord) to elide over roots and/or content words.

(16) *Vowel elision patterns* (Casali 1997: 496–497)

a.	LexWord LexWord	$V_1\ V_2 \rightarrow V_2$	no language in which only V_2 elides
b.	LexWord FunctWord	$V_1\ V_2 \rightarrow V_2$	
		$V_1\ V_2 \rightarrow V_1$	for 12 languages
c.	Prefix–root	$V_1\ V_2 \rightarrow V_2$	no language in which only V_2 elides
d.	Root–suffix	$V_1\ V_2 \rightarrow V_2$	
		$V_1\ V_2 \rightarrow V_1$	for 14 languages

As can be seen from the summary above, when both categories are the same as in (16a) only the first vowel elides: this illustrates the universal preference for V_1 to delete. However, when a root (or LexWord) is followed by an affix (or FunctWord), as in (16b) and (16d), then in some languages the second vowel elides:

the preference to elide a vowel in the affix (FunctWord) in these languages overrides the other tendencies. The pattern in (16c) illustrates that root vowels do not elide when they follow affix vowels. To summarize, the only condition in which V_2 does elide is when it is part of an affix (or FunctWord). This is consistent with the RAA subset pattern of alternations, where root vowel alternations are a subset of affix vowel alternations.

In terms of consonant deletion, St'at'imcets coronal–coronal sequences are resolved differently, based on the morphological affiliation of the segments. The data in (17a) illustrate that the "indirective" suffix /-xit/ ends with a coronal stop. In (17b) this suffix-final /t/ is deleted when followed by a coronal. In (17c), the roots retain the final /t/ when followed by a coronal.

(17) *St'at'imcets coronal–coronal sequences* (Interior Salish; Blake 1998: 2–3)[7]

a.	*Suffix–suffix*		
	/√nas-xit-aʃ/	[nas.xi.taʃ]	's/he gave it to him/her'
	/√hal'a-xit-aʃ/	[ha.l'a.xi.taʃ]	's/he showed it to him/her'
b.	*Suffix–suffix*	$C_1 C_2 \rightarrow C_2$	
	/√tɬ'ɛq-xit-tumuɬ/	[tɬ'ɛq.xi.tu.muɬ]	'bring it to us'
	/√tɬ'ɛq-xit-ʧ/	[tɬ'ɛq.xiʧ]	'bring it to me'
c.	*Root–suffix*	$C_1 C_2 \rightarrow C_1 C_2$	
	/n-√ʕʷɔj't=tən/	[nʕʷɔj't.tən]	'bed'
	/n-√pət=ʧ-an'/	[npət.ʧan']	'to cover an opening'

The pattern above parallels that found with vowel elision in terms of the first instance of an affix consonant deleting, while root segments are retained.

4.5 Morphological accent

Just as with vowel harmony, there are two types of morphological accent systems: root-controlled and dominant–recessive (Alderete 2001c). In morphological accent systems, morphemes are specified as accented or unaccented and/or as dominant or recessive. Accented morphemes have a stress in the input, while unaccented ones do not. Dominant morphemes are those that exert an influence over recessive morphemes, regardless of whether the affix is accented or unaccented.[8]

In terms of understanding morphological accent RAAs, Alderete (2001c) examines a wide array of morphological accent systems, finding that there is a preference for expressing root accents rather than affix accents. The system found in Cupeño (Uto-Aztecan) illustrates this. As can be seen below, when both roots and affixes are accented, the root accent will surface (18b).

[7] I have modified Blake's representation of the data, so that her original underlying representations have the same segmental allophones as the surface forms.

[8] Much as in harmony systems, dominant–recessive morphological accent systems are analyzed as involving cyclic application, which can erase previous morphological structure. See Czaykowska-Higgins (1993) for a detailed analysis of Nxa'amxcin (Interior Salish) stress.

(18) *Cupeño accented roots with accented affixes* (Alderete 2001a: 456)

a. /ˈpə + ˈ√miʔaw + lu/ → [pə-ˈmiʔaw-lu]
3SG + come + MOTION 'he came'
b. /ˈ√ʔaju + ˈqa / → [ˈʔajuqa]
want + PRES SG 'he wants'

The following illustrates that affix accent surfaces if the root is unaccented, providing evidence that affixes have an underlying accent.

(19) *Cupeño unaccented root with accented affixes*

a. /ˈpə + √jax/ → [ˈpə-jax]
3SG + say 'he says'
b. /nəʔən √jax + ˈqa/ → [nəʔən ja-ˈqaʔ]
1SG say + PRES SG 'I say'

However, recent work by Hargus and Beavert (2006) on Sahaptin has revealed a case of affix dominance. The following data illustrate that, when an accented root is preceded by an accented prefix, the prefix accent surfaces (20a). If the prefix is unaccented, then the root accent surfaces (20b).

(20) *Yakima Sahaptin morphological accent* (Hargus and Beavert 2006: 179)

a. /ˈpa-/ (INVERSE) /ˈpa-ˈ√watʼa-na/ [ˈpawatʼana] 'he struck at him'
b. /pa-/ (3PL NOM) /pa-ˈ√watʼa-na/ [paˈwatʼana] 'they struck'

This is clearly a case to look at more closely. In examining the system, a key difference was found between Sahaptin and a system like Cupeño, with root-controlled accent. While in Cupeño only some roots are accented, it turns out that in Sahaptin all roots have some form of lexical accent (Jacobs 1931; Hargus and Beavert 2006). Combining this with the fact that only some affixes have a lexical accent (20), it would seem that once again the affixes that are lexically specified for accent represent a subset of contrasts found on roots. If all roots are accented and root dominance prevailed, one would never see the effect of the affix accent at all.

To sum up the findings with respect to alternations in general, it appears that the types of alternations that roots undergo are a subset of the types of alternations affixes undergo. The reverse was not found in which affix alternations are a subset of root alternations. The only exceptions to this are instances of dominant–recessive vowel harmony or accent systems. The latter seem to be characterized as permitting only one value to appear within a particular domain, so they seem to have different properties than other types of alternations.

5 Approaches to root–affix asymmetries

Having provided an overview of the types of patterns found (or not) with respect to root–affix asymmetries, one may well ask whether they should be accounted for within a generative theory of grammar, i.e. as part of our linguistic competence (i-language; Chomsky 1986), or whether the randomness found by Bybee (2005) suggests that the patterns are the result of linguistic performance (e-language). By finding that some possible asymmetries are not attested, I hope to have teased apart some of the issues involved in undertaking research on RAAs and I suggest that this provides some evidence that grammatical principles are active in accounting for aspects of RAAs (though more research is needed to clarify what can be attributed to competence *vs.* performance).[9] The discussions of the approaches taken to accounting for RAAs thus assume that the asymmetry can be accounted for with grammatical principles. The approaches can be grouped into two broad categories: implicit approaches, which do not refer to root and affix directly, *vs.* explicit approaches, which do.

5.1 *Implicit approaches*

In implicit approaches to root–affix asymmetries, patterns arise due to mechanisms that do not refer directly to roots and affixes. This section surveys some of the ways in which RAAs can be achieved.

One example of an implicit approach was mentioned briefly at the outset of the chapter: directionality. In autosegmental phonology (Leben 1973; Goldsmith 1976) contrasting features (such as tones) are listed in the lexicon along with the relevant morphemes, but are not attached to segments. The features become properties of segments once they are linked to them via association conventions. The default direction of association is left-to-right. This direction of association is able to derive spreading of some listed feature of a morpheme to its right that lacks that feature. In the case of vowel harmony, this can account for root-controlled vowel harmony, when there is a following suffix, as in Turkish, but not for cases where prefixes also participate in the harmony, as in Akan.

A significant amount of research on the phonology–morphology interface has been undertaken in the theory of Lexical Phonology (Kiparsky 1982). In Lexical Phonology, words are built up incrementally by interspersing morphological operations with phonological processes; the various levels are often referred to as strata. There is evidence for (at least) two kinds of affixes in many languages: stem-level (non-neutral) are associated with changes to a base, and word-level (neutral) are not associated with changes to a base (CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME). Given that phonological rules can apply after affixes are added, this approach can account for processes that affect affixes, but not roots: for the root to not be affected, the rule does not apply until after an affix is added. A key issue in the application of phonological rules is how to prevent an alternation from applying to the whole word, leaving the root unaffected. The failure of some rules to be able to look back into the root is known as non-derived environment blocking (NDEB; see CHAPTER 88: DERIVED ENVIRONMENT EFFECTS). A well-known example that illustrates the phenomenon is found in Finnish, in which assibilation occurs when roots and affixes are concatenated, turning /t-i/ into [si], as can be seen in (21a). This process does not occur root-internally, but only at root–affix junctures (21b).

[9] See de Lacy's (2006) proposal and discussion of evidence that some types of phonological markedness are part of competence and others are part of performance.

(21) *Finnish NDEB* (Kiparsky 1993)

a.	/tilat-i/	→	[tilasi]	'order-PAST'	*[tilati, silasi]
b.	/vaati-vat/	→	[vaativat]	'demand-3PL'	*[vaasivat]

The failure of root-internal /ti/ sequences to undergo an alternation could also be viewed as a subtype of root–affix asymmetry.

Another approach to maintaining the identity of roots falls under the general umbrella of paradigm uniformity effects. Because roots form the basis of many paradigms, and we know that paradigm pressure can inhibit the application of processes (see CHAPTER 83: PARADIGMS), this is also a potential area to investigate RAAs.

Finally, some patterns of root–affix reversals are related to analyses that propose a dominant–recessive system for roots and affixes. As mentioned in footnotes 6 and 8, cyclicity is one way to account for dominant–recessive morphemes. Another way to view dominant–recessive systems is that only the feature associated with the dominant affix will surface within a phonological word. If this is true, then the types of alternations found with dominant–recessive systems are fundamentally different from other types of alternations. Having a fundamentally different approach to analyzing root–affix reversals, distinct from other types of processes, is therefore not unexpected, given the larger picture of the properties of RAAs.

5.2 *Explicit approaches*

In explicit approaches to accounting for root–affix asymmetries, reference is made directly to roots and affixes, as is the case with morpheme structure conditions/constraints (Halle 1959; Stanley 1967) and in research within Optimality Theory (OT; Prince and Smolensky 1993).

Morpheme structure conditions (MSCs) involve statements about the phonotactic patterns of morphemes in a language. As such, they encode information about roots and affixes. The formulation of MSCs relates also to what is redundant or predictable. For example, with Turkish vowel harmony, roots would be specified for all their vocalic features, while affixes would not. By directly encoding predictable information in MSCs, differences between roots and affixes emerge, even though MSCs do not directly refer to root–affix asymmetries. (See CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS for further discussion of MSCs.)

Perhaps the largest body of research that analyzes RAAs directly has been carried out in OT. McCarthy and Prince (1995, 1999) propose that the identity of morphologically related strings (input–output, base–reduplicant, and word–word) is mediated by a correspondence relation. They refer to this approach as Correspondence Theory (CT). CT is not a necessary component of OT; however, this framework has led to a growing body of theoretical research on RAAs. Monitoring the identity of strings, such as between input and output (underlying representation and surface representation), is done through the use of faithfulness constraints, so any alternation correlates with a violation of some faithfulness constraint. In identifying the types of correspondence relations that can exist, McCarthy and Prince propose that the correspondence relation is relativized to roots and affixes. Several OT approaches make use of CT in analyzing RAAs; these will be discussed in the remainder of this section.

In order to account for some of the observations noted above – that roots tend to have more marked contrasts and to resist alternations – McCarthy and Prince propose the following universal ranking.

(22) *Root-affix faithfulness metaconstraint* (RAFM; McCarthy and Prince 1995: 364)

FAITH-Root >> FAITH-Affix

In OT, constraints are ranked and violable; any deviation from identity between strings results in a violation of FAITH. Lower-ranked constraints are more likely to be violated, and the location of some markedness constraint with respect to FAITH-Root or FAITH-Affix can compel alternations resulting in asymmetrical patterns. For example, the following constraint ranking accounts for the Sanskrit RAA presented in (2), whereby roots have complex onsets, but affixes do not (McCarthy and Prince 1995: 365).

(23) FAITH-Root >> *COMPLEX >> FAITH-Affix

Because markedness constraints (among others) can intervene between these two FAITH constraints, the universal ranking in (23) predicts that affixes will be the target of alternations and will exhibit less marked structure than roots. Thus this general approach has a way to capture exactly the two types of asymmetries found. While a great deal of literature has supported this general approach (Casali 1997; Beckman 1999; Alderete 2001a, 2001b, 2001c, 2003; Urbanczyk 2001; Pensalfini 2002), there has also been a growing body of research which proposes that the ranking in (22) is not universal (Noske 2000; Ussishkin 2005, 2006; Hargus and Beavert 2006).

A modification of how to obtain root–affix asymmetries in OT, known as positional faithfulness (PF), is developed by Beckman (1999) to accommodate a range of privileged positions. Beckman proposes that roots are just one of several positions within a word, such as root, initial syllable, and stressed syllable, which illustrate more contrasts and are resistant to change. Instead of having faithfulness specific to affixes and adopting the RAFM in (22), Beckman proposes that there is generalized faithfulness along with several specialized faithfulness constraints, which are relevant to different prominent positions. To recast the constraints in (23) into a PF approach, one would have the following ranking.

(24) *Positional faithfulness approach to Sanskrit*

FAITH-Root >> *COMPLEX >> FAITH

The way that the FAITH constraints are evaluated in PF is that *every* change in the identity of a string – regardless of whether it is a privileged position or not – will incur a violation of FAITH. If there is a change in the identity of the privileged position – in this case roots – that will incur a violation of both FAITH-Root and FAITH. This means that violations of privileged positions will incur two violations, inherently worse than violations in a non-privileged position. The ranking of FAITH-Root over FAITH is not proposed to be universal, and is instead emergent. This key difference between how faithfulness violations are calculated in RAFM and PF approaches translates into a difference of complement set *vs.* subset asymmetries. While in PF the violations of FAITH-Root are literally a subset of the violations of FAITH, in the RAFM approach the violations of FAITH-Root cannot be a subset of the violations incurred by FAITH-AFFIX.

It is significant to note that PF is well suited to analyzing instances of RAAs. Let us consider how constraint re-ranking – a core feature of OT – can derive just the subset pattern. In OT, unless there is a fixed universal ranking (as with the RAFM), all possible permutations of constraint rankings are possible. If, for any phonological phenomenon being investigated, there are two types of faithfulness constraints (FAITH and FAITH-Root) and one markedness constraint (*M), this gives us 3!, i.e. six (3 × 2 × 1), possible rankings. It turns out that several of these rankings will result in the same pattern. For example, as long as FAITH dominates *M, the language will have the marked structure M throughout the entire language – roots and affixes alike (25a). The following table summarizes how the six different rankings map onto the patterns of a language, where specification of root *vs.* affix is indicated in the first two columns: M indicates that the marked feature is found, while ¬M indicates that it is not found. For alternations, A indicates that an alternation occurs, while ¬A indicates no such alternation.

(25) *Factorial typology*

	root	*affix*	*constraint ranking*		
a.	M, ¬A	M, ¬A	FAITH	>> FAITH-Root	>> *M
			FAITH	>> *M	>>FAITH-Root
			FAITH-Root	>> FAITH	>> *M
b.	¬M, A	¬M, A	*M	>> FAITH	>> FAITH-Root
			*M	>> FAITH-Root	>> FAITH
c.	M, ¬A	¬M, A	FAITH-Root	>> *M	>>FAITH

Only three patterns are generated. In three rankings, (25a), roots and affixes have the marked structure, but not the alternation. Two constraint rankings, (25b), produce a pattern where both roots and affixes do not have the marked structure, but do have the alternation. And one ranking, (25c), results in unmarked structure emerging in the affix, along with an alternation; this is "the Emergence of the Unmarked" (TETU) effect showing up in non-roots (for more about TETU, see CHAPTER 58: THE EMERGENCE OF THE UNMARKED). As one can see, there is no ranking such that affixes will have the marked structure (M) not found in roots or such that roots will exhibit an alternation (A) not occurring in affixes. This matches the types of RAAs found. The complement set type of asymmetry cannot be derived, because either there is a difference between roots and affixes, as with the TETU ranking in (25c), or roots and affixes are the same, as in (25a) and (25b). There is nothing that will favor markedness in affix classes by constraint ranking alone (though see Pater 2000, 2009 and Gouskova 2007 for discussion of indexed constraints for specific morphemes).

An alternative OT approach to privileged positions is Positional Markedness (Zoll 1998). Rather than having faithfulness constraints relativized to position, markedness constraints are relativized to positions. So the Sanskrit pattern would have the following constraints.

(26) *Positional Markedness approach to Sanskrit*

*COMPLEX >> FAITH >> *COMPLEX$_{ROOT}$

See Alderete (2003) for arguments against the Positional Markedness approach for Navajo RAAs.

A further approach to RAAs in OT includes research on domains and morpheme-specific alternations within a co-phonology framework (Inkelas *et al.* 1997; Inkelas 1999). In co-phonologies, each morpheme can be associated with a different constraint ranking. There can be one ranking for roots and another for affixes. The ability to freely re-rank constraints for a specific morpheme can result in systems where complement set asymmetries can be derived. A language in which voiced stops are present only in affixes can be derived by the following ranking.

(27)	a.	Root co-phonology	*VOICED-STOP	>> FAITH
	b.	Affix co-phonology	FAITH	>> *VOICED-STOP

The survey conducted here was not able to verify any instance of a complement set asymmetry. So it would seem that, without some internal constraints, the co-phonology model overgenerates possible RAAs.

6 Form–function mappings

One of the secondary themes regarding RAAs relates to form–function mappings. Three topics will be examined briefly: non-concatenative morphology (§6.1), morphologically conditioned alternations (§6.2), and psycholinguistic grounding (§6.3).

6.1 Non-concatenative morphology

As discussed in §2, there is a range of non-concatenative morphological processes that make the identification of roots and affixes a challenging task. Some of these have been touched upon above. However, numerous other processes are relevant as well, including root-and-pattern morphology, reduplication, vowel and consonant mutations, subsegmental affixes, and tone (see CHAPTER 105: TIER SEGREGATION for a survey of many of these patterns from the perspective of tier segregation).

The discussion begins by examining a purported case of affix dominance in Hebrew (Ussishkin 2005, 2006). As is well known, Hebrew words can be formed by a system of intercalcating root consonants and affix vowels, in the form of *binyanim* (see CHAPTER 108: SEMITIC TEMPLATES). The following illustrates the basic system for /gadal/ 'to grow'.

(28) *Hebrew verbal paradigm* (Ussishkin 2006: 114)

underived lexical representation	*base form + affix*		*derived form*	
/gadal/	[gadal]			'he grew'
		[i e]	[gidel]	'he raised'
		[u a]	[gudal]	'he was raised'
		[hi i]	[higdil]	'he enlarged'
		[hu a]	[hugdal]	'he was enlarged'

Working within an OT framework, Ussishkin proposes that the affix vowels in the input must be parsed in the output, arguing that this is a case in which Faith-Affix dominates Faith-Root.

However, there are two reasons to believe that this is not an authentic counterexample to RAAs. First, the expression of the affix vowels is compelled by a morphological criterion, not a phonological one. Failure to parse the input vowels would result in homophony throughout the system, as discussed by Ussishkin. Secondly, there is an assumption that the vowels in the input stem are part of the stem and not part of any affix. However, the entire Semitic *binyanim* system of morphological contrasts is based on the assumption that the pattern of contrasts in consonants is linked with roots, while that of vowels is associated with affixal meanings. Why would the vocalic melody /a-a/ in /gadal/ not be associated with any meaning in just this one word, while in all the other words in the paradigm it is associated with some type of aspectual meaning? As indicated in Ussishkin (2005: 200), the /a-a/ cell in the system of vowel contrasts is associated with "PAST TENSE" meaning. Therefore, this is not an actual counterexample to the trend for affixes to be more likely to be subject to alternations. In actuality, the vowels that are lost are associated with affixal meaning as well.

Reduplication is a morphological process whereby part of a word is copied, in order to indicate a difference in meaning (CHAPTER 100: REDUPLICATION; CHAPTER 119: REDUPLICATION IN SANSKRIT). There is a great deal of evidence that reduplication targets roots rather than affixes (see McCarthy and Prince 1993; Urbanczyk 2001, 2007). For example, in Axininca Campa root segments are copied over affix segments (McCarthy and Prince 1993). There is a disyllabic minimum for reduplication. If the root meets the disyllabic target, then only root segments are copied (29a). However, if the root is subminimal, then it is augmented to meet minimality requirements, or the prefix material is recruited for copying (29b).

(29) *Axininca Campa reduplication* (McCarthy and Prince 1993: 63–64)

	stem size	*without prefix*	*with prefix*		
a.	stem ≥ disyllable	kawosi-kawosi-	noŋ-kawosi-kawosi	'bathe'	
		kintha-kintha-	noŋ-kintha-kintha	'tell'	
b.	stem < disyllable	paa-paa-	no-wa-no-wa-	'feed'	/p-/
		nata-nata-	no-naa-no-naa-	'carry'	/na-/

6.2 *Morphologically conditioned alternations*

Languages which exhibit consonant mutations and other types of stem modifications have been excluded from the discussion of purely phonological alternations (see CHAPTER 82: FEATURAL AFFIXES; CHAPTER 65: CONSONANT MUTATION; CHAPTER 117: CELTIC MUTATIONS). It is interesting to note that, for the most part, these types of alternations seem to target roots rather than affixes, and also to create marked segments rather than eliminate them. Recall that, in Halkomelem, progressive morphology is accompanied by resonant glottalization (6), creating an extremely rare class of sounds cross-linguistically.

6.3 *Psycholinguistic grounding*

There is a range of psycholinguistic evidence to show that roots are accessed differently from affixes as reported in Beckman (1999). In addition, Ussishkin and Wedel (2002) discuss a psycholinguistically grounded explanation for RAAs on the basis of the concept of effective contrast. On the basis of the hypothesis that the ease of lexical retrieval is facilitated by token frequency and neighborhood density (Luce 1986; Luce and Pisoni 1988), Ussishkin and Wedel propose that an effective contrast is one that balances these two factors. High-frequency words with few neighbors are the easiest to access, while low-frequency words with many similar neighbors are the most difficult to access. Because there are many more meanings of roots to be encoded, having sparse neighborhoods and distinct sounds will aid in lexical recovery. This has implications for patterns found in Hebrew and Nuu-chah-nulth.

In Hebrew, the affixal vocalic melodies utilize the bulk of the available affix space. With five distinctive vowels and two possible slots, there are 25 possible combinations, of which there are 17 distinct meanings (Ussishkin 2006).

Languages like Nuu-chah-nulth (Southern Wakashan), with over 400 suffixes, illustrate more patterns than languages with relatively few affixes, suggesting that it is also important to consider the proportion of roots to affixes when considering markedness patterns. Lee and Urbanczyk (2006) found a strong correlation between phonetic similarity of the affixes (parallel to neighborhood density) and whether or not an affix triggers stem modifications, such as vowel lengthening or reduplication.

7 Summary

This paper has investigated RAAs, with two key goals: to tease apart some of the complications associated with studying RAAs, and to discuss the various theoretical approaches. In doing so, some unexpected patterns emerged. First, apparent cases of RAA reversals are correlated with dominant–recessive morphological accent and vowel harmony systems. Analyses which aim to fit these into the RAFM approach – a model of root–affix correspondences which is complementary – are forced to give up the universal ranking of Faith-Root over Faith-Affix. Secondly, some types of processes were found to be less susceptible to RAAs. And finally, the range of RAAs found seems to suggest that some patterns are due to competence while others are due to performance. It is hoped that further research into root–affix asymmetries will undertake significantly detailed case studies, in an attempt to verify the findings reported here.

ACKNOWLEDGMENTS

Many thanks to Ewa Czaykowska-Higgins and Sunghwa Lee for discussion of some of the points in this paper, and to the editors of the *Companion* for helpful feedback in revising it. Research was funded in part by a University of Victoria Internal Research Grant and SSHRC 410-2003-1523 awarded to the author, who bears the responsibility for any factual errors or oversights.

105 Tier Segregation

Adam Ussishkin

1 Introduction: Tier segregation as phonological representation

At or near the top of the job description of the phonologist is the goal of finding, describing, and explaining patterns of behavior among features, sounds, and other phonological elements in languages of the world. For theories stemming from the generative approach that began most conspicuously with Chomsky and Halle (1968, henceforth *SPE*), the most highly valued explanations are rooted in Universal Grammar (UG). *SPE*-based phonology centered on alternations in phonological patterns, and one of its primary contributions to linguistic theory was to shift the burden of the explanatory basis for such patterns away from the lexicon and onto the grammar (the hypothesized computational system responsible for the relationship and mapping between the hypothesized lexical representations and observed surface forms). Therefore, all evidence for such impoverishment of lexical representations is *indirect* evidence adduced from patterns and alternations observed on the surface. The cost of reliance on such indirect evidence was nonetheless thought by generative phonologists to be outweighed by the explanatory benefit that resulted from the ability to pare down lexical representations and concomitantly endow the grammar with a rich array of rules (or constraints, depending on one's theoretical commitment) that provided structure necessary for the mapping from underlying to surface form.

With a firm commitment to the bare bones, abstract lexical representation with no redundant information encoded, *SPE*-based phonology and its practitioners in the 1960s and 1970s focused on the content and form of grammatical rules, where the majority of the phonological action was to be found. A crucial (and quite obvious) benefit of this approach was the ability to grammatically relate variant forms of the same underlying abstract elements, such as the phoneme and the morpheme (CHAPTER 11: THE PHONEME; CHAPTER 1: UNDERLYING REPRESENTATIONS). A simple example at the phoneme level can be found in the following pairs of words from Maltese, a Semitic language spoken on the island nation of Malta, where voiceless and voiced obstruents turn out to be in complementary distribution:

(1) *Maltese voicing assimilation* (data from Borg 1975)[1]

voiceless obstruent		*voiced obstruent*	
hapta	'knock (N)'	habat	'he knocked'
aatsa	'ducking'	oodos	'he ducked'
hasat	'he startled'	hazda	'fright'
fadal	'it remained'	vdaal	'remains'

Such examples of alternation are quite common cross-linguistically, and can be further subdivided into various principled types; such details need not concern us here. The important point about such examples for the generative phonologist is that they establish the need for abstract, underlying elements such as the phoneme and the morpheme, which are the primary ingredients for word formation. Rather than listing the underlying form of the Maltese morpheme for 'knock' as /hapta/ and 'he knocked' as /habat/, the fact that the two words share some core set of semantics is captured by the fact that they are formed from the same lexical element. Whatever this lexical element turns out to be, it should nonetheless contain only the unpredictable information. Therefore, the voicing specification of the labial obstruent in the lexical representation of these words will either be underspecified or specified in a marked way (see CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION for more on underspecification). The surface form of the consonant in question is context-dependent, and determined by the computational system, or grammar, that operates on the concatenation of elements in word formation, and not on the underlying representation, which is consequently simpler. From a morphological perspective, the paired words above can be observed to share their consonants, and so in a similar vein the underlying morphological representation of each form might reflect this by storing a set of non-contiguous consonants as a lexical item; more on this type of representation will be discussed below.

Early generative phonology maintained this focus on representational issues, though for the most part the debates on representation centered on morphophonemic structure and the abstract representations of phonemes and morphemes in the lexicon, as illustrated in the Maltese examples above. However, the groundbreaking work on tone and tonal alternations by Leben (1973) literally introduced a new level of analysis, in which tonal elements were viewed not as segment-delimited specifications within a feature matrix, but rather as freed from the grasp of the segment and allowed to behave as independent units on a tonal *tier*. An important result from this work is the genesis of the Obligatory Contour Principle (OCP), taken to be responsible for tonal distribution patterns (e.g. surface tone patterns in Mende, as analyzed by Leben 1973). In its original guise, the OCP was defined by Leben as follows:

(2) *Obligatory Contour Principle*[2]

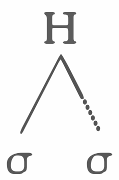
At the melodic level, adjacent identical elements are prohibited.

[1] Both voiced and voiceless obstruents are phonemic in Maltese. This alternation is an example of contrast neutralization.

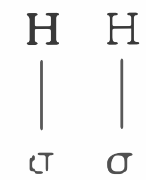
[2] While the OCP is a crucial motivating ingredient in the development of tier segregation, it is nonetheless not the main focus of this chapter. See CHAPTER 14: AUTOSEGMENTS.

The OCP is invoked as an explanation for the existence of tone patterns such as H+, HL+, LHL, L+, and LH+ in Mende,[3] and the exclusion of patterns such as HHL and LLH in the language. Note the repeating elements in these latter, unattested cases. It is only under a view in which tones are freed from their segmental manifestations that the argument becomes clear: if tones occupy a distinct tier, it is possible to capture the asymmetry in distribution of tone patterns. Thus, Leben's work invoked a more complex, non-linear style of representation. In this representation, sequences of the same tone are represented by a multiply linked tonal element (3a), rather than multiple tonal elements with single linking (3b).

(3) a. *Multiple linking* (respects OCP)



b. *Single linking* (violates OCP)



In addition to the OCP, non-linear representation was also capable of capturing the fact that, when some phonological alternation requires a change in tone, all elements in that sequence of tone tend to change. The argument requires additional assumptions regarding representation; namely, that tones and segments are arrayed on separate tiers, and the invocation of the various conditions:

(4) a. *Association Convention*
Associate tones to syllables one-to-one and left-to-right.

b. *Well-Formedness Condition*
At each stage in the derivation, all syllables are associated with at least one tone, and all tones are associated with at least one syllable.

c. *No-Crossing Condition*
Association lines may not cross.

This is the original use of tier segregation, though not the one focused on in this chapter. Nonetheless, its genesis was a crucial step in the development of non-linear models of phonology, and led to the subsequent application of tier segregation at the featural level in phonology and to the segregation of vowels and consonants into separate tiers in Semitic and other languages.

In the tier-segregated view, a representation consists not of a string of concatenated, independent feature matrices, but rather is composed of a set of multi-tiered elements linked by association lines. This more complex and non-linear representation permits principles of association, spreading and the OCP as explanatory devices for patterns difficult to explain in the strictly linear model. The non-linear view found further support in subsequent work, most importantly Goldsmith (1976), McCarthy (1979, 1981, 1989, 2000), and Clements and Keyser (1983). Goldsmith (1976) generalized Leben's (1973) model to all phonological interactions, capturing much more intuitively the notion of featural alternations, especially phonological assimilation. The behavior of certain phonological features appears suspiciously similar to tonal behavior, so that in fact the extension to these

[3] Kleene "+" in these representation refers to a tone that associates to a syllable and to any following syllables.

features seems logical once the data are viewed under the autosegmental lens. In fact, this logical extension applied not only to local (or adjacent) environments, but additionally to seemingly non-adjacent sets of elements, thus allowing for a unified explanation of both local and long-distance phonological behavior.

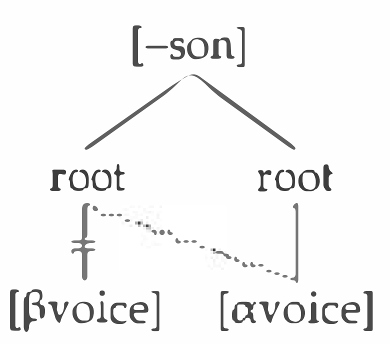
The primary focus of this chapter on tier segregation is the segregation of consonants and vowels into distinct tiers. This idea has its roots in the autosegmental approach of Goldsmith (1976), who, based on work on the behavior of tone in tone languages, proposed extending the notion of tiers beyond tones to the phonological domain in general. The earlier generative approach to phonological behaviors such as Maltese voicing assimilation was the application of linear rules to an underlying or intermediate representation. Phonological rules capturing this sort of behavior have the generic form A → B / C __ D, where A refers to a structural description, B to a structural change and the portion of the rule following the / to the phonological environment. For instance, returning to the case of voicing assimilation in Maltese as presented above, a linear rule could be written as follows (CHAPTER 81: LOCAL ASSIMILATION):

(5) *Maltese voicing assimilation* (*SPE*-style)

[−sonorant] → [αvoice] / __ [−sonorant, αvoice]

Such a rule successfully describes the alternation, and for *SPE*-style phonologists would be seen as explanatorily adequate, but proponents of autosegmental phonology would argue that it misses a crucial fact. Note the double occurrence of the feature [αvoice] in the rule: once in the structural change, and a second time in the phonological environment, or trigger. Use of the Greek letter variable notation forces the phonologist to hypothesize that, in fact, there are not two separate voicing specifications in the representation (as the linear rule would lead us to believe) but rather that the voicing feature of the trigger *spreads* to the target under this type of assimilation behavior. In other words, despite the double occurrence of the changing feature, there really is only a single token of it at work here. Such an approach involves a more complex representation, which is needed to capture the idea that segments are composed of features that themselves have autonomy; that is, that are not strictly bound to the segment they are underlyingly associated with (hence the name *autosegmental*). An autosegmental rule, then, involves a type of decomposition along with a higher degree of complexity, and for the case of voicing assimilation could appear as follows:

(6) *Maltese voicing assimilation* (autosegmental)



Note that unlike the linear rule, which explicitly denotes the input and output of a phonological process by explicitly referring to a structural description (to the left of the arrow) and a structural change (to the right of the arrow), the autosegmental rule collapses these into the same representation, where the structural change is denoted by the dashed line indicating the spreading of the voicing feature regressively from the second segment (segments are represented here as non-sonorant root nodes) and by the dissociation of the first segment's original voicing specification (which is not explicitly indicated in the linear rule).

In the late 1970s, the representational force of this sort of rule was carried even further by McCarthy (1979, 1981, 1989, 2000), whose prosodic model of non-concatenative morphology resulted in yet further unification: Semitic languages and their well-known root-and-pattern morphology could also be analyzed as involving autosegments; in other words, the idea of autosegmental representation was lifted to the level of the morpheme. The result of this work is consonant–vowel tier segregation, the best-known example of tier segregation, and the one that this chapter will focus on. On McCarthy's view, various patterns specific to Semitic were explained (e.g. OCP effects, morpheme structure constraints, and long-distance consonantal spreading/copying), while invoking a simple yet natural additional extension of the autosegmental view to the morpheme level. The notions of the consonantal root, the vocalic pattern affix, and the prosodic template follow naturally from this extension. At the same time, the tier-segregated representation opened the door to a more advanced understanding of complex phonological behaviors in another well-known set of data outside Semitic: templatic languages that lack root-and-pattern morphology, such as Yawelmani Yokuts (Archangeli 1983, 1984, 1985).

In fact, the influence of autosegmental representation and tier segregation was so great that many of the most important results in phonology in the 1980s stemmed from this revolutionary representation. During this period, an enormous amount of attention was devoted to the representational details of the tier segregation model, leading to a growth industry in feature geometry, the nature of UG-provided structures, and ultimately to other models, such as Articulatory Phonology (Browman and Goldstein 1986, 1989; among others), in which the notion of the segment itself was almost so diluted that it seemed epiphenomenal.

While interest in the representation of the internal structure of segments has comparatively waned since the advent of models such as Articulatory Phonology (see CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATION), and especially since Optimality Theory (henceforth OT; Prince and Smolensky 1993), the issue shaped the field of phonology quite dramatically for a significant period. In this chapter, tier segregation will be explored in detail: §2 reviews evidence for tier segregation from Semitic data; §3 provides further evidence, with data from non-Semitic languages; §4 presents some of the more current debates regarding tier segregation, along with external evidence that bears on the issue; and finally, §5 concludes the chapter.

2 The evidence for tier segregation from Semitic

2.1 Roots and patterns

In his 1979 dissertation and subsequent 1981 article, McCarthy took non-linear representation an enormous step further. The basis of his contribution comes from Semitic languages (McCarthy focuses mainly on Classical Arabic and Tiberian

Hebrew), which have long been characterized by their non-concatenative morphological behavior (dubbed "root-and-pattern morphology" by McCarthy). In these languages, much of the word structure displays a strikingly unusual characteristic: rather than forming words from sequences of contiguous elements, words appear to have a non-concatenative structure in which the consistent phonological material within a given paradigm is non-contiguous. This can be illustrated with a typical paradigm from the verbal system of Modern Hebrew:

(7) *Hebrew verbal paradigm*

verb	*template*	
ganav	CVCVC	'to steal'
higniv	CVCCVC	'to smuggle in'
hitganev	CVCCVCVC	'to sneak in'
nignav	CVCCVC	'to be stolen'

Basic morphological analysis reveals that the consistent phonological material in the paradigm is the discontiguous string of consonants /gnv/, which in the traditional root-and-pattern approach to Semitic is called a consonantal root and has the status of a morpheme. Prior to McCarthy, the consonantal root had long been recognized as the likely center of gravity in the Semitic lexicon (cf. Chomsky 1951; but see also work from much earlier, including de Alcala 1505; de Volney 1787; de Sacy 1810; Bopp 1824; Ewald 1827; Gesenius 1910; Gaon 1932, 1942, 1969; Harris 1941). It is clear why this is the case: superficially at least, the consonantal root appears to have an obvious and consistent semantics associated with the examples given above (something to do with stealing or sneaking). What's more, a similar case can be made for the parts of each word that form the complement to the consonantal root. For instance, in the word /higniv/, there is clearly a causative meaning, and causatives frequently occur with the same /hi-i/ pattern combined with a consonantal root (for the sake of comparison, a related (non-causative) form is also provided for each example):

(8) *Hebrew causatives with* /hi-i/

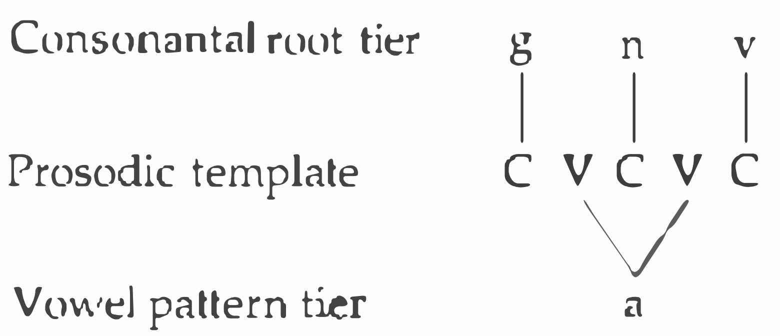
verb		*related form*	
higniv	'to smuggle in'	ganav	'to steal'
hizrik	'to inject'	zarak	'to throw'
hixnis	'to bring in'	nixnas	'to enter'
hirdim	'to put to sleep'	nirdam	'to fall asleep'

Not every verb with /hi-i/ is causative (e.g. /hirgiʃ/ 'to feel'; /himtin/ 'to wait'), and not every causative verb has /hi-i/ (e.g. /limed/ 'to teach, cause to study'; /simeax/ 'to make happy'), but nonetheless verbs in a particular class (known as a *binyan*, the Hebrew word for building or structure) all demonstrate the same phonological behavior and pattern together morphologically.[4] In order to formalize the notions of consonantal root morphemes and pattern morphemes,

[4] See Laks (2006) for a contemporary view of such relations from a syntactic-morphophonological point of view.

McCarthy's (1979, 1981) theory of non-concatenative morphology proposes C/V tier segregation based on morphological grounds: each morpheme is said to occupy its own tier in the representation. Lexically, as far as stem formation is concerned, three types of morpheme are found: consonantal root morphemes, pattern morphemes, and prosodic templates.[5] Word formation involves the concatenation of these units according to autosegmental principles (association of segmental elements to appropriate prosodic positions, going one-to-one from left to right). A form like Hebrew /ganav/ therefore has the following representation in the phonology after association of morphemes:

(9) *Tier-segregated representation of /ganav/*



There are several things worth noting about this type of representation. First of all, note the multiply associated vowel /a/, which is linked to both V positions in the prosodic template. This multiple association is a necessary consequence of the OCP, which would prohibit a representation containing two tokens of the vowel /a/ located on the same tier (because identical adjacent elements are prohibited by the OCP). Secondly, this representation does not capture the pronunciation of the word /ganav/ directly, because it is not a linear representation. In later work, McCarthy (1986) cites Younes's (1983) concept of tier conflation, a mechanism responsible for linearizing a tier-segregated representation in order to pronounce it. Tier conflation is essentially the bridge between the autosegmental, tier-segregated non-linear representation, and the surface form, which is viewed as linear.[6]

2.2 *Templates*

Another motivation for McCarthy's approach – and the reason tier segregation was so widely adopted following his theoretical innovations – was that it was able to capture the fact that consonants and vowels occur in different combinations, depending on the particular pattern that a consonantal root is found in. In other words, the precedence relations between consonants and vowels change, depending on the template they associate to. If rules of association govern these precedence relations, then it would be redundant to record this information in the lexicon as well. Tier segregation achieves the goal of redundancy avoidance by remaining silent on the issue of precedence relations among elements belonging to distinct morphemes. To illustrate the argument, recall the paradigm above for

[5] Hebrew also has the more familiar type of concatenative morphology in the form of prefixes and suffixes (as do all Semitic languages), in addition to its non-concatenative structure. These prefixes and suffixes tend to be correlated with inflectional morphology.

[6] See Bat-El (1988) for an important discussion and review of tier conflation and its consequences.

/gnv/: sometimes all three consonants are separated by vowels (e.g. /ganav/ 'to steal'), other times the first two consonants of the root are adjacent (e.g. /nignav/ 'to be stolen'). The ordering relationships between elements from different morphemes are determined by the prosodic template, and therefore fall into the category of predictable information (for a review and current assessment, see CHAPTER 108: SEMITIC TEMPLATES). Even in a more current view (one beginning with McCarthy and Prince 1986, 1990, 1993), in which the prosodic template is no longer lexically specified but rather is derived from independent grammatical principles (cf. Ussishkin 2000, 2005), it is nonetheless possible to predict the relative placement of consonants and vowels. No matter the template to which a consonantal root morpheme or a vowel melody morpheme is associated, the ordering of elements *within each morpheme* is the only unpredictable and consistent information, and thus the only ordering-related information encoded lexically. Essentially, the benefit of tier segregation is that since the grammar will provide the information regarding ordering of consonants and vowels via association, that information can be removed from the lexicon. As McCarthy (1989: 88) points out:

> planar V/C segregation emerges from the redundancy of linear order relations between vowels and consonants in languages with templatic morphology [not just Semitic but also others like Yawelmani] or sufficiently rigid constraints on canonical form.

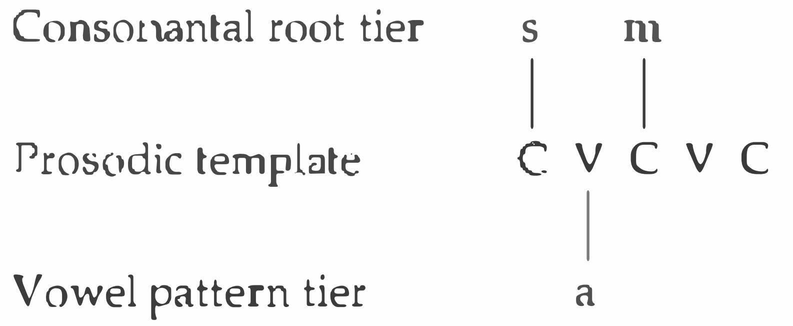
2.3 *The OCP, morpheme structure constraints and alternation*

Further motivation for tier segregation is offered by some well-known distributional facts regarding Semitic word structure (McCarthy 1979, 1981; and many others): a word never contains the same consonant tautomorphemically in both the first and second C positions of a template, while words frequently contain the same consonant tautomorphemically in the second and third positions.[7] The well-known examples cited by McCarthy from Arabic are the non-existent form */sasam/ and the commonly encountered type of form such as /samam/ 'to poison'. Under an approach that recognizes the consonantal root and the segregation of morphemic tiers, forms such as /samam/ are formed from the root /sm/ associated to a CVCVC template in which the /m/ is multiply associated to both the second and the third C positions. This is a natural outcome under autosegmental phonology, in which the default direction of association is left to right. Once the /s/ associates to the first C and the /m/ associates to the second C, the third C is left without segmental content, so the /m/ spreads again to the third C position (spreading the /s/ to that position is impossible because doing so would violate the constraint against line-crossing). This mechanism is known as "long-distance consonantal spreading." The following diagrams illustrate each step in the derivation.

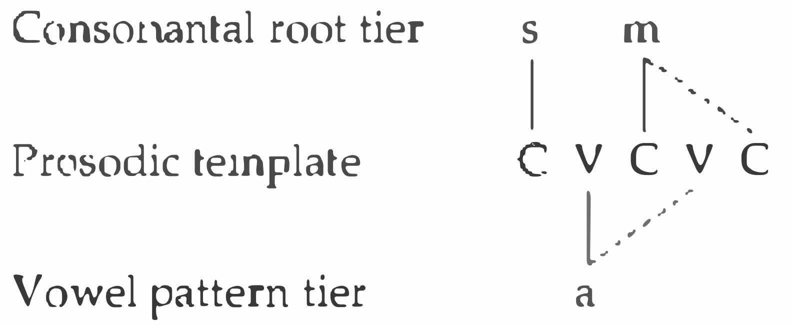
[7] Many thanks to an anonymous reviewer for pointing out that some Semitic languages have exceptions to this generalization; e.g. Hebrew /mimen/ 'to finance'. Since these exceptions are fairly uncommon, most previous research has tended to ignore them.

(10) *Deriving Arabic* /samam/

a. *Associate elements one-to-one, left-to-right*



b. *Fill empty templatic positions via long-distance spreading*



Under this model, it is impossible to generate unattested */sasam/-type forms, but attested /samam/-type forms should be the only possible output from biconsonantal roots. To complete the argument, it is necessary to rule out unattested */sasam/-type forms generated from a root like /ssm/ – such a root is easily ruled impossible, since its underlying representation violates the OCP by the presence of two adjacent, identical consonants. The same holds for an underlying representation like /smm/ (for a more general discussion of morpheme structure constraints, see CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS). This argument is perhaps the strongest argument in favor of tier segregation, since without tier segregation the OCP violation is not triggered.[8] The only way to generate the attested type (/samam/) is with a biconsonantal root and one-to-one, left-to-right association, resulting in the multiple linking of the second consonant to the second and third C positions.

Another well-known piece of evidence for the consonantal root discussed by McCarthy (1981) and subsequently cited by many authors (e.g. Hume 1994; Odden 1994; Suzuki 1998; Rose 2000) is found in Akkadian labial dissimilation. In Akkadian, the prefix /ma-/ is realized as [na-] if the stem it attaches to contains a labial consonant in the root. That is, the place specification of the prefix alternates depending on whether or not the root of the stem it attaches to contains a labial consonant. This type of alternation can be viewed as triggered by the OCP:

(11) *Akkadian labial dissimilation* (data from Rose 2000)

Akkadian noun	
ma-zuukt	'mortar'
ma-ʃkanu-m	'place'
na-phar	'totality'
na-rkabt	'chariot'

[8] See Rose (2000) for a reformulation of the OCP that would count both */sasam/ and /samam/ as OCP-violating forms.

The first two examples above contain roots with no labial consonants, and thus the nominalizing prefix is realized with the labial [m] (note that the suffix /in/ in the second case does not trigger dissimilation of the prefix). In the last two examples, there is a labial root consonant, and the prefixal consonant is realized as [n] as a result.

2.4 *Language games and other external evidence*

McCarthy (1981) also discusses evidence from languages games that appears to argue in favor of the consonantal root occupying its own tier at some level of representation. At issue are forms from the Bedouin Hijazi dialect of Arabic brought to light by Al-Mozainy (1981). As an example, McCarthy cites the variant forms of the verb /difaʕna/ 'we pushed': [daʕafna, fidaʕna, ʕadafna, faʕadna, ʕafadna]. The argument here is that without tier segregation, there is no way to array just the root consonants separately in a way that allows for their permutation as a target of the language game process. This is because the game distinguishes between root consonants (e.g. /dfʕ/ in these examples), which can permutate, and non-root consonants (e.g. /n/ in these examples), which cannot.

A similar type of argument is put forward by Prunet *et al.* (2000) and Idrissi *et al.* (2008). These researchers document a series of metathesis errors in a bilingual French–Arabic aphasic patient; of relevance is the observation that these errors only take place in the subject's Arabic utterances and never in his French utterances. Further, the errors involve metathesis of root consonants only; it is never the case that vowels or affixal consonants are metathesized. The authors take this as clear evidence for tier-segregated consonantal roots along the same lines as McCarthy and others, though Ussishkin (2006) rejects their account and proposes a constraint-based alternative that does not require reference to the consonantal root.

In closing, this section has provided many cases of evidence in favor of tier segregation based on phonological and morphological behavior in Semitic languages. In the following section, evidence from other languages is considered.

3 Non-Semitic evidence for tier segregation

3.1 *Yawelmani*

Evidence from non-Semitic languages has also provided arguments in favor of tier segregation. Archangeli's work on a number of dialects of the California Penutian language Yokuts is the best known, and will be the focus of the discussion and data here. In Yawelmani Yokuts, morphology looks strikingly Semitic; there appears to be, as in Semitic, a distinction between consonants, vowels, and the prosodic templates in which the consonants and vowels are realized. The template selected is dependent on morphology: essentially, the suffix selects the template. Archangeli (1983, 1984, 1985) provides stem alternations from Yawelmani illustrating multiple templates for verbs with three consonants:

(12) *Yawelmani CV templates* (adapted from Archangeli 1983: 351) *and data* (stems are underlined)

template		
CVCC	ʔamtsʼit	'be near'
CVVCC	deejilhin[9]	'guard'
CVCVVC	bineetit	'ask'

This pattern, in which the stem templates alternate, is persistent throughout the language, and it is typically the case that the suffix appended to the stem determines which template is chosen for the surface form. A tier-segregated representation, in which consonants and vowels of a morphological root occupy distinct tiers, captures the fact that the order of vowels and consonants is template-dependent and predictable, thus allowing for lexical representations that are rendered simpler by the absence of prespecified precedence relations between vowels and consonants. If the templates supply those orderings, and the templates are independently necessary, Yawelmani can be viewed much like Semitic, where the templates also supply the orderings between consonants and vowels. A crucial difference, of course, is that Yawelmani lacks the morphological distinction between consonants and vowels; both the vowel(s) and the consonants are viewed as part of the same morpheme in the cases above, yet nonetheless occupy separate tiers.[10]

3.2 Rotuman

Although he later rejects it (McCarthy 2000; see discussion below) as an example of tier segregation, McCarthy (1989) strongly suggests that the Oceanic language Rotuman provides evidence from outside the Semitic languages in favor of tier segregation. In this case, the data come from an alternation involving morphological metathesis (CHAPTER 59: METATHESIS).[11] Rotuman has a morphological distinction between what are known as different phases, of which there are two: the complete phase and the incomplete phase,[12] their occurrence being governed by syntactic and semantic principles (see McCarthy 2000: App. B for a review of Churchward's 1940 rules for use of the different phases). The two phases can be distinguished phonologically by a number of different alternations: final vowel deletion, umlaut, diphthongization, and, importantly for our purposes, metathesis (there are also cases in which forms in the two phases are homophonous). McCarthy (2000) gives the following examples of phase distinction by metathesis.

[9] The first [i] in this form is epenthetic, and therefore appears to disrupt the template. For much discussion on this issue, see Archangeli (1983).

[10] While the use of the term "tier" is maintained here, it is important to acknowledge Archangeli's (1985) more precise formulation of the distinction between "tier" and "plane." Much of the literature following Archangeli (1985) subsequently adopted the term "plane" for what is being termed here a "tier," and for the sake of consistency in this chapter I will continue to refer to "tiers."

[11] Though see Hume (1991) for metathesis evidence from Maltese that argues against McCarthy's (1989) claims for planar segregation.

[12] McCarthy (1986) states that the morphological difference between the complete *vs.* the incomplete phase corresponds to "a kind of free versus bound form, respectively."

(13) *Rotuman complete and incomplete phases distinguished by metathesis*

complete	*incomplete*	
iʔa	iaʔ	'fish'
seseva	seseav	'erroneous'
hosa	hoas	'flower'
pure	puer	'to rule'
parofita	parofiat	'prophet'

McCarthy (1989) considers Rotuman as a possible (but not, in his words, "iron-clad") case favoring tier segregation (referred to in McCarthy 1989 as "planar V/C segregation"). Despite the fact that this language has no templatic morphology, and no morphological distinction between consonants and vowels, allowing tier segregation in this language can explain the metathesis evidence in the phase distinctions above. In terms of linear order, with tier segregation in place in Rotuman, the metathesis can be viewed as templatic, since for each of the pairs of forms above the consonants always occur in the same linear order, as do the vowels; this is true because metathesis always involves a consonant and a vowel in this language. In other words, the precedence relations between consonants are preserved, as are the precedence relations between vowels. Tier segregation allows for this, though McCarthy acknowledges that other mechanisms could explain it as well. What differentiates the phases, then, is something template-like. Depending upon which phase is being selected by the grammar, the consonant–vowel ordering will differ.

This concludes the section in which non-Semitic evidence for tier segregation is discussed. In the following section, some debates concerning tier segregation are reviewed.

4 Debates

The extension of tier segregation beyond Semitic is not uncontroversial. The principal reasons behind this controversy can be divided into two principal types. One type concerns the non-morphological motivations for tier segregation in non-Semitic languages like Yawelmani and Rotuman. The second type is based on more recent developments in phonological theory.

4.1 *Non-Semitic languages*

4.1.1 Yokuts

Steriade (1986) attacks ideas from Archangeli (1984, 1985) concerning tier segregation in Yokuts. In particular, Steriade argues against separate tiers for consonants and vowels when the language has no morphological distinction between them. The idea advanced in Steriade (1986) is that only morphologically motivated tier segregation is legitimate. Since Yokuts does not distinguish consonants and vowels morphologically, her view is that tier segregation in Yokuts is not licit. An important consequence of this argument is that Steriade must explain the templatic effects so easily captured via tier segregation. She proposes an alternative analysis, in which a mechanism of "melody copy" (analogous to copying processes in reduplication) explains the templatic patterns found in this type of language. Prince (1987) responds to Steriade's approach with a vigorous argument against Steriade and in favor of Archangeli's original proposals for tier segregation. Again focusing primarily on Yokuts, with some additional Arabic and Hebrew evidence, Prince (1987) defends Archangeli's claims that tier segregation is *phonologically* motivated.[13]

4.1.2 Rotuman

Arguing against claims found in previous work, McCarthy (2000) rejects Rotuman as a possible case of tier segregation. Recall that the metathesis process encountered in the complete and incomplete phases in this language seems like a good candidate for tier segregation, since the two phases could be thought of as templatic. McCarthy's more recent (2000) account is couched within OT, and argues that

> OT takes much of the burden of explanation off of representations (e.g. tier segregation) and places it on substantive constraints . . . [t]hus, consonant–vowel tier segregation is completely superfluous in an Optimality Theoretic analysis of Rotuman, and in fact it is antithetical to fundamental premises of OT.

This is because of OT's assumption of Richness of the Base, which states that restricting the form of input material is disallowed. Under this assumption, every potential input form must be considered a legitimate input form, and despite this potential variation in inputs the actual attested output must nonetheless emerge as optimal. But with tier segregation, an OT analysis yields undesirable results, since with tier segregation it becomes impossible to capture the contrast between pairs such as /usi/ 'bush (sp.)' and /sui/ 'bone', which form a contrastive pair despite sharing the same consonant and the same vowel sequence in a tier-segregated view. That is because, under the tier-segregated view, the vowels would be represented separately from the consonants, yielding the same input (/ui + s/) for these two surface-contrastive pairs. McCarthy goes on to show that various attempts to patch the holes resulting from such an approach turn out to be unsuccessful, and concludes that "[n]o superficial technical fix is appropriate, because the problem derives directly from the core assumption of tier segregation theory."

Essentially, tier segregation is incompatible with OT, provided the basic assumption in OT that input forms may not be restricted, and that linguistic properties must be viewed as the result of output-oriented constraints. The argument continues, McCarthy suggests, as an even more fundamental result of this output-oriented focus: all underspecification, tier segregation included, is highly undermined by OT's principle/ingredient of output-based constraints. Since tier segregation underspecifies the linear order relations between consonants and vowels (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION), any tier-segregated input is an underspecified input. In earlier approaches, on the one hand, this was viewed as beneficial, since the linear order relations in question are predictable, and in pre-OT generative phonology no predictable information

[13] For another paper arguing against consonant–vowel tier segregation on a strictly phonological basis, see Odden (1987), who argues that McCarthy's (1982) proposals for phonologically based tier segregation in the Munda language Gta? are unmotivated and predict unattested data. Odden (1987) proposes an alternative analysis based on two rules: one of initial melody linking, and another (optional) rule of melody spreading.

is granted the status and luxury of residing in underlying representations. But OT, on the other hand, argues that the content of constraints, rather than the elegance of representations, bears responsibility for phonological behaviors, and thus tier segregation should be dispensed with.

4.2 *Semitic languages*

A number of researchers have proposed rejecting tier segregation even for Semitic languages, which formed the original case for tier segregation in the late 70s and early 80s. These researchers have various reasons for rejecting tier segregation, ranging from concerns regarding the highly abstract nature of lexical repres-entation under tier segregation (e.g. Ussishkin 2000, 2005, 2006) to the need to reformulate principles that tier segregation seemed to stem from originally, like the OCP (Rose 2000). Some of these arguments will be reviewed here.

Tier segregation relates directly to lexical storage of linguistic units and much scholarly activity on Semitic languages over the last decade or so has focused on lexical representations in Semitic. Bat-El (1994) was among the earliest researchers to propose that Semitic consonantal roots were explanatorily inadequate, and based her arguments on Hebrew data in which consonant clusters are preserved in the formation of verbs from nouns, such as the following:

(14) *Hebrew denominal verb formation with cluster transfer* (Bat-El 1994: 577–578; preserved clusters underlined)

noun		*denominal verb*	
transfer	'transfer'	trinsfer	'to transfer'
sandlar	'shoemaker'	sindler	'to make shoes'
psanter	'piano'	psinter	'to play the piano'
nostalgia	'nostalgia'	nistelg	'to be nostalgic'

If denominal verb formation were dependent on consonantal roots, it would be impossible to explain why the sets of adjacent consonants in these pairs are preserved in the related verbs, rather than all conforming to a uniform template. This is because, under an account based on tier segregation, the consonantal roots, on their own tier, are not stored lexically with any information regarding which consonants are surface-adjacent. Further, Ussishkin (1999) noted that another set of denominal verbs in Hebrew consistently preserves information from the vowel in the base – information that is not available from the base consonants alone:

(15) *Hebrew denominal verb formation with vowel feature transfer* (Ussishkin 1999: 405; corresponding vowel–consonant transfer effects underlined)

noun		*denominal verb*	
tik	'file'	tijek	'to file'
ˀir	'city'	ˀijer	'to urbanize'
sug	'kind, type'	siveg	'to classify'
hon	'capital, wealth'	hiven	'to capitalize'

Again, reliance on the consonantal root is insufficient to explain this phenomenon, because if the consonants are the only material that matters, then information about the vowel of the base is absent. Nonetheless, for these forms, there is a clear correlation between the vowel in the base and the medial consonant in the verb. Bat-El and Ussishkin both conclude that the Hebrew lexicon may not encode consonantal roots, thus invalidating an original motivation for tier segregation. They propose that, for denominal verbs, the lexicon stores stems or whole words, in which case no level of representation involves segregations of vowels and consonants into distinct tiers. In subsequent work, both Bat-El (2003) and Ussishkin (2000, 2005, 2006) extend these results and propose such a view not just for these verbs but for the entire language. That is, the lexicon stores stems or words, not consonantal roots, and these stems or words form the basis for morphological relationships and derivations.

Similar conclusions are reached for Semitic by Gafos (1998), who focuses on apparent spreading in the Malaysian language Temiar. Gafos (1998) concentrates on the theoretical device known as "long-distance consonantal spreading," which was previously thought (cf. McCarthy 1979, 1981, 1989, 2000) to be responsible for patterns such as doubled consonants in Semitic verbs (e.g. the discussion of Arabic /samam/ above). In Gafos's proposal, however, such long-distance spreading is rejected as an explanation for forms like /samam/, which are instead reformulated as examples of segmental copying rather than segmental spreading. Under the alternative copying-based account, no level of representation involves a multiply linked consonant (seen in (10b) above). The penultimate section of Gafos (1998) argues against tier segregation. The argument, like that of McCarthy (2000), is theory-internal from an OT perspective, and centers on the fact that within OT, properties of lexical forms do not result from underspecification, but rather from the interaction of universal constraints on surface forms.[14] This is essentially the same Richness of the Base argument proposed by McCarthy regarding Rotuman. Since tier segregation was originally motivated as a way to avoid lexical redundancy by avoiding lexical storage of predictable information, it falls under the rubric of underspecification and is therefore, at the very least, subject to deep scrutiny under OT. And indeed, Gafos concludes that tier segregation should be eliminated altogether. Gafos goes on to argue that not only does this apply at the phonological level (e.g. for languages with no morphological distinction between consonants and vowels, such as Yokuts), but that it should also apply at the morphological level, to Semitic languages in which one might posit a morphological distinction between consonants and vowels. Even this distinction can be captured via universal, output-oriented constraints, Gafos claims, and thus tier segregation receives no support.

In order for such a view to be maintained, alternative explanations for various phenomena are required. Gafos, for instance, proposes that, rather than viewing doubled consonants in Semitic as resulting from a spreading operation, we should see them as the result of a copying operation analogous to the copying seen in reduplication phenomena (CHAPTER 100: REDUPLICATION; CHAPTER 119: REDUPLICATION IN SANSKRIT). This argument echoes the proposals of Steriade

[14] See also Hudson (1986) for a tier-free analysis of Semitic, with a focus on Arabic. A related aspect of Hudson's (1986) analysis is that it foreshadows later OT accounts with its emphasis on output representations.

(1986) in her argument against Archangeli's phonological tier segregation, and finds further support in Ussishkin's (1999) treatment of doubled consonants in Hebrew denominal verbs, where a subset of verbs double the second base consonant to fill a verbal template:

(16) *Doubled consonants in Hebrew denominal verb formation* (Ussishkin 1999)

noun		*denominal verb*	
dam	'blood'	dimem	'to bleed'
sam	'drug'	simem	'to drug, poison'
xad	'sharp'	xided	'to sharpen'
mana	'portion'	minen	'to apportion'

Again, rather than viewing the repeated consonant in each denominal verb as resulting from long-distance spreading over a vowel position in a template, the repeated consonant is simply viewed as a copy. The template still plays an important role here, in that it is responsible for inducing the copy, but no spreading is invoked to explain the doubled consonant.

Another OT-based argument arguing against tier segregation can be found in Rose's (2000) reformulation of the OCP, which bears direct relevance to this discussion. In Rose's view, the OCP applies across intervening vowels to penalize identical consonants such as those seen above in consonant doubling denominal verbs in Hebrew. Rose additionally claims that consonant doubling results from copying, and not spreading, and also relies on a rejection of segregating vowels and consonants into distinct tiers. Focusing on evidence from Ethio-Semitic languages, Rose shows that a reformulation of the OCP into a surface-based constraint provides exactly the explanatory adequacy that is needed while at the same time avoiding the various pitfalls resulting from a combination of tier segregation and the input-based version of the OCP that would be incompatible with any output-oriented approach.

4.3 *Behavioral evidence*

Various experiments in Semitic have been reported in the literature that bear on tier segregation, and the results of these experiments are mixed, so it is impossible to adjudicate definitively based on these results. It is also important to note that these experiments have the explicit goal of testing the nature of lexical representations; in particular, whether lexical representations are root-based or word-based. The assumption being made in such work, and in this chapter as well, is that root-based representations are congruent with tier segregation, while word-based representations are not. The best-known studies have been carried out with Hebrew and Arabic (Frost *et al.* 1997; Deutsch *et al.* 1998; Frost *et al.* 2000 on Hebrew; Boudelaa and Marslen-Wilson 2000, 2001, 2004 on Arabic) using a variety of techniques, most commonly a masked priming lexical decision task using visual stimuli.[15] These

[15] In this task, subjects respond to pairs of stimuli consisting of a masked prime that they do not consciously perceive, followed by a target that they do perceive, and are asked to make a lexical decision about the target (i.e. decide whether the target is a word of their language or not). For instance, in a single trial the masked prime might consist of the Hebrew word /higdil/ 'to enlarge' followed by the target /gidel/ 'to raise'.

studies consistently demonstrate that when a target word shares a consonantal root with a masked prime, there is a significant priming effect manifested in a faster reaction time for such target items than when the masked prime does not share the consonantal root. This robust finding supports lexical storage of roots, and therefore supports a form of tier segregation. Conflicting results exist with respect to the decomposition of vocalic patterns: Frost *et al.* (1997) found no priming effect for vocalic patterns, while Deutsch *et al.* (1998) did find such priming. As for results that might argue against tier-segregated representations lexically, one reported study on Hebrew using visual stimuli (Moscoso del Prado-Martín *et al.* 2005) found a word frequency effect (which supports word-based storage and therefore does not support tier segregation), though the same study also found an effect of morphological family size, which supports representing consonantal roots in the lexicon.

These studies are not without their problems. First, all stimuli were presented visually. Because the orthographies of Hebrew and Arabic do not contain graphemes for many of vowels, visually presented primes and targets may bias participants to process consonants preferentially. For example, because there is no letter for the sound [a] in Hebrew, the word for 'to write', pronounced [katav], is written as *ktv* in Hebrew orthography. Visual presentation therefore introduces a very serious confound for any study that aims to see whether consonants play a special role in processing. Secondly, these studies have been carried out on languages with a consonantal orthography in which all educated native speakers receive explicit pedagogical instruction based on the consonantal root. Because of this, it is not entirely clear that studies are probing online processing of lexical units; earlier work has shown that literacy affects lexical organization (e.g. Morais *et al.* 1986). Another weakness of these earlier studies is that they do not manipulate root or word frequency, which would be the ideal probing mechanism for distinguishing root from whole-word access.

For Arabic, Boudelaa and Marslen-Wilson (2000, 2001, 2004) report consistent effects of priming by consonant-vowel patterns as well as by roots and patterns separately in a series of auditory lexical decision tasks with auditory primes (Marslen-Wilson and Zhou 1999). These results come from work on both Standard Arabic and Southern Tunisian colloquial Arabic, and, due to the fully auditory nature of both primes and stimuli, they avoid orthographic confounds inherent in any study that employs visual stimuli. The results suggest a decompositional route for lexical processing, thus supporting a tier-segregated view. One published study on Maltese (Ussishkin and Twist 2009) reports mixed results: in a visual masked priming experiment, a significant priming effect for consonantal roots was found, but the same paper also reports an auditory experiment whose results support storage of whole forms.

In recent work on Hebrew, Berent *et al.* (2007) provide experimental evidence that whole-word representations in the lexicon are needed in order to account for speakers' acceptability ratings of words in different paradigms that share identical consonantal roots. Such results argue against tier segregation, and although they are consistent with lexical storage of words, previous work on acceptability ratings (Berent *et al.* 2001, 2002, 2004) is consistent with both word-based and root-based storage. Finally, other work on Hebrew that supports word storage is reported in Sumner (2003), who ran auditory lexical decision experiments with auditory priming to test lexical access for a class of irregular verbs in Hebrew known as weak verbs. These are verbs whose final root consonant does not occur in pronounced forms. Sumner's results show that, for one class of weak verbs, there is evidence for whole-word storage, while, for the second class of weak verbs, age turns out to be a factor: younger speakers exhibit evidence of whole-word storage, while older adult speakers show an inhibitory effect of weak verb primes.

Despite their importance, these psycholinguistic studies leave open the issue of lexical representation. Given the range of evidence in favor and against tier segregation based on these studies, one tenable hypothesis is that the lexicon can store both root-based and word-based representations, thus allowing for the possibility of tier segregation.

More general studies also leave open this possibility. In a series of experiments testing learnability of statistically regular patterns, Newport and Aslin (2004) exposed subjects to invented words in a nonsense language, and manipulated the parts of the words that were consistent across stimuli. When subjects were exposed to stimuli consisting of non-adjacent regularities in the consonants (Newport and Aslin 2004: Experiment 2), they readily learned the patterns. These results contrast with those from words where non-adjacent syllables, rather than the consonants, were consistent. In the non-adjacent syllable case, subjects performed poorly. The fact that subjects were able to learn the pattern when it was manifested in non-adjacent consonants shows at the very least that humans can attend to such regularities, thus indirectly supporting an ability to segregate consonants from vowels. Similar results obtained by Newport and Aslin (2004: Experiment 3) show that, when non-adjacent vocalic patterns were held constant, subjects readily learned the pattern. Again, this result shows at the very least that subjects are capable of attending to regularities that hold across non-adjacent sets of segments.[16]

5 Conclusion

This chapter has focused on introducing and discussing the theoretical and representational concept of tier segregation. As the introductory paragraphs explain, this mechanism furthered the generative phonologist goal of reducing the burden on the lexicon by removing from lexical specification the ordering relationships between consonants and vowels. This was seen as a positive development by most phonologists, since it allowed for a highly grammatical explanation of patterns not only in Semitic, where it was first invoked, but also in non-Semitic languages such as Yokuts.

As discussed, the benefits associated with tier segregation were not without their costs. For the non-Semitic cases in which tier segregation has been called upon, some reactions have been negative, proposing that tier segregation should be limited to cases in which it is fully justified solely on morphological grounds. From the standpoint of phonology, tier segregation has also been challenged as imposing too strict a limit on potential underlying representations, thus conflicting with some principles that underlie Optimality Theory.

[16] Interestingly, Newport *et al.* (2004) report similar studies carried out with non-human primates (cottontop tamarin monkeys) as the subjects. The results showed that these subjects demonstrated learning of the non-adjacent syllable and non-adjacent vowel patterns, but were unable to learn the non-adjacent consonant patterns that adult human subjects learned.

And, finally, the external evidence brought to bear on the issue is unable at this point to provide a final answer regarding the psychological reality of tier segregation. While some studies suggest that tier segregation is cognitively viable, others demonstrate that it can be done without. This is not a surprising situation; after all, only a limited number of such studies have been carried out at this point. It is clear that many more experiments could and should be conducted in order to further our understanding of the patterns that tier segregation was proposed to account for, and to help determine whether tier segregation should be maintained or discarded in phonological theory.

ACKNOWLEDGMENTS

Discussions with Dafna Graf, Lior Laks, Hadas Velan, and Andy Wedel have helped greatly with portions of this chapter. Many thanks are also due to Marc van Oostendorp, Beth Hume, and two anonymous reviewers. All errors remain the author's responsibility.

7 Feature Specification and Underspecification

Diana Archangeli

1 Introduction

The concept of minimal feature specification has been part of the phonological dialogue throughout the modern era, from the introduction of archiphonemes (Jakobson 1929; Martinet 1936; Trubetzkoy 1936) through various types of specification: Markedness (Kean 1975), Radical Underspecification (Archangeli 1984, 1988), Contrastive Underspecification (Steriade 1987; Mackenzie and Dresher 2004; Dresher 2009), and Combinatorial Specification (Archangeli and Pulleyblank 1994) to Richness of the Base (Prince and Smolensky 1993; Itô *et al.* 1995; Smolensky 1996). What is common to the various approaches is that features may be absent from at least some segments at any level of representation. Theories differ on when – or whether – the missing features are provided. For example, the Markedness rules of Chomsky and Halle (1968) provide values (the unmarked specifications) for all features on every segment before the application of any phonological rules, whereas under more recent perspectives, some segments exit the entire phonological-phonetic component without receiving specifications for every feature (Keating 1988; Pierrehumbert and Beckman 1988; Archangeli and Pulleyblank 1994).

A challenge in evaluating underspecification is to separate the essence of the arguments for minimal feature specification from the theoretical context in which the feature specification model is presented. In fact, the very term "underspecification" is testament to this challenge: the model was developed in the early 1980s in opposition to a model of full feature specification, and the term "underspecification" emphasized this changed role. Changing the focus to the motivation for specifications led to the term "Combinatorial Specification" (Archangeli and Pulleyblank 1994), while Optimality Theory's "Richness of the Base" makes no direct reference to feature specification at all (Prince and Smolensky 1993).

In retrospect, developing a theory of "feature specification" rather than of "underspecification" is more important. Which features are *necessarily present* regardless of the theory one adopts? Those which are not necessarily present can be unspecified, if the theory allows it. In a very basic way, then, the essence of feature specification hinges on the "necessary and sufficient" criterion: is a feature specification necessary to account for this pattern? Is that same specification sufficient to account for the pattern? Where the answer to both questions is "yes," the feature is critical to an analysis of that part of the language; where the answer to both is "no," whether the feature is specified depends on the theory in which the analysis is couched, not on the requirements of the data.

In this survey, we consider a wide array of phenomena, ranging from the morphological to the phonological to the phonetic, which demonstrate that at all levels, there are features that meet the "necessary and sufficient" criterion and there are others which do not. Those that do must be specified, regardless of the theory one adopts. Those that do not are features that may be left unspecified if one's theory allows for unspecified features.

In many of the examples, there is a secondary argument. If segments are fully specified, then the analysis includes a component simply to deal with those specified features – features which are not necessary to account for the basic pattern. The analysis then is more complex, and the necessary elements of the pattern are obscured. This provides a second set of arguments in favor of minimal specification: omitting unnecessary feature specifications reveals patterns; including them obscures patterns.

2 Morphological evidence

The first cases we consider are those in which a single feature differentiates one morphological class from another (see also CHAPTER 82: FEATURAL AFFIXES). That single feature is both necessary and sufficient. No other features are necessary, and so have no empirical role; they can be omitted from the representation. No fully specified segment is needed in these cases; in fact, positing such a representation obscures the patterns observed. Cases from Chaha (McCarthy 1983), Tiv (Pulleyblank 1986), and Yokuts (Archangeli 1991) make the argument.

2.1 *Single-feature morphemes*

In Chaha, a Western Gurage (Semitic) language of Ethiopia, the 3rd person singular object is marked by labialization of the rightmost labializable consonant (1) (McCarthy 1983).[1]

(1) *Chaha* (McCarthy 1983; CHAPTER 82: FEATURAL AFFIXES)

		no object	*with object*	
a.	*final*	dænæg	dænæg^w	'hit'
		nækæb	nækæb^w	'find'
b.	*medial*	mækær	mæk^{w}ær	'burn'
		s'æfær	s'æf^{w}ær	'cover'
c.	*initial*	qætær	q^{w}ætær	'kill'
		mæsær	m^{w}æsær	'seem'
d.	*none*	sædæd	sædæd	'chase'

[1] Zoll (1996) presents a similar case from Inor; Rose (1994) delves further into the similar palatalization pattern, also explored in McCarthy (1983) and CHAPTER 82: FEATURAL AFFIXES.

There are two aspects to the analysis. First, the sound component of the lexical representation need only include a labialization feature, [labial]. Should this affix be represented as a fully featured segment, rather than simply as the feature [labial], then it is critical (i) that [labial] be free to dissociate from that segment and associate to another segment and (ii) that all other features of the segment disappear completely regardless of whether [labial] successfully associates or not (1d). In short, all features other than [labial] are unnecessary; [labial] alone is sufficient.

Second, the segments of the roots need no [−labial] specification despite the fact that they are not round unless the object marker is added. Any [−labial] specifications complicate the analysis because some mechanism must be introduced to eliminate those specifications when the [labial] object marker is added.[2]

A similar example is found in Tiv, a Niger-Congo language of Nigeria, where the general past is indicated by downstep of a verb-initial high tone (2a); there is no overt marker when the verb is low-toned (2b).

(2) *Tiv general past* (Pulleyblank 1986)

	a. H-stem		b. L-stem	
1 syllable	ꜜH	ꜜvá 'came'	L	dzà 'went'
2 syllable	ꜜHL	ꜜúngwà 'heard'	LL	vèndè 'refused'
3 syllable	ꜜHLL	ꜜjévèsè 'fled'	LLL	ngòhòrò 'accepted'

These contrast with stems in other tenses, such as the recent past (3), where there is no downstep. Note the effect of vowel ablaut on the vowels /a/ and /u/, and the addition of a recent past high tone.

(3) *Tiv recent past* (Pulleyblank 1986)

	a. H-stem		b. L-stem	
1 syllable	H	vé 'came (recently)'	H	dzé 'went (recently)'
2 syllable	HH	óngó 'heard (recently)'	LH	vèndé 'refused (recently)'
3 syllable	HHL	jévésè 'fled (recently)'	LHL	ngòhórò 'accepted (recently)'

Treating the general past morpheme as a low tone directly results in these patterns since high tones regularly downstep after low tones in Tiv, while low tones are unaffected. Representing the general past affix as a low tone is necessary in order to account for the sound alternations; it is also sufficient. What is not necessary is to represent the general past marker with a fully specified vowel – crucially including the tone specification, but with no other critical features; all that would surface of such a vowel would be the tone.

[2] In some models, [labial] is a privative feature, and there is no "[−labial]" specification. In other models, [round] (or [±round]) might be used instead of [labial[. The name of the feature is irrelevant to the issues of feature specification.

The location of the H-tone recent past marker also supports a level of representation without specifications, as pointed out in Pulleyblank (1986). Were all vowels fully specified for either H-tone or L-tone, then it would be surprising for the recent past H-tone to dock on the second vowel of polysyllabic forms. However, if only the initial vowel is specified for a tone – which is the only location for contrastive tone in Tiv verbs – then the second vowel is the leftmost available vowel, and the location of the recent past H-tone is no surprise.

2.2 *Ghost segments*

A different type of case involves a "ghost segment," a segment that surfaces in some environments, but that is not realized in other environments.[3] For example, in French, many final consonants are realized only when there is a following vowel or there is a feminine suffix, *peti*[ ] but *peti*[t] *oiseau* and *la peti*[t]*e* (Tranel 1981; CHAPTER 112: FRENCH LIAISON). Archangeli (1984, 1991) and Zoll (1996) argue that such segments have feature representations, but crucially lack other structure: for Archangeli, the ghost segment is a floating feature, while for Zoll it is a feature or set of features without a root node. (While this chapter is focused on degrees of feature specification, we briefly visit the issue of prosodic specification in §3.5.) A particularly intriguing case of ghost segments is found in Yokuts, a Penutian language of Northern California. In Yokuts, there are several morphemes with ghost segments that may or may not surface. In one class of cases, there is good evidence that the ghost should be viewed as a single feature, rather than as a full-fledged segment. In this class of cases, a glottal stop surfaces in some environments (4a) but does not in other environments (4b), the typical ghost behavior. However, there is a third set of environments, where the ghost is realized as glottalization of a sonorant consonant, (4c): "the floating glottal stop of suffixes . . . may infect only the second consonant of a stem, if that consonant is a nasal, semivowel, lateral" (Newman 1944: 15). Thus, in this third class of cases, the Yokuts ghost [ʔ] is similar to the single-feature morphemes. However, in Yokuts, there are other segments in the morpheme (in this example, the sequence *-in'aj*): it is not simply a single feature morpheme. There are several Yokuts suffixes with the "floating glottal"; there are also suffixes with a floating /l/, /n/, /h/, or /m/. See Newman (1944), Archangeli (1984, 1991), and Zoll (1996) for examples with other suffixes.[4]

(4) *Yokuts contemporaneous gerundial* -ʔin'aj (Archangeli 1984)

	root	*affixed form*		
a.	root with 2 Cs gets glottal stop			
	dub	dubʔun'aj	*dubun'aj, *dub'un'aj	'while leading by the hand'
	doos	dosʔin'aj	*dosin'aj, *dos'in'aj	'while reporting'

[3] These are called "latent segments" in Zoll (1996).

[4] Other effects can be found in (4), both phonological (rounding harmony giving *-un'aj* after roots with /u/) and templatic. The root column shows the syllabic pattern taken by the root with about half of the suffixes in the language. The other half of the suffixes determine the prosodic structure to the root, and *-in'aj* is among these: in each case, the root has the minimal prosody possible given its segments. See Prince (1990) and Archangeli (1991).

b. root with 3 Cs gets nothing

lihim	lihmin'aj	*lihmʔin'aj, *lih'min'aj	'while running'

c. root with sonorant C2 gets glottalization, whether root has 2 Cs or 3

panaa	pan'in'aj	*panin'aj, *panʔin'aj	'while arriving'
c'oow	c'ow'in'aj	*c'owin'aj, *c'owʔin'aj	'while grasping'
taan	tan'in'aj	*tanin'aj, *tanʔin'aj	'while going'
hiwiit	hiw'tin'aj	*hiwtin'aj, *hiwtʔin'aj	'while walking'

The feature that is necessary to account for this pattern is a glottal constriction feature, e.g. [+constricted glottis]. Interestingly, this feature is sufficient to account for the sonorant behavior in (4c). This feature is also necessary and sufficient to account for the realization of a glottal stop, all other features being predictable once it is known that the segment has [+constricted glottis].

2.3 *Summary*

These morphological examples demonstrate two points. First, in some cases, a single feature is necessary and sufficient to explain the phonological behavior of some morpheme: [+constricted glottis] is sufficient to explain the three-way Yokuts patterns while [labial] accounts for the distribution of the object marker in Chaha. Second, while additional features might be included in the representation of such morphemes, any such additional features serve no necessary phonological purpose; the only reason to include such features is to satisfy the demands of the theory, not the demands of the data. The data themselves make no such requirement.

In the next section, we examine phonological cases which make the same point, with the difference being that the motivation for active *vs.* inert features is phonological, not morphological.

3 Phonological evidence

There are a variety of types of phonological patterns that support the absence of at least some feature specifications. The cases are similar in that there are asymmetric behaviors among the segments of a language, and that asymmetry is consistent with the absence or presence of feature specification. Variety arises when the effects of this asymmetry are considered: morphemes with invariable feature specifications *vs.* those with variable specifications, revealed *vs.* obscured phonological patterns, inert segments *vs.* involved segments, and segments that behave ambiguously.

3.1 *Variable and invariable feature specification*

The first class of evidence comes from the completely phonological distribution of features. In these cases, a contrast is found in some part of the lexicon that does not occur in some other part of the lexicon. In the Margi example, roots and suffixes differ by whether they bear invariable tone or not (Williams 1976; Pulleyblank 1986, 2006). We focus on roots here; the same argument can be made based on suffix behavior.

Some Margi roots are always high-toned (5a), some always low-toned (5b), and some have a low–high contour (5c) (data from Pulleyblank 2006).

(5) *Margi roots*

a. *High-toned roots*

tá	'cook'	tábá	'cook all'
ŋgúlí	'roar'	ŋgúlíbá	'surpass in roaring'

b. *Low-toned roots*

ptsà	'roast'	ptsàbá	'roast thoroughly'
tsàvè	'pierce'	tsàvèbá	'pierce thoroughly'

c. *Low–high contoured roots*

fǐ	'swell'	fìbá	'make swell'
və̌l	'fly, jump'	və̀lbá	'make jump over, across'

These forms reveal a three-way contrast among roots: those which are invariably high-toned, those which are invariably low-toned, and those which surface with a contour in isolation, but simplify that contour when suffixed. However, there is a fourth class of roots, the alternating roots. In this class, the tone of the root varies depending on the tone of the suffix that is attached. The root is high-toned with a high-toned suffix, and otherwise low-toned.

(6) *Margi alternating roots* (Hoffman 1963; Evans 2008)

a. *With high-toned suffixes*

ɗə̀l	'buy'	ɗə́lbá	'buy'
ɲàl	'bite'	ɲálbá	'bite a hole'

b. *With low-toned suffixes*

pʧì	'wash'	pʧìnà	'wash'
tlǎ	'cut'	tlànà	'cut off'

Pulleyblank (1986, 2006) argues that in the latter case, the roots are toneless in lexical representation and receive their surface tones through the phonological component. Note that requiring all roots to be fully specified, and so to bear lexical tone, would require either a completely arbitrary third tone (which never surfaces) or non-phonological diacritics on the variable-tone class to distinguish the roots with low tones in isolation that are always low-toned (5b) from those that are low-toned in isolation, but are high-toned when they have high-toned suffixes (6a).

A similar case is found in Tiv, and has already been illustrated in (2). The only location in a word where tones vary unpredictably is the first syllable. All other tones are predictable. Consequently, the two patterns in (2) are the extent for verb roots in Tiv. Requiring full specification of tones leads to the expectation of far more patterns than are attested in the language.

There are numerous cases of completely predictable features, with behavior comparable to that of Margi tone. For example, the distribution of [ATR] in Pulaar (Paradis 1986; Archangeli and Pulleyblank 1994) and Kinande (Archangeli and Pulleyblank 1994, 2002) follows this pattern, as does the distribution of all vowel features in Tiv (Archangeli and Pulleyblank 1994).

3.2 *Patterns revealed*

The second class of cases involves phonological patterns which are seen to be quite simple patterns if only the necessary and sufficient features are present in representations. These same patterns appear to be rather complex patterns if all features are present on all segments. Two brief examples from Yokuts are presented. In each case, the essence of the phenomenon is revealed when only the necessary and sufficient features are present. One case involves vowel harmony, a feature phenomenon, and the other involves epenthesis, a prosodic phenomenon.

3.2.1 *Yokuts vowel harmony*

The Yokuts vowel harmony system is relatively simple. The language has a four-vowel system, /i a o u/, and vowels of like height agree for roundness. See Newman (1944), Archangeli (1984, 1985), and Steriade (1986) for more on Yokuts harmony. In (7a), the vowels in the non-initial syllables arise either from epenthesis or from the suffix *hin* (aorist).[5]

(7) *Yokuts vowel harmony*

a. [u] *after* /u/, *else* [i] *in* -hin *(aorist)*

	ʔugunhun	*ʔuginhin	'drank'
but	lihimhin	*lihumhun	'ran'
	baṭ'inhin	*baṭ'unhun	'fell down'
	hoginhin	*hogunhun	'floated'

b. [o] *after* /o/, *else* [a] *in* -(h)atin *(desiderative)*

	doshotinhin	*doshatinhin	'was trying to tell'
but	bintatinxokʾ	*bintotinxokʾ	'be trying to ask!'
	hudhatinxoʔ	*hudhotinxoʔ	'wants to know about'
	ṭʾawhatinxoohin	*ṭʾawhotinxoohin	'was trying to win from'

It is possible to represent the vowel system as the result of the logically possible combinations of the features [round] and [non-high]: /o/ is specified as [round, non-high] while /i/ has neither feature; /a/ is [non-high] and /u/ is simply [round]. Under this view, the harmony effect is achieved by a manipulation of the feature [round] where [non-high] values are identical.

Were features fully specified, the harmony process would need to change both [round] and [back] features on /i/, for /i/ to surface as [u]. Additionally, it would need to change [round] and [low] for /a/ to surface as [o]. Thus, with full specification, the harmony process must mention not only [round], but also [back] and [low], a far more complex process than one that involves only [round]. The complexity is brought on by the fully specified segments, not by properties inherent to the process itself. The essential properties of the alternation are revealed by minimally specified representations.

[5] The suffix *(h)atin* (desiderative) requires the minimal prosody for the root segments; see footnote 4 and §3.5. It also has a "floating /h/" which surfaces only with biconsonantal roots. See §2.2 for discussion of this phenomenon.

3.2.2 *Yokuts epenthesis*

A further phenomenon in Yokuts is that of vowel epenthesis; the inserted vowel surfaces as [i], or [u] in harmonic environments. Vowel epenthesis occurs when consonants would otherwise be unsyllabifiable: the motivation is purely prosodic. See Kisseberth (1970) and Archangeli (1984, 1991) for more on Yokuts syllabification.[6]

(8) *Yokuts epenthesis* (Archangeli 1984, 1991)

(epenthetic vowels are underlined; forms without epenthesis have "__" showing the absence of a high vowel in that environment)

	root	-hin (aorist)	-t (passive aorist)	
a.	*no epenthesis with either affix*			
	hojoo	hojoohin	hojot	'name'
b.	*epenthesis with* -t *(passive aorist)*			
	caw	cawhin	cawit	'shout'
	bok'	bok'hin	bok'it	'find'
	ṣil'	ṣil'hin	ṣil'it	'shout'
	dub	dubhun	dubut	'lead by the hand'
	biniit	binethin	bineetit	'ask'
c.	*epenthesis in different places with* -hin *(aorist) and* -t *(passive aorist)*			
	diijl	deejil__hin	dej__lit	'guard'
	bilṣ	biliṣ__hin	bil__ṣit	'finish'
	ʔamc	ʔamic__hin	ʔam__cit	'be near'
	diijl	deejil__hin	dej__lit	'guard'
	ʔogl	ʔogil__hin	ʔob__lit	'emerge'
	luk'l	luk'ul__hun	luk'__lut	'bury'

With a fully unspecified /i/, the formal account of epenthesis is solely prosodic. No features are necessary: the resultant vowel is equivalent to the lexical representation of /i/, fully unspecified.

These examples are representative of the way in which minimal feature specification reveals phonological patterns. In both cases, requiring full specification obscures the essence of each process, in the harmony case making [round], [low], and [back] formally equivalent while only [round] is critical and in the epenthesis case making the prosodic phenomenon appear to critically involve specific features.

3.3 *Inert segments*

Inert segments are segments that do not participate in some alternation, despite surface appearances suggesting that they would be involved. These segments function in contrast to their apparent specifications.

[6] Forms show the effect of other, interacting phenomena. Items with /u/ exhibit round harmony, for example *dubhun* and *dubut*, **dubhin*, **dubit*; see discussion of (7). Long vowels typically surface as non-high (*deejilhin*, **diijilhin*), and closed syllables typically have short vowels (*dejlit*, not **deejlit*).

3.5 *Prosodic specification*

Prosody includes at least syllable and foot structure.[8] In contrast to features, the standard approach is to assume that input representations do not include syllables or feet, and sometimes moras: these are provided by the phonology. For run-of-the-mill cases, the primary argument is that it isn't possible to tell what the syllabification or footing of a particular sequence is until it is placed in context: whether a morpheme-final consonant is an onset or a coda depends on whether it is followed by a vowel (*dual vs. duality*, etc.); stress placement also depends on the root and any affixes (*'atom vs. a'tomic*, etc.). Similarly, whether a high sonorant is a vowel or a consonant depends on context which may be provided through morphological concatenation, for instance in Berber (Guerssel 1986). In such cases, lexically specified syllable or foot structure is neither necessary nor sufficient.

Morphological patterns sometimes exploit underspecified prosodic structure, particularly reduplication (Marantz 1982; McCarthy and Prince 1986, 1993b, 1995b; CHAPTER 100: REDUPLICATION) and templatic morphology (Archangeli 1984, 1991; McCarthy 1985; CHAPTER 108: SEMITIC TEMPLATES). The hallmark of prosodic morphology is that (a significant part of) the prosody is determined by one morpheme, distinct from that which provides the segments. Examples of templatic morphology appear in (4) and (7b); see also footnote 4. (13) includes some key examples from (4). The first column in (13) shows the segments and the prosodic pattern taken by the verb root with about half the suffixes in the language; the second column shows suffixation with a couple of these "normal" suffixes. (Note that the [ee] in *hiweeten* is due to the lowering of long high vowels to mid, a well-documented process in the language. See references cited.) Comparison of forms in the column headed "supplied CVC" shows what happens to those roots when the following suffix imposes a prosody on the root, supplanting its default prosodic structure.

(13) *Yokuts templatic morphology* (Archangeli 1984, 1991)

	root prosody	*affixation*	*supplied* CVC ...	*non-occurring*
a.	panaa	panaahin	pan'in'aj	*pan'aan'aj
	'arrive'	'arrived'	'while arriving'	
b.	hiwiit	hiweeten	hiw'tin'aj	*hiw'eetin'aj
	'walk'	'will walk'	'while walking'	

If the suffix *(?)in'aj* did not provide a prosodic structure for the verb root, the forms in the column headed "non-occurring" would be expected. Both roots typically begin with an iambic pattern preceding the suffix; with *(?)in'aj*, the root takes as little prosodic space as possible. See references cited for further exemplification.

There are, in addition, cases of "a-templatic" morphology, where the morphology provides no template (Bat-El 1989, 1994; McCarthy 1993). Putting this together with minimal feature specification suggests instances where there is a morpheme with neither prosodic nor segmental structure. Gafos (1998) argues for just such

[8] This section is included at the recommendation of an anonymous reviewer who pointed out the relevance of prosodic cases for generalizing the notion of necessary and sufficient specification.

an analysis of reduplication in Temiar, noting that the "invariable" aspects of reduplication can be explained without reference to imposed prosody or features.

While these brief paragraphs can do little justice to the diversity involved with prosodic specification, the intent of including this discussion is more modest: to demonstrate that the concept of considering whether a representation is both necessary and sufficient is not limited to features, but extends to the prosodic aspects of phonological representations.

3.6 *Summary*

In this section, we have reviewed a number of examples from phonological patterning. In each case, specifying only the necessary and sufficient features provides a more revealing explanation of the phonological patterns than does full specification of the relevant segments.

Phonological accounts must be able to handle cases of the type presented in the next section, where phonological features are irrelevant for the phonetic realization of a form – a possibility that is expected given minimally specified representations.

4 Phonetic evidence

Phonological representations with minimal feature specifications result in segments that are unspecified for unnecessary features. The minimization of feature specifications leaves open the possibility that these specifications are provided phonetically. Of interest are cases where the phonetic feature specification has an impact that is different from the phonological specification of features, for example the striking difference between the phonological (categorical) specification *vs.* the phonetic (gradient) realization such as a cline, a feature whose impact gradually increases or decreases phonetically over a span of one or more segments.

The cases of most interest are where the cline correlates to some phonological feature, such as tongue body height, tone, lip rounding, etc. In the relevant cases, some feature is phonologically active for some segments (either because it is distinctive, because it plays a role in a phonological pattern, or both), while for other segments there is a cline effect, with the greatest articulation of the feature found on the segment(s) for which it is distinctive, otherwise gradually building to and/or decreasing from that point.

4.1 *The cline effect in vowel harmony*

In Akan (a Niger-Congo language), [ATR] harmony has a phonological effect on all non-low vowels, rendering them categorically either advanced or retracted. [ATR], then, is necessary on non-low vowels (Clements 1981; Archangeli and Pulleyblank 1994). By contrast, low vowels are typically retracted. Since this is a general state for low vowels, [RTR] (or [–ATR] – the difference is irrelevant to the point being made) is not necessary. Furthermore, specifying low vowels for a tongue root feature would be contradictory, because to the *left* of an advanced vowel, a series of normally retracted vowels (whether low or not) exhibits a gradual increase and, in particular, no phonological or phonetic tone specification specifically associated with moras between the initial mora with its low boundary tone and the pitch-accented mora with its high tone. As in other cases, while it is possible to specify phonological tone on these moras, the choice of tone is arbitrary for it never surfaces: the surface pitch contour derives from the interpolation from the initial low tone to the high pitch accent tone.

4.3 *Co-articulation* vs. *allophonic variation*

A final example of this type is the pattern of tongue body height in Russian VCV sequences (Keating 1988). As Keating points out, in Russian most consonants have both a palatalized and a plain counterpart. An exception is the velar fricative /x/. The backness or frontness of /x/ is dependent on the context. Because there are no lexical requirements on the backness dimension for /x/, it might be considered unspecified for [front/back], in contrast to other consonants.

Keating (1988) compares formant patterns in [x] in three environments: /ixa/, /axi/, and /axa/. The spectrograms clearly demonstrate a continuous transition throughout the articulation of the consonant from a high F2 to a low F2 in /ixa/, and no change in F2 in the fricative in /axa/. However, in /axi/, the fricative shows a sharp rise to a steady high F2, consistent with the consonant being [front]. Keating's conclusion (1988: 285) is that "[t]he /x/ before /i/ acquires a value for [back] by spreading from /i/, whereas other /x/'s remain unspecified for [back], and therefore show interpolatory effects."

This pattern arises only when the intervening consonant evinces no phonological or allophonic palatalization. When the /i/ follows the consonant, the contour of the formant is consistent with Russian palatalization that takes place between [i] and any preceding consonant. Otherwise, the contour of the tongue's trajectory is consistent with an interpolated gesture between the palatal and the non-palatal vowels, consistent with the intervening consonant having no specification for the interpolating tongue body features.

4.4 *Summary*

The three examples presented in this section converge on a set of properties consistent with minimal feature specification. The domain in which the interpolation pattern is found is segments that have no necessary phonological specification for a feature. The boundaries of each pattern are defined by specified features. And finally, the effect seen is consistent with simply interpolating the specified values from one boundary to the next. In each case, more phonological specifications would get in the way of the phonetic pattern, and would obscure any characterization of the process.

Evidence of this sort is relevant to the discussion of Optimality Theory in that the phonological constraints need to be constructed in a way that allows for this class of phonetic effects. This might be done by integrating phonetic constraints into the constraint hierarchy along with the phonological constraints; it might be done by developing a constraint hierarchy to force unspecified segments in the (phonological) output which then feeds into a phonetic component. In either case, it is critical that segments are without specifications for certain phonological features.

5.3 *Future directions*

Very recent developments in Evolutionary Phonology (Blevins 2004) and, in particular, Emergent Phonology (Mielke 2008; Mohanan *et al.* 2009) and "substance-free phonology" (Hale and Reiss 2000a, 2000b; Morén 2007; Blaho 2008) have implications for how our understanding of feature specification might develop in the future. Emergent Phonology intends to account for the growing body of evidence that the features and patterns found in language sound systems are strongly influenced by the physical system, i.e. the human's articulatory and perceptual systems (Archangeli and Pulleyblank 1994; Flemming 1995, 2002, 2005; Boersma 1998; de Boer 2000; Hume and Johnson 2001; Blevins 2004; Hayes *et al.* 2004). In order for the formal model to capture this concrete influence, Emergent Phonology proposes that there is no universal, innate set of features. Consequently, in an optimality approach, there can also be no innate constraints referring to features. Rather, the necessary entities are generated on an as-needed basis as each language is learned.

As laid out in Mohanan *et al.* (2009), if there is no specific inventory of innate distinctive features, then the necessary features emerge from the data encountered by the learner. With no inventory of innate features to map to, in the absence of evidence for a particular feature there will be no feature proposed. Minimal specification results. Lack of specification for irrelevant features is expected. There is no need to wonder about what happens with features that are not phonologically active in a language, since there is no motivation to learn such features. This same argument extends to subsets of the sounds of a language for which a feature is inactive: without evidence, the feature will not be learned for that subset, producing segments unspecified for a feature that is active elsewhere in the language.

A further implication under Emergence is due to the heavy responsibility placed on the learning process, a responsibility also exploited in Evolutionary Phonology (Blevins 2004), where mislearning leads to language sound change. Under Emergence, there is the potential also for overlearning, i.e. learning more than is necessary and sufficient in some cases. When overlearning creates a conflict with the ambient grammar, language change is predicted, leading to item-by-item language change until a critical mass is reached and the pattern is generalized.

6 Conclusion

The cases examined here present a variety of arguments in favor of minimal feature specification. Morphological arguments include accounting for single-feature morphemes and morphemes with floating features. Among the phonological arguments are accounting for inert segments, for ambiguous segments, and for the contrast between variable and invariable surface forms, as well as the demonstration that the essence of patterns is revealed when fewer feature specifications are present. Finally, the interpolation of phonologically active feature effects across spans of segments for which that feature is not necessary provides phonetic evidence for the absence of feature specification. Throughout, evidence is consistent with all and only the necessary and sufficient features being present in representations.

106 Exceptionality

MATTHEW WOLF

1 Introduction

The work of phonologists is, in part, to discover empirical generalizations about the sound shape of utterances in each of the world's languages, and to formulate theories which predict these generalizations. The "in part" comes from the mentalist stance of generative linguistics: its ultimate goal is not merely a theory which accounts for generalizations in surface data, but a theory that accounts for these data in the same way that native speakers' internalized grammars do. In a sense, then, generative analyses are not really theories of (corpus-internal) linguistic data per se; they are theories of native speakers' tacit theories about those data – the grammars which speakers arrive at during language acquisition. In Chomsky's (1965) terms, generative linguistics aims at theories that possess *explanatory adequacy* – the ability to account for how language acquisition occurs (and thus also for the knowledge resulting from acquisition) – and not merely *observational* adequacy – the ability to correctly predict the grammatical or ungrammatical status, for the language in question, of any given form.

This mentalist stance creates two complications for how phonologists deal with generalizations in linguistic data. First, a language's lexicon might contain generalizations which speakers have not incorporated into their mental grammars, perhaps because Universal Grammar does not give them the resources to do so (see Becker *et al.* 2008 and Becker 2009 for a proposed instance). Second, speakers might have mentally internalized a generalization, but in a way that seems to be sub-optimal according to the standards of theory comparison, for instance Occam's Razor, which phonologists are used to calling upon. The Māori passive (Hale 1973; McCarthy 1981; de Lacy 2004) is a well-known case in which the seemingly most simple account of the data is arguably not the way in which speakers have internalized those data.

An inverse situation obtains in the cases where a language displays an apparent generalization to which there are exceptions. Say, for instance, we observe in some language that all stems begin with a consonant, except for two stems [eda] and [opu]. Strictly speaking, the statement "stems must begin with a consonant" is not a true generalization about this language. Nevertheless, it is conceivable that speakers have mentally internalized this restriction, and have somehow marked [eda] and [opu] as exempt from the restriction. That is, we can imagine that speakers have internalized a theory which might be considered sub-optimal for the reason that it contains stipulations. Two questions therefore face the linguist. The first is to establish whether the imperfect generalization has in fact been internalized – we might check, for example, whether speakers productively apply a process of consonant epenthesis or vowel deletion to vowel-initial loanwords, or to nonce forms elicited in a wug test (Berko 1958; see also CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY). The second question, assuming that a restriction against vowel-initial words has been internalized, is *how* the exceptional status of [eda] and [opu] is diacritically indicated in speakers' grammar and/or lexicon. One possibility is that they bear an *abstract* diactritic feature like [−vowel deletion], stating that a certain rule should not apply to these forms. The other possibility is to make diacritic use of *phonological* features. Say for instance that our hypothetical language lacks the segment [x] on the surface. Then we might assume that underlying forms of the exceptional items are /xeda/ and /xopu/, and that the rule that deletes /x/ is ordered after whatever rule is responsible for ensuring that stems are consonant-initial. Either way, we are adding to an item's lexical representation something that causes it to behave phonologically in a special way. No matter how analyzed, then, exceptionality ultimately reflects the arbitrary nature of sound/meaning pairings, and the manner in which the underlying form (or some other stored representation) holds information about those aspects of an item's pronunciation which are not predictable from general principles (an idea traceable to work on exceptionality in structuralist morphophonemics by Swadesh and Voegelin 1939).

Despite this commonality, the two approaches to exceptionality can be implemented in different ways, which make different predictions about exactly what kinds of exceptional patterns languages can have. §2 of this chapter discusses approaches to exceptionality that have been proposed in rule-based generative phonology, and §3 considers approaches in Optimality Theory (Prince and Smolensky 1993). As we shall see, the abstract-diacritic and phonological-diacritic approaches have both appeared in a number of different forms in both rule-based and constraint-based phonology. §4 discusses predictions about exceptionality in Lexical Phonology and Stratal OT. §5 offers a concluding summary of some of the issues about how exceptionality works which we will encounter in examining the strengths and weaknesses of various proposals.

2 Exceptionality in rule-based phonology

2.1 *The theory of diacritic features in* SPE

Lexical exceptionality is treated in two sections of Chomsky and Halle (1968; hereafter *SPE*): §4.2.2, "Treatment of exceptions," and §8.7, "Diacritic features." The latter lays out three kinds of diacritic features with distinct uses. One kind are features which define conjugation classes, native *vs.* foreign lexical strata, and similar kinds of word classes. A second is what Coats (1970) dubs "alphabet features"; these are, as Zonneveld (1978: 132) notes, "rather vague[ly]" defined, and are called on in *SPE* to perform several tasks, which are reviewed in Zonneveld (1978: §3.2.3). As we shall see, and as Zonneveld (1978) argues, these features can be used to handle the various types of exceptionality which were argued in the late 1960s

An important question which can be raised in regard to minor rules is whether major *vs.* minor status is a strictly binary matter, or is instead a continuum. Most work on minor rules seems to assume binarity (Levy and Fidelholtz 1971 invoke a feature [±major]). An equally binary approach to minor-rule effects would be to assume that minor rules are not rules at all, and that the morphemes which "undergo" a minor rule simply have multiple listed allomorphs. This is argued for by Hudson (1974), and more recently, in an optimality-theoretical context, by Mascaró (2007) and Kager (2009). Kager's example is that of open syllable lengthening in Dutch. Normally, both short (3a) and long (3b) vowels stay the same length, even as the syllable they are in alternates between closed and open, as can be seen by comparing singular and plural forms of nouns:

(3)	a.	*kl*[ɑ]*s*	~	*kl*[ɑ].*sen*	'class(es)'
		k[ɪ]*p*	~	*k*[ɪ].*pen*	'chicken(s)'
	b.	*b*[aː]*s*	~	*b*[aː].*zen*	'boss(es)'
		p[oː]*t*	~	*p*[oː].*ten*	'paw(s)'

However, certain exceptional nouns show an alternation between a short vowel in the bare root and a long vowel in the plural:

(4)	*gl*[ɑ]*s*	~	*gl*[aː].*zen*	'glass(es)'
	sl[ɔ]*t*	~	*sl*[oː].*ten*	'lock(s)'

This appears to indicate a minor rule of open syllable lengthening. Kager's (2009) analysis is that the alternating roots have two listed allomorphs, one with the short vowel and one with the long vowel, with the appropriate form being selected in the appropriate environment.

This assumes that the minority alternation pattern in Dutch actually *is* unproductive and not really the default. In inflectional morphology, at least, minority patterns arguably can be used as the default (Marcus *et al.* 1995), so in cases of apparent "minor rules" like this we might need to run a wug test or the like to see whether the minority or the majority pattern were the one which speakers extended to nonce forms. If the minority pattern truly is not the default, then either a minor-rules or a listed-allomorphy treatment would reasonably lead us to expect that the minor alternation should be *perfectly* unproductive – it might seem odd for speakers to set up multiple listed allomorphs for a nonce word if they don't yet have evidence that it alternates. Is this expectation borne out?

Coetzee (2009) investigated this using an artificial language learning paradigm. If trained on novel-language data, in which some stems alternate and some do not, and then tested on novel stems, subjects tended to assume by default that the novel stems were non-alternating. However, this was not a categorical preference, and, moreover, the degree to which novel stems were assumed to be non-alternating decreased if the ratio of alternating to non-alternating stems in the learning data was increased.

Several responses can be given to such results. One is to pursue a model like that proposed in Zuraw (2000), discussed in §3.4 below, which combines fixed, listed pronunciations for existing forms with a stochastic grammar that will reproduce, for novel forms, statistical trends about items in the existing lexicon. This would be, effectively, a hybridization of a minor-rule approach and an allomorphy one. Alternatively, we could use minor rules (or indexed OT constraints), and assume that nonce words are assigned the diacritic features of a randomly chosen existing word (Becker 2009). Here again, existing forms would have a fixed behavior, and a nonce form's likelihood of taking on a certain mode of behavior would be in part determined by the proportion of existing forms which had that behavior.

Another option would be to assume that the difference between major and minor rules, between default and exception, is not one of kind but only of degree. Within a generative paradigm, this kind of move is exemplified by Jackendoff's (1975) theory of the lexicon. In this theory, the lexicon consists of fully specified entries for all words (even morphologically derived ones). Morphological rules, including those like English umlaut (2) which form irregulars, serve not to actually *produce* existing forms, but instead function as statements of speakers' knowledge of which properties of certain existing forms are predictable from those of other existing forms. These *lexical redundancy rules* are, however, available for creatively generating novel forms.

A more radical move in the same conceptual direction would be to adopt an exemplar-based theory (e.g. Bybee 2001; Pierrehumbert 2001), in which words are mentally represented as clusters of concrete, phonetically detailed tokens which have been heard and recorded in memory. Diachronic change is assumed to result from updating the exemplar clouds associated with certain words or phonological categories. A central argument for exemplar approaches is the observation (Fidelholtz 1975; Phillips 1984) that leniting changes tend to appear first in more frequent words (see CHAPTER 66: LENITION). In an exemplar model, this follows from the very fact of frequent words being encountered more often, which results in their exemplar clouds being updated more often. With the novel pattern entrenched in part of the lexicon, its diffusion over time to new forms (Wang 1969) is entirely expected. The case of apparent "minor rules" – patterns restricted to a few items – being extended to new words might be seen in such a model as simply a micro-scale manifestation of this process of lexically diffusing diachronic change.

For a comparison of exemplar models with classical generative feed-forward models in their predictions about historical change, including lexical diffusion and the role of frequency, and discussion of possible problems for a purely exemplar-based approach, see Bermúdez-Otero (2007a) (see also CHAPTER 93: SOUND CHANGE).

2.2.2 *Rule-environment features*

Suppose that rule *n* is:

(5) A → B / X __ Y

Under the convention proposed in *SPE* (1968: 173, 374), the [±rule *n*] value of the focus *A* is relevant to whether the rule applies or not, but the [±rule *n*] values of the matrices *X* and *Y* making up the context do not matter. Chomsky and Halle note (1968: 375) that this limitation could be relaxed, such that, for rule *n* to apply, all of the matrices making up the environment (*X* and *Y*), as well as the focus *A*, would have to be [+rule *n*]. While they report having "no clear cases in a real language" requiring this move, they do point out one prediction of restricting reference to rule features to the focus of the rule: that rules of epenthesis (CHAPTER 67:

VOWEL EPENTHESIS) cannot have lexical exceptions. In an epenthesis rule, the focus is zero, which can have no features (diacritic or otherwise) because it is, literally, nothing. Chomsky and Halle therefore suggest a small-scale tweak to their original convention, whereby a rule *n* (A → B / X __ Y) applies to a string *X'A'Y'* except when (i) A' is [−rule *n*] or (ii) the formative containing A' is [−rule n]. (Karen Jesney (personal communication) points out that, if the focus of a rule must be [+rule *n*] for the rule to apply, then by exactly the same argument, rules of epenthesis could never apply at all unless the [±rule *n*] features of the environment are allowed to count.)

Subsequently, Coats (1970) and Kisseberth (1970) proposed not only that rule features had to be relevant in the environment, but also that there had to be distinct rule features for foci and for environments. This was also advocated by Coats (1974) and Coats and Lightner (1975). Kisseberth's (1970) proposal is based on data from Yine (then referred to as Piro), an Arawakan language spoken in Peru; the data are from Matteson (1965).

Yine has a rule that deletes a preconsonantal, morpheme-final vowel, unless it is preceded by a consonant cluster (CHAPTER 68: DELETION):

(6) V → Ø / VC __ + CV

This is exemplified by alternations like the following:

(7)	*bare root*		*nominalization in* /-lu/	
	[jimaka]	'teach'	[jimaklu]	'teaching'
	[kakonu]	'build a hunting shelter'	[kakonru]	'hunting shelter'
	[kama]	'make'	[kamlu]	'handicraft'

Rule (6) has two kinds of exceptions. First, there are affixes of the appropriate phonological shape before which vowel drop does not take place:

(8)	[meji-ta]	please-VERBAL THEME	'to please'
	[meji-wa-ta]	please-INTRANS-VERBAL THEME	'to celebrate'
	[heta-wa]	see-DURATIVE	'still see'
	[hata-ta]	illuminate-VERBAL THEME	'to illuminate'
	[heta-nu]	see-ANTICIPATORY	'going to see'

As can be seen, a morpheme-final vowel preceding one of these suffixes will not delete. In addition, the intransitive suffix /wa/ not only fails to trigger vowel-drop, but also fails to undergo it. In this regard, intransitive /wa/ differs from durative /wa/, verbal theme /ta/, and anticipatory /nu/. These latter three suffixes fail to trigger vowel drop, but they do *undergo* vowel drop:

(9)	[meji-w-lu]	please-DURATIVE-NOMINALIZER	'celebration'
	*[meji-wa-lu]		
	[jona-t-nawa]	paint-VERBAL THEME-REFL	'to paint oneself'
	*[jona-ta-nawa]		
	[heta-n-ru]	see-ANTICIPATORY-NOMINALIZER	'going to see him'
	*[heta-nu-ru]		

the "detached exception" problem. Zonneveld (1978: 204) notes, however, that one of the rules of Russian discussed by Coats and Lightner (1975) in support of rule-environment features instantiates just this phenomenon. The rule in question is:

(12) V → Ø / __ jV [after certain bases; MW]

This rule affects suffixes such as comparative /-eje/ when they are attached to certain bases, but not when they are attached to other bases. The applicability of 12 to the suffix is thus being decided by another morpheme, even though /-eje/ by itself contains the rule's entire structural description (Coats and Lightner 1975: note 3; Zonneveld 1978: 193).

Detached exceptions may also exist in the genitive plurals of nouns in Czech and Serbo-Croatian (Halle and Nevins 2009). Slavic nouns have the structure root + theme vowel + case-number. In Czech, while vowels normally delete in the environment / __ + V, in certain declensions the theme vowel fails to delete before the yer of the genitive plural ending. Simply making the genitive plural ending [−environment vowel deletion] will not do, because it is only following roots of certain declension classes that the genitive plural ending fails to trigger deletion of the theme vowel. In terms of Zonneveld's (1978) proposal for Yine, we might set up for Czech a re-adjustment rule which marks the theme vowel [−vowel deletion] in the environment of the genitive plural ending and of roots of the appropriate declension classes (cf. Halle and Nevins 2009: 367 (26)). The ban on superheavy syllables in the perfect conjugation of Vedic Sanskrit (Cooper, forthcoming) may also represent an example of a detached exception.

2.3 *Representational approaches to exceptions in rule-based phonology*

In addition to abstract diactric features like [−rule *n*], *SPE* also calls upon diacritic use of phonological features to analyze exceptions to several rules (1968: 233–234). For example, in *righteous* [ɹaɪ.ʧəs], the first vowel is unexpectedly tense, rather than lax. This is attributed to the underlying form of the stem *right* being /ɹixt/, and there being a rule of Pre-/x/-tensing which is ordered after Laxing. Such analyses provoked debate over how abstract underlying forms could be. One of the earliest entries in this debate on the side of concreteness came from Kiparsky (1968, 1973), who proposed to ban absolute neutralization via the Alternation Condition (CHAPTER 80: MERGERS AND NEUTRALIZATION).

(13) Neutralization rules cannot apply to all occurrences of a morpheme.

Adopting (13) would close off the *SPE* analyses based on underlying /x/ in English, since English lacks [x] on the surface, and so a rule of /x/-deletion would have to apply to every instance of a morpheme with underlying /x/. Kiparsky (1968, 1973) accordingly proposes that all cases of exceptionality be handled via abstract rather than phonological diacritics.

In response to (13), a number of counterexamples were proposed, perhaps most notably by Brame (1972) for Maltese, and Selkirk and Vergnaud (1973) for French (see Kiparsky 1973 for references to additional examples). In this section I will focus on Selkirk and Vergnaud's example of French *h-aspiré*, as it is simpler than they don't meet the rule's structural description (they do not have a C immediately after the word boundary). Selkirk and Vergnaud note (1973: note 5) that one might entertain a theory in which diacritic features could endow morphemes with the ability to trigger a rule even without meeting the rule's structural description. They rebut this possibility by relating the following "old Hallean tale":

(15) In Armenia, there is a special kind of nightingale which sings when the moon shines.
– And when the moon does not shine?
– It sings anyway.

That is, if morphemes can be listed as triggering a rule without meeting its structural description, then the rule is stripped of content as a phonological generalization. This objection is the exact inverse of Kisseberth's (1970) and Coats' (1970) "detached exception" argument against the alphabet-feature alternative to [−environment rule *n*]. In both cases, the analysis being argued against is one in which the exceptional triggering or blocking of a process is attributed to a morpheme which has no phonological relevance to the process.

This idea, that exception features can allow a morpheme to trigger some rule without meeting its structural description, was advocated in contemporaneous works by Harms (1968; cf. Karttunen 1970: 150; Zonneveld 1978: 166–167) and Kenstowicz (1970). Drawing inspiration from the alphabet-feature analysis outlined by Zonneveld (1978) for Kenstowicz's (1970) Lithuanian example, we could rewrite the French VN coalescence rule as follows:

(16) $\text{VN} \rightarrow \text{V}_{[+\text{nas}]}$ / __ # {C, [+*h-aspiré*]}

That is, we can make words that fail to meet the phonological structural description of the unaltered rule by virtue of lacking an initial C nevertheless trigger the rule by using curly brackets to make that phonological element of the structural description disjunctive with a diactritic feature. While this does work, formally speaking, the availability of such an analysis does not diminish the force of the Armenian nightingale objection: it allows us to stipulate that phonological rules apply to arbitrary lists of morphemes which might not have anything in common phonologically, putting us on the slippery slope to phonology becoming merely a list of morpheme-specific instructions in which no generalizations are expressed.

A different diacritic analysis of *h-aspiré* was advocated by Kiparsky (1973). He responded to Selkirk and Vergnaud's (1973) absolute-neutralization analysis by noting the tendency of *h-aspiré* to be lost under morphological derivation (CHAPTER 88: DERIVED ENVIRONMENT EFFECTS): *le Hitler* [lɔ.it.lɛʁ] 'the Hitler' but *l'hitlérisme* [lit.lɛ.ʁizm] 'the hitlerism'. Disappearance of an initial consonant only in suffixed words would be decidedly odd and certainly does not otherwise exist in French. Morphological idiosyncrasies, however, as Kiparsky (1973) notes, are well known to be able to disappear under derivation. In English, for instance, the root *stand* in isolation takes the irregular past tense *stood*, but the compound verb *grandstand* takes the regular past tense: *grandstanded*, **grandstood*. (However, see Burzio 2000 and Yu 2000 for frameworks in which marked structures can be lost exclusively in affixed words.)

which devoice in coda position, and morphemes containing stops of the first class as being exceptions to devoicing, they propose to mark the distinction between the three kinds of stops in underlying representations alone. Non-alternating voiced stops would be underlyingly [+voice], and non-alternating voiceless stops underlyingly [−voice]. The alternating stops would be underlyingly [0voice], with [−voice] being filled in on them in coda position and [+voice] in onset position (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION).

A problem for this approach is pointed out by Kager (2009), and had previously been noted by Kiparsky (1993a), who argues for an underspecification account of derived environment effects. This is that underspecification cannot work for exceptional alternations, where the alternating phonological property is represented privatively. For example, in the case of the Dutch "minor rule" of open syllable lengthening, an underspecification account would need to assign distinct underlying representations to the three kinds of vowels: non-alternating long vowels, non-alternating short vowels, and alternating vowels. The first would presumably be bimoraic and the latter monomoraic. But what representation are we then to assign to the alternating vowels? Privative representations allow only a two-way contrast, but when contrasts are neutralized only in an exceptional class of morphemes, the underspecification approach needs a three-way underlying contrast. (In the case of the Dutch example, this objection will not go through if the apparent length contrast is really a tense/lax contrast, as van Oostendorp 2000 argues.) One final issue with the prespecification approach, as with all representational approaches to exceptions, is how to account for the loss of exceptionality under derivation.

For additional critiques of the input-underspecification approach, see Becker (2009: §2.6), which deals specifically with Turkish, and Albright (2002: ch. 5), which discusses a similar pattern in Lakhota.

3.4 *Exceptionality via listing*

Besides the underspecification model, there are two other approaches in OT which locate exceptionality in underlying forms. The first is the one discussed earlier in which "minor rules" always involve selection of lexically listed allomorphs.

The other is proposed by Zuraw (2000). Her concern is with the following paradox. Often in a language a phonological process will either fixedly apply or not apply to any given existing word. At the same time, if we examine the lexicon as a whole, there will be identifiable statistical trends regarding where the rule applies and where it does not. These statistical trends often can be shown to be psychologically real to native speakers; for instance they affect speakers' willingness to apply the process in nonce words. We thus need a model of grammar which incorporates both statistical trends as well as fixed pronunciations for existing words.

Zuraw (2000) focuses on the example of Tagalog nasal substitution. Prefix-final nasals in Tagalog sometimes simply assimilate to the place of articulation of a following root-initial consonant (CHAPTER 81: LOCAL ASSIMILATION); other times, the nasal and following consonant coalesce into a nasal segment homorganic with the underlying root-initial consonant. Nasal substitution is lexically irregular, in that some polymorphemic words undergo it and some don't. Indeed, simply marking morphemes as to whether they trigger or undergo nasal substitution is were found of rules which were undeniably post-lexical (because they applied between words) but which showed properties of lexical rules. One example (Kaisse 1990): in English the Rhythm Rule (Liberman and Prince 1977) retracts word-level primary stresses to avoid clash with a primary stress in a following word:

(25) *ˌthir'teen ~ 'thirˌteen 'men* (**ˌthir'teen 'men*)

There are several words, for instance *discrete,* which fail to undergo this retraction, implying that they are exceptions to the Rhythm Rule:

(26) *dis'crete ~ dis'crete 'math* (**ˌdiscrete 'math*)

Another standard view in rule-based Lexical Phonology is that only post-lexical rules can introduce non-contrastive features (Mohanan 1982; Kiparsky 1985). Here too, examples have been proposed of rules that would qualify as post-lexical on this basis, but which nevertheless have exceptions – see for instance Chomsky (1962), Withgott (1982), and Steriade (2000) on North American English flapping (though cf. Davis 2005; Bermúdez-Otero, forthcoming: §2.4.5.2). The many documented cases of word-specific sub-contrastive phonetics which have helped to motivate exemplar-based theories of phonology (see e.g. Pierrehumbert 2001 and references therein) are also relevant to this question.

Stratal OT (Kiparsky 2000; Bermúdez-Otero, forthcoming, among many others) is a version of Lexical Phonology in which the phonology of each stratum is an OT grammar rather than a rule-based grammar. In this theory it is predicted that any process which misapplies cyclically must be able to have lexical exceptions; see Bermúdez-Otero (2007b, 2008, as well as references therein), who calls this "Chung's Generalization" in recognition of Chung (1983: 63). The idea is this: for a rule to misapply cyclically, it must apply in a surface-true manner at stratum *n,* and the result of applying it at stratum *n* must be protected by faithfulness at stratum *n*+1 (which may be identical to stratum *n,* in the case of cyclicity at the stem level). This entails that stratum *n*+1 will also be faithful to exceptional inputs which are supplied to it directly by the rich base rather than by an earlier stratum. For some possible counterexamples to this prediction, see Benua (1997: ch. 3) and Albright (2008). Benua's example is from Sundanese, where nasal harmony operates cyclically, even though vowel nasality is not contrastive anywhere in the language, including in affixes that are added after an earlier cycle's application of nasal harmony.

5 Conclusion

The study of exceptions is all about the nature of linguistic generalizations, and how and whether speakers can internalize generalizations that are imperfect. As such, exceptionality is an issue of central importance to any theory of language.

There are two ways in which an item can be arbitrarily marked to behave exceptionally. The first is to assign an abstract diacritic which indicates that parts of the grammar (rules, constraints) or whole grammars (co-phonologies) are or are not applicable to that item. The second is to give the item a special underlying

Volume I: General Issues and Segmental Phonology

Volume II: Suprasegmental and Prosodic Phonology

Volume III: Phonological Processes

Volume IV: Phonological Interfaces

Volume V: Phonology across Languages

The Blackwell Companion to Phonology is a major reference work drawing together 124 new contributions from leading scholars in the field. Led by a team of renowned international scholars, the *Companion* represents a diverse range of approaches and methodologies to key phenomena in phonological research. In contrast to other handbooks and reference works currently available for phonology, these volumes focus on phenomena and case studies that highlight past and ongoing debates in the field. Interdisciplinary connections, such as those with the social and computational sciences, are covered, as well as statistical and experimental techniques. The *Companion* will be a touchstone for future phonological theorists, giving an overview of data and insights which any theory of phonology should be able to cover.

Simultaneously offering broad coverage and a high level of detail, *The Blackwell Companion to Phonology* is a landmark work available in both print and online editions that will be indispensable to students and researchers in the field for years to come.

Phonology across Languages

107 Chinese Tone Sandhi

Bao Zhiming

1 Introduction

It has long been recognized that tone in Chinese (and other mainland Asian tone languages) is different from tone in African languages. Two differences are noteworthy (see also CHAPTER 45: THE REPRESENTATION OF TONE). First, while African tone languages have small inventories of tones which can be characterized in terms of pitch levels of H (high), M (mid), and L (low), Chinese has a larger number of contrastive tones, a fact recognized in the numbers 1 (low) through 5 (high) widely used in Chinese linguistics to transcribe tones. Second, Chinese tonal inventories contain more tones with complex contours than their African counterparts. African tone has played a major role in the development of generative phonology, with Asian tone languages contributing empirical data to support or refine theoretical claims based on African tonal phenomena. Many of the tone sandhi processes that are common in African languages, such as spreading, are also attested in Chinese. Naturally, tone sandhis which involve a contour are either unique to or more common in Chinese and other Asian languages with large tonal inventories. The complexity and range of tone sandhi in Chinese have contributed to our understanding of tonal phenomena in general. The difference in the size of tonal inventory between Chinese and African languages has received scant attention from phonologists, and its theoretical significance is not fully understood.

Chinese tones are typically described in terms of the four Middle Chinese (ca. 900 CE) categories: *ping* 'even', *shang* 'rising', *qu* 'departing', and *ru* 'entering'. Each of the four categories is realized in two registers, *yin* and *yang*, giving rise to a total of eight tones. These are illustrated in (1) with the tonal inventory of Songjiang, a Wu dialect spoken in what is now metropolitan Shanghai (Bao 1990, 1999a):

(1)	I	*ping*	a.	53	t'i	'ladder'
					ti	'low'
			b.	31	di	'lift'
	II	*shang*	a.	44	t'i	'body'
					ti	'bottom'
			b.	22	di	'brother'

III	*qu*	a.	35	t'i	'tear'
				ti	'emperor'
		b.	13	di	'field'
IV	*ru*	a.	$\underline{5}$	p'aʔ	'tap'
				paʔ	'hundred'
		b.	$\underline{3}$	baʔ	'white'

Throughout the chapter, Roman numerals refer to the tonal categories, and underlining marks the *ru* tones, which are realized on syllables ending in voiceless or glottal stops. As the Songjiang inventory shows, the *yin* tones (a) occur with voiceless onsets and are higher in pitch, and the *yang* tones (b) occur with voiced onsets and are lower in pitch.

2 Common tone sandhis in Chinese

When tones occur in a compound or phrase, they may undergo change. I use the term *citation tone* to refer to tones that are lexically specified for each morpheme, which for our purpose coincides with a single character and a single syllable. I use *sandhi tone* to refer to tones derived from citation tones in specific context. In the Chinese linguistics literature, a tone is commonly described in terms of two dimensions: pitch height (or register) and pitch movement (or contour) over the duration of the syllable, which is the presumed tone-bearing unit in Chinese. We can approach tone sandhi from the perspective of an individual tone or from the perspective of an entire tonal inventory. The term *tone sandhi* is used in these two senses. Where the difference in perspective is important, I will use the term *tone sandhi system* or simply *system* to refer to the sandhi processes that affect the entire tonal inventory of a dialect.

Tone sandhi patterns vary enormously across Chinese dialects, and Pike's (1948) contour-based Africanist–Asianist characterization is, as we shall see, simplistic. We can recognize four broad types of tone sandhi in Chinese. The first type includes sandhis which target register, contour, or both (the whole tone) and are sensitive to neighboring tones. I call this type *contextual tone sandhi*. The second type refers to tone sandhis which target tones in a particular position, typically the left or right edge of a polysyllabic string. In this type, tonal context does not play a role. I call this type *positional tone sandhi*. The third type is what I call *templatic tone sandhi*, where the sandhi patterns cannot be derived from the lexically specified citation tones without referring to some prespecified tonal template. The fourth type is *tone spread*, which is commonly attested in African tone languages and familiar in the generative phonological literature. To the extent possible, I will cite data from the original sources, with the original tonal and segmental transcriptions. Often tones from the original data are given different featural interpretations in the theoretically oriented secondary literature. This is especially true for contour tones with a slight curvature, such as 21, 45, or 214. By using the tonal transcriptions from the sources, I hope not only to give credit to the field linguists, but also to highlight the interpretive possibilities of numerically transcribed tones.

2.1 *Contextual tone sandhi*

The tonal phonology of Tianjin, 150 km to the east of Beijing, offers us a good case study of sandhi processes targeting the register and contour separately. The Tianjin sandhi system, which involves all citation tones in all disyllabic combinations, has been studied intensely in generative phonology; see M. Chen (1986, 2000) for a summary. Tianjin has four citation tones, 21, 45, 213, and 53. Compared with the dialect of nearby Beijing, Tianjin's tone sandhi is richer. The relevant data are displayed in (2) (unless otherwise stated, all Tianjin data are cited from Li and Liu 1985).

(2) a. 21-21 → 213-21
b. 213-213 → 45-213
c. 53-53 → 21-53
d. 53-21 → 45-21

Other combinations do not exhibit sandhi. The analytical details often depend on the interpretation of the numerically transcribed citation tones. If we consider 213 to be low rise, 21 to be low fall, and 45 to be high rise, the four Tianjin tone sandhis can be reduced to two processes, informally stated as follows:

(3)	a.	low rise	→	high rise	cf.	(2b)
		high fall	→	low fall		(2c)
	b.	fall	→	rise		(2a, d)

The rules in (3a) target the register by raising it to derive 45 or lowering it to derive 21. Rule (3b) targets the contour, turning fall to rise. It is worth noting that (3a) does not affect the contour, while (3b) does not affect the register. This is significant, since it suggests a formal separation between register and contour. We will return to this issue in §3.1.

Not all tone sandhi phenomena can be analyzed with rules that manipulate either the register or the contour. There are sandhis which involve the lowering or raising of the pitch, as well as a change in contour. The Beijing Mandarin tone sandhi is one such example. Since Beijing Mandarin is designated as standard Chinese, its phonology is well known, and has been analyzed extensively in the scholarly literature (Chao 1968; Yip 1980, 1995, 2002; Z. Wu 1984; M. Chen 2000; Duanmu 2000). The account here follows M. Chen (2000). Like Tianjin, Beijing has four tones, 55 (T1), 35 (T2), 214 (T3), and 51 (T4). In disyllabic phrases, the third tone 214 becomes 35 when it is followed by another 214. This is the T3 Sandhi of Beijing Mandarin (M. Chen 2000: 102):

(4) 214 → 35 / __ 214

To derive 35, we need to change the contour from concave to rising and raise the pitch height at the same time. The T3 Sandhi is a composite process.

More specimens of tone sandhis are displayed in (5).

(5) a. *Sandhi involving register*
Luoyang (Mandarin; He 1996)
53-53 → 31-53
Pinggu (Mandarin; S. Chen 1998)
13-13 → 35-13
Pingyao (Mandarin; Hou 1980)
35-13 → 13-13
13-53 → 35-423

b. *Sandhi involving contour*
Mingshui (Mandarin; Gao 2000)
55 55 → 53-55
Pingyao (Mandarin; Hou 1980)
53-53 → 35-423
Pucheng (Min; Norman 1987)
35-24/<u>12</u> → 53-24/<u>12</u>
24-24/<u>12</u> → 31-24/<u>12</u>

c. *Sandhi involving register and contour*
Gaomi (Mandarin; Li 2004)
53-31 → 24-31
Pingyao (Mandarin; Hou 1980)
35-35 → 31-35
Yongkang (Wu; Yuan 1989)
35-T → 11-T
Raoping (Kejia; Zhan and Liu 2004)
<u>21</u>-T → <u>55</u>-T

In (5), T represents any tone. For each dialect, the major group to which it belongs is indicated, together with the source. Context-sensitive tone sandhi is attested in all major dialect groups, especially among Mandarin dialects.

2.2 Positional tone sandhi

Besides the context-sensitive tone sandhis that we see in Beijing, Tianjin, and some of the dialects in (5), many dialects exhibit sandhi conditioned by the position of the tone undergoing the sandhi. When we examine the sandhi behavior of the entire inventory of citation tones of a given dialect, we see two types of tonal systems that exhibit positional tone sandhi. In the first type, all citation tones in the inventory undergo sandhi by virtue of position. In the second type, some citation tones undergo positional tone sandhi, but other citation tones in the inventory either do not undergo sandhi or undergo sandhi conditioned by tonal context. We will describe these two subtypes in turn.

The Southern Min dialect of Xiamen has been analyzed extensively in generative phonology, and its tonology is well understood (see Yip 1980; M. Chen 1987, 2000; Duanmu 1995; Barrie 2006; among others). Xiamen has a total of seven citation tones, including two checked tones. The five non-checked tones are listed below (the Xiamen data are cited from M. Chen 2000):

(6)

Ia	44	Ib	24
II	53		
IIIa	21	IIIb	22

All five citation tones undergo sandhi in phrase-initial position, regardless of the tone that follows. The sandhi rules are illustrated below:

(7) a. 44 → 22 p'ang 44 'fragrance'
b. 24 → 22 we 24 'shoes'
c. 22 → 21 pī22 'sick'
d. 21 → 53 ts'u 21 'house'
e. 53 → 44 hai 53 'ocean'

These rules can be arranged in a circular fashion, as follows:

(8) 24 → 22 → 21 → 53 → 44 → 22

This is the so-called Min Circle (cf. M. Chen 1987). The checked tones 32 and 4 also exhibit positional tone sandhi, but do not participate in the Min Circle.

While all Xiamen citation tones change in phrase-initial position, only some of the tones in the Kejia dialect of Raoping exhibit this sort of sandhi behavior. Raoping has six citation tones, as shown below (the Raoping data are cited from Zhan and Liu 2004):

(9)

Ia	11	Ib	55
II	53		
III	35		
IVa	21	IVb	55

In disyllabic phrases, all six tones, except 11 and 55, undergo sandhi in phrase-initial position. The sandhis are summarized in (10).

(10) a. 55 → 31 / __ 11, 53, 21
55 → 33 / __ 55, 35, 55
b. 53 → 33 / __ 11, 35
53 → 11 / __ 55, 53, 21, 55
c. 35 → 33 / __ T
d. 21 → 55 / __ T

As can be seen, 55 and 53 undergo sandhi conditioned by context (10a, 10b), but 35 and 21 undergo positional sandhi (10c, 10d).

2.3 *Templatic tone sandhi*

In addition to contextual and positional tone sandhis, polysyllabic compounds or phrases in some dialects exhibit tonal patterns that cannot be derived in a straightforward manner from the lexically specified tones of the component syllables. Such tone patterns can be most profitably analyzed on the basis of a template with prespecified tones. The tone patterns of reduplicated doublets in two Mandarin dialects, Harbin and Wanrong, are typical examples of templatic tone sandhi. We will examine the two dialects in turn.

Monosyllabic nouns in Chinese reduplicate to express universal quantification, *ren* 'person' *vs. ren ren* 'each/every person'. In Wanrong, such reduplicated doublets surface with two tone patterns, illustrated below:

(15)		*base*	*reduplicant*		
	a.	51	24-51	tɕia tɕia	'every home'
	b.	24	24-51	p'ei p'ei	'every plate'
	c.	55	55-51	k'uei k'uei	'every bundle'
	d.	33	33-51	tɕy tɕy	'every sentence'

As can be observed in (15), the second copy has 51 regardless of the citation tone of the base. Furthermore, 51 reduplicates as 24-51. The patterns in (15) can be derived through a fixed template with prespecified tone 51, to which rule (14b) applies to derive pattern (15a). The template is shown below:

```
(16)  σ - σ
          |
          51
```

Unlike the template for disyllabic compounds (14a), the tonal template of nominal reduplication applies to all four citation tones in the inventory of Wanrong.

Templatic tone sandhi is not restricted to reduplicated doublets. Liujia, a Chinese dialect spoken in the linguistically mixed area of northern Guangxi, has a single robust disyllabic sandhi template for all citation tones that undergo sandhi. Liujia has a total of ten citation tones, including four checked tones. According to Zeng and Niu (2006), the dialect affiliation of Liujia is not easy to establish, perhaps due to contact with the Miao and Yao languages spoken in the region. Since the checked tones exhibit similar sandhi behavior to the non-checked tones, we will exclude the checked tones from our consideration. The six non-checked tones are 53, 343, 33, 35, 41, and 22. The falling tone 41 does not undergo sandhi, nor does 33, except when it is followed by 22. In phrase-initial position, 53 and 343 become 11. The sandhi behavior of 35 and 22 is more complex. In the vast majority of disyllabic phrases involving the two tones they surface as 11 in phrase-initial position, but in a small number of phrases they remain unchanged or surface as 22, due to a complex and idiosyncratic interplay between the syllable-initial consonant and the phrase-final tone. By Zeng and Niu's (2006) calculation, out of a total of 100 disyllabic tonal combinations (including the four checked tones), 60 combinations exhibit tone sandhi, out of which 51 combinations have 11 as the sandhi tone. Some of the disyllabic tone patterns are exemplified below:

(17)	a.	53-53 → 11-53	kou tei	'height'
		53-35 → 11-35	fɔŋ y	'wind and rain'
	b.	343-53 → 11-53	lɪaŋ sem	'conscience'
		343-35 → 11-35	nan min	'unavoidable'
	c.	35-53 → 11-53	ma tɕ'ie	'horse wagon'
		35-35 → 11-35	lou ma	'old horse'
	d.	22-53 → 11-53	lu təŋ	'street lamp'
		22-35 → 11-35	liu li	'manage'

The data support the template for disyllabic tone sandhi displayed in (18).

(18) σ - σ
     |
     11

According to Zeng and Niu (2006), the sandhi is triggered by iambic rhythm, where a citation tone is reduced to 11 in the metrically weak position. In view of M. Chen's (2000) accentual analysis of New Chongming (see §3.4 below), Zeng and Niu's (2006) characterization may be given an accentual interpretation: the prominent syllable retains its citation tone, and the other syllable assumes the default tone 11. What is clear from the data is that the robust sandhi template (18) has a strong neutralizing effect on disyllabic tonal contrasts.

2.4 Tone spread

In both contextual and templatic tone sandhis, the citation tone and its sandhi counterpart are confined to the lexically specified tone-bearing syllable. The sandhi tones do not spread to neighboring syllables of a polysyllabic string. While tone spreading is characteristic of African tone languages (cf. Odden 1995), it is also attested among Wu dialects. The Wu tonology has been discussed widely in the literature (see Zee and Maddieson 1979; Ballard 1980; Xu *et al.* 1981, 1982, 1983; Selkirk and Tong 1990; Qian 1992; Zhu 1999; M. Chen 2000; Rose 2000; Cao 2002; among many others). The Shanghai tone sandhi is representative of what I will call *limited tone spread* characteristic of the Wu dialects. Since it is well discussed in the generative literature, I will use it as an example. Unless otherwise stated, the data are cited from Xu *et al.*'s (1981, 1982, 1983) detailed work on Shanghai tone sandhi.

Shanghai has a total of five citation tones, 53, 34, 13, 55, and 12. The tone patterns of disyllabic, trisyllabic, and quadrisyllabic compounds are largely determined by the initial tones. The tone patterns with the initial tones 53, 34, and 13 are displayed in (19).

(19)

base	disyllabic	trisyllabic	quadrisyllabic
53	55-31	55-33-31	55-33-33-31
34	33-44	33-55-31	33-55-33-31
13	22-44	22-55-31	22-55-33-31

The checked tones exhibit the same sandhi behavior. Three properties of the Shanghai tonology are worth noting. First, the lexically specified tone spreads from the initial syllable to the neighboring syllable only, but not beyond. In other words, the spreading is local. Second, the morphosyntactic structure of the polysyllabic compound does not play a role in tone sandhi, as shown in the trisyllabic compounds below:

(20) 53-σ-σ → 55-33-31

a. tɕ'iɤ 53 [bi 13-tɕ'i 34] 'bad temper'
   bad temper

b. [ʔi 53-tsɿ 34] ti 34 'tobacco shop'
tobacco shop

The two compounds have different morphosyntactic structure, but exhibit the same tone pattern. Third, for trisyllabic strings, the remaining syllable is prespecified with the default tone 31, and for the quadrisyllabic strings, the default tones are 33-31. The default tones cannot be derived from the initial tone through spreading or some other means; Shanghai tonology retains the templatic tone sandhi that we have seen in other Chinese dialect families. Details aside, the Shanghai tone pattern can be summarized as follows (T = citation tone):

(21) *Tone sandhi of Shanghai compounds*

σ σ (σ σ)
T 33 31

The Shanghai tone patterns can be easily analyzed in generative phonology (see also CHAPTER 14: AUTOSEGMENTS). The precise analysis depends on what we assume to be the internal structure of the tones, especially contour tones (see §3.1). Here, we sketch the analysis of Selkirk and Shen (1990), which takes contour tones to be composed of level tones. Selkirk and Shen (1990) propose a three-step analysis: delete all non-initial citation tones, spread the initial tone, and insert the default tones. The derivation of (22) illustrates this analyis:

(22) Underlying tɕʻiɤ bi tɕʻi 'bad temper'
53 13 34

Tone deletion tɕʻiɤ bi tɕʻi
53

Tone spread tɕʻiɤ bi tɕʻi
5 3

Default tone tɕʻiɤ bi tɕʻi
53 33 31

Shanghai-style limited tone spread is widely attested among Wu dialects; see Qian (1992) and Cao (2002).

Tone spreading is freed from the Shanghai-type restriction in Danyang, a Wu dialect spoken in a region that borders on the Mandarin-speaking area. Danyang tone sandhi has attracted a lot of attention from generative phonologists; see Chan (1991), Yip (1989), Duanmu (1994), M. Chen (2000), and Bao (2004). All these works are based on the detailed analysis by Lü (1980). Danyang has a total of six of what Lü (1980: 88) calls Type A word melodies, listed in (23).

3 Theoretical issues in Chinese tonology

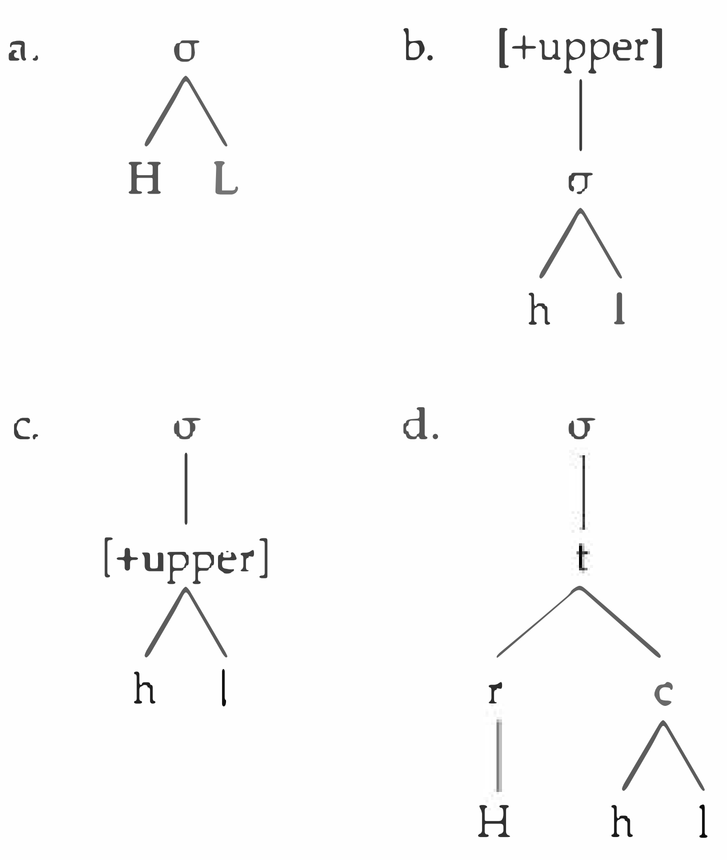
The tonal phenomena of Chinese have attracted a great deal of attention from linguists working in formal linguistics, especially in generative phonology. M. Chen (2000) summarizes the theoretical work on Chinese tone in terms of four 'leitmotifs': the internal structure of tone, the mechanism of tone sandhi, the relationship between tone and accent/stress, and the tone sandhi domain. Here, we will briefly summarize the results in these four areas of research on Chinese tone. The last section summarizes recent OT analyses of some of the same tonal phenomena.

3.1 *Internal structure of tone*

Among the world's tone languages, it has long been recognized that Chinese has contour systems, and African or native American languages have, by contrast, level (or even) systems; see Pike (1948). Both systems have tones that are phonetically level in pitch, such as H or L, and tones that are falling or rising in pitch movement. The crucial difference between the two systems is the treatment of contour tone. For Pike (1948) and early generative phonologists, contour tone is a basic unit, so a falling or rising tone is not phonemically equivalent to a combination of H and L, even though phonetically a presumptive unitary falling tone is indistinguishable from a sequence of H-L. Chinese dialectologists typically treat contour tones as basic units.

The far richer representational architecture of non-linear phonology (CHAPTER 45: THE REPRESENTATION OF TONE; CHAPTER 14: AUTOSEGMENTS; CHAPTER 27: THE ORGANIZATION OF FEATURES) allows different approaches to the structure of tone, especially contour tone. Using the high falling tone 53 as an example, we will examine four models that have been proposed by scholars working in generative phonology. They are shown in (26).

(26)



In (26), σ is the tone-bearing unit, and the tonal elements H, L, h, and l are defined in terms of the features [upper] and [raised], as follows (Yip 1980).

(27) H: [+upper]
L: [−upper]
h: [+raised]
l: [−raised]

Returning to the models shown in (26), (26a) is the Africanist model, in which H and L are associated with a single tone-bearing unit. This model is consistent with Woo's (1969) analysis, which attempts to reduce Chinese contour tones to combinations of level tones, in the same way that contour tones in African languages are typically analyzed. Here, σ is a tone-bearing unit which is sufficiently long to accommodate two tones with different pitch levels. In Woo's formulation, the two tones (H and L) are arranged sequentially within the feature matrix of the tone-bearing unit. The Africanist model is further argued for in Duanmu (1994).

The structures in (26b, 26c) are non-linear representations. In (26b), proposed by Yip (1980), the register feature [upper] and the pitch level feature [raised] are independent autosegments associated with a common tone-bearing unit. In (26c), proposed by Yip (1989), the register is analyzed as the tone root, to which h [+raised] and l [−raised] attach to specify the falling contour. The register feature is then associated with the tone-bearing unit. In (26d), proposed by Bao (1990, 1999a), tone consists of register and contour as sister nodes. The model in (26a) does not recognize the registral difference – the *yin–yang* opposition – in Chinese tones. The *yin–yang* opposition is expressed in (26b)–(26d), with register being expressed by the feature [upper] (*yin* [+upper], *yang* [−upper]). The formal difference among (26b)–(26d) is twofold. First, contour tone is treated as a unit in (26c, 26d), but not in (26b). Second, contour is dependent on register in (26c), not in (26b, 26d), where register and contour are independent structural elements. (26d) is the closest to the traditional analysis of tone in Chinese linguistics.

There is ample empirical evidence in support of the separation of register and contour. We have seen individual sandhis in (5); here we will pay attention to tone sandhi that involves an entire tone inventory of a given dialect. We will discuss two types of evidence. First, tones with the same contour may undergo the same tone sandhi process; in other words, contour can be used to define natural classes. Second, tones may harmonize their register without affecting the contour. We will look at contour-related sandhi phenomena first.

Yiyang, a Xiang dialect, has an interesting tone sandhi pattern in disyllabic compounds. Yiyang has two rising tones, 34 and 13, and two falling tones, 41 and 21. (It also has the checked tone <u>45</u>, which does not concern us here.) In disyllabic compounds, the tones undergo sandhi, as shown below (Xu 2001: 11–13):

(28) a. 34 → 33
i 34 sã 34 (33) 'doctor'
tɕiau 34 (33) fa 34 'to water flowers'
b. 13 → 33
fa 34 pu 13 (33) 'flowery cloth'
tɕi 13 (33) ma 41 'to ride horses'
c. 41 → 11
sã 34 tin 41 (11) 'hilltop'
ta 41 (11) li 13 'to thunder'

d. 21 → 11
ts'ə 34 tsã 21 (11) 'bus stop'
lo 21 (11) ts'ə 34 'to ride buses'

The sandhi tones are given in parentheses.

Yiyang exhibits a peculiar form of positional sandhi. In disyllabic compounds of the form verb–object, the first tone undergoes sandhi; in compounds with other morphosyntactic structures, the second tone undergoes sandhi. The sandhi process, regardless of position, is the same: the rising tones become 33 (28a, 28b), and the falling tones become 11 (28c, 28d). Tonal contour is used to define natural classes.

The same type of contour-driven tone sandhi is reported in disyllabic compounds in Yongfu, a Min dialect. Yongfu has a total of seven citation tones, shown below (Z. Zhang 1992: 23–25):

(29) Falling: 31, 53, <u>53</u>
Rising: 24
Level: 11, <u>55</u>, 21

In addition to the seven tones, Yongfu has the mid-level tone 33 in sandhi context only. The treatment of 21 is crucial for our analysis of the Yongfu tone sandhi. Since Yongfu already has a low falling tone 31, we will treat 21 as a lower-mid-level tone, despite the slight declination in pitch. In any given dialect, 21, 22, or 11 could very well be allotones; see Rose's (1990) detailed acoustic analysis of the Zhenhai tonology. The featural interpretation of the numerically transcribed tones needs to pay attention not only to the phonetic pitch that the numbers represent, but also to the tonal oppositions within the tonal inventory of a given dialect. For this reason we treat 21 as a lower-mid-level tone, identical to 22. We will, however, continue to follow Z. Zhang's (1992) transcription.

In Yongfu disyllabic compounds, the tones 24, 11, 21, and 55 become 33, and 31, 53, and <u>53</u> become 21. Some relevant compounds follow:

(30) a. kim 24 (33) tsam 24 'golden needle'
sioŋ 11 (33) loŋ 53 'pine nut'
p'ĩ 21 (33) au 53 'behind back'
siok <u>55</u> (33) go 11 'big goose'
b. gia 31 (21) gei 53 'skill'
ts'ie 53 (21) tsiŋ 24 '(purified) water'
tsuat <u>53</u> (21) ts'iaŋ 21 'extreme'

(30a) is the dominant pattern. According to Zhang (1992), these four tones become 55 when followed by 31 or <u>21</u>; we will ignore this detail here. It is clear from the data in (30) that Yongfu exhibits positional sandhi. Since we interpret 21 as the lower-mid tone 22, in opposition with the low tone 11 and the mid tone 33, we can state the Yongfu tone sandhi informally as follows:

(31) a. falling tones → 33
b. non-falling tones → 21 (= 22)

The rules apply to tones in initial position.

Zhangzhou, another Min dialect, has the same type of tone sandhi, which affects the stem tone when the stem is affixed with the diminutive suffix /a/ 53. Some examples are shown below.

(32) ts'ia 34 (33) a 53 'car'
hi 13 (33) a 53 'fish'
haŋ 22 (33) a 53 'lane'
kau 53 (55) a 53 'dog'
ts'i 21 (55) a 53 'house'

The data are cited from Yang (2006), where they are given in Chinese characters. Here, IPA transcriptions are used. The analysis crucially depends on the treatment of 21 in the Zhangzhou inventory. Assuming that 21 is the low falling tone in opposition to the high falling tone 53 in the Zhangzhou inventory, the tone sandhi can be formulated informally as follows:

(33) a. falling tones → 55
b. non-falling tones → 33

Like their counterparts in Yongfu, the two rules apply to tones in initial position. The Yongfu and Zhangzhou tone sandhi demonstrates the independent role that contour plays in defining natural classes, supporting the structure of tone shown in (26e), which encodes contour as sister to register.

Contour is not only used to define natural classes, it also participates in tone sandhi independently of register. This is the tone sandhi found in the dialect of Pucheng, which is located in northern Fujian. Pucheng has a total of seven citation tones: 35, 24, 55, 54, 12, 11, and 43. According to Norman (1987: 331), 12 has a "very tense glottal quality throughout." We can analyze 12 and 24 as allotones of the low rising tone. In Pucheng, as we saw in (5b), the rising tones 35 and 24 become 53 and 31, respectively, before the low rising tones 24 and 12; all other disyllabic combinations maintain their citation tones. The Pucheng sandhi system can be described with a simple rule, informally given in (34):

(34) rising → falling / __ low rising

Changes in contour do not affect the register: high rising 35 becomes high falling 53, and low rising 24 becomes low falling 31. Contour and register are independent.

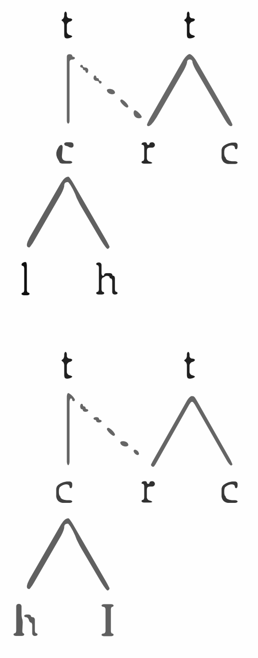
Register also plays a crucial role independently of contour. Here, we will examine the register harmony in the Min dialect of Chaozhou, based on the dialect of Jieyang (Cai 1991; Bao 1999b). The citation and sandhi tones are displayed in (35).

(35)

	citation	*sandhi*	*environment*
a.	53	35	53, 55, 5
		24	33, 213, 11, 2, 35
b.	213	53	53, 55, 5
		42	33, 213, 11, 2, 35
c.	33	33	all tones
d.	55	11	all tones
e.	35	21	all tones
f.	11	11	all tones

Chaozhou also has two checked tones, 2 and 5, which exhibit the same sandhi behavior as 213 and 55, respectively (35b, 35d). The sandhi affects tones in the initial position of disyllabic compounds. Like other Min dialects we have seen, Chaozhou exhibits a strong tendency toward positional sandhi. Of interest to us are the sandhis in (35a, 35b). Here, the citation tone 53 becomes rising, but the register is determined by the following tone. Similarly, the citation tone 213 becomes falling, with the register determined by the following tone. Using a tone model that allows the formal separation between register and contour, we can express the sandhis in (35a, 35b) as in (36):

(36) a. b.



While the register harmony is strong in Chaozhou's tone sandhi, the behavior of 35 presents a serious challenge to the analysis. In Yip's (1980, 1989) models, and in Bao's (1990, 1999a) model assumed in the analysis presented in (36), 35 must be a high-register tone, in opposition to the low-register 24. We would expect 35 to behave like other high-register tones, namely 53, 55, 5, but it behaves like a low-register tone. The behavior of 35 can be understood if it is not treated as a simple tone, but as a sequence of two level tones, 3 (L) and 5 (H), consistent with the Africanist model (26a). Although the Chaozhou data show robust register harmony, they leave a "wrinkle" that opens up the possibility of an Africanist analysis of contour tone.

3.2 Tone sandhi domain

By *tone sandhi domain* we mean the string of syllables in which tone sandhi rules apply. Most descriptive field reports and theoretical works on tone sandhi in Chinese linguistics focus on polysyllabic compounds, which serve as the default tone sandhi domain. Our survey of the typology of Chinese tone sandhi reveals significant variation among Chinese dialects in the way sandhi rules apply within such tone sandhi domains. This is, however, not the only way in which tone sandhi domains are formed. There are tone sandhi domains which are not morphosyntactic constituents. M. Chen (2000) calls them phonological words, which are bounded by edges of major phrases (CHAPTER 51: THE PHONOLOGICAL WORD). The tone sandhi processes are the same.

Xiamen and Shanghai offer interesting case studies of how phonological words are formed. We look first at Xiamen. We have seen the tonal inventory of Xiamen in (6) and the positional tone sandhi encapsulated in the Min Circle (8). The formation of the phonological word in Xiamen is illustrated in (37) (M. Chen 2000: 439):

(37) a. [ji [sia k'a kin]$_{VP}$]$_S$ 'he writes faster'
he write more fast
(44 53 53 53) → (22 44 44 53)

b. [ji [sia]$_{VP}$ #]$_S$ k'a kin 'it would be faster for him to write'
(44 53) (53 53) → (22 53)(44 53)

The brackets indicate syntactic structure, and the parentheses tone sandhi domains. The string is ambiguous: in (37a), *k'a kin* 'more fast' functions as an adjunct, modifying the verb *sia* 'write'. In (37b), *k'a kin* functions as the predicate, and the sentence *ji sia* 'he write' is the subject. The presence of a major phrasal boundary (VP) in (37b) is crucial; it separates the string into two tone sandhi domains. In (37a), by contrast, there is no string-internal major phrasal boundary, and the whole string is a single tone sandhi domain. M. Chen (2000: 441) formulates the rule as follows:

(38) {Right, X^{max}}, X^{max} not an adjunct

This rule places the boundary # to the right of VP in (37b), creating two tone sandhi domains. The rules in the Min Circle apply to derive the two surface tone patterns.

Shanghai offers a near mirror image of Xiamen. We have seen the Shanghai sandhi in §2.4, which is based on polysyllabic compounds. In phrases, the same local spreading rule applies. The key to understanding the tonology of sentences is phrasing – the formation of tone sandhi domains, which is illustrated in (39) (Selkirk and Shen 1990: 322).

(39) a. zɿ [ləʔ [zɑ̃ hɛ]]
(13 <u>12</u>) (13 34) → (22 44) (22 44)
live at Shanghai
'live in Shanghai'

b. ma [[liɑ̃ bən] [sɿ]]
(13 13 34) (53) → (22 55 31)(53)
buy some CL book
'buy some books'

For consistency, I use the segmental and tonal transcriptions of Xu *et al.* (1981, 1982, 1983), with [ɛ] for their [E]. As in the Xiamen data (37), the square brackets mark syntactic structure, and the parentheses tone sandhi domains. As can be seen, there is a mismatch between syntactic and phonological structures. According to Selkirk and Shen (1990), the crucial information is the left edge of the maximal projection of a lexical item, here the nominal phrases /zɑ̃ hɛ/ 'Shanghai' and /sɿ/ 'book'. The tone sandhi domains are determined by the following parameter (Selkirk and Shen 1990: 332):

(40) {Left, Lex^{max}}

With the tone sandhi domains set by (40), the sandhi rule informally shown in (21) applies to yield the observed tone patterns.

3.3 *Cyclicity and directionality*

In §2 we established the typology of tone sandhi among Chinese dialects. In positional and spreading sandhis, the tone sandhi domain plays a crucial role. Once the tone sandhi domain is formed, tone sandhi proceeds in a straightforward manner. As we have seen in §3.2, in dialects such as Xiamen and Shanghai, the domain-internal morphosyntactic structure, if it exists, does not influence the way tone sandhi rules apply. In many Mandarin dialects, tone sandhi is cyclic, where tone sandhi rules are regulated by morphosyntactic structure. Beijing T3 Sandhi (4) offers a classic example of cyclic application (M. Chen 2000: 102):

(41) a. [lao-hu] dan 'brave'
tiger gall
214-214 214 → 35 35 214
b. zhi [lao-hu] 'coward'
paper tiger
214 214-214 → 214 35 214

T3 Sandhi applies cyclically, first to *lao-hu*, destroying the context in (41b) in the second cycle. Such cyclic application of tone sandhi rules appears to be found in context-sensitive and non-spreading tone sandhi systems. In the spreading (Wu) and positional (Min) types, tone sandhi is not cyclic.

The matter is more complex. Even among Mandarin dialects, cyclicity cannot be taken for granted. In Tianjin, which we first saw in §2.1, the sandhi patterns of trisyllabic compounds do not exhibit the effect of cyclicity. The disyllabic sandhi rules shown in (2) are repeated below:

(42) a. 21-21 → 213-21
b. 213-213 → 45-213
c. 53-53 → 21-53
d. 53-21 → 45-21

Most trisyllabic patterns can be derived through the left-to-right application of these basic sandhi rules. This is illustrated in (43) (Li and Liu 1985: 79).

(43) 213-213-213 → 45-45-213

a. tʂ'aŋ [taŋ uei]
factory party committee
'factory party committee'
b. [ɕi lian] ʂuei
wash face water
'water for washing faces'

The two compounds have different morphosyntactic structure, but the same tone pattern. The syntactic bracketing plays no role in the sandhi process. Treating the whole compound as a single tone sandhi domain, we can derive the pattern by applying rule (42b) left to right iteratively:

(44) (213-213)-213 → 45-(213-213) → 45-45-213

But the left-to-right application of the sandhi rules does not work for all cases. Li and Liu (1985: 80) point out the "exceptional" sandhi behavior of compounds composed of three 53 tones, shown below:

(45) 53-53-53 → 53-21-53

The left-to-right iterative application of (42c) yields the wrong pattern 21-21-53, or 213-21-53 with the additional application of (42a); see (46a). Here the pattern can be derived through the right-to-left application of (42c), bleeding the environment for the second iteration of the rule; see (46b).

(46) a. *Left-to-right application*
(53-53)-53 → 21-(53-53) → (21-21)-53 → 213-21-53
b. *Right-to-left application*
53-(53-53) → 53-21-53

Given the understanding of rule application in generative phonology, one would expect cyclicity or directionality to be consistent in regulating tone sandhi in any given system. The Tianjin tone sandhi facts are unexpected. What is clear is that the trisyllabic tone patterns avoid tonal sequences that would violate any of the four rules in (42). The directionality-related phenomena resist straightforward analysis.

3.4 Tone, accent, and stress

Tone, accent, and stress are notoriously slippery notions in the Chinese tonological literature. Whereas tone is part of the lexical specification of morphemes, it is not clear how it relates to accent and stress in a given tone sandhi system, if indeed the latter two notions can be made precise (see CHAPTER 42: PITCH ACCENT SYSTEMS). Here I will follow McCawley (1968) in characterizing the distinctions as in (47):

(47) a. Tone: (σ)(σ)(σ)(σ)
b. Stress: (σσ)(σσ)
c. Accent: (σσσσ)

The three notions are differentiated in terms of the size of units in which tonal contrasts are maintained. In the tonal system, tonal contrast is maintained in the syllable – in a polysyllabic string each syllable is associated with a tone. In the metrical (stress) system, it is maintained in the foot, and in the accentual system, in a unitary domain. We will see that not all Chinese dialects are tonal; some have developed into an accentual system, as argued by M. Chen (2000).

We can approach the relationship of tone with accent and/or stress from two perspectives: tonal reduction and the prominence relations that underpin tone sandhi. Generally speaking, the former is the focus of research in the Chinese linguistic circle, and the latter the focus within the general framework of generative phonology. We will discuss tonal reduction first.

Across Chinese dialects, there is a widespread phenomenon known as the "light tone." The light tone can be found on system words or affixes, which may be proceeds not by position but by tone, in accordance with the Middle Chinese (ca. 900 CE) classification. Chongming has all the Middle Chinese tones, shown below:

(50) *Citation tones of old and new varieties of Chongming*

	Old	New		Old	New
Ia	55	H	Ib	24	L
IIa	424	HM	IIb	242	ML
IIIa	33	MH	IIIb	313	LM
IVa	<u>55</u>	<u>H</u>	IVb	<u>22</u>	<u>L</u>

The Old Chongming tones are cited from H. Zhang (1979, 1980), and the New Chongming tones from M. Chen (1997, 2000). The checked tones <u>55</u> and <u>22</u> exhibit the same sandhi behavior as 55 and 24, respectively. The citation tones of New Chongming have undergone slight change from their Old Chongming counterparts, especially IIIa. M. Chen (1997: 199) treats LM and L as allotonic variants of Ia; the former variant is equivalent to 24 in Old Chongming. Other than the slight difference in the phonetic realization of IIIa, there is little difference between the old and new varieties of Chongming.

According to Chen (1997), the disyllabic tone sandhi in New Chongming divides the eight tones into two natural classes: the even tones I and IV (H/<u>H</u> and L/<u>L</u>) and the oblique tones II and III, all of which exhibit contour in New Chongming. The robust sandhi patterns involve I/IV, which surface invariably as H in phrase-final position, and retain their citation pitch values in phrase-initial position. We summarize the patterns below (O = oblique tone; E = even tone; σ = syllable with default tone; adapted from M. Chen 1997: 194):

(51) a. O-E → σ-H
b. E-O → E-σ
c. E-E → E-H

When the final tone is E (H/<u>H</u>, L/<u>L</u>), it surfaces as H. When the first tone is E, it remains unchanged, yielding two broad patterns: H-σ (< Ia/IVa-σ) and L-σ (< Ib/IVb-σ). E-E doublets surface as either H-H (< Ib/IVb-σ) or L-H (< Ib/IVb-σ). The syllable σ with an oblique tone loses its lexically specified citation tone, and acquires the default tone. The sandhi behavior of O-O is similar to the sandhis shown in (51), but involves more complex pitch realizations. To avoid complications, we will not include the O-O sandhis in our discussion; for a complete OT-inspired analysis, see M. Chen (1997, 2000).

The sandhi patterns summarized in (51) are also attested in Old Chongming, with negligible differences in the pitch values of the default tone, which is 31 in initial position, and 33 or 3 in final position (H. Zhang 1979). Incidentally, by Zhang's (1979) description and analysis, we cannot use contour to classify the Chongming tones as a natural class, since Ia is 55 and Ib is 24; see (50). The tonal categories I and IV play a crucial role in determining the observed surface tone patterns of doublets.

The patterns in (51) lend themselves to a two-step analysis: (1) mark accentual prominence on the even tones (I, IV), which surface as H in final position, and remain unchanged in initial position; (2) the unaccented syllable loses its lexical and output 13s to match their slope, and prevent 23s from matching theirs. Furthermore, the local left-to-right spread of Shanghai (see (21)) is due to MATCH-SLOPE, instead of the usual OT treatment of spreading in terms of alignment.

4 Conclusion

In the preceding sections we have surveyed the whole range of tone sandhi across Chinese dialects, and some of the central issues in Chinese tone that have attracted the attention of theoretical phonologists. Through the collective effort of field linguists and theoretical phonologists, we now have a good understanding of the sandhi phenomena in Chinese dialects. While Pike's (1948) Asianist–Africanist dichotomy has ample empirical support from Chinese dialects, it presents Chinese tonology as a monolithic block that obscures a varied landscape of the tone sandhi typology. This typology is summarized below:

(54) a. Contextual sandhi, e.g. Tianjin
b. Positional sandhi, e.g. Xiamen
c. Templatic sandhi, e.g. Liujia
d. Tone spread, e.g. Shanghai

Our survey shows a strong clustering tendency that coincides with major dialect boundaries. Contextual sandhi is most commonly found in Mandarin, positional sandhi in Min, and tone spread in Wu. All three types may contain tonal templates.

The complex landscape of tone sandhi presents interesting empirical data for phonological theory. The tone sandhi data have contributed to our understanding of the theoretical issues such as the structure of tone, tone sandhi domain, cyclicity, and the interaction of tone with accentual and/or metrical prominence. For the past half century, Chinese tone sandhi has attracted the attention of phonologists working mainly in the evolving theories of generative phonology, from the rule-based approach of classical generative phonology to the rule- and constraint-based approach of non-linear phonology, and now to the constraint-based approach of Optimality Theory. Due to the complexity of the sandhi phenomena, many of the theoretical issues remain unresolved.

108 Semitic Templates

Outi Bat-El

1 Introduction

Semitic morphology is characterized by phonological restrictions on the shape of the words, allowing only a limited set of prosodic templates and vocalic patterns. The prosodic templates, which set the size restrictions on words and display the permissible syllable structure, host a limited set of vocalic patterns, and in some cases also affixes. The stem consonants fit into the consonantal positions provided by the prosodic templates, as do the vowels of the vocalic pattern.

To clarify these notions, consider the derivational paradigm in Table 108.1. The words in Table 108.1 are structurally related on both the vertical and horizontal axes of the paradigm. On the horizontal axis, they share the stem consonants. On the vertical axis, they share a prosodic template, a vocalic pattern, and, in the two rightmost columns, an affix. The properties on the vertical axis provide words with their phonological structure. When these properties are combined, i.e. CaCaC, hiCCiC, CCiCa, they form what is known as "Semitic templates" (McCarthy 1981). Throughout the chapter, I use the term "configuration" for this

Table 108.1 Derivational paradigm in Modern Hebrew

Prosodic template:	CVCVC		CVCCVC		CCVCV		*Stem consonant*
Vocalic pattern:	{a a}		{i i}		{i}		
Affix:			*h-*		*-a*		
	ga'dal	'to grow'	hig'dil	'to enlarge'	gdi'la	'growing'	{g d l}
	sa'gar	'to close'	his'gir	'to extradite'	sgi'ra	'closing'	{s g r}
	ʃa'tak	'to keep quiet'	hiʃ'tik	'to quieten'	ʃti'ka	'silence'	{ʃ t k}
	ka'lat	'to absorb'	hik'lit	'to record'	kli'ta	'absorption'	{k l t}
	za'rak	'to throw'	hiz'rik	'to inject'	zri'ka	'throwing, injection'	{z r k}

combination of properties, while the term "template" is used exclusively for prosodic templates.

The system of configuration is found in all Semitic languages in various paradigmatic relations, although to various degrees. This is demonstrated in §2 with examples from several languages. As the configurations consist of both segmental and prosodic elements, their structure is non-linear (see CHAPTER 105: TIER SEGREGATION). The structure of the configurations, and of Semitic words in general, is introduced in §3, with emphasis on theoretical developments in the representation of the prosodic template. The two ensuing sections illustrate the mapping of the configurations, where §4 is devoted to a procedural approach and §5 to a constraint-based approach. Within each of these two sections, two types of input are considered: the consonantal root and the word/stem. The concluding remarks in §6 draw attention to the status of the configurations within a cross-linguistic perspective.

2 The nature of Semitic morphology

In Semitic morphology, words are organized into classes, identified by their configuration. The class system in verbs (§2.1) is more prominent and restricted than in nouns (§2.2); nevertheless, the same structural generalizations hold, regardless of the lexical category.

2.1 *Verb classes (binyanim)*

Verbs belonging to the same class have an identical configuration, as exemplified in (1). The designator of a verb class is the 3rd masculine singular perfect, which is free of inflectional affixes.[1]

(1) *Verb classes in Palestinian Arabic* (Elihay 2004)

CiCeC		tCaCCaC		staCCaC	
'misek	'to grasp'	'tʕallam	'to study'	'staʕmal	'to use'
'fihem	'to understand'	'tdarraʕ	'to burp'	'staqbal	'to welcome'
'nizel	'to go down'	'tbaddal	'to be replaced'	'stawʕab	'to take in'
'ħimeq	'to lose temper'	'tbaxxar	'to evaporate'	'staslam	'to submit'
'liħeq	'to catch'	'tdawwaʃ	'to shower'	'staʃhad	'to quote'

The restricted structure of the configurations is evident in (1), where all the configurations are disyllabic, with a final CVC syllable. They differ in the first syllable, CV in Ci.CeC and CCVC in staC.CaC and tCaC.CaC. The latter two configurations are distinguished by their prefixes, where consonant positions (C-slots) not occupied by an affix are left for the stem consonants. In staC.CaC the prefix

[1] Throughout the chapter, I do not consider irregular verbs, which for phonological reasons (often only historically motivated) deviate from the regular configuration. I also ignore the epenthetic [ʔi] in Arabic, which rescues word-initial clusters. Epenthesis is obligatory in Standard Arabic (e.g. [ʔis'taʕmal] 'to use'), but optional in spoken dialects, unless the word appears phrase-initially or after a consonant-final word (e.g. ['baːsil is'taqbalo] *vs.* ['faːdi (i)s'taqbalo] 'Basil/Fadi welcomed him').

occupies the two positions of the initial complex onset, thus leaving three slots for the stem consonants, while in tCaC.CaC the prefix occupies only one position in the complex onset, thus leaving four slots for the consonants. When a configuration provides four slots for stem consonants but the stem has only three different consonants, one consonant occupies two slots (e.g. ['tʕallam] 'to study' *vs.* ['tħarkaʃ] 'to provoke').

Semitic languages vary with regard to prosodic "plasticity." Hebrew verbs accommodate as many stem consonants as possible (i.e. respecting the OCP and the Sonority Sequencing Generalization; CHAPTER 49: SONORITY), as long as the verb does not exceed the disyllabic maximal size (Bat-El 1994a, 2003a). In contrast, Amharic adjusts the number of syllables in the template according to the number of consonants (McCarthy 1985; Rose 2003). That is, Hebrew expands its syllabic inventory beyond CV and CVC, keeping the disyllabic template, while Amharic expands its syllabic template, keeping a restricted syllabic inventory (see Bender and Fulass 1978 for a study of Amharic verbs).

(2) *Templatic plasticity (Amharic)* vs. *syllable plasticity (Hebrew)*

	Amharic		*Hebrew*	
3 Cs	səbbər-ə	'to break'	siper	'to tell'
4 Cs	məsəkkər-ə	'to testify'	tirgem	'to translate'
5 Cs	tə-ngədaggəd-ə	'to walk in a zigzag'	flirtet	'to flirt'
6 Cs	aqənatt'ər-ə	'through violently'	trinsfer	'to transfer'

The vocalic pattern of the configuration is an arbitrary subset of possible combinations of vowels. The vocalic patterns in Tigrinya verbs, for example, employ only four ([i ɨ ə a]) out of the seven vowels ([i ɨ u e ə o a]) in the language (Buckley 2003).

(3) *Vocalic patterns in Tigrinya* (Buckley 2003)

		'offend'		'bless'
simple perfective	əə	bəddəl-ə	aə	barək-ə
simple gerundive	əi	bəddil-u	ai	barik-u
causative jussive	əɨ	jə-bəddɨl	aɨ	jə-barɨk

In Standard Arabic, however, which has only three vowels in its inventory, the vocalic patterns in the verb inflectional paradigm are partially predicted, given a base with a specified vowel (Guerssel and Lowenstamm 1996).

(4) *Predictable vocalic patterns in Standard Arabic (binyan I)*

perfective			*imperfective*		
Ø	'dˤarØb	→	i	'jadˤrib	'to hit'
i	'labis	→	a	'jalbas	'to dress'
a	'katab	→	u	'jaktub	'to write'
u	'kabur	→	u	'jakbur	'to be great'

Verb configurations are often associated with thematic-syntactic properties, such that verbs in different configurations are derivationally related if they share the same stem consonants.

(5) *Derivational relations in Modern Hebrew verbs*

CaCaC		CiCeC		hitCaCeC	
ga'dal	'to grow'	gi'del	'to raise'	hitga'del	'to aggrandize'
xa'ʃav	'to think'	xi'ʃev	'to calculate'	hitxa'ʃev	'to consider'
ka'dam	'to precede'	ki'dem	'to promote'	hitka'dem	'to progress'
pa'rak	'to unload'	pe'rek	'to dismantle'	hitpa'rek	'to disintegrate'
ka'ʃar	'to bind'	ki'ʃer	'to connect'	hitka'ʃer	'to get in touch'

The thematic-syntactic properties of the configurations are relational rather than absolute, such that the property assigned by a configuration is largely contingent upon the base of the derived verb (Berman 1978; Horvath 1981; Doron 2003; Laks 2007). For example, the Hebrew configuration hitCaCeC assigns deaccusative in [hir'giz] 'to make someone angry' → [hitra'gez] 'to become angry', but reciprocal in [xi'bek] 'to hug' → [hitxa'bek] 'to hug each other'. Moreover, [hitʔa'lel] 'to torture' is neither deaccusative nor reflexive, as it is not derived from another verb. Similarly in Arabic, ʔaCCaC assigns causative in ['ʤalas] 'to sit down' → ['ʔaʤlas] 'to bid one to sit down', but ['ʔarsal] 'to send' is not causative, since it does not have a base verb (Wright 1962). Verbs sharing a configuration may also share a semantic property, as is the case with Arabic (t)CajCaC verbs. Watson (2006: 192) reports that in most dialects these verbs refer to "physical state with pejorative overtones of pretence," but in San'ani Arabic they denote "harmless childish naughtiness."

The grammatical function of the configuration is apparent in various Semitic languages, but not in all. In Modern Aramaic, which has only two verb classes (as opposed to five in Hebrew, 11 in Maltese, and 14 in Standard Arabic), the configurations have only structural properties, to the extent that there are hardly any related verbs from the two classes (Hoberman 1992).

A verb class defines the inflectional paradigm of the verb, such that verbs belonging to the same class have the same configuration in every form in the paradigm (Aronoff 1994; see also CHAPTER 83: PARADIGMS).

(6) *Inflectional paradigms in Palestinian Arabic verbs* (Elihay 2004)[2]

perfect	*imperfect*		*perfect*	*imperfect*	
CiCeC	-iCCaC		CaCCaC	-iCaCCeC	
'misek	-'imsak	'to grasp'	'massak	-'massek	'to let hold'
'fihem	-'ifham	'to understand'	'fahham	-'fahhem	'to explain'
'nizel	-'inzal	'to go down'	'nazzal	-'nazzel	'to bring down'
'ħimeq	-'iħmaq	'to lose temper'	'ħammaq	-'ħammeq	'to make angry'
'liħeq	-'ilħaq	'to catch'	'laħħaq	-'laħħeq	'to manage'

Since the inflectional paradigm of a verb is contingent upon its configuration, every new verb must belong to one of the verb classes. This is manifested by the native configuration found in loan verbs, such as [til'fen] 'to phone', [si'mes] 'to send

[2] Person/number/gender features are indicated by suffixes in the perfect (e.g. ['fihm-u] 'they understood', [fah'ham-ti] 'you (FEM SG) explained') and prefixes + suffixes (in some forms) in the imperfect (e.g. ['t-ifham-u] 'you (PL) will understand', [n-'fahhem] 'we will explain'). As all imperfect forms take a prefix, the imperfect stems are preceded by a dash.

However, a rich configuration system in the nominal category is found in the singular/plural paradigm of several Semitic languages (see Ratcliffe 1998b for a comparative study), such as Arabic (Hammond 1988; McCarthy and Prince 1990; Ratcliffe 1997, 1998a; McCarthy 2000; Watson 2002, 2006), Tigre (Palmer 1962; Raz 1983), and Tigrinya (Palmer 1955; Buckley 1990). In Arabic, for example, most underived nouns and lexicalized derived nouns (Abd-Rabo 1990; Boudelaa and Gaskell 2002) are pluralized in a configuration system called "broken plural," which contrasts with the suffixation mode of pluralization called "sound plural."

(8) *Broken plurals*

a. *Standard Arabic* (Wright 1962)

	plural	*singular*	
ʔaCCa:C	ʔaħ'ka:m	ħukm	'judgment'
	ʔaq'da:m	'qadam	'footstep'
	ʔaj'ma:n	ja'mi:n	'oath'
ʔaCCuC	'ʔabħur	baħr	'sea'
	'ʔazmun	'zaman	'time'
	'ʔalsun	li'sa:n	'tongue'
CuCuC	'suquf	saqf	'roof'
	'ʔusud	'ʔasad	'lion'
	'surur	sa'vri:r	'throne'
CiCa:C	ri'ma:ħ	rumħ	'spear'
	xi'ba:l	'xabal	'hill'
	li'ʔa:m	la'ʔi:m	'base'

b. *Tigre* (Palmer 1962)

	plural	*singular*	
ʔəCCiC	ʔəkbid	kəbid	'belly'
	ʔəbʔis	biʔis	'husband'
	ʔəbħɨr	biħər	'sea'
ʔəCCuC	ʔəqlub	qəlɨb	'root'
	ʔəmtud	mɨtid	'stake'
	ʔədhub	dihəb	'gold'
CəCəCCi	ħənəddi	ħɨndi	'hoof'
	kətərri	katra	'pigeon'
	kədəbbi	kədbet	'floor'
CəCaCit	məsanit	məsni	'friend'
	wərazit	wəreza	'bachelor'
	ʔərawit	ʔərwe	'serpent'

While in the verb system, every class has a fixed confiiguration for each tense/aspect form, allowing a predictable system of one-to-one correspondence, in the noun system there is one-to-many correspondence (Bateson 2003). As shown in (8) above, a singular configuration may correspond to several plural configurations (e.g. Arabic CVCC in [ħukm] – [ʔaħ'ka:m] *vs.* [rumħ] – [ri'ma:ħ]). In addition, a singular noun may have two or three alternative corresponding plural forms, more so in the spoken dialects (e.g. Arabic ['ʕanzi] – [ʕi'na:z] ~ [ʕu'nu:z] ~ ['ʔaʕnuz] 'goat(s)', ['qafil] – [ʔaq'fa:l] ~ ['ʔaqful] 'lock(s)'). However, as discussed in §4.2 below, there are some tendencies for nouns with certain configurations to select particular plural configurations.

The system of configurations is not limited to nouns and verbs. As shown below, Amharic argot (Leslau 1964) and Arabic hypocoristics (Davis and Zawaydeh 2001) take specific configurations (Caj(C)CiəCi and CaCCuːC, respectively) regardless of the shape of the base. Similarly, Arabic adjectives and superlatives (Wright 1962) each take a consistent configuration.

(9) *Other configurations*

a. *Arabic adjectives*

CaCiːC		ʔaCCaC	
ka'biːr	'big'	'ʔakbar	'bigger'
sˤa'ɣiːr	'small'	'ʔasˤɣar	'smaller'
tˤa'wiːl	'long'	'ʔatˤwal	'longer'
ba'ʕiːd	'far'	'ʔabʕad	'farther'

b. *Arabic hypocoristics*		c. *Amharic argot*			
CaCCuːC		Caj(C)C$_i$əC$_i$			
bas'suːm	'basma		bajtət	bet	'house'
sal'luːm	sa'liːm		gajbəb	gəbba	'enter'
jas'suːr	'jaːsir		zajfnən	zəffənə	'sing'
sam'muːr	sa'miːra		wajrk'ək'	wərk'	'gold'

The preference for disyllabic forms, also exhibited in (9), is overwhelming, although, as noted above, some languages display a limited flexibility. This preference is found also in Hebrew acronym words (Bat-El 1994b; Zadok 2002), which are mostly disyllabic, regardless of the number of words in the input. For example, both the two-word base [mat'bea xuc] 'foreign currency' and the three-word base [mer'kaz texno'logia xinu'xit] 'educational technology center' surface as the acronym word [ma'tax]. Moreover, four-word bases also give rise to disyllabic acronym words, as in [mam'ram], whose base is [mer'kaz maxʃe'vim (ve-)ri'ʃum memu'kan] 'automated computer center'.

3 The structure of Semitic configurations

The term configuration correlates with the traditional Semitic template/pattern, represented as fully specified words, such as [qaːtˤal, qitˤtˤel, hiqtˤil], etc. (also [paːʕal] or [paːqad] in Hebrew and [faʕal] in Arabic).[4] As the stem consonants ({qtˤl}, {pʕl}, {pqd}, {fʕl}) are not part of the configuration, replacing them with C-slots gives us the type of structure used in the previous sections, i.e. CaːCaC, CiCCeC, hiCCiC, etc.

Configurations play a central role in the older grammarian studies (see §4.2) of Semitic morphology, mostly with reference to class membership and relations among words. In the absence of a theoretical model of non-linear phonological structure, these studies do not consider the internal structure of the configuration, and refer to relations among words in terms of phonological alternations, such as vowel change/ablaut and gemination.

4 The traditional terminology associated with the configurations is *wazn* (plural *ʔawzaːn*) in Arabic, and *binyan* (plural *binyanim*) for verbs and *miškal* (plural *miškalim*) for nouns in Hebrew.

McCarthy (1981) points out the restrictive nature of the templates in (11). Every template in (11a) has a counterpart with an initial complex onset in (11b), and another with an additional CV syllable in (11c). The absence of CVCVCVC in the first row in (11c) is due to a constraint prohibiting a sequence of two light syllables. These templates can be expressed with an archi-template, which generalizes all and only the possible templates in (11), with the addition of a vowel deletion rule that resolves the prohibited sequence of two light syllables.

(12) *Archi-template of the prosodic templates in Standard Arabic verbs* (McCarthy 1981)

$$\left(\begin{Bmatrix} C \\ CV \end{Bmatrix}\right) \; CV \; \left(\begin{Bmatrix} C \\ V \end{Bmatrix}\right) \; CVC \qquad (V \rightarrow \text{Ø} \; / \; CVC \_\_ CVC)$$

As shown in Table 108.2, there are more configurations than CV templates, where the difference among configurations sharing a template is in the affixes and their position, as well as in the distribution of the stem consonants.

Although the templates consist of CV-slots, reference to the syllable is inevitable, as seen in McCarthy's (1981) generalizations, such as "no binyan which begins with a consonant cluster is three or more syllables long overall" (1981: 386). This statement refers directly to the restriction on the number of syllables in the template, which is not explicitly expressed in the CV template. There is definitely a disyllabic core template, which can be minimally expanded with either CV or C (see Kiparsky 2003 for C as a demi-syllable). Moreover, as shown in Table 108.2 (c), the CV expansion is always a derivational prefix. In addition, Lowenstamm and Kaye (1986), in their study of compensatory lengthening in Tiberian Hebrew, demonstrate the essential role of the syllable in the configurations.[5]

3.2.2 *Syllabic templates*

The templates in (a) and (b) of Table 108.2 are disyllabic. The two trisyllabic templates in (c) are disyllabic on the stem level, since the initial CV, as noted above, is occupied by a derivational prefix (e.g. [ta-'baddal] 'to be replaced', [ta-'dˤa:jaq] 'to be disturbed'). That is, verbs in Arabic are disyllabic either on the stem level, the word level, or both. The same is true for Hebrew verbs, which can be disyllabic with or without a derivational prefix (e.g. [hik'dim] 'to come first', [ki'dem] 'to promote'), or trisyllabic, but only with a prefix (e.g. [hitka'dem] 'to progress').

As argued in McCarthy and Prince (1986, 1993a, 1995), the disyllabicity restriction found in Semitic morphology reflects a universal preference for a binary foot (see also CHAPTER 40: THE FOOT; CHAPTER 44: THE IAMBIC–TROCHAIC LAW). Thus, the most general template of Arabic verb is a binary syllabic foot. The advantage of the syllabic template has been supported with data from Modern Hebrew (McCarthy 1984), where verbs from the same class have different CV templates but an identical syllabic template, consisting of two syllables, i.e. a foot (see, however, Amharic templatic plasticity in (2)).

5 Note that also the theory of Government Phonology refers to syllables, but the only possible syllable is CV (Lowenstamm 1996), in which case reference to syllables seems to be redundant. Within this theory, Arabic template consists of CV-CVCVCV, where the initial CV is the derivational head.

Table 108.2 CV templates and verb configurations in Standard Arabic[a]

	CV template				Configuration		Verb	
a.	1.		CV	CVC[b]	Ia	CaCaC	'fataħ	'to open'
					Ib	CaCiC	'ħasib	'to think'
					Ic	CaCuC	'qabuħ	'to be ugly'
	2.		CVC	CVC	II	CaC$_i$C$_i$aC	'kassar	'to break'
						CaCCaC	vʃamʕal	'to scatter'
					IV	ʔaCCaC	'ʔakram	'to honor'
	3.		CVV	CVC	III	Ca:CaC	'sa:baq	'to run a race'
b.	1.	C	CV	CVC	VII	nCaCaC	'nbasatˤ	'to be pleased'
					VIII	CtaCaC	'qtabal	'to receive'
					IX	CCaC$_i$aC$_i$	'ħwalal	'to squint'
	2.	C	CVC	CVC	X	staCCaC	'staʕmal	'to use'
					XII	CCawC$_i$aC	'hdawdab	'to be curved'
					XIII	CCawwaC	'ʕlawwad	'to be heavy'
					XIV	CCanC$_i$aC$_i$	'ʕʃanʤaʤ	'to go quickly'
						CCanCaC	'branʃaq	'to bloom'
					VI	CCanCay	'ʕlandaj	'to be strong'
	3.	C	CVV	CVC	XI	CCa:C$_i$aC$_i$	'swa:dad	'to be black'
c.	2.	CV	CVC	CVC	V	taCaC$_i$C$_i$aC	ta'farraq	'to be dispersed'
						taCaCCaC	ta'ʕafrat	'to act like a devil'
	3.	CV	CVV	CVC	VI	taCa:CaC	ta'ka:lam	'to converse'

[a] As Watson (2002) notes, most dialects of Arabic do not retain configurations above X. In addition, merger in the prosodic template (but not the configuration) is found in several dialects, including Palestinian Arabic, where (c) merged with (b) via the deletion of the vowel in the first syllable. That is, Standard Arabic [ta'farraq] (c2) corresponds to Palestinian Arabic ['tfarraq] (b2).
[b] The CVCVC template is considered one configuration (due to a unified inflectional paradigm), although it has several sub-configurations that differ in the quality of the second vowel (see (4) above).

(13) *Modern Hebrew verb configurations*

Syllabic configuration		*CV configuration*		
I	$\sigma_a\ \sigma_a$	CaCaC	pa'tax	'to open'
II	$^{n}\sigma_i\ \sigma_a$	niCCaC	nix'nas	'to enter'
III	$^{h}\sigma_i\ \sigma_i$	hiCCiC	hig'dil	'to enlarge'
		hiCCCiC	hiʃ'prits	'to squirt'
IV	$\sigma_i\ \sigma_e$	CiCeC	gi'del	'to raise'
		CiCCeC	tir'gem	'to translate'
		CCiCCCeC	trins'fer	'to transfer'
V	$^{hit}\sigma_a\ \sigma_e$	hitCaCeC	hitla'beʃ	'to get dressed'
		hitCaCCeC	hitbar'gen	'to become a bourgeois'

In Arabic, unlike in Hebrew, syllable structure plays a major role in distinguishing among configurations, as is evident from the distinction among CaCaC (I), CaCCaC (II), and Ca:CVC (III). The first configuration is distinguished from

Empirical support for this view is provided by the transfer phenomena in broken plurals (§2.1.2), where properties of the singular form that cannot be encoded in the consonants are transferred to the plural form. Arabic broken plurals (17a) exhibit vowel-quantity transfer in trisyllabic plurals: a short vowel in the plural corresponds to a short vowel in the singular and a long vowel in the plural corresponds to a long vowel in the singular (McCarthy and Prince 1990; McCarthy 2000). Broken plurals in Tigre (17b), as well as in Tigrinya (Palmer 1955), exhibit vowel-quality transfer in trisyllabic plurals: a high front vowel in the plural corresponds to a front vowel in the singular, a high back vowel in the plural corresponds to a back vowel in the singular, and a central vowel in the plural corresponds to a central vowel in the singular (Palmer 1962).

(17) *Vowel quantity transfer*

a.	*Yemeni Arabic* (Qafisheh 1992)			
		singular	*plural*	
	short vowel	ˈdarzan	daˈraːzin	‘dozen’
		ˈmaktab	maˈkaːtib	‘office’
	long vowel	finˈʤaːn	faˈnaːʤiːn	‘cup’
		makˈtuːb	maˈkaːtiːb	‘letter’
	Standard Arabic (Ratcliffe 1998a)			
		singular	*plural*	
	short vowel	ˈxaːtam	xaˈwaːtim	‘signet ring’
		ˈʕaqrab	ʕaˈqaːrib	‘scorpion’
	long vowel	ʤaːˈmuːs	ʤawaːˈmuːs	‘buffalo’
		mifˈtaːħ	mafaːˈtiːħ	‘key’
b.	*Tigre* (Palmer 1962)			
		singular	*plural*	
	central vowel	misgid	məsagid	‘mosque’
		ʤənʤər	ʤənaʤir	‘chain’
	front vowel	bərmil	bəramil	‘barrel’
		bistˤan	bəsatˤin	‘garden’
	back vowel	kitkut	kətakut	‘young bird’
		maskot	məsakut	‘window’

Similarly, Ratcliffe (1998a) mentions cases of vowel polarity in Arabic CVCC nouns: when the vowel in the singular is low the vowel in the plural tends to be high ([qalb] – [quˈluːb] ‘heart(s)’), and when the vowel in the singular is high the vowel in plural tends to be low ([qufl] – [ʔaqˈfaːl] ‘lock(s)’).

Other cases of transfer, which cannot be attributed to the consonantal root or the configuration, are drawn from the formation of Hebrew denominative verbs (Bolozky 1978; Bat-El 1989, 1994a, 2003a, 2003b; Gafos 1998; Ussishkin 1999, 2000). A verb derived from a noun with an affix may include the affix consonant as part of its stem (e.g. [merˈkaz] ‘center’ → [mirˈkez] ‘to center’; cf. [riˈkez] ‘to concentrate (INTRANS)’; [parˈʃan] → [pirˈʃan] ‘to commentate’; cf. [peˈreʃ] ‘to interpret’). Also, when the base consists of consonant clusters, these clusters are preserved in the derived verb (e.g. [guʃˈpanka] ‘approval’ → [giʃˈpenk] ‘to approve’; *[gʃiˈpenk], *[giʃˈpnek]).

in the formation of [ħu'ru:b] 'wars' from [ħarb], the circumscribed material <ħar> is mapped into the template $[\sigma_\mu\sigma_{\mu\mu}]_F$, yielding $[\hbar araa]_F$. Melodic overwriting assigns the appropriate vocalic pattern of the plural form and the residual base segments ([b] in this case) are adjoined. In longer singular forms, however, the residue is an entire syllable, in which case the basic iambic template is expanded. This is the case in ['madxal] – [ma'da:xil] 'entrance(s)', where the material within the iambic template is $[\text{mada:}]_F$, while [xil] forms an additional syllable. As the final syllable is outside the template, it preserves its original structure from the singular form, reflecting faithfulness to the base (McCarthy 2000). This explains the transfer phenomena in (18) above, which appear, as predicted, only in the final syllable.

5 Mapping a configuration: A constraint-based approach

As noted in §3.2.3, the prosodic structure of the configuration is assigned by the independently motivated constraints in (14): FtBin, which sets the lower bound at two syllables, and Align(σ, PrWd), which sets the upper bound at two syllables. The segmental elements of the configuration, i.e. the vocalic pattern and affix (if any) are considered an affix, and thus provided in the input. The position of the affix within the word is determined by independent universal constraints.[6] The type of constraints involved depends on the assumption regarding the input, i.e. whether it is a consonantal root (§5.1) or a fully specified word/stem (§5.2). Throughout this section, I assume the effect of the templatic constraints in (14), and thus do not consider candidates that exceed the disyllabic template.

5.1 *Root + configuration*

Under the root-based approach, the input consists of a consonantal root and the segmental elements of the configuration, which are considered an affix. When the affix consists of vowels only, markedness constraints are responsible for syllable structure, and thus for the linear order of the vowels and the consonants.

(19) **Complex, FinalC,[7] Onset >> *Coda (Hebrew [xi'ber] 'to connect')*

{xbr}+{ie}	*Complex	FinalC	Onset	*Coda
a. xbier	*!			*
b. xibre		*!		*
c. ixber			*!	**
☞ d. xiber				*

[6] Within the standard OT approach to morphology, affixes, just like bases, are introduced as lexical items in the input, as well as in alignment constraints. Russell (1995, 1999) eliminates this duality, arguing that affixes should be introduced as constraints only (see also Yip 1998; Adam and Bat-El 2008). An analysis of Hebrew configurations within this approach is provided in Bat-El (2003b).

[7] FinalC (McCarthy 1993), formally stated as AlignR(PrWd, C), requires a word to end in a consonant.

In general, whether the root consists of three consonants or four (e.g. [tir'gem] 'to translate'), or whether the affix consists of vowels only or vowels plus a prefix (e.g. [hig'dil] 'to enlarge'), the templatic constraints in (14) determine the prosodic template and the markedness constraints in (19) are responsible for the sequential order of the segments.

Note that the root consonants (with the exception of glides) must be surface-true, which can be attributed to an undominated constraint MAX(Root). Amharic and Hebrew both respect this constraint, but they differ with regard to the violability of other constraints. As exemplified in (2), Amharic verbs can be trisyllabic in order to accommodate all root consonants without violating *COMPLEX (e.g. [məsəkkər-ə] 'to testify'). Therefore, the templatic constraints are violated. Hebrew verbs always respect the templatic constraints, but *COMPLEX can be violated (e.g. [trins'fer] 'to transfer') in order to accommodate all consonants.

5.2 *Word + configuration*

Under the word-based approach, the input consists of a base word or stem and the segmental elements of the configuration (i.e. vocalic pattern and affix). The constraint ranking FAITHAFFIX >> FAITHSTEM (Ussishkin 2000) is responsible for melodic overwriting (18b), ensuring that all affix segments are surface-true. As in the root-based approach (§5.1), markedness constraints provide the syllable structure.

However, the markedness constraints derive the correct output only when the input consists of CV and CVC syllables (e.g. Hebrew [ga'dal] 'to grow' → [gi'del] 'to raise', ['telefon] 'phone' → [til'fen] 'to phone'). Hebrew denominative verbs derived from bases with more than four consonants violate the markedness constraints. For example, [prig'res] 'to progress' has an initial complex onset and [kim'pleks] 'to make complex' a medial complex onset, while [ib'strekt] 'to make abstract' has no initial onset at all, although a glottal stop is inserted in phrase-initial position. The crucial observation is that consonants adjacent in the base are also adjacent in the derived verb. For such cases, it is necessary to adhere to the faithfulness constraint CONTIGUITY, which preserves adjacency between consonants in the input. Of course, the phenomenon justifying CONTIGUITY cannot be accounted for within the root-based approach.

(20) [ab'strakti] 'abstract' → [ib'strekt] 'to make abstract'

abstrakti+{i e}	CONTIGUITY	ONSET
a. bistrekt	*! (b s)	
☞ b. ibstrekt		*

In Arabic verbs, CONTIGUITY is low-ranked, as seen in denominative verbs such as in [baql] 'herbage' → ['ʔabqal] 'to produce herbage', [sˤajf] 'summer' → ['tsˤajjaf] 'to go on a summer vacation' (cf. Hebrew [faks] 'fax' → [fik'ses] 'to send a fax'), [frans] 'France' → ['tfarnas] 'become French, act li e a Frenchman' (cf. Hebrew [flirt] 'flirt' → [flir'tet] 'to flirt').[8]

As for configurations with affixes, Arabic is challenging, as it employs both prefixes and infixes. Arabic configurations display two types of contrast: contrast

[8] Note that Arabic loan nouns do preserve the source clusters, as in [blastik] 'plastic' and [ʔekspres] 'express' (Thornburg 1980).

in the prosodic template – medial *vs.* initial CC (ʔaCCaC (IV) *vs.* nCaCaC (VII)) – and contrast in affixation: prefix *vs.* infix (nCaCaC (VII) *vs.* CtaCaC (VIII)). All these configurations respect the templatic constraints in (14), which set the minimal and maximal bound of two syllables. According to Wright (1962), verbs in these configurations are all derived from the basic configuration CaCaC (1).

Regardless of their position in the word, the affixes are attached via an alignment constraint ALIGN-L(Aff, PrWd), which requires the affix to be aligned with the left edge of the prosodic word (McCarthy and Prince 1993b). Each affix has its alignment constraint, competing with ALIGN-L(Stem, PrWd), which requires the left edge of the stem to align with the left edge of the prosodic word. The ranking ALIGN-L(Aff, PrWd) >> ALIGN-L(Stem, PrWd) yields a prefix, and the opposite ranking yields an infix.

(21) *Arabic prefix* [ʔ, n] vs. *infix* [t]

ALIGN-L(ʔ, PrWd), ALIGN-L(*n*, PrWd) >> ALIGN-L(Stem, PrWd) >>
ALIGN-L-(*t*, PrWd)

Assuming gradient alignment, where the further the relevant element is from the edge the more violation marks it gets, the constraints above account for nCaCaC and CtaCaC only; ʔaCCaC is worse than *ʔCaCaC with respect to ALIGN-L(Stem, PrWd), and thus predicted not to be selected as the optimal candidate. However, with the constraint *ʔC, which prohibits a glottal followed by a consonant, all the three configurations are derived.[9]

(22) a. nCaCaC

{n}, {CaCaC}	*ʔC	ALIGN-L (ʔ, PrWd)	ALIGN-L (*n*, PrWd)	ALIGN-L (Stem, PrWd)	ALIGN-L (*t*, PrWd)
a. naCCaC				**!	
☞ b. nCaCaC				*	
c. CanCaC			*!*		
d. CnaCaC			*!		

b. CtaCaC

{t}, {CaCaC}	*ʔC	ALIGN-L (ʔ, PrWd)	ALIGN-L (*n*, PrWd)	ALIGN-L (Stem, PrWd)	ALIGN-L (*t*, PrWd)
a. taCCaC				*!*	
b. tCaCaC				*	
c. CatCaC					**!
☞ d. CtaCaC					*

[9] A glottal stop is perceptually weak, and a preconsonantal position is also weak, and thus this constraint is highly motivated. Other effects of this constraint can be seen in the deletion of stem-initial ʔ (plus compensatory lengthening) in /ʔaʔθar / → [ˈʔaːθar] 'to prefer' (cf. [ˈakram] 'to honor') and /ʔuʔmul/ → [ˈʔuːmul] 'work!' ([ˈʔuktub] 'write!') (Wright 1962).

c. ʔaCCaC

{ʔ}, {CaCaC}	*ʔC	Align-L (ʔ, PrWd)	Align-L (n, PrWd)	Align-L (Stem, PrWd)	Align-L (t, PrWd)
☞ a. ʔaCCaC				**	
b. ʔCaCaC	*!			*	
c. CaʔCaC		*!*			
d. CʔaCaC		*!			

6 Concluding remarks

At the very beginning of her 1982 monograph *The syntax of words*, Selkirk notes the delimitations of her model: "The W-syntax of the Semitic languages, then, includes two components, only one of which is of the sort I am attempting to characterize here" (1982: 2–3). The two components are affixation and configuration, where the latter one is excluded from Selkirk's model.

The system of configurations is characteristic of Semitic morphology and is often considered unique, and therefore excluded from various theoretic models. However, a universal perspective of the system of configurations proves the contrary (Bat-El 2003a). A configuration consists of a prosodic template and vocalic pattern, and thus relation among words exhibit alternations in these structural properties. With reference to the vocalic pattern, the structural relation between [pi'ter] 'to dismiss' and [pu'tar] 'to be dismissed' in Hebrew is like that between *sing* and *sang* in English. With reference to the prosodic structure, the structural relation between [ni-mi'ʃax] 'to last (PAST)' and [ji-ma'ʃex] 'to last (FUT)' in Hebrew is like that between [hiwt-inaj] 'to walk-GERUND' and [hiwiit-al] 'to walk-DUB' in Yawelmani (Kisseberth 1969; Archangeli 1984). Moreover, broken plurals are found also in Hausa, a non-Semitic language (Rosenthall 1999).

That Semitic languages seem to be unique is due to combination and pervasiveness (Bat-El 2003a). While English exhibits only ablaut and Yawelmani exhibits only prosodic alternation, Semitic languages combine both within the same paradigms (combination). While English exhibits ablaut in a subclass of paradigms and Yawelmani exhibits prosodic alternation in stems associated with specific suffixes (template suffixes), Semitic languages exhibit ablaut and prosodic alternation in most paradigms (pervasiveness). See, however, Maltese in §2.1.1.

Viewing the configuration as a combination of independent structures allows the analysis of Semitic morphology within the same theoretical models proposed for other natural languages.

ACKNOWLEDGMENTS

I would like to thank Anbessa Teferra and Tareq Muhalwas for their help with the Amharic and Arabic data, respectively. I appreciate the comments on this chapter provided by Lior Laks, the editors Keren Rice and Marc van Oostendorp, and two anonymous reviewers. All disclaimers apply.

109 Polish Syllable Structure

Christina Y. Bethin

The syllable as a phonological prosodic constituent serves to organize segment sequences in terms of sonority, associating sonority peaks/syllabic segments with syllable nuclei and non-syllabic segments with syllable margins as onsets and codas (Blevins 1995; Zec 2007). The sequencing of segments within onsets and codas is also said to be governed by sonority, in that sonority rises toward the syllable peak and falls after it (Sievers 1881; Jespersen 1904); this has been formalized in the generative phonological literature as a sonority sequencing principle/generalization (Selkirk 1982, 1984; Clements 1990; chapter 49: sonority). Because syllable structure is not contrastive, it is most likely created by syllabification processes as part of a phonological derivation or selected by a set of syllable structure constraints in an output-oriented framework. In either case, certain organizational principles hold on segment sequencing within a syllable, and the question is how these properties of syllables are implemented. Polish has contributed to discussions on syllable structure primarily by virtue of its extraordinarily complex consonant clusters, which appear to violate the sonority sequencing generalization. It also has a set of nasal vowels that bear on the structure of the syllable nucleus, and vowel–zero alternations that interact with syllabification.

In derivational approaches where syllables are constructed on the basis of the segmental string in some principled way, surface sonority sequencing violations have raised questions about the structure of syllables, the existence of unsyllabified (extrametrical) segments and their incorporation into prosodic levels, and about syllabification and resyllabification at various derivational levels. In constraint-based grammars such as Optimality Theory (Prince and Smolensky 2004), the complexity of the Polish syllable puts it in the category of languages in which faithfulness constraints on segment deletion and insertion appear to be ranked above markedness constraints on syllable margins, so one question is whether and when syllable structure constraints have visible effects on output forms. In non-derivational Government Phonology or CV Phonology, the syllable level is independent of the melodic or segmental tier, and consists of a series of onsets and rhymes/nuclei, some of which may be empty or have unassociated melodies, so consonant clusters that violate sonority sequencing in pronunciation do not violate it in the phonology when they are treated as onsets followed by empty nuclei. The fact that syllable structure seems to be implicated in certain aspects of Polish morphology presents a challenge to all of the above, and to any model of phonology–morphology interaction.

The chapter is organized as follows: §1 deals with the syllable margins: sonority sequencing, syllabification, and extrasyllabicity (§1.1), resyllabification (§1.2), and the phonological *vs.* the phonetic syllable (§1.3). §2 concerns the syllable nucleus, primarily the description of nasal vowels as potential complex nuclei (§2.1) and the treatment of glides and high vowels (§2.2). Because it is unusual to find that a language which tolerates extraordinarily complex sequences of consonants sometimes does not, as seems to be the case in some aspects of Polish allomorphy, there is a discussion of syllable structure and morphology in §3. Concluding remarks are in §4.

1 The syllable margins

Polish has complex clusters of various types both in onset and coda position within the syllable, exemplified by words such as *rtęć* [rt] 'mercury', *teatr* [tr] 'theater', *ptak* [pt] 'bird', *szept* [pt] 'whisper', *bzdura* [bzd] 'nonsense', *wzbronić* [vzbr] 'to forbid', *siostr* [str] 'sister (GEN PL)', *z pstrągiem* [spstr] 'with a trout', *przestępstw* [mpstf] 'transgression (GEN PL)'.[1] Complex consonant clusters in Polish are in large part the result of historical change: (i) the loss of short high vowels (yers) in weak position (word-final or in the syllable before one with a non-yer or strong yer vowel) as in Common Slavic *mĭgla > *mgła* 'mist' (see also CHAPTER 122: SLAVIC YERS); (ii) the obstruentization of palatalized /rʲ/ and /w/ to /ʒ/ and /v/, respectively; and (iii) the decomposition of nasal vowels into sequences of vowel plus nasal consonant, as in *prěstǫpĭstvŭ > [pʃestempstf] 'transgression (GEN PL)'. Prefixation by /z/ (/s/), /v/ (/f/), and /vz/ (/fs/) contributes to the large number of complex clusters across morphemes (e.g. *skrwawić* [s+krf-] 'to inflict bloody wounds'), and word-medial clusters are enhanced by prepositions and prefixes such as *ob-*, *-od-*, *przed-*, *pod-*, etc. Loanwords further extend the possibilities in codas, e.g. *tekst* 'text', *filtr* 'filter', *asumpt* 'inducement'.

1.1 *Sonority sequencing and syllabification*

A fundamental question is whether Polish consonant clusters are organized in any particular way in the syllable, and specifically, whether syllable onsets and codas obey the principle of rising sonority toward the syllable peak and decreasing sonority after the syllable peak. If allowance is made for *s/z*+C and *f/v*+C sequences, then most Polish clusters in onsets and codas do exhibit sonority sequencing: *strach* 'fear', *dno* 'bottom', *kart* 'cards (GEN)', *sens* 'sense', *kar-ty* 'cards', *sios-tra* 'sister'. But sonority violations in both onsets (1) and codas (2) and in word-medial clusters (3), both morpheme-internally as well as across morphemes, have

[1] A complete typology of Polish consonant clusters is given in Bargiełówna (1950), where morpheme boundaries within clusters and clusters of foreign origin are noted. Sawicka (1974: 67–75) provides an inventory of word-initial and word-final clusters (ignoring voicing assimilation and final devoicing); see also Rowicka (1999a: 309–344). In Mikoś (1977) and Rochoń (2000: 283–301) palatalized labials decomposed into labial + /j/ sequences are counted as onset clusters, and final devoicing is represented in codas.

(3) *Sonority sequencing violations in medial clusters/onsets/codas*

/ʑdʑʨ/	*najeźdźcze*	'invasive'
/bwk/	*jabłko*	'apple'
/brn/	*srebrny*	'silver'
/snk/	*czosnku*	'garlic (GEN SG)'
/trk/	*wiatrka*	'wind (GEN SG)'
/ndrk/	*mędrkować*	'to act like a smart alec'

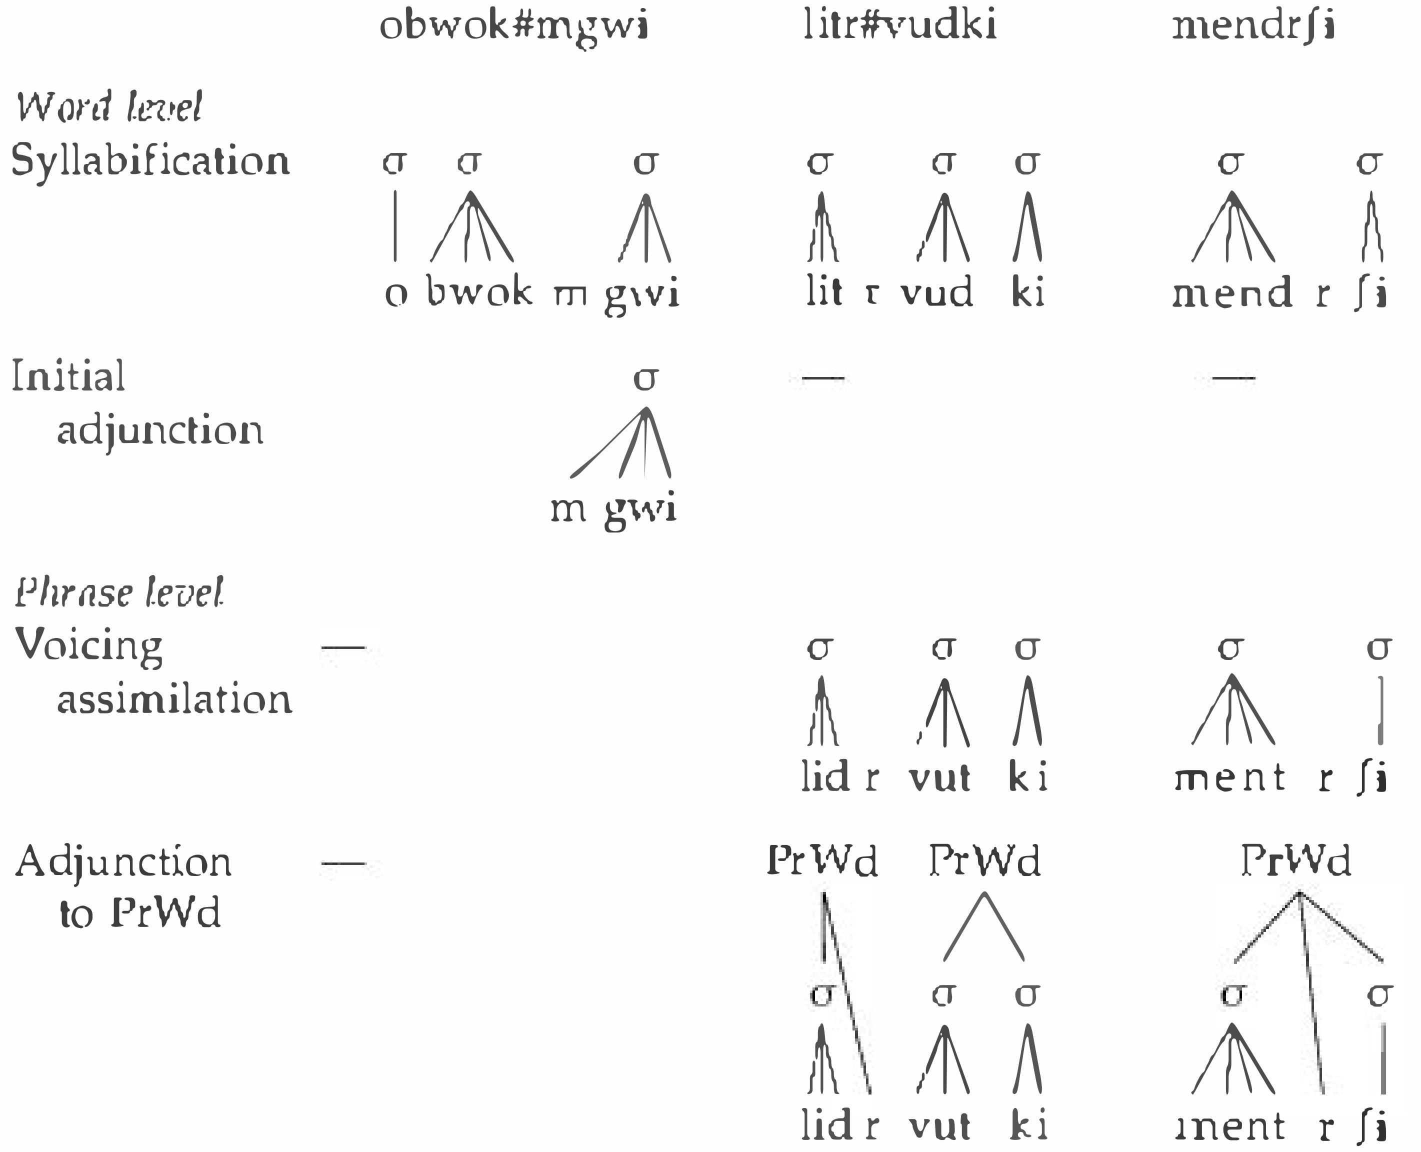
It was Kurylowicz (1952) who first related the typology of consonant clusters to syllable structure by proposing a type of syllable template with branching onsets and codas and a classification of sounds as belonging either to groups or elements. In addition to onset groups with *s/z* followed by an obstruent and sonorant (e.g. *str, skr, zdr*), he identified sets of two-member groups consisting of obstruent + sonorant, *s/z* + obstruent, and *s/z* + sonorant. (For historical reasons and in their alternations /v/ (/f/) and /ʒ/ (/ʃ/) sometimes pattern with sonorants if they derive from *w and *rʲ, and they are often treated as sonorants in synchronic phonology [Rubach 1984; Gladney 2004; Gussmann 2007: 208–210, 307–312].) Syllable onsets are said to be maximally binary branching, with terminal nodes which can be filled by a combination of groups and/or elements, e.g. /v-str/ consists of an element followed by a group, /skr-f/ is a group + an element. Coda clusters are taken to be the mirror image (sonorant + obstruent (RC)) of onset (obstruent + sonorant (CR)) types, with the additional important proviso that onset groups (CR) may also occur in codas. Thus, codas may contain two elements (*k-t*), a coda group (*rb*), a coda group + element (*rt-f*), an element followed by an onset group (*m-st*), a coda group followed by an onset group (*mp-sk*), or simply an onset group (*dr*), as in *kadr* 'frame (in film)'. This approach does not distinguish among consonant types beyond obstruent and sonorant and thus implies that there are no systematic gaps in onset and coda sequences. Furthermore, morphology and phonology do not necessarily coincide: *zmrozić* 'to freeze' [z+mroʑitɕ] is said to have an onset of /ʑm-r/.

The basic insights of Kuryłowicz (1952) have been developed in versions of Government Phonology or CV phonology, where phonetic consonant clusters are said to contain empty nuclei in the phonological representation and thus are not really complex clusters (Gussmann 1991, 1992, 2007: 180–247; Cyran and Gussmann 1999; Rowicka 1999a; Cyran 2003: 161–321; Scheer 2004; and elsewhere). For example, the onset in *krnąbrny* 'unruly, restive' is said to have a branching onset (O = *kr*) before an empty nucleus (N = Ø), followed by a simplex onset (O = *n*) (Gussmann 2007: 215), and there are no sonority violations to speak of within onsets as such. Phonetic word-final codas are said to be onsets before an empty nucleus: *tkwić* 'to pierce, stick' [tkfʲitɕ] is /t-N-kw-i-tɕ-N/. Government Phonology does predict certain gaps in cluster types due to governing relations, but as there is no issue of syllabification, this approach will not be discussed in detail here.

In derivational generative phonology syllable structure is built up by a series of ordered syllabification rules, first constructing the syllable nucleus and then building the syllable onset (Steriade 1982; Clements and Keyser 1983; Levin 1985; and others). The ordering of the onset rule before coda formation is a way of accounting for the well-known asymmetry that no language prohibits onsets or requires codas (in Optimality Theory this is implicit in the formulation of the constraints

As these differences are fairly robust, a distinction has to be made between initial and final/medial sonority reversals. The R in #RC sequences is prosodified by initial adjunction, either to the phonological word (Rubach and Booij 1990b), or to the initial syllable as a complex onset (Bethin 1992: 41, 171–174; Gussmann 1992). The prosodification of #RC sequences takes place early in the derivation, at the word or lexical level, while that of sonorants in CR# or CRC contexts is done by adjunction to the phonological word at the phrase or post-lexical level. The differences with respect to transparency in voice assimilation are said to be due to the interaction of prosody and voicing rules, with voicing processes applying to syllabified or prosodified segments in word-initial position but before adjunction takes place elsewhere, as exemplified in (5).

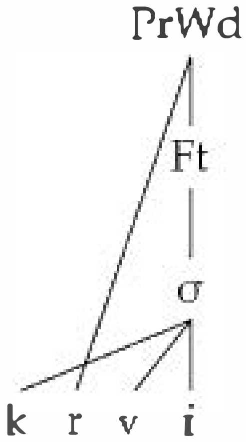
(5) *Prosodification of sonorants in* #RC, #CR, *and* CRC *sequences*



In non-derivational frameworks such as Optimality Theory, this is translated to differences in representation. Sonorants in #RC sequences are said to be associated to the syllable or foot (Rubach 1997; Rochoń 2000: 135–144), where they are specified for voice and not transparent to voicing assimilation. Final and medial sonorants are associated to the prosodic word and are thus transparent to voicing processes. Evidence supporting proposals for different prosodification of sonorants in Polish comes from variation in word medial position in how speakers syllabify the sonorant, e.g. *piosn-ka* or *pios-nka* 'song', and from the fact that sonorants in CRC and CR# clusters may sometimes be lost, e.g. *jabłko* 'apple' [japko], *mógł* 'he could' [mukw̥], [muk], but initial sonorants are not deleted.

Other problematic cases are sonorants trapped within onsets (#CRC-), because these sonorants lose voice in the environment of voiceless obstruents, e.g. *płci* 'sex (GEN SG)' [pw̥ytɕi], and they are transparent with respect to progressive devoicing of fricatives, e.g. *krwi* /krvi/ 'blood (PREP/DAT SG)' [kr̥fi]; *trwać* /trvatɕ/ 'to last' [tr̥fatɕ] (Booij and Rubach 1987; Bethin 1992: 175–178; Gussmann 1992, 2007: 311–312; Rubach 1997; Rochoń 2000: 143; on the relation between sonorants and voice, see also CHAPTER 8: SONORANTS). If the initial obstruent is syllabified as an onset and if sonorants which are transparent to voicing processes are not syllabified but adjoined at a higher prosodic level, then the adjunction of trapped sonorants to the Prosodic Word not only violates the Strict Layer Hypotheses (prosodic structure is said to be strictly hierarchical in organization, cf. Selkirk 1978 and CHAPTER 51: THE PHONOLOGICAL WORD), as do all cases of adjunction above, but here adjunction to the PrWd also forces the crossing of association lines, as shown in /krvi/ (6).

(6)



This case has been a challenge and it served as an argument in support of Derivational Optimality Theory (DOT) in Rubach (1997), where the SSG dominates PARSESEGMENT (segments must be associated to prosodic structure) at one level, leaving the /r/ not incorporated into the syllable onset, and Progressive Voicing selects the [k<r>fi] candidate over [k<r>vi]. This output then becomes the input to level two, where constraint ranking may be different; here the ranking of PARSESEGMENT over SSG chooses [krfi] over [k<r>fi], with the sonorant incorporated into the syllable and pronounced. In Gussmann (1992) this case served as an argument for postulating delinking from voice specification and resyllabification rules in order to meet well-formedness conditions on syllable structure. A different view of so-called trapped sonorants and syllabic consonants is given in Rowicka (1999a: 258–265), and there is an extensive discussion of these and related problems in Scheer (2004: 165–193).

The connection of voicing processes in Polish to prosodic structure (Bethin 1984) was further explored with respect to the licensing of voice only in syllable onset position and the assignment of sonorant voice by default only to prosodified sonorants (Rubach and Booij 1990b; Bethin 1992; Gussmann 1992; Lombardi 1995a, 1995b). Rubach (1996) argues against a syllabic analysis of voice assimilation and for binary specification of voice with no reference to syllable structure, though he retains the notion that sonorant voicing is subject to prosodification, which in Rubach (1997: 562) is formulated as SONORANT DEFAULT: all and only syllabified sonorants are [+voice]. Given that there is variation in syllabification in actual implementation where voiced segments are parsed into codas (Szpyra-Kozlowska 1998), voicing in Polish is probably segmentally conditioned and not a syllable-based process (Steriade 1997; Blevins 2003).

1.2 Resyllabification

When syllable structure is built up by a series of syllable-building rules in a derivational framework, it is in principle possible for these rules to interact with other phonological rules of the grammar, so there has been some discussion about whether syllable structure rules are ordered with respect to other rules; whether they reapply if the application of an earlier rule disturbs syllable structure, when they are triggered to reapply; and what happens to segments that lose their association to syllable structure in the course of a derivation. In non-derivational frameworks it is a question of what determines whether a potential syllable nucleus becomes activated and how this relates to prosodic well-formedness.

Polish exhibits a well-known set of vowel–zero alternations that bear on syllable structure in various ways. If the vowel is said to be present in the lexical representation and deleted under certain conditions, then one has to assess its viability as a syllable peak and potentially the loss of a syllable nucleus in vowel deletion. If the vowel is for some reason exempt from syllabification, what are its properties and what happens to adjacent consonants in the absence of a potential syllable nucleus? If the vowel gains prosodic status during a derivation, what are the consequences for syllable structure? If, on the other hand, the alternation is taken to be the result of epenthesis under certain conditions, what properties of syllable structure trigger epenthesis?

The vowel–zero alternations are found in inflection and derivation in roots, stems, prefixes, and prepositions, and primarily involve the vowel /e/ (which sometimes alternates with /o/), and also [i] or [ɨ] in derived imperfectives or adjectives, as shown in (7).

(7) *Vowel–zero alternations* ([e ɨ] indicate alternating vowels)

kr[e]*w* (NOM SG)	*krwi* (GEN SG)	'blood'
ł[e]*b* (NOM SG)	*łba* (GEN SG)	'forehead'
wiad[e]*r* (GEN PL)	*wiadro* (NOM SG)	'pail'
świat[e]*ł* (GEN PL)	*światło* (NOM SG)	'light'
des[e]*k* (GEN PL)	*deska* (NOM SG)	'board'
cuki[e]*r* (NOM SG)	*cukru* (GEN SG)	'sugar'
cukier[e]*k* (NOM SG)	*cukierka* (GEN SG)	'candy'
cukierecz[e]*k* (NOM SG)	*cukiereczka* (GEN SG)	'candy (DIM)'
wini[e]*n* (MASC SG)	*winna* (FEM SG)	'guilty'
umrzeć (PERF)	*umi*[e]*rać* (IMPERF)	'to die'
pod[e]*brać* (PERF)	*podbi*[e]*rać* (IMPERF)	'to select'
od[e]*pchnąć* (PERF)	*odp*[ɨ]*chać* (IMPERF)	'to push away'
lekcja (N)	*lekc*[ɨ]*jny* (ADJ)	'lecture'

The alternating vowels are known as yers (to distinguish them from the historical "jers") since many derive from the historical change lowering (or vocalizing) or deleting the Common Slavic high lax vowels ("jers") in strong and weak position, respectively (Lightner 1963, 1972; for an overview, see Rochoń 2000: 46–86). The alternation has been generalized to forms in which it is not etymological and to loanwords, e.g. *sweter* 'sweater', *swetra* (GEN SG). (For more detail about yers in Slavic, see CHAPTER 122: SLAVIC YERS.)

Earlier proposals that the vowel–zero alternation is the result of vowel epenthesis (CHAPTER 67: VOWEL EPENTHESIS), primarily motivated by the need to syllabify non-syllabic roots or complex consonant clusters (Czaykowska-Higgins 1988; Gorecka 1988; Piotrowski 1992), faced problems. The presence of vowel epenthesis, as in *kalka* 'carbon paper' ~ *kalek* (GEN PL) and *serek* 'cheese (NOM SG, DIM)' ~ *serka* (GEN SG), in an otherwise fine coda sequence (*lk* or *rk*), the lack of epenthesis in many clusters violating sonority sequencing, e.g. *jabłko* 'apple', *krnąbrny* 'restive, unruly', and the existence of many minimal or near-minimal pairs, e.g. *miotła* 'broom', *miotel* (GEN PL), but *zamiotł* 'he swept', *barka* 'barge', *barek* (GEN PL), and *bark* 'shoulder', *barka* (GEN SG), *oset* 'thistle', *osty* (NOM PL), and *most* 'bridge', *mosty* (NOM PL), made the prediction of epenthesis questionable. The vowel in some form is present in the lexical representation.

Most analyses postulate some type of underlying yer vowels which are distinguished from non-alternating vowels, either by a diacritic/feature or by the (partial) absence of feature specification, by no association to the skeletal tier (floating matrices) or the mora (mora-less vowels), by being an empty position on the skeletal tier, or by being a special type of empty nucleus in the lexicon (Lightner 1963, 1972; Laskowski 1975; Gussmann 1980a, 2007; Rubach 1984, 1986; Spencer 1986; Szpyra 1989, 1992a, 1995: 90–135; Rubach and Booij 1990a, 1990b; Bethin 1992; Zoll 1993; Yearley 1995; Scheer 1997, 2004; Rowicka 1999a; Cyran 2003: 161–202). In this view, the presence and location of the alternation are given and it appears as a full vowel under certain set conditions.

Analyses that postulate underlying yers with no representation on a level at which they could be prosodified (no skeletal slot, no mora) incorporate procedures for the full vocalization of yers at some point in the derivation when they become potential syllable nuclei. The vocalization and deletion of yers is usually controlled by the following vowel: if it is a yer, the preceding yer will vocalize; if it is a non-yer vowel, the preceding yer will delete. Typically, this alternation is found in the last syllable of a stem. In generative analyses it is implemented by a rule of Lower (Lightner 1972; Gussmann 1980a: 39–40) vocalizing a yer before a yer in the following syllable and deleting yers elsewhere; this requires the postulation of yers (represented here as V) at the end of words that never vocalize in that position: /desVkV/ 'board (GEN PL)' becomes [desek].

It has long been known that yer behavior in derivational morphology is different from that in inflectional morphology (Isačenko 1970), in that consecutive yers all tend to vocalize except for the last one in derivation: *cukier* 'sugar' ~ *cukru* (GEN SG), *cukierek* 'candy' ~ *cukierka* (GEN SG), *cukiereczek* 'candy (DIM)' ~ *cukiereczka* (GEN SG).[3] Here recourse to the phonological cycle was proposed as one solution; this raises questions about when the syllable-building rules apply and how much of the original syllable structure, if any, is preserved on subsequent cycles when resyllabification takes place. Rubach and Booij (1990a) argue that syllabification is cyclic and continuous (Hayes 1980; Itô 1986), but because onset and nucleus

[3] These problems have been extensively discussed in the literature (Rubach 1984, 1986; Nykiel-Herbert 1985; Szpyra 1989: 200–225, 1992b, 1995: 90–135; Rubach and Booij 1990a; Rowicka 1999a: 267–298, 1999b; Scheer 1997, 2004: 167–172; Gussmann 2007: 234–245, 301–307; Kraska-Szlenk 2007: 54–100). In the Government Phonology or CVCV framework, yer vocalization is treated as association to the melody if the yer is not immediately followed by a filled nucleus (Gussmann 2007) or as the association of alternating melodies that are not subject to Proper Government (Scheer 2004), and iterativity is not an issue per se.

structure from an earlier stage is preserved at later stages, resyllabification essentially involves the reassignment of codas as onsets when a nucleus becomes available. An abbreviated derivational example is given in (8), where consonant palatalization is ignored. An underlying yer cannot be syllabified until it vocalizes; unvocalized yers are simply deleted. Codas are said to resyllabify as onsets on subsequent cycles when yer vocalization provides a potential syllable nucleus, but otherwise CV structure is preserved.

In non-derivational analyses where syllabification processes do not apply and reapply, the interaction of yers and syllable structure is implemented as constraint interaction with respect to giving yers full vowel status in some form and constraints on complex margins or prosodic alignment. These approaches rely more on syllable structure constraints, in addition to other prosodic and morphological requirements. Analyses that operate with a yer in the input representation have an advantage over purely epenthetic accounts in designating the position of the alternation. Yearley (1995) proposes that yers (in Russian) are mora-less vowels that vocalize by acquiring a mora as a result of syllable structure requirements (a prohibition on complex codas and various prosodic alignment constraints disfavoring extrasyllabic segments). Sequential yers are vocalized by recursive evaluation. Rochoń (2000: 101–108) takes syllabification to be driven by the interaction of sonority sequencing, permitting clusters of equal sonority and a set of syllable structure constraints (ONSET, *CODA, *σ[CC, *σ[CCC, *σ[CCCC, CC]σ; 2000:

123–130). Jarosz (2006) suggests that yer vocalization is controlled by constraints on syllable structure specific to codas. The idea is that principles of syllable well-formedness come into play in creating a potential syllable nucleus.

In terms of syllabification within phonological words, the prefix/preposition boundary is somewhat of an issue. Unlike inflectional and derivational boundaries, the prefix boundary is maintained with respect to syllable structure, even if this produces surface violations of the core CV syllable: the prefixes /od-/, /nad-/ in *odosobnić* 'to isolate', *nadużyć* 'to abuse', and prepositions such as /nad-/ in *nad oknem* 'above the window' are syllabified [od-o-], [nad-u], [nad-o] (Kuryłowicz 1952; Booij and Rubach 1984, 1987). This leads Booij and Rubach (1984) to conclude that prosodic words may be different from morphological words, and that syllable structure is built up within a prosodic word domain. Non-syllabic prefixes/prepositions cannot constitute syllables on their own, and are necessarily syllabified with the stem across the boundary, e.g. *znieść* {z+ɲeɕtɕ} 'take, carry down'. The problematic cases are prefixes before glide-initial stems/roots, as in {rozV+jVm+ov+ɨ} 'truce (ADJ)', syllabified across the prefix boundary as [ro-zej-mo-vɨ], and sonority reversals which permit variation: {o+mdletɕ} 'to faint' is [o-mdletɕ] or [om-dletɕ], {pʒɨ+mknoɲtɕ} 'to close, shut' is [pʒɨ-mknoɲtɕ] or [pʒɨm-knoɲtɕ], with a strong preference for the second variant, which resyllabifies across the prefix boundary (Rubach and Booij 1990b). Here adjunction plays a role. These syllabification restrictions as well as exceptional vowel–zero behavior support the strength of the prefix boundary as a special case in Polish (see also Szpyra 1989, 1992b; Rowicka 1999a: 267–298, 1999b; Gussmann 2007: 234–245; and references therein).

1.3 *Phonological* vs. *phonetic syllables*

Most phonologists agree that sonority sequencing in some form is operative in the phonological syllable of Polish, while sonority sequencing violations abound in the phonetic syllable; the latter led some linguists to reject any role for principles of sonority sequencing in Polish (Sawicka 1974, 1995; Dukiewicz 1995; and others). Phonetic syllables are not always functioning phonological ones in terms of sonority peaks: the two sonority peaks in *trwa* 'it lasts' make it phonetically disyllabic [tr-va] (Dukiewicz 1995: 76), though for purposes of penultimate stress assignment in Polish and when pronounced at normal speech rate as [tr̥fa], the word is monosyllabic. In careful speech, word-final Cw sequences may be fully voiced/syllabic, e.g. *mógł* 'he could' is [mugw], [mugu], but commonly [mukw̥], [muk] (Sawicka 1995: 76, 139; Rochoń 2000: 250–255; Gladney 2004).

The phonetic syllable may have sonority sequencing violations not admitted into the phonological syllable, yet frequency data show that Polish syllable structure tends to favor the less marked type postulated in the phonology. Complex clusters are more common in onset than in coda position both in inventory and in textual frequency. Bargiełówna (1950) lists 231 two-member onsets but only 100 two-member codas. Initial clusters have a text frequency of 86.7% and coda clusters that of 13.3% (Sawicka 1974: 117–121). Simple clusters are more common than more complex ones: Sawicka (1974: 119) notes that CC clusters constitute 88.9% of occurring clusters in texts and CCC only 9.3%, in spite of a more equal distribution in the inventory where CC clusters comprise 53.6% and CCC 42.7% of all clusters. Two-member codas are much more frequent than three-member codas, constituting 98.7% *vs.* 1.3% of tokens in written texts compared to inventory, where the ratio is 74.4% to 19.6%. There are some systematic gaps in clusters, such that /j/ occurs only adjacent to a vowel, no /rl/, /lr/ occur in onsets, and no /lr/ in coda position (Sawicka 1995: 169), and there are no sequences of three or four sonorants in general.

There are also significant differences in terms of occurring cluster types in Polish: Dukiewicz (1985) documents that consonant (C) + sonorant (R) clusters are more frequent than are RC types in word-initial position: CR = 10,423, CCR = 2025, RR = 1435, CRR = 135, CCCR = 120, CRC = 80, RC = 10, RCR = 6, CRCR = 4, CCRR = 3, CCRC = 0 per 100,000 tokens in journalistic texts. Sawicka (1974: 122–123) reports on onset cluster types in written texts: sonorant + sonorant = 7%, sonorant + fricative = 0%, sonorant + stop = 0%, fricative + sonorant = 17.6%, stop + sonorant = 22.0%, fricative + stop = 21%, stop + fricative = 16.5%, fricative + fricative = 14.2%, stop + stop = 8.0%, where the high incidence of fricative + stop and fricative + fricative onsets is in large part due to prefixes and prepositions, as is also the case for spoken data (Dunaj 1985).

The most frequent coda types are fricative + stop = 53.3%, and sonorant + stop = 26.0%. The high frequency of fricative + stop (Sawicka 1974) is due to the high textual frequency of the verb *jest* 'is'; in spoken texts 35.5% of Dunaj's (1985) fricative + stop tokens were due to *jest*. Among the sonorant + stop clusters, nasals were most common, and this is most likely the contribution of nasal vowels which are pronounced as nasal consonants before stops.

Native speaker intuitions sometimes differ from structures proposed for the phonological syllable and speakers accept some variation in syllabification at the phonetic level, especially in longer medial sequences of four or more obstruents as in [skompstfo] 'avarice' or in RCR clusters as in *pośmiertny* [rtn] 'posthumous': subject data in Rubach and Booij (1990a: 126–127) shows [lʲis-tfa] (40 tokens), [lʲist-fa] (11 tokens), but [lʲi-stfa] (8 tokens) for 'board', [skomp-stfo] (28 tokens), [skom-pstfo] (19 tokens), [skomps-tfo] (2 tokens), but no tokens of [skompst-fo] or [sko-mpstfo] for 'stinginess'.[4] Variation is found within morphemes as well as across morpheme boundaries. Szpyra-Kozlowska (1998: 70) reports that subjects accept variation between complex onsets and coda-onset syllabification even for CC and CR sequences, but sonority/syllable contact principles were respected in RC, which was overwhelmingly R-C, e.g. *ma-tka* 'mother' (9 tokens), and *mat-ka* (36 tokens), *mo-dry* 'blue' (22 tokens) and *mod-ry* (23 tokens), but *ko-tlet* 'cutlet' (6 tokens) and *kot-let* (39 tokens), also *ła-dny* 'pretty' (7 tokens) and *ład-ny* (38 tokens).[5] How variation is to be represented in phonological grammars is still under investigation.

[4] The test consisted of a list of words dictated to students who were asked to write them with syllable divisions. It is not clear how many students took this test initially, but ten students took the test three times at one-week intervals (60 tokens) to determine intra-speaker variation, which for *patrzeć* 'look' was 3:10. Intra-speaker variation in CRC sequences such as *karmnik* 'feeder' was tested with 19 subjects, and here variation was of the order of 7:19 and 9:19 (Rubach and Booij 1990a: 438). It is difficult to say how much an effect orthography and orthoepy played in the task of hyphenating written items.

[5] Szpyra-Kozlowska (1998) used 300 word stimuli of varying length and cluster types (as well as stimuli with one intervocalic consonant) dictated (twice) to the same 45 subjects (native speaker students aged 19–23) in two sessions of 150 words per session. Items included 175 CC words, 65 CCC, 25 CCCC, 5 CCCCC, and 30 with C (C = obstruents and sonorants, e.g. *warta* 'guard' and *watra* 'guard fire'), but results are given only for CC syllabification (1998: 68–69). Subjects were asked to write the words with hyphens at syllable breaks. In a follow-up experiment 20 of the subjects syllabified selected items orally, with results almost identical to the written test, so the written test was taken to be reliable.

selection takes place and that the /-ij-/ surfaces as a syllable nucleus in order to syllabify the stem-final consonant (Bethin 1987, 1992: 189–221; Szpyra 1989: 131–158; Rubach and Booij 1990, 2001). Thus 'kick!' /kop<n> + ii/ is fully syllabified as [kop-nʲij] and 'defend' /broɲ + ii/ is fully syllabified as [broɲ]. However, there are examples with RR or CR structures (*karm* 'feed!', *módl* [dl] 'pray!', *rozświetlij* and *rozświetl* 'illuminate!'), or syllabifiable sequences which still take *-ij* (*uwielbij* or *uwielb* 'adore!'). Variation in the imperative forms is exemplified by some verb stems in (11) (see also Gussmann 2007: 167–178). Final devoicing is indicated in the forms below.

(11) *Variation in the imperative*

mądrzyj	[mondʒij]	~	*mądrz*	[montʃ]	'mouth off'
naświetlij	[naɕfʲjetlʲij]	~	*naświetl*	[naɕfʲjetl̥]	'illuminate'
zaczernij	[zatʃerɲij]	~	*zaczerń*	[zatʃerɲ]	'blacken'
karmij	[karmʲij]	~	*karm*	[karm]	'feed'
wątpij	[vontpʲij]	~	*wątp*	[vontp]	'doubt'

Not all variant forms show sonority reversals in stem-final clusters and some verbs with sonority reversals occur without the syllabic suffix. One possibility is that adjunction may take place before allomorphy selection for some speakers, another is that the availability of a syllabic allomorph may make it possible to choose less marked structures with simple onsets and no complex codas, or the status of any cluster-final segment may be ambiguous and thus produce variation. To some extent, the explanation depends on the analytical framework, but the consensus in the literature is that imperative allomorphy for the most part is sensitive to syllable structure in some form, either to unsyllabifiable consonants (Rubach 1986; Rubach and Booij 1990a, 1990b, 2001; Bethin 1992: 204–218) or to the presence of underlying yers or empty nuclei (Gussmann 1980b, 2007: 178).

3.2 Comparative allomorphy

The comparative suffix is *-sz-* [ʃ] or *-ejsz-* [ejʃ], and it also appears to be sensitive to syllabification: the syllabic suffix is favored when there is an unsyllabified stem-final consonant, usually a sonorant in a CR sequence (Bethin 1987, 1992: 189–218; Rubach and Booij 1990a, 1990b), as shown in (12), where voicing assimilation and progressive devoicing are given in the phonetic representation.

(12) *Comparative allomorphy*

nowy	[novi]	*nowszy*	[nofʃɨ]	'newer'
stary	[starɨ]	*starszy*	[starʃɨ]	'older'
trudny	[trudni]	*trudniejszy*	[trudnʲejʃi]	'more difficult'
łatwy	[watfi]	*łatwiejszy*	[watfʲjejʃi]	'easier'

The extrasyllabicity of the stem-final segment is resolved when it can syllabify as an onset with the syllabic allomorph: *wierny* 'loyal' is /vʲjer<n>/ and becomes /vʲjer-nʲej-ʃi/ in the comparative in preference to the /vʲjer-<n>-ʃi/ option. Rubach and Booij (1990a) use comparative allomorphy as an argument that syllabification must take place in the cyclic component and when the cluster-final segment, usually yers, the prosodic independence of prefixes and prepositions, the representation of nasal vowels as distinct from vowel + nasal sequences, and syllable effects in morphology have stimulated work fundamental to phonological theory and they will continue to be a challenge for the field.

110 Metaphony in Romance

Andrea Calabrese

The term metaphony, which was first used in French (*metaphonie*) as a translation of the German word *Umlaut*, is traditionally used in Romance linguistics to refer to a process in which a vowel assimilates partially or totally to the height of a following vowel. Metaphony is one of the most characteristic phonological processes characterizing the Romance languages, and in particular Italian varieties (although not Tuscan and, therefore, standard Italian, which is based on Tuscan). For example, in many Italian dialects, high mid vowels are raised to high before a high vowel. In the same context, low mid vowels can be raised to high mid, or diphthongized. This has resulted in numerous alternations, as in the examples /'verde ~ 'virdi/ 'green (SG~PL)', /'pɛde ~ 'pedi/ or /'pɛde ~ 'pjedi/ 'foot (SG~PL)', where the plural form shows metaphonic effects. Less commonly, a stressed low vowel may also be affected by metaphonic raising, and other changes may take place as well (cf. Maiden 1991; Calabrese 1985, 1998). The conditioning factor in the metaphonic alternations has been obscured in many dialects by the neutralization or deletion of final vowels. This has produced vowel alternations in nominal and verbal paradigms for which there is no overt trigger.

As observed by Anderson (1980: 43), the formal mechanism characterizing metaphony is not distinct from that underlying other sorts of vowel harmony (CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY): it involves the spreading of a vowel feature from a given vowel to other vowels. As this term is used in Romance linguistics, however, the fundamental difference lies firstly in the feature that is spread – a height feature ([high], [low], or [ATR]; CHAPTER 21: VOWEL HEIGHT) in the case of metaphony – and secondly in the restriction on the target of the process – a stressed vowel. In "normal" vowel harmony, all vowels in a word can be targets of the harmonic process. In §2.1.3, I will consider Walker's (2005) analysis of metaphony, which accounts for the local properties of this phenomenon – i.e. for the fact that the target is a stressed vowel and the trigger a post-tonic high vowel – in a functional perceptual perspective. I will later (§4.1) briefly discuss an analysis of metaphony in terms of domain of application.

Other processes with the same restriction on a stressed target, but spreading non-height features, are found in other languages, starting from Germanic Umlaut. In this chapter I will restrict my attention to the phenomena that are traditionally referred to by the term metaphony in the Romance languages. This is an arbitrary choice from a theoretical point of view, but this delimitation will allow a tighter and more adequate exposition of facts and analysis.

1 Description of Italian metaphony

1.1 Types of vowel systems

In order to describe Italian metaphony adequately, a brief description of the vowel systems found in Italian dialects is needed. In stressed syllables, the typical system of Standard Italian (Tuscan) and many Italian dialects is the seven-vowel system in (1), which is given in (2) in terms of distinctive features (CHAPTER 17: DISTINCTIVE FEATURES; CHAPTER 19: VOWEL PLACE; CHAPTER 21: VOWEL HEIGHT).

(1)

i		u
e		o
ɛ		ɔ
	a	

(2)

	i	e	ɛ	a	ɔ	o	u
high	+	–	–	–	–	–	+
low	–	–	–	+	–	–	–
back	–	–	–	+	+	+	+
round	–	–	–	–	+	+	+
ATR	+	+	–	–	–	+	+

An important issue concerning (2) involves which feature accounts for the contrast between high mid and low mid vowels. Chomsky and Halle (1968), following Bloch and Trager (1942) and Jakobson *et al.* (1952), use the feature [tense] to account for this contrast. Problems with the feature [tense] were pointed out by Catford (1977) (see also Ladefoged and Maddieson 1996). In recent years, Romance phonologists have started to employ the feature [Advanced Tongue Root] ([ATR]), which was first used to account for vocalic contrast in West African languages (Ladefoged 1964; Lindau 1975; see also Halle and Stevens 1969), and I adopt this feature in (2). Ladefoged and Maddieson (1996) argue against this trend and propose that height contrasts in mid – and high – vowels in Germanic and Romance languages are simply due to different dislocations of the tongue body. Calabrese (2008) instead argues that these contrasts should indeed be accounted for in terms of advancement/non-advancement of the tongue root and that the apparent dislocation of the tongue body is due to the fact that the tongue is an elastic mass: thus, an advancement of the tongue root results in a slight raising and fronting of the tongue body. Evidence for this may be found in a recent ultrasound study of vowel articulations in the southern Salentino dialect of Tricase by Grimaldi *et al.* (2010), where it is shown that the difference found in this dialect between high mid /e/ and low mid /ɛ/, where the former is the result of metaphonic tensing before /i/, is the result of tongue root advancement as shown in Figure 110.1:

1.2 *Italian metaphony*

In seven-vowel systems, the typical targets of metaphony are the mid [+ATR] vowels /e o/, which raise to /i u/ when followed by a high vowel.[2] There is dialectal variation in the case of the mid [−ATR] vowels, where we essentially find three groups of dialects. In one group of dialects, these vowels diphthongize. In another group of dialects, they are raised to mid [+ATR] vowels. And finally, in still another group of dialects, they do not change in a metaphonic context. Typical metaphonic systems are exemplified by the dialects in (4), (5), and (6).

(4) *The dialect of Calvello* (Gioscïo 1985)[3]

Metaphonic alternations: /e o/ → [i u]; /ɛ ɔ/ → [je wo]

a. [+ATR] /e o/

i. Class I/II adjectives

	singular	*plural*	
masc	'sulu	'suli	'alone'
fem	'sola	'sole	
masc	'niru	'niri	'black'
fem	'nera	'nere	

ii. Class III adjectives and nouns

singular	*plural*	
ka'vrone	ka'vruni	'charcoal'
'mese	'misi	'month'
'verde	'virdi	'green'

iii. Metaphonic alternations in the present singular of verbs

'mitti	'kurri	(2nd person)
'mette	'korre	(3rd person)
'put'	'run'	

b. [−ATR] /ɛ ɔ/

i. Class I/II adjectives

	singular	*plural*	
masc	'ɣrwossu	'ɣrwossi	'big'
fem	'ɣrɔssa	'ɣrɔsse	
masc	'vjekkju	'vjekkji	'old'
fem	'vɛkkja	'vɛkkje	

ii. Class III adjectives and nouns

singular	*plural*	
'pɛre	'pjeri	'foot'
'dɛnte	'djenti	'tooth'
'fɔrte	'fworti	'strong'

[2] In some dialects only /i/ triggers the change. This issue will be discussed later.

[3] The examples from this dialect are given in intermediate forms. There is a low-level process that neutralizes unstressed vowels to [ə] in the final position of a phonological word so that there are alternations such as the following: /sandə/ 'saint' vs. /sandu pjetrə/ 'St Peter'; /kwirə/ 'that' vs. /kwiru kanə/ 'that dog' (see Gioscio 1985; Kaze 1991).

vowel system in (3). The neutralization in [ATR] values rendered the old metaphony system opaque, as in (9), where the same set of phonetically mid [−ATR] vowels has two different phonological behaviors according to the metaphonic context. The additional raising of mid vowels in unstressed syllables (['sɛntu ~ sin'timu] 'feel-PRES (1SG~1PL)', [ka'nɔsku ~ kanuʃ'ʃimu] 'know-PRES (1SG~1PL)' complicates the situation further (see Calabrese 1985 for an analysis).

(9) *Northern Salentino*

singular	*plural*	
'mɛsi	'misi	'month'
'nɔʧi	'nuʧi	'nut'
'pɛti	'pjɛti	'foot'
'kɔri	'kwɛri	'heart'

2 Analyses of metaphony

The major theoretical problem in characterizing Italian metaphony lies in the different phonological behavior of the mid [+ATR] and mid [−ATR] vowels. Recall that whereas mid [+ATR] vowels are consistently raised to high vowels across dialects in a metaphonic context (i.e. before high vowels), mid [−ATR] vowels may be diphthongized (4), raised to mid [+ATR] (5) or high [+ATR] (7), or even fail to undergo any change (6) in the same context. As we will see below, there is substantial agreement in the literature with respect to the basic nature of the process affecting mid [+ATR] vowels: it essentially involves height assimilation between a high vowel and the preceding stressed vowel. In contrast, there is no such agreement with regard to the nature of the process(es) affecting the mid [−ATR] vowels in a metaphonic context. On the one side, there are those who aim to achieve a unified account for metaphony and therefore propose that the same process applies to mid [+ATR] and mid [−ATR] vowels. For these scholars, the different outcomes observed in the case of the mid [−ATR] vowels are due to further phonological operations that apply to the outputs of height assimilation. On the other side, there are those who propose that an adequate account of the different outcomes observed in the case of the mid [−ATR] vowels requires the postulation of two independent processes: one of height assimilation applying to mid [+ATR] vowels, and a different one applying to mid [−ATR] vowels. In this section I will discuss the different proposals addressing the problem of the different phonological behaviors of the mid [+ATR] and mid [−ATR] vowels in a metaphonic context. A brief critical assessment of the different analyses of metaphony discussed in §2.1 and §2.2 is given in §2.3.

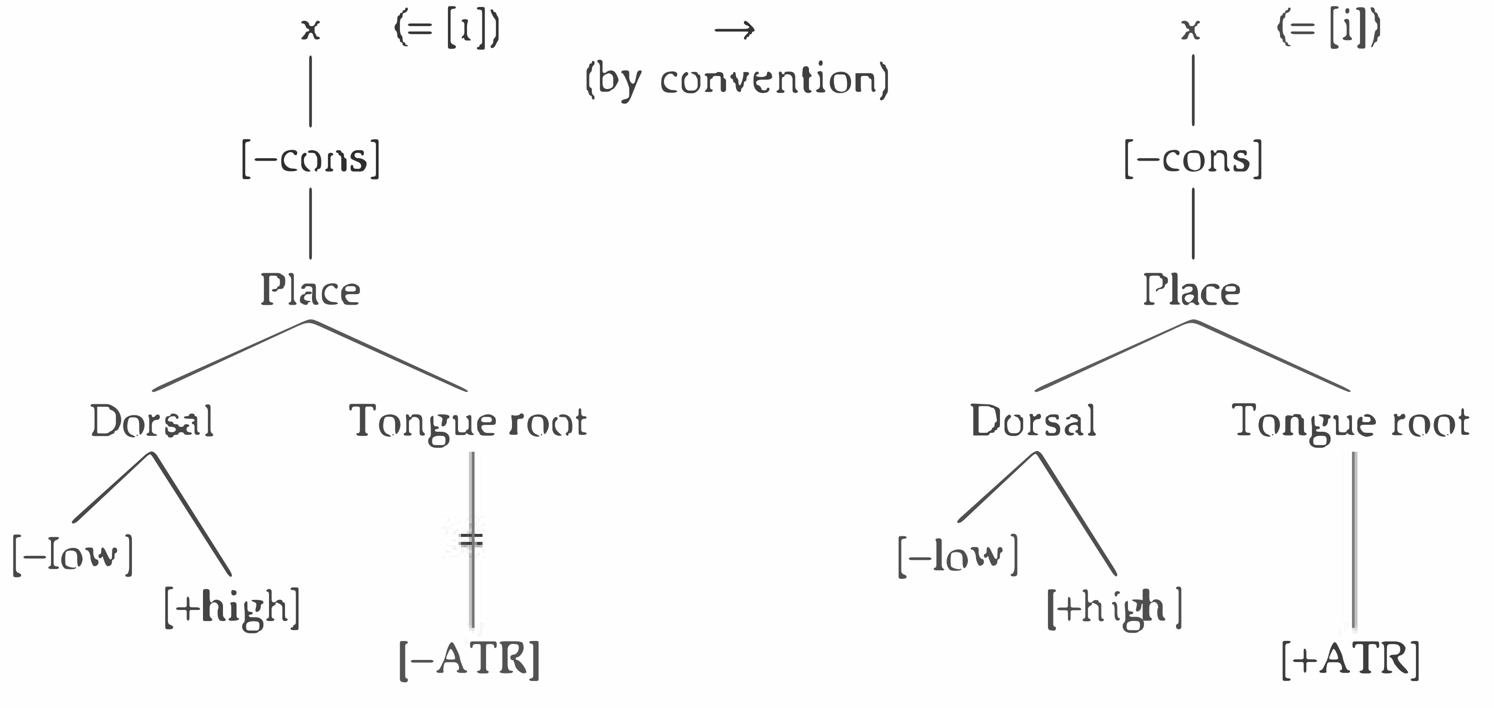
2.1 Metaphony as a unitary process

2.1.1 The analysis of metaphony in Calabrese (1985, 1998)

Calabrese (1985) was the first to analyze Italian metaphony in a generative and, more specifically, non-linear phonological framework. The dialect he studied was that of Francavilla Fontana (Ribezzo 1912) in northern Salento, where, despite some obscuring surface changes, one can easily reconstruct a metaphony system rules to the same disallowed configuration [+high, −ATR], created by metaphony in the case of mid [−ATR] vowels. In historical terms, he hypothesizes that the same rule of height assimilation spread across the southern Italian dialects. Each dialect reacted to the problem posed by the output of the application of this rule to the mid [−ATR] vowels in a different way.

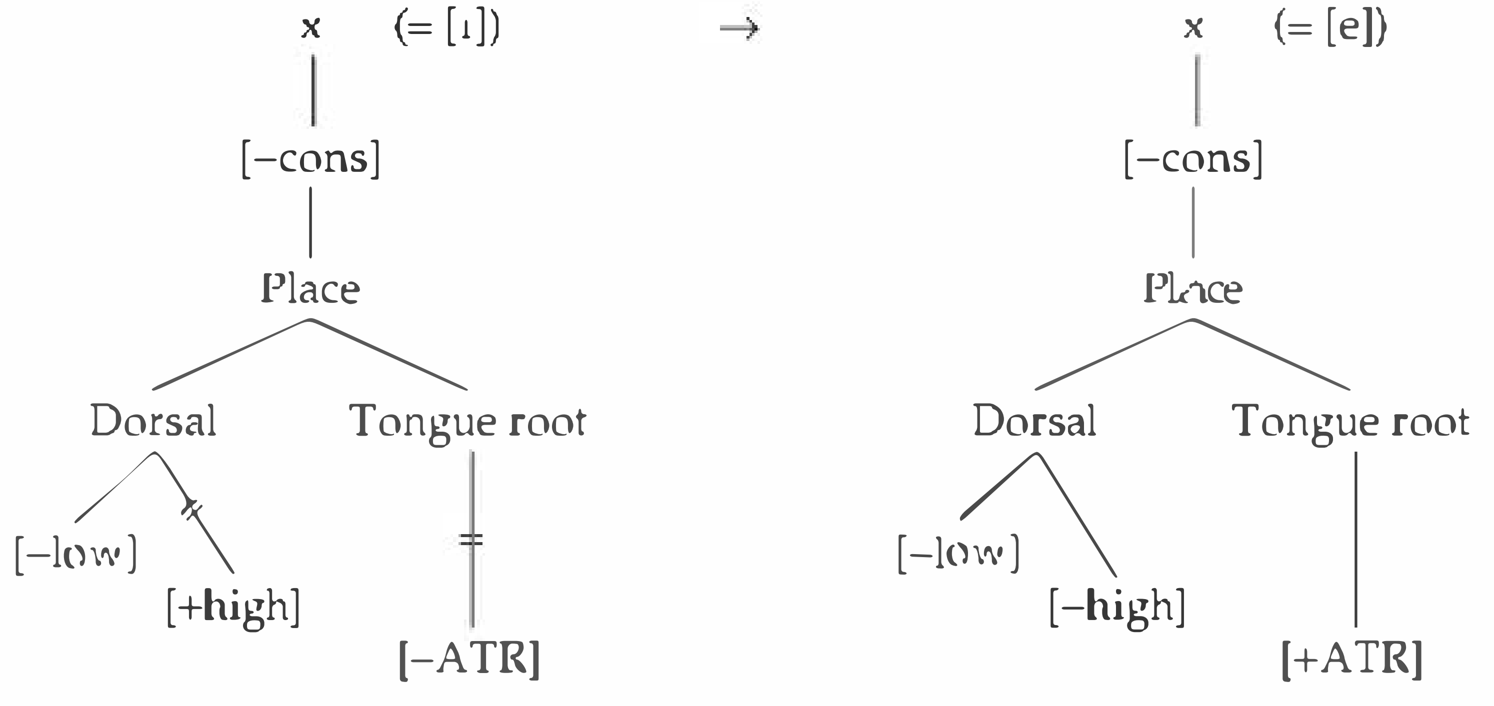
The relevant repairs he proposes are delinking and excision. Delinking involves an operation that removes one of the feature specifications disallowed by an active marking statement. The opposite feature specification is inserted by convention. This operation accounts for metaphonic raising to high vowels. In this case the feature specification [−ATR] of the disallowed configuration [+high, −ATR] created by the metaphony rule is delinked and the opposite feature specification [+ATR] is inserted, as shown in (12).

(12)



Excision involves removing both the feature specifications of the disallowed configuration and replacing them with their opposite specifications (see Calabrese 1995, and especially 2005, for further discussion of excision). If we assume that the rule of metaphony is the same across dialects and that the variation is due to the application of a different repair, we can hypothesize that excision is the relevant repair in southern Umbro. Thus, we have a repair like the one in (13).

(13)



That is, the [–ATR] high vowels produced by metaphony are changed into [+ATR] mid vowels.[10]

Calabrese (1985, 1995) accounts for metaphony systems where only mid [+ATR] vowels, but not mid [–ATR] ones, undergo metaphony (see the dialect of Grado in (6)) by postulating that there is a parametrized option that governs the interaction between rules and active constraints. If applying a rule would generate a violation of a constraint, the application of the rule could either be (i) blocked (structure preservation) or (ii) allowed to apply. Under option (ii), a repair then fixes the illicit configuration that is so produced. The dialects discussed above select this option. The dialects where metaphony does not apply to mid [–ATR] vowels select option (i): so the rule in (10) is prevented from applying to these vowels because of the active constraint *[+high, –ATR] (see Calabrese 1998 for further discussion of this case).

I will now discuss two different accounts of Italian metaphony that essentially preserve Calabrese's hypothesis that there is a single metaphonic process raising all mid vowels to high ones and that the different treatments found in the case of the mid [–ATR] vowels are due to different processes. These are the analyses of Maiden (1991) and Walker (2005). Observe that only Walker accounts for the dialectal variation we find in the case of metaphony of the mid [–ATR] vowels. Maiden (1991) accounts only for the diphthongization observed in dialects such as that of Calvello. In this section I will also consider Nibert's (1998) analysis of metaphony in Servigliano.

2.1.2 *The analysis of metaphony in Maiden (1991)*

Maiden (1991) provides a detailed study of metaphony in its diachronic development and in its synchronic phonological and morphonological aspects. In his analysis of the phonology of this sound change, Maiden treats metaphony as an assimilation in height, as proposed by Calabrese; however, he disagrees with Calabrese's account of the diphthongization process found in lower mid vowels. In his account of metaphony, Maiden assumes the framework of dependency phonology. Following dependency phonology, he proposes that vowel height in a seven-vowel system like that of the Italian dialects should be represented as in (14), where vowel space is characterized by four components: |i| (palatality or acuteness); |a| (lowness or sonority); |u| (roundness or gravity); |ə| (centrality (not used here)).

(14) {|i|}	= /i/	{|u|}	= /u/
{i;a}	= /e/	{u;a}	= /o/
{a;i}	= /ɛ/	{a;u}	= /ɔ/
{|a|}	= /a/		

(Curly brackets indicate that the segment is characterized phonologically by just that component or combination of components, and ";" symbolizes asymmetrical right-to-left "government" relationships between components.)

[10] Calabrese (1985) uses excision to account for the metaphonic raising of /a/ to a mid vowel [ɛ ɔ]. The application of the metaphony rule to /a/ creates the disallowed configuration [+high, +low] which by excision becomes [–high, –low].

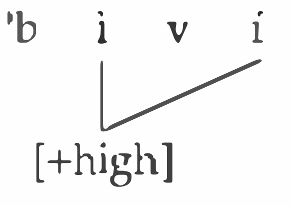
Metaphony, in other words, accomplishes improved perceptibility by extending the height features to the stressed syllable. She uses the positional licensing constraint in (18) to represent the need for high vowels to be associated with a prosodically strong position.

(18) LICENSE([+high]post-tonic, 'σ)

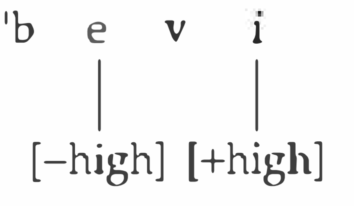
[+high] in a post-tonic syllable must be associated with a stressed syllable.

The constraint in (18) is satisfied in (19a), but not in (19b). The alternative solution in (19c), where the mid character of the stressed vowel overrides the post-tonic vowel, would result in unstressed vowel lowering. Walker eliminates this solution by assuming a preference for minimized sonority (CHAPTER 49: SONORITY) in unstressed syllables (CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE).

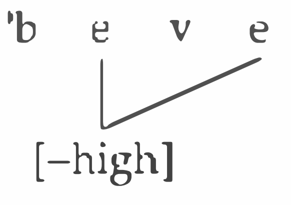
(19) a. *Licensing: satisfied*



b. *Licensing: violated*



c. *Licensing: satisfied (sonority minimization in unstressed syllables violated)*



In the OT scheme Walker proposes, all height features of post-tonic high vowels ([+high], [±ATR], [−low]) in metaphonic systems require licensing. This is implemented by LICENSE(height), which subsumes (18). In all of these systems, LICENSE(height) is ranked over IDENT[high], thus forcing spreading of the feature [high]. At the same time, *[+high, −ATR] is strictly enforced across patterns to block [+high, −ATR], as in Calabrese's analysis discussed in §2.1.1.

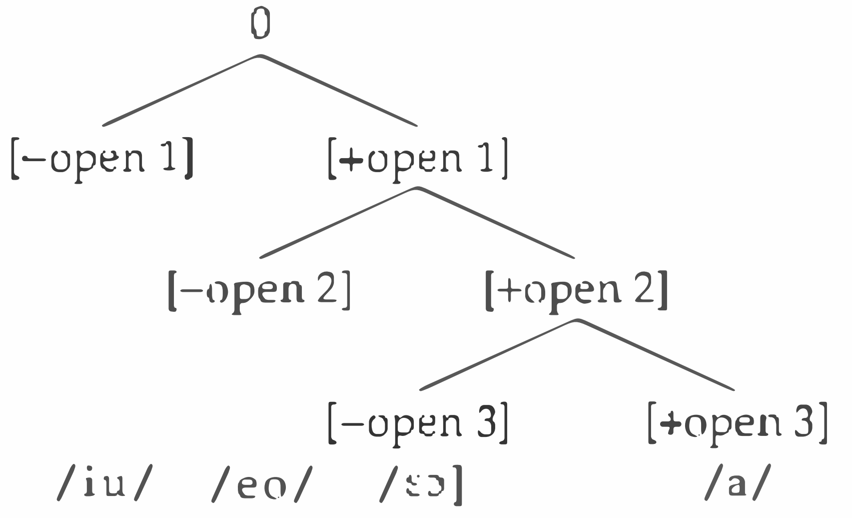
The dialectal variation we observe across the dialects is obtained as follows in Walker's OT analysis.

In Veneto, where metaphony applies only to [+ATR] mid vowels, the higher ranking IDENT[ATR] and IDENT[low] prevent [−ATR] vowels from being affected in metaphony. LICENSE(height) is ranked above IDENT[high]. Therefore the only allowed pattern is that in (6).

In the Pugliese dialect of Foggia (see (7)), where /ɛ ɔ/ raise to [i u], licensing for all height features is also capable of overriding IDENT[ATR]. Hence, in contrast to Veneto, LICENSE(height) dominates IDENT[ATR] in the dialect of Foggia.

Like Pugliese, metaphony in southern Umbro (see (5)) has the capacity to violate IDENT[ATR], but it shows gradual raising. Walker follows Kirchner (1996) in accomplishing this by local conjunction of faithfulness constraints for height features, which moderates satisfaction of height licensing (CHAPTER 62: CONSTRAINT CONJUNCTION).

(22) *Recursive expansion of* [open]



Servigliano has the seven-vowel inventory /i e ɛ a ɔ o u/. Metaphony induces a one-step raising of both the high mid vowels /e o/ and the low mid vowels /ɛ ɔ/. Nibert specifies the vowel height features for Servigliano in (23). Note that this is a center-embedding structure, as opposed to the right-branching structure in (22). The choice between the center-embedding and right-branching analysis of a four-height system depends on the behavior of the mid vowels in an individual language. (22) best represents a system in which the low mid vowels pattern with the low vowel with respect to vowel height, while (23) is an appropriate specification for languages like Servigliano, in which the low mid and high mid vowels pattern together.

(23)

	i	e	ɛ	a	ɔ	o	u
open 1	–	–	–	+	–	–	–
open 2	–	+	+	+	+	+	–
open 3	–	–	+	+	+	–	–

Nibert shows that under this analysis of vowel height, the raising of /e o/ requires assimilation of [–open 2] from the triggering vowels. But spreading [–open 2] onto /ɛ ɔ/yields the feature bundle [–open 1, –open 2, +open 3], which doesn't correspond to any of the available vowel qualities. In order to raise /ɛ ɔ/ in one step to /e o/, it is the feature [–open 3] that must be assimilated. Nibert argues that metaphony can spread either feature, [–open 2] or [–open 3], subject to structure preservation, which bans the spread of [–open 2] onto /ɛ ɔ/. In order to guarantee that [–open 2] and not [–open 3] spreads onto /e o/, since spread of [–open 3] would be vacuous, and would not accomplish raising, Nibert's rule must be modified to apply disjunctively, spreading [–open 2] unless spreading is blocked, in which case [–open 3] will spread.

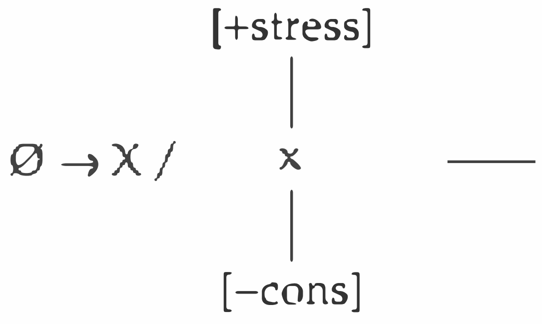
2.2 *Italian metaphony as two different processes*

The analyses that I consider in this section reject the idea that there is a unitary metaphonic process, and propose to break metaphony into two distinct processes – one targeting the mid [+ATR] vowels and raising them to high ones and the other targeting the mid [–ATR] vowels, leading to diphthongization or tensing. These are the analyses of Sluyters (1988) and Cole (1998).

2.2.1 *The analysis of metaphony in Sluyters (1988)*

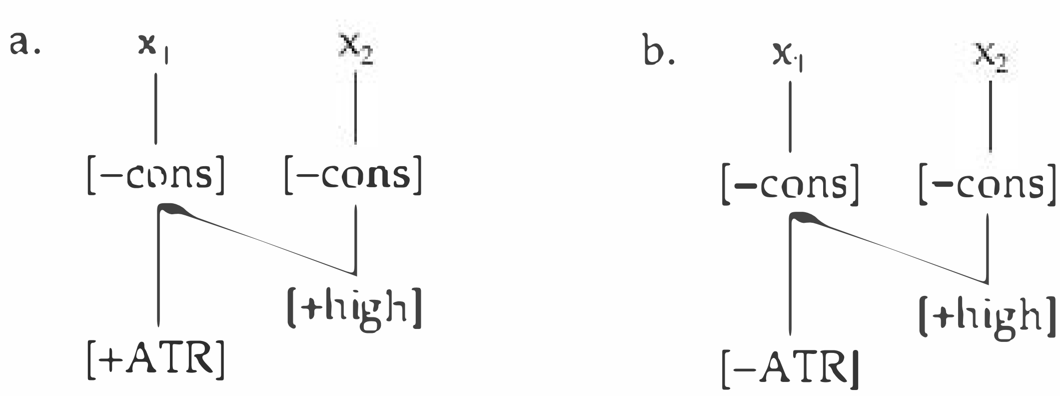
Sluyters (1988) proposes a reanalysis of Calabrese's (1985) account of metaphony in the northern Salentino dialect of Francavilla Fontana (see (9)). Assuming an underlying system as in (2) for this dialect, he adopts Calabrese's rule (10) (see §2.1.1 above) to account for height assimilation before high vowels. However, he proposes a different account of diphthongization in metaphony. Sluyters suggests that the metaphonic diphthongs /iɛ uɔ/ are characterized by a second x-slot which is contextually determined by stress and introduced by a rule like that in (24).

(24)



In Sluyters' analysis, Calabrese's rule (10) directly accounts for the raising observed in the case of mid [+ATR] vowels. According to Sluyters, however, (10) does not apply in the case of the mid [−ATR] vowels until after rule (24) has applied. However, the facts cannot be accounted for by simply applying (10) before and after (24). The first application of (10) would also affect mid [−ATR] vowels. It is therefore necessary to split rule (10) into two different rules: one applying to mid [+ATR] vowels and the other to mid [−ATR] vowels as in (25).

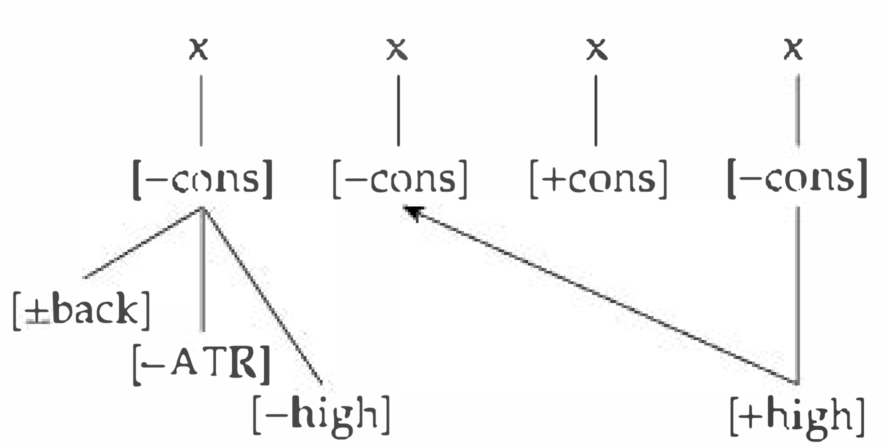
(25)



where x_1 is the head of the main stress foot

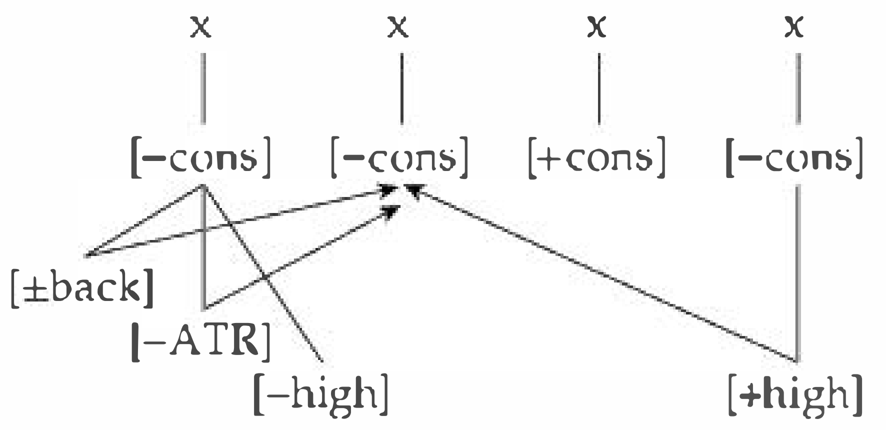
(25a) applies first. Then (24) applies. After the application of (24), rule (25b) fills in the empty x-slot with the feature [+high] as shown in (26) (tree structures are simplified).

(26)



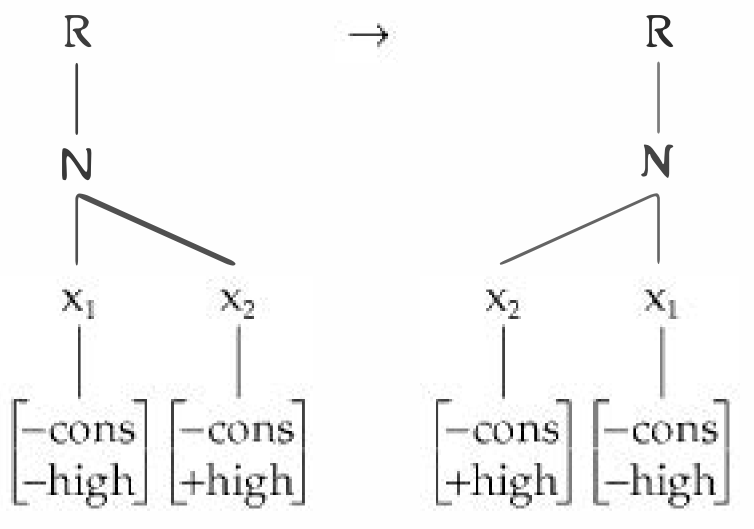
The other features of the inserted empty vowel are filled in by spreading from the preceding vowel, according to Sluyters.

(27)



Such an analysis produces the falling diphthongs /ɛj ɔw/. In order to get the correct outputs, Sluyters assumes the rule of metathesis in (28).

(28)



Application of (28) to the outputs of (27) generates the metaphonic outcomes /jɛ wɔ/.

2.2.2 *The analysis of metaphony in Cole (1998)*

Cole (1998) argues that the vowel raisings that define metaphony systems in Italian dialects do not result from a unified operation of height assimilation. Instead, metaphony is claimed to be the product of the assimilation of the mid [+ATR] vowels /e o/ to the high vowels [i u] within the stress foot (CHAPTER 40: THE FOOT), and a subsequent vowel shift by which the non-high /(a) ɛ ɔ/ are raised one step.

Like Walker (2005), Cole views the height assimilation of the mid [+ATR] /e o/ to /i u/ in functional terms. Following Cole and Kisseberth (1994), she assumes that assimilation promotes perceptual salience by reducing or eliminating marginal contrasts between two phonetically similar segments. Small phonetic differences between the trigger and target of assimilation are resolved, and in many vowel harmony systems the target emerges as fully identical to the trigger. Thus the assimilated target provides additional or extended acoustic cues for the identification of the triggering segment.

Cole then proposes that the assimilation in height of the mid [+ATR] leaves a vacancy in the vertical dimension of the vowel space, and a vowel shift takes place to raise the lower mid [−ATR] vowels, and thereby fill the gap.[11] This accounts for the tensing of the mid [−ATR] vowel observed in southern Umbro.

[11] Vowel shift is governed by two principles, according to Cole. One prohibits the neutralization of contrastive height categories, while the other one requires the preservation of the relative underlying height of raised vowels (see Cole 1998 for more discussion).

is filled by the spreading |i| component. In this way, according to the reviewer, it is possible to explain why lower mid is changed to a rising diphthong. (See Calabrese 1998 for further discussion of Maiden 1991.)

2.3.3 *Discussion of Walker's analysis*

Walker's (2005) article (see §2.1.3) not only provides an excellent description of metaphony in Veneto and other Italian dialects, but also an exhaustive overview of metaphony-like phenomena from a wide range of languages. Her analysis is the first to deal successfully and convincingly with all aspects of metaphony in an OT framework. Her constraint in (18) could provide a functional basis for the metaphony rule in (10). However, this can be true only diachronically, as an account of the phonological innovation that lead to metaphonic alternations. In contrast, it is difficult to hypothesize that the constraint in (18) is operative synchronically, at least for most Italian dialects where metaphony is morphologized or obscured by subsequent phonological processes (see §1). Functional explanations by their nature must be surface-true. This is not the case in Italian metaphony.

2.3.4 *Discussion of Nibert's analysis*

Nibert's analysis of the Servigliano dialects (see §2.1.4) holds only for this dialect and cannot account for the diphthongization or the dialectal variation we observe in the case of this phenomenon (see Zetterstrand 1998 for a criticism of Clements' 1989 approach to vowel height). Furthermore, as observed by Cole (1998), Nibert's analysis cannot deal with metaphony systems in which the low vowel also participates, undergoing a one-step raising to [e]. In such a system, a different [open] feature would have to assimilate for each of the low, low mid, and high mid vowels. Under an assignment of height features as in (24), raising [a] one step would require the assimilation of [−open 1], in addition to the assimilation of the features [−open 2] and [−open 3] required for the raising of [ɛ ɔ] and [e o], respectively. See Cole (1998) for further discussion of Nibert (1998).

2.3.5 *Discussion of Sluyters' analysis*

Sluyters' analysis (see §2.2.1) has several problematic aspects. Rule (24) is a rule of lengthening and applies independently of metaphony. It then predicts long vowels in all stressed syllables in non-metaphonic contexts. This is false. Lengthening in Italian dialects is restricted to open stressed syllables in penultimate position (Rohlfs 1966).[13] Furthermore, (24) must apply only to [−ATR] mid vowels, and not to the [+ATR] ones; otherwise it wrongly creates diphthongs in the case of the latter vowels. Rule (24) is thus simply wrong. The metathesis rule in (28) fares no better, and cannot be motivated either for Salentino or for any other dialects having metaphonic diphthongization. Furthermore, Sluyters' analysis does not account for either the tensing or the raising of mid [−ATR] vowels found in other Italian dialects.

[13] On the other hand, metaphonic diphthongization, as shown in Calabrese (1985, 1988), is not restricted to such an environment. It applies both in closed syllables and in stressed syllables of all types in antepenultimate position.

2.3.6 *Discussion of Cole's analysis*

Cole's (1998) functional analysis of metaphony (see §2.2.2) faces the same problems as Walker's (2005): it may hold diachronically for the stage of Italian in which metaphony was introduced as a phonological innovation, but it cannot hold synchronically for most, if not all, Italian dialects where metaphony is either morphologized or obscured by subsequent phonological processes. Another problematic aspect of her account involves diphthongization as a way to maintain contrasts. According to Cole:

> by diphthongizing a raised low mid vowel, the surface form unambiguously identifies the contrastive category of the vowel, countering the neutralization that would otherwise result from compressing four contrastive height categories into three. (1998: 93)

The problem is that metaphonic diphthongization of mid [−ATR] vowels also occurs in Sicilian or central Salentino dialects that have an underlying five-vowel system. Given that in these dialects there are no mid [+ATR] vowels, diphthongization cannot be explained as a way to counter the neutralization between the two sets of mid vowels.

3 Typological variation in metaphony as a height assimilation process

The term metaphony is also used to refer to processes of height assimilation in which features other than [+high] are spread. In this section I will survey the variation we find with respect to the features spread by metaphony across Romance.

3.1 *Metaphonic processes spreading* [+ATR]: *Sardinian metaphony*

There are Romance varieties in which we find metaphonic alternations that are better analyzed as involving the spreading of feature [+ATR], instead of [+high], of the high vowels. This is for example the case of Sardinian metaphony.[14] Frigeni (2003) discusses the following examples from Campidanese and Nuorese, the main varieties of Sardinian. Sardinian has the vowel system in (3).

(30) *Campidanese*

a.	*masc sg* [-u]	*fem sg* [-a]	
	'lentu	'lɛnta	'slow'
	'veru	'vɛra	'true'
	'nou	'nɔa	'new'
	'mot:u	'mɔt:a	'dead'
b.	*sg*	*pl*	
	'tempus	'tɛmpos	'time'
	'krop:us	'krɔp:os	'body'
	'betʃ:u	'bɛtʃos	'old (MASC)/parent'
	'ot:u	'ɔt:os	'vegetable garden'

[14] See also southern Salentino, discussed in §1.1, for another example of this type of metaphony (see also Grimaldi 2003).

THE REPRESENTATION OF WORD STRESS). In fact, in dialects such as Neapolitan, metaphony in words with antepenultimate stress appears to apply regularly across the non-high post-tonic vowel, although this occurs only when the final vowel is /i/: [ˈmɔnako ~ ˈmuonatʃi] 'monk (SG~PL)', [ˈtʃɛfaro ~ ˈtʃiefari] 'mullet (SG~PL)', [kaˈrɔfano ~ kaˈruofani] 'carnation (SG~PL)', [ˈfekato ~ ˈfiiekati] 'liver (SG~PL)' (Rohlfs (1966: 22). Note that these are intermediate representations; final [-o, -i] become [ə], due to a surface process of vowel reduction. However, there are also cases in which it applies before /u/: Centrache [ˈmuɔnaku] 'monk' (Lausberg 1939: 10; Rohlfs 1966: 427).[19] What matters in these cases is the target of the process – the stressed vowel – and the element that appears in post-tonic position can be disregarded. This type of situation is even more clear in the Asturian dialects that are characterized by [+high] metaphony (cf. [ˈnenos ~ ˈninu] 'child (MASC PL~SG)', [ˈtsobos ~ ˈtsubu] 'wolf (MASC PL~SG)' (Hualde 1998). In these dialects, metaphony also targets /a/, which is raised to a mid vowel. In words with antepenultimate stress, metaphony can target a stressed /a/ leaving unaffected a post-tonic /a/, as illustrated in the following examples.

(36) *Lena*

ˈpeʃaru	ˈpaʃarin	ˈpaʃara	'bird ~ little bird ~ female bird'
ˈpempanu	ˈpampanos	'old and decrepit person (MASC SG~PL)'	
ˈkendanu	ˈkandanos	'dry branch (SG~PL)'	

If metaphony is characterized as applying to the last foot, it cannot be explained why the intermediate vowel can be skipped over by this process. The best characterization of metaphony is not in terms of domain of application, but in terms of target of application: metaphony applies to stressed vowels.[20]

4.2 *Metaphony and morphology*

A debate that has existed for some time in connection with metaphony is the role of morphology (e.g. Maiden 1991; Hualde 1992). A central question is whether metaphony processes are conditioned by morphology, phonology, or some combination of the two. The fact is that in many Italian dialects, historical changes such as reduction to schwa, or deletion, of unstressed or final vowels can no longer be motivated synchronically through alternations. Since these historical processes removed the phonological conditions for metaphony, in these dialects the metaphonic changes affecting the stressed vowels have become the only surface markers of inflectional categories such as the masculine singular and

[19] In many, perhaps most, Italian dialects the phonological conditions for the application of metaphony in words with antepenultimate stress are obscured by schwa-reduction of post-tonic vowels [mɔnakə ~ muonəkə] (Campobasso; Rohlfs 1966: 22) or regressive total harmony between post-tonic vowels [ˈmɔnuku ~ ˈmwɛnitʃi] 'monk-(SG~PL)', [kɔfimu ~ ˈkwɛfini] 'barrel (SG~PL)', [ˈmjɛtucu ~ ˈmjɛtitʃi] 'physician-(SG~PL)' (Francavilla Fontana; Ribezzo 1912; Calabrese 1985). Metaphony is constrained by a further condition in many dialects: it applies only between adjacent vowels, so there is no metaphony in [ˈkɔfanu ~ ˈkɔfani] 'chest (SG~PL)', [ˈmɔnaku ~ ˈmɔnaki] 'monk (SG~PL)' (Aprigliano; Rohlfs 1966: 189, 427).

[20] Note that under such an analysis we still have to account for why the non-contrastive feature [−high] of the post-tonic vowel does not interfere with the metaphonic spreading process: either it must be underspecified or one must assume that the metaphony rule accesses only contrastive features, as in Calabrese's (1995) re-analysis of underspecification theory (see also Nevins 2010).

plural of nominal class II, the plural of nominal class III, the 2nd singular of the present indicative, etc. (CHAPTER 82: FEATURAL AFFIXES; CHAPTER 103: PHONOLOGICAL SENSITIVITY TO MORPHOLOGICAL STRUCTURE). Therefore they are most adequately analyzed in terms of a morphophonological rule. An example is provided below from Arpinate (see also (8) for examples in other morphological categories in this dialect) where the marking of the 2nd person singular is obtained solely through the application of metaphony to the stressed vowel of the verbal stem.

(37) *Metaphonic alternations in the present singular of verbs*

'vedə	'korrə	'sɛntə	'mettə	'kɔʎʎə
'vidə	'kurrə	'sjentə	'mittə	'kwoʎʎə
'vedə	'korrə	'sɛntə	'mettə	'kɔʎʎə
'see'	'run'	'feel'	'put'	'pick'

For the dialects in which metaphony is morphologized, Calabrese (1998) proposes the rule in (38), which must be specified as applying in morphological contexts such as the masculine singular and plural of nominal class II, in the plural of nominal class III, in the 2nd singular of the present indicative, etc.

(38) 
where x_1 is the head of the main stress foot

In the account developed above, metaphony was originally a phonologically motivated innovation that later became morphologized. However, an alternative view of how "morphological" metaphony developed is proposed by Devoto (1974). He assumes that, when in a language the exponence of inflectional categories is obscured or lost because of phonological processes, speakers of the language may react to the loss of morphological information by introducing alternative morphological realizations for these categories. Italian metaphony, according to him, then originated in order to realize morphologically the inflectional features whose exponence was threatened by the phonetic erosion of inflectional endings. This was done by marking the height features of the endings onto the stressed vowels. Under such an approach, metaphony is a morphologically motivated innovation. The presence of dialects that display metaphonic alternations and fully preserved inflectional endings – see for example the dialect of Servigliano in (5), which did not undergo changes neutralizing final vowels – shows that this idea is too strong (see Maiden 1991: 212 for more discussion). A recent contribution that argues for the relevance of morphology in the origin of metaphony is Finley (2009) on Lena, who labels metaphony as a type of "morphemic harmony" (see also Kurisu 2001, who analyzes umlaut as a kind of "morpheme realization").

A more nuanced position on the role of morphology in metaphony is taken by Maiden (1991), who argues that morphological conditioning does play a role in the development of at least some metaphonic processes. This is the case of the

111 Laryngeal Contrast in Korean

Young-mee Yu Cho

1 Introduction

Starting from the structuralist tradition (Martin 1951, 1954), and continuing into the generative framework, attempts to identify the laryngeal contrast in the obstruent system of Korean have led to intense discussion. Even today, it is one of the areas that still actively engage researchers of Korean grammar.

There is general consensus that on the surface there are three types of phonation in Korean; to be more precise, there is a three-way contrast for stops and a two-way contrast for fricatives, as shown in the consonantal inventory in (1).[1]

(1) *Korean consonantal phoneme inventory*

	labial	alveolar	prepalatal[2]	velar	glottal
plain stops	p	t	ts	k	
aspirated stops	pʰ	tʰ	tsʰ	kʰ	
tense stops	p'	t'	ts'	k'	
plain fricatives		s			h
tense fricatives		s'			
nasals	m	n		ŋ	
liquid		l			

(2) lists minimal pairs exemplifying the consonantal inventory of (1).

[1] The two fricatives /s/ and /s'/ exhibit an interesting array of paradoxical behavior. They clearly pattern as plain and tense consonants respectively in phonology, as demonstrated in such phenomena as post-obstruent tensing and the consonantal correspondences in sound symbolism, but their phonetic behavior is less clear. Building on Kagaya's characterization of laryngeal contrasts in terms of glottal width at the moment of articulatory release, Iverson (1983) concludes that the /s/ belongs to the lax category in phonology, and he claims that it even undergoes the intervoiced slackening process, if not voicing itself, as do the other lax obstruents. In contrast to its phonological behavior, /s/ could be better characterized phonetically as an aspirate. On the other hand, T. Cho *et al.* (2002) arrive at the conclusion that it is better characterized as "lenis" than as "aspirated," mainly on the strength of the observation that it is unaspirated medially and sometimes undergoes gradient voicing in a parallel fashion to stops.

[2] Regarding the place of articulation for the affricate series, there is some debate whether they are dental (H. Kim 1999) or alveopalatal, as most phonologists assume, but in this chapter I eschew the controversy and represent the affricates as /ts tsʰ ts'/. Nothing crucial hinges on this particular characterization.

(2) *Korean laryngeal contrasts exemplified*

pul	'fire'	p^hul	'grass'	p'ul	'horn'
tal	'moon'	t^hal	'mask'	t'al	'daughter'
tsa-ta	'to sleep'	ts^ha-ta	'to kick'	ts'a-ta	'to be salty'
koŋ	'ball'	k^hoŋ	'bean'	k'oŋ	'frozen'
sal	'flesh'			s'al	'rice'

Plain consonants (also called "lenis" or "lax" consonants) are produced with slight aspiration in word-initial position, while aspirated consonants are heavily aspirated. In addition, it should be noted that plain obstruents undergo systematic changes in medial positions. They become voiced between voiced segments within a phonological phrase, except for /s/, and are realized as tense consonants after any obstruent. As mentioned in footnote 1, phonetically intervoiced slackening of fricatives might be considered the same process as intersonorant voicing (T. Cho *et al.* 2002). The same slackening process in the voicing environment may be also responsible for the relatively newly emerged obligatory disappearance of intersonorant /h/, as in /tsoh-a/ → [tsoa] 'to be good-CONT'. In final position, all obstruents are unreleased and, as a result, there is no aspiration or realization of tenseness.

The tense series (sometimes termed "fortis" consonants) is characterized by some sort of "laryngeal tension." Whereas voicing and aspiration are cross-linguistically common laryngeal features for obstruent systems, having a tripartite system involving aspiration and tenseness within one language is rather unusual. This rare pattern has motivated a number of researchers to argue against the existence of a tense contrast in Korean; in more radical cases, both features of the laryngeal contrast are re-analyzed as non-laryngeal features, which will be the topic of §3. Not only tense, but also aspirated, consonants are treated as geminates, and their phonetic properties are derived from the structural configuration rather than from phonetic features.

The unsettled state of laryngeal contrasts in Korean in some ways reflects the diachronic emergence of laryngeal obstruents; according to Poppe (1965) and Starostin *et al.* (2003), the Proto-Korean consonant system lacked phonemic aspiration and tenseness. By early Middle Korean, the aspirated series had emerged – first labials and dentals, followed by velar aspirates – as evidenced by the way Chinese aspirated consonants were adopted into Middle Korean (Park 1996). By early Modern Korean, tense consonants (or geminates for those who do not assume tense consonants as a single phoneme) emerged from consonant clusters resulting from vowel deletion and the ubiquitous addition of the linking /s/ between morphemes (K. M. Lee 1985).[3]

Treating tense consonants as phonologically geminate versions of the corresponding plain consonants might have the advantage of doing away with a rather unusual phonation contrast, i.e. the coexistence of aspiration and tenseness within one and the same system, but it carries the burden of explaining why it is better to interpret surface tension as a phonetic property of length contrast derived from the geminate property.[4] The geminate account of tense consonants

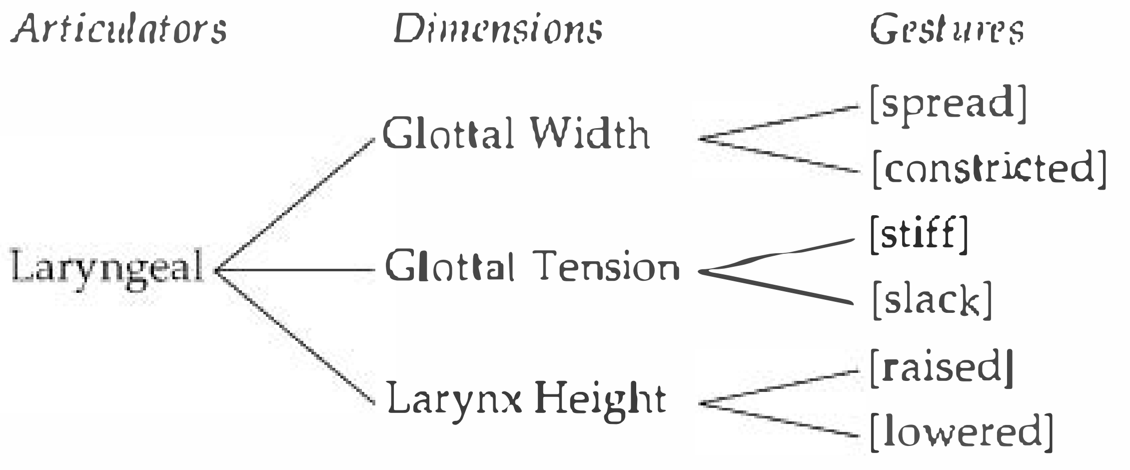
[3] Among tense consonants, the affricate /ts'/ is the last one to emerge.

[4] As an anonymous reviewer points out, there are a number of languages with a fortis/lenis contrast, such as Upper Cross languages like Lokka and Leggbo, in which there is evidence (e.g. vowel shortening before tense consonants) to treat fortis consonants as geminates.

(1971). More recently, S.-C. Ahn and Iverson (2004: 13) have drawn attention to two aspects of difference between typical ejectives and Korean tense consonants: (i) Korean in-phase constriction *vs.* persisting glottal closure of ejectives, and (ii) a raising effect on the pitch of the following vowel by Korean tense consonants, as opposed to a lowering effect by ejectives (Kingston 1985).

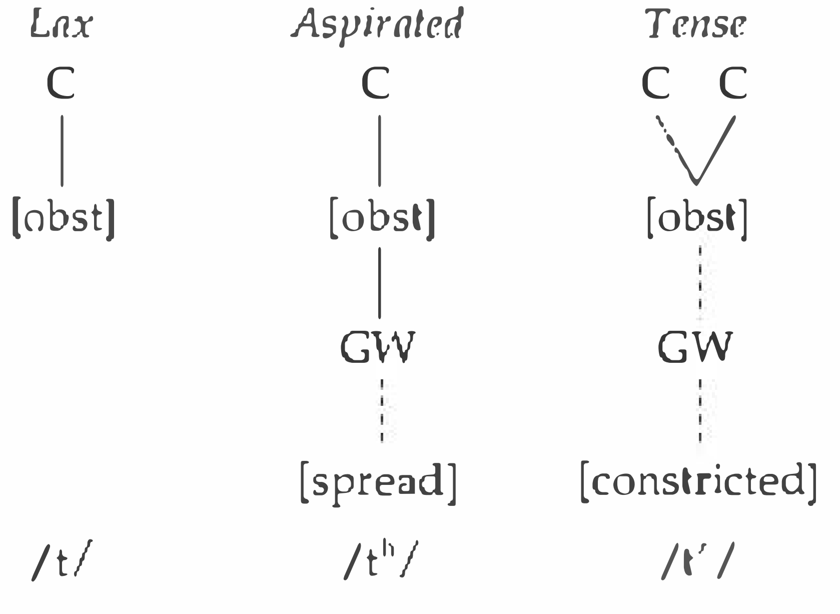
S.-C. Ahn and Iverson (2004) employ Avery and Idsardi's (2001) Dimensional Theory. In this theory, the Laryngeal articulator is defined by three dimensions, Glottal Width, Glottal Tension and Laryngeal Height, as shown in (3) (see also CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION).

(3) *Geometry of laryngeal representation in Dimensional Theory* (Avery and Idsardi 2001)



Glottal dimensions implicate antagonistic "gestures," and in particular, Glottal Width implicates two antagonistic gestures of [spread] and [constricted]. For theory-internal reasons and in an attempt to account for cross-linguistically robust laryngeal patterns, only one member of a gestural pair is stipulated to function contrastively in a given system (see also CHAPTER 2: CONTRAST). This set of assumptions predicts that no language will have tense and aspirated consonants contrasting with lax consonants at the same time. According to this theory, tense consonants in Korean are phonetically augmented with Glottal Width, resulting in surface tension, but they are characterized neither by Glottal Width nor by Glottal Tension phonologically. On the phonemic level they are laryngeally lax, with their phonetic property being derived from geminate structure, implemented by "Korean Enhancement," a language-specific redundancy. (4) illustrates the contrast with the dimension of Glottal Width only, because the other dimensions, Glottal Tension and Larynx Height, are not relevant in Korean.

(4) *Korean obstruent contrasts in Dimensional Theory* (S.-C. Ahn and Iverson 2004)



Also contributing to the complications are recently observed acoustic facts that contemporary Seoul Korean may be developing a tonal system in lieu of laryngeal contrasts (see also CHAPTER 97: TONOGENESIS). According to S.-C. Ahn and Iverson (2004), Silva (2006), and Wright (2007), over the past 40 years Seoul speakers have shown a dramatic change in their use of VOT to mark the language's distinction among tense, lax, and aspirated stops. Data indicate that while VOT for tense stops has not changed since the 1960s, VOT differences between lax and aspirated stops have decreased, in some cases to the point of complete overlap. Concurrently, the mean F0 for words beginning with tense or aspirated stops has become significantly higher than the mean F0 for comparable words beginning with plain stops.[6]

Silva's proposal of tonogenesis is quite interesting, in that it mirrors a cross-linguistically common pattern reported for Tibetan (Duanmu 1992) and Kamuu (Svantesson and House 2006), but perhaps it is too early to assume that the laryngeal contrast in Korean is being completely replaced by tones, as the new development is observed in only some speakers of Korean, and only Seoul speakers at that. Silva's position can be summarized as follows: (i) the underlying contrast between lax and aspirated stops that is maintained by younger speakers is phonetically manifested in terms of differentiated tonal melodies, rather than by laryngeal features, and (ii) laryngeally unmarked (lax) stops trigger the introduction of a default L tone, while laryngeally marked stops (aspirated and tense) introduce H, triggered by a feature specification for [stiff]. To distinguish the tense series from the aspirates, however, VOT or some sort of laryngeal features is needed, since both phrase-initial aspirates and tense stops should be marked by a High tone. In addition, the less flamboyant behavior of phrase-medial stops needs to be accounted for.[7] In order to explain this new phenomenon, Silva proposes a replacement of the feature of glottal aperture [spread glottis] and [constricted glottis] with a more abstract laryngeal "tensity feature," [stiff], in the spirit of C.-H. Kim (1965). According to Silva (2006), this single feature has the advantage of unifying the VOT distinction on the one hand and expanding to characterize the newly emerging tonogenesis.

M.-R. Kim and Duanmu's (2004) categorization of "lax" stops as voiced stops and "tense" stops as regular voiceless unaspirated stops is another attempt to do away with an additional feature of tensity as well as to explain the above-mentioned consonant–tone correlation. Their rather unorthodox classification is based on Kingston and Diehl (1994: 435), who attribute the paradoxical behavior of a voiceless unaspirated stop which may both elevate and depress F0 to the phonological specification of these phones:

> when it represents the [−voice] category, as in Hindi, Thai, Spanish, French, Portuguese, Italian, and Japanese, then F0 is elevated; but when it represents the [+voice] category, as in English, German, Swedish, Danish and Korean, then F0 is depressed.

[6] It should be noted that the affricates pattern in exactly the same way as the stops in phonology, e.g. in processes such as intersonorant voicing and accentual realization (Y. Y. Cho 1990b; S.-A. Jun 1993) as well as in morphology as manifested in sound symbolism (Y. Y. Cho 2006).

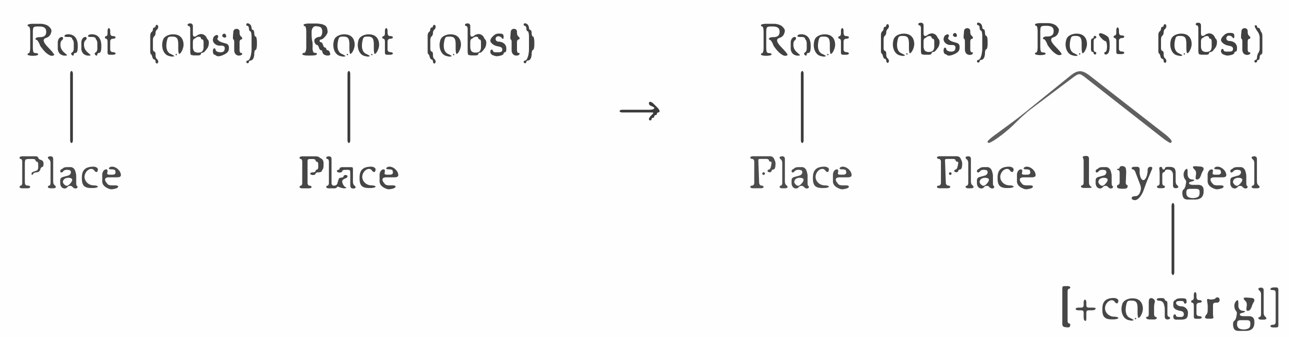
[7] Jun, in her analysis of the Chonnam Accentual Phrase (1993: 53), also observes that when the phrase-initial segment is either a tense or an aspirated obstruent, the HHL tonal pattern is chosen instead of the usual LHL. It is interesting to note here that /s/ triggers the HHL pattern in parallel with the other laryngeal obstruents.

dimension of contrast, namely gemination. Alternatively, a few more extreme unary analyses emerged where no underlying laryngeal contrast is assumed, and the so-called "tense" and "aspirated" consonants acquire their surface specifications by other means (S.-H. Kim 1989; J. Jun 1994).

The singleton analysis of tense and aspirated consonants acquires its primary support from the restrictions on Korean syllables, in particular from the fact that no clusters are allowed in onset position in Modern Korean. If tense and aspirated consonants that freely occur in syllable-initial position are singletons with a unique laryngeal specification, nothing more needs to be said with regard to tense consonants or aspirates. On the other hand, if these laryngeal consonants are geminates, a further stipulation is required about this unexpected distribution. If laryngeal consonants were geminates in Korean, these would be the only type of clusters allowed in onset position, a highly unlikely phenomenon cross-linguistically.[9] Therefore, even people who espouse the geminate nature of tense consonants treat these as singletons on the surface, with phonetic tenseness being derived from the underlying geminate structure.

J.-I. Han (1992, 1996) is worth mentioning, because her work is the most concrete and detailed in the debate. She observes that there is a significant difference in length between intervocalic tense consonants on the one hand and word-initial tense and intervocalic plain consonants on the other. Word-initial tense consonants are singletons, due to Stray Erasure, thereby avoiding the problem associated with the syllable structure condition against onset clusters. The manifestation of tenseness comes from its geminate structure; i.e. tense consonants are plain geminates underlyingly. Furthermore the relationship between length and tension is explained by stipulating that the surface tension is derived from the underlying geminate structure by a rule of Geminate Reinforcement (5), which inserts the tense feature on all geminate obstruents.

(5) *Geminate Reinforcement* (J.-I. Han 1996)



However, a problem with this account's reliance on closure duration is that, as noted by Y. Y. Cho and Inkelas (1994), not only tense consonants but also

[9] A further study is needed to support the position espoused here that all geminates are clusters. An anonymous reviewer wonders whether all languages that allow initial geminates allow non-geminate clusters initially. According to Stuart Davis (personal communication; see also CHAPTER 37: GEMINATES), there are two types of languages with initial geminates: those in which the initial geminate is the only type of initial cluster and those that allow almost any type of initial cluster, including geminates. While languages like Trukese (also called Chuukese) and Pattani Malay have initial geminates but do not have initial consonant clusters, there are languages like Leti and Moroccan Arabic that have initial geminates as well as initial consonant clusters (Muller 2001). He also points out that in languages that have geminates as well as onset clusters with sonority restrictions, the geminates typically cannot occur in initial position (e.g. Italian). This line of typological argument would not be decisive either for or against the geminate analysis of tense consonants in Korean.

aspirated consonants have been observed to be longer than plain consonants in intervocalic position (Pyo-Ih 1973; Zhi 1982, cited by S.-H. Kim 1989), although the length contrast is not as pronounced in the aspirated case (Silva 1992). According to some measurements, if duration were the primary phonetic indicator of phonological geminates, aspirated consonants would have to be considered geminates as well. These moves would lead to a drastic reduction in the number of phonemic contrasts in Korean: instead of three series of obstruents, there would be only one type of laryngeal consonant, and, moreover, all of its laryngeal members would be geminate. Furthermore, the distinction between the tense and aspirated consonants would be derived from yet another contrast, probably an unnecessary complication in the grammar. Finally, getting rid of all laryngeal contrast seems implausible in view of the cross-linguistic generalization (noted by Scobbie 1991) that in any language the inventory of geminate consonants is a subset of singleton consonants.[10]

One issue with the data in J.-I. Han (1996), as well as in subsequent publications, is what kind of speech was used in measuring the duration of intervocalic tense consonants. In particular, it has often been observed that certain intervocalic tense and aspirated consonants are phonologically geminated in emphatic speech. In particular, as illustrated in (6b), it has words whose intervocalic tense or aspirated consonant cannot be geminated.

(6) *Gemination in emphatic speech (optional)*

a. *Emphatic speech gemination*

ap'a	app'a	'Dad'
ak'a	akk'a	'a while ago'
tok'i	tokk'i	'ax'

b. *Emphatic speech gemination is not allowed in non-initial syllables*

atsəs'i	*atsəss'i	'uncle'
tsaŋats'i	*tsaŋatsts'i	'pickle'

It so happens that all of Han's examples of intervocalic tense consonants belong to the class in (6a), and can be readily geminated in slow emphatic speech. Thus it is not clear that extra duration must be attributed to the putative underlying geminate status of tense consonants, or whether it might not in fact be due to emphatic rendering of these forms by the subjects in the experiment, especially in the citation forms.

Han's other argument comes from the phenomenon of degemination, in which, as shown in (7), a sequence of homorganic plain obstruents is often simplified in allegro speech (Kim-Renaud 1987; see also CHAPTER 79: REDUCTION).

(7) *Allegro speech degemination*

ak+ki	akk'i	ak'i	'musical instrument'
tat-ta	tatt'a	tat'a	'to close'

[10] In view of the cases where there is a kind of complementarity, for instance *ww* vs. *bbw/ggw*, or Italian affricates that always surface as geminates, as pointed out by an anonymous reviewer, Scobbie's generalization may be revised to a weaker form.

contrast in emphatic speech is in itself sufficient to undermine any account in which all tense consonants are underlyingly plain geminates which tensify and degeminate by later processes.[13]

J.-I. Han (1996) uses as a piece of supporting evidence an allegedly robust typological tendency for sonorant geminates to occur with obstruent geminates in many languages, rather than having only sonorant geminates in one given system (CHAPTER 8: SONORANTS). Such would be the case in Korean, if a singleton analysis were to be adopted. However, invoking this general tendency as one of the arguments is not fully warranted at this point. While sonorant geminates are clearly distinct from a single sonorant, as exemplified in (9), the supposed minimal pairs (e.g. /tal/ *vs.* /t'al/ and /aka/ *vs.* /ak'a/) have a different status from sonorant geminates, thus undermining an attempt to establish the geminate contrast in obstruents. The short and the long forms of obstruent geminates are mere variants in the ESG environment, which the geminate account would be hard-pressed to account for.

(9) *Tautomorphemic sonorant geminates*

manna-	'to meet'	an-	'to hug'
kənnə-	'to cross'	kam-	'to wind'
nolla-	'to be surprised'	al-	'to know'
əmma	'mom'	ama	'perhaps'
pəlle	'worm'	alɛ	'below'

In sum, none of the arguments for the geminate account of tense consonants seems to be compelling enough to rule out the view of these consonants as single phonemes, at least morpheme-internally.

It has been claimed, however, that a certain explanatory economy is gained by the geminate account in morphology. What is relevant is the fact that partial reduplication (CHAPTER 100: REDUPLICATION) of bases with tense and aspirated onsets results in the loss of tenseness and aspiration on the second syllable, as illustrated in (10).

(10) *Loss of laryngeal features in partial reduplication* (J. Jun 1994)

tsulu	tsulu-lu-k	'falling rain'
asak	asa-sa-k	'crunchy'
tʰaŋ	tʰa-ta-ŋ	'bang'
p'aŋ	p'a-pa-ŋ	'exploding'
ts'ik	ts'i-tsik	'(the sound of) tearing'

In a pioneering theoretical approach, J. Jun (1994) proposes a generalized account of Korean reduplication, based on the assumptions listed in (11).

[13] In order to see if there is a clear durational difference between lax and tense consonants in intervocalic position that cannot be reduced to ESG, we need data where the laryngeally marked consonants appear in contexts where ESG cannot apply. The currently available studies examine consonants in CVCV context, and all involve a list of citation forms obtained in an experimental setting, rather than from natural speech.

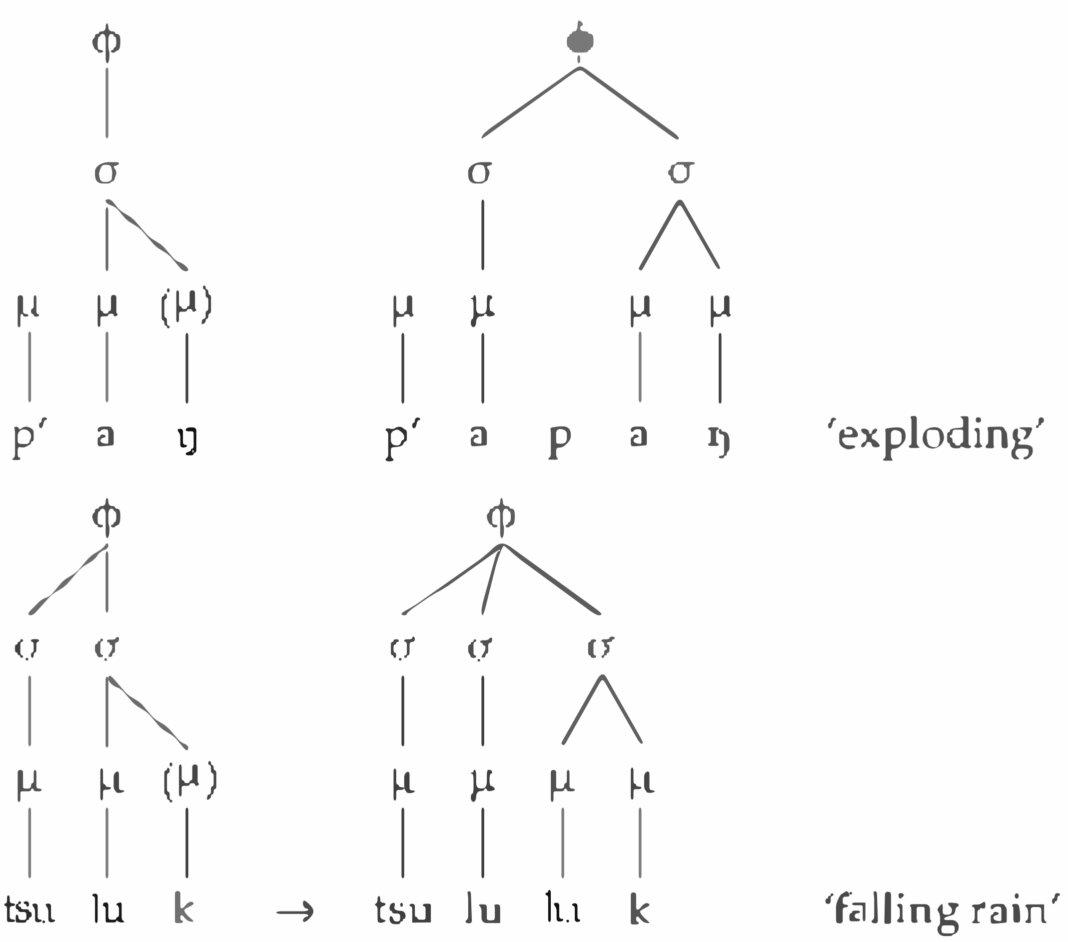
(11) *Phonological assumptions*

a. In both input and output, a closed syllable constitutes a single foot.
b. The final base syllable is suffixed, with its coda deleted.
c. Laryngeal consonants are geminates.
d. Coda consonants are moraic.

His analysis of reduplication crucially relies on the principle of Metrical Weight Consistency, which requires that the number of metrical feet in the input be conserved in the output. This principle is based on the following assumptions about foot structure, moras, and syllable weight. The base for reduplication consists of one foot with a final heavy syllable, and the output also observes the same weight constraint. He assumes the Korean foot to be quantity-sensitive, right-headed, unbounded, and constructed from the left edge, without any motivation from the rest of the Korean grammar. Moreover, treating tense and aspirated consonants as geminates is essential in calculating metrical weight. In this account, the loss of the laryngeal feature in partial suffixal reduplication (e.g. /p'aŋ/ → [p'a-paŋ], /tʰaŋ/ → [tʰa-ta-ŋ]) is accounted for by demorification (the loss of a mora), so that the output can remain as a single foot, with any number of light syllables occurring before the last mora-bearing consonant.[14] Laryngeal feature loss in the reduplicant is an automatic consequence of applying metrical weight consistency. All the inputs to partial reduplication contain a single foot (either a single heavy syllable or a disyllabic stem consisting of a light syllable and a heavy syllable). As a consequence, the output words should contain only one foot. If the output were to preserve the laryngeal features on the second syllable, as in *[p'a-p'aŋ], then the tense consonant would be moraic, making the output consist, incorrectly, of two feet.

Based on (11), some derivations are shown in (12).

(12) a. / b.



[14] One piece of evidence for this is multiple outputs such as [p'a-paŋ], [p'a-pa-paŋ], [p'a-pa-pa-paŋ], [p'a-pa-pa-pa-paŋ], etc. There are other ways to handle iteration in other approaches; one straightforward way would be to have reduplication reapply to its own output.

It is, however, extremely plausible to have an optimality account of partial reduplication whereby the loss of laryngeal features is merely a case of emerging unmarked constraints by relevant constraint ranking. In fact, the Emergence of the Unmarked (TETU; CHAPTER 58: THE EMERGENCE OF THE UNMARKED), the name given to the striking tendency of reduplicants to be "less marked" in some dimension than in the language generally, is an effect that helps elucidate phonological constraints of Universal Grammar in Optimality Theory (McCarthy and Prince 1993, 1994; Prince and Smolensky 1993). There are numerous examples of TETU in the literature that are motivated by the very architecture of Optimality Theory. For Korean partial reduplication, there is consequently no need to represent tense and aspirated consonants as geminates, nor any need to invoke J. Jun's foot type (quantity-sensitive, unbounded, and right-headed), which seems to play no role in other parts of Korean phonology. Like other TETU cases, a particular ranking produces a TETU effect of selecting a reduplicant without a coda consonant. This loss of laryngeal features is accomplished by sandwiching the markedness constraint, NoLaryngeal, between IO-faithfulness and BR-faithfulness; Ident-IO protects underlying laryngeal features, whereas the ranking NoLaryngeal >> Ident-BR[Lar] chooses the output without laryngeal specification, as in [t'a-ta-k]. The TETU effect, which militates against laryngeal features, is accounted for by the relative ranking of markedness and faithfulness constraints, in exact parallel to other TETU cases. When re-analyzed from this theoretical angle, there still seem to be no compelling arguments from Korean morphophonology for the geminate analysis of laryngeal consonants.

As laid out in the preceding discussion, researchers differ in their analyses of the two types of laryngeal consonants, some arguing that (i) tense consonants should be treated as singletons on a par with plain consonants, differing only in the specification of laryngeal features, and others that (ii) tense consonants pattern with aspirated consonants. Even though there are many parallels between tense and aspirated consonants, most studies readily accept the existence of an aspiration contrast, but not that of a tense contrast. This is due mainly to the phonetic characteristics of tense consonants and the typological rarity of a system with a simultaneous aspiration/tense contrast, but not voicing, as detailed in §2 (Kingston and Diehl 1994; S.-C. Ahn and Iverson 2004; M.-R. Kim and Duanmu 2004). Given that a substantial number of arguments for the geminate analysis apply to both of the laryngeal consonants, the burden falls on the proponents of the geminate analysis to clarify how the two types of laryngeal consonants pattern together or differently, and to choose in a principled manner which patterns are relevant for establishing the laryngeal contrast in Korean.

In the discussion of laryngeal contrasts, Korean Post-Obstruent Tensing (POT)[15] is quite relevant. Plain obstruents in Korean undergo tensification immediately after another obstruent (Kim-Renaud 1974), as illustrated in (13a).[16] The obstruents in (13b) are not subject to POT, since they are not preceded by an obstruent.

[15] POT should be distinguished from other processes of tensification such as post-nasal tensing in verbal morphology (e.g. /an-ta/ → [ant'a] 'to sit-verbal ending') and post-lateral coronal tensing in the Sino-Korean vocabulary (e.g. /il-tsa/ → [ilts'a] 'one word').

[16] As noted earlier, the behavior of lenis fricative /s/ is ambiguous. It undergoes POT, as in /pat-so/ → [pats'o] 'to receive-verbal ending'; but it is not voiced in an inter-sonorant environment, unlike the other plain obstruents, although Iverson (1983) regards the slackening of [s] as the same process of voicing.

Following Cook (1987), Y. Y. Cho and Inkelas (1994) assume that the so-called "*Bindungs*-/s/," which applies in the sub-compounding construction in (15b), involves morphological gemination. This is supported by the fact that the effects of the *Bindungs* element appear only when the second member of the compound begins with a consonant.[18] Note that even those morphologically derived geminates are, due to a preceding consonant, simplified to singletons and surface as tense. From this it can be concluded that POT is fed by gemination, as in [mukk'uk] and [pamt'otuk], regardless of whether or not the geminates which undergo POT ultimately survive to the surface.

A closely related problem has to do with the domain of Post-Obstruent Tensing. As observed in Y. Y. Cho and Sells (1995), the domain of POT is the phonological word.[19] As illustrated in (16), tensing applies within underived words, as in [kaks'i] 'bride', within lexical compounds, as in [talk k'ogi] 'chicken meat', between a clitic and its host (as in [hal s'u] 'ability to do' and [kal p'a] 'way to go'), and between a stem and a case marker or a verbal suffix. It is, however, blocked between two phonological words, as shown in (16d).

(16) *Post-Obstruent Tensing as word-level process* (Y. Y. Cho and Sells 1995)

a.	*Monomorphemic forms*			
	kaksi	→	kaks'i	'bride'
	maktɛ	→	makt'ɛ	'stick'
b.	*Compounds*			
	talk+koki	→	talkk'ogi	'chicken meat'
	pat^h+kolaŋ	→	patk'oraŋ	'furrow'
c.	*Host + clitic*			
	halC su	→	hal s'u	'ability to do'
	kalC pa	→	kal p'a	'way to go'
d.	*Phrasal combinations*[20]			
	k'amp'ak kolat'ɔlɔtsita	→	ka'amp'ak korat'ɔrɔdzida	'doze off'
	pap tewə	→	pap tewə	'warm the rice'

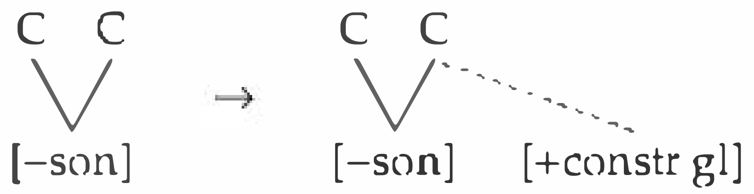
Again, if Han is to be able to relate the two tensification environments and capture Post-Obstruent Tensing and "Geminate Reinforcement" as the same process, the facts in (15) would require that Geminate Reinforcement (GR) precede POT, and therefore that it apply at the word level or earlier. This is in conflict with Han's claim that GR is a late phonetic rule. J.-I. Han (1996) collapses GR and POT as a single process in response to this particular opposition. Two separate rule formations in (17) are unified as the generalized form in (5). GR and POT each target geminates and singletons separately and are completely unrelated, although the effect in both cases is to insert the tense feature ([+constricted glottis]) on an obstruent in the post-obstruent position.

18 The only exception to this generalization involves the morpheme /u/ 'upper' as in /u+əlini/ → [utɔlin] 'elders'.

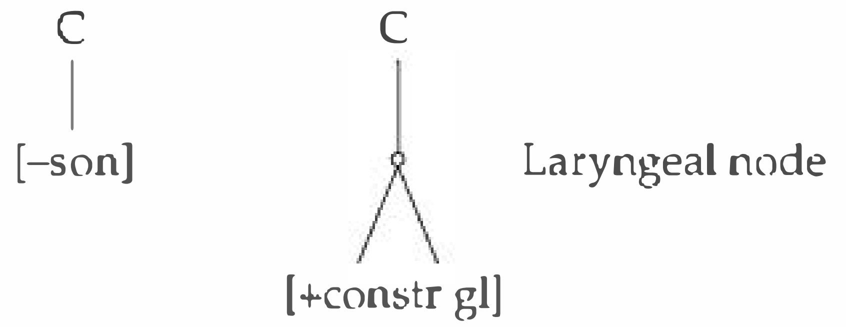
19 Choi (1991) claims that POT is a post-lexical rule whose domain is larger than a phonological word, but all of his data involve cases in which plain and tense consonants occur in free variation in casual speech and in certain dialectal forms, as in /tsuŋkuk/ and /ts'uŋkuk/ 'China', /təntsita/ and /t'əntsita/ 'to throw'.

20 S.-A. Jun (1993) proposes that POT is bound by Accentual Phrase and is attested across word boundaries in close phrasal combinations.

(17) a. *Geminate Reinforcement*

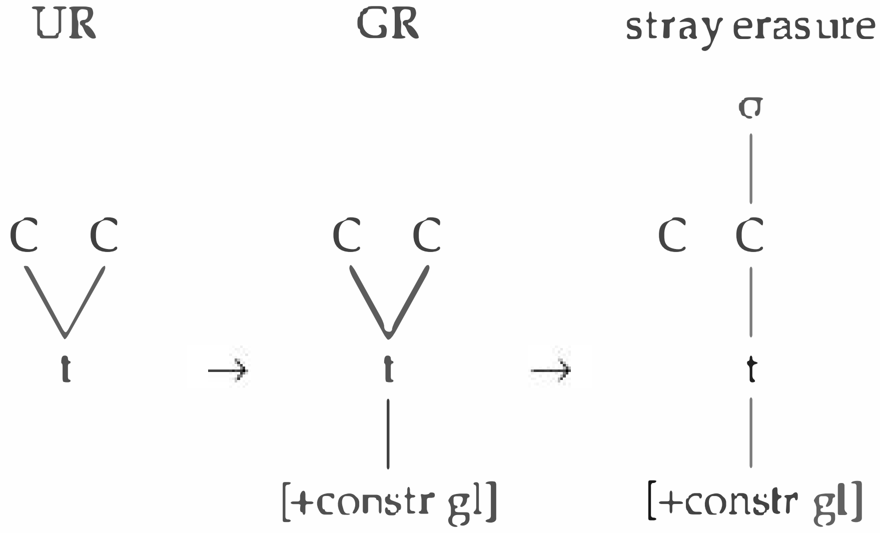


b. *Post-Obstruent Tensing*



As a process of phonetic implementation, GR interacts with stray erasure for the purpose of syllabification, and simplifies abstract geminates to their surface singleton counterparts in word-initial position, as shown in (18):

(18) *Geminate Reinforcement precedes stray erasure* (J.-I. Han 1992)



As a consequence, stray erasure must also be treated as a late phonetic rule. However, this is at odds with the fact that Korean syllabification is a cyclic process (CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME). Inasmuch as stray erasure is connected to syllabic well-formedness, it ought also to apply cyclically. There is some positive evidence for this as well. As argued in Kang (1992) and E. Han (1993), the domain of lexical syllabification is a sub-lexical constituent consisting of a stem and a suffix. Prefixes and the individual members of a compound form separate syllabification domains, as illustrated by the example /nəks+əps-i/ → [nəkəps'i] 'listlessly'. In this form, the unsyllabifiable cluster [ks] is simplified, because it precedes a compound juncture and is thus domain-final; [ps], by contrast, is not simplified, as it precedes a suffix with which it can syllabify. The fact that stray erasure, which is responsible for the simplification of obstruent clusters, is sensitive to morphological boundary distinctions confirms its lexical status and may be used to argue against any analysis that treats stray erasure as a late phonetic process.[21]

[21] An anonymous reviewer suggests an analysis whereby syllabification is bound by prosodic word, but stray erasure only applies at the end of derivation. This account goes against the received view of the morphology–phonology interaction, where earlier-level processes are closed off and are opaque to following operations (Kiparsky 1982; Inkelas 1990, forthcoming; Anttila 2002). Until an alternative theory is put forward to supersede this view of morphology–phonology interface, this option is not tenable.

4 Conclusion

The previous sections described two opposing positions regarding laryngeal contrast in Korean. One camp advocates treating tense consonants (and in some cases aspirated consonants as well) as geminates, thus eliminating the distinctive feature(s) referring to tenseness (and aspiration in some cases) in phonology and obtaining the phonetic realization of tenseness as a by-product. The other camp assumes that Korean obstruents manifest a three-way distinction, which cannot be further reduced, thus refuting the evidence from historical evolution and phonetic idiosyncrasy. When a three-way laryngeal distinction is maintained, the simple onset structure of Korean syllables can be maintained without further stipulation, while the economy gained in the account of laryngeal contrast needs to be compensated by complications in the treatment of syllabification and the different behavior of plain *vs.* laryngeal consonants. Some arguments for both positions are more theory-internal than others, but we can safely conclude this chapter with the following observations.

(23) *Generalizations about Korean laryngeal contrast*

a. Having tense and aspiration in one system is quite unusual cross-linguistically, thus motivating some researchers to do away with tense consonants in phonology, although there is no systematic study that argues for removing both tense and aspiration features from phonology.[24]

b. Phonetic details on Korean laryngeal contrast are quite complicated; such considerations as glottal width, laryngeal tension, VOT, and even High-tone association have been used to argue for a certain phonological position.

c. Tense and aspirated consonants are not always treated in the same manner in the geminate account; some treat only the former as geminates, but others treat both as geminates. In the latter case, no explanations have been offered to account for the total absence of laryngeal features in Korean.

d. Treating tense (and sometimes aspirated) consonants as geminates purely on the basis of phonetic length is ambiguous, and comparing length in initial *vs.* medial positions is not yet well established.

e. Arguments based on moraic distinction between singletons and geminates in Korean seem untenable, and thus cannot be used to support the position that laryngeal consonants are structurally geminates.

f. Laryngeal consonants in a particular medial position can be lengthened to close the previous syllable, but because of the restricted environment and the optional nature of gemination, this fact cannot be used to argue for tense consonants as geminates across the board.

[24] Keren Rice (personal communication) points out that it is not unusual to have tenseness and aspiration in one system when tenseness involves glottalization, but it is clear that Korean tense consonants are not glottalized.

g. Post-Obstruent Tensing, a robust phenomenon in Korean, is treated as the same process of Geminate Reinforcement (or Korean Enhancement) by the proponents of the gemination analysis. While it is true that all obstruents in post-obstruent position are tensed, it still remains to be demonstrated that all instances of tense consonants can be derived from POT.

112 French Liaison

Marie-Hélène Côté

1 Introduction

Liaison is a type of external sandhi, one of several occurring at word boundaries in French. It corresponds to the pronunciation of a consonant (liaison consonant = LC) between two words, the second being vowel-initial, in certain liaison-triggering contexts. Liaison may apply categorically or variably, depending on the context. The data in (1) illustrate this process. The words preceding and following the LC are referred to respectively as Word1 and Word2; their canonical pronunciation in non-liaison contexts, including in isolation, is indicated in the relevant columns. In (1b), for example, the words *vous* and *allez* are pronounced in isolation [vu] and [ale]; when the two words are concatenated, an intervening [z] surfaces. LCs are underlined in all examples for ease of identification.[1]

(1)

			Word1	*LC*	*Word2*	*Context*
a.	*un homme*	'a/one-MASC man'	[œ̃	n	ɔm]	det + noun
b.	*vous allez*	'you-PL go'	[vu	z	ale]	pronoun + verb
c.	*grand ami*	'big-MASC friend'	[gʁɑ̃	t	ami]	adj + noun
d.	*très utile*	'very useful'	[tʁɛ	z	ytil]	adv + adj

Most LCs originate from fixed final consonants that progressively ceased to be pronounced between the twelfth and the sixteenth century, first before a consonant, later at the pause. These consonants remained only in prevocalic position between words displaying a high degree of cohesion. Some LCs also evolved through analogy as part of restructuring processes affecting liaison (see Morin 1986 for a discussion of final consonants in the history of French). The system of liaison has been in evolution for almost a millennium and is still subject to change and reinterpretation.

[1] In most cases, only word-by-word translations are provided. Grammatical information such as PL and MASC is added when relevant, if it is not already clear elsewhere in the example. The word-by-word translation is followed by a free translation (introduced by "=") when the literal translation is opaque or when minimal pairs with the same lexical material but different meanings are involved.

Liaison is a complex and multifaceted phenomenon, involving various components of linguistic analysis. As a segmental process that finds its historical source in unexceptional cases of coda reduction, it is considered essentially phonological. But its synchronic conditioning goes much beyond phonology as traditionally defined. Liaison in contemporary French raises a number of challenging descriptive and analytical issues, pertaining to the status of LCs and the segmental, prosodic, and morphosyntactic contexts in which they surface. It has figured prominently in a number of important theoretical debates in the last half-century, including abstractness in phonology, autosegmental representations, the syntax–phonology interface, and, more recently, the roles of frequency and usage.

The analysis of liaison is complicated by the variability and controversial nature of some of the data on which it is based (see Morin 1987). Even within what may be referred to as Standard French (see Francard *et al.* 2000–01), the use of liaison is subject to substantial sociolectal and stylistic variation (CHAPTER 92: VARIABILITY). Dialectal differences are also observed. Formal accounts of liaison tend to rely on a relatively limited set of conventionalized generalizations. Standard adult data and theory-internal arguments have been increasingly complemented, however, with results from a variety of perspectives: corpus studies of spontaneous and formal French, acquisition, psycholinguistics, phonetics, and liaison errors in adults. This empirical renewal has led to a more nuanced understanding of the functioning of liaison, its conception as a unified phonological process having partly given way to a multidisciplinary and fragmented approach.

The chapter is organized as follows. §2 provides basic data and concepts, organized around two dimensions of liaison: the LCs, and the contexts in which they occur. This presentation sets the stage for the discussion of two central analytical issues in the study of liaison: the nature and status of LCs (§3), and the characterization of liaison contexts (§4). On each topic the main theoretical proposals are introduced, and their merits and shortcomings are discussed with regard to the range of empirical results available.

2 Basic facts and concepts

2.1 *Liaison consonants*

LCs are special in at least two ways. First, they are only allowed in certain segmental and grammatical environments, while other French consonants are stable across contexts (e.g. *net* 'clear' is invariably pronounced [nɛt] with an initial [n] and a final [t]).[2] Second, all consonants are possible as stable segments, whereas LCs are restricted to a small set of consonants, essentially [z n t] (with [n] appearing only after nasalized vowels). Residual LCs include [ʁ p], which together account for less than 0.2 percent of all cases of liaison in a corpus of

[2] Final consonants are implicated in two variable processes independent from liaison: optional final consonants in some words (e.g. *but* 'goal' [by] ~ [byt]) and variable cluster reduction (e.g. *couple* 'couple' [kup(l)]). Numbers between *cinq* 'five' and *dix* 'ten' behave idiosyncratically: their final consonant is stable at the pause but subject to variable preconsonantal deletion and/or prevocalic voicing. These special items will not be considered here; see CHAPTER 36: FINAL CONSONANTS for general discussion of final consonants.

spontaneous speech (Mallet 2008: 212). Liaison in [ʁ] occurs after infinitive forms and a handful of prenominal adjectives ending in *-er* (e.g. *premier* 'first'); [p] only appears after the two adverbs *trop* 'too much' and *beaucoup* 'a lot'.[3]

LCs that follow the prescriptive norm are always represented in the orthography, usually as permanent final letters of Word1: liaison [z] corresponds to written <s>, <x>, or <z>, liaison [n] to <n>, and liaison [t] to <t> or <d>. Liaison between verbs of the *-er* conjugation and enclitic pronouns is special in being marked orthographically by consonants that only appear in liaison (e.g. *vas-y* 'go there' [vazi], *va-t-il* 'goes he' [vatil] *vs. va* 'go' [va]). Non-standard cases of liaison, many of which are mentioned in the following sections, depart from the standard written form (e.g. *cent amis* 'a hundred friends' pronounced [sɑ̃zami], *donne-m'en* 'give me of-it' surfacing as *donne-moi-en* [dɔnmwazɑ̃]).

The relative frequency (CHAPTER 90: FREQUENCY EFFECTS) of the three LCs [n t z] has been debated (see Ranson 2008). Mallet (2008: 213) provides measures based on a corpus of conversational speech containing more than 28,500 potential contexts for liaison, with a global rate of realization of 45 percent. Potential contexts involve, in that order, [z], [t], and [n] (2a); however, [n] is realized more often than [t] (2b). This reversal results from the fact that [n] is implicated essentially in contexts of categorical liaison, and [t] in cases of variable liaison (2c).

(2)		[z]	[t]	[n]
a.	% of all potential instances of liaison	49%	28%	19%
b.	% of all realized instances of liaison	46%	15%	39%
c.	Rate of realization	43%	23%	90% (Mallet 2008)

Both LCs and stable final consonants are subject to a regular process of *enchaînement* or (re)syllabification before a following vowel, favoring open syllables and CV sequences at word boundaries. The example in (1b) normally syllabifies as in (3a), and a similar example with a stable final consonant appears in (3b).

(3)	a.	LC	*vous allez*	'you-PL go'	[vu.za.le]	cf. *vous* [vu]
	b.	stable final C	*douze allées*	'twelve alleys'	[du.za.le]	cf. *douze* [duz]

Liaison may also apply without *enchaînement*, the LC syllabifying with the preceding segment, as in [vuz.(ʔ)a.le] (Encrevé 1988; Laks 2009). As noted by Durand and Lyche (2008), however, liaison without *enchaînement* is found almost exclusively in read speech or elevated discursive styles (e.g. formal presidential speeches), and essentially in cases of variable liaison. It is highly exceptional in spontaneous speech. The status and theoretical significance of liaison without *enchaînement* have been debated; it has been considered on a par with liaison with *enchaînement* (Encrevé 1988), simply irrelevant (Scullen 1993), or marginal and directly related to spelling and to a specific type of public discourse (Laks 2005, 2009; Côté 2008).

[3] Historically, LCs included [k], a consonant that is clearly no longer productive (see Morin 1987: 819), but liaison with [g] may be observed after the prenominal adjective *long* 'long-MASC'. Quebec French also has [l] as a possible LC, which surfaces between proclitics ending in [a] and vowel-initial verbs, as in *ça arrive* 'this happens' [salaʁiv] (Morin 1982).

The length of the following sequence may also influence the frequency of liaison, although this effect remains to be fully tested. Morin and Kaye (1982) offer the contrast in (9) and suggest that liaison between *mangent* and *après* is more natural in (9a) than in (9b). Post (2000) observed in her reading task more liaison when the following context was non-branching than when it was branching.

(9) a. *Ils travaillent d'abord et mangent après.*
'They work first and eat after.'
b. *Ils mangent après qu'ils aient fini leur travail.*
'They eat after that they have-SUBJ finished their work.'

It has been suggested that liaison is more frequent if Word1 ends in a vowel than a consonant, and more frequent after one consonant than after two (Delattre 1955); liaison is then predicted to apply with decreasing likelihood from (10a) to (10c). This generalization would follow from a constraint against hiatus or empty onsets (e.g. Steriade 1999; Davis 2000; Tranel 2000; CHAPTER 61: HIATUS RESOLUTION; CHAPTER 55: ONSETS), which favors liaison intervocalically and when *enchaînement* is less likely to occur. Morin (2005), however, argues against these factors being a driving force in the evolution and application of liaison, and Ågren's (1973) corpus study does not confirm the hierarchy of frequency in (10).

(10)	a.	*ponts étroits*	'bridges narrow'	[pɔ̃z̩etʁwa]
	b.	*murs étroits*	'walls narrow'	[myʁz̩etʁwa]
	c.	*portes étroites*	'doors narrow'	[pɔʁtz̩etʁwat]

2.2.3 *Lexical factors*

Keeping the number of syllables, word class, and syntactic configuration constant, there remains substantial lexical variation in the frequency of liaison. For example, the proportion of realized liaison after four monosyllabic adverbs in two corpora is given in (11) (de Jong 1994; Mallet 2008; see also Encrevé 1988 and Laks 2009). The variation is extreme and obviously involves factors independent from the phonological structure of Word1. Perhaps even more telling is the comparison between different monosyllabic forms of the verb *être* 'be', which trigger liaison at proportions varying between 0 percent and 71 percent (de Jong 1994; see also Ågren 1973).

(11)	*très* 'very'	*plus* 'more'	*bien* 'well'	*pas* 'not'
Mallet (2008)	97%	64%	43%	1%
de Jong (1994)	99%	96%	82%	7%

These statistics illustrate the extent to which liaison is lexicalized and cannot be reduced to independent structural factors. Lexical distinctions in the realization of liaison have been significantly correlated with Word1 frequency, more frequent words triggering liaison more often than less frequent ones (de Jong 1994; Fougeron *et al.* 2001a; Fougeron *et al.* 2001b; see also CHAPTER 90: FREQUENCY EFFECTS).

2.2.4 *Stylistic and dialectal variation*

The use of liaison is highly dependent on speech style and register, more elevated styles being typically associated with an increased rate of liaison realization (e.g. Lucci 1983; Moisset 2000; Fougeron *et al.* 2001a). If, for example, liaison with plural prenominal adjectives (6a) is almost categorical across styles, liaison after plural nouns (6f) is exceptional in colloquial speech and frequent only in formal production. In some contexts not listed in (5)-(6), liaison may be allowed exclusively in hyperformal registers. According to Fouché (1959: 443) and Delattre (1947), a LC may intervene between a plural subject and its inflected verb (12), but Durand and Lyche (2008) mention that liaison was never realized in this context in a reading task (a context that strongly favors the realization of liaison) performed by 100 speakers.

(12) *les gens obéirent* 'the-PL people obeyed' [leʒɑ̃z̲obeir]

Laks (2009) compares the rates of liaison realization following 28 invariable words belonging to categories (6c) and (6d) in two stylistically contrasting corpora: formal political speeches and informal conversation. The global rate of realized liaison is 78 percent in the former against 47 percent in the latter, but the distinction may be more dramatic for individual words, e.g. 78 percent against 1.5 percent after the adverb *pas* 'not'.

Dialectal variation has not inspired as much research as the sociolinguistics of liaison, and the extent of this variation remains to be more fully documented. Variation essentially concerns liaison contexts: their classification, the nature of the LC that appears in each of them, and the frequency of liaison in specific variable contexts (see notes 3 and 7 for other aspects of dialectal variation). In Quebec French, for instance, one of the better-described non-standard varieties (see Côté 2010 for references), liaison after the proclitics *on* 'we/one' and *ils/elles* 'they-MASC/FEM' (5b) is variable rather than categorical (de Jong 1993) and liaison in [t] occurs after all forms of the present tense of *être* 'be', including those that trigger liaison in [z] in the standard variety (e.g. *tu es assis* 'you are seated' [tet̲asi] rather than [tyez̲asi]; van Ameringen and Cedergren 1981).

3 The phonological and lexical status of LCs

LCs, by definition, appear between two words and their relationship to each of these words has remained a matter of debate. Five main options for the lexical affiliation of LCs have been considered. They are summarized in (13), with a schematic lexical representation of the elements contained in the sequence *deux amis* 'two friends' [døz̲ami].

(13)
a. LCs are final consonants of Word1
   i. Truncation analysis /døz/ /ami/
   ii. Suppletion analysis /dø, døz/ /ami/
   iii. Autosegmental analysis /dø(z)/ /ami/
b. LCs are epenthetic /dø/ /ami/
c. LCs are initial consonants of Word2 /dø/ /zami/
d. LCs are morphemic
   i. Prefix of Word2 /dø/ /z + ami/
   ii. Suffix of Word1 /dø + z/ /ami/
e. LCs are part of a (partially) lexicalized contruction /dø z ami/

Non-standard or marginal instances of liaison and experimental evidence have played an important role in supporting or arguing against specific proposals. Observed gaps between normative descriptions and actual usage correspond either to processes established in the grammar of non-standard (spoken) varieties or to less systematic "mistakes" often characterizable as hypercorrective. The latter type tends to occur when speakers perform under some normative pressure (e.g. non-professional speakers in media contexts), which favors liaison, and in cases of variable liaison that are not used productively in colloquial registers (see Desrochers 1994 for a typology and analysis of a corpus of liaison errors). §3.1 reviews the approaches in (13), while §3.2 specifically addresses experimental evidence drawn from aquisition, phonetics, and psycholinguistics. The relationship between liaison and morphological relatedness, relevant to the nature of adjectival LCs, is discussed in §3.3.

3.1 Competing approaches

3.1.1 LCs as final consonants of Word1

The vast majority of studies on liaison adopt the classic position in (13a), according to which LCs belong to Word1, mirroring the historical origin (and the modern spelling) of most LCs. This approach has been implemented in a number of ways, which have in common that the lexical form of *deux* contains a final /z/, but differ with respect to the representation of that consonant and the status of the non-liaison form [dø] (see Klausenburger 1984 and Encrevé 1988: ch. 3 for reviews). Three main groups of analyses may be identified: truncation, suppletion, and autosegmental, presented roughly in chronological order. All must establish a distinction between final stable consonants and those pronounced only in liaison (e.g. the liaison [z] in *deux* 'two' *vs.* the stable [z] in *douze* 'twelve').

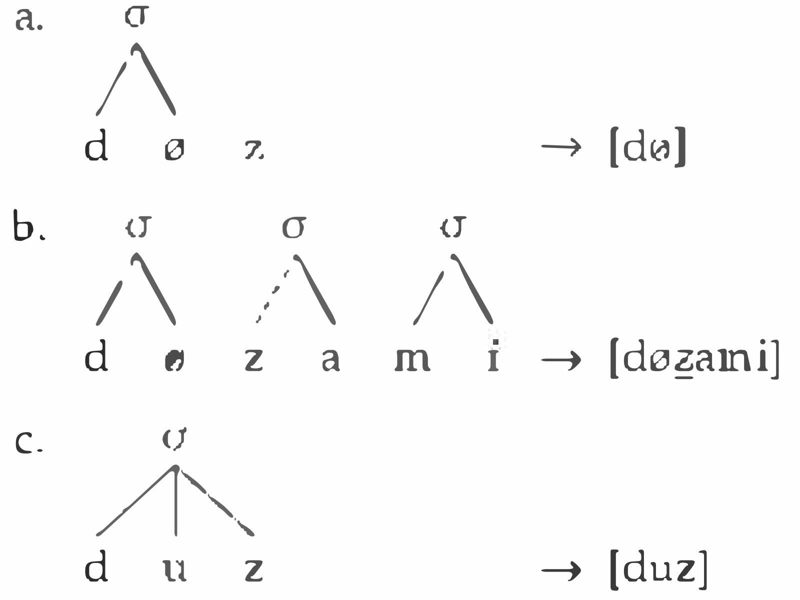
The truncation analysis coincides with the early phase of generative phonology (Milner 1967; Schane 1968; Selkirk and Vergnaud 1973; Selkirk 1974). It relies on a general rule that deletes word-final consonants in non-liaison contexts. Liaison, then, results from the non-application of deletion (CHAPTER 68: DELETION). Stable final consonants escape the truncation rule either because they are lexically specified as exceptions to it or because they are followed by a final ("protective") schwa. This schwa makes the rule inapplicable and is itself subject to a later deletion rule. One intriguing feature of this analysis is that liaison forms, which may be considered marked, result from the simplest derivation, while non-liaison forms and stable final consonants, which are in no way exceptional, involve deletion rules or special devices.

Suppletive analyses (Gaatone 1978; Klausenburger 1984; Green and Hintze 1988; de Jong 1994; Perlmutter 1998; Plénat 2008) consider that the liaison and non-liaison forms of a word are listed separately in the lexicon (e.g. /dø, døz/ for *deux*). Words ending in a stable consonant have a single allomorph (e.g. /duz/ for *douze*) (CHAPTER 99: PHONOLOGICALLY CONDITIONED ALLOMORPH SELECTION).[9]

[9] Suppletion may not characterize liaison in general but may be limited to prenominal adjectives with a different vowel in their liaison and non-liaison forms, as illustrated in (8) (Tranel 1990; Scullen 1993; Côté 2005). Adjectival LCs may also be indirectly suppletive in being derived from the listed feminine form (Steriade 1999).

The development of non-linear phonology has renewed the interest in final LCs, represented as floating segments with respect to the skeleton (CHAPTER 54: THE SKELETON), the syllable, or both (Booij 1983; Clements and Keyser 1983; Hyman 1985; Encrevé 1988; de Jong 1990, 1994; Tranel 1990, 1996, 2000; Prunet 1992; Scullen 1993; Paradis and El Fenne 1995; Davis 2000; Wauquier-Gravelines 2005, 2009; Nguyen *et al.* 2007; cf. Tranel 1995a, 1995b for an elaborate discussion and comparison of the different autosegmental accounts). Consonants left floating remain unpronounced, as is the case for *deux* produced in isolation (14a). Floating segments make it to the surface only when properly inserted into the prosodic structure, typically by filling a following empty onset position, as in (14b). As in truncation approaches, liaison and non-liaison allomorphs are derived from a unique underlying form. Fixed and liaison consonants, however, are representationally distinct, fixed ones being prosodically anchored in the lexicon, as shown in (14c) for *douze* 'twelve'. This representational approach simultaneously avoids specific deletion rules and the exception devices needed for stable consonants, but it involves more complex lexical representations (see Côté 2008 for arguments against the floating approach to LCs).[10]

(14)



Final consonant accounts are challenged by instances of LCs that appear to be separated from the preceding word by an intonational boundary or some lexical material. Liaison has regularly been shown to occur across pauses and intonational boundaries (Ågren 1973; Morin and Kaye 1982; Lucci 1983; Green and Hintze 1988; Tranel 1990; Post 2000; Morin 2003; Miller and Fagyal 2005). This phenomenon can be observed in standard parenthetical structures ((15a), from Morin 2003) and in colloquial right dislocation constructions (15b) (Tranel 1990; Côté 2005; Plénat 2008). Crucially, stable final consonants do not cross the intonational boundary in the same constructions.

(15) a. *un robuste, mais petit, enfant* [œ̃ʁɔbyst mɛpœti t̲ɑ̃fɑ̃]
'a robust, but small-MASC, child'

b. *j'en ai un, ami* [ʒɑ̃neœ̃ n̲ami]
'I of-it have one-MASC, friend'

[10] Post's (2000) account combines features of both floating and suppletive approaches. She adopts floating segments in underlying representations, but derives liaison allomorphs in the lexicon. At the point of lexical insertion, the distinction between stable and latent consonants is lost.

A verbal marker [t] has also been identified, although its morphemic status is not as firmly established as that of plural [z]; Morin and Kaye (1982) describe verbal [t] as involving a sort of "morphologized epenthesis." This [t] seems to be an extension across verbal forms of the liaison [t] that is standardly triggered by a subset of persons, verb classes, and tenses (19).

(19) a. *le corps sera exposé* [. . . sœʁatɛkspoze]
'the body will be exhibited'
b. *image qui m'est venue à l'esprit* [. . . vœnytalɛspʁi]
'image that me is come to the mind' = 'image that came to my mind'

Finally, the morphemic account has been applied to prenominal singular adjectives: the liaison [t] in *grand arbre* 'big tree' [grɑ̃taʁbʁ] has been treated as a suffix to *grand*, comparable to a case marker (Morin 1992), and as a prefix to Word2 (Klausenburger 2001; Morin 2003).

3.1.4 LCs as initial consonants of Word2

The affiliation of LCs to Word2 is taken a step further by Ternes (1977), who conceives liaison as a case of initial consonant mutation: LCs belong to the following word and vowel-initial words subject to liaison have several variants, for example [ami], [tami], [nami], and [zami] for *ami* 'friend'. The correct variant is selected by the preceding context. The initial approach to LCs has been applied more restrictively to LCs before enclitics (5c): *y, en* in imperative constructions and *il(s), elle(s), on* in subject inversion are lexicalized as [zi zɑ̃ til tɛl tɔ̃] (Morin 1979, 1986; Côté 2005, 2008). This analysis is supported, among other evidence, by non-standard imperative forms as in (20), with an obligatory [z] after another enclitic.

(20) *donne-moi-*[z]*-en* 'give me of-it' [dɔnmwazɑ̃]

3.1.5 LCs as part of larger constructions

Finally, LCs have been viewed as part of constructions larger than the word that are (partially) lexicalized (Bybee 2001a, 2001b, 2005; Dugua 2006; Chevrot *et al.* 2007, 2009). Constructions may be more or less specific: general constructions like [DET NOUN] coexist with more specific ones like [*un* 'a/one' NOUN]$_{MASC}$ or [*un* [-n-] (vowel) NOUN]$_{MASC}$. This last construction establishes a liaison [n] between *un* and a masculine vowel-initial noun. The assumption is that more specific constructions apply first but are subject to a generalizing pressure from the less specific (and more frequent) constructions. Liaison is involved in highly specific constructions, whose strength and maintenance are argued to depend on their frequency of usage.

LCs occur at the boundary of Word1 and Word2, which prevents an a priori determination of their lexical affiliation with either word. We should not be surprised, then, by the available range of conceptions of LCs, which covers the full distance between Word1 and Word2. A schematic representation of the distance between LCs and their adjacent words appears in (21). LCs analyzed as final and initial consonants are most closely associated with Word1 and Word2, respectively. Suffixes and prefixes are partially independent from their host. LCs in epenthetic or constructionist approaches are equally (in)dependent from both words and lie at an equal distance from them.

and perceptual weakness of LCs also challenges morphemic accounts, in that consonants with a morphemic status have been shown to be longer than corresponding non-morphemic consonants, for example the inflectional [s] in English *wrecks vs.* the non-morphemic [s] in *Rex* (Walsh and Parker 1983; Losiewicz 1992). If LCs were morphemic (prefixes or suffixes), their shorter duration would be unexpected. One issue in interpreting these acoustic/perceptual results, however, is that they combine different liaison contexts, without distinguishing LCs that are associated with specific morphological categories (in particular the plural [z]) from those that appear to be strictly lexical (following invariable words or singular adjectives). It is in fact the latter type, in particular prenominal singular adjectives, that has been used predominantly, sometimes exclusively, in most studies. A morphemic analysis of other types of LCs therefore remains to be investigated.

A number of experiments have also tested the productivity of liaison with words that do not normally appear in liaison contexts (Morin 1992; El Fenne 1994; Sampson 2001). Adjectives that are either novel or usually appear postnominally (as most adjectives do in French) are tested in adjective + noun sequences. Liaison applies variably in this situation, a result that has been used to argue both for and against a final-consonant analysis of LCs (Paradis and El Fenne 1995; Côté 2005). But since the variability of liaison in noun + adjective sequences is now acknowledged, it is difficult to draw firm conclusions.

The acquisition of liaison by children is a growing area of investigation. Categorical liaison is mastered by the age of five; variable liaison develops until much later, adults varying considerably in their control and use of it. The acquisition process is characterized by numerous forms that depart from the target ones. Five main categories of mistakes involving liaison are identified (see Dugua 2006: 114–137): the substitution of the expected LC by an erroneous one (23a), the omission of a LC in categorical liaison contexts (23b), the insertion of a LC in non-liaison contexts (23c), the substitution of a stable initial consonant by a LC (when the initial consonant corresponds to a possible LC) (23d), and the omission of a stable initial consonant (23e).

(23)				*child*	*adult*
	a.	*un âne*	'a/one-MASC donkey'	[œ̃t̲an]	[œ̃n̲an]
	b.	*des étoiles*	'DET INDEF stars'	[deetwal]	[dez̲etwal]
	c.	*papa aigle*	'Daddy eagle'	[papan̲ɛgl]	[papaɛgl]
	d.	*un zèbre*	'a/one-MASC zebra'	[œ̃n̲ɛbʁ]	[œ̃zɛbʁ]
	e.	*un zèbre*	'a/one-MASC zebra'	[œ̃ɛbʁ]	[œ̃zɛbʁ]

These mistakes are sensitive to different contextual factors, and their relative frequency evolves over time. On the basis of both experimental results and the analysis of spontaneous productions, different developmental scenarios have been elaborated. It is generally agreed that in the early stages of the acquisition of liaison, around the age of two to three, LCs appear to be encoded as initial consonants of Word2, in conformity with a preference for CV syllabifications (e.g. *nami, tami, zami* for *ami* 'friend') (see Chevrot *et al.* 2005, 2009; Chevrot *et al.* 2007 for arguments and references). The acquisition of liaison then consists, for the child, in identifying the contexts in which each of these variants should be used.

Subsequent stages are more controversial. Morel (1994), Wauquier-Gravelines (2005, 2009) and Wauquier-Gravelines and Braud (2005) consider that LCs belong syntactic relationship holding between *vous* and *écouter* in the second example. (26c) displays a noun–adjective structure that excludes liaison with singular nouns, while (26d) corresponds to an adjective-noun sequence typically involving liaison. The pair (26e, 26f), from Prunet (1992: 42), differ in whether the PP introduced by *à* is a complement of *dire* or *partait*; only in the latter case is liaison between *partait* and *à* possible.

(26) a. *allez-vous écouter* [alevuekute] (no liaison)
'go you-PL listen' = 'are you going to listen'
b. *allez vous écouter* [alevuz̲ekute] (categorical liaison)
'go you-PL listen' = 'go listen to yourselves'
c. *savant anglais* [savɑ̃ɑ̃glɛ] (no liaison)
'savant English-MASC'
d. *savant Anglais* [savɑ̃(t̲)ɑ̃glɛ] (variable liaison)
'knowledgeable-MASC Englishman'
e. *il fallait dire qu'on partait à Marie* [. . . diʁkɔ̃paʁtɛamaʁi]
'it needed say that one/we left to Marie' (no liaison)
= 'somebody had to tell Marie that we were leaving'
f. *il fallait dire qu'on partait à Paris* [. . . diʁkɔ̃paʁtɛ(t̲)apaʁi]
'it needed say that one/we left to Paris' (marginal liaison)
= 'somebody had to say that we were going to Paris'

Traditional descriptions of liaison essentially present liaison contexts as sequences of standard parts of speech such as noun and preposition. Such lists are viewed as carrying little explanatory power, and more theoretically oriented analyses have tried to subsume these contexts under unified configurations, prosodic or syntactic. At a more conceptual level, syntactic approaches also raise the question of whether a phonological process (insofar as liaison is such a process) may refer directly to syntactic structure. Alternatively, frequency of co-occurrence has been proposed as an explanatory factor of the degree of cohesion between Word1 and Word2. Structural and frequency-based approaches are briefly reviewed below.

4.1 Structural approaches

Syntactic accounts of liaison contexts follow in part the evolution of syntactic theory and approaches to the syntax–phonology interface. They establish a syntactic configuration or domain in which liaison applies. Proposals rely, directly or indirectly, on a small set of morphosyntactic distinctions: (i) a distinction between lexical and functional categories; (ii) a distinction between specifier–head and head–complement relations; (iii) a distinction between inflected heads, marked for person or number, and non-inflected heads. A representative schema is given in (27) and exemplified with the NP *mes amis américains* 'my friends American'. Liaison is categorical between a specifier (the determiner *mes*) and a head (the noun *amis*), and variable between an inflected head (the plural *amis*) and a following complement (the adjective *américains*). Note that a singular noun would not trigger liaison, hence the inflectional restriction on liaison in the head–complement configuration.

According to de Jong (1990), the categorical–variable distinction in liaison contexts corresponds to different prosodic levels. Alternatively, one may exploit the variability in prosodic parsing: liaison is systematic within PhPs but its optionality in certain contexts results from the possible restructuring of adjacent PhPs. If Word1 and Word2 belong to different PhPs, these may merge if Word1 is inflected, Word2 is in the complement of Word1, and the second PhP is non-branching; see Post (2000) for a discussion and assessment of this type of approach.

More recently, Davis (2000) has proposed to associate the domain of liaison with the concept of Extended Projection (EP), a syntactic unit defined as a combination of a functional and a lexical category. This approach differs from the preceding ones in that all word categories project a phrasal level, rendering irrelevant the distinction between heads and specifiers. Liaison applies obligatorily within EPs, and its variability in several contexts is attributed to independent factors: variable underlying representations, with and without a final latent consonant, and interference from prosodic structure and the number of syllables. Unlike all previous approaches, the EP domain predicts liaison to be impossible after lexical categories (except prenominal adjectives). Occurrences of liaison after nouns and verbs, which remain marginal in informal speech, follow from the possibility of using the left edge of a PhP (a prosodic category) rather than that of an EP as a liaison boundary.[13]

Although they invoke similar concepts, these analyses make different predictions. The sentence in (28), which contains nine potential contexts of liaison, is used to compare four specific proposals: X″ (Selkirk 1974), PhP (de Jong 1990), c-command (Prunet 1992), and EP (Davis 2000). For each context, Table 112.1 indicates the prediction of each analysis and, for comparison, its relative frequency in real speech, based on the generalizations in (5), (6), and (7) above, complemented with Morin and Kaye's (1982) observations. The contexts are listed in order of frequency. We may consider that all contexts involve a relationship between a head and a syntactically dependent element, except 2 and 8.

(28) le petit enfant a vait appris aux hommes attentifs à ses prouesses à
1 2 3 4 5 6 7 8
voler sans ailes
9
'the small-MASC child had taught to-the men attentive to his feats to fly without wings'

In only the first and last contexts do all the analyses make exactly the right prediction. Otherwise all underpredict and overpredict liaison in at least some contexts. The adjective + noun context (*petit enfant*) is wrongly predicted to be obligatory, but this is consistent with the earlier classification of this context as categorical. A past participle followed by its prepositional complement (*appris aux hommes*) is predicted not to trigger liaison, since Word1 (*appris*) is not inflected. Liaison is indeed rare, but not unattested, as shown by Morin and Kaye (1982). On the other hand, a plural adjective followed by its complement (*attentifs à ses*

[13] This makes the questionable prediction that the use of the PhP increases with formality. Since formal liaison is closer to the written form, it is not expected to be more strongly driven by prosodic structure than informal liaison.

Table 112.1 Status of liaison in the nine contexts in (28), as observed in real speech and predicted by four analyses

	context	*observed*	Selkirk 1974	de Jong 1990	Prunet 1992	Davis 2000[14]
5	Det+N (4a)	categorical	obligatory	obligatory	obligatory	obligatory
1	Adj+N (5a)	frequent	obligatory	obligatory	obligatory	obligatory
9	Prep+NP (5b)	variable	obligatory	frequent	formal style	variable
3	Aux+Past part (5d)	variable	obligatory	frequent	obligatory	obligatory
6	N_{PL}+Adj (5e)	infrequent	variable	rare	formal style	no
4	Past part+PP (5d)	marginal	no	no	no	no
7	Adj_{PL}+PP	no	variable	rare	formal style	no
2	Subj+V (6a)	no	no	no	no	no
8	N+non-comp	no	no	no	no	no

prouesses, context 7) should trigger variable liaison, as nouns and verbs do in similar configurations, but the absence of liaison after postnominal adjectives has often been noted (e.g. Morin and Kaye 1982; de Jong 1994; Davis 2000).

Syntactic approaches, direct or indirect, contrast with strictly prosodic ones, where prosodic domains are defined by intonational and durational patterns rather than syntactic structure. It is traditionally claimed that liaison is only realized inside a rhythmic or accentual group, therefore never between a stressed vowel and a following word (e.g. Béchade 1992; Léon and Léon 1997: 40; cf. Morrison 1968). A more recent and theoretically driven attempt to establish the Accentual Phrase (AP) as the domain of liaison is presented in Scarborough and Jun (2003).

Structural accounts of the relationship between Word1 and Word2 raise a number of general objections, and have failed to receive solid support from corpus-based or experimental testing. Fougeron *et al.* (2001a) found a strong positive correlation between liaison and syntactic distance (measured as the number of nodes separating Word1 and the common ancestor of Word1 and Word2); this confirms the basic intuition that Word1 and Word2 tend to be syntactically close in order for liaison to apply. But studies of read speech corpora indicate that c-command, the PhP, and the AP are not good predictors of liaison, either because liaison is often realized outside of the proposed domains (i.e. without c-command and across PhP boundaries, but only rarely across APs) or because liaison is not realized in a large proportion of potential liaison contexts within these domains (liaison is not produced in 50 percent of liaison contexts with c-command, against 49 percent within APs and 24 percent within PhPs) (Fougeron *et al.* 2001a; Fougeron and Delais 2004; see also Post 2000).

Generally, syntactic approaches predict a homogeneous behavior of liaison across categories, admitting a distinction between functional and lexical ones. This is not the case. On the one hand, non-prenominal adjectives almost never trigger liaison, unlike other lexical categories, nouns and verbs. Adverbs, which tend to

[14] These predictions are based only on the EP part of Davis's analysis and do not take account of the possibly interfering factors mentioned above.

(Culetto 2008). Fougeron *et al.* (2001a) and Fougeron *et al.* (2001b) observe that the frequency of the Word1-Word2 sequence is a better predictor than transitional probability, but a general statistical model is not yet in sight.

5 Conclusions

French liaison offers a microcosm of the challenges of linguistic analysis. Although typically classified as a phonological process, it lies at multiple interfaces, involving internal and external dimensions: morphology, syntax, and the lexicon, dialectal and sociolectal variation, registers, and spelling. This complexity has motivated the inclusion of liaison in a number of important conceptual debates, such as those surrounding abstractness, representations, and usage.

The last 50 years of study of liaison have seen a shifting balance between formal elegance and empirical adequacy, data idealization, and analytical scattering. One central goal of this chapter has been to convey a sense of the empirical and conceptual richness involved. With respect to the lexical status of LCs, the traditional relationship between the LC and the preceding word has been loosened, by establishing a morphological or semantic motivation to liaison that is independent of Word1, introducing prosodic or lexical material between Word1 and the LC, or dissociating liaison from Word1's morphological paradigm. Studies of liaison contexts have revealed the deficiencies of global structural accounts, syntactic or prosodic. It is hoped that the recent surge of experimental and corpus-based research will lead to new analytical developments on both issues.

ACKNOWLEDGMENTS

I would like to thank Jacques Durand for his support and Chantal Lyche, Sophie Wauquier, two anonymous reviewers, and the *Companion* editors for their contribution to this chapter.

8 Sonorants

Bert Botma

1 Introduction

The class of sonorants includes vowels, semi-vowels, liquids, and nasals, with the sonorant consonants sometimes being referred to as "resonants" (e.g. Laver 1994). There is abundant cross-linguistic evidence for natural class behavior of these segments. For example, in languages where consonants can be syllabic, the class of syllabic segments is almost always restricted to sonorants (Imdlawn Tashlhiyt Berber is an exception; see Dell and Elmedlaoui 2002). Further, there are quantity-sensitive languages in which the set of weight-bearing segments is restricted to sonorants, or to a subset thereof (see Zec 2007 and CHAPTER 57: QUANTITY-SENSITIVITY for examples). Similarly, in languages where consonants can support tone contrasts, the consonants involved are almost always sonorant (e.g. Yip 2002). In addition, in languages which permit complex onsets, the second element is typically restricted to a sonorant consonant (disregarding sC clusters). Taken together, these observations suggest a distinctive feature, e.g. [sonorant], which distinguishes sonorants from obstruents (i.e. plosives and fricatives). These examples further suggest that the most straightforward evidence for the class behavior of sonorants comes from their patterning with respect to suprasegmental aspects such as syllable structure, moraic structure, and tone – an observation to which we return in §3.

While the class of sonorants is well established, there are a number of issues relating to sonorants which are a matter of debate. This chapter focuses on three such issues:

(i) How should sonorancy be represented in a theory of segmental structure? (§2)
(ii) How should less straightforward cases of sonorant class behavior be accounted for, in particular those cases in which voiced stops and voiced fricatives display sonorant-like behavior? (§3)
(iii) How should sonorancy be defined phonetically? (§4)

On closer inspection, each of these issues pertains to the relation between sonorancy and voicing. Any approach to sonorancy must do justice to the observation that voicing in sonorants is never contrastive (see §2.3), but may nevertheless be phonologically active. §2 considers a range of proposals that have been advanced to account for this observation, and also provides a more general discussion of laryngeal modifications in sonorants. The relation between sonorancy and voicing is also relevant in the class behavior of sonorants and voiced stops and fricatives, which is considered in §3. §4 reviews a number of possible phonetic correlates of sonorancy. It will be suggested that sonorants are best characterized acoustically, in terms of a clearly marked formant structure – a position that is perhaps most closely identified with the work of Ladefoged (e.g. 1971, 1982, 1997). It will also be suggested, somewhat more tentatively, that the class behavior of sonorants and voiced obstruents is phonetically natural to the extent that both are voiced, with the latter involving "active voice facilitation," although there is some reason to believe that aerodynamic correlates may also be relevant.

In what follows, my concern will be with the class of sonorants as a whole. Thus I will have little to say about the specific properties of sub-types of sonorants, some of which are discussed in other contributions (e.g. CHAPTER 15: GLIDES; CHAPTER 30: THE REPRESENTATION OF RHOTICS; CHAPTER 31: LATERAL CONSONANTS), or about the relation between sonorancy and syllable structure (for this, see e.g. CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE; CHAPTER 49: SONORITY; CHAPTER 53: SYLLABLE CONTACT).

2 How should sonorancy be represented in a theory of segmental structure?

2.1 *Representations of sonorancy*

Different proposals have been made regarding the formalization of sonorancy in phonological theory. The mainstream view, as espoused in Chomsky and Halle (1968; *SPE*) and subsequent work in Feature Geometry (e.g. Clements 1985; Sagey 1986; McCarthy 1988; Clements and Hume 1995; Halle *et al.* 2000), recognizes a major class feature [sonorant]. An alternative proposal within Feature Geometry is the "SV hypothesis," in which [sonorant] is replaced by a "Spontaneous Voicing" or "Sonorant Voice" node (e.g. Rice and Avery 1989, 1991; Piggott 1992, 1993; Rice 1993; Avery 1996). A quite different approach is taken in Dependency Phonology and related frameworks such as Radical CV Phonology, where sonorancy is viewed as a particular manifestation of a vocalic "component" or "element," e.g. |V| (Anderson and Ewen 1987; van der Hulst 1995) or |L| (Botma 2004; Botma and Smith 2006, 2007). However, while these frameworks assume different "atoms" of representation, they share important insights with both *SPE* and Feature Geometry, as we will see below. Finally, some approaches, e.g. most versions of Element Theory (see Harris and Lindsey 1995; Harris 1996), do not recognize a feature or "element" representing sonorancy. This section considers each of these approaches in some detail.

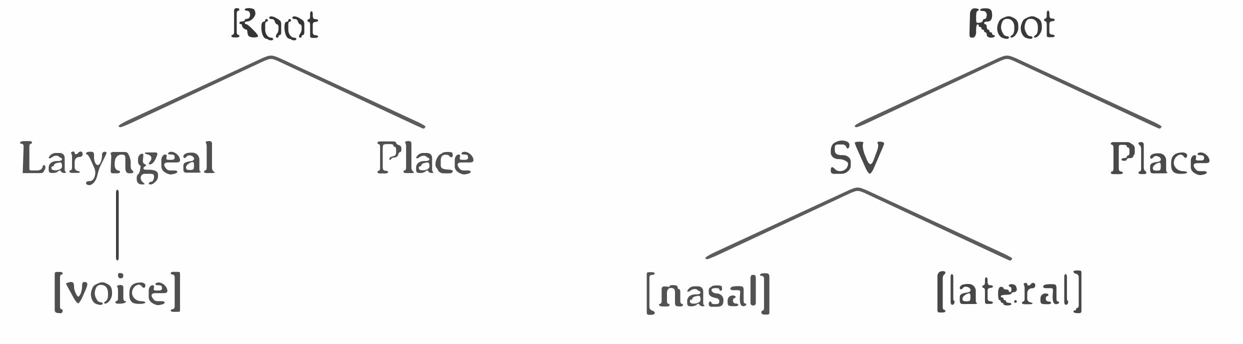
In *SPE*, [sonorant] is assumed to be a "major class feature," together with [consonantal] and [continuant]. What sets major class features apart from other features is that the former are not bound to any particular articulator. Thus, as Kenstowicz (1994: 36) puts it, [sonorant] specifies "phonologically relevant degrees of constriction imposed by essentially any articulator." However, since segments in *SPE* consist of unordered feature bundles, major class features do not have any independent theoretical status.

of the output already inheres in the lenition target. This option is not considered in Harris (1996), though it is perhaps compatible with Harris's more recent approach to sonority (see Harris 2006).

Harris goes on to make a compelling case for rejecting [consonantal], noting in passing that there are few processes in which major class features function as the target or trigger of phonological processes. However, it is questionable whether this last point can be maintained for the feature [sonorant], not just in light of the examples of sonorant class behavior mentioned in §1, but also in view of the kind of arguments advanced by proponents of the SV hypothesis.

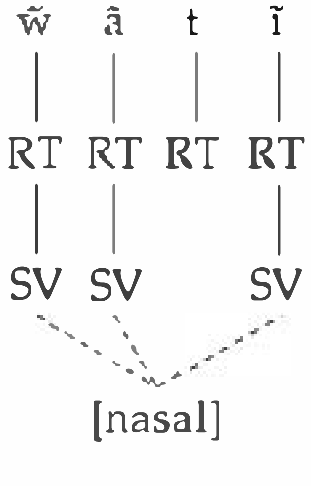
The SV hypothesis can be regarded as an attempt to accord [sonorant] the same status as other, non-major class features. The key insight of this approach is that there are two types of phonological voicing: one realized through a laryngeal feature ([voice], dominated by the Laryngeal node) and a property of obstruents (2a), and one through SV ("Spontaneous Voice" or "Sonorant Voice") and a property of sonorants (2b).

(2) a. *Obstruent voicing* b. *Sonorant voicing*



The SV node organizes sonorant features such as [nasal] and [lateral], and acts as both a trigger and a target for autosegmental processes such as spreading and delinking. For example, Piggott (1992) accounts for the nasal harmony pattern of Southern Barasano (discussed in more detail in §3) on the assumption that all targets are specified for SV, which provides a landing site for a harmonic feature [nasal]. Thus a form like [w̃ãtĩ] 'devil' involves association of [nasal] to all SV-specified segments in the word:

(3)



Spreading of the SV node itself is assumed to take place in sonorant-induced voicing phenomena, such as post-nasal voicing assimilation (see §2.2).

The function of the SV node is similar to class nodes such as Laryngeal and Place, in that it designates functional feature groupings (see especially Piggott 1993 for an elaboration of this idea). In addition, some phonologists have argued that the unmarked dependent of the SV node is the feature [nasal], which captures the observation that nasals are the unmarked type of sonorant consonants. According to this view, nasals are underlyingly specified for SV only, with their nasal aspect supplied by a default rule which fills in [nasal] (e.g. Rice and Avery 1991; Rice 1993). However, this assumption seems difficult to combine with an account of post-nasal voicing assimilation in terms of SV spreading (see §2.2).

A difference between class nodes and the SV node is that the latter is construed as having phonetic content. This assumption is not unproblematic. While a distinction between sonorant voicing and obstruent voicing seems well motivated on phonological grounds, the question whether there is phonetic support for this distinction is rather more contentious (see §4.1 for further discussion). To this extent at least, a more promising approach is taken in Dependency Phonology and related frameworks, where sonorancy and voicing are viewed as manifestations of a single component, whose interpretation depends on its position in the phonological structure. For example, van der Hulst (1995) represents sonorancy in terms of a |V| in the "head" component of a segment (4a) and voicing in terms of a |V| in the "dependent" component (4b). (The possibility of expressing the relative prominence of voicing can also be used to represent the difference between sonorants and sonorant-like obstruents, as we will see in §3.)

(4) a. *Sonorancy* b. *Voicing*

Van der Hulst further assumes that in (4b) the head may be either an obstruent, i.e. |C|, or a sonorant, i.e. |V|. The latter assumption attempts to do justice to the observation that there are languages in which sonorants trigger voicing. Such processes cannot involve the head |V|, given van der Hulst's (1995: 96) assumption that "dependent properties can spread independently, while heads can only spread together with their dependents." This makes head components similar to major class features, while the possibility of "active" voicing in sonorants is reminiscent of the SV hypothesis.

2.2 *The relationship between sonorancy and voicing*

Phonetically, the natural state of sonorants is to be voiced. Phonologically, this is reflected by the observation that voicing in sonorants is unmarked. Inspection of the UPSID database (Maddieson 1984) reveals that most languages have voiced sonorants only (96.6 percent) and that the presence of non-voiced sonorants in a language implies the presence of voiced ones. Furthermore, voicing in sonorants is often redundant. This has been interpreted to mean that [voice] is underspecified for segments specified as [sonorant] and supplied by default in the post-lexical phonology (e.g. Kiparsky 1985; Archangeli 1988; Lombardi 1994; Steriade 1995).

One phenomenon which suggests that sonorants are underlyingly unmarked for voice is Japanese Rendaku (e.g. Itô and Mester 1986; Itô *et al.* 1995; Nasukawa 2005). This concerns a voicing process which targets an initial voiceless consonant of the second member of a compound, converting it into its voiced counterpart, as in /onna + kokoro/ → [onna gokoro] 'woman's heart'. Rendaku interacts with a constraint known as Lyman's Law, which bans multiple occurrences of voiced

3 Fuzzy class behavior: Sonorant obstruents

While the class of sonorant consonants traditionally includes liquids and nasals, it has been observed that voiced fricatives and voiced stops sometimes also pattern as sonorants, at least with respect to certain phenomena. Following Rice (1993), such sounds will be referred to as "sonorant obstruents." This section considers some examples of sonorant obstruents that have been reported in the literature and discusses the kinds of arguments that have been advanced for treating these sounds as sonorants. The recognition of a class of sonorant obstruents also has repercussions for the phonetic underpinnings of sonorancy (see §4).

Consider first the following data from Turkish. In this language, syllable-final voiced plosives undergo devoicing (7a) while voiced fricatives retain their voicing in this position (7b), like sonorants (7c) (cf. Rice 1993: 332–333):

(7)	a.	*sara*[p]	'wine-NOM SG'	*vs.*	*sara*[b]*i*	'wine-ACC SG'
	b.	*a*[z]	'few'			
		e[v]	'house'			
	c.	*gü*[n]	'day'			
		güze[l]	'pretty'			

Two possible analyses of the Turkish pattern suggest themselves. The first limits the structural description of devoicing to stops, e.g. by specifying the targets of devoicing as [−sonorant, −continuant]. As Rice notes, the problem with this analysis is that it does little more than stipulate that devoicing is limited to stops. The alternative is to specify the voiced fricatives for the same feature as sonorants, e.g. [sonorant] or, in Rice's analysis, SV. This account is more parsimonious, since devoicing can now be restricted to whatever feature it is that obstruents have in common. In Rice's account this is the Laryngeal node, which dominates the feature [voice]. In this analysis, [voice] is therefore a property of voiced obstruents, while the voicing of sonorants, including "sonorant fricatives," is supplied by SV. Rice offers a similar account of the voiced fricatives of Athapaskan languages such as Navajo and Chipewyan.

There is reason to suspect that "sonorant fricatives" may in fact be rather widespread. For example, voiced uvular /ʁ/ and pharyngeal /ʕ/ often pattern as sonorants (e.g. CHAPTER 25: PHARYNGEALS). Further, /v/ has been shown to display sonorant-like behavior in languages such as Norwegian (Kristoffersen 2000), Russian (Padgett 2002), Hungarian (Bárkányi and Kiss 2006), and Icelandic (Botma 2008). Hamann (2006) proposes the same for German /v/, providing acoustic measurements (duration, intensity, and harmonics-to-noise ratio) which suggest that the sound is phonetically a narrow approximant. More generally, Maddieson (1984: 48) observes that in UPSID, "bilabial, dental and palatal non-sibilant fricatives are found to occur without a voiceless counterpart more often than with one." To the extent that this is due to a difference in markedness between voiced and voiceless fricatives (and not to diachronic lenition, say), specifying these voiced fricatives for [voice] seems ill advised. Their relative frequency could instead support an analysis in which voiceless fricatives are specified for [spread glottis] (e.g. CHAPTER 28: THE REPRESENTATION OF FRICATIVES). However, it might also be the case that at least some of these voiced fricatives are in fact sonorants. While such a hypothesis is phonetically feasible (vocal fold vibration leads to lower airstream velocity, making it relatively difficult to produce turbulence), it must of course be demonstrated for each of the sounds in question that they pattern as sonorants phonologically.

One type of evidence that is often adduced for the sonorant status of voiced stops is the presence of oral–nasal alternations such as [b ~ m] (e.g. Piggott 1992; Rice 1993; Clements and Osu 2002; Botma 2004). Implicit in this approach is the claim that only sonorants can be nasalized. Phonetically, this claim is not unreasonable. The presence of nasal airflow is antagonistic to the buildup of oral air pressure required for obstruents. This rules out nasalized plosives (provided a different interpretation is given to nasal contours) and makes nasalized fricatives distinctly rare. Voiced nasalized fricatives have been reported in languages such as Inor, Itsekiri, and Umbundu (see Walker 2000 and references there), though it remains to be verified instrumentally whether these sounds are truly fricatives phonetically. Ohala and Ohala (1993) observe that the high rate of airflow required for friction is difficult to combine with a lowered velum, suggesting that many of the sounds described as voiced nasalized fricatives may in fact be approximants. Some phonetic studies have also reported nasal airflow in voiceless fricatives, e.g. in Coatzospan Mixtec (Gerfen 1999). Such nasalization seems to be possible only if there is an adjacent nasalized vowel, and so is presumably the result of co-articulation.

Oral–nasal alternations involving voiced stops occur in many languages with nasal harmony (see also CHAPTER 78: NASAL HARMONY). In a sub-type of nasal harmony displayed by a number of Amazonian languages, all voiced segments in the harmonic domain are nasalized, including what appear to be voiced obstruent stops phonetically. This gives rise to complementary distribution between voiced stops and nasals, as illustrated in (8) for Southern Barasano, a Tucanoan language of Colombia (cf. Piggott 1992: 46; see also Smith and Smith 1971). In this language, nasalization spreads rightwards from the leftmost nasalized vowel, skipping any intervening obstruents, as well as leftwards to an immediately preceding nasalizable consonant:

(8) a. *"Oral words"* b. *"Harmonic words"*

[^{m}ba^{ŋ}go ~ ^{m}bago]	'eater'	[kãmõkã]	'rattle'
[ta^{m}boti ~ taboti]	'grass'	[mãnõ]	'none'
[^{n}diro]	'fly'	[ẽõnõ]	'mirror'
[wesika]	'above'	[mãsã]	'people'
[wati]	'going'	[w̃ãtĩ]	'going'

Smith and Smith (1971: 82) note that voiced stops are optionally prenasalized. Their transcriptions suggest that this prenasalization is obligatory in word-initial position.

The complementary distribution of voiced stops and nasals in Southern Barasano suggests that they share a single underlying representation. This is corroborated by patterns of allomorphy of the kind in (9) (cf. Piggott 1992: 47; see also Piggott and van der Hulst 1997):

(9) a. *"Oral words"* b. *"Harmonic words"*

[ji-re]	'to say'	[ɲãɲõ-nẽ]	'to speak'
[^{ŋ}gahe-ja]	'another stream'	[mĩnõ-ɲã]	'leaf stream'
[wa-^{m}bi]	'I went'	[ĩã-mĩ]	'I saw'

Different accounts have been offered as to the underlying representation of alternating voiced stops. According to one analysis, nasal harmony in languages like Southern Barasano targets all segments specified for [voice], nasalizing sonorants and turning voiced stops into nasals (e.g. Pulleyblank 1989; Noske 1995). The problem with this analysis is that it is stipulative, since it is unclear why voicing and nasalization should have this affinity. Alternatively, it has been suggested that this type of harmony is limited to sonorants (e.g. Piggott 1992; Rice 1993; Botma 2004; Botma and Smith 2007). This analysis implies that the voiced stops in Southern Barasano are "sonorant stops," and as such permits a uniform account of the nasalization process (see e.g. Piggott and van der Hulst 1997, who offer an analysis of Southern Barasano in terms of the spreading of nasality at the level of the syllable).

Botma (2009) maintains that some Amazonian languages with a similar harmony pattern, e.g. Yuhup, are best analyzed as having underlying nasals, which denasalize in certain contexts. It is reasonable to assume that this scenario mirrors the historical situation, given the cross-linguistic frequency of nasals. (Perhaps Southern Barasano represents an innovation of this pattern.) Denasalization is also the diachronic source of alternating sonorant stops in other language families. For example, Krauss and Leer (1981) observe that in many Athapaskan languages **m* (< **w*) and **n* have developed into /ᵐb/, /ⁿd/ (e.g. in Han, Tanacross, and Southern Slave) or into /b/, /d/ (e.g. in Tahltan, Sekani, and Bearlake Slave). In all of these languages these stops still alternate with nasals before nasalized vowels. In some of them, e.g. in Bearlake Slave, the nasal realization is also still found in certain morphological contexts (Rice 1993).

Further illustration of the sonorant-like behavior of voiced stops comes from West African languages such as Cama (Ebrié), Gbe, and Ikwere. For example, Botma and Smith (2006) observe that Cama, a Kwa language of the Ivory Coast, contrasts two types of voiced stops, which Stewart (1973) describes as "fortis" and "lenis", respectively. The voiced lenis stops pattern with sonorants in that (unlike the voiced fortis stops) they alternate with nasals before nasalized vowels and do not trigger tone lowering. The voiced labial stop of Gbe, a Kwa dialect cluster of Togo and Benin, also displays oral–nasal alternations, in contrast to voiced alveolar and velar stops (Capo 1981). This /b/ derives from an earlier implosive *ɓ, which in many African languages patterns as sonorant (e.g. Kaye 1981; Clements 2000): like sonorants, implosives have unmarked voicing, are disfavored in NC clusters, often display alternations with both liquids and nasals, and fail to trigger tone lowering.

These properties are also characteristic of the voiced "non-explosive" labial stops of Ikwere, an Igboid language of Nigeria. However, Clements and Osu (2002: 337) observe that these sounds do not pattern with sonorants with respect to their "sonority-related distributional properties," nor do they behave as sonorants with regard to suprasegmental aspects such as tone and weight. This ambivalence appears to be representative of sonorant obstruents in general, and suggests that the internal structure of these sounds contains both obstruent and sonorant properties. To this end, Clements and Osu propose two distinct binary features, [obstruent] and [sonorant]. The former is an articulatory feature defined in terms of "air pressure build-up in the oral cavity," the latter an acoustic feature defined in terms of "a periodic, well-defined formant structure" (cf. Clements and Osu 2002: 338). Sonorants in this account are [–obstruent, +sonorant], while non-explosives have been criticized on the grounds that they are unable to account for phenomena that are acoustically motivated, such as the frequent interaction between labials and velars (e.g. Hyman 1973). The appropriateness of an articulatory characterization of [sonorant] has also been questioned, perhaps most notably in the work of Ladefoged (e.g. 1971, 1982, 1997), who maintains that sonorancy is best defined in acoustic terms, in line with the previously dominant approach to features of Jakobson *et al.* (1952).

Central to the *SPE* approach to sonorancy is the notion of "spontaneous voicing," which Chomsky and Halle claim is different from obstruent voicing, both phonologically and phonetically. The former claim is also the main tenet of the SV hypothesis, as we have seen in §2.1. However, it is not clear whether proponents of this hypothesis also take sonorant voicing to be phonetically distinct from obstruent voicing (cf. e.g. Rice 1993: 341), nor is it clear whether in the SV approach distinct features are required to have distinct phonetic correlates.

There are two general problems with spontaneous voicing as used in *SPE*. The first is that while in *SPE* spontaneous voicing is a key ingredient of sonorancy, Chomsky and Halle's definition does not in fact require sonorants to be voiced. This has a number of unfortunate consequences. One of these concerns the interpretation of "voiceless" sonorants, which are usually voiceless (at least for part of their duration; see §2.3) despite the fact that their vocal tract shape is conducive to voicing. Another is that in *SPE* the set of [+sonorant] segments includes the laryngeals, [h ʔ]. While these are like sonorants with respect to their vocal tract shape, their laryngeal setting is antagonistic to voicing, and for [ʔ] is in fact incompatible with it. This leads Ladefoged (1971: 109) to qualify this proposal as "counter-intuitive to say the least." An analysis of [h ʔ] as sonorants is also dubious on phonological grounds. Consider the interpretation of the lenition processes in (12), both of which are common sound changes in languages of the world (see e.g. Campbell 2004 for examples).

(12) a. f s x > h

b. p t k > ʔ

McCarthy (1988) argues that these processes are best treated as involving the loss of oral place features, which leaves behind segments specified for laryngeal structure only. According to this interpretation, [h ʔ] are therefore "defective" obstruents, like the "complete" obstruents from which they are derived. Notice further that [h ʔ] also do not display class behavior with sonorants with respect to the properties mentioned in §1. Laryngeals are never syllabic or tonal, nor do there seem to be any languages in which they are weight-bearing to the exclusion of non-sonorants.

The second problem with spontaneous voicing is that the phonetic evidence which Chomsky and Halle adduce for it is questionable, as pointed out by Ladefoged (1971), among others. Twenty-five years later, in joint work with Maddieson, Ladefoged sees no reason to change this view:

> The physiological position for modal voice can be regarded as one in which the arytenoid cartilages are in a neutral position for speech, neither pulled apart nor pushed together (Stevens 1988). The vocal folds would be very slightly apart, if there were no air flow. We assume that the same position as occurs in ordinary voiced

> vowels and in voiced continuant consonants such as nasals is normally maintained in stops that are phonologically voiced. (Ladefoged and Maddieson 1996: 50)

If sonorants and voiced obstruents do not differ in the laryngeal physiology of their voicing, then the difference between them must lie in the effect that the supralaryngeal configuration has on vocal fold vibration. Sonorants involve an unconstricted vocal tract, so that in these sounds sustained voicing is possible. Obstruents, on the other hand, involve a constricted vocal tract, which for aerodynamic reasons inhibits vocal fold vibration (e.g. Ohala 1983). The effect of this is that voiced obstruents lack a well-defined formant structure. This is presumably the reason why in many languages sonorants behave as a class to the exclusion of both voiceless and voiced obstruents. A case in point is a language like Dutch, where final devoicing targets voiced obstruents (13a) but leaves sonorants unaffected (13b).

(13)	a.	*bed*	/bɛd/	[bɛt]	'bed'	cf.	[bɛd-ə]	'beds'
		reis	/rɛis/	[rɛis]	'journey'		[rɛiz-ə]	'journeys'
	b.	*bel*	/bɛl/	[bɛl]	'bell'		[bɛl-ə]	'bells'
		trein	/trɛin/	[trɛin]	'train'		[trɛin-ə]	'trains'

For a detailed discussion of final devoicing in Dutch and other languages, see e.g. Warner *et al.* (2004), CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION, and references there.

A possible challenge to the claim that sonorants and obstruents do not differ in the physiology of their voicing comes from tone. Research on tone languages has shown that obstruent voicing often conditions a lower tone on a following vowel, and is in many cases the diachronic origin of low tone (e.g. Matisoff 1973; Bradshaw 1999; Yip 2002; see also CHAPTER 97: TONOGENESIS). Sonorants generally do not have such an effect, although there are exceptions, such as in Ewe (Smith 1968, cited in Yip 2002). It could therefore be suggested that the characteristics of obstruent voicing differ from those of sonorant voicing after all. This is the position taken by e.g. Yip, who, following Halle and Stevens (1971), maintains that voiced obstruents involve slacker vocal folds than sonorants. The reasoning behind this is aerodynamic: the oral constriction characteristic of obstruents raises the supraglottal air pressure, which slows down the rate of vocal fold vibration; to counteract this, the vocal folds are slackened, which lowers the pitch of a following vowel. The degree of oral constriction in sonorants, on the other hand, does not raise the air pressure to such an extent that this inhibits vocal fold vibration.

While this is not the place to focus on consonant–tone interaction in any detail, a couple of brief comments are in order. The experimental findings reported in Hombert *et al.* (1979) show that both voiced obstruents and sonorants trigger pitch lowering in a following vowel, both in tonal languages like Yoruba and in non-tonal ones like English. This is unexpected if obstruent-induced lowering is caused by aerodynamic factors. Hombert *et al.* reject this kind of explanation, arguing instead that in voiced obstruent stops the larynx is actively lowered during the latter part of the stop's closure phase, and that this is responsible for pitch lowering. However, as Hombert *et al.* themselves note, this account, too, fails to explain why sonorants, whose realization does not normally involve downward movement of the larynx, also lower the pitch of a following vowel.

best that can be said is that sonorant stops are consistently realized with *active* voice facilitation, and that the degree of voice facilitation is such that these sounds are voiced throughout their duration.

Thus, while the presence of voice facilitation cannot be used as a diagnostic for the sonorant status of a sound, two reasonable hypotheses can be made. The first is that active voice facilitation is a prerequisite for sonorant but not for obstruent stops. The second is that in languages where sonorant stops contrast with obstruent stops, the former involve a greater degree of voice facilitation than the latter. Support for the latter hypothesis comes from Bearlake Slave, a Northern Athapaskan language, which contrasts plain, aspirated, and ejective stops, and an additional series of voiced alternating stops. The description in Rice (1994, 2006) suggests that the realization of the plain stops is similar to the lenis stops of English. The voiced alternating series, on the other hand, is fully voiced and optionally prenasalized, suggesting a greater degree of voice facilitation. This phonetic difference correlates with a phonological difference. The two types of stops behave differently under perfective formation, where alternating stops are nasalized (14a) while non-alternating ones remain unaffected (14b) (cf. Rice 1993: 322–333; the vowel changes are due to an independent ablaut process):

(14) a.	*Alternating stops*		b. *Non-alternating stops*	
	-de	'win-IMPERF'	-da	'move-IMPERF'
	-nǭ	'win-PERF'	-dǭ	'move-PERF'

Rice analyzes the alternating stops as sonorants, specified for an SV node, and the plain stops as obstruents, unspecified for any laryngeal structure.

Some cases of class behavior of sonorant obstruents and sonorants appear to support the relevance of aerodynamic aspects of sonorancy. The most compelling evidence for this comes from Ikwere (Clements and Osu 2002). This language has a contrast between voiceless and voiced "explosive" stops, and an additional contrast between voiced and glottalized labial "non-explosive" stops. We saw in §3 that the latter display sonorant-like behavior (they alternate with nasals, do not occur in NC-clusters, and fail to trigger tone lowering). Clements and Osu transcribe the non-explosive stops as /ḅ/ and /'ḅ/, noting that they derive from historical labial-velars. Phonetically, /ḅ 'ḅ/ are non-implosive, and they are characterized by the absence of heightened air pressure. /'ḅ/ is pre-glottalized, and as a result voiceless throughout the initial part of the closure phase; the latter part of /'ḅ/ has modal voicing. /ḅ/ has modal voicing throughout. Importantly, the same is true of the voiced explosive /b/, which also has roughly the same duration as /ḅ/. The contrast between /b/ and /ḅ/ thus resides first and foremost in their air pressure characteristics. This difference certainly also leads to an acoustic difference (otherwise children acquiring Ikwere would not be able to discriminate between the two sounds), but Clements and Osu's data show that this difference does not seem to lie in the sounds' voicing characteristics. If the class behavior of non-explosives with sonorants is taken to be phonetically natural, then this can be achieved either by extending the correlates of sonorancy to include air pressure characteristics or, as Clements and Osu argue, by differentiating between an acoustic feature [sonorant] and an articulatory/aerodynamic feature [obstruent].

Alternatively, it might be argued that the phonetic motivation for class behavior of non-explosives with sonorants lies in the history of Ikwere. Such an account would have to show that the historical labial-velars can be reasonably treated as acoustically closer to sonorants. It is worth noting in this respect that labial-velars are sometimes produced with an ingressive airstream mechanism (e.g. Ladefoged 1968; Cahill 2008). This makes them similar to implosives, which frequently pattern as sonorants (see §3). It is also worth noting that Ikwere /ḅ 'ḅ/ are velarized, which, as Clements and Osu suggest, may be a reflex of their earlier velar articulation (cf. also Ladefoged and Maddieson 1996: 89, 343). Clements and Osu conjecture that velarization expands the oral cavity to such an extent that the non-explosive release of /ḅ 'ḅ/ is characterized by ingressive airflow, though, as noted, this does not appear to lead to more prominent voicing.

5 Discussion and conclusion

This chapter has considered three issues in the phonology of sonorants: (i) the representation of sonorancy in segmental structure (and its relation to laryngeal contrasts); (ii) the interpretation of fuzzy class behavior of sonorants and sonorant obstruents; and (iii) the phonetic correlates of sonorancy. As the preceding discussion makes clear, the thread that runs through these issues is the relation between sonorancy and voicing.

The main challenge facing a theoretical interpretation of sonorancy is to provide an adequate account of the observation that voicing is never contrastive in sonorants, but may nevertheless be required in their phonological specification. A further challenge concerns the observation that if voicing is not contrastive in sonorants, then sonorants evidently entertain a different relationship with laryngeal contrasts than do other segment types, such as stops and fricatives. It would seem that none of the segmental theories currently on offer can account for this difference in any straightforward way. A further challenge is posed by the class of "voiceless" aspirated sonorants, whose sonorant status is not entirely clear.

The relation between sonorancy and voicing is also relevant in the interpretation of fuzzy class behavior of sonorants and voiced stops and fricatives. In some languages where this is observed, such as Southern Barasano, the relevant class consists of all voiced sounds of the language, viz. sonorants and voiced stops, suggesting that the latter function phonologically as sonorants. In other languages, such as Cama and Bearlake Slave, some voiced sounds pattern with sonorants whereas others do not. In such languages, it appears to be the case that the sonorant obstruents involve active voice facilitation, manifested phonetically by such gestures as prenasalization and implosion, making their voicing more prominent than that of their voiced obstruent congeners.

Finally, the relation between sonorancy and voicing is also important with regard to the phonetic underpinnings of sonorant class behavior. There is good reason to believe that class behavior of true sonorants is phonetically natural in that these sounds are characterized by a clearly defined formant structure, an acoustic property which sonorants share to the exclusion of other sounds. Such a characterization is not only simpler than an articulatory one but also avoids the dubious notion of spontaneous voicing, for which little phonetic support has been found. The class behavior of sonorants and sonorant obstruents seems natural to the extent that both involve sustained vocal fold vibration. However, in some languages, such as Ikwere, sonorant stops do not appear to differ from their obstruent counterparts in terms of their voicing characteristics, suggesting that in this language sonorancy correlates with a combination of periodicity and lack of supraglottal air pressure buildup. While this is perhaps a "far-fetched notion," as Ladefoged asserts, there is recent evidence that listeners do indeed make use of the multisensory integration of perceptual events. Gick and Derrick (2009) show that *pa/ba* syllables are more likely to be heard as aspirated by English listeners (i.e. causing them to mishear *b* as *p*) when these are accompanied by cutaneous air puffs at the right hand or the neck, suggesting that information from the auditory and the tactile domain may combine to form a salient psychological percept. We should not be surprised, then, to find that similar multisensory integration is found within the auditory domain itself.

ACKNOWLEDGMENTS

The author acknowledges the assistance of the Netherlands Organization of Scientific Research (NWO) for funding project no. 2008/01214/GW. Thanks are also due to two anonymous reviewers and to the editors of this volume for useful and constructive comments, suggestions, and criticism. One reviewer deserves special thanks for drawing my attention to Gick and Derrick (2009). Needless to say, none of them is responsible for any remaining errors of fact and interpretation.

113 Flapping in American English

Kenneth J. de Jong

1 Original insights

In the mid-1930s, several scholars of American English from around the USA noted a peculiarity that, apparently, was becoming a pervasive and characterizing feature of the production of coronal stops in certain intervocalic positions. A high-profile notation of the phenomenon was by John Kenyon in the sixth edition of *American Pronunciation*, where he notes the presence of /t/s that are voiced in American, as opposed to British, productions. What gathered more original scholarly attention to this phenomenon is the question of how to characterize these productions. Haugen (1938) noted in particular that the productions of /t/ in words like *pity* had become so different from that in words like *typical* that classifying them as the same segment was becoming untenable, and so he posited the presence of an allophone of /t/ in American English.

Haugen noted a variety of aspects of the allophonic variant. Along with Kenyon, he noted the dialectally specific occurrence of voicing and lack of aspiration, but noted in addition a shortening and weakening of the closure. The closure weakening, then, contributes to a classificatory issue as to whether the allophone of /t/ is, in fact, not just a voiced version of the same consonant, but actually crosses into the same phonetic region inhabited by liquid sonorants. In order to evaluate this possibility, he compared the allophone with other liquid sonorants, with British rhotics, e.g. between British *porridge* and American *pottage*, with cross-language mapping comparisons, and with non-native substitution of rhotics for the allophone, e.g. Italian American *siri* for *city*. In addition, there had been many earlier observations of British dialectal variants involving substitution of /r/ for /t/, noted by Jespersen (1928), which probably indicate the seeds of the characterizing American feature in British dialects. These observations led various scholars, such as Bloomfield (1933), to describe the allophone as a ballistic flap (or "flip"). In these early discussions of segmental classification, a prominent issue is how to deal with the apparent level of variability in the voiced allophone, with Haugen (1938) suggesting that the variability in production is general to the nature of these sorts of ballistic rhotics. Oswald (1943), on the other hand, suggests three distinguishable outcomes – a voiced stop, a tap, or a "flip" (presumably, a coronal approximant) – but also states his belief that the three representations are probably just artificial divisions of a single continuum.

Complicating the analysis of the phenomenon was the realization by Kenyon (1936) that the process is sometimes a neutralizing process, collapsing productions of /t/ with those of /d/. Again, earlier works had noted dialectal (Wright 1905) or lexically specific (Krapp 1919) substitution of /d/ for /t/ in the flapping environment. While the general discussions in the 1930s usually did not treat the process as neutralizing (Bloomfield 1933; Twaddell 1935; Trager 1942), both Haugen and Kenyon noted that actual neutralization of the /t/–/d/ contrast can occur in the speech of some speakers. Even more striking, Oswald (1943) a little later documented the pervasive nature of the neutralization, in an experiment in which high school students were asked to produce and identify 14 pairs of potential homophones in sentential contexts; there was no difference in identification of items produced with orthographic *t* and *d*. However, Haugen (1938) in particular noted that the duration of the preceding vowel might not be neutralized, and suggests this as an important area of research. Also of interest in these discussions is the question of whether the outcome of the process is directional, creating [d] from /t/, or whether, as claimed by Haugen (1938), the process collapses both /t/ and /d/ into a third category, as is typical of later analyses.

A second major subject of the early discussions concerned how to characterize the context in which the allophonic shift happens. Haugen (1938), for instance, corrected Uldall's (1934) claim that voicing shift happens in final position. He then went on to summarize Kenyon's claims with a fairly simple formula for the allophone's occurrence:

> [I]t cannot occur unless it is *preceded* by a vowel or a sonorant (*n, l, r*), and is *followed* by an unstressed syllable-forming element (vowel, *l, r*, but not the homorganic *n*). (1938: 631)

His basic analysis has withstood the test of time; it is remarkably similar to those found in most of the subsequent discussions of the phenomenon (e.g. Kahn 1976; Hayes 1995).

One complicating aspect of the early observations is a failure to distinguish cases which later would be treated as a slightly different phenomenon, the glottalization of /t/ in word-final position. Thus, Kenyon's (1936) treatment considered the lack of aspiration in a sequence like *get here* as another example of the same flapping phenomenon, complicating his analysis of the overall pattern of occurrence.

Haugen (1938) noted various segmental restrictions on the rule as well. Specifically, he noted that a preceding consonant does not block the weakening, nor do following syllabic consonants, except /n/. He also noted that the flapping of /t/ is gradiently sensitive to consonant context, with greater weakening after /n/ than /r/; Oswald similarly suggests that the outcome of the process after /r/ is actually a voiced stop. Further, in the post-nasal context, Haugen noted that both the stop and the homorganic nasal are subject to weakening. He also noted greater weakening before /r/ than before /l/.

While the early works on flapping thus covered much of what is currently known about the phenomenon, although only in seminal form, one aspect of the phenomenon that is wholly absent is the question of how and whether this segmental effect might generalize beyond the coronal consonants. In all of the treatments in process might be profitably understood in terms of a gradient set of production constraints whose application is determined by the exigencies of speech rate and segmental context. This gradient variation, then, becomes quantized in the acoustic domain, yielding quasi-categorical output variation. Fujimura (1986) similarly suggested that flapping might be the output of tongue–jaw interactions, such that lower jaw positions tend to weaken and retract coronal closures, yielding the typical acoustic effects of flapping.

If this is the case, it raises the question of whether the flapping phenomenon requires any categorical shift at all, i.e. it could be, then, that flapping results from the dynamics of the speech motor system, rather than from a specification of a categorically different speech goal. To make this sort of explanation tenable, it is necessary to link the conditions on the occurrence of flaps to processes that would yield the appearance of flapping as a by-product without the need to stipulate an overt rule. The advantage to this approach is potentially on two fronts. First, if a general characterization of the prosodic and segmental conditions of the flapping rule will get the outcome of flapping automatically, the statement of an additional phonological process becomes superfluous. Developing models of prosodic and segmental dynamics is a pressing research goal in its own right, and if it obviates a phonological rule, so much the better. Second, this approach would likely be amenable to explaining the troublesome variability in the outcome of the rule that has been noted since the earliest detailed descriptions of the phenomenon.

De Jong (1998) reported a series of analyses that attempt to explain flapping in this way, as it occurs in a small corpus of singleton consonants in coda position before a vowel-initial word. This study corroborated Oswald's (1943) impressions that the stops vary in transcription along a continuum from a flap to a fully articulated [t], with many instances of orthographic *t* being transcribed as a fully articulated [d]. While this continuum of weakening would appear to be amenable to explanation as an articulatory-to-acoustic by-product, the acoustic and articulatory analyses in de Jong (1998) failed to find any straightforward way of characterizing the articulatory processes that would yield the right impressionistic outcomes. The candidates examined there included jaw dynamics and timing models, both of which failed to make the right predictions concerning causal factors. For example, while jaw mechanics would suggest that flaps result from lower jaw positions, the data indicate no systematic difference in actual jaw position during the occlusion for flaps and stops. Similar problems were found for treating flapping as a sort of durational undershoot induced by the proximity of neighboring vowels. Here, while there are different tongue body positions for flaps and stops, such that the tongue body is closer to the positioning for the vowel with flaps, this difference in overall lingual posture is more apparent during the closure itself than it is during the vowel that is supposed to be driving the occurrence of flapping.

Fukaya and Byrd (2005) examine the dynamics of overlap between the consonant and vowel in the /t/-flapping cases in greater detail, adding an additional condition in which a phrase boundary follows the target stop. They find that the transcribed flaps in different conditions with different talkers exhibit different kinematic patterns. One general observation from their data is that, despite the traditional description of flaps as being "ballistic" in nature, there is no apparent increase in the acceleration peaks for flaps over non-flaps. In general, what is consistent across events transcribed as flaps is the occurrence of a short acoustic with glottal trans-illumination (de Jong *et al.* 2002) find three very distinct glottal movement patterns for /t/s in different conditions. Onset and typical slow-rate coda /t/s exhibit large glottal openings corresponding to aspiration; in coda /t/s the glottal opening may fluctuate with a glottal closing gesture corresponding to glottalization; at fast rates, productions of coda /t/ typically exhibit no large glottal movements, yielding what would be perceived as instances of flapping. Thus, even in extreme production circumstances, glottalization is a distinct outcome from flapping.

However, this does not solve the larger problem of understanding how the environments for flapping and glottalization get resolved. Selkirk (1982) noted the inherent competition for targets between these two processes, and differentiated them by reference to a release feature on the target; consonants in the flapping environment have a release characteristic in the relevant prosodic domain, while glottalized targets are final and unreleased. Thus the apparent difference between the two would be one of prosodic domain, whether a boundary corresponds to the consonant release. However, there are obvious cases in which coronal stops in the glottalization position are flapped, even though the constraints on the flapping rule are not met. An example of this is in function word clusters such as *at all*. Here, the medial stop is typically flapped, even though the following vowel is stressed (cf. *atoll*, which has an aspirated stop). These forms suggest a possible role of word sequence frequency in triggering the rule, although it is not clear how such a trigger would work in descriptions of the process.

Other research in prosodic conditioning of flapping locates the level of affiliation at a lower level, the level of the syllable. All logically possible affiliations of the affected stops have been espoused. Selkirk (1982), due to the general observation that the onset allophone is really the odd man out, suggested that the consonant weakening is due to the stop being resyllabified (or in the case of cross-word-boundary application, syllabified) as a coda. Davis and Summers (1989) concur with this analysis. Kahn (1976) and Gussenhoven (1986) – to create a structure that would distinguish the flapping environment from the coda environment which would trigger glottalization – posit ambisyllabicity as the conditioning factor, doubly associating the medial consonant. De Jong (1998) – to complete the typology of possible analyses – suggested that the weakened consonants are onsets to the following syllable, based on the analogy of flapping with vowel reduction; both effects would be weakening processes that target unstressed syllables. Elicited syllabifications of flaps in Eddington and Elzinga (2008) show that, while aspiration is strongly associated with onset syllabification, flapped stops tend to be syllabified in various ways, depending on a number of contextual factors.

This disagreement in syllabic representation indicates a more fundamental difference of opinion as to the underlying mechanisms that should account for the occurrence of flapping, and that is whether flapping is refllex of syllable-level or higher-level (foot- or phonological phrase-level) position, or whether it is more properly viewed as a segmental effect.

The prosodic position is taken up by Davis (2005), who along with Steriade (2000) points out that the medial *t* in words like *Mediterranean* should be flapped, in the classic specification of the flapping environment. However, stops in this position, in parallel with non-coronals (VanDam 2003), are systematically non-neutralized and even lightly aspirated. This, according to Davis (2005) (Steriade espouses a different position, and notes these forms as exceptions), is due to the stop occurring at the beginning of a metrical foot (see CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE and CHAPTER 40: THE FOOT for further instances of foot-internal segmental processes). The flapping rule, then, is an indicator of a foot-medial and post-stress position. Pre-stress positions are regularly marked with aspiration with voiceless stops, and so fit with the "normally articulated" stops that Kenyon and Haugen posited for onset positions. A complicating factor in these analyses, and one that is the focus of other recent analyses, is a typical difference noted by Withgott (1982), and confirmed by Steriade (2000), that words like *capitalistic* with a base form containing a /t/ in flapping position tend to be flapped, while words like *militaristic* with a base form with /t/ in a non-flapping pre-stress position tend not to be. One problem with the *militaristic/capitalistic* pair is that the unflapped *t* is before a rhotic, which can syllabify with the previous *t*, creating a cluster, while the flapped *t* is before a lateral, which cannot form a cluster. However, this sort of paradigm uniformity effect (see CHAPTER 83: PARADIGMS) can also be seen in the data in Turk (1992), where the /t/ in *diameter* is clearly flapped, while the /d/ in *pyramidal* appears not to be (since closure durations are exceptionally long). Here, the /d/ in the base form is in final position. Also, Withgott (1982) notes a similar contrast between unflapped *militarize* and flapped *parameterize*, both of which have coronal stops followed by a rhotic.

One final point about prosodic analyses is that the flapping phenomenon is similar to consonant lenition processes in other languages, such as "spirantization" (actually "approximantization," usually) of voiced stops in most varieties of Spanish (see CHAPTER 66: LENITION). Lewis (2001) shows conclusively that this weakening process is an indicator of a medial position in a prosodic phrase. Flapping would be similar, although the domain indicated would be smaller, sometimes smaller even than a lexical item.

2.5 *The scope of flapping*

The previous discussion of prosodic conditions on flapping points out that the flapping rule, although often not noted as such, should be situated within an array of parallel lenition processes that affect other consonants. The parallelism is more obvious if we examine the voiceless stops in onset position. In onset (and foot-initial) positions, all three voiceless stops in English exhibit aspiration. This aspiration is systematically modulated by various prosodic factors, such as the occurrence of a preceding sibilant, which removes aspiration from all three stops. In addition, the presence of heavy stress increases aspiration duration for all three stops, and the aspiration that is foot-initial is weaker than the aspiration that is immediately preceding a stressed vowel (VanDam 2003). All of these facts about aspiration are systematically found for all three stops.

When we switch to non-initial positions, we also find some parallelism, in that all three stops can be subject to glottalization, although glottalization is much more common in the coronals than in the others. A very similar situation holds with the flapping environment; there is a greater proportion of voicing in closure and a much shorter closure not only for the coronal targets of the flapping rule, but also for dorsal and labial consonants as well. This observation is one of the driving factors in such works as de Jong (1998), which seek to explain flapping as part of a larger prosodic organizational process. While positing a flapping rule of some sort will explain the coronal process, such a rule would not account for the parallel, although less obvious, weakening processes in the other points of articulation.

On the reverse side, a persistent challenge to explaining flapping as a general prosodic process is the fact that the coronals are markedly different from the labials and dorsals in degree of weakening. While coronals are commonly noted as being neutralized, labial and dorsal consonants in the same environment, while perhaps exhibiting some voicing confusion, cannot be said to be neutralized in speakers of American English. For example, Davis and Summers (1989) compare coronals with labial and dorsal stops, finding much shorter closure durations for coronals, as well as very little difference between /t/ and /d/ closure which differs from stops at other points of articulation that have shorter closures with voiced stops. Turk (1992) finds even more striking differences by point of articulation.

The approach taken in de Jong (1998) was to point to the linkage of the coronal articulation to the jaw. Previous work on interarticulator variability, e.g. de Jong (1995), notes that coronal consonants tend to impinge on jaw movement patterns more than do dorsal and labial consonants. This linkage to the jaw, then, if we reverse it, would suggest that coronal articulations are particularly vulnerable to jaw perturbation by other speech goals, such as those for the neighboring vowels. Thus, coronals may be particularly susceptible to neighboring segment effects. It should be noted that such a model was not particularly successful at explaining the articulatory patterns in de Jong (1998).

A problem, then, with this generalized approach is that lenition processes, e.g. "spirantization" in Spanish, do not exhibit this radical difference between coronal and non-coronal segments. If anything, studies of spirantization such as Lewis (2001) indicate that the dorsal closures are most weakened by vocalic environment as would be expected on the basis of overlap of tongue body articulation between the stop and the neighboring vowels. Considering the weakening of voicelessness, Lewis (2001) finds labial stops exhibit the greatest amount of decrease in voicelessness and noise generation. While there may be some additional consideration, such as the fact that Spanish coronals tend to exhibit more anterior articulations than those in American English, the difference between the lenition processes in the two languages is striking.

There are further differences that emerge as one tries to generalize the flapping rule as an example of general medial lenition. For example, a persistent issue for functional explanations of lenition processes is the different outcomes for different languages. Hock's (1991: 83) treatment of historical lenition processes shows clearly that lenition processes of this kind can run in two different directions; either they can tend toward closure weakening and hence spirantization, or they can tend toward aerodynamic weakening and hence voicing and sonorantization. The traditional treatment of Spanish lenition suggests a lenition process of the former variety, while flapping appears to be of the latter variety.

It is possible that part of the explanation of the difference in outcome between, for example, Spanish and English medial lenition lies in the historical paths of the two phenomena. An intriguing oddity in Haugen's (1938) description of the weakened coronal stops is that they should be analyzed as spirants, in parallel to the weakened sounds at other points of articulation. This description is parallel to traditional descriptions of Spanish. While it might indicate an analytic bias on Haugen's part (perhaps even from his contemporaries' analyses of languages such as Spanish), it could also indicate that the "flaps" of the time period were more like fricatives.

A different line of reasoning with respect to the difference between Spanish and English would lie in the phonemic inventory of the languages and the potential for a neutralization of the stop categories with short rhotics in Spanish (Gurevich 2004). Gurevich proposes a limiting constraint on lenition processes of a functional pressure to maintain contrasts. Since English has an approximant rhotic, the weakened coronal stops can safely become flaps without incurring neutralization with the rhotics; the same outcome in Spanish would create (near-)neutralization with the Spanish rhotic. (This observation was inherent in the discussion of stop weakening as a flapping rule in the 1930s.) On the other hand, spirantization of the stops in English would incur (near-)neutralization of the stops with the dental fricatives. (See also CHAPTER 30: THE REPRESENTATION OF RHOTICS.)

One aspect of this analysis is that is incomplete, however, is the fact that it does not explain why it is that the American English coronal is exceptional, while the Spanish coronal is not. While Gurevich examines cases of lenition irregularity across point of articulation, there is no apparent source for the coronal exceptionality, based on contrastive pattern. While the dorsal non-sibilant fricative does not exist in English, the parallelism between non-sibilant labials and coronals is fairly striking, and yet the coronal is subject to extensive sonorantization lenition, while the labial is not. (For further discussion of cross-linguistic coronal exceptionality, see CHAPTER 12: CORONALS.)

2.6 *The larger context of flapping*

If we consider general models, it becomes readily apparent that, whatever model of explaining flapping might be attempted, the model must account for a critical fact about the rule, that it specifically indicates American English. The fact that Spanish does not flap might be attributed to the fact that Spanish has different phonemic contrasts. However, it is not only Spanish that does not flap; other varieties of English do not either. Whatever information can be gleaned from generalizing models, this historically rooted fact needs to be accounted for.

Interestingly, Haugen's (1938) analysis posited the outcome of the rule as being a spirant. This is curious, given the fairly accurate level of observational detail in the analysis in other respects. It is possible that he was simply in error in this observation. However, it is also possible that the outcome of the lenition process in the 1930s was a spirant of some sort. If this is the case, the process has actually changed within the 70 years of observation, since spirantization is not found in any later instrumental analysis. Current varieties of Southern British English, however, are replete with spirantized productions of coronal stops in the flapping environment.

What these observations suggest is that flapping historically might be better seen as at least a two-stage process, including an initial weakening and neutralization stage with a more obvious connection between the segmental and prosodic triggers of the process and the weakened outcome of the process. Currently, however, it is clear that the process goes much further than what would be expected from a general weakening process. If this is true, the peculiar feature of American English lenition as creating flaps could be a later development from a more typical development of spirants as seen in other languages. Hence, what we see currently is a highly grammaticized version of a lenition process.

This is what would be expected from a process of grammaticalization that takes variability rooted in the exigencies of natural production and categorizes this gradient variability into a separate segment. The new category generally fits what we would expect if it were merely an outcome of general segmental co-articulation, or if it were just another example of prosodic modulation. However, upon closer inspection, we find that the co-articulatory effects and prosodic effects in this case are not the same as in parallel cases, since there appears to be a different category of segment. This segment has the prosodic contextual effects "packed in it"; the formerly transparent contextual triggers' effects get encoded in the consonant itself.

Two further considerations should be included at this juncture, however. The first concerns the conditions that would grammaticize the lenition process. While it is quite difficult to ascertain at this juncture, the documentation examined above would suggest that, while sporadic cases of coronal lenition appear in most varieties of English, and lexically specific cases are documented in the early twentieth century, it was in the 1930s that the literature on the phenomenon expanded rapidly and instrumental studies begin finding robust support for it. While this is quite speculative, it does appear as if the specific lenition of coronal stops to flaps rapidly became a marker of American English. This general historical sketch would suggest that an important consideration in the development of categorical flapping is specifically social in nature, connected with the continued development of a specifically American English in the mid-twentieth century, following the First World War.

The second consideration that must be brought in at this juncture concerns the pervasive issue of variability in production (see CHAPTER 92: VARIABILITY). One strike in favor of the segmental or prosodic by-product approach to flapping is that of understanding the gradient nature of the outcome of the process. This remains an important consideration for anyone wishing to understand the process; while the various linguistic factors in the process – segmental and prosodic – do much for characterizing the process, the actual occurrence of the phenomenon in running speech is very messy. One consideration in explaining this degree of variability is the fact that the process is largely (despite descriptions by structuralist phonologists up to the present day) a neutralizing process. While much is made of the non-homophonous nature of flapped *t* and flapped *d*, the fact is that /t/–/d/ minimal pairs are distinguished very poorly relative to other segmental contrasts.

This neutralizing property is something that speakers of American English, most of whom are literate, must come to grips with during the process of learning to read (even if they never notice any morphological relationship between words with flapped and non-flapped stops). This focus on orthography ensures that nearly all speakers under the right conditions will produce a flapped stop as its unflapped variant. This pool of unflapped versions is continuously being contributed to the pool of experiences that speakers encounter. In addition, the presence of unflapped variants is even more likely in speech directed at children in the learning process. This, in turn, ensures that there will be some proportion of speakers that, during the process of acquisition will do such things as produce words such as *Florida* with a voiceless [t], creating cases in which the distribution

114 Bantu Tone

Laura J. Downing

1 Introduction

1.1 Some background

There are roughly 500 Bantu languages, spoken in Africa south of a line going from Cameroon, in the west, to southern Somalia, in the east. It is a large language family both in terms of number of languages and in terms of number of speakers: roughly 240 million Africans speak Bantu languages, and several of the more well-known Bantu languages – like Swahili, Kikuyu, Zulu, or Kongo – have a few million speakers each (Nurse and Philippson 2003a).

Proto-Bantu is reconstructed with two contrasting tone levels.[1] While many Bantu languages remain poorly described, especially with regard to their prosodic systems, the available descriptions show that most modern Bantu languages have maintained this two-tone system. Only a few either are non-tonal, like Swahili, or have more than two phonological tone levels, like Kamba. Tonal minimal pairs are not common, but one finds them, as shown by the Jita data in (1a). The data in (1b) show that tone can be morphemic in Jita, as in other Bantu languages. Note that only tone pattern distinguishes between the perfective and distant past II tenses; segmentally, they are identical.[2]

[1] See Kisseberth and Odden's (2003) overview chapter on Bantu tone for a more detailed discussion of the issues summarized very briefly in this section. Most of the individual language and language group chapters in Nurse and Philippson's (2003b) compendium discuss tone and so provide the interested reader with an idea of the commonalities and the diversity of tone systems in this large language family.

[2] The data presented in this chapter copy the transcription conventions of the source cited, unless explicitly indicated otherwise. Readers should therefore not mistake these transcriptions for IPA representations, as they are influenced by the orthographic conventions of the respective languages. The original sources should, instead, be consulted for more information about phonetic details of pronunciation that are outside the scope of the issues discussed in this chapter. Long vowels are written as geminates and tone is marked independently on each vowel: e.g. [áá] is a long High-toned 'a'; [áa] is a long Falling-toned 'a'; [aá] is a long Rising-toned 'a'; [aa] is a long Low-toned 'a'.

(1) *Jita tonal minimal pairs* (Downing 1996: 48, 63, 183)

a.	oku-ííga	'to look for'	oku-iiga	'to pass (a test)'
b.	aa-lamuuye	's/he has already decided (PERFECTIVE)'	aa-lamúúyê	's/he decided (DISTANT PAST II)'

As Kisseberth and Odden (2003) note, it is an analytical problem for each Bantu language to determine whether the mora or the syllable is the "tone-bearing unit" (TBU). In the Bantu languages which have lost the Proto-Bantu contrast in vowel length, the choice is moot, in most cases. If one assumes, as most authors do, that only open syllables are licensed in Bantu languages, then the syllable and mora define identical TBUs in a language with only short vowels.[3] However, predictably lengthened penult vowels and moraic (or syllabic) nasals in NC sequences potentially provide evidence for a choice. When relevant, the TBU is mentioned in presenting the data in the examples below.

It has been argued since work like Stevick (1969) that High tone is the active tone in many Bantu languages, while Low tone is often best analyzed as a default (or underspecified) tone, predictable from context (see also CHAPTER 45: THE REPRESENTATION OF TONE). For example, in (1b), above, the Low component of the final falling tone is an intonational final Low tone, which, as Downing (1996) shows, predictably occurs at the end of statements in Jita. The asymmetry in the phonological activity of High and Low tones is reflected in the tone marking convention adopted by Bantuists (and used in this chapter) of only marking High tone with an acute accent, while leaving Low tone generally unmarked. As we will see in this chapter, the analysis of Bantu tone patterns is mainly preoccupied with accounting for the surface distribution of High tones.

Another asymmetry found in many Bantu tone systems, noted since at least McCawley (1970, 1978), is that in verbs only the initial syllable of the verb root contrasts for tone, while in nouns, every syllable can bear contrastive tone. Again, data from Jita illustrate:

(2) *Jita lexical tone contrasts in verbs* vs. *nouns* (Downing 1996)

	High-toned stems		*Low-toned stems*	
a.	*Verbs* (infinitive form is shown; *oku-* is the infinitive prefix)			
	oku-lyâ	'to eat'	oku-sya	'to grind'
	oku-βóna	'to see'	oku-βuma	'to hit'
	oku-ííga	'to look for'	oku-iiga	'to pass a test'
b.	*Nouns* (stem follows hyphen; initial morpheme is the class agreement prefix)			
	omu-gási	'woman'	omu-saani	'friend'
	omu-tuungâ	'rich person'	omu-lamusi	'judge'
	li-nanáji	'pineapple'		
	li-darinâ	'tangerine'		

These two asymmetries will be discussed in more detail in §2.

[3] See Downing (2005) for critical discussion of this assumption.

As Clements and Goldsmith (1984a) and Philippson (1998) argue, Meeussen's Rule is one of the important synchronic and diachronic processes lending an accentual character to Bantu tone systems, because it results in culminative prominence of High tone within some large morphological domain.

Another common process resulting in culminativity is tone shift. The Jita data in (4) provide examples of this process. As we can see, an input High tone is systematically realized one syllable to the right of its input sponsor unless the sponsor is in the penult or final syllable. The example in (4e) shows that tone shift crosses word boundaries. (We return to such phrasal tone processes in §4.)

(4) *Jita tone shift*

a.	oku-[βó̲na	'to see'
b.	oku-[βo̲nána	'to see each other'
c.	oku-[βuma	'to hit'
d.	oku-mu̲-[βúma	'to hit him/her (class 1)'
e.	oku-[fwa̲ kúmugera	'to die by the river'
	(oku-[fwá̲ 'to die'; kumugera 'by the river')	

As Kenstowicz (1993), Cassimjee and Kisseberth (1998), and Kisseberth and Odden (2003) show, tone shift is clearly related to the assimilatory process of tone spread. What is puzzling is why the High tone should delink from its sponsor syllable, since other types of feature assimilation do not typically involve such delinking. Kenstowicz (1993) argues that delinking is best understood as an accentual process, leading to High tone culminativity. By eliminating the sequence of High tones on adjacent syllables derived by tone spread, it makes one syllable in the word more prominent than the others.

Most Bantu languages appear to be like Jita. The tone system is not entirely stress-like, since it preserves a contrast between stems which have a High tone and those which are toneless. High tone assignment is not obligatory like stress would be. However, some Bantu languages have taken a step further toward having a stress-like accentual system in that all words have a single High tone, consistently assigned to a limited number of positions in the word. For example, Odden (1988) shows that in Bena, every noun must have a High tone, realized on either the penult or the pre-stem vowel, and most verb forms require a High tone on the penult:

(5) *Bena* (Odden 1988: 236)

a. *Nouns*		b. *Verbs*	
mú-goosi	'man'	kwaamíle	'put to pasture (SUBJ)'
hí-fuva	'chest'	ndi-líma	'I will cultivate (NEAR FUT)'
mu-gúunda	'field'	ndaa-limága	'I used to cultivate'
lu-fwiíli	'hair'	ndaa-limiíge	'I was cultivating'
li-fulúha	'cloud'	ndihaa-limíle	'I cultivated (INTERM PAST)'
		ndaa-limíle	'I cultivated (FAR PAST)'
		hu-limíla	'to cultivate for'

Other languages like Bena are discussed in Odden's (1988, 1999) critical overviews of what he calls "predictable" tone systems in Bantu languages.

edges. These properties have all been argued to motivate the interaction of tone with prosodic structure in work beginning with Goldsmith (1976). Let us briefly review, in roughly chronological order, some of the leading proposals.

In Goldsmith's (1976, 1984a, 1984b) accent theory, Bantu words do not have an underlying High tone *vs.* toneless contrast. Instead, the contrast is formalized as the presence *vs.* absence of accent (*). For example, the Jita High-toned words in (2) would have an accent on the underlyingly High-toned syllable, while Low-toned words would be unaccented, as shown in (8a). Processes like Meeussen's Rule (MR) would be motivated by stress clash, formalized to eliminate sequences of accents (rather than High tones), as shown in (8b; cf. (3b), above). Tone melodies are associated with accents at a later stage of the derivation:

(8) *Accentual analysis* (à la Goldsmith 1976, 1984a, 1984b) *of the Jita data in* (2)–(4)

a. Underlying contrast:

   /oku-βo*na/ 'to see' *vs.* /oku-βuma/ 'to hit'
   accented — unaccented

b. MR as clash resolution:

   /oku-mu*-βo*na/ 'to see him/her' → [oku-mu*-βona]

(Accents (*) are printed above the accented syllables: βo in /oku-βona/; mu and βo in /oku-mu-βona/; mu in [oku-mu-βona].)

The use of accent to formalize High tone culminativity was mostly abandoned by the mid-1980s, after influential work like Hyman and Byarushengo (1984) and Pulleyblank (1986) argued that the lexical High tone *vs.* toneless (or inactive default tone) contrast motivated by the output tone patterns can be straightforwardly represented by associating High tones with particular input syllables and underspecifying Low tone. The OCP-motivated process, Meeussen's Rule, eliminates sequences of identical adjacent High tones without appealing to stress clash. It is an unnecessary complication to have linked accents at one stage of the derivation and linked High tones at another, when an analysis that appeals only to High tones can account for this "accentual" property. (See Hyman 1989, Odden 1999, and Yip 2002 for detailed discussion.)

Accent continued to be appealed to in work like Goldsmith (1987), Kisseberth (1992), and Downing (1996), though, to account for the demarcative output position of High tone in many Bantu languages, illustrated by the Digo data in (6) and (7) above. This alternative accentual approach accounts for the fact that High tones tend to surface near word or morpheme edges – that is, syllables that are often assigned stress in stress languages – by assigning metrical prominence – accent – to these edges. In the unmarked case, High tones are "attracted" to these accented syllables (Goldsmith 1987; de Lacy 2002). In other words, in this theory, accent is redefined as metrical prominence, and accentual languages are defined as those in which (High) tone and metrical prominence interact. These points can be illustrated by an accentual analysis of the Digo data in (7a). Recall that in Digo the rightmost (or only) High tone surfaces on the penultimate mora (i.e. in the stressed syllable), while a second High tone, if any, surfaces on the verb-stem initial mora. This attraction of High tones to particular positions can be accounted for, as shown in (9), by assigning them an accent. (To formalize the generalization that if there is only one High tone, it surfaces on the penultimate mora, one could assign it a higher degree of metrical prominence than the stem-initial mora):

We can find other arguments supporting Cassimjee and Kisseberth's (1998) proposal that High tone realization in Bantu languages is mediated by prosodic tone domains, if we briefly return to Odden's (1999) non-accentual analysis of positional High tone realization in languages like Digo, sketched in (10). The non-accentual analysis was argued to be superior to an accentual one, as it requires no special prosodic representations, appealing to processes like extratonality, tone spread, and delinking of multiple associations which are commonly found in Bantu languages. Under closer examination, though, one notices that only tone spread – i.e. a form of assimilation – is considered an unmarked featural process, common outside of Bantu tone. It would be very surprising, though, to find a vowel harmony process, for example, which excluded the final syllable of a word through "extra-harmonality." It would also be unusual to find a vowel harmony system where only the rightmost vowel of a harmony span surfaced with the harmonizing feature, while it delinked from the other vowels in the span. In contrast, non-finality (extrametricality) is a typical property of prosodic constituents and accentual processes like stress assignment. And, as noted above, Kenstowicz (1993) argues that delinking of High tones from all syllables except the rightmost in a span falls out if the rightmost syllable is a prosodic head. Delinking results in a prosodic prominence asymmetry that is a defining property of prosodic heads.

In short, one must conclude that the jury is still out on whether the prosodic properties, including accentual properties, of Bantu tone systems are best accounted for by appealing to prosodic representations. One can account for many accentual properties of Bantu tone systems without appealing to accent or prosody. However, in doing that one often loses explanatory force, by ignoring the fact that many common restrictions on Bantu tone realization are also common restrictions on headed prosodic constituents but rare for other types of feature assimilation processes.

3 Depressor consonants

Bantu languages are well known for their so-called "depressor consonants": that is, sets of consonants, often voiced, which block High tone spread and interfere with productive processes of High tone realization by lowering the pitch of a following vowel in some way. (An example of depressor interference with High tone shift was noted in presenting the data from Digo in (6) above.) Bantu depressor effects, at first blush, appear to illustrate the typologically common pattern of phonologizing the phonetic lowering effect voiced obstruents have on the pitch of a following vowel (Hyman and Schuh 1974; Hombert 1978; Kingston and Diehl 1994; see also CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). One basic approach to formalizing this lowering effect is to propose that depressor consonants introduce a Low tone into the representation as an automatic result of bearing a [voice] feature: Halle and Stevens (1971); Kisseberth (1984); Harris (1994); Halle (1995); Hyman and Mathangwane (1998); and Bradshaw (1999). The other basic approach is to propose that phonetically grounded implicational constraints (*à la* Archangeli and Pulleyblank 1994) penalize realizing a High tone (and/or optimize realizing a Low tone) on a syllable with a depressor onset: Peng (1992); Cassimjee (1998); and Hansson (2004). In this section, I first present on the depressor syllables violates the no-line-crossing constraint, as it interrupts the multiply associated High tone sequence derived by autosegmental High tone spread.

To resolve this problem, Hyman and Mathangwane (1998) propose that a process of tone "fission" (somewhat simplified here) applies to derive a well-formed autosegmental output:

(21)

However, the tone fission analysis raises the question of why the Low tone associates with the depressor syllable in the first place, when this violates the no-line-crossing constraint invoked to account for why depressors block High tone spread in other contexts. Further, one wonders why fission is commonly triggered by depressor Low tones but has not been motivated for Low tones from other sources or when spreading non-tonal features.

Problems like these have led to the development of an alternative approach to depressor transparency (and depressor blocking), inspired by the use of phonetic grounding constraints to account for transparency in vowel harmony systems. For example, in many West African ATR harmony systems, [i] does not participate in the harmony; it is either transparent or opaque. Archangeli and Pulleyblank (1994) argue that this can be accounted for through constraints which formalize that [+high]/[RTR] is a phonetically antagonistic feature combination. The high, front position of the tongue required for [i] is in conflict with the low, retracted position that defines [RTR]. Transparency of [i], like its harmonic opacity, follows from a grammar which penalizes vowels for realizing this antagonistic combination.

The transparency of depressor syllables for some High tone displacement processes in Bantu languages can be given a similar account. As work like Peng (1992), Cassimjee (1998), and Hansson (2004) argues, tone–segment interactions can be formalized in terms of grounding constraints which define both enhancing and inhibiting interactions between tone and particular laryngeal features. For example, Cassimjee (1998: 53) proposes that the grounding constraint in (22) defines the basic interaction between depressor syllables and High tone in Nguni languages like Xhosa or Ndebele:

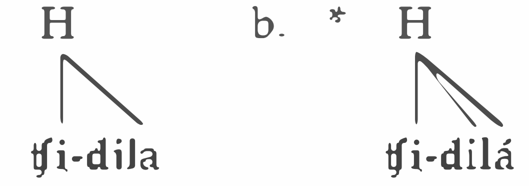
(22) *(Depress, H)

If depressor syllable, then not High tone.

The output of the High tone spread processes relevant to the form in (21) in this analysis is given below, adopting an autosegmental representation for ease of comparison rather than Cassimjee's (1998) tone domain account. The representation in (23b) is ill formed, as it violates the grounding constraint. The output in (23a) satisfies the constraint and is well formed if one adopts Archangeli and Pulleyblank's (1994) proposal that No Gap (or its OT equivalent) – a constraint penalizing representations where potential targets of High tone association are skipped over – is violated in systems with harmonic transparency:

(23) *Grounded depressor transparency*

a. b. *



Notice that the grounding constraint in (22) captures the generalization that High tones are not optimally realized on a syllable with a depressor onset without directly associating a Low tone with the depressed syllable. This means that the association of a Low tone at some stage of the derivation plays no role in this approach in accounting for why depressors are opaque for some tonal processes. For this reason, no representational problem arises if depressors are transparent for other processes in the same language. Instead, in an OT analysis of Bantu High tone realization like Cassimjee (1998), it is the relative ranking of the grounding constraint with other constraints which accounts for this variability.

The grounding constraint approach also has the advantage of linking depressor consonant transparency to the wider phonological problem of how best to account for transparency in harmony assimilation systems. While the representation in (23a), like the one in (21), violates an autosegmental well-formedness constraint, No Gap is routinely violated by grounded accounts of transparency in other assimilatory systems (Archangeli and Pulleyblank 1994). In contrast, the featural fission represented in (21), required by analyses which account for depressor blocking with a linked Low tone, has not been motivated for other phonological processes involving other features.

The analysis of the opacity and transparency of depressor consonants to High tone displacement in Bantu languages, then, raises questions that are of general interest to phonological theories which aim to account for harmonic opacity and transparency. Another important theoretical question raised by the analysis of depressor consonants is which phonetic or phonological consonantal feature grounds the tone lowering effect that accompanies these consonants. Single-source theories of consonant–tone interaction make the strong claim that: "Depressor effects [. . .] always indicate a special relationship between voicing and L[ow] tone" (Bradshaw 1999: 43). As work like Halle and Stevens (1971), Halle (1995), and Harris (1994) argues, the same laryngeal configuration that favors vocal fold vibration (slack vocal cords) also lowers fundamental frequency. And, conversely, work like Bradshaw (1999: 163) claims that Low tone implies vocal fold vibration. These theories implement the strong correlation between depressor effects and phonetic voicing of a preceding consonant by proposing that [voice] and Low tone are reflexes of a single laryngeal feature, with different realizations depending on whether the feature is linked to a consonant or a vowel.

The proposal that [voice] and Low tone are expressions of a single feature faces two problems in accounting for Bantu depressor effects. First, as we have seen in the preceding discussion, uniformly associating a Low tone with a depressor accounts well for depressor opacity (i.e. blocking effects); however, accounting for depressor transparency requires some special theoretical assumptions or devices, like tone fission or No Gap violations. A more serious problem for a single-source approach is that depressor consonants are not all voiced in all Bantu languages. For example, voiceless depressors are found in Nambya and Kalanga, two languages of the Shona group, and also in the Nguni languages. As Downing (2009) shows, these sounds are not only synchronically voiceless, there is no evidence that they were voiced historically. Instead, they have other phonetic properties that plausibly correlate with pitch lowering: frication duration (for the Shona group) and lax vocal fold tension (for the Nguni group). Surveys like Yip (2002) show that, in fact, a number of laryngeal properties besides [voice] condition tone realization and correlate with pitch lowering. Single-source theories of depressor consonants are flawed, then, in linking tonal depression only to [voice].[8]

The grounded constraint approach can get around this problem by defining an implicational relationship between tone realization and a "depressor syllable," with a depressor syllable further defined as one with an onset consonant that has a phonetic property which demonstrably correlates with lowered fundamental frequency: negative VOT, vibrating vocal cords, breathy voice release, long frication duration, lax vocal fold tension (Downing 2009). This list of possible correlates of depressor consonants serves to highlight, though, that the phonetics of consonant–tone interactions remains poorly understood.

4 Phonology–syntax interface

So far, we have discussed (High) tone realization within words, noting only in passing, in presenting the Jita tone shift data in (4), that High tones commonly cross word boundaries in Bantu languages. More interesting is that tonal processes are often sensitive to syntactic information: i.e. High tones cross some word boundaries but not all. For this reason, Bantu tonal phenomena have played an important role in the development of theories of the phonology–syntax interface: see e.g. Hyman and Byarushengo (1984); Selkirk (1986, 2000, forthcoming); Odden (1987, 1990, 1995b); Kanerva (1990); Truckenbrodt (1995, 1999, 2007); and several papers in Inkelas and Zec (1990). A central question for these theories is, as Chen (1990) so neatly puts it, "What must phonology know about syntax?" One finds two leading approaches, which provide two very different answers to this question, in work on Bantu phrasal tonology. In the direct reference approach (Odden 1987, 1990, 1995b), phonology has relatively unrestricted access to information in the morphosyntactic representation. In contrast, in the End-based (indirect reference) approach (Selkirk 1986, 2000; Truckenbrodt 1995, 1999, 2007), phonological phrasing algorithms can only refer to the edges of major syntactic constituents. Another central question is, naturally, whether syntax is all that phonological phrasing algorithms need to know.

In this section, I first present data illustrating a range of syntactic contexts for phrasal tonal processes. Then I briefly review the indirect and direct reference approaches to accounting for these syntactic contexts. As we shall see, a challenge for both of these approaches is that reference to non-syntactic factors like prosodic branching or focus is necessary to account for phrasing in some languages.

From the earliest work on phrasal phonology, including tonology, in Bantu languages – Byarushengo *et al.* (1976) on Haya, and Kisseberth and Abasheikh

[8] As Hyman (forthcoming) notes, a further challenge for single-source theories of consonant–tone interactions is that while the laryngeal properties of consonants are uncontroversially characterizable in terms of distinctive features, solid arguments for a universal set of tonal features are hard to come by.

phrasal constituent as its founding tenet. That is, it proposes that phonology needs to know very little about syntax: only where the edge – right or left – of major constituents like XP, *v*P, and CP are located in the string. The Edge-based approach is considered an indirect reference theory, as phonological processes refer directly to prosodic constituents like Phonological Phrase, and so only indirectly reference the syntactic constituents that define the prosodic ones. The repertoire of prosodic phrasal domain types is also limited in this theory to just those found in the Prosodic Hierarchy (Selkirk 1986, 1995): Phonological Phrase, Intonation Phrase, and Phonological Utterance. In OT, an Edge-based parse of a string into prosodic phrase domains is implemented straightforwardly by means of alignment constraints (Selkirk 1995, 2000; Truckenbrodt 1995, 1999, 2007). For example, ALIGNR(XP, Phonological Phrase) would be relevant for a language like Tsonga, where Phonological Phrase breaks (indicated by parentheses) are found following XPs: the NP subject and the first of two post-verbal objects: $_{NP}$[Subj)] $_{VP}$[V $_{NP}$[Obj)] $_{NP}$[Obj)]]. Recent Edge-based OT analyses of prosodic phrasing in Zulu (Cheng and Downing 2009), in Mwiini, Matuumbi, and Chewa (Truckenbrodt 1995, 1999, 2007), and in Northern Sotho (Zerbian 2006, 2007) demonstrate how effectively this minimalistic approach accounts for many phrasal phenomena in Bantu languages.

The limits of the Edge-based theory are thoughtfully surveyed in Odden (1995b), who argues instead for the direct reference approach to defining syntactic contexts for phrasal processes. Odden points out two general problems with the Edge-based approach. First, the prosodic phrase types are limited to those provided by the Prosodic Hierarchy: Phonological Phrase, Intonation Phrase, Phonological Utterance. For languages with complex phrasal phonology, though, this might not be enough levels. A second problem is that phrasal phonology is often sensitive to more specific morphosyntactic information than just the edges of major syntactic constituents. Tsonga (Kisseberth 1994) illustrates both of the problems, as Odden (1995b) shows. We saw in (26) that the verb's High tone spreads to the penult of the first following object noun only, not to the second object noun of affirmative verbs. However, we find a different pattern with negative verbs: the grammatical High tone of the negative verb is realized through the *final* vowel of the entire verb phrase if both following objects are toneless (27a, 27b). The negative High tone spreads through the *penult* of a postposed subject, though – the same pattern found with affirmative verbs with a final High tone (cf. (c) and (d)). As (27e) shows, the High tone from a verb prefix does *not* spread to a postposed subject:

(27) *Tsonga negative VPs* (Kisseberth 1994: 150, 162, 163; Odden 1995a: 66)[9]

a. a-vá-xav!êlí xí-kóxá nyáámá cf. (26a)
NEG-they-buy old woman meat
'They are not buying meat for the old woman'

b. a-ndzí-nyíkí mú-fáná tí-n-gúúvú cf. (26b)
NEG-I-give boy clothes
'I am not giving the boy clothes'

[9] In this dataset, an exclamation mark indicates that the following High tones are downstepped (i.e. lowered in pitch register) with respect to preceding High tones.

c. vá-ꜜfáámbá váá-nhu 'They are going, the people.'
d. a-má-yángá má-láándza 'They did not go, the servants.'
e. v-á-tíírha) vaa-nhu 'They are working, the people.'

Finally, the alert reader will have noticed that these data illustrate another phrasal rule of Tsonga, namely, phrase penult vowel lengthening. As Odden (1995b) points out, an inspection of the data shows that the domain for this process is also often distinct from that of High tone spread to the penult (HTS). For example, in (26), the domain for HTS is the verb plus first object noun, while the domain for lengthening is the entire sentence; conversely, in (27d), the domain for HTS is the entire sentence (verb plus postposed subject), while both the verb and the postposed subject are in separate domains for penult lengthening. In short, in Tsonga, we have several phrasal processes – HTS to penult from a verbal prefix; HTS to penult from a verb stem; HTS to final syllable from a negative verb; penult lengthening – and each process takes a slightly different domain. Further, some of these processes must refer to specific morphosyntactic information, like negative aspect or verb prefix, as the source of the High tone to determine the phrasal domain. It is hard not to agree with Odden (1995b) that the Edge-based approach does not straightforwardly provide either enough domains or access to enough morphosyntactic information to define the contexts for all of these processes. Other examples discussed in Odden (1995b) reinforce this point.[10]

Let us close this section by showing that syntactic properties of a string are not all that phonology needs to know to define the contexts for phrasal tone domains. As Bickmore's (1990) study of Nyambo shows, another factor that can condition phrasing is branchingness: that is, whether or not a syntactic constituent (in this case, maximal XP) has more than one member. The role of branchingness is motivated by data like those in (28), which illustrate the phrasal process of High tone deletion (HTD): the rightmost High tone of a word is deleted if the following word has a High tone. Examples (a) and (c) show that the entire sentence can be the domain of HTD if none of the XPs contained in it branch. Examples (b) and (d) show that a branching XP (underlined) is not phrased with what follows:

(28) *Nyambo prosodic phrasing* (Bickmore 1990: 14–15)

a. (Ba-kuru bá-ka-júna).
Mature ones helped
'The mature ones helped.'

b. (Aba-kozi bakúru) (bá-ka-júna).
workers mature helped
'The mature workers helped.'

c. (Nejákworech' ábakoz' émbwa.)
he will show workers dog
'He will show the workers the dog.

d. (Nejákworech' ómukama w'ábakózi) (émbwa).
he will show chief of workers dog
'He will show the chief of the workers the dog.'

10 See Selkirk (forthcoming) for a recent re-analysis of the Tsonga phrasal tone domain data discussed here which takes up these and other criticisms of the Edge-based approach.

Focus also often plays an important role in conditioning prosodic phrasing. An especially detailed demonstration of this is found in Kanerva's (1990) study of Chewa. We saw in (25), above, that in Chewa the entire VP (verb plus complements) forms a single tone realization domain under broad focus. As Kanerva shows, narrow focus within the VP interferes with syntactically motivated phrasing: a phrase boundary must follow the focused element, and each subsequent XP constituent of the VP is parsed into a separate prosodic phrase. As a result, the VP is parsed into more, smaller prosodic phrases – indicated with parentheses – under narrow focus:

(29) *Focus and phrasing in Chewa* (Kanerva 1990: 98)

a. anaményá nyumbá ndí mwáála 'He hit the house with a rock.'
   he hit house with rock
b. What did he do? (VP focus)
   (anaményá nyumbá ndí mwáála)
c. What did he hit the house with? (Oblique PP focus)
   (anaményá nyumbá ndí mwáála)
d. What did he hit with the rock? (Object NP focus)
   (anaményá nyuúmba) (ndí mwáála)
e. What did he do to the house with the rock? (V focus)
   (anaméenya) (nyuúmba) (ndí mwáála)

While Bickmore (1990), Kanerva (1990), and Truckenbrodt (1995, 1999, 2007) show that the effect of branchingness and focus on phrasing can be accommodated in the Edge-based approach, it is also clear that neither that approach nor the direct reference approach predicts that such non-syntactic factors should interact with syntactic ones in defining the contexts for phrasal processes.

5 Conclusion

As we have seen, Bantu tone has played a role in several areas of phonological theory, notably in the areas of phonological representation and the role of prosodic factors in conditioning featural realization. The accentual properties of many Bantu tone systems have raised the question of whether some form of prosodic representation – accent and/or prosodic constituents – mediates tone realization, or whether the accentual properties are best considered the result of non-prosodic processes which conspire to produce an accentual output. Depressor tones raise questions of how to formalize the interaction of tone with other laryngeal features. The opacity and transparency of depressor consonants to High tone displacement processes raise the same representational problems as opacity and, especially, transparency in harmony systems. The phrasal realization of High tone raises again the question of whether prosodic constituency best defines the domains for High tone realization, or whether independently motivated syntactic constituents and principles provide all that phonology needs to know about syntax. The Bantu tone data illustrating these issues are complex enough that phonological theories will surely be wrestling with these questions for some time to come.

115 Chinese Syllable Structure

San Duanmu

1 Introduction

The title of this chapter may seem both too broad and too narrow. On the one hand, Chinese dialects are probably as diverse as Romance languages. Should one not treat them separately? However, I shall show that there are considerable similarities among them and that a single treatment is useful. On the other hand, the study of syllables is closely related to the studies of phonemes, stress, and tone. Therefore, the discussion cannot be limited to syllable structure alone, but will cover some of its relations to other areas as well.

The Chinese writing system is not alphabetic, but Chinese scholars have studied syllables for a long time. For example, Sun Yan of the Three Kingdoms period (about 200–280) invented a method, known as *Fanqie* "reverse cut," to indicate the pronunciation of written graphs (characters), each of which represents a monosyllabic word. The method uses two familiar graphs, where the first has the same onset as the target graph and the second has the same rime as the target. Similarly, there were riming books that grouped Chinese graphs into different sets, based on their initial consonants and whether they rime with each other.

Despite the traditional scholarship, and the fact that Chinese syllables seem less complicated than those in English, disagreements exist over most major issues. For example, what is the maximal size of the Chinese syllable? Does every syllable have a vowel? How does the analysis of syllables interact with the analysis of phonemes? What is the interaction between syllable weight, stress, and tone? What are major phonotactic restrictions that rule out non-occurring syllables? What is the cause of the massive loss of syllable types in Chinese? In this chapter I address such questions. Following the editors' guidelines, I shall focus on major empirical facts, rather than arguing for my own analysis.

However, the distinction between facts and theories is not always clear. For example, the word 'outside' in Standard Chinese, which sounds the same as the English word *why*, has been transcribed as [waj] (Hartman 1944), [uai] (Cheng 1966), and [ua^{i}] (You *et al.* 1980). For Hartman (1944) the syllable has two glide phonemes and a vowel phoneme, for Cheng (1966) it has three vowel phonemes, and for You *et al.* (1980) it has two vowel phonemes. Accordingly, the syllable analyses are GVG (or CVC), VVV, and VV respectively. One could see that even basic terms like glides, diphthongs, and triphthongs are not always transparent or meaningful. Such problems exist in English and other languages, too. Therefore, our discussion is, inevitably, also of general theoretical interest.

2 The maximal syllable structure

A maximal Chinese syllable, regardless of the dialect, is often thought to contain four positions, or CGVX, where C is a consonant, G a glide, V a vowel, and X either a consonant or the second part of a long vowel or diphthong. Syllables with a syllabic consonant will be discussed later, as will syllables whose rime seems to be longer than VX. In CGVX, a diphthong takes two positions and cannot be followed by a consonant coda. Some examples from Standard Chinese are shown in (1). For simplicity, I enclose phonetic transcription in square brackets, regardless of the level of analysis. As noted above, some analyses would transcribe a pre-nuclear glide as a high vowel (e.g. Cheng 1966; T. Lin and Wang 1992).

(1) *The* CGVX *analysis of the maximal syllable in Standard Chinese*

[kʰwai]	'fast'	[kwaŋ]	'light'
[kwaː]	'melon'	[tswan]	'diamond'
[tʰjan]	'day'		

Different Chinese dialects can use different phonemes to fill the four slots of a syllable. Three dialects, Standard Chinese, Cantonese, and Shanghai, are shown in (2).

(2) *Dialect variation: Phonemes which can fill each position in* CGVX

	C	G	V	X
Standard Chinese	most Cs	[j w ɥ]	any V	[i u n ŋ ɚ]
Cantonese	any C	[w]	any V	[i u n m ŋ p t k]
Shanghai	any C	[j w ɥ]	any V	([ʔ ŋ])

In all dialects, the C position can be filled by almost any consonant, with occasional exceptions; for example, similarly to English, [ŋ] is not used in the C position in Standard Chinese. The G position can be filled by one of three glides in Standard Chinese and Shanghai. In Cantonese, there are two glides [w j] which can occur without C, but when the C is filled only [w] can be used. The V position can be filled by any V (and sometimes by a syllabic consonant, such as [n] 'fish' in Shanghai, to be discussed later). For the X position, Cantonese is among the most conservative dialects, which has kept a full set of nasals and a full set of unreleased stops. In contrast, Shanghai is among the most advanced dialects with regard to the X position, which only allows a glottal stop or a nasal; in addition, these two sounds often combine with the preceding vowel to form a single sound, i.e. a glottalized V or a nasalized V. Therefore, all syllables in Shanghai behave like open syllables. I shall return to this issue below.

There is a fair amount of disagreement on the analysis of CGVX, especially with regard to the affiliation of G. Three proposals are shown in (3).

Standard Chinese ends in [m], but in casual speech such syllables are found, for example [wom], shown in (13).

(13) *New syllable created by syllable merger*

wo mən → wom 'we'
I PL

Similarly, devoicing of non-low vowels often happens in syllables that have an aspirated onset (including voiceless fricatives) and a low tone. Some examples are shown in (14). The transcription is based on Duanmu (2007). HL, H, LH, and L are four lexical tones in Standard Chinese. When a sound is devoiced, the tone cannot be heard, which is indicated by Ø.

(14) *Devoicing of non-low vowel with a low tone in Standard Chinese*

	L-LH		Ø-HL	
[ɤ] → [x]	kʰɤ-nəŋ	→	kʰx-nəŋ	'possible'
	HL-L		HL-Ø	
[i] → [ɕ]	ji-tɕʰi	→	ji-tɕʰɕ	'together'
	H-L		H-Ø	
[y] → [ɕʷ]	ʈʂəŋ-tɕʰʷy	→	ʈʂəŋ-tɕʰʷɕʷ	'strive for'
	L-H		Ø-H	
[y] → [ɕʷ]	ɕʷy-tʷo	→	ɕʷɕʷ-tʷo	'many'
	L-HL		Ø-HL	
[u] → [xʷ]	ʂʷu-tɕa	→	ʂʷxʷ-tɕa	'summer vacation'
	H-L		H-Ø	
[u] → [xʷ]	ɕin-kʰʷu	→	ɕin-kʰʷxʷ	'working hard'
	L-HL		Ø-HL	
[u] → [xʷ]	tʰʷu-tʲi	→	tʰʷxʷ-tʲi	'land'

Devoicing can affect syllables in any position (initial, medial, or final). Devoiced [i ɤ u y] sound like [ɕ x xʷ ɕʷ], respectively. A reviewer suggests that [ʷ] would imply [+back] for [ɕʷ] and recommends [ɕᶣ] instead. There are two reasons not to follow the suggestion. First, while [w] is indeed an IPA symbol for labial-velar, [ʷ] is a diacritic for "labialized," without implying velar or [+back]. Second, [ɥ] has two articulatory components, palatal and labial. Since the palatal component is already present in [ɕ], [ɕᶣ] has internal redundancy, while [ɕʷ] does not.

Devoiced syllables have durations similar to the originals (although rime length is not indicated in the above transcription), and therefore they still sound like separate syllables. If one assumes that every syllable must have a vowel, one would propose devoiced vowels [i̥ ɤ̥ u̥ ẙ]. Syllabic consonants can be devoiced, too. Some examples are shown in (15).

(15) *Devoicing of syllabic consonants in Standard Chinese*

	HL-L		HL-Ø	
[ʋ] → [f]	təu-fʋ	→	tou-ff	'tofu'
	HL-L		HL-Ø	
[z] → [s]	ʂaŋ-tsʰz	→	ʂaŋ-tsʰs	'last time'

Duanmu (1990, 2007) proposes an analysis that maintains both a small syllable size and a small phoneme inventory. The maximal syllable is CVX, similar to that in Ao (1992, 1993). However, unlike Ao, who assumes that C is filled by a single phoneme, Duanmu assumes that C can be filled by two phonemes, a consonant and a glide, which will merge into a complex sound. In Duanmu's analysis of Standard Chinese, the phoneme inventory is slightly smaller than that of traditional analyses, and about half the size of Ao (1992).

Hartman (1944) proposes to minimize the phoneme inventory even further. For example, while Ao (1992) assumes [k k^h k^w k^{hw}] to be four phonemes in Standard Chinese, Hartman assumes the representation [k kh kw khw], in which there is only one velar stop [k], and [kh khw kw] are clusters of two or three phonemes each, where [w] and [h] are independently needed. The cost, of course, is a more complicated syllable structure, which has three positions before the vowel, and it vastly overpredicts the possible syllables of Chinese.

In (17) I compare the analysis of some syllable-initial units in Standard Chinese by Hartman (1944), Cheng (1966), Ao (1992), and Duanmu (2007), where "onset" refers to the maximal size of the given units and "stops" refers to the number of velar stop phonemes.

(17) *Analyses of four syllable-initial units in Standard Chinese*

Author	Underlying	Surface	Onset	Stops
Hartman	[k kh kw khw]	[k kh kw khw]	CCC	1
Cheng	[k k^h ku k^hu]	[k k^h kw k^hw]	CC	2
Ao	[k k^h k^w k^{hw}]	[k k^h k^w k^{hw}]	C	4
Duanmu	[k k^h ku k^hu]	[k k^h k^w k^{hw}]	C	2

Hartman (1944) represents an extreme position in which phonemic economy overrides syllable structure. At the opposite extreme, Ladefoged (2001: 170) believes that phonemes have no place at all. Instead, he suggests that syllables are the basic units of analysis and that "consonants and vowels are largely figments of our good scientific imaginations."

8 Missing syllables

I use the term "missing syllables" to refer to those that do not occur in the language, although their structure fits the maximal size. In Chinese, the majority of conceivable syllables are missing. Consider an example from Nantong Chinese, which allows CVC syllables. According to Ao (1993), Nantong has 15 vowels and 38 consonants. Given that the initial or final C can be absent, there are 39 choices for the initial C and 39 for the final C, and the total number of possible syllables is 39 × 15 × 39 = 22,815, of which only about 400 occur in Nantong, or barely 2 percent. Ao's illustration is perhaps intended to be dramatic. Given the fact that the final C in Nantong can only be [k] or [ŋ], a more reasonable estimate is 39 × 15 × 3 = 1,755 possible syllables, of which 23 percent occur. Still, most conceivable syllables are missing, and an explanation is needed.

Let us consider Standard Chinese in some detail. The phonemes of Standard Chinese are shown in (18) and (19), based on Duanmu (2007).

18 × 3 = 54 CG combinations. However, only 29 (54 percent) are found. The restrictions turn out to be quite systematic: labial Cs do not combine with [w ɥ], and velar and retroflex Cs do not combine with [j ɥ]. In traditional feature terms, the former shows a restriction against two labials, and the latter shows a restriction against [+back, −back] or [−palatal, +palatal]. The details are shown in (22). Given the restrictions, we expect 32 CG forms, of which just three are missing.

(22) *Expected* CG *forms in Standard Chinese (missing numbers in parentheses)*

		j	w	ɥ
Labials (3)	[p p^h f m]	4 (−1)	–	–
Dentals (7)	[t t^h ts ts^h s n l]	7	7	7 (−2)
Velars (3)	[k k^h x]	–	3	–
Retroflexes (4)	[tʂ $tʂ^h$ ʂ ʐ]	–	4	–
Expected	32			
Occurring	29			
Missing	[fj tɥ t^hɥ]			

Next, let us consider GVX combinations. In Standard Chinese there are 100 possible GVX forms, calculated in (23). I have ignored tonal contrasts. In addition, I have omitted the vowel [ɚ] and syllabic consonants.

(23)

Position	*Choices*	*Notes*
G	4	One of [j u ɥ], or no G
V	5	One of five vowels
X	5	One of [i u n ŋ], or no X
Total	100	

The 100 possible GVX forms are shown in (24). The first column indicates choices for X, the top row indicates choices for G, and 0 indicates lack of G or X. High vowels are written as glides before the nuclear vowel.

(24)

	0-	j-	w-	ɥ-		
-0	i	+	(+)	–	–	ji = i
	u	+	–	(+)	–	wu = u
	y	+	–	–	(+)	ɥy = y
	ə	+	+	+	+	
	a	+	+	+	–	
-n	in	+	(+)	–	–	jin = in
	un	–	–	–	–	
	yn	+	–	–	(+)	ɥyn = yn
	ən	+	–	+	–	
	an	+	+	+	+	
-ŋ	iŋ	–	–	–	–	
	uŋ	+	+	(+)	–	wuŋ = uŋ
	yŋ	–	–	–	–	
	əŋ	+	+	+	–	
	aŋ	+	+	+	–	

(25) *Stability of citation tones in Standard Chinese*

Surface	H	H	H	LH	HL	H	HL	LH
Citation	H	H	H	LH	HL	H	HL	LH
	san	pei	san	pʰan	sz	pei	sz	pʰan
	'three cups'		'three plates'		'four cups'		'four plates'	

(26) *Instability of citation tones in Shanghai Chinese*

Surface	H	L	H	L	L	H	L	H
Citation	HL	HL	HL	LH	LH	HL	LH	LH
	se	pe	se	pø	sz	pe	sz	pø
	'three cups'		'three plates'		'four cups'		'four plates'	

It can be seen that while citation tones are stable in Standard Chinese, they all split in the Shanghai examples. A longer example is shown in (27), in fairly broad transcription, where | indicates a boundary between tonal domains in Shanghai.

(27) *Tonal patterns in Shanghai and Standard Chinese*

Shanghai	ku-poʔ	lu		laʔ-laʔ		tʰi-se	lu		pã-pi
Citation	LH-LH	LH	|	LH-LH	|	HL-HL	LH	|	LH-HL
Surface	L-H	0	|	L-H	|	H-L	0	|	L-H
Standard	ku-pei	lu		zai		tʰian-şan	lu		pʰaŋ-pʲan
Citation	L-L	HL	|	HL	|	H-H	HL	|	LH-H
Surface	LH-L	HL	|	HL	|	H-H	HL	|	LH-H
	Gubei	road		be-at		Tianshan	road		vicinity

'Gubei Road is in the vicinity of Tianshan Road.'

We see again the stability of citation tones in Standard Chinese (except for one rule, which changes L to LH before L, as seen on the first syllable). In contrast, citation tones are lost in Shanghai unless they occur in the initial position of a domain; in addition, each surviving citation tone is split between the first two syllables of a domain.

There are two approaches to the difference between the dialects. The first is typological. For example, Yue-Hashimoto (1987) suggests that Shanghai has left-dominant tonal domains but Standard Chinese does not. Similarly, Chen (2000b) suggests that tonal domains in Shanghai are determined by left-headed stress, whereas those in Standard Chinese are not. Moreover, Yip (1989) proposes that there are two kinds of tones: those in Standard Chinese are units that cannot be split, and those in Shanghai are clusters that can. However, the typological approach in effect restates the difference and offers no explanation why Shanghai behaves one way and Standard Chinese behaves another way.

In the second approach, proposed by Duanmu (1990, 1999), the difference in tonal behavior is related to an independent difference in rimes: dialects that are like Shanghai in tonal behavior (with unstable citation tones) have no diphthongs or true codas, while dialects that are like Standard Chinese in tonal behavior (with stable citation tones) have diphthongs and/or true codas. In other words, Shanghai has only "simple rimes" (V or C) while Standard Chinese has many "complex rimes" (VC or VG). Consider the data in (28) and (29).

(28) *Rime types in the basic vocabulary of 2,500 morphemes in Standard Chinese*

VC or VG	1,519	61%	e.g. [man] 'slow', [mai] 'sell'
V or C	981	39%	e.g. [ma] 'scold', [sz] 'four'
Total	2,500	100%	

(29) *Rimes in Shanghai Chinese* (Duanmu 2008)

[m n ɚ z u ø ɔ y i o ɤ e a ỹ ĩ ø̃ ɤ̃ ã iˀ aˀ oˀ]

The nasal vowels in Shanghai can be represented as [Vŋ] underlyingly, and the glottalized vowels can be represented as [Vʔ] underlyingly. Both [Vŋ] and [Vʔ] can merge into a single sound without loss of underlying segmental features.

Given the difference in rime structure between Shanghai and Standard Chinese, it is possible to explain their difference in tonal behavior. First, most rimes in Standard Chinese are inherently heavy. In contrast, syllables in Shanghai have no inherent weight: they can be heavy or light, depending on the prosodic environment. They are long when spoken in isolation or in a stressed position, such as the first syllable of a disyllabic word or compound, which is a trochaic foot; otherwise the syllables are short. Phonetic studies confirm the predictions (Zhu 1995).

The relation between syllable structure and tone is mediated by stress: heavy syllables have stress and stressed syllables can carry tone (see CHAPTER 42: PITCH ACCENT SYSTEMS). The principles are stated in (30) and (31).

(30) *Weight–Stress Principle*

a. Stressed syllables are heavy (or light syllables are unstressed).
b. Unstressed syllables are light (or heavy syllables are stressed).

(31) *Tone–Stress Principle*

a. Stressed syllables can be accompanied by a lexical tone (pitch accent).
b. Unstressed syllables are not accompanied by a lexical tone (pitch accent).

The Weight–Stress Principle has been proposed in various forms in the literature (e.g. Prokosch 1939; Kager 1989; Prince 1990; Hammond 1999; CHAPTER 57: QUANTITY-SENSITIVITY). Kager (1999) refers to (30a) as the Stress-to-Weight principle, and Prince (1990) refers to (30b) as the Weight-to-Stress principle. The Weight–Stress Principle is a bidirectional requirement on the relation between weight and stress, regardless of which comes first.

The Tone–Stress Principle has also been proposed in various forms in the literature (e.g. Liberman 1975; Clements and Ford 1979; Pierrehumbert 1980; Goldsmith 1981). In Chinese, the Tone–Stress Principle is evidenced by the fact that unstressed syllables lose their lexical tones. In English, it is evidenced by the fact that only stressed syllables are assigned a pitch accent.

If a language has many complex rimes, then many syllables will remain heavy and stressed. And because they are stressed, they will keep their lexical tones. The chance of tone split will be low, because most syllables have their own tones and cannot take those from others. In contrast, if a language has no complex rime, then many syllables can become light and unstressed (unless they occur in prosodically strong positions, which are initial positions in trochaic feet). And because they are unstressed, they will lose their lexical tones. The chances for tone split will be high then, because many syllables are toneless and can take a piece from another syllable. A detailed analysis is offered in Duanmu (2008: ch. 7).

Leben (1973) observes a similar pattern in the African language Mende. For example, in a compound made of two monosyllabic words, the second word will lose its underlying tone, and the tone of the first word will spread over both syllables. The Mende case would be expected if it lacks CVX syllables and if its compounds form trochaic feet.

10 Suffixation and rime changes

Many Chinese dialects have suffixes that merge with the preceding syllable. The most common case is the diminutive suffix. In some dialects the rime change is quite simple, whereas in others it can be quite complicated. Let us begin with Chengdu, shown in (32). The process is quite straightforward: in the diminutive form, the rime is replaced by [ɚː].

(32) *Diminutive suffix in Chengdu*

Word	*Diminutive*	
[kən]	[kɚː]	'root'
[kau]	[ka˞ː]	'cake'
[kou]	[kɚː]	'dog'
[pʲan]	[pʲa˞ː]	'side'
[kʷan]	[kʷɚː]	'hall'
[ja]	[jɚː]	'bud'
[wan]	[wɚː]	'bowl'
[yan]	[ya˞ː]	'yard'

Next we consider diminutive forms in Standard Chinese, which are more complicated. Some examples are shown in (33).

(33) *Diminutive forms in Standard Chinese*

Word	*Diminutive*	
[pʰai]	[pʰaɚ]	'plaque'
[pʰiː]	[pʰʲɚː]	'skin'
[pʰan]	[pʰaɚ]	'dish'
[jaŋ]	[jãɚ̃]	'lamb'
[nʲau]	[nʲauᵊ˞]	'bird'
[tʰuː]	[tʰuᵊ˞ː]	'rabbit'

In the first three cases the suffix replaces [n] and [i], although in the third case [i] survives as a glide on the onset. In the fourth case the suffix replaces the coda, but part of the coda is preserved as nasalization on the rime. In the last two cases the suffix is realized as a retroflex color on the original vowel. A number of

(37) *Truncation of polysyllabic morpheme to monosyllabic ones*

Non-truncated	*Truncated*	
bian-fu chao	*bian chao*	'bat nest'
蝙蝠巢	蝙巢	
jia-na-da yuan	*jia yuan*	'Canadian dollar'
加拿大元	加元	
jia-li-fu-ni-ya zhou	*jia zhou*	'California State'
加利福尼亞州	加州	

The compound *bian chao* 'bat nest' was made up by me, but seems quite acceptable. The compounds *jia zhou* 'California State' and *jia yuan* 'Canadian dollar' are real ones.

Overall, it is fair to say that every syllable is a morpheme (or a perceived morpheme) in Chinese. In addition, since most morphemes are also words in Chinese, it is fair to say that most Chinese syllables are words, or that most Chinese words are monosyllabic.

The close relation between syllables and words in Chinese raises an interesting question. If we find a generalization for the Chinese syllable, how do we know whether it is indeed a generalization for syllables and not a generalization for words? For example, should we say that every syllable in Chinese has a tone, or should we say that every word in Chinese has a tone?

12 Statistical data on syllables in Standard Chinese

Compared to English, Standard Chinese has a fairly small inventory of syllables. Consider the data in (38) and (39). A simplex word is one that contains one morpheme.

(38) *Monosyllabic simplex words in English in the CELEX lexicon* (Baayen *et al.* 1995)

All simplex words	7,401
Monosyllabic simplex words	3,834
Different pronunciations	3,219

(39) *Syllables in Standard Chinese*

Vocabulary type	*All*	*Common*
Characters	12,041	2,500
Syllables (with tones)	1,334	1,001
Syllables (without tones)	413	386

English has over 3,000 monosyllables in simplex words. In contrast, Standard Chinese has about 1,000 syllables including tones, or 400 excluding tones.

Although Standard Chinese has just 1,334 syllables (including tones), only about 1,000 are commonly used. Therefore, up to 300 syllables are unfamiliar to the average speaker. This is confirmed by the study of Myers and Tsay (2005), who found that acceptability judgments on possible syllables in Standard Chinese are gradient and influenced by lexical frequency.

116 Sentential Prominence in English

Carlos Gussenhoven

1 Introduction

In the linguistic expressions of many languages, words vary in prominence. In the English compound (1a), there is some sense in which *tax* has more prominence than *relief*, and in the sentence (1b) the same can be said about the subject NP *My bike* as compared to the verbal phrase *has been stolen*. Example (1c) illustrates how the perception of prominence can be more differentiated than this: *English* appears to be more prominent than *teacher*, which in turn may seem more prominent than *Old*.

(1) a. tax relief
  b. My bike has been stolen!
  c. an Old English teacher

The above observations touch on two aspects of the phonological structure of English which have been the topic of intense debate over the past decades. The first concerns the phonological nature of this prominence: how is it represented in the structure? There have been widely different answers to this question. The main division is between views that see prominence as a single dimension and views that separate word stress from intonational pitch accents. A number of representations that fall in the first class of views are discussed in §2. §3 introduces the second class and explains the difference between word stress and accentuation. §4 then returns to some of the examples discussed in §2, offering an account for them first by assuming that the sentence prominences are pitch accents, and second by identifying the accent assignment or deletion rules that are held responsible for the distribution of the pitch accents in each case. In doing this, §4 also takes a position on the second main controversy: why are the various levels of prominence to be found where they are? What determines that in (1a) through (1c) *tax*, *bike*, and *English* have the most prominence within their structures and what determines that *teacher* may seem more prominent than *Old* in (1c)? Finally, §5 considers the question of whether there are residual differences in prominence that are not covered by the description in §3 and §4. It concludes by suggesting that such differences arise during phonetic implementation rather than being due to differences in representation.

2 The phonological representation of prominence

A useful simplification of the changing perspective on the nature of sentential "stress" is to distinguish two views. The first view, to be referred to as the Infinite Stress View (ISV), takes the impression of multiple degrees of prominence as a starting point and translates these into a representation of gradient stress. This is the older of the two views, and was the basis of an early treatment of stress above the level of the word in generative phonology (Chomsky and Halle 1968). The other view, the Pitch Accent View (PAV), takes sentential prominence to be due to intonational tones that are associated with specific syllables. This view was first expressed by Bolinger (1958), who introduced the term "pitch accents" for these tones (see CHAPTER 32: THE REPRESENTATION OF INTONATION; CHAPTER 50: TONAL ALIGNMENT for related discussion). Today, there are probably no linguists who adhere to the ISV in its original form. Many, however, adopt some version within a newer conception of sentential prosodic structure, which is also, or even largely, composed of an intonational structure.

2.1 *The infinite stress view*

The earliest views saw stress as an increase in loudness due to greater amplitude of the sound wave (CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE). This implies that stress is a continuous phonetic variable, which can have different values within words as well as across words. The idea that word stress and prominence differences among words are essentially the same phenomenon is expressed in Bloomfield (1933: 111), for instance. He distinguished "emphatic stress," as on the syllable *my* in (2) (where I have reproduced his original transcription of *This is my birthday present*), from "high stress," as in the syllables *this* and *birth-*, which is different from "low stress" on *pres-*, which in its turn is distinct from "no stress," on all other syllables.

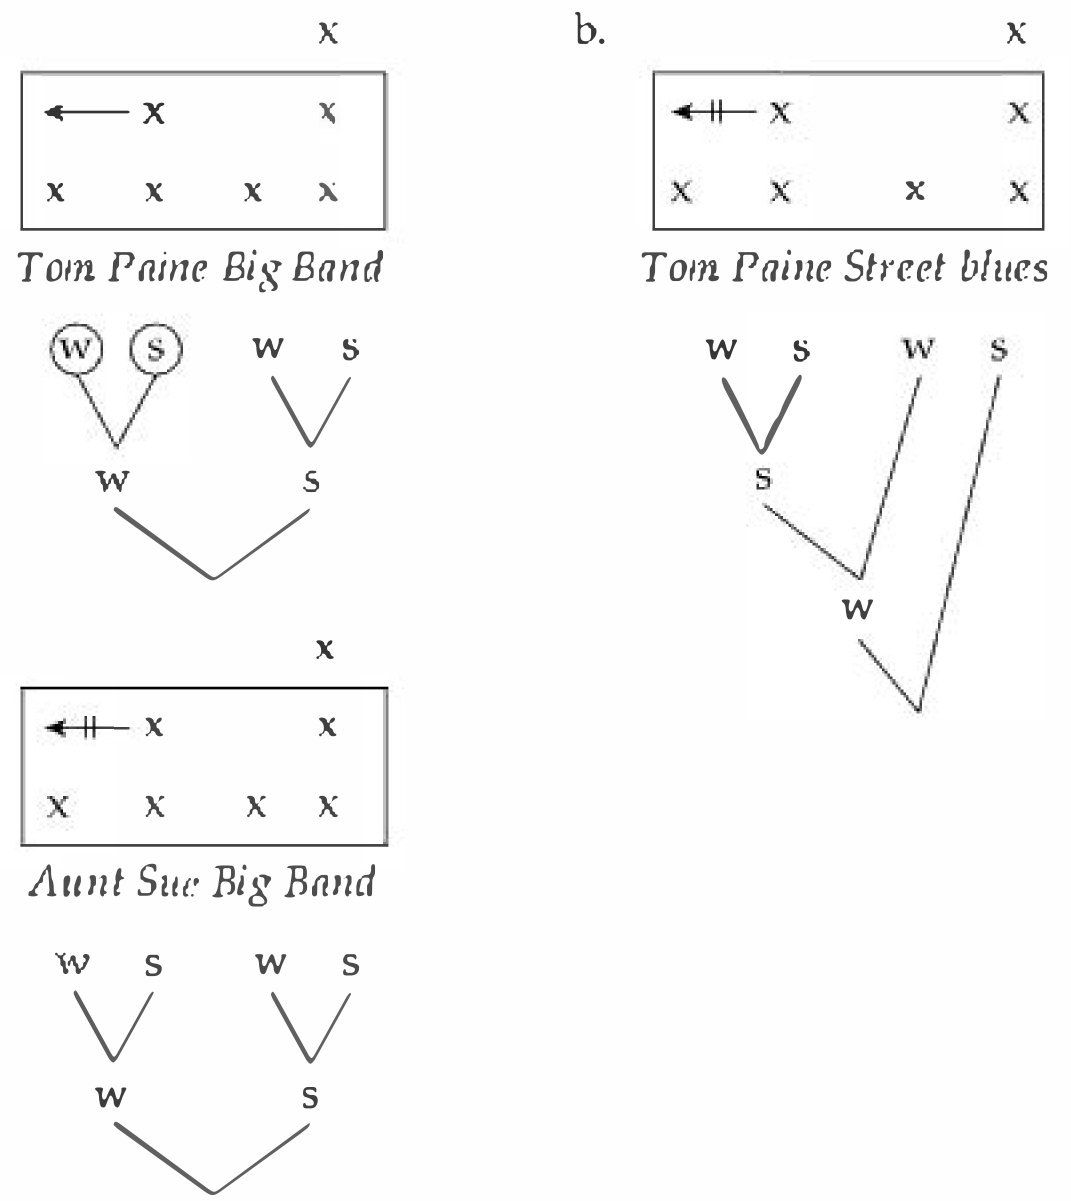
(2) ˈðis iz ˈˈmaj ˈbəːθdej ˌpreznt ("i.e. not yours")

Chomsky and Halle (1968: 20) incorporated the ISV in their rule-based grammar of English stress. Example (3a) has the most prominence on *board*, but *black* can be felt to have more prominence than *eraser*. The stress pattern is therefore 2 1 3. In (3b), *black* is most prominent, while *eraser* has more prominence than *board*, giving 1 3 2. Finally, (3c) again has the most prominence on *board*, but of the other two words it is *eraser* that seems more prominent than *black*, giving 3 1 2. The stress levels 2 and 3 are best compared across the three structures, instead of within them, for instance by comparing *black* in (3a) and the same word in (3c).

(3)	a.	*a black board-eraser*	'a board-eraser that is black'	2 1 3
	b.	*a blackboard eraser*	'an eraser for a blackboard'	1 3 2
	c.	*a black board eraser*	'an eraser of a black board'	3 1 2

Chomsky and Halle accounted for this three-way distinction by postulating two rules, reproduced in (4a) and (4b), plus a convention, (4c). The order of

(10) a. b. c.



2.2 *The problem with the ISV*

The deeper problem lies in the conception of phonological prominence, more specifically in the hypothesis that prominence levels above the word are of the same kind as prominence levels within the word. The next section will argue that word prosodic structure is essentially different from sentential prosodic structure. Part of the reason why they have been conflated is that acoustic measurement techniques have only been readily available since the last quarter of the twentieth century and, where they existed before, the implications of the data they provided were not always adequately incorporated into the way linguists thought about stress. As we will see in §3, when a speaker produces even a single word, we do not only observe the word prosody, but also its sentence prosody. While the connections between these two representations are strong, they are separate components of the phonological structure of English.

3 The pitch accent view

3.1 *Pitch and stress as independent components in syllable prominence*

The new conception of phonological prominence followed various demonstrations that differences in stress are not expressed in acoustic intensity differences, or even auditory loudness differences. Mol and Uhlenbeck (1956) showed that no

If we abstract away from the presence of a pitch accent, the difference between stressed and unstressed syllables is phonetic in many languages (CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE). The stressed syllables may be longer and have greater intensity, as in Spanish (Ortega-Llebaria 2006), or the segments in them may additionally be more precisely articulated, as in Catalan (Astruc and Prieto 2006; cf. Sluijter and van Heuven 1996). In English, such differences have been phonologized, meaning that the greater duration and the articulatory precision have led to constraints on the segmental composition of stressed and unstressed rhymes. A stressed rhyme in English must consist of a long vowel or diphthong or a short vowel plus a consonant. An unstressed rhyme cannot contain any vowel other than [ə i u] (Bolinger 1986: 347).[2] Most importantly from the point of view of our topic, only stressed syllables can be accented.

3.3 *Accent*

Accent is a place marker in the phonological structure where tones are to be inserted (Goldsmith 1977; Hyman 1978; CHAPTER 42: PITCH ACCENT SYSTEMS). The location of these accents, as well as their presence, may be lexically determined, as in Japanese (see also CHAPTER 120: JAPANESE PITCH ACCENT). For instance, (12a) and (12b) are accented words, but differ in the location of the accent, while (12c) is an unaccented word.

(12) a. hási 'chopsticks' b. hasí 'bridge' c. hasi 'edge'

In other languages, accent is assigned on the basis of phonological or morphological information, as in Nubi, a creole spoken in Uganda and Kenya. All Nubi words have one accented syllable, but a verb loses its accent when it combines with an object into a nominalized VP. In (13a) and (13b), a minimal pair of verbs is illustrated in combination with an object; in (13c) the nominalization is shown, and since both 'rent' and 'rent out' now lose their accent, the sentence is ambiguous (Gussenhoven 2006).

(13) a. ána gí pángisa júa 'I will rent out a house.'
I will rent-out house
b. ána gí pangisa júa 'I will rent a house.'
c. pangisa júa séme má 'Renting (out) a house is good.'
rent(-out) house good be

How does English differ from Nubi? The first difference concerns the existence of a choice among the tone(s) to be inserted in any accent position. In Nubi, an accented syllable must have an H* pitch accent. In English, the requirement is merely that a pitch accent be inserted, but which one, out of the many that could be

[2] The final vowel in words like *fellow* was taken to be an allophone of unstressed [u] by Bolinger. Before consonants, [ɪ] may appear, but the situation varies across varieties. In mainstream American English, [ə] and [ɪ] are allophones, with [ɪ] appearing before velars, as in *secure* [sɪ'kjur], and [ə] elsewhere, as in *Sinatra* [sə'natrə]. In a number of varieties, including ones spoken in the USA, [ə] varies with [ɪ] in some contexts (e.g. *peerless* is ['pɪɹləs] or ['pɪɹlɪs], while contrasting them in other contexts, as in *roses vs. Rosa's* or, for non-rhotic dialects, *offices vs. officers*. In unstressed syllables, a syllabic consonant may take the place of a historical [ə] (e.g. *listen* /'lɪsn̩/).

English has a rather large number of accentuation and deaccentuation rules. First, words may have more than one accent, specifically words that have stressed syllables before the main stress, as in *CALiFORnia* (Selkirk 1984). Second, in addition to two rules that resemble the two Nubi rules, it has a rule deleting initial accents and, importantly, a rule that distributes accents to mark information structure. §4 is devoted to accentuation in English.

4 Accent in English

There are two ways in which the description of accentuation in English could be approached. We could either assume that accents are absent and assign them where they are needed, or we could assume that syllables are accented by default and assume they are removed where they do not occur. The second approach is in tune with descriptions of information structure in which accents are removed for "givenness," instead of assigned for "newness" (Schwarzschild 1999) and was adopted for other rules in Gussenhoven (1991, 2005). In the deaccentuation option, accents are first assigned to all syllables that can ever be accented, and then removed where they are not needed. In §4.1, I define the accented syllables of English in two steps, one for primary stressed syllables and one for secondary stressed syllables. §4.2 then describes three deaccentuation rules, the compound deaccentuation rule (henceforth the "Compound Rule"), the Initial Accent Deletion rule, and a rule I will refer to as the "Inverse Compound Rule." §4.3 is devoted to the Rhythm Rule. §4.4 contains three sections dealing with meaningful phrase-level effects: Schmerling's generalization (§4.4.1), phatic elements (§4.4.2), and information structure (§4.4.3). §4.5 deals with the status of pre-nuclear accents. Finally, §5 discusses prominence distinctions that cannot be attributed to stress or accent, and §6 concludes the chapter.

4.1 Lexical generalizations in English

Taking the position of main stress for granted, the first accentuation rule is straightforward: place an accent on the primary stress of every word. The words in (12) come out as in (17) as a result.

(17) aLASka, sarDINE, cigaRETTE, HELicopter, marihuAna, MELancholy

Secondary stressed syllables before the primary stress are also provided with pitch accents. As a result, the representations of *sardine, cigarette,* and *marihuana* are as in (18).

(18) SARDINE, CIGaRETTE, MARiHUAna

Two comments are required here. First, English has "cyclic" stress (Kiparsky 1979). This means that the primary stress of a base survives a morphological derivation that adds a primary stress to the right of the base. The old primary stress will now be a pre-primary secondary stress. In (19a) and (19b), the secondary stress is on the second syllable of the word, because that is where the base has its primary stress; in (19c) it is on the first syllable, for the same reason. In terms of their accentability, there is no difference between the primary stressed syllables

4.2.3 Reverse compounds

"Reverse compounds" are structures in which the first constituent is deaccented. When the first constituent in the NP denotes the category and the second constituent is the name of the item belonging to that category, the first constituent is deaccented. Example (25b) is from Selkirk (1984: 221), who pointed out the contrast with the phrasal *LAKE HILL* 'a hill called after Mr or Mrs Lake', where no deaccenting takes place. The example is representative of geographical names of this type, like *Mount Kilimanjaro*; (25c) illustrates a person category.

(25)	a.	the BOOK JOSHua	→	the book JOSHua
	b.	LAKE HILL	→	lake HILL
	c.	AUNT AGatha	→	aunt AGatha

4.2.4 Initial Accent Deletion

Initial Accent Deletion causes all accents except the last to be deleted in a class of morphological formations, most strikingly compounds. In (26), examples are given in which the first constituent has two accents underlyingly. In the compound noun (26a), the double-accented word *marihuana* loses its pre-final accent, and in (26b) *Tom* undergoes the same fate, as it is the pre-final accent of the name *Tom Paine*, a noun phrase included as the first member of a compound noun. Similarly, *Old* loses its accent in the noun phrase *Old English*, because it too is embedded in a noun compound, while (26d) shows that multiple pre-nuclear accents will all be deleted. Example (26c) forms a minimal pair with the noun phrase *old English teacher* 'an English teacher who is old', where the head noun is the compound *English teacher*: here *old* retains its accent. Similarly, *a Second Language Conference* ("a conference on the study of L2") has an accent just on *Language*, while *a second Language Conference* ("the second of a series of conferences on language") has accents on *second* and *Language*.

(26)	a.	MARiHUAna cigarette	→	mariHUAna cigarette
	b.	TOM PAINE street	→	tom PAINE street
	c.	OLD ENGlish teacher	→	old ENGlish teacher
	d.	i-COULDn't-CARE-LESS attitude	→	i-couldn't-care-LESS attitude

Initial Accent Deletion also applies to English words formed with the help of suffiixes that leave the stress pattern of their base intact. These are known as "stress-neutral" suffixes, and include *-ish*, *-ist*, *-ly*, *-ness*, and *-less*. ("Stress-changing" suffixes include *-ian*: compare *ALbuquerque* – *ALbuquerqueish*, but *ALbuquerque* – *ALbuQUERquian*.) The suffixes *-based*, *-fast*, *-free*, *-like*, *-proof*, *-prone*, *-style*, *-tight*, *-type*, *-wise*, and *-worthy* also belong here, as does the accented suffix *-esque*. The examples in (27) are presented without a "walk-through," but notice the case of (27d), where the base, *REMbrandt*, starts out with only a single accent. Here it is the accent on the suffix that is the last accent in the derived word.

(27)	a.	UNKINDness	→	unKINDness
	b.	TAIPEI-based	→	taiPEI-based
	c.	NORTH-koREa-style	→	north-koREa style
	d.	REMbrandTESQUE	→	rembrandTESQUE

Reverse compounds, too, undergo Initial Accent Deletion. If the second member has two accents, only the last of these survives. In fact, the Reverse Compound Rule could be subsumed by Initial Accent Deletion, but I have preferred to treat the reverse compounds separately, in order to identify them as a group that requires further research.

(28) a. mount KIlimanJAro → mount kilimanJAro
b. route SIXty-ONE → route sixty-ONE

4.3 A post-lexical phonological generalization in English

Once words are inserted into phrases, further deletions of accents may take place. These "post-lexical" generalizations are in part phonological, meaning they are triggered by specific phonological contexts, and in part morphosyntactic, in which case the deletion of the accent is the direct expression of a meaning distinction. The most widely discussed phonological generalization, earlier illustrated in (8), concerns "stress shift," more properly "rhythm-induced accent deletion," also known as the Rhythm Rule. In the PAV, this rule deletes medial accents in the phonological phrase (Gussenhoven 1991; Shattuck-Hufnagel *et al.* 1995). Consider the alternants of *Japanese* in (29). In (29a), we have an isolated pronunciation, in which both accents are retained. In (29b) the first syllable loses its accent, as it is medial in the phonological phrase, while in (29c) the third syllable loses its accent, because *it* is medial. The phonological phrase (ϕ) is a prosodic constituent above the phonological word, and corresponds in the default case with a syntactic phrase.

(29) a. $(\text{JAPaNESE})_{\phi}$
b. $(\text{GOOD japaNESE})_{\phi}$
c. $(\text{JAPanese GOODS})_{\phi}$

The Rhythm Rule makes it clear that it is important to describe the presence of pre-primary accents in words. For instance, (30a) shows that words like *sepTEMber* and *senSAtional* – cf. (20) – really lack an accent on the word-initial foot, while (30b), from Jones (1967), shows that disyllables like *DUNDEE* do have one, just as words like *inTERpreTAtion* and *asSOciAtion*, shown in (32c); cf. (19). Example (30d) shows the effect of *-esque*, due to Initial Accent Deletion. In (30e) (cf. (12a) from Prince 1983), we again see the effect of that rule. *Street* has lost its accent through the Compound Rule and *Tom* lost its accent through Initial Accent Deletion, meaning that there is no medial accent left for the Rhythm Rule to delete. In (30f), there are two medial accents to be deleted by the Rhythm Rule. Next, in (30g)-(30i), we see the effect of Initial Accent Deletion on reverse compounds, and the subsequent inability of the Rhythm Rule to contribute to their prosodic shape.

(30) a. $(\text{sepTEMber STORMS})_{\phi}$ *not* $(\text{SEPtember STORMS})_{\phi}$
b. $(\text{DUNDEE MARmalade})_{\phi}$ → $(\text{DUNdee MARmalade})_{\phi}$
c. $(\text{asSOciATion FOOTball})_{\phi}$ → $(\text{asSOciation FOOTball})_{\phi}$
d. $(\text{rembrandTESQUE LIGHT})_{\phi}$ *not* $(\text{REMbrandtesque LIGHT})_{\phi}$
e. $(\text{tom PAINE street BLUES})_{\phi}$ *not* $(\text{TOM paine street BLUES})_{\phi}$

f.	(TOM PAINE BIG BAND)$_{\varphi}$	→	(TOM paine big BAND)$_{\varphi}$
g.	(aunt SUE BIG BAND)$_{\varphi}$	→	(aunt SUE big BAND)$_{\varphi}$
		not	(AUNT sue big BAND)$_{\varphi}$
h.	(mount kilimanJAro BLUES)$_{\varphi}$	*not*	(MOUNT kilimanjaro BLUES)$_{\varphi}$
		not	(mount KIlimanjaro BLUES)$_{\varphi}$
i.	(route sixty-ONE BLUES)$_{\varphi}$	*not*	(ROUTE sixty-one BLUES)$_{\varphi}$
		not	(route SIXty-one BLUES)$_{\varphi}$

4.4 *Meaningful distinctions at the phrasal level*

The motivation for having pitch accents on particular words in English sentences has traditionally been looked at from a syntactic perspective. The Nuclear Stress Rule of Chomsky and Halle (1968), given in (4b), applied inside phrases, as illustrated in (5a) and (5c), as well as to combinations of phrases. As a result, (31a) was interpreted as having the primary stress on the object NP *Mary*, a pattern known as "normal" stress. Other prosodic versions of the same sentence, like (31b), were said to have "contrastive stress," due to contextual constraints that more recently have been collectively called "information structure." In (31b), a contrastive stress rule, not formalized, has retained the primary stress on *John*, demoting the stress levels on *kissed* and *Mary* as a result.

(31) a. [[*John* $]_{NP}$ [*kissed* [*Mary* $]_{NP}]_{VP}]_{S}$

1	1	1	Starting point
	1	1	(4b)
	2	1	
1	2	1	(4b)
2	3	1	Output

b. A: *Who kissed Mary?*

1 3 2

B: [[*John* $]_{NP}$ [*kissed* [*Mary* $]_{NP}]_{VP}]_{S}$

Schmerling (1976) and others have pointed out that the distinction between "normal" and "contrastive" is not easily maintained. "Normal" stress may seem an unproblematic concept in (31a): this is how the sentence would be produced when read from a contextless written presentation. In many situations, however, such a reading may strike the listener as quite marked. In (32a), the prominence on *two* seems both "contrastive," in the sense that the two-year-old is compared with some older individual, and "normal," in the sense that this is how any native speaker would read it. Schmerling (1976) also pointed out that the way her husband announced the death of President Johnson to her was as (32b), an out-of the-blue statement, with no accent on *died*. As it happened, some weeks earlier, her mother had announced the death of another American president, Truman, as (32c). Unlike Johnson, Truman had been critically ill for some time and his death came as no surprise. I here give Schmerling's (1976) prominence patterns as accentuations. It is hard to see which utterance has "normal stress"; if a choice must be made, it would be (32b), unlike what the Nuclear Stress Rule predicts.

(32) a. Even a TWO-year-old can do that
b. JOHNson died
c. TRUman DIED

(41) I'm sitting here very NICEly, thank you very much.

Hearer-appeal markers intend to engage the listener, like vocatives, "softening" expressions like *don't you think, eh,* and equal polarity tags (42).

(42) It's SUCH a cute CHILD, don't you think, Peter?

Textual markers include comment clauses, as in (43a), and reporting clauses, as in (43b). Reporting clauses may be complex, and still show a sustained absence of accents. Unaccented reporting clauses may be integrated in the intonational structure in two ways. They may be included in the intonational phrase, just like comment clauses, in which case any final boundary tone appears after the reporting clause, or be cliticized, in which case the final boundary tone occurs before the reporting clause, to close off the reported direct speech, as well as after it. In the latter option, probable for (43a), there is a noticeable boundary between the reported direct speech and the reporting clause.

(43) a. It's tomorrow, I think.
b. 'Then why not GO there?', he interrupted, no longer feeling he didn't care.

Approximatives are expressions that indicate that information is less than precise. This is a quite varied group, with items like *or more, the way he did, or something, and all that, kind of thing, in a way.*

(44) I suppose we all ARE in a way.

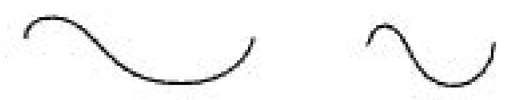
Epithets are appositive descriptions, often derogatory, as illustrated in (45). Example (45a) is from Bing (1979). In Gussenhoven (1986: 128), I erroneously argued, contra Bing (1979), that epithets are accented. My confusion was due to the frequent occurrence of a final H% boundary tone in this kind of sentence, added to the fact that, like many reporting clauses, epithets are typically set off from the preceding clause by an intonational phrase boundary. Thus, if *neighbors* in (45a) is giving a falling–rising contour (H*L H%: high pitch on *neigh-* and low-to-high pitch on *-bors*), the pitch on *the finks* will repeat L H%, the low-to-high pitch of *-bors*. To see how the pattern goes without H%, (45b) naturally ends in L%, once after *is* (H*L L%) and once after *boy* (L L%). As Bing pointed out, this pattern contrasts with the repetition of the pitch accent: if the H*L H% is repeated on *the finks*, the expression changes into an appellative apposition, *Fink* now being their surname; see (46b). Similarly, a polar tag is accented, as shown in (46b), where *IS* repeats the contour of *ILL*, H*L L%.

(45)

a. My nextdoor NEIGHbors, the finks, have been coming over EVery NIGHT.

b. Here he IS, the stupid boy.

(46)



a. My nextdoor NEIGHbors, the FINKS, will be OUT tonight.

b. He ¡ISn't ILL then, IS he?

4.4.3 *(De)accenting for "newness" and "givenness"*

Deaccenting for "givenness" is illustrated in (47a), where the phrase *in the city* is a stand-in for *Toulouse*. The absence of a pitch accent on *city* causes the predicate *set foot* to have the last pitch accent. By contrast, in (47b) *in the city* refers to a specific district in London, and therefore conveys different information from *London*. Pitch accents thus express "information structure," the way the information in the sentence relates to the state of understanding. The lack of accent on *city* in (47a) indicates that reference is made to existing information, just as the presence of the accent on the same word in (47b) indicates that some referent other than "London" is to be understood, i.e. the financial district known as "the City."

(47) a. They can't have been seen in Toulouse. They NEVer set FOOT in the city.
b. They haven't really seen much of London. They NEVer set foot in the CITy.

The relation between accentuation and information structure in English and other European as well as Asian languages is a widely studied phenomenon. Recent volumes are Bosch and van der Sandt (1999), Molnár and Winkler (2006), and Lee *et al.* (2007). Here I discuss two issues that have played a role in the discussion over the past decades: (i) highlighting and (ii) the focus constituent.

(i) *Highlighting*: Dwight Bolinger was the main proponent of the position that a pitch accent lends significance to the word it is used on, even in a compound or a predicate–argument combination. This "highlighting view" was originally launched in reaction to the syntax-based derivation of "normal stress" illustrated in (31a) (Bolinger 1972), but later repeated in response to Schmerling (1976) (Bolinger 1977) and Gussenhoven (1983a) (Bolinger 1985, 1987). The highlighting role of pitch accents is evident not only in the expressive use of pitch accents in (48a) – cf. Bolinger (1987: example (145)), which goes against Predicate Deaccentuation – but also in the unusual locations of pitch accents, "distortion," as in (48b) (Bolinger 1985: example (32)). Counterpresuppositional accentuations like that in (48c), which can be analyzed as representing negative polarity focus, must thus be motivated by the meaning of *in* in Bolinger's analysis (Bolinger 1985).

(48) a. Your FEET STINK.
b. A: You've overlooked the possibility of dealing with him personally.
B: Not at all. There never really was a POSsibility.
c. They can't have been seen in Toulouse. They were never IN the city.

The expressive power of pitch accents and the expressive motivation for some pitch accent locations is undeniable (cf. also Ladd 2008: 246), but the consensus in *A and* [*B and* C] than in [*A and B*] *and* C. Second, Katz and Selkirk (2009) produce evidence that a contrastive accent like that on *Modigliani* in (52) has greater acoustic prominence than the phonetically less salient thematic accent in *Moma*, which Zubizaretta (1998: 84) might call a "miniature" accent. Katz and Selkirk (2009) argue that there is a binary contrast here.

(51) Gary is a really bad art dealer. He gets attached to the paintings he buys. He acquired a few Picassos and fell in love with them. The same thing happened with a Cezanne painting. So he would *only* offer that $[\text{Modigliani}]_{FOC}$ to $[\text{MoMA}]_{New}$. I bet the Picassos would have fetched a much higher price.

The third case concerns "second occurrence focus" (SOF). It refers to the unaccented repetition of a constituent in the scope of a "focus operator" like *also, even, only* which was accented in the preceding sentence. Féry and Ishihara (2009) found small but significant differences between postnuclear SOF, as illustrated in the B response in (52a), and non-focus, as illustrated in the B response (52b), even though both instances of *song* are unaccented. Their experiment was on German; (52) improvises on the kind of data they used (cf. also Beaver *et al.* 2007).

(52) a. A: It was a fun party. Michael even sang a SONG.
B: And WALdemar even sang a [song].
b. A: Did MANy people sing a song at the party?
B: Yes! WALdemar even sang a song.

Fourth, there may be durational differences and possibly pitch differences between unaccented primary stresses and unaccented secondary stresses. For instance, if we placed the compound *SPANish student* and the phrase *a SPANish STUdent* in a reporting clause (where their accents must disappear), are these structures still different phonetically? And is the answer the same in the case of a minimal pair of single words, like the noun *INterchange* and the verb *INterCHANGE* (cf. Schmerling 1976: 24; Gussenhoven 1991)? Fifth, even though listeners may not use the information, there are reports that narrow focus, shown in (53a), is pronounced differently from broad focus, shown in (53b). Depending on the language, the narrow focus pronunciation may have a longer duration, a steeper slope, a later peak, an earlier peak, or a higher peak (Avesani and Vayra 2004; Smiljanić 2004; Sityaev and House 2004; Baumann *et al.* 2007; Hanssen *et al.* 2008).

(53) a. A: Were you going to drive to Bristol, you said?
B: We're going to drive to [WINDsor].
b. A: What are you going to do today?
B: We're going to [drive to WINDsor].

There are two possible responses to these five (real and potential) effects. One is that the PAV needs to be enriched with a representation of gradient prominence, thus returning to the position in Chomsky and Halle (1968). In the context of the differences in phrasal branching referred to above, Ladd (2008) suggested that this representation should be *tonal*, rather than be in terms of levels of stress. Accordingly, he proposed a tree structure much like the metrical tree

ACKNOWLEDGMENTS

I thank Haruo Kubozono and Hubert Truckenbrodt for their productive discussion of some of the issues in this chapter and two anonymous reviewers for their useful comments on an earlier version. I am grateful to Luise Dorenbusch for spotting a number of errors at proof stage.

117 Celtic Mutations

S. J. Hannahs

1 Introduction: Initial consonant mutation

Initial consonant mutation is one of the best known, although not best understood, phonological characteristics of the Celtic languages: the initial consonant of a word form undergoes a systematic alternation with a phonetically distinct consonant in specific contexts. (On mutation in languages other than Celtic see CHAPTER 65: CONSONANT MUTATION.)

As an example of such a systematic alternation in the initial consonant of a word, consider Welsh. The Welsh word for 'father', *tad*, has four distinct forms: the citation form *tad* [taːd], the "soft mutation" form *dad* [daːd], the "aspirate mutation" form *thad* [θaːd], and the "nasal mutation" form *nhad* [n̥aːd].

(1) *Welsh initial consonant mutations*

citation form	*tad*	[taːd]	'father'
soft mutation	*dy dad*	[də daːd] (2SG father)	'your father'
aspirate mutation	*ei thad*	[i θaːd] (3FEM SG father)	'her father'
nasal mutation	*fy nhad*	[ə n̥aːd] (1SG father)	'my father'

Which of these four forms occurs in any particular instance depends on the wider context in which the word appears, as discussed below. Here we see that following the 2nd person singular possessive pronoun *tad* mutates to *dad*, following the 3rd person feminine singular possessive pronoun *tad* mutates to *thad*, and following the 1st person singular possessive pronoun *tad* mutates to *nhad*. The number and nature of the mutations differ between the modern Celtic languages, though there are some overarching similarities across the family, such as mutations following specific prepositions, mutations associated with particular grammatical contexts, and so forth. Within each of the two branches of the Celtic family, the Brythonic languages (also known as "P-Celtic"), Breton and Welsh, have very similar patterns to each other, as do the Goidelic languages (or "Q-Celtic"), Irish and Scottish Gaelic.[1]

[1] Note the conventional difference in pronunciation between Irish Gaelic [geilɪk] and Scottish Gaelic [gælɪk], often called simply *Gaelic* [gælɪk], reflecting the pronunciation of each in its own language.

Although initial consonant mutation has its origin in phonetics as a series of phonetically triggered external sandhi alternations, the overwhelming bulk of initial consonant mutation in the modern languages is not phonetically triggered. Indeed, it is not phonologically transparent. Rather, it is lexical and/or grammatically conditioned. Nonetheless, it is possible to sketch an outline of the historical phonetic bases of initial consonant mutation, and to discuss the general absence of phonological transparency. Moreover, despite this general absence of phonological transparency, there are a number of recent accounts (syntactic, phonological, and morphological) of productive instances of initial consonant mutation, for instance analyses of "soft mutation" (i.e. lenition) in Welsh. Beyond such productive occurrences of initial consonant mutation there is a large "residue," that is, phonologically non-productive (typically lexicalized or grammaticalized) aspects of mutation. This residue – which may well be syntactically or morphologically productive – nevertheless has phonological implications: even in the absence of productive phonological processes, initial consonant mutation still requires some sort of phonological representation, along with a phonological characterization of the alternations themselves.

A brief word on terminology is in order here before looking at the languages and the data involved. The statement above that initial consonant mutation has its origins in phonetics means simply that the alternations were originally phonetically transparent, e.g. lenition involved voicing and/or frication of intervocalic consonants; nasal mutation involved contact with a nasal segment. In the modern languages many of the alternations have become grammaticalized and phonologically opaque in various ways. The object of a specific preposition may undergo a particular mutation, and the complement of a particular pronoun may show a specific mutation, in both cases in the absence of a transparent phonetic context triggering the alternation. This in turn leads to an interesting analytical dilemma: although the mutations affect the phonological shape of word forms, the alternations themselves may be triggered by non-phonological structures in a phonetically opaque way. That is, they may be subject to grammatical (e.g. syntactic or morphological) considerations outside the phonology proper. Indeed, some (e.g. Stewart 2004; Green 2006, 2007) have taken the lack of a unitary cause of mutation and an absence of unitary effect as evidence that it is not a unitary phenomenon and not therefore properly phonological.

After a brief discussion of the languages involved, the diachronic origins of initial consonant mutation, and the problem of determining whether the mutations are best analyzed in terms of phonology, morphology, or syntax (or some combination thereof), this chapter will look at the data of initial consonant mutation in the Celtic languages, discuss the theoretical interest in initial mutation, and survey some of the more influential analyses of initial consonant mutation.

2 Background

2.1 *The Celtic languages*

There are four living Celtic languages, belonging to two branches of the Celtic family of Indo-European. The Brythonic (or Brittonic) branch includes Breton (spoken in Brittany in France) and Welsh (spoken in Wales and parts of Patagonia), whilst the Goidelic branch includes Irish (spoken in Ireland) and Scottish Gaelic (spoken in Scotland and on Cape Breton Island, Canada). The family also includes the relatively recently extinct Cornish (Brythonic) and Manx (Goidelic), which are both subject to current revival movements, but which will not be considered here. (Pre-)historically, the Celtic family also included Gaulish, Cumbric, and Celtiberian, and the evidence suggests that they also displayed initial mutations (see for instance Fleuriot 1975 and Gray 1944; though Jackson 1953: 548 is more skeptical).

2.2 *Origins of initial consonant mutation*

The Celtic mutations were originally phonetically triggered external sandhi forms. For example, the initial mutation variously referred to as "soft mutation" in Welsh and Breton, "lenition" in Breton or Scottish Gaelic, and "aspiration" in Irish, is traceable to phonetically conditioned intervocalic lenition (see CHAPTER 66: LENITION). Writing about lenition in "British," i.e. Brythonic, Jackson (1953: 543) notes that it occurred "intervocally, whether in the interior of a word or initially when preceded in a close speech-group by a proclitic ending in British in a vowel . . ." It affected the British single voiceless stops [p t k], which became voiced [b d g]. [b d g], in turn, along with [m], spirantized to [β ð ɣ] and [ṽ].[2] The [ṽ] subsequently denasalized to [v], while the voiced velar fricative [ɣ] later deleted in Welsh (in certain cases becoming [j]); it became [x] in Cornish and Breton.

Generally, then, in British (and in Celtic more widely) intervocalic stops lenited word-internally. Word-initially, single consonants lenited when preceded by a vowel-final word. According to Falc'hun (1951: 84f.), "Originally, mutations were purely phonetic. In words closely linked with each other, the ending of one word, depending on whether it was vowel final or consonant final, triggered the alternation of particular consonants at the beginning of the following word."[3] As Hickey (1997: 146f.) points out, "Any consideration of the origin of mutation must start with phenomena which are purely allophonic. . . . Low-level phonetic lenition is a necessary precondition to the development of morphological lenition at a much later point." Thus, the process that started out as a phonetically motivated allophonic alternation became morphologized.

This distinction between allophonic lenition and morphological lenition goes to the heart of the difficulty of trying to account for initial lenition – or any of the other initial consonant mutations – in the Celtic languages as solely phonological. Although initial consonant mutation does have its origins in phonetics, it has long since ceased to be a transparent phonological phenomenon.

Falc'hun (1951: 85), for example, notes that certain phonological changes led to the grammaticalization of initial consonant mutation. Specifically, stress shift and the subsequent loss of endings in Celtic removed the phonetic context for across-the-board initial mutations, yet the mutations themselves persisted, having become grammaticalized. Given that older forms of Celtic had large numbers of

[2] Jackson uses the symbols ƀ, đ, ʒ, and μ, respectively. I have replaced these here with the standard IPA symbols.

[3] "A l'origine, les mutations étaient des faits purement phonétiques. Dans les mots intimement liés entre eux, la désinence du premier mot, suivant qu'elle finissait par une voyelle ou par une consonne, entrainait l'alternance de certaines consonnes au début du mot suivant." [Translation SJH]

Syntactic soft mutation in Welsh has long been alleged to mark the direct object (see Zwicky 1984, and more recently Roberts 2005). However, as Tallerman (2006) shows unambiguously, and as Borsley *et al.* (2007) discuss at length, an account of soft mutation based on direct objects (or abstract accusative case marking) fails to account for the data. Even considering just the data in (4), the mutated word doesn't have a single grammatical function nor does it belong to a single syntactic category – in (a) it's a direct object, in (b) it's the head of a verb phrase, in (c) it's the verb belonging to an embedded clause, in (d) it's the verb in an embedded infinitival clause, in (e) it's the subject of the sentence. So, even leaving aside the absence of phonological conditioning and restricting the focus to grammatical conditioning, the grammaticalization of initial consonant mutation is both highly complex and multidimensional.

It is important to note, too, that although the examples above are of a single initial mutation in a single language, the lenition process known as "soft mutation" in Welsh, these examples are nevertheless indicative of the variety of triggers for initial consonant mutation in the Celtic languages in general. Taking the example of Irish, the Christian Brothers' grammar (n.d.: 15) includes the following under the "rules for eclipsis" (i.e. a type of nasalization, discussed below):

(5) *Eclipsis in Irish occurs following*

a. the plural possessive adjectives *ár* 'our', *bhur* 'your', and *a* 'their'
b. the article when followed by the genitive plural (both genders)
c. a simple preposition followed by the article and a noun in the singular
d. the numeral adjectives *seacht* (7), *ocht* (8), *naoi* (9), and *deich* (10)
e. the particles *cha* 'not', *an* 'whether', *cá* 'where', *nach* 'whether . . . not', *go* 'that', *muna* 'unless', *dá* 'if', and after the relative particle *a* when it is preceded by a preposition, or when it means 'all that' or 'what'.

So, although initial consonant mutation was originally phonetically motivated, it is now overwhelmingly phonologically opaque. Moreover, even while various mutations are robust and productive, they may also be associated with a number of different contexts, making reasonably comprehensive accounts of initial consonant mutation very difficult to articulate. Nonetheless, over the years there have been attempts to account for initial consonant mutation within various linguistic frameworks and to analyze it from various perspectives, including phonological, morphological, syntactic, or some combination of these, such as morphophonological or morphosyntactic. Furthermore, some success can be achieved through narrowly focusing on a particular aspect of a specific type of mutation in a single language, though this is often not easily generalizable across mutations or necessarily extensible to other languages.

While it is clear that initial consonant mutation in the modern Celtic languages is not primarily phonological, at least five relevant questions still remain for phonology:

(i) What phonological alternations are involved in the mutations?
(ii) How can the alternations be characterized phonologically?
(iii) Where do the alternations occur, i.e. (how) can the alternation site be defined in phonological terms?
(iv) What triggers the alternations?
(v) How are the alternations represented phonologically?

These questions will be referred to again below with reference to various accounts of mutation. Before looking more closely at these accounts, the next section presents the primary data of initial consonant mutation in Irish, Scottish Gaelic, Welsh, and Breton. Note that the data presented are representative of the initial consonant mutations in each of the languages. However, given the wide and significant dialect variation within and across the Celtic languages, coupled with the absence of a spoken standard, the data given will not match the specifics of every dialect.[5]

4 The data

The tables in the following subsections summarize the alternations involved in the principal initial consonant mutations in the four living Celtic languages. The symbols are broadly phonetic rather than orthographic. In each case the top row indicates the radical or underlying form, typically matching the initial consonant in a citation form or dictionary entry; the changes shown are those indicated by the type of mutation in the left-hand column. For example, an Irish word beginning with /b/, e.g. *bó* [bo] 'cow', shows up as *bhó* [vo] under "aspiration" and as *mbó* [mo] under "eclipsis."

(6) *Irish initial consonant mutations* (cf. Grijzenhout 1995: 8)

citation form	*bó*	[bo]	'cow'
aspiration	*a bhó*	[ə vo]	'his cow'
eclipsis	*a mbó*	[ɔ mo]	'their cow'

Note, too, that not all consonants are subject to mutation. Those that do not mutate are not included in the tables in the "Radical" row.

4.1 Q-Celtic (Irish and Scottish Gaelic) mutations

4.1.1 Irish

For an overview of Irish mutation, see Ní Chiosáin (1991) and Grijzenhout (1995: 9), for example. Note that the Irish and Scottish Gaelic consonant systems include a contrast between palatalized ("slender") consonants and non-palatalized ("broad" or "velarized") consonants. The palatalized consonants are indicated by an apostrophe. Both types of consonant undergo mutation, as indicated in the tables. Note also the sonorants represented with a capital letter, [N], [R], and [L], again in both Irish and Scottish Gaelic. Historically, these appear to have been geminate sonorants and their behavior in the modern languages is different from other sonorants, particularly with respect to mutation; synchronically, their phonetic nature

[5] It is of importance to phonological research to note that none of the modern Celtic languages recognizes a single spoken standard. Therefore, unlike analyses of English, in which accounts of specific dialects can refer for example to Received Pronunciation, General American, or some other standard English, there is no standard point of reference for the sound systems of Irish, Scottish Gaelic, Welsh, and Breton.

varies from dialect to dialect, though current research seems to indicate that – at least for Skye Gaelic – they are associated with Advanced Tongue Root, as compared with "normal" sonorants (see Archangeli 2009). Finally, note that Irish [f] is traditionally a voiceless bilabial fricative; this is now giving way to a voiceless labiodental fricative (cf. Christian Brothers, n.d.: 9 and Mac Eoin 1993: 110). For both /f/ and /f′/ in Irish and Scottish Gaelic, the "aspirated" reflex is loss of the consonant (hence "zero" in the table); for /f′/ this results in palatalization of a preceding consonant.

(7) *Mutation table for Irish, showing the radical consonant, aspiration* (a.k.a. lenition), séimhiú, *and eclipsis* (a.k.a. nasalization), urú

Radical	p	p′	t	t′	k	k′	b	b′	d	d′	g	g′
Aspirated ("lenited")	f	f′	h	h′	x	x′	v~w	v′	ɣ	ɣ′~j	ɣ	ɣ′~j
Eclipsed ("nasalized")	b	b′	d	d′	g	g′	m	m′	N	N′	ŋ	ŋ′

Radical	f	f′	s	s′	R	R′	L	L′
Aspirated ("lenited")	zero	zero	h	h′	r	r′	l	l′
Eclipsed ("nasalized")	v	v′	s	s′	R	R′	L	L′

4.1.2 *Scottish Gaelic*

For Scottish Gaelic mutations, see MacAulay (1992b: 238ff.) and Rogers (1972), for example. In addition to the observations above concerning the palatalized *vs.* non-palatalized contrast and the sonorants represented with capital letters, relevant for both Irish and Scottish Gaelic, there is another representational issue with respect to Scottish Gaelic. The stop contrast in Scottish Gaelic is typically represented as a [±voice] contrast, i.e. using the symbols p/b, t/d, k/g. However, the phonetic reality is that in virtually every major dialect the contrast is actually [±aspiration]. Traditionally, the p/b, t/d, k/g notation has been used for typographical convenience – the visual contrast is maintained and it is easier to read, e.g. [b] *vs.* [p] *vs.* [p′] in lieu of [p] *vs.* [pʰ] *vs.* [p′ʰ]. The principal allophones of the stops in Scottish Gaelic are in fact voiceless; the phonological contrast in the stop series is really one of aspiration.

In the mutation table below I have followed the typographic tradition and used the voiced and voiceless symbols. Thus *b* here represents plain unaspirated [p], while *p* represents aspirated [pʰ], *p′* represents [p′ʰ], etc. Absence of a cell in the table, e.g. at the intersection of /s/ and "Eclipsed," indicates that the radical consonant appears in that particular environment.

(8) *Mutation table for Scottish Gaelic, showing eclipsis* (a.k.a. nasalization), uradh, and *lenition* (a.k.a. aspiration), sèimheachadh

Radical	p	p′	t	t′	k	k′	b	b′	d	d′	g	g′
Lenited	f	f′	h	h′	x	x′	v	v′	ɣ	ɣ′	ɣ	ɣ′
Eclipsed ("nasalized")	mp	mp′	nt	nt′	ŋk	ŋk′	mb	mb′	nd	nd′	ŋg	ŋg′

Radical	f	f′	s	s′	L	L′	m	m′	N	N′	R
Lenited	zero	zero	h	h′	L	l′	ṽ	ṽ′	n		r
Eclipsed ("nasalized")	mf	mf′									

4.2 P-Celtic (Welsh and Breton) mutations

4.2.1 Welsh

For Welsh mutations, see for example Morris-Jones (1913: 176) and Borsley *et al.* (2007: 19–26). The radical consonants shown typically have their IPA values, though phonetically /p t k/ tend to be aspirated and /b d g/ tend toward devoicing. /ɬ/ (orthographic <ll>) is realized as a voiceless lateral fricative. /ʰr̥/ represents a voiceless pre-aspirated trill (which either contrasts with a voiced [r], cf. Ball and Williams 2000: 16, or is allophonically related to it, cf. Awbery 1986: 13); this is variously realized as voiceless pre-aspirated [ʰr̥], voiceless post-aspirated [r̥ʰ], a sequence of trill followed by aspiration, [rh], or a sequence of aspiration followed by a trill, [hr]. The soft mutation reflex of /g/ is absence of the segment (zero). The voiceless nasals, [m̥ n̥ ŋ̊], occur only as the nasal mutation reflexes of /p t k/.

(9) *Mutation table for Welsh, showing soft mutation,* treiglad meddal, *nasal mutation,* treiglad trwynol, *and aspirate mutation,* treiglad llaes

Radical	p	t	k	b	d	g	m	ɬ	ʰr̥
Soft	b	d	g	v	ð	zero	v	l	r
Nasal	m̥	n̥	ŋ̊	m	n	ŋ			
Spirant	f	θ	χ						

4.2.2 Breton

For Breton mutations, see for example Press (1986), Hemon (2007: 1), and Jackson (1967: 311). As with the Welsh, the Breton consonants also typically have their IPA values. The only issue of note is the differing behavior of the singleton /g/ *vs.* the complex onset /gw/: in both the soft and mixed mutations the reflex of /g/ is [x], whereas the reflex of /gw/ is [w].

(12) *Illustration of the Old Irish morphophonemes L, G, and N; base form* [kna:ˈṽʹ][7]

mo chnáim	[mo xna:ˈṽʹ]	moL kna:ṽʹ	'my bone'
do chnáim	[do xna:ˈṽʹ]	doL kna:ṽʹ	'your bone'
a chnáim	[a xna:ˈṽʹ]	aL kna:ṽʹ	'his bone'
a cnáim	[a kna:ˈṽʹ]	aC kna:ṽʹ	'her bone'
a gcnáim	[a gna:ˈṽʹ]	aN kna:ṽʹ	'their bone'

(Hamp 1951: 235)

Thus, Hamp's account, very much within the American structuralist tradition, relies on diacritic association of morphophonemes with the specific items which trigger mutation. By listing the effect of each of the morphophonemes, the correct phonetic form derives from spelling out the effects of a specific morphophoneme on a particular target, i.e. a particular initial consonant.

The emergence of generative phonology (following Chomsky and Halle 1968) led to a re-evaluation of the morphophonemic approach to initial consonant mutation. Rogers (1972), for example, explicitly rejects Hamp's morphological approach to initial consonant mutation. Instead, Rogers develops a set of *SPE*-type phonological rules to account for the alternations associated with Scottish Gaelic mutations.

Although Rogers acknowledges the morphological nature of initial mutation,[8] he views the morphophonemic approach of Hamp (1951) and Oftedal (1962) as arbitrary. Instead, he "attempts to describe the conditioning in terms of either natural phonological segments or morphological features" (1972: 64). In order to do this, Rogers develops a set of 14 distinct *SPE*-type phonological rules. In fact, these rules essentially address the second of our five questions relevant for phonology: How can the alternations be characterized phonologically? In addition to his phonological rules, Rogers also needs a morphological trigger for the specific mutation in question. For example, the rule leniting /f/ to zero includes in its context of application the morphophoneme for lenition [+Lnt] at a morpheme boundary:

(13) $f \rightarrow \emptyset$ / [+Lnt] + __

So even though Rogers's explicit goal is to take the mutations out of the morphology and put them in the phonology, the attempt is only partly successful. Although he is able to develop a set of phonological rules to account for the changes involved in initial mutation in Scottish Gaelic, the rules themselves refer crucially to morphological information. Furthermore, the "lenition feature" [+Lnt] appears to enjoy a life of its own, rather than necessarily being anchored to a lexical item, as Hamp's morphophonemes are. From the vantage point of current phonology, it appears that while Rogers avoided the American structuralist practice of listing employed by Hamp, his own account is not free of crucial dependency on morphology and thus is only a partially phonological account.

7 Hamp also includes *kna:Lmʹ* as a possible base form to show that the *L* diacritic can also appear word-internally. This form is omitted here for clarity.

8 "The fact that the possessive pronouns for 'her', 'his', and 'their' are homophonous shows the morphological conditioning of the mutations" (Rogers 1972: 63).

One area of initial consonant mutation that has drawn a great deal of syntactic attention in recent years is "syntactic soft mutation" in Welsh (see §3 above). Growing from initial work by Harlow (1989), and further developed in a number of subsequent publications, including Tallerman (1990, 2006, 2009), Borsley and Tallerman (1996), Borsley (1997, 1999), and Borsley *et al.* (2007), the environment of Welsh syntactic soft mutation is shown to be analyzable in terms of phrasal syntax. Specifically, the central idea behind this work is that a mutable initial consonant immediately preceded by a syntactic phrase, i.e. an XP, undergoes soft mutation. This is known as the XP Trigger Hypothesis, or XPTH. In the examples in (15), the XP in question is an NP, though other maximal projections also trigger the mutation (see Borsley *et al.* 2007 and Tallerman 2009).

(15) a. Dechreuodd [Huw]NP *olchi* 'r llestri (golchi)
begin.PAST.3SG Huw wash.INF the dishes
'Huw began to wash the dishes.'

b. Mae yn [yr ardd]NP *gi* (ci)
be.PRS.3SG in the garden dog
'There's a dog in the garden.'

Thus, the XPTH provides a structural account of Welsh soft mutation distinct from attempts to characterize soft mutation as marking direct object or abstract case marking (cf. Zwicky 1984; Roberts 1997, 2005) mentioned earlier. Clearly in the cases in (15) the object of mutation is not a direct object: in (15a) it's an infinitive, in (15b) it's a subject.

In terms of comparing the phonological account with the XPTH, it is difficult to decide between them. On the one hand, a phonological account of a phonological phenomenon might be preferred, yet if the conditioning environment for syntactic soft mutation really is syntactic structure – the XP rather than the Phonological Phrase – the XPTH might be preferable.

5.3 *Morphological accounts*

Recently, both Stewart (2004) and Green (2006) have returned to the argument initiated by Hamp (1951) that mutation is morphology. A difference, however, lies in the fact that Hamp's approach is morphophonological, where Stewart and Green both argue for a non-phonological morphological position. Stewart (2004) reviews the primary literature on Celtic mutation, coming back to the conclusion that the Celtic mutations are entirely morphological, not phonological. As he puts it:

> once it is admitted that the mutations are not subject to natural class behavior and that their distribution crucially must make reference to non-phonological information . . . it seems evident that what we are dealing with is not live synchronic phonology . . . but is now a set of surface correspondences that has been quite fully morphologized. (Stewart 2004: 63)

In dealing with these "quite fully morphologized" correspondences in Scottish Gaelic initial mutation, Stewart proposes three specific types of morphological domains: "intralexemic morphology," dealing with paradigms of inflected forms on the basis of stems of individual lexemes, "interlexemic morphology," and "supralexemic morphology." According to Stewart, each of the various mutations in Scottish Gaelic falls into one of these domains.

In addition to these domains of morphology, Stewart proposes "meta-redundancy-rules" to describe each mutation type, thereby defining a "Lenition constellation" and a "Nasalization constellation," a "constellation" being "the collection of rules which instantiate the meta-rule" (2004: 125). By removing non-automatic (i.e. non-phonological) alternations from the phonology and relieving the syntax of the burden of morphological marking (at least with respect to initial mutation), his stated goal is to allow for more constrained theories of phonology and syntax. Despite the interesting possibilities raised, Stewart explicitly avoids "a rigorous formalization of the concepts involved" (2004: 145).

In an examination of initial consonant mutations and the evidence they provide for phonological theory, Green (2006, 2007) argues that the mutations lie "entirely outside the phonology" (2006: 1948). Instead, Green maintains that the mutations "are properties of the lexicon, which consists . . . of whole words listed in all their actual surface forms and connected to each other through their shared properties" (2006: 1948). Thus, rather than viewing initial consonant mutation as the instantiation of some change in an initial consonant, Green takes a Bybeean view (cf. Bybee 1985, 2001), assuming that a mutating word form will belong to a set of forms related in the lexicon (see also CHAPTER 1: UNDERLYING REPRESENTATIONS). For example, Irish *bróg* [bro:g] 'shoe' will be related in the lexicon to *bhróg* [vro:g] 'shoe' (lenited) and *mbróg* [mro:g] 'shoe' (eclipsed). Crucially, the mutated forms are not derived from an underlying /bro:g/. Rather, it is proposed that various determiners, complementizers, and other proclitics in the Celtic languages subcategorize for specific mutations, thus selecting from the lexicon the appropriate shape for the lexical item in question. Recalling Lieber's (1987) prespecification analysis, Green's proposal shifts the burden from the phonological implementation of a morphological diacritic firmly to subcategorization and lexical selection.

Maintaining the position that initial consonant mutation is morphological in nature, Green (2006: 1958–1959) adduces four primary arguments against the processes (as distinct from the environments) of Celtic mutation being phonological: (i) no feature or bundle of features can produce the wide variety of effects found within a single mutation; (ii) syntactically triggered mutation requires a mutation-triggering feature, yet there is no independent evidence, apart from mutation itself, for such a feature; (iii) mutations are sometimes triggered by non-adjacent proclitics; and (iv) the variety of exceptions and irregularities in mutation is inconsistent with a phonological analysis.

Turning to theory-internal issues, Green also points out that a phonological account of Celtic mutation is incompatible with the strong version of Optimality Theory (Prince and Smolensky 2004 and a large body of subsequent work), in that the Celtic mutations do not reflect the interaction of faithfulness constraints with universal principles of markedness. In OT terms, a mutated word-form is "unfaithful" to its input, the citation form. OT predicts that an unfaithful form will be selected as optimal only if markedness is improved by the unfaithful form. In the case of the initial mutations in Celtic, however, the selection of an unfaithful, mutated word form does not improve markedness, and thus runs counter to the predictions of OT. This is taken by Green as further evidence that initial mutation is not phonological.

6 Theoretical issues informed by initial consonant mutation

Accounts of initial consonant mutation are necessarily connected with the theoretical frameworks within which they have been proposed. Nonetheless, just as phonological theory informs the analysis of phonological data, the accounts themselves may inform various theories. Apart from the questions and issues surrounding the analysis of mutation itself, whether in accounting for the changes, the triggers, the contexts, or the representations, initial consonant mutation has played an interesting role in various aspects of the development of linguistic theory. As we have seen, these include Hamp's (1951) use of mutation to argue for the role of morphological marking in linguistic analysis, Lieber's (1983) use of mutation to support autosegmental theory, Gnanadesikan's (1997) use of mutation to argue for a system of ternary feature scales in phonology, and Green's (2006) rejection of phonological mutation to argue for the strong version of Optimality Theory, i.e. that phonological processes result only from the interaction of markedness and faithfulness.

The phenomenon of initial mutation has also been used as evidence for the relationship between linguistic operations. Hannahs and Tallerman (2006), for example, use the evidence of initial mutation and its interaction with the shape of the Welsh definite article (which appears variously as *yr* [ər], *y* [ə], or *r* [r]) as a diagnostic for determining the sequence of lexical insertion in the syntax. The definite article may trigger mutation (e.g. of a feminine singular noun), thereby altering the shape of a following noun. The shape of the definite article, on the other hand, is conditioned (in part) by whether it is followed by a consonant-initial or a vowel-initial word. Recalling that the Welsh soft mutation reflex of /g/ is zero, a feminine singular noun such as *gorsaf* 'station' will appear as *orsaf* after the definite article; the definite article itself appears as *yr* [ər], since *orsaf* is vowel initial. Masculine singular *gosteg* 'silence', however, does not mutate after the definite article and so retains its initial [g].

(16)	gorsaf	'station (FEM SG)'	gosteg	'silence (MASC SG)'
	yr orsaf	'the station'	y gosteg	'the silence'
	*y gorsaf, *yr gorsaf		*yr osteg, *yr gosteg	

The examples in (16) show that in this context *gorsaf* mutates to *orsaf* and the article surfaces as *yr* [ər]. In the same context, though, masculine singular *gosteg* 'silence' does not mutate, as shown, and the article appears as *y* [ə], since it precedes a consonant. Since the shape of the noun depends on the presence of the definite article, and since the shape of the definite article depends on the initial segment of the following noun, the interaction provides evidence relative to lexical insertion and distinctions between function words and content words.

7 Conclusion

Celtic initial consonant mutation has its origin in phonetics as a series of phonetically triggered external sandhi phenomena. The overwhelming bulk of initial consonant mutation in the modern languages, however, is not transparently phonological. Rather, initial consonant mutation in the living Celtic languages – Irish, Scottish Gaelic, Breton, and Welsh – is a complex set of lexically, syntactically, morphologically, and/or structurally triggered alternations reflected in the phonology. Moreover, the alternations themselves are not phonologically unitary. As such, a full account of initial consonant mutation necessarily involves reference to a number of different levels of linguistic description and analysis.

Nonetheless, there are several phonologically relevant questions (as outlined above in §3), some of which have been addressed in various ways in the literature. For example, among the accounts considered above, questions (ii) (How can the alternations be characterized phonologically?) and (v) (How are the alternations represented phonologically?) have been addressed by a number of linguists, including Hamp (1951), Rogers (1972), Ewen (1982), Lieber (1987), Ni Chiosáin (1991), Grijzenhout (1995), Pyatt (1997), Stewart (2004), and Green (2006, 2007). Fewer have addressed the third question (Where do the alternations occur, i.e. (how) can the alternation site be defined in phonological terms?), among them Hannahs (1996) and Neeleman (2005). Question (i) (What phonological alternations are involved in the mutations?) is superficially addressed by all – in that some mention must be made of the segmental alternations involved in mutation – but few have looked at this explicitly in detail, Ní Chiosáin (1991) being the exception. Question (iv) (What triggers the alternations?) has received various answers; Hamp (1951) and Oftedal (1956), for example, attribute the trigger to a morphophoneme, while Rogers (1972) and Ni Chiosáin (1991) cite phonological rules.

Clearly, there is still work to be done to develop a comprehensive account of initial consonant mutation in Celtic. Just as clearly, the account will need to consider the grammar as a whole – syntax, morphology, and phonology – in order to provide the full picture of this intriguing but complex phenomenon.

118 Turkish Vowel Harmony

Barış Kabak

1 Introduction

Turkish vowel harmony is a cover term for a set of well-formedness conditions that dictate which vowels can co-occur within what we will simply call a non-compounded word, irrespective of its morphosyntactic complexity. This chapter aims to bring forth various issues surrounding the mechanism that realizes these vowel co-occurrence conditions in Turkish, and discuss the ways in which they contribute to the understanding of the nature and dynamics of phonological representations and processes. We will explore Turkish vowel harmony in terms of three sets of issues, each of which has proved highly instructive for theory building and testing, and provoked decade-long debates in the field of phonology. These are: (i) what is it that vowel harmony targets and what are the surface effects that it achieves?, (ii) how does it propagate in roots and suffixes?, and (iii) how can vowel harmony be obstructed, and what are the consequences of this for the nature of phonological representations? We will touch upon relevant theories and proposals in the literature in so far as they shed light on the interpretation of empirical facts, and also introduce new data and insights where necessary.

2 The substance of Turkish vowel harmony

Vowel harmony could be defined in at least two different ways, with fundamentally different assumptions. First, along the lines of the structuralist tradition (e.g. Bloomfield 1933), one can approach it through the surface effects it achieves, forming a set of observations about a pattern where an individual vowel may only co-occur with certain vowels, hence, by inference, the co-occurrence of the same vowel with certain others is assumed to yield ill-formed structures. In this sense, vowel harmony is only a set of vowel co-occurrence (phonotactic) constraints, the motivation of which may not be obvious. Vowel harmony could also be described as an operation whose purpose is to achieve some form of "identity" among certain types of vowels that co-occur within a word. In this sense, vowel harmony is viewed as a process that has the power to actively manipulate structures with the aim of neutralizing vowels on its way that meet its criteria. The crucial ingredients of this approach to vowel harmony are then a trigger, a target, and a context. Below, we will use both approaches to describe the two different types of vowel harmony patterns observed in Modern Turkish.

2.1 Front–back harmony

With perfectly symmetrical front–back, high–low, and round–unround oppositions, Turkish has eight phonemic vowels. (1) displays the vowel phonemes of Turkish and their phonological characterization based on features that are largely agreed upon.[1]

(1) *Turkish vowel phonemes*

	front		back	
	unround	round	unround	round
high	i	y	ɯ	u
low	e	ø	ɑ	o

Within a non-compound word, including both the root and following suffixes, vowels from the set /ɑ ɯ o u/ (i.e. "back" vowels) cannot combine with those from the set /e i ø y/ (i.e. "front" vowels).[2] As such, forms like */dɑniz/ and */demuɪz/ are ruled out, but /deniz/ 'sea' and /dɑmɯz/ 'animal shed' are predicted to be well-formed. As early as Trubetzkoy (1939), and later on in the works of Jakobson (1941) and Jakobson *et al.* (1952), such surface co-occurrence patterns in Turkish vowels played a significant role in motivating "phonological contrasts" or "oppositions" as valid notions for phonological operations instead of individual phonemes themselves (See CHAPTER 17: DISTINCTIVE FEATURES). The set of vowels is not a random set of individual phonemes; rather, it forms a phonetically motivated set of oppositions: front vowels as opposed to back ones, not, say, /e/ as opposed to /ɑ/. Each distinct vowel is then viewed as a bundle of features, which is composed of features characterizing the frontness, height, and roundness of the vowel in question (/e/: "front," "low," "unround"); /ɑ/: "back," "low," "unround"). That /ɑ/ co-occurs with /o/, as well as /ɯ/ and /u/ on the surface, is not random, then, but principled: it falls out straightforwardly from the nature of the feature that the vowels in question share, namely back.

In Turkish, all eight vowels can occupy the initial syllable of a root, while the quality of the vowels in non-initial syllables is constrained by the initial vowel. Accordingly, front–back harmony (also known as palatal harmony) is viewed as a process whereby the frontness/backness (henceforth frontness) of a non-initial root vowel or any subsequent suffix vowel (with some exceptions) is obligatorily determined by the preceding vowel. If that vowel is back, the following vowel,

[1] Instead of adhering to the conventions of Turkish orthography, we will use IPA symbols throughout the chapter, ignoring allophonic variation (e.g. palatalization in the context of front vowels). The letter known as "soft g" (ğ) is represented as a velar glide (/ɰ/), which may be realized in careful speech but is generally deleted in casual speech in standard Istanbul Turkish, the variety of the author and most of the data discussed in this chapter. See Kabak (2007: 1381) and the references therein for details on the phonological behavior of this phoneme.

[2] This does not entail that vowels from a single set can freely combine with one another, due to the effects of rounding harmony discussed below.

and consequently all subsequent vowels within a word, must be back. Likewise, if an initial vowel is front, then all the subsequent vowels are front. This is demonstrated in (2) by polysyllabic morphologically simplex roots which meet the description of vowel harmony – what is often referred to as "internal/root harmony" – and by two regular Turkish suffixes in (3) – "external/suffiix harmony." The suffixes in question are the plural and the genitive, whose height features are invariable (i.e. they contain a non-high and a high vowel, respectively), and they are attached to the roots /dɑl/ 'branch' and /jer/ 'place', containing an invariable back and a front vowel, respectively. Compounded words do not constitute a single vowel harmony domain, as indicated by the failure of the second member of the compound to undergo harmony with the first, or vice versa in (3c, 3d).

(2) *Front-back harmony in roots* (morphologically simplex words)

a.	jɑnlɯʃ	'wrong'	*jɑnliʃ, *jenlɯʃ
b.	josun	'moss'	*josyn, *jøsun
c.	zengin	'rich'	*zengɯn, *zɑngin
d.	kømyr	'coal'	*komyr, *kømur

(3) *Front-back harmony in morphologically complex non-compounded words*

a.	dɑl-lɑr-ɯn	'of branches'	*dɑl-ler-in, *dɑl-ler-ɯn,*dɑl-lɑr-in, *dɑl-ler-ɯn
b.	jer-ler-in	'of places'	*jer-lɑr-ɯn, *jer-lɑr-in, *jer-ler-ɯn, *jer-lɑr-in
c.	ɑk#deniz	'the Mediterranean'	*ɑkdɑnɯz, *ekdeniz
d.	ɯzgɑrɑ#køfte	'grilled meatball'	*ɯzgɑrɑkoftɑ, *izgereкøfte

2.2 *Rounding harmony*

Apart from front–back harmony, the rounding of non-initial vowels within a word must also agree with that of the preceding vowel. However, this condition only holds for high vowels (irrespective of the height of the preceding vowel), low vowels remaining invariably unrounded unless they are underlyingly round. Rounding harmony is illustrated in (4) with roots (see also examples (2b, 2d) above), and in (5) with the genitive suffix that contains a high vowel attached to roots with a round vowel.

(4) *Rounding harmony in roots* (morphologically simplex words)

a.	torun	'grandchild'	*torɯn, *tɑrun
b.	kuru	'dry'	*kurɯ, *kɯru
c.	køty	'bad'	*køti, *kety
d.	dyɰyn	'wedding'	*dyɰin, *diɰyn

(5) *Rounding harmony in morphologically complex words*

a.	jol-un	'of a/the road'	*jol-ɯn
b.	søz-yn	'of a/the word'	*søz-in
c.	buz-un	'of a/the ice'	*buz-ɯn
d.	jyz-yn	'of a/the face'	*jyz-in

It is not the case that the genitive suffix in (5) must surface with a round vowel. The same suffix appears with a non-round high vowel following a non-round root vowel (6a), or a non-round suffix vowel (6b).

(6) a. jɑʃ-ɯn 'of an/the age' *jɑʃ-un
age-GEN
b. jol-lɑr-ɯn 'of (the) roads' *jol-lɑr-un, *jol-lor-un, *jol-lor-ɯn
road-PL-GEN

Despite the fact that it appears after a rounded vowel, the plural morpheme in (6b) obligatorily surfaces as a non-rounded vowel (i.e. */lor/), since it is low, demonstrating that only a non-initial high vowel, be it a root or a suffix vowel, can undergo rounding harmony.[3] Furthermore, we see that the roundness of the first vowel does not determine the roundness quality of the vowel of the genitive suffix, although it is high. Instead, whether the vowel in question will be round or unround is determined by the preceding vowel, a point we will come back to below.

For completeness, it should be noted that roundness and frontness do not always come from the same segment. This is observed in cases where certain root-final consonants, most notably the palatal lateral, are assumed to determine the frontness of the suffix vowel while the rounding property comes from the preceding vowel (e.g. /petroʎ-dy/ (petrol-PAST) 'it was petrol'), which we will discuss in more detail in §4.

In summary, both harmony processes impose a number of restrictions on the phonological shape of Turkish words, and hence entail a number of *expected* patterns and gaps:[4]

(7) a. All vowels must agree in terms of frontness or backness.
b. High vowels must also agree in roundness with the immediately preceding vowel, hence no high rounded vowels can be found after non-round vowels within a word.
c. No low round vowels (i.e. [o] and [ø]) may be present in a non-initial syllable of a word.[5]

3 The mechanism of Turkish vowel harmony

3.1 *Earlier treatments*

So far, we have demonstrated that vowel harmony in Turkish is an agreement operation within an extended domain, such as a morphologically complex word. What is not obvious, however, is the way in which a particular harmony feature

[3] See Charette and Göksel (1996, 1998) for an analysis that accounts for the blocking of rounding harmony on low vowels by the use of licensing constraints that are also argued to derive the vowel inventory of Turkish.

[4] Note that there are several words in the Turkish lexicon, mostly borrowings, that violate these patterns. These are known as disharmonic words, which will be discussed in §4. Despite the presence of disharmonic words, Kabak *et al.* (2010) show a facilitatory effect of vowel disharmony in Turkish (but not in French) in signaling word boundaries, suggesting that Turkish listeners can exploit vowel harmony regularities in speech segmentation.

[5] Low round vowels are allowed to surface in non-initial syllables if they are underlyingly present, as in some loanwords, e.g. [kɑmjon] 'truck', [fritøz] 'deep fryer', or in native roots due to the presence of a labial consonant preceding the vowel, a phenomenon known as the Labial Attraction Rule (e.g. /ʧɑbuk/ 'quick'; see §4 for details).

(i) the rounding value, just like the frontness of non-initial vowels, is predicted to originate from some source on the left, and (ii) rounding can be realized only on high vowels in this position. This, in and of itself, speaks for the highly special character of this suffix compared to other exceptional suffixes, and furthermore suggests that it comes from a once-independent lexical item, which Turkish vowel harmony has not been pervasive enough to domesticate (see Kabak and Revithiadou 2009 and the references therein for the emergence of similar suffix complexes). Due to its invariability, the second vowel of this suffix is arguably fully specified for its phonological content, blocking any phonological operations from manipulating it. Nevertheless, the variable portion of the suffix, namely the initial high vowel, does not get its harmonic properties from its right neighbor, but from what precedes. The apparent mono-directionality here could also be explained by notions such as "root control," which refers to a widely attested principle that root vowels have an effect on suffix vowels, rather than the other way around. Notice that while the root-control analysis also straightforwardly accounts for the so-called "epenthetically driven vowel harmony," a *regressive* harmony process observed in roots where the quality of epenthetic vowels is determined by the following vowel, the mono-directionality analysis encounters problems with these cases. However, as we will see in §5 below, this sort of harmony runs on different principles than regular vowel harmony. As such, there are reasons to keep the two processes distinct, and hence continue to regard Turkish vowel harmony proper as a strictly progressive assimilation process.

These observations have provoked skepticism about the very nature of vowel harmony and raised questions as to whether it operates by means of a fundamentally different principle than other assimilatory processes such as umlaut (see Anderson 1980 for a thorough discussion). Indeed, a famous "assimilation" treatment to vowel harmony was proposed in Lees (1961), where the first vowel of a root, being fully specified for frontness and roundness, acts as a trigger by the use of linear rules of the type made prominent in Chomsky and Halle (1968; henceforth *SPE*). These rules ensure that those vowels unspecified for the same features are filled in iteratively. Similar iterative rules, though only reserved for suffix harmony, have been put forth in the works of Kardestuncer (1982, 1983). A simplified version of a linear vowel harmony rule, taken from van der Hulst and van de Weijer (1991), is illustrated in (9).

(9) SPE-*type linear rules of vowel harmony*

a. *Front–back harmony*
$V \rightarrow [+\text{back}] \ / \ [V_{+\text{back}}]\ C_0 \_\_$

b. *Rounding harmony*
$[V_{+\text{high}}] \rightarrow [+\text{round}] \ / \ [V_{+\text{round}}]\ C_0 \_\_$

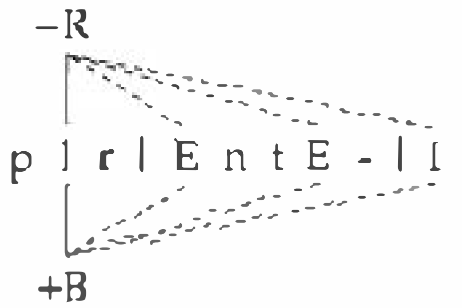
This sort of treatment handles all cases of harmony in Turkish, including the problematic ones for the root marker approach in a straightforward way. As for disharmonic roots, all that has to be stipulated is that the vowels that do not undergo harmony are marked with a diacritic, such as [–Vowel Harmony], which blocks the effect of the preceding root vowels.

SPE-type rule notations have been rejected on empirical and conceptual grounds, which significantly weakened the liability of linear rules for explaining phonological phenomena in the field. In the case of Turkish vowel harmony, however, the major objection to the type of linear rule-based treatments came from observations that it does not achieve unity with other harmonic systems across the languages of the world, where vowel harmony is bidirectional and extend to both prefiixes and suffiixes (Crothers and Shibatani 1980). This problem is trivial in the case of Turkish, where one can assume that the directionality is determined on a language-specific basis.

The core of the problem that Crothers and Shibatani (1980) raised against linear rules had rather to do with the nature of harmony regularities and irregularities in roots, and their incompatibility with rules like (9) above that crucially depict assimilation. Essentially, there is no observable assimilation in root vowels, which suggests that front–back harmony in (2) and rounding harmony in (4) above constitute at best "static" regularities, hence assimilation-type rules cannot account for them. We will discuss harmony in roots in §4 below.

Furthermore, what linear rules failed to capture was in fact more than the issue of directionality. It was rather the autonomy of specific vocalic features (backness, roundness) from other vocalic features, and most importantly from consonantal features. Turkish vowel harmony was important for another theory brewing at the time, Autosegmental Phonology, influenced largely by the Firthian school of Prosodic Analysis, but more elaborate about the way and the reason vowel features can or cannot propagate within a word (see CHAPTER 14: AUTOSEGMENTS). In this approach, which is thoroughly extended to Turkish vowel harmony in the seminal work of Clements and Sezer (1982), distinctive features are believed to be present on independent tiers specifying, among others, the frontness, height, and rounding properties of segments. Harmonizing root and suffix vowels are left unspecified. This can be observed in (10), where –R and +B stand for non-round and back features respectively that are prespecified on the initial vowel of the root.

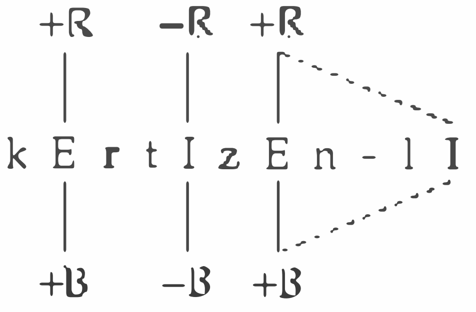
(10) *Autosegmental representation of front–back and rounding harmony*
(from Kabak and Vogel 2010)



[pɯrlanta-lɯ] 'with brilliants'

The subsequent root and suffix vowels are not specified for these two features, as indicated by archiphonemic representations such as E and I. As such, vowel harmony is described as the association of these feature specifications to different vowels lacking the same specifications within an extended domain. Whenever harmony is blocked, be it in roots or suffixes, autosegmental analyses resort to prespecification to indicate the invariable harmonic feature. Since association lines are not allowed to cross, only the rightmost prespecified feature in disharmonic roots prevails, thereby opening up its own harmony domain for the suffixes that follow (11).

(11) *Lexical prespecification of disharmonic root vowels*
(from Kabak and Vogel 2010)



[kortizon-lu] 'with cortisone'

While straightforwardly capturing the autonomy of vowel features, and hence making phonological operations less abstract, autosegmental approaches also have to make a number of assumptions about the precise shape of phonological representations, without which the theory would fail to explain the spreading of harmony features, their blocking, and the inactivity of vowel harmony operations in the face of static harmony regularities in roots, which we turn to below.

4 Vowel harmony and the shape of phonological representations

4.1 *Separating root (dis)harmony from suffix harmony*

Despite the overwhelming number of harmonic roots in Turkish,[7] no vowel *alternation* can be observed in them. In other words, front–back harmony in (2) and rounding harmony in (4) above are nothing more than static surface regularities, hence assimilation-type rules such as the ones given in (9), as well as autosegmental spreading-type analyses we have seen above, cannot properly account for them. However, the constraints on vowel co-occurrences in nearly all roots of native origin are almost the same as those in suffixes in Turkish. As such, we are dealing with one single phenomenon, realized, however, in two different ways: (i) harmony as a co-occurrence restriction, and (ii) harmony as an active phonological process. To remedy this problem, Kiparsky (1973), in his "two-pronged" analysis of vowel harmony, suggested that vowel harmony on the surface must be handled by two different mechanisms, one reserved for purely static harmony patterns in roots/stems, and the other for suffix harmony that is purely assimilatory in nature. While the earlier is handled by Morpheme Structure Constraints (henceforth MSCs; see also CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS), the other is the job of phonological rules.

Three such MSCs are proposed by Zimmer (1969b) for Turkish roots, two of which are essentially the same as the front–back and rounding harmony for suffixes (the *palatality* MSC and the *labiality* MSC, respectively). The third MSC, the *labial consonant* MSC (also known as the Labial Attraction Rule; Lees 1966), is specifically reserved for *disharmonic* occurrences of round vowels after non-round vowels in roots: a high vowel following an /ɑ/ with an intervening labial consonant, /p b f v m/, will be round (e.g. /ɑvutʃ/ 'palm of hand', /tʃɑbuk/ 'quick').

[7] Kabak *et al.* (2008), based on the first two vowel occurences of a carefully selected 8944 set of polysyllabic roots (morphologically simplex) from the TELL database, reports that 29 percent of all such roots are disharmonic with respect to front–back harmony.

Notice that this condition does not apply across morpheme boundaries: /av-ɯ/ (hunt-ACC), not */av-u/, suggesting that MSCs are not always the replication of active phonological rules.[8]

The separation of root harmony from suffix harmony in Turkish fits well with the Derived Environment Condition, developed most notably in Kiparsky (1973) (see CHAPTER 88: DERIVED ENVIRONMENT EFFECTS). This condition essentially blocks neutralization processes, vowel harmony being one of them, to take place in non-derived (morphologically simplex) environments, and reserves such rules to only apply in derived environments.[9] The details of such an analysis do not concern us here. Two empirical and theoretical issues that fall out from such a differential treatment of root and suffix harmony, however, must be highlighted, since they yield serious consequences for the nature of lexical representations and the way phonological processes operate.

First, it entails that vowel harmony must be "inactive" in roots, and hence automatically raises questions with respect to the lexical representation of Turkish roots. Are root vowels fully specified despite harmony? How can our representational device insightfully separate disharmonic roots from harmonic ones? What are the psycholinguistic implications of this separation for the language learner and user?

Second, it fails to capture the formal similarity and functional redundancy between pervasive harmony patterns (handled by MSCs) and phonological rules, which is known to be the "Duplication Problem" in the literature, most notably addressed by Kenstowicz and Kisseberth (1977). As McCarthy puts it, "if MSCs and rules really are distinct components of linguistic theory, then they should be clearly differentiated in form and function, but they are not" (1998: 123). The question here is how can we combine seemingly two, but essentially the same, phenomena in a single grammar? We will unpack these issues in the context of root harmony and disharmony below, which have also received a great amount of attention in recent history of phonological theorizing, most notably in Optimality Theory, where the duplication problem is rendered irrelevant (see below).

4.2 *The limits of harmony and disharmony in roots*

From a scientific point of view, investigating harmony is not just to account for what is possible as a harmonic sequence, but also for what is possible as a disharmonic sequence. Any theory should hence be able to explain both harmonic and disharmonic patterns, ideally using the very same apparatus.[10] This has been the prevalent force behind much work done in the last two decades. Various restrictions on disharmony are stated in a seminal paper by Clements and Sezer (1982). Their observation is that the vowels from the set /i e ɑ o u/ may combine freely in roots, leading to the violation of both types of harmony. This is illustrated in (12), where all examples violate front–back harmony, and additionally rounding harmony in (12b) and (12c), where the non-initial vowel is expected to be round

[8] There are several exceptions to the Labial Attraction Rule in Turkish and the rule does not act as magnet for analogy (see Inkelas *et al.* 1997 for details).

[9] It should be noted that, rather than a structure-changing process, if vowel harmony is viewed as a feature-filling process, it cannot be blocked in underived environments.

[10] The source of disharmony in roots is primarily and predominantly loanwords, which are well integrated into Turkish, and perhaps except for a few recently borrowed items, an average Turkish speaker may not even know that they are foreign.

since it is high, and in (12d), where the non-initial vowel is round despite the fact that it is non-high (i.e. there is no harmony-related reason why rounding should appear on the second vowel).

(12) *Root disharmony: /*i e ɑ o u*/ are freely combined*

			Type of violation
a.	gɑrip	'strange'	Front–back harmony
b.	polis	'police'	Front–back and rounding harmony
c.	butik	'boutique'	Front–back and rounding harmony
d.	pilot	'pilot'	Front–back and rounding harmony

On the contrary, vowels from the set /y ø ɨ/ are shown not to occur in disharmonic roots, even though this observation is not without exceptions (e.g. /byro/ 'office'). Goldsmith (1990: 304–309) argues that /i e ɑ o u/ is in fact not a random set of vowels, but coincides with the cross-linguistically favored five-vowel system. In such a system, the specification for the frontness and backness (i.e. [back] according to Goldsmith) is redundant since it is fully predictable from rounding. As such, [back] is underspecified in roots that combine these five vowels, consequently leading to no violation of front–back harmony. The specification of [back] is required, however, when the root contains any of the other three vowels, /y ø ɨ/, since they involve marked combinations of frontness and rounding. This argument finds further support from Clements and Sezer's (1982) documentation of harmony regularizations on disharmonic loanwords, where the same set of vowels tends to be changed to fit at least into the five-vowel system, as can be seen in (13) below. Note that this process does not necessarily turn disharmonic roots into harmonic ones (e.g. (13e)).

(13) *Regularization of /*y ø ɨ*/ in disharmonic roots*

a.	mersørize	~	merserize	'mercerized'	
b.	kupyr	~	kypyr	'clipping'	(also kipyr)
c.	biskyvit	~	byskyvyt	'biscuit'	(also bisky:t/bysky:t)
d.	pyro	~	puro	'cigar'	
e.	komynist	~	kominist	'communist'	(also komunist)
f.	motør	~	motor	'motor'	
g.	ʃøvɑlje	~	ʃovɑlje	'knight'	

Yet another observation from Clements and Sezer (1982) is that while /ɯ/ does not occur in roots which are disharmonic with respect to rounding, the other two marked vowels, /ø/ and /y/ do, as can be seen in (14). However, it should be noted that disharmonic sequences containing /ø/ and /y/ also undergo regularization of the type shown above, as indicated in (14), suggesting that rounding harmony may be equally effective on /ø/ and /y/.

(14) */ø/ and /y/ in disharmonic roots*

a.	virys	~	vyrys	'virus'
b.	myhim	~	myhym	'important'
c.	døviz	~	døvyz	'foreign currency'
d.	minør	~	mynør	'minor'

A number of accounts have been proposed to handle such patterns, mostly on the basis of Clements and Sezer's (1982) observations in different frameworks (e.g. van der Hulst and van de Weijer 1991, and for optimality-theoretic treatments, see Kirchner 1993, Polgárdi 1999, and Kiparsky and Pajusalu 2003). Although the details of these accounts are not of concern here, what should be pointed out is that accounts couched within the framework of Optimality Theory are uniformly capable of accounting for both root and suffix harmony, whereby the duplication problem discussed above becomes a moot point. More specifically, the fact that harmony is optimal regardless of the marked or unmarked status of the vowels in a sequence and that disharmony is tolerable if it comes from unmarked vowels (*à la* Clements and Sezer 1982) are handled within the same grammar by using a combination of (i) featural markedness constraints, essentially banning marked segments from surfacing (e.g. *ɯ, *y, *ø), (ii) a constraint that achieves harmony (e.g. AGREE(F), HARMONY), and (iii) some faithfulness constraint that ensures that the fully specified vowels are realized the way they underlyingly are (e.g. IDENTROOT(F)).

These proposals, however, must be given a serious reconsideration in light of data that have not been considered so far. Here I present a set of data that will amount to the observation that any vowel combination may become legitimate in Turkish as long as the donor language permits them and may remain stable despite overwhelming vowel harmony regularity in the language. Let us start with the sequence /y–ɑ/ (or vice versa), which is not expected to be tolerated. Closer inspection, however, reveals that they are surprisingly common in Modern Turkish. In fact, they constitute the seventh most common *disharmonic* sequence in a recent corpus study (Kabak *et al.* 2008). Some words of this sort are illustrated in (15). Notice that they are highly stable disharmonic patterns, exhibiting no regularization or variation of the sort illustrated in (13) and (14).

(15) /y–ɑ/ *combinations in some common disharmonic roots*

a.	kyrtɑj	'abortion'
b.	syrɑt	'speed'
c.	mɑːmyl	'product'
d.	kɑktys	'cactus'
e.	ɑky	'battery'

As for /ɯ/, it should be remembered that the claim has been that, first of all, it does not occur in front–back disharmonic roots since it is from the marked vowel set, and is the only one from that set that cannot escape rounding harmony. If we consider that disharmonic words come primarily from other languages into Turkish, the chances of finding /ɯ/ in such combinations should be remarkably low, since many languages from which Turkish imported its foreign lexical stock do not contain such a vowel. Furthermore, there is no reason to assume that /ɯ/ is the most marked vowel of all, as is assumed via high-ranked constraints such as *ɯ in a number of optimality-theoretic analyses of harmony (e.g. Kirchner 1993; Kiparsky and Pajusalu 2003), since the same vowel emerges to repair syllable structure violations, disproving its alleged "marked" status in the language. Aside from these external and internal factors, what is perhaps more important to note is that

(17) */ɯ/ substitution going against lexical diffusion and regularization*

a. kɯrlent 'pillow' from *ghirlanda* (Italian)
b. kɯdem 'rank' from *kidem* (Arabic)
c. kɯble 'mecca' from *kible* (Arabic)

Furthermore, the English schwa in borrowings is almost always mapped onto /ɯ/, as evinced by the fact that the subsequent suffix is realized as back. This can give rise to perfectly acceptable front vowels co-occurring with, presumably a non-epenthetic /ɯ/, as illustrated in (18). Since these are recent borrowings, time will show whether they will prevail as disharmonic.

(18) *English schwa is mapped onto Turkish /ɯ/, yielding disharmony*

a. [pirintɯr-a] 'to the printer'
printer-DAT
b. [bilendɯr-dan] 'from the blender' (also as [bilendir], but rarely)
blander-ABL
c. [kɯlintɯn-lar] 'the Clintons'
Clinton-PL
d. [tikɯt-lar] 'tickets' (especially in the context of 'ticket restaurants')
ticket-PL

The same generalization can be made in the context of /ø/. It is arguably not a common vowel in languages which Turkish has borrowed from, except for some French borrowings, where we see their frequent occurrence in disharmonic sequences (19).

(19) */ø/ in disharmonic words of French origin*

a. røtar 'delay' (sometimes also as rotar)
b. dansøz 'belly dancer'
c. firitøz 'deep frier'
d. ordøvr 'hors d'œuvre' (sometimes also as ordevr, ordev)
e. rømork 'trailer' (sometimes also as romørk)

Notice that /ɯ/ in combination with /ø/ and /y/ (as opposed to /i/, /e/, or /o/) is not attested. However, the fact that there are such lexical gaps should not be readily taken to mean that there are constraints, dormant or active, that militate against such sequences. A more plausible explanation lies in the unlikelihood of donor languages that have /ɯ/, /ø/, and /y/ or contain words where these vowels co-occur.

The above data cast doubts on models that try to account for disharmony by compartmentalizing vowels into different sets based on notions such as markedness. Furthermore, they suggest that we may need to change our approach toward disharmony: any combination of vowels seems to be legitimate as long as the donor languages permit them, whose likely adaptation may additionally but not necessarily be determined by how often the item is used and the acoustic/phonetic properties of the vowel in question. Variation is perhaps the most challenging phenomenon to account for in regularization, which makes it apparent which emerges when no lexically specified feature is able to fill in an unspecified feature.[12] More research is necessary here.

4.4 *Is vowel harmony active in roots?*

This is perhaps one of the most controversial issues in Turkish vowel harmony, the answer to which has had serious consequences for the shape of phonological representations in the lexicon, and consequently the whole mechanism for handling harmony.[13] Notice that the same question is equally valid in the context of disharmonic roots since their shape has also been shown to be determined, at least partially, by the dictates of vowel harmony. As stated before, no alternation could be detected in root vowels; hence, there may be no reason to assume harmony operations there. This is perhaps the most important reason to resort to full specification of vowel features in roots. Indeed, the full specification of root vowels is essentially the approach taken in some treatments couched within Optimality Theory, where given two competing input forms, one fully specified (i.e. prespecified as containing a particular harmony property), and one fully or partially underspecified, Lexicon Optimization (Prince and Smolensky 1993) will ensure that the fully specified alternative will be preferred (see Inkelas 1995 and Kabak and Vogel 2010 for discussion; also CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION). On the other hand, resorting to underspecification for harmonic roots,[14] and hence assuming that harmony is still in operation there, typically stem from the following reasons.

The first has to do with issues such as economy and simplicity in representations, and keeping redundancies to a minimum. Vowel harmony is then regarded as an economical device since it gives harmonic vowels a "free ride" in roots (e.g. van der Hulst and van de Weijer 1991). Second, vowel harmony can be argued to be active in roots since it seems to impose certain restrictions on the type of disharmonic vowel combinations, as shown in (13). Notice, however, that regularizations do not always achieve optimal harmonic sequences. Rather, they seem to be dictated by the five-vowel set, which are the five most frequent vowels of Turkish. The fact that there are many disharmonic roots that are well integrated into the Turkish lexicon, as indicated for instance by their resistance to harmonization due to their high frequency of occurrence, further suggests that regularization is not necessarily a strong indicator of harmony governing the underlying shape of Turkish roots.

12 Here it could be assumed that the relevant feature is blocked from spreading via truncation, as in tonal phenomena. That is, while the relevant harmonic feature is pronounced on the vowel that it is associated with, it is not allowed to spread onto the following vowels. When the backness feature is blocked from further spreading, the underspecified suffix vowels surface as front (Coronal), which is argued to be the default place feature for Turkish vowels (see Kabak 2007 and Kabak and Vogel 2010 for details).

13 Some of the treatments of Turkish vowel harmony with some form of full specification can be found in the work of, for example, Kiparsky (1973), Clements and Sezer (1982), Kirchner (1993), Inkelas (1995), Inkelas *et al.* (1997), and Polgárdi (1999). Analyses that assume underspecification of harmonic root vowels are presented in van der Hulst and van de Weijer (1991), Lahiri (2000), Harrison and Kaun (2001), Kabak (2007), and Kabak and Vogel (2010).

14 See Kabak (2007) and Kabak and Vogel (2010) for Maximal Underspecification, which assumes the presence of underspecified vowels also in disharmonic roots.

following vowel. The roundness triggering vowel is typically a high one (23a)–(23c), as suggested by the unacceptability of rounded epenthetic vowels before low round vowels in (23d)–(23e). There are cases, however, where a low vowel also triggers rounding albeit with perhaps additional impact from the rounding of the first consonant (23f)–(23g).

(23) *Epenthesis-driven regressive rounding harmony*

a.	gurup	'group'	
b.	kulyp	'club'	
c.	fylyt	'flute'	
d.	sɯpor	'sport'	*supor
e.	sɯmokin	'smoking'	*sumokin
f.	fylørt	'flirt'	(also as filørt)
g.	buroʃyr	'brochure'	(also as bɯroʃyr)

On the basis of about 100 loanwords containing word-initial consonant clusters, Kaun (1999) reports that Turkish speakers consistently provide rounded epenthetic vowels when the trigger is high round. When it is non-high, however, Kaun finds a lot of individual variation, but there is a stronger tendency toward regressive rounding harmony when the low trigger vowel is front than when it is back (see also Yavaş 1980c). Kaun (1999, 2004) takes these observations to indicate that, although epenthesis-driven vowel harmony does not much resemble native vowel harmony processes, it follows cross-linguistic patterns of rounding harmony. More specifically, cross-height rounding harmony is avoided in harmony systems that employ some form of rounding agreement among vowels. This may be taken as an explanation for why rounding harmony with epenthetic vowels, which are always high, is more prevalent when the trigger is also high. Furthermore, typological inspection suggests that rounding harmony systems typically prefer front rounded triggers, explaining why front low vowels tend to trigger the rounding of the epenthetic vowels more than back low vowels. The reader is referred to Kaun (2004) for various phonetic and perceptual explanations for such typological tendencies in rounding harmony.

Can we derive the properties of epenthesis-driven vowel harmony from the general properties of native vowel harmony processes? As demonstrated in (16) above, the regressive harmony process is highly sensitive to the quality of the consonants in the consonant cluster: after a velar consonant such as /k/ and /g/, the epenthetic vowel is back even in the context of a following front vowel (e.g. [kɯrem] 'cream', [kɯristal] 'crystal', [kulyp] 'club', [gɯri] 'gray', [gɯlikoz] 'glucose', etc.), yielding disharmony. This is unlike native vowel harmony, whereby consonants, except often for root-final underlying palatals (see (20) above; cf. (21)), are impartial to vowel harmony. Furthermore, the involvement of the height and frontness properties of the *trigger* vowel in epenthetically driven rounding harmony crucially deviates from the native rounding harmony process, where the tongue height specification of the *target*, not the trigger, is crucially imposed. When coupled with a great deal of individual variation, which we do not observe in native harmony patterns (at least within the same dialect), all of the above properties suggest that regressive harmony as realized on word-initial epenthetic vowels is not yet as fully phonologized as the progressive front–back and rounding harmony in Turkish.

It is insightful to compare the behavior of epenthetic vowels in word-initial consonant clusters to those occurring in word-final consonant clusters. Word-final consonant clusters are assumed to be present in the underlying representation of some native Turkish words as well as (primarily Arabic) borrowings (Yavaş 1980b). Yet again, an epenthetic vowel is inserted to prevent these clusters from surfacing in the coda position, as can be seen in the nominative singular (where no overt marker follows) and the locative forms in (24). Unlike in the case of word-initial epenthetic vowels, but just like with the suffix vowels underspecified for harmonic features, the regular front–back harmony and rounding harmony are *fully* imposed on word-final epenthetic vowels (24a)–(24c). Notice that there are commonly used borrowings where the epenthetic vowel that occurs within word-final consonant clusters is disharmonic (24d)–(24e).

(24) *Epenthetic vowels in root-final consonant clusters*

	UR	*nom sg*	*2nd pers poss*	*loc*	
a.	/bojn/	bojɯn	bojn-un	bojun-da	'neck'
		(*bojun)	(*bojun-un)	(*bojn-da)	
b.	/aln/	alɯn	aln-ɯn	alɯn-da	'forehead'
		(*alin)	(*alɯn-ɯn)	(*aln-da)	
c.	/gøɰs/	gøɰys	gøɰs-yn	gøɰys-te	'breast'
		(*gøɰis)	(*gøɰys-yn)	(*gøɰs-te)	
d.	/vakt/	vakit	vakt-in	vakit-te	'time'
		(*vakɯt)	(*vakit-in)	(*vakt-te)	
e.	/kavm/	kavim	kavm-in	kavim-de	'tribe'
		(*kavɯm)	(*kavim-in)	(*kavm-de)	

The emergence of the disharmonic epenthetic vowels in (24d)–(24e) can be taken to illustrate yet another instance of harmony blocking in Turkish. This is especially evident when the following suffixes surface as front (i.e. /vakt-in/, /kavm-in/, etc.) although the root vowel is back. Since the consonants at the right edge of these words are not palatals, it is not clear where the frontness feature comes from, providing additional data for the observation that the unexpected front variants of suffixes is not necessarily due to palatals (cf. (20) and (21) above). Instead, the disharmonic epenthetic vowel surfacing in (24d)–(24e), /vakit/ and /kavim/, can be considered as the result of the blocking of the harmonic features on the root vowel to further spread (see footnote 12 for a potential analysis), causing the epenthetic vowel (and the subsequent suffix vowels) to bear the default feature, which is arguably [Coronal] (i.e. front) in Turkish. Indeed, the fact that there are no roots where the final epenthetic vowel is back *and* disharmonic to the root vowel (e.g. */kevm/ → *[kevɯm]) provides a compelling argument in favor of this view.

In summary, there are several reasons to believe that word-final epenthetic vowels behave just like any other high vowel within roots or affixes, under the dictates of vowel harmony. The asymmetric behavior of word-initial and word-final epenthetic vowels, which are presumably identical elements, under front–back and rounding harmony suggests that what we call "harmony" in the case of word-initial epenthetic vowels runs on different principles, which nevertheless share some common properties with our classic progressive harmony, possibly due to universal tendencies and phonetic/perceptual factors.

119 Reduplication in Sanskrit

ROBERT KENNEDY

Sanskrit, a classical and liturgical language of India, has been central to the advancement of linguistic analysis in a number of respects. It is notable for the support it provides for the "Indo-European hypothesis," the theory advanced by scholars such as Sir William Jones, Thomas Young, and Franz Bopp that the Indic languages are descended, along with those of the Romance, Germanic, Celtic, Slavic, and myriad others, from a common ancestral proto-language. Sanskrit has also been crucial to the development of autosegmental phonology and prosodic morphology, with its reduplicative system providing a wealth of illustrative data, such as syllable transfer effects (Steriade 1988) and the emergence of unmarked phonological structure (McCarthy and Prince 1994). The range of patterns also underscores the role of morphological conditioning in reduplication. This chapter provides an overview of reduplication in Sanskrit, portraying the range of formations, and their implications for modern theories of representation and derivation.

Sanskrit is an ancient language spoken on the Indian subcontinent. It was spoken as a living language in the third millennium BCE, and has since survived as a liturgical language of Hinduism. Eighteenth-century scholars noted similarities between Sanskrit and Classical Greek and Latin, giving rise to the Indo-European hypothesis and the comparative method in historical linguistics. Whitney (1885, 1889), Wackernagel (1896, 1905, 1930), and Wackernagel and Debrunner (1954) are comprehensive and authoritative sources on the language, though Wackernagel's volume on verbs was never completed. Monier-Williams (1864) is another early source. Sanskrit data are drawn from Vedic literature, a corpus of histories, ceremonies, legends, dramas, and sacrificial formulae, some of it versed, hymnal, or mantric, spanning centuries in the classical period. Written records of the language have been preserved in Devanagari script, which is phonetically transparent and thus expresses alternations. Many of the generalizations discussed in §3 and §4 are explicitly observed in Whitney (1889).

This chapter proceeds as follows. §1 introduces and summarizes Sanskrit reduplication, noting phonological and morphological alternations, while §2 is an overview of reduplicative models. §3 examines segmental alternations in reduplicated structures, with a discussion of their implicationsfor auto-segmental and output-oriented theories. §4 deals with prosodic effects, in particular the size, position, and syllable structure of reduplicative affixes. Here I consider the data from the perspectives of templatic autosegmental phonology, full-copy approaches, template constraints, and atemplatic approaches to reduplication. I conclude by suggesting a reorientation of analysis for Sanskrit reduplication along dimensions of both phonological and morphological alternation, as also suggested by Janda and Joseph (1986).

1 Overview of Sanskrit reduplication

Reduplication is a phenomenon in which part of a word is repeated to indicate a morphological function (see CHAPTER 100: REDUPLICATION). For example, the Sanskrit perfect stems [ta-tap] 'PERF-heat', [pa-pat-a] 'PERF-fly', and [sa-sarj-a] 'PERF-send forth' are derived by repeating the first consonant and vowel of the root. Reduplication bears on phonology for several reasons: (a) phonological similarity between reduplicant and base, (b) prosodic concerns such as the size and position of the reduplicant, and (c) scenarios in which the reduplicant's segmental or featural structure is not fully identical to any contiguous substring of the base.

Sanskrit reduplication comprises five prefixal patterns, each associated with a distinct stem formation: the intensive, the perfect, the aorist, the present, and the desiderative. In turn, each pattern has its own set of predictable phonological alternations. In this section I provide examples of each formation. Data are cited from Whitney (1885, 1889), Janda and Joseph (1986), and Steriade (1988); the latter two also use Whitney (1889) as a primary source. In some cases, missing glosses have been recovered from Monier-Williams (1864) or Deshpande (1997).

As a preview, we can make the following generalizations about the form of the various reduplicative affixes, using prosodic templates for the moment as a means of description (CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS). The intensive (1a) is /CVX/ or $\sigma_{\mu\mu}$, while the others are /CV/ or σ (1b) and (1c), and the size of the template determines how much of the copied string persists to the surface representation. The template can also be used to describe the fixed vowel of the reduplicant; thus, the intensive template includes a prespecification of [a] (1a), while the desiderative includes a [+high] specification (1b). The perfect template need only be CV (1c). Both the aorist and present may follow the desiderative pattern in some cases and the perfect in others.

(1)	a. *Intensive*	b. *Desiderative*	c. *Perfect*
	/C V X/	/C V/	/C V/
	|	|	
	[a]	[+high]	

1.1 *Intensive reduplication*

Display (2) provides examples of the intensive formation.[1] A variety of phonological formations is evident: CVC (2a), as in [bad-badh] 'INT-oppress'; CVCi (2b), as in [bhariː-bhr̥] 'INT-bear'; CVː (2c), as in [daː-dhjaː] 'INT-think'; and CV (2d),

[1] Data are transcribed generally in an IPA transliteration of Devanagari representations, except that aspirates are transcribed with [-h-]. Data tables note the source of each form: W = Whitney, S = Steriade, JJ = Janda and Joseph.

svar	sa-svara	'sound'	S
sjand	sa-ṣjade	'move on'	S

aç	aːn-amç	'attaːn'	JJ
auc	uvoca	'please'	S
av	aːv	'favor'	JJ

1.3 Present stem reduplication

The third reduplicative pattern derives the present stem for the class of verbs illustrated in (4). Its formation is very similar to the perfect, except that base /ṛ/ and /a/ (in most cases) are reflected by [i] in the reduplicant, as in [ti-stha] 'PRES-stand' and [bi-bhṛ] 'PRES-bear'. Otherwise, the same properties of cluster reduction, palatalization, and loss of aspiration are evident.

(4) *Present stem formation*

vac	vi-vac	'speak'	W
vaç	vi-vaç, va-vaç	'eager'	W

1.4 Aorist stem reduplication

Many verbs also use reduplication in the derivation of their aorist stem (5).[3] Whitney notes an alternation in vowel length in the aorist stem: the reduplicant has a long vowel if the base contains a short vowel followed by one consonant (5a), as in [a-duː-duṣam] 'AOR-spoil'. The reduplicant has a short vowel if the base has a

[3] Whitney's examples include a prefix element /a-/ and the 1st person suffix /-am/, while other scholars provided abstractions without these elements; their examples are cited as such.

long vowel (5b), as in [a-bu-bhu:ṣam] 'AOR-adorn', or a short vowel followed by two consonants (5c), as in [a-da-dakṣam] 'AOR-be able'. Forms such as [a-ci-kṣipam] 'AOR-throw' show that vowel length is also avoided in the reduplicant if the base has an initial consonant sequence (5d), while the forms in (5e) show that vowel-initial roots also receive reduplicants with short vowels.

Typically the length alternation leaves the root's vowel length unchanged, but in some aorist forms derived from long-vowel roots, the reduplicative vowel is long and the base vowel is short, as seen in [a-si:-ṣadham] 'AOR-accomplish', from /sa:dh/. Furthermore, like the present stem formation, the reduplicant's vowel is typically [i] or [i:] where the root contains /a/, /ṛ/, or /ḷ/, as in [a-ɟi:-ɟanam] 'AOR-be born' and [a-vi:-vṛdham] 'AOR-grow'.

Note that that the aorist formation shows the same segmental effects as other forms: aspirates and velars are not copied as such, while only one consonant of an onset cluster is reduplicated.

1.5 *Desiderative stem reduplication*

The last reduplicative pattern is the desiderative stem (6), whose structure resembles the present stem pattern of §1.3, and whose addition to a verb derives forms with a meaning roughly equivalent to 'to want to VERB'. The desiderative is derived with a CV reduplicative prefix and also includes a suffix /sa/, sometimes preceded by /i/. The vowel of the reduplicative element is uniformly high; it is always [i] (6a) or [u] (6b), the latter only if the base contains [u]. As with other reduplicative forms, aspirates and velars are not copied as such, and only one consonant of an onset cluster is reduplicated.

(CHAPTER 14: AUTOSEGMENTS; CHAPTER 54: THE SKELETON). Derivationally, these models fit into three general categories: the rule-ordered copy-and-associate approach, the correspondence approach, and the full-copy approach.

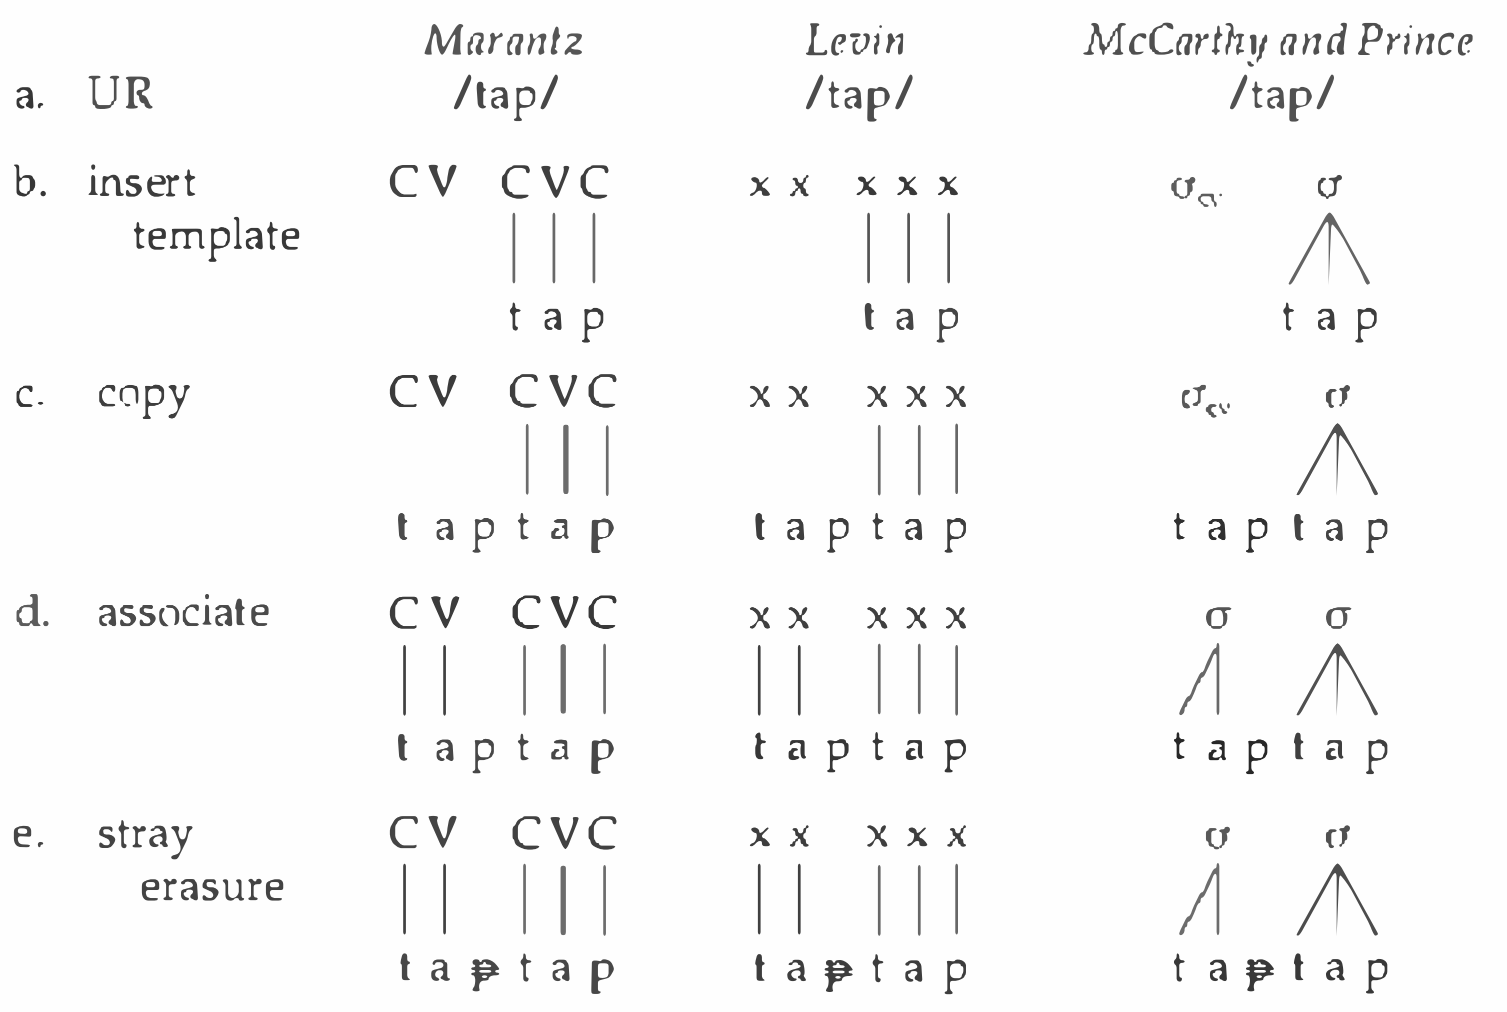
In this section, I briefly discuss how each approach would model Sanskrit reduplication, using the present stem formation of the root /tap/ 'heat'. I should note explicitly that of the models discussed in this section, only Steriade (1988) offers any detailed elaboration on the Sanskrit data. Thus, the exemplifications of how other models would handle Sanskrit reduplication are drawn from my own attempts at applying such models to these data. Further, while I note some strengths and shortcomings of each model here, I return to a fuller evaluation of all of them in §4, after a description of segmental processes in §3.

2.1 *Rule-ordered template satisfaction*

The rule-ordered approaches of Marantz (1982), Levin (1985), and McCarthy and Prince (1986) combine an autosegmental templatic morpheme with a derivational model of copy and association: the reduplicative morpheme is an empty prosodic shell, whose addition to a stem (7b) precipitates a copy operation that doubles the segmental melody of the root (7c). The doubled melody associates maximally to the template (7d), and left-over unassociated segments are erased (7e). Such models allow rules to precede or follow the copy operation, which accounts for the observation of a phonological process in one or both morphemes of a reduplicated word.

The three derivational templatic models differ from each other in the nature of the template: Marantz (1982) uses a CV skeleton, Levin (1985) uses a bare X-slot skeleton, while McCarthy and Prince (1986) use units of the prosodic hierarchy – in this case, the core syllable (one which precludes onset clusters and coda consonants).

(7)



The full-copy models are capable of capturing the syllable transfer effects discussed in §4.3; indeed such data motivate Steriade's approach in the first place. However, Steriade's model suffers from the ordering paradoxes discussed in §3.1, while Inkelas and Zoll's model may be troubled by the opacity found in the activity of the *ruki* rule discussed in §3.2, and also incurs the expense of positing an entirely distinct phonological grammar for different morphemes of the same word.

3 Segmental phonology of Sanskrit reduplication

Whitney notes a number of segmental effects which interact with reduplication:

> A non aspirate is substituted in reduplication for an aspirate . . . A palatal is substituted for a guttural or for h . . . Of two initial consonants the second if it be a non nasal mute preceded by a sibilant is repeated instead of the first. (1889: 222)

He notes elsewhere that "the dental sibilant [s] is changed to the lingual [ṣ] if immediately preceded by any vowel save [a] and by [k] or [r] unless the [s] be final followed by [r]" (1889: 61); this process, called the *ruki* rule by modern scholars, also interacts with reduplication.

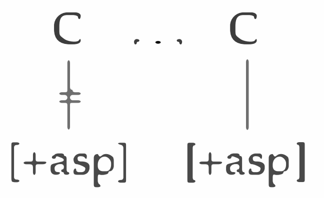
In this section I describe how these processes interact with reduplication and evaluate how well the models in §2 capture them. I first discuss deaspiration and palatalization in §3.1, processes which apply generally in the language to proximate consonants, and which affect the initial consonant of the reduplicative consonant. I then discuss the *ruki* rule in §3.2, focusing on its instantiation of reduplicative overapplication. In §3.3, I discuss cluster simplification in the reduplicants of roots with onset consonant sequences.

3.1 Consonant dissimilation

Two patterns of dissimilatory consonantal alternation are observable in Sanskrit reduplication: velar root consonants and /h/ have palatals as their reduplicative counterparts, and aspirates have unaspirated reduplicative counterparts. Both processes are observed in all CV reduplicative formations; the intensive CVC prefix sometimes allows velars and aspirated consonants.

Palatalization applies to velar consonants regardless of the nuclear vowel of the base or reduplicant (CHAPTER 71: PALATALIZATION); for example, the forms [ɟa-gam] 'PERF-go', [ci-kiːrṣa] 'DESID-do', and [a-cu-krudham] 'AOR-get angry' have palatal consonants in their reduplicants. Aspiration is not copied in the reduplicant; for example, the reduplicative consonant in [ti-sthaːsa] 'DESID-stand', [di-dhiːrṣa] 'DESID-hold', [ɟa-ghasa] 'PERF-eat', and [bi-bhṛ] 'PRES-bear' is unaspirated despite the aspiration in the base. The loss of aspiration in the reduplicant is an instance of Grassman's Law, a general process that prevents adjacent aspirates, accounting for Sanskrit exceptions to consonant correspondences in historical comparative analysis. Though a diachronic process which affects the form of roots in Sanskrit, its role in reduplication suggests a synchronic sensitivity to it. An autosegmental dissimilation rule that removes aspiration is provided in (13). Note that this rule may apply regardless of the number of intervening segments.

(13) *Grassman's Law*



Consonant dissimilation creates a paradox in derivational copy-and-associate models such as Marantz (1982) and McCarthy and Prince (1986), as well as the full-copy analysis of Steriade (1988). The fact that unreduplicated roots generally adhere to palatalization and to Grassman's Law suggests a set of morpheme structure conditions (MSCs; CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS) on the representation of underlying forms. Yet the application of these rules in reduplicated forms requires ordering them after the copying operation, which duplicates the MSCs post-lexically.

Consider for example the perfect stems [bi-bhed] 'PERF-split' (from /bhid/)and [bu-bodha] 'PERF-know' (from /baudh/). Both have one aspirated consonant; there are no roots with two proximate aspirated consonants, a fact attributed to the activity of an MSC holding over underlying representations. Following the formation of the present stem with reduplication, the intermediate form /bhi-bhaid/ contains a sequence of aspirates, to which the synchronic Grassman's Law must apply. Meanwhile, the intermediate reduplicated form /bu-baudh/ copies an unaspirated consonant, so Grassman's Law does not apply.

(14)	UR (MSC applies)	bhid	baudh
	present stem formation	bhi-bhaid	bu-baudh
	Grassman's Law	bi-bhaid	—
	other rules, output	bi-bhed	bu-bodh

One resolution is to posit a unitary post-reduplicative ordering of these processes, without any MSC. In such a scenario, without any underlying MSC, a hypothetical two-aspirate root such as /bhaudh/ is a possible lexical representation, but because of Grassman's Law, it would still surface as [-budh]. However, the rules that instantiate palatalization and Grassman's Law must follow the copy operation, as forms like [bi-bhed] show. This ordering allows velars and aspirates to occur in reduplicants as the counterparts of bases which themselves have undergone these processes. In the case of hypothetical /bhaudh/, the copying process produces /bhu-bhaudh/; Grassman's Law then yields [bhu-baudh], with aspiration remaining in the reduplicative [bh]. Thus, without the MSC, the rule-ordered approach fails to preclude a certain class of unattested reduplicated structures.

(15)	UR (no MSC)	bhaid	*bhaudh
	present stem formation	bhi-bhaid	bhu-bhaudh
	Grassman's Law	bi-bhaid	bhu-baudh
	other rules, output	bi-bhed	*bhu-bodh

Optimality Theory (Prince and Smolensky 1993) abandons MSCs for Richness of the Base, and formalizing palatalization (16a) and Grassman's Law (16b) as output constraints avoids any overgenerative result. Both constraints are respected in unreduplicated stems, and in each morpheme of reduplicated stems. This suggests that they are ranked higher than a constraint requiring faithful realization of underlying aspiration (16c).

(16) a. *[VEL][VEL]
Adjacent specifications of velar consonant place are forbidden.
b. GRASSMAN
Adjacent specifications of [+asp] are forbidden.
c. MAX-IO[+asp]
Each input [+asp] feature has a correspondent in the output.

As summarized in (17), Grassman's Law is respected in unreduplicated words by virtue of an output-oriented constraint, and the hypothetical unreduplicated form /bhaudh/ would appear as [bodh-]. Meanwhile, this alternation also motivates faithfulness constraints to target elements other than the segment.

(17)

	/bhaudh/	GRASSMAN	MAX-IO[+asp]
	a. bhodh	*!	
☞	b. bodh		*

In the reduplicative context, these consonant alternations motivate additional faithfulness constraints. For example, in [bi-bhed], the reduplicative [b] must be seen as the faithful correspondent of the base [bh]. The fact that the consonants have opposite specifications for [+asp] suggests that the constraint IDENT-BR[+asp], which requires corresponding base and reduplicative segments to have identical [asp] features, is violable. This is illustrated in (19), where IDENT-BR is ranked below MAX-IO[asp].

(18) IDENT-BR[+asp]
Segments in correspondence have identical [asp] specifiications.

The interpretation of MAX-IO needs to be quite narrow in this analysis: the aspiration feature on the reduplicative consonant is not to be taken as the output correspondent of the underlying aspiration feature. Thus, in (19b), the absence of aspiration in the base consonant triggers a violation of MAX-IO[+asp].

(19)

	/PRES+bhaid/	GRASSMAN	MAX-IO[+asp]	IDENT-BR[asp]
☞	a. bi-bhed			*
	b. bhi-bed		*!	*
	c. bhi-bhed	*!		
	d. bi-bed		*!	

Furthermore, when we return to the hypothetical problem form /bhaudh/, this additional correspondence constraint avoids the overgenerative consequence of the rule-ordered approach. IDENT ensures that the reduplicant has an unaspirated consonant to match the unaspirated consonant of the root. Thus reduplicated and unreduplicated roots both respect a unitary surface-oriented instantiation of Grassman's Law in the correspondence approach.

(28)

/PERF+smr̥/	MAX-IO	ONSET	*[+son]/ONS	*[+sib]/ONS	MAX-BR
a. smaː-smr̥			**!	**	
☞ b. saː-smr̥			*	**	*
c. maː-smr̥			**!	*	*
d. saː-sr̥	*!			**	
e. a-smr̥		*!	**		**

The correspondence approach restricts the cluster reduction pattern to the reduplicative substring; it does so through the TETU interaction between markedness and the formal distinction between reduplicative and base substrings. The base is not exceptional to the general markedness constraint, and the reduplicant is not subject to any morpheme specific process.

4 Prosodic morphology

In addition to the segmental effects discussed in §3, Sanskrit reduplication presents some particular challenges in its prosodic morphology. In particular, there is some morphological conditioning within the reduplicative prefix, both in its size and in its vocalism. In §4.1 I describe these conditions in more detail, while §4.2 shows how each of the models in §2 would handle them. Section 4.3 describes the syllable transfer effect, with an accompanying discussion again of how various models may or may not capture it.

4.1 Morphological conditioning

Despite the range of surface forms of reduplicative affixes in Sanskrit, there is sufficient regularity to attribute much alternation in form to phonological concerns, and what remains to morphological conditioning. There are two points of morphological conditioning: whether the affix indicates intensive, and whether it has a fixed vowel. CVC-, CVː-, CVG-, VC-, and CVCi- can be treated as predictable alternants of the intensive prefix: most such forms never map to the other functions, save the CVː- alternant of the aorist. Conversely, no CV- prefix ever carries an intensive function. The remaining phonological alternants are then predictable variants of a separate reduplicative formation. Vocalism is another dimension of morphological conditioning: the intensive always has [a], while the desiderative always has a high vowel. The perfect copies the base vowel, but the present and aorist vacillate between a fixed vowel and a faithful copy.

4.2 Patterns and templates

Sanskrit is a multi-pattern reduplicative system; such systems have received relatively less theoretical attention from theorists, but it is worth investigating how each of the prominent models of reduplication handles them. The templatic models could model a multi-pattern system by positing distinct inputs from different reduplicative affixes: as shown in (1) (repeated as (29)), the intensive is underlyingly

/CVX/ or $\sigma_{\mu\mu}$ (1a), while the others are /CV/ or σ (1b) and (1c). All reduplicants can then be generated by a single copying rule, but the size of the template determines how much of the copied string persists to the surface representation. The template can also be used to determine the fixed vowel of the reduplicant; thus, the intensive template includes a prespecifiication of [a] (29a), while the desiderative includes a [+high] specification (29b). The perfect template need only be CV (29c). The aorist and present formations, as we will see, both variably converge with the desiderative in some cases and the perfect in others.

(29) a. *Intensive* b. *Desiderative* c. *Perfect*

a. *Intensive*	b. *Desiderative*	c. *Perfect*
/C V X/	/C V/	/C V/

[a]	[+high]	

However, the choice of a fixed-vowel or faithful-vowel template for the present and aorist stems must be left to allomorphic devices, as some formations require a general CV prefix, e.g. [da-daː] 'PRES-give', while others call upon a fixed high-vowel prefix, e.g. [ɟi-gaː] 'PRES-go'. In a copy-and-associate approach, a root must be specified for which of the two CV templates it takes when deriving the present or aorist stems. Further, the length alternation in the aorist motivates a rule specific to that formation; it must lengthen the reduplicative vowel under specific conditions, but it must not be allowed to apply to any of the other reduplicative stems.

Steriade's model uses no templates to distinguish reduplicative morphemes. Instead, the intensive differs from the others because of a rule which assigns a nuclear [a] just to that morpheme, along with different licensing conditions on coda consonants. Forms like [car-karṣ] 'INT-plough' and [kani-krand] 'INT-cry out' keep their postvocalic reduplicative consonants, because intensives are not subject to the same restrictions on coda consonants as perfect stems; otherwise, the intensive affix would not remain distinct from the other reduplicants. Meanwhile, though Steriade's focus is on the intensive and perfect markers, her model readily accommodates the fixed [+high] feature for the desiderative, inserting it in the same way the vowel [a] is inserted just for intensive prefixes.

Optimality-theoretic models vary in their treatment of multi-pattern systems. Template constraints such as those in McCarthy and Prince (1993) would demand that a particular reduplicative morpheme map to a specified prosodic category, for example foot or syllable. Sanskrit thus motivates two constraints: a specific INTENSIVE=$\sigma_{\mu\mu}$ and a general RED=σ. Generalized Template Theory (Urbanczyk 1996) would instead label the intensive as a root and the other reduplicants as affixes. A general prosodic constraint would force the intensive reduplicant, by virtue of its being a root, to project a foot. Conversely, another constraint would restrict other reduplicative morphemes, by virtue of their being affixes, to project at most a syllable. More general approaches (Gafos 1998; Kennedy 2003) do not use the root *vs.* affix distinction for different kinds of reduplicants, and without any morphological distinction among types of affixes, they cannot model morphologically conditioned size alternation.

To resolve this, Kennedy (2008) draws size differences from the morphological position of the affix relative to the stem: reduplicative morphemes are either stem-internal or stem-external in this model, and are thus subject to different general constraints on the alignment of morphological and prosodic elements. For example, the Sanskrit intensive would be posited as stem-external, aligning to a foot boundary, and is thus relatively larger than other reduplicants which need not align to foot boundaries.

To handle fixed vowels in reduplicants, correspondence approaches have three general strategies. One is to place the fixed vowel feature in the input representation of the reduplicant, in which case the present affix underlyingly is /Red, [+high]/, while the desiderative is underlyingly /Red, [a]/. These features are then maintained in the reduplicative substring via faithfulness constraints. Alternatively, the vowel features could be represented as part of the template constraint, in which case one constraint encodes Intensive= $\sigma_{\mu\mu}$+[a] and another encodes Desiderative=σ+[+high], while the perfect is subject to Red=σ. The reduplicant thus remains segmentally empty, and acquires its fixed vowel by satisfying the template constraint. A third approach is to leave the vowel choice to emergent markedness constraints, which would assign vowels by default (Alderete *et al.* 1995). Since some reduplicants contain fixed low vowels and others contain fixed high vowels, this approach is not appropriate for Sanskrit. Regardless, none of these approaches resolves the vacillation within the present and aorist stem affixes.

4.3 *Syllable transfer effects*

A final aspect of Sanskrit reduplication is the phenomenon of syllable transfer, discussed in depth by Steriade (1988). In short, the segment which appears in the nucleus of the reduplicant's syllable must have a base correspondent occurring somewhere in a rhyme, and a base onset segment can only have a counterpart in the reduplicant's onset. For example, in intensives like [car-karṣ] 'int-plough' and [kani-krand] 'int-cry out', the reduplicant copies a sonorant from a rhyme position in the base. In contrast, in [ɟaː-grah] 'int-seize' and [saː-smr̩] 'int-remember', the base has a sonorant as part of an onset cluster which is not copied; syllable transfer precludes forms such as *[ɟr̩-grah] or *[ɟari-grah] and *[sm̩-smr̩] or *[sami-smr̩]. The same effect is seen in perfect stems: the underlying glides in rhyme position in roots such as /baudh/ 'know' and /bhaid/ 'split' are reflected as the nuclei of the prefix syllable, as in [bu-bodha] 'perf-know' and [bi-bhed] 'perf-split'. However, the underlying onset glides in roots such as /svaɟ/[4] 'embrace' and /khjaː/ are not copied in [sa-svaɟa] 'perf-embrace' and [ca-khjau] 'perf-see'.

Of the rule-ordered models discussed here, only Steriade's full-copy approach handles this effect: the entire root is copied and syllabified, and the resulting structure is subject to a series of processes removing unlicensed material from the reduplicative substring. One process removes glides from onset clusters, turning /svaɟ/ to /saɟ/. In contrast, because copy-and-associate models generate a segment melody and associate it to an empty prosodic template, there is nothing barring the association of the reduplicant melody's /v/ in the melody to the nuclear position of the template. In other words, the copy-and-associate model predicts forms such as *[su-svaɟa] instead of [sa-svaɟa] and *[sami-smr̩] or *[sm̩-smr̩] instead of [saː-smr̩].

Nevertheless, this generalization has some limited exceptions, as in forms such [su-ṣvaːpa] 'perf-sleep', [i-jaɟa] 'perf-offer', and [u-vasa] 'perf-shine', where onset

[4] See note 2, p. 2858.

glides do vocalize as nuclear vowels in the reduplicant (see CHAPTER 15: GLIDES). To address this, Steriade argues that the adherence of a root to the syllable transfer effect is related to whether it has a distinction between its zero-grade and full-grade stems. Generally, full-grade stems include [a], and each grade is used only in specific morphosyntactic contexts, but some roots exceptionally are invariant across grades, keeping the [a] in both the zero and full grade.

For example, the full-grade and zero-grade stems for /svaɟ/ 'embrace' converge upon [sa-svaɟa], illustrating syllable transfer, while the full-grade stem in [su-svapa] 'sleep' differs from the corresponding zero-grade stem in [su-sup]. Steriade handles this by ordering perfect reduplication (30a) ahead of a rule of Syncope (30b), which removes unaccented [a] (thus deriving the zero grade from the full grade). Syncope also applies to any instances of [a] in the prefix regardless of grade, thus turning /svap-svap/ to /sup-svap/, in which the glide is necessarily vocalized – and since it is no longer part of an onset cluster, it survives the later step of removing unlicensed material (30c). In contrast, roots such as /svaɟ/ are exceptions to Syncope (30b); their intermediate forms keep their /a/, and the onset /v/ is deleted from the prefix in the removal of unlicensed material (30c).

(30)			svap (full grade)	svap (zero grade)	svaɟ (full grade)	svaɟ (zero grade)
	a.	perfect	svap-svap	svap-svap	svaɟ-svaɟ	svaɟ-svaɟ
	b.	Syncope	sup-svap	sup-sup	*exception*	*exception*
	c.	Licensing	su-svap	su-sup	sa-svaɟ	sa-svaɟ

Syllable transfer effects are exceptions to the typological claim made by Moravcsik (1978) that reduplication does not copy prosodic constituents. Sanskrit thus challenges the notion of template satisfaction (McCarthy and Prince 1986, 1993), which holds that reduplicative melodies are copied irrespective of the syllabicity of base segments. Other examples of syllable transfer have been noted, such as in West Tarangan (Nivens 1992, 1993; Takata 1992; Takata and Takata 1992; Spaelti 1997), Yaqui (Haugen 2003), and Temiar (Benjamin 1976; Broselow and McCarthy 1983). Though such effects are problematic for the copy-and-associate approach, correspondence approaches can model syllable transfer; for example, McCarthy and Prince (1993, 1994) propose the constraint ST-ROLE, which requires segments in base–reduplicant correspondence to occupy similar prosodic positions. This constraint marks structures in which base onset segments have rhyme segments as their reduplicative correspondents, and would rule out candidates such as *[su-svaɟa] instead of [sa-svaɟa] and *[sami-smr̥] instead of [saː-smr̥].

5 Summary

Reduplication in Sanskrit is a rich source of data with a variety of implications for phonological theories and models. The very breadth of the data is daunting, given the variety of formations, the phonological alternations evident in each, and the persistent exceptionality to some generalizable patterns. Even so, the exceptionality is generally principled, and the system is a fruitful source of data on reduplicative segment alternations and prosodic structure.

As Janda and Joseph (1986) note, a unitary notion of reduplication in Sanskrit is not attainable, given the larger size of the intensive marker and the appearance of fixed segmentism in only some of the remaining formations. Yet the various formations maintain a fairly consistent respect for palatalization, Grassman's Law, and cluster reduction, diverging from the former two only in certain examples of the intensive. Meanwhile, the vocalism of the present and aorist markers is not entirely predictable, but also not random: it always converges with the perfect or the desiderative vocalic pattern, and is attributable to a single point of allomorphic variation.

The multitude of prosodic shapes for reduplicative structures in Sanskrit is reducible almost to two, save the weight alternation observed in the aorist marker. Given the general trend in phonological approaches to reduplication to reduce the set of prosodic targets and generalize the relationship between reduplicative morphemes and prosodic structure, accounting for this alternation will be a necessary step in any coherent theory of multi-pattern reduplication.

The study of Sanskrit reduplication illustrates the progression of phonological theory from rule-ordered template satisfaction to generalized morphoprosodic output constraints. Yet in one respect, the rule-ordered approach is better equipped. It is only with cyclicity that the opaque interaction between reduplication and the *ruki* rule can be sensibly captured. In contrast, other aspects of Sanskrit reduplication are better modeled with optimality-theoretic constraints, such as Grassman's Law, palatalization, cluster reduction, and, ironically, the overapplication effect brought about by the interaction of reduplication and the *ruki* rule.

Clearly, no single phonological framework handles all the data flawlessly, though a constraint-based approach that incorporates intermediate representations to handle the opacity of the *ruki* rule, and allomorphic prespecification to handle variation, seems the best fit. In contrast, the two serial approaches seem less amenable to any theoretical repair to address their weak spots, most notably the segmental phenomena discussed in §3.

Regardless of their derivational character, modern generative approaches offer some additional insights into the data which grammarians such as Whitney were unable to provide. Although Whitney's own approach to reduplication in Sanskrit was to describe it thoroughly with sensible generalizations, he offered little more than a taxonomic list of subpatterns and the conditions under which they arise. In contrast, modern approaches have at their disposal a number of theoretical constructs, such as the feature, the autosegment, the template, the prosodic hierarchy, and the mora, all of which help unify this widely disparate data set, providing order to Whitney's taxonomy.

120 Japanese Pitch Accent

Haruo Kubozono

1 Introduction

The goal of this chapter is to sketch Japanese pitch accent systems, focusing in particular on the major debates and findings in the past and the present. Many Japanese dialects, including the standard Tokyo dialect (henceforth Tokyo Japanese), have a lexical pitch accent, but pitch accent systems vary greatly from one dialect to another. This can be exemplified by (1), which shows how the recent loanword /ma.ku.do.na.ru.do/ 'McDonald's' is pronounced in different dialects. In (1) and the rest of this chapter, high-pitched portions are denoted by capital letters, while syllable boundaries are indicated by dots wherever necessary.

(1)	Tokyo	ma.KU.DO.NA.ru.do
	Kyoto/Osaka	ma.ku.do.NA.ru.do
	Nagasaki	MA.KU.DO.NA.RU.DO
	Kagoshima	ma.ku.do.na.RU.do
	Miyakonojo	ma.ku.do.na.ru.DO
	Koshikijima	MA.KU.DO.na.RU.do

Given this geographical diversity of accent patterns, it is necessary both to discuss Japanese pitch accent for each dialect, and to compare different systems. Since much previous work has centered around the pitch accent system of Tokyo Japanese, we will focus on this system in the first half of this chapter, while discussing other systems in the second half, to illustrate the diversity of pitch accent in the language.

Before going into the main discussion, let us define some basic notions (see CHAPTER 42: PITCH ACCENT SYSTEMS for more general discussion of the notion of pitch accent). The term "accent" is used in two different ways in Japanese phonology. This can be illustrated by the pitch patterns in (2) in Tokyo Japanese, where both the presence and location of a sudden pitch fall are distinctive. In many generative studies of Japanese phonology, "accent" is used to refer to phonological prominence that is assigned to a particular position of a word. According to this definition, words in (2a)–(2c) have an "accent" on a particular syllable or mora; this position is phonologically marked as "accented" since pitch abruptly falls immediately after it. On the other hand, (2d) has no accent, i.e., /sakana/ is an "unaccented word," since no abrupt pitch fall occurs even if a particle is attached to it (/ga/ is a nominative particle).

(2)	*word*	*surface pitch*	*accent representation*	
a.	inoti	Inoti-ga	í.no.ti	'life'
b.	kokoro	koKOro-ga	ko.kó.ro	'heart'
c.	otoko	oTOKO-ga	o.to.kó	'man'
d.	sakana	saKANA-GA	sa.ka.na	'fish'

In addition to this definition, the term "accent" has conventionally been used more loosely to refer to the overall pitch pattern or shape of a word. According to this definition, every word in (2) has an accent: even the so-called "unaccented word" in (2d) has an accent in the sense that it has a fixed pitch pattern with which it must be pronounced. To avoid confusion, I will adopt the first definition of the term in this chapter, while using the term "pitch pattern" or "accent pattern" to refer to the surface pitch pattern of words.

Japanese pitch accent as defined in this way is different from word stress in English, in that its phonetic correlate is primarily pitch or fundamental frequency (F0) and is independent of duration or intensity (Beckman 1986; see also CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE). This phonetic nature of pitch accent is supposedly consistent across dialects.

This chapter is organized as follows. In the next section, we will briefly consider a typology of Japanese pitch accent systems, including that of Tokyo Japanese. §3 discusses various aspects of Tokyo Japanese, focusing in particular on past debates about accent computation and representation. §4 and §5 describe other prosodic systems, to illustrate the diversity of pitch accent in the language. Kagoshima and Koshikijima Japanese are chosen in these sections as typical examples of pitch accent systems which are strikingly different from that of Tokyo Japanese. The final section summarizes the main points, as well as some issues for future work.

2 Typology of Japanese pitch accent systems

Based on the number of lexical pitch contrasts, Uwano (1999) proposes a dichotomy of Japanese pitch accent systems: multiple-pattern systems *vs.* N-pattern systems (where N can be any integer starting from one). In the former type, the number of contrastive patterns varies depending on the phonological length of the word. The accent system of nouns in Tokyo Japanese is a typical example of this type, since lexical contrasts increase in number as words become longer. On the other hand, N-pattern systems have a fixed number of lexical pitch contrasts, which is independent of the phonological length of words. For example, the Miyakonojo dialect spoken in Miyazaki Prefecture in the south of Japan has a one-pattern system where every word has a high pitch on the final mora, as illustrated in (3). In this system, the pitch feature need not be specified for each word in the lexicon, since it can be assigned by a redundancy rule (see CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION).

accent patterns for nouns of *n* syllables, where *n* represents an integer equal to or greater than one (McCawley 1968; Akinaga 1985; Shibatani 1990; Uwano 1999).[1] Thus monosyllabic words have two distinctive pitch patterns, as in (6a), disyllabic nouns have three, as in (6b), and trisyllabic nouns have four, as in (6c), etc. Each case involves a contrast in accentedness, i.e. between accented and unaccented patterns; disyllabic or longer nouns additionally involve a contrast in accent position. Phonetic patterns are shown in parentheses. In the rest of this chapter, unaccented words are marked with a superscript circle (°) for the sake of description.

(6)	a.	hí-ga	(HI-ga)	'fire-NOM'
		hi°-ga	(hi-GA)	'sun-NOM'
	b.	áki-ga	(Aki-ga)	'autumn-NOM'
		akí-ga	(aKI-ga)	'weariness-NOM'
		aki°-ga	(aKI-GA)	'vacancy-NOM'
	c.	ínoti-ga	(Inoti-ga)	'life-NOM'
		kokóro-ga	(koKOro-ga)	'heart-NOM'
		otokó-ga	(oTOKO-ga)	'man-NOM'
		sakana°-ga	(saKANA-GA)	'fish-NOM'

The *n* + 1 rule holds for nouns, but not for verbs and adjectives. Verbs and adjectives in Tokyo Japanese have only two pitch patterns, irrespective of their length. They exhibit a contrast in accentedness, just like nouns, but not in accent position, as accented verbs and adjectives are accented on the penultimate mora, as shown in (7) (see also CHAPTER 102: CATEGORY-SPECIFIC EFFECTS).

(7)	a.	*Verbs*			
		accented		*unaccented*	
		náru	'to be completed'	naru°	'to ring'
		haréru	'to clear up'	hareru°	'to become swollen'
		arúku	'to walk'	akeru°	'to open'
	b.	*Adjectives*			
		accented		*unaccented*	
		atúi	'hot'	atui°	'thick'
		umái	'tasty'	amai°	'sweet'

Research on pitch accent in Tokyo Japanese has centered around the following four questions: (i) how to derive surface pitch patterns, (ii) how to generalize accentual phenomena into accent rules, (iii) how to account for the distribution of unaccented words as opposed to accented ones, and (iv) how to compute accent patterns in a theoretical framework. Due to limitations of space, we will focus on the first three questions in the following sections.

3.1 Accent-to-pitch conversion

Traditionally, the four pitch patterns in (2) have been represented as in (8), where every mora is assigned either a high tone (H) or a low tone (L) (Haraguchi 1977).

[1] This rule does not hold for relatively long words and compound nouns, as we will see in §3.2.4.

nouns – whether native, SJ, or foreign – can remain unspecified as long as they obey the accent rule in (10a), while other accented nouns are marked in the lexicon as to their accent location. This analysis entails that native nouns primarily differ from loanwords in the extent to which lexical exceptions are permitted: the former group permits a greater number of lexically marked words than the latter group.

This idea leads to a sparsely specified representation like the one in (11), where * denotes a floating accent that is not linked to any particular position of the word in the lexicon (Kubozono 2008b). In other words, * marks a word as accented, but without saying where it is accented. This floating accent – or unlinked high tone – is subsequently anchored on a particular position by the antepenultimate accent rule.

(11) inoti*, kokóro, otokó, sakana

This representation is crucially different from those in (9), in that it treats the antepenultimate pattern as a default pattern for accented nouns. In other words, it predicts that new nouns will take this accent pattern if they are accented at all. This prediction can be readily borne out by an analysis of nonsense nouns such as /go.re.se/ and /ma.ta.go.ra.sa/, which display a strong bias towards the antepenultimate pattern (Tanaka 1996). The representation in (11) is also compatible with the fact that accent patterns are asymmetrically distributed if their frequencies are considered, namely, that the antepenultimate pattern predicted by (10a) accounts for a majority of accented nouns, irrespective of the lexical stratum they belong to (Kubozono 2006a, 2006b, 2008b).

The analysis of lexical specification in (11) implies that nouns in Tokyo Japanese permit only two productive accent patterns in addition to lexically marked ones. What this means is that nouns in this dialect basically constitute a two-pattern accent system like adjectives and verbs of the same dialect, as well as all words in Kagoshima Japanese (see (4) above and §4 below). In all these systems, the contrast between accented and unaccented patterns – equivalently, presence or absence of an abrupt pitch fall in phonetic terms – is relevant, whereas the position of accent (or pitch fall) is largely redundant. The accent system of nouns in Tokyo Japanese differs from that of adjectives and verbs in the same dialect and the system of Kagoshima primarily in the extent to which lexical exceptions are permitted: the former system permits a greater number of lexically marked words than the latter two systems.

3.2.2 *Exceptions to the antepenultimate rule*

Returning to the loanword accent in (10a), we must not overlook the fact that this rule admits a fairly large number of exceptions (CHAPTER 106: EXCEPTIONALITY). There are at least three groups of exceptions which can be accounted for by linguistic factors.

The first group consists of unaccented loanwords such as /amerika°/ 'America' and /monariza°/ 'Mona Lisa'. Generally speaking, the ratio of the unaccented pattern is relatively low in loanwords – about 10 percent, according to Sibata (1994) – but this ratio varies greatly, depending on the length and syllable structure of the word. We will consider these phonological factors in detail in §3.3.1.

A second group of exceptions to the antepenultimate accent rule in (10a) consists of trimoraic loanwords made up of a sequence of light and heavy syllables.

Loanwords of this phonological structure fall into two accent classes, those that obey the antepenultimate rule in (10a) and those that do not. Typically, the former class contains an underlying vowel in the initial syllable, while the latter contains an epenthetic vowel in the same position (Kubozono 2001, 2006a).[4] These two cases are illustrated in (12).

(12)	a.	sé.dan	'sedan'	b.	tu.ín	'twin'
		há.wai	'Hawaii'		to.rái	'try'
		dé.byuu	'debut'		do.rái	'dry'
		ká.nuu	'canoe'		gu.rée	'grey'
		gí.taa	'guitar'		bu.rúu	'blue'
		pú.rin	'pudding'		do.róo	'draw'

The examples in (12) may seem to suggest that epenthetic vowels tend to avoid bearing an accent (CHAPTER 67: VOWEL EPENTHESIS), but the facts are not that simple. An epenthetic vowel can, and actually does, bear an accent if it is followed by a sequence of light syllables, as in (13).

(13)	kú.ra.su	'class'
	dó.re.su	'dress'
	pú.ra.mu	'plum'
	dó.ra.mu	'drum'

The irregular accent pattern in (12b) emerges if the following two conditions are met: (i) the initial syllable contains an epenthetic vowel, and (ii) the following syllable is heavy. In other words, a penultimate light syllable attracts word accent more strongly than a final heavy syllable, but this strength relation is reversed if the light syllable contains an epenthetic vowel. This shows an interesting interaction between syllable weight and the nature of the vowel (epenthetic *vs.* non-epenthetic) in accent assignment.

A certain type of four-mora or longer loanword constitutes a third group of exceptions to the antepenultimate rule in (10a). These exceptions typically end in a sequence of a light syllable plus a heavy one, as exemplified in (14): σ_H and σ_L stand for heavy (bimoraic) and light (monomoraic) syllables, respectively. Words in (14a) end in a sequence of light syllables followed by a heavy syllable, whereas those in (14b) involve a heavy–light–heavy sequence in the same position. Unlike the words in (10b), these loanwords are accented not on the syllable containing the antepenultimate mora, but one syllable to the left.

(14)	a.	$\sigma_L\sigma_L\sigma_H$ #		b.	$\sigma_H\sigma_L\sigma_H$#	
		bí.gi.naa	'beginner'		ín.ta.byuu	'interview'
		tó.ro.fii	'trophy'		góo.ri.kii	'Gorky (Russian writer)'
		sú.ri.raa	'thriller'		báa.ku.ree	'Berkeley'

Statistical study has shown that this "pre-antepenultimate" accent pattern is much more common than the antepenultimate pattern in (15) for the two prosodic structures (Kubozono 1996; Katayama 1998; Shinohara 2000; Tanaka 2008).

[4] /ta.búu/ 'taboo' is one of the few words that show final accent even though the initial vowel is not epenthetic.

(15) a. bi.tá.min 'bitamin' b. ren.tó.gen 'X rays'
a.sé.an 'ASEAN' baa.bé.kyuu 'barbecue'
pi.ká.tyuu 'Pikachu' kuu.dé.taa 'a coup'

Not surprisingly, many words of the phonological structures in question fluctuate between the two accent patterns, as shown in (16). As the pre-antepenultimate pattern tends to be preferred by young speakers, the variations in (16) suggest that the pre-antepenultimate pattern in (14) represents a newer accent pattern and is replacing the traditional antepenultimate pattern shown in (15).

(16) a. do.rá.gon ~ dó.ra.gon 'dragon'
a.re.rú.gii ~ a.ré.ru.gii 'allergy'
re.bá.non ~ ré.ba.non 'Lebanon'
b. myuu.zí.syan ~ myúu.zi.syan 'musician'
en.dé.baa ~ én.de.baa '(space shuttle) Endeavor'
kaa.di.gan ~ káa.di.gan 'cardigan'

3.2.3 *Comparison with the Latin rule*

It is important to point out here a striking similarity between the Japanese antepenultimate rule in (10a) and the accent rule of Latin in (17) (Kubozono 1996, 1999). The Latin accent rule is known to be shared by English and many other languages of the world (Hayes 1995).

(17) *Latin accent rule* (Prince and Smolensky 1993; Hayes 1995)

Accent falls on the penultimate syllable if it is heavy; otherwise, it falls on the antepenultimate syllable (whether it is heavy or light).

Although the two rules might look quite different at a glance, they have in fact much in common. This can be seen from (18) and (19), where the effects of the two rules are compared with reference to the three syllables in word-final position:[5] underlined syllables are those to which an accent is assigned by each rule.

(18) *Effects of the Japanese antepenultimate accent rule in* (10a)

a. $\ldots\sigma_H\underline{\sigma_H}\sigma_H\#$ e. $\ldots\underline{\sigma_H}\sigma_L\sigma_H\#$
b. $\ldots\sigma_H\underline{\sigma_H}\sigma_L\#$ f. $\ldots\underline{\sigma_H}\sigma_L\sigma_L\#$
c. $\ldots\sigma_L\underline{\sigma_H}\sigma_H\#$ g. $\ldots\underline{\sigma_L}\sigma_L\sigma_H\#$
d. $\ldots\sigma_L\underline{\sigma_H}\sigma_L\#$ h. $\ldots\underline{\sigma_L}\sigma_L\sigma_L\#$

[5] Superheavy, i.e. trimoraic, syllables are excluded here, since there are severe restrictions on this structure in Japanese, just as in many other languages. See Kubozono (1999) for a full discussion.

	hime	'princess'	kaguyá-hime	'Princess Kaguya'
			sirayukí-hime	'Snow White'
	sikí	'ceremony'	sotugyóo-siki	'graduation ceremony'
			nyuugakú-siki	'entrance ceremony'
	ko°	'child'	tínomí-go	'infant'
			minasí-go	'orphaned child'
	musi°	'bug, insect'	kabutó-musi	'beetle'
			tentóo-musi	'ladybird'
b.	*Initial-accenting morphemes*			
	néko	'cat'	perusya-néko	'Persian cat'
			maneki-néko	'cat with a beckoning paw'
	gásu	'gas'	metan-gásu	'methane gas'
			puropan-gásu	'propane gas'
c.	*De-accenting morphemes*			
	iró	'color'	orenzi-iro°	'orange color'
			nezumi-iro°	'gray'
	tóo	'party'	minsyu-too°	'Democratic Party'
			kyoowa-too°	'Republican Party'
	gó	'word, language'	nihon-go°	'Japanese language'
			tyuugoku-go°	'Chinese language'

Under this analysis, all monomoraic and bimoraic morphemes are marked in the lexicon as to their accentual behavior in compounds. An alternative view to this idea of exhaustive specifications in the lexicon is that only morphemes of the type in (20c) are lexically marked, while other types of morphemes lack such lexical specifications (Kubozono 1997). This underspecification analysis is based on the general observation that all "initial-accenting" morphemes are invariably initially accented when they are pronounced in isolation (although not necessarily vice versa),[6] as well as the observation that (20a) represents the default accent pattern of compound nouns with a short N_2 (Akinaga 1985).

Adopting these two observations, the two compound accent patterns in (20a) and (20b) can be largely computed by rule or constraint interaction in an optimality-theoretic framework (Prince and Smolensky 1993). Descriptively, (20a) and (20b) can be derived by the rules in (21), which are based on two notions, the syllable and the (bimoraic) foot (Kubozono 1997).[7,8]

[6] Some bimoraic morphemes fail to keep their non-final accent in compounds and attract a default compound accent immediately before them instead: e.g. /siráyuki/ 'white snow' + /híme/ 'princess' → /sirayuki-hime/, */sirayuki-hime/ 'Snow White'. Initially accented morphemes of this type must be marked in the lexicon.

[7] Poser (1990) introduces the notion of foot into the analysis of Japanese accent, to account for the accent patterns shown by compound nouns with a long N_2, in particular. He specifically assumes that the final bimoraic foot is invisible to the compound accent rule that applies to compound nouns with a long N_2. However, the generalization of compound accent proposed in this chapter is different from Poser's in assuming that N_2's accent on its penultimate mora can be preserved in compounds unless it is on the very final syllable.

[8] The rule in (21b) is here stated descriptively, and can be formally understood as resulting from the interaction of several constraints, including NON-FINALITY and FOOTFORM, as well as accentual constraints (see Kubozono 1995, 1997, and Itô *et al.* 1996 for a proposal in this direction).

(24) a. ti[nomi]-go
in[dasú]-[gawa]
sotu[gyóo]-[siki]
b. yama-[óto]ko
minami-[áme][rika]

In terms of lexical specification, none of the N_2s in these compound nouns need to be marked in the lexicon with respect to the compound accent behavior they exhibit. Rather, their compound accent behavior can be readily computed on the basis of their phonological structure. All in all, compound nouns with a short N_2 and those with a long N_2 can be grouped together with respect to their compound accent patterns. Those with a short N_2 permit lexical exceptions to the generalization in (21), i.e. unaccented compounds like (20c), but their accent patterns are otherwise the same as those of compound nouns with a long N_2. We will develop this generalization further in §3.3.4, where unaccented compounds are discussed.

Finally, the descriptive generalization in (21) has a further advantage in allowing us to capture the fundamental similarity between the compound accent rules and the accent rule for simplex nouns, i.e. the antepenultimate rule given in (10a). In fact, the antepenultimate rule has basically the same effects as the rule in (21b), as can be seen from the foot structure of the loanwords in (25) (= (10b)). This is not accidental, but simply reflects the fact that the accent rule for accented simplex nouns and that for morphologically complex nouns have basically the same nature: they both put an accent maximally towards the end of the word (edgemostness), while avoiding the final position aligned with the right edge of the word (non-finality).

(25) [bá.na]na wa[sin][ton]
[ká.na]da [ba.do][min][ton]
o[rén]zi [pai][náp][pu.ru]

In sum, the accent rules for compound nouns and the rule for accented simplex nouns only differ in (21a): simplex words are free from this faithfulness principle, which is a natural consequence resulting from the morphological non-complexity of simplex nouns.

3.3 *Unaccented words*

I have so far deferred the discussion of unaccented words, words that are pronounced with a flat pitch pattern even when a particle is attached to them. About half of the vocabulary of Tokyo Japanese belongs to this accent category (Hayashi 1982: 331). Presence or absence of a lexical pitch accent is contrastive, and in fact accounts for most homophonous word pairs that can be accentually distinguished: e.g. /áme/ 'rain' *vs.* /ame°/ 'candy', /haná/ 'flower' *vs.* /hana°/ 'nose', /sénsi/ 'soldier' *vs.* /sensi°/ 'death in battle'. The main question in this research area then is when the seemingly peculiar class of unaccented words occurs and to what extent their distribution can be predicted by linguistic factors.

The distinction between accented and unaccented words seems arbitrary and item-specific in the native and SJ strata of the lexicon, as can be seen from the homophonous word pairs given above and below: /náru/ 'to be completed' *vs.*

(34)	a.	*Tone A*	
		A.ka	'red'
		a.KA-pen	'red pen'
		a.ka-SIN.goo	'red signal'
		aka-en.PI.tu	'red pencil'
		aka-en.pi.tu-MON.dai	'red pencil problem'
	b.	*Tone B*	
		a.O	'blue, green'
		a.o-PEN	'blue pen'
		a.o-sin.GOO	'green signal'
		a.o-en.pi.TU	'blue pencil'
		a.o-en.pi.tu-mon.DAI	'blue pencil problem'

This rule is, in a sense, a mirror-image of the compound accent rule in Tokyo Japanese. In Tokyo, the compound accent rule only considers the phonological structure of the final constituent (N_2), so that compounds basically take one and the same accent pattern if they share an N_2 (see (20) and (27), for example).

Kagoshima Japanese employs the opposite strategy, whereby it considers the initial constituent, keeping its prosodic feature in compounds. Interestingly, the tonal feature of the initial morpheme is realized at the very end of the compound in this system. Take the two morphemes /A.ka/ and /a.O/ in (34), for example. Compound nouns starting with /A.ka/ bear a high pitch on their penultimate syllable, no matter how long they may be. Similarly, compounds starting with /a.O/ are high-pitched on their final syllable. Since compound nouns can consist of three or more morphemes and hence can be very long, the speaker must remember the tonal property of the initial morpheme up to the very end of long expressions.

Finally, Hirayama's Law also applies to phrasal expressions in Kagoshima Japanese. As illustrated in (35), basic syntactic phrases (*bunsetsu*), consisting of a content word plus one or more particles, undergo the compound tone rule. Thus syntactic phrases beginning with a Tone A morpheme all take Tone A, realizing a high pitch on the penultimate syllable within the phrasal domain. Similarly, those beginning with a Tone B morpheme all take Tone B, with a high pitch on their very final syllable.

(35)	a.	A.ka	'red'
		a.KA-ga	'red-NOM'
		a.ka-KA.ra	'from red'
		a.ka-SIN.goo	'red signal'
		a.ka-sin.GOO-ga	'red signal-NOM'
		a.ka-en.PI.tu	'red pencil'
		a.ka-en.pi.tu-KA.ra	'from (the) red pencil'
	b.	a.O	'blue, green'
		a.o-GA	'blue-NOM'
		a.o-ka.RA	'from blue'
		a.o-sin.GOO	'green signal'
		a.o-sin.goo-GA	'green signal-NOM'
		a.o-en.pi.TU	'blue pencil'
		a.o-en.pi.tu-ka.RA	'from (the) blue pencil'

b.	*Tone B*		
	O.to.KO	(o.to.KO)	'man'
	NI.WA.to.RI	(ni.wa.to.RI)	'chicken'
	NI.WA.toI	(ni.wa.TOI)	'chicken (coll. form)'
	SEN.seI	(sen.SEI)	'teacher'
	HA.RU.YA.su.MI	(ha.ru.ya.su.MI)	'spring vacation'

The basic rule employed here is to start words with a high pitch and have one low-pitched portion before the second peak starts (Kubozono 2008a).[21] In autosegmental terms, this means that high tone cannot spread onto a syllable that is adjacent to another high tone.[22] This is true of both tonal types, Tone A and Tone B, which are differentiated basically by the loci of the second peak. It must be noted in this connection that the low-pitched portion is a syllable-sized unit rather than a mora, as shown by the following forms.

(42)	a.	KE.da.MOn	'wild animal'
		KE.da.MOn-ga	'wild animal-NOM'
		KE.DA.mon-KA.ra	'from (the) wild animal'
	b.	E.FU.bii.Ai	'FBI'
		E.FU.bii.Ai-ga	'FBI-NOM'
		E.FU.BII.ai-KA.ra	'from FBI'

There are two interesting facts to note about the second peak. One of them is the fact that non-syllabic moras like the moraic nasal and the second member of long vowels and diphthongs can form the second peak in Tone B words, but not in Tone A words. Thus, word-final moras in /mi.kan/ in (40b), /ni.wa.toi/ and /sen.sei/ in (41b), constitute a second peak on their own, but the penultimate moras in /ke.da.mon-ga/ and /e.fu.bii.ai-ga/ in (42) cannot.[23] In the latter case, the high pitch moves one mora to the left, so that the antepenultimate mora constitutes the second peak on its own. In both Tone A and Tone B, the second peak is always monomoraic, but the two tonal patterns exhibit an asymmetry.

This asymmetry is interesting in itself, but more interesting is the fact that the first peak is always dependent on the second peak. Compare the two forms in (43), the second of which is a colloquial form of the first.

(43)	a.	KE.DA.mo.NO-ga	'wild animal-NOM'
	b.	KE.da.MOn-ga	

Although these two forms consist of the same number of moras, the first high pitch is on /ke.da/ in (43a), but on /ke/ in (43b). This difference directly reflects the difference in the second peak, which is on /no/ in (43a), but on /mo/ in (43b). This indicates that the domain of the first high pitch can be computed on the

21 Kubozono's (2008a) work is based on his fieldwork data obtained in Teuchi, a small village located at the southern edge of the Koshikijima Islands.

22 Myers (1990) reports a similar phenomenon in Shona, a Bantu language spoken in Zimbabwe.

23 Consequently, the penultimate mora is high in /KE.DA.mo.NO-ga/ 'wild animal-NOM', but the antepenultimate mora is high in its colloquial form /KE.da.MOn-ga/.

basis of the position of the second peak. The whole strategy can be summed up as follows.

(44) a. Assign a high pitch (second peak) to the final mora in Tone B words and to the penultimate mora in Tone A words.
b. If the second peak is on a non-syllabic mora in Tone A words, the peak moves one mora to the left, i.e. to the syllabic mora of the same syllable.
c. Keep one syllable low-pitched before the second peak.
d. Assign a high pitch (first peak) to word-initial syllables up to the low-pitched syllable defined in (c).

This right-to-left computation means that the second peak phonologically dominates the first peak. This may not be very surprising in itself, but its real significance lies in the fact that the dominance relationship between the two peaks is reversed in sentence-level phonology. In a sequence of phrases, every phrase except the sentence-final one can have only one peak and it is always the second peak that disappears (Kubozono 2008a). This is illustrated in (45), where some nouns in (41) are followed by the nominative marker /ga/ and put in the carrier sentence /...ga mieta/ '...was seen' (/mi.e.ta/ is a Tone B verb). The forms in parentheses represent the tonal forms when the noun-NOM phrases are pronounced in isolation.

(45) a. *Tone A*

KE.DA.mo.no-ga MI.e.TA	'a wild animal was seen'
(KE.DA.mo.NO-ga)	'wild animal-NOM'
KE.da.mon-ga MI.e.TA	'a wild animal was seen'
(KE.da.MOn-ga)	'wild animal-NOM (coll)'

b. *Tone B*

NI.WA.TO.ri-ga MI.e.TA	'a chicken was seen'
(NI.WA.TO.ri-GA)	'chicken-NOM'
NI.WA.toi-ga MI.e.TA	'a chicken was seen (coll)'
(NI.WA.toi-GA)	'chicken-NOM (coll)'

Words and phrases thus lose one of their two high-pitched portions when they appear in the non-final position of a sentence. It is of special interest that a phonologically dominant peak (the second peak) is defeated by a less dominant peak (the first peak) in sentence-level phonology.

6 Conclusion

In this chapter we have considered some pitch accent systems of Japanese, focusing on the major debates and findings in the past and present. The first half of the chapter discussed the accent system of Tokyo Japanese, the dialect most extensively studied in the literature of Japanese phonetics and phonology. One of the most important findings about this dialect is that accent patterns, including the unaccented one, can be predicted by the linguistic structure of words. Another crucial point is that many seemingly different accent rules can be generalized if we incorporate the foot as a relevant prosodic unit in the language. Specifically, the so-called antepenultimate accent rule and the set of compound accent rules can be generalized with one another and can be expressed by general notions such as non-finality and edgemostness.

The second half of the chapter described the pitch accent systems of Kagoshima and Koshikijima Japanese, to illustrate the diversity of prosodic systems in the language. Unlike Tokyo Japanese, these dialects have a two-pattern system, a system that exhibits only two distinctive pitch patterns irrespective of the length of the word.

There are many important issues that must be addressed in the future. In empirical studies, the most important issue concerns endangered dialects and their prosodic systems. While some dialects such as Tokyo Japanese and Kagoshima Japanese have been studied in considerable depth in the literature, there are many regional dialects that remain largely unstudied or even undocumented. Extensive data must be collected about these dialects before they become extinct. Serious analyses of these dialects may shed a new light on the typology of Japanese pitch accent systems, as well as on the typology of prosodic systems in general. It is equally important to look at the endangered dialects from a sociolinguistic perspective, by examining how their pitch accent systems change under exposure to standard Tokyo Japanese.

There are also interesting questions that remain unanswered about the theoretical aspect of Japanese pitch accent. One of them is how to formalize pitch accent rules of the language in the non-derivational framework of Optimality Theory (Kubozono 1995, 1997; Katayama 1996; Shinohara 2000). How to account for the underspecification of lexical accent in a theoretical framework is also an important issue for future work.

121 Slavic Palatalization

Jerzy Rubach

1 Introduction

Slavic languages more than any other languages contribute to the understanding of palatalization processes (see also CHAPTER 71: PALATALIZATION). The historical source language – Common Slavic – exhibited several different types of palatalization, and these are reflected in the phonology of its descendants. Palatalization can affect all consonants, producing changes that are either allophonic or phonemic. The determination of whether a change is allophonic or phonemic depends on the system of contrasts in a given language. Looking at /s z t d/ as examples, the identical outcomes have a different status in Russian and Polish. I call the type of palatalization exhibited in (1) Surface Palatalization. The environments are discussed in §2.

(1) *Surface Palatalization*

a. *Russian (phonemic palatalization)*
s z t d → s^j z^j t^j d^j

b. *Polish (allophonic palatalization)*
s z t d → s^j z^j t^j d^j

The difference between (1a) and (1b) is that palatalized consonants are members of the phonemic inventory in Russian but not in Polish. In Polish, a phonemic effect of palatalization for the inputs in (1) yields prepalatal fricatives and affricates. I call this process Coronal Palatalization.[1]

(2) *Coronal Palatalization in Polish*
s z t d → ɕ ʑ tɕ dʑ

How is it possible for Polish to have both types of palatalization: allophonic (1b) and phonemic (2)? The question is intriguing because the environments in which

[1] Coronal Palatalization did not exist in Common Slavic. It is a later development that occurred in some Slavic languages.

(1b) and (2) apply are virtually the same (see §2). Answering this question is a challenge for the researcher, regardless of what theoretical framework is assumed.

Velars can undergo two different kinds of palatalization in addition to Surface Palatalization (3a). I will identify them by the traditional names: First Velar Palatalization and Second Velar Palatalization. The example in (3) is the velar stop /k/.

(3) a. *Surface Palatalization*
k → kʲ
b. *First Velar Palatalization*
k → ʧ
c. *Second Velar Palatalization*
k → ts

The challenge is how to distinguish the three kinds of palatalization in (3) when they occur in overlapping environments in a single language.[2] The problem is compounded by the fact that the outputs of First Velar Palatalization and Second Velar Palatalization do not always bear the feature [−back] that is expected to characterize the outcome of a palatalization process.

Palatalization processes may differ in different Slavic languages in all four relevant ways: with regard to the input, the output, the environment, and the domain. For example, in Polish, the inputs to Coronal Palatalization (2) are dental fricatives, stops, and sonorants, while in Slovak, the class of inputs is limited to /t d n l/. In Czech, on the other hand, the inputs are /t d n r/, so /r/ but not /l/ undergoes palatalization.

Looking at /t d/ as examples of inputs to Coronal Palatalization, the outputs in Slovak and Czech are the prepalatal stops [t̠ʲ d̠ʲ], where underlining denotes that the stops are prepalatal rather than dental. In Eastern Polish /t d/ change into dental affricates [tsʲ dzʲ], whereas in Standard Polish they change into prepalatal affricates [tɕ dʑ].

The environments for palatalization are invariably front vowels and glides (see also CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS), but languages differ from each other with regard to their front vowel inventory. For example, Slovak has three front vowels /i ɛ æ/ and, predictably, they all cause palatalization (see §4). Russian lacks /æ/, so its palatalization triggers are the vowels /i ɛ/. More intriguing is the situation where only a subset of front vowels in a given language induces palatalization. This is exemplified by Ukrainian, which has /i ɛ/, but only /i/ triggers palatalization. Similarly, Polish Surface Palatalization applies only before /i/ (and /j/) but not before /ɛ/ (see §2). Finally, palatalization before front vowels may be different from palatalization before /j/, a process that is called Iotation (Steele 1973). This is illustrated in (4), where I look at dental obstruents in Polish.

(4) a. *Coronal Palatalization in Polish*
s z t d → ɕ ʑ tɕ dʑ / __ i ɛ

b. *Iotation in Polish*
s z t d → ʃ ʒ ts dz / __ j

[2] The example here is Polish. The added difficulty is that [ʧ] and [ts] are hard (velarized) rather than soft (palatalized) consonants. See the discussion in §4.

§4 illustrates how palatalization and related processes can be analyzed in the current phonological theory. The paradigm selected for the analysis is Optimality Theory. For a review of the data and descriptive generalizations referring to particular Slavic languages, the reader is referred to the collection of studies in de Bray (1980) and Comrie and Corbett (1993).

2 Inventories

This section reviews types of consonants in Slavic languages that are products of palatalization as a historical process. The contexts considered here make it impossible to derive these consonants from their original historical sources. The consequence is that the consonants are phonemes, that is, underlying segments.

Descriptive grammars of Slavic languages draw a distinction between "soft" and "hard" consonants. Soft consonants are a product of palatalization, either historically or synchronically in the contemporary Slavic languages. Other consonants are hard. The point is illustrated by Russian. Soft consonants exhibit palatalization whereas hard consonants show velarization. There are no neutral consonants that would be neither palatalized nor velarized. Palatalization and velarization are secondary articulations as the raising of the tongue body that they involve is a gesture that does not affect the primary place of articulation. For example, the soft [d^j] and hard [d] in *d'ad'a* 'uncle' and *da* 'yes', respectively, are dental rather than palatal or velar. Palatalization means that, in the example at hand, the production of the dental stop is accompanied by the simultaneous raising of the front part of the tongue toward the hard palate. Velarization is the raising of the back part of the tongue toward the velum. In terms of distinctive features, palatalized consonants are [−back], while velarized consonants are [+back], a distinction that reflects the part of the tongue that is raised. I will follow the Slavic tradition in leaving velarization unmarked, so [d^j] is palatalized while [d] is velarized.

In the typical case, velarized and palatalized consonants are paired, that is, they constitute minimal or near-minimal pairs that contrast in terms of [±back]. This is illustrated by Russian labials and dentals (Halle 1959; Avanesov 1968).[5]

(5) *Velarized–palatalized contrasts in Russian*

[p]	*pat*	'stalemate'	[p^j]	*p'at'*	'five'
[b]	*burak*	'beetroot'	[b^j]	*b'uro*	'office'
[f]	*forma*	'form'	[f^j]	*šof'or*	'driver'
[v]	*vazon*	'vase'	[v^j]	*v'az*	'elm'
[m]	*maslo*	'butter'	[m^j]	*m'aso*	'meat'
[t]	*tot*	'that'	[t^j]	*t'ot'a*	'aunt'
[d]	*da*	'yes'	[d^j]	*d'ad'a*	'uncle'
[s]	*sud*	'court'	[s^j]	*s'uda*	'here'
[z]	*zad*	'back'	[z^j]	*z'at'*	'son-in-law'
[l]	*luk*	'bow'	[l^j]	*l'uk*	'hatch'
[r]	*rasa*	'race'	[r^j]	*r'asa*	'cassock'

[5] I use the term "dental" to refer to both dentals proper and alveolars. That is, dentals are [+anterior] coronals.

skład	[t]	'storage room'	*składzi+e*	[dʑɛ]	(LOC SG)
			składz+ik	[dʑi]	(DIM)
brud	[t]	'dirt'	*brudzi+e*	[dʑɛ]	(LOC SG)
			brudz+i+ć	[dʑi]	'to make dirty'
kran	[n]	'faucet'	*krani+e*	[ɲɛ]	(LOC SG)
			kran+ik	[ɲi]	(DIM)
dzwon	[n]	'bell'	*dzwoni+e*	[ɲɛ]	(LOC SG)
			dzwon+i+ć	[ɲi]	'to ring'

The palatalization of velars is ascribed to two different rules that apply to the same set of targets but yield different results. Following the traditional parlance, I will refer to these rules as First Velar Palatalization and Second Velar Palatalization. The latter is restricted morphologically, making the former the default palatalization for velars.

First Velar Palatalization turns velars into post-alveolar stridents. This is illustrated by Kashubian, where the outputs are soft segments, as would be expected of a palatalization process (Breza and Treder 1981, Treder 2001, and my fieldwork).

(18) *Kashubian First Velar Palatalization*

k g x → tʃʲ dʒʲ ʃʲ / __ i ɛ

kalek+a	[k]	'invalid'	*kalecz+i*	[tʃʲi]	(NOM PL)
drog+a	[g]	'road'	*drodż+i*	[dʒʲi]	(NOM PL)
much+a	[x]	'fly (N)'	*musz+i*	[ʃʲi]	(NOM PL)
bek	[k]	'bleating'	*becz+e+ć*	[tʃʲɛ]	'to bleat'

Second Velar Palatalization yields dental rather than post-alveolar stridents. In Ukrainian, underlying /k ɣ x/ surface as [tsʲ zʲ sʲ] before the suffix /i/ of the dative/locative singular (Medushevs'kyj and Zyatovs'ka 1963; Bilodid 1969; Rusanovs'kyj *et al.* 1986).

(19) *Ukrainian Second Velar Palatalization*

k ɣ x → tsʲ zʲ sʲ / __ i $]_{\text{DAT/LOC}}$

nom sg		*dat/loc sg*		
ruk+a	[k]	*ruc+i*	[tsʲi]	'hand'
noh+a	[ɦ][12]	*noz+i*	[zʲi]	'leg'
much+a	[x]	*mus+i*	[sʲi]	'fly'

First Velar Palatalization and Second Velar Palatalization are active in all Slavic languages with the exception of Russian, which has the former but not the latter rule. Since the two rules are in competition if velars are inputs, the conflict is resolved by introducing partial morphological conditioning of Second Velar Palatalization. In Ukrainian, the morphological context is that of the dative and the locative declension cases. Other Slavic languages may be subject to other morphological limitations. For example, in Polish, Second Velar Palatalization applies before the /i/ suffix of the nominative plural, the /ɛ/ suffix of the dative and the locative singular (as in Ukrainian) and before the adverb-forming /ɛ/ suffix (see Rubach 1984).

[12] I assume that the surface laryngeal [ɦ] derives from the voiced velar fricative /ɣ/. The arguments parallel those for Slovak /ɣ/ → [ɦ] presented in Rubach (1993).

(30) rux+i+tɕ

ruʃʲitɕ	First Velar Palatalization	x → ʃʲ / __ i
ruʃitɕ	Hardening	ʃʲ → ʃ
ruʃɨtɕ	Retraction	i → ɨ after a hard consonant

The operation of First Velar Palatalization in Polish is not limited to /x/ → [ʃ]. It extends to all velars, as the following examples show.

(31) *Polish velar stops*

a.	*voiceless stop*: k → ʧ					
	krok	[k]	'step (N)'	*krocz+ek*	[ʧ+ɛ]	(DIM)
	skok	[k]	'jump (N)'	*skocz+y+ć*	[ʧ+ɨ]	'to jump'
b.	*voiced stop*: g → ʤ					
	mózg	[k]	'brain'	*móżdż+ek*	[ʤ+ɛ]	(DIM)
	miazg+a	[g]	'pulp'	*miażdż+y+ć*	[ʤ+ɨ]	'to squash'
c.	*voiced stop*: g → ʒ					
	Bóg	[k]	'God'	*Boże*	[ʒ+ɛ]	(VOC SG)
	śnieg	[k]	'snow'	*śnież+ek*	[ʒ+ɛ]	(DIM)
				śnież+y+ć	[ʒ+ɨ]	'to snow'
	sług+a	[g]	'servant'	*służ+eb+n+y*	[ʒ+ɛ]	(ADJ)
				służ+y+ć	[ʒ+ɨ]	'to serve'

The data in (27), (31a), and (31b) show that Polish First Velar Palatalization is the same as Kashubian First Velar Palatalization (18), but the parallel is obscured by Hardening: /ʃʲ ʧʲ ʤʲ/ → [ʃ ʧ ʤ]. The data in (31c) add a new generalization: /ʤ/ is spirantized to [ʒ]. The rule applies if the segment preceding /ʤ/ is a sonorant, hence we see [ʒ] in *śnież+ek* but [ʤ] in *móżdż+ek* in (31c) and (31b), respectively. The [ʒ] derived from /ʤʲ/ is hard, showing that hardening affects all post-alveolars.

(32) *Polish Hardening*

ʃʲ ʒʲ ʧʲ ʤʲ → ʃ ʒ ʧ ʤ

Polish also has a process of Spirantization. Since there is no way to tell whether the rule applies before or after Hardening, the choice between /ʤʲ/ → [ʒʲ] and /ʤ/ → [ʒ] is arbitrary. Assuming that the latter is true, the rule is stated schematically as follows (Rubach 1984).

(33) *Polish Spirantization*

ʤ → ʒ / [+son] __

Spirantization is a derived environment rule in the sense that it applies only to the /ʤ/ that is a result of First Velar Palatalization. The /ʤ/ that comes from the underlying representation resists Spirantization. This is exactly what Kiparsky's (1973, 1982) Derived Environment Constraint (DEC) predicts (see CHAPTER 88: DERIVED ENVIRONMENT EFFECTS). Its instantiation that is relevant here refers to phonologically derived segments. In (34), I look at the derivation of *Boż+e* 'God (VOC SG)' and *brydż* 'bridge (card game)', whose underlying representations are representations because we find velarized rather than palatalized consonants as outputs of palatalization.

The opacity of palatalization is also manifested by the fact that palatalization processes appear to have exceptions in the surface representation. That is, they are not surface true. The problem is illustrated by Polish.

Recall that Polish Coronal Palatalization turns, among other consonants, /s z t d/ into [ɕ ʑ tɕ dʑ] before front vowels, as documented in (17). The process is not observed on the surface in hundreds of words of both native and foreign origin.

(40) *"Exceptions" to Polish Coronal Palatalization*

a.	*ser*	[sɛ]	'cheese'		
	zegar	[zɛ]	'clock'		
	deszcz	[dɛ]	'rain'		
b.	*seps+a*	[sɛps+a]	'sepsis'	*sepsi+e*	[sɛpɕ+ɛ] (LOC SG)
	zez	[zɛs]	'squint'	*zezi+e*	[zɛʑ+ɛ] (LOC SG)
	internet	[intɛrnɛt]	'Internet'	*interneci+e*	[intɛrnɛtɕ+ɛ] (LOC SG)
	dywidend+a	[divʲidɛnd+a]	'dividend'	*dywidendzi+e*	[divʲidɛɲdʑ+ɛ] (LOC SG)

It appears that the words in (40a) are simply exceptions to Coronal Palatalization and should be encoded as such in the lexical representation. This reasoning is faulty, however. The words in (40b) appear to be simultaneously exceptions and regular inputs to Coronal Palatalization. Looking at the word for 'squint', the underlying representation of the locative singular form is /zɛz+ɛ/, with two instances of /z/ followed by /ɛ/. The surface effect is contradictory: one /z/ palatalizes to [ʑ] but the other does not: [zɛʑ+ɛ]. If the morpheme /zɛz/ were an exception, then none of the /z/s should palatalize, yielding *[zɛz+ɛ]. On the other hand, if /zɛz/ were a regular input to Coronal Palatalization, then both of the /z/s should palatalize before /ɛ/, yielding *[ʑɛʑ+ɛ]. Since none of these predictions is true, the generalization concerning Coronal Palatalization must be different from the default assumption that the rule applies whenever its environment is met.

As mentioned above, Kiparsky (1973, 1982) observes that phonological rules may be sensitive to derived environments. The part of the Derived Environment Constraint that is relevant here refers to morphologically derived environments, that is, to concatenations of segments that arise due to the application of a word formation rule. In effect, then, the Derived Environment Constraint limits the application of the rule to the portion of the string that strides a morpheme boundary. This requirement is fulfilled by the second /z/ and /ɛ/ in /zɛz+ɛ/, because the input /z/ and the environment /ɛ/ occur across a morpheme boundary: /z+ɛ/. This structure counts as "derived" because it is not found in the morpheme /zɛz/ listed in the lexicon. Rather, the input to Coronal Palatalization is derived via the application of the word formation rule (WFR) that adds the locative singular suffix /ɛ/. Schematically:

Standard Polish (17). Recall that Slovak coronals surface as prepalatals, as in *advokat* [t] 'lawyer' – *advokat+ik* [t̠ʲ] (DIM). The observation is that palatalization induces a shift in the place of articulation from [+anterior], which characterizes dentals, to [–anterior], which characterizes posteriors. The markedness constraint enforcing this change is Posterior (Rubach 2003a).

(48) Posterior
Palatalized coronals must be [–anterior].

The change from [+anterior] to [–anterior] that Posterior asks for violates the faithfulness constraint Ident[+anterior].

(49) Ident[+anterior]
[+anterior] on an input consonant must be preserved as [+anterior] on a correspondent of that consonant in the output.

The effect of Coronal Palatalization in Eastern Polish is different from that found in Slovak: dental stops are affricated without changing the place of articulation, as shown by the alternation *bat* [bat] 'whip' – *bac+ik* [batsʲik]. Affrication is enforced by Stridency (Rubach 2003a) at the cost of violating the faithfulness constraint Ident[–strident], both of which are stated in (50).

(50) a. Stridency
Palatalized coronals must be [+strident].[24]

b. Ident[–strident]
[–strident] on an input consonant must be preserved as [–strident] on a correspondent of that consonant in the output.

The pattern attested in Standard Polish, /t/ → [tɕ], as in *bat* [bat] 'whip' – *bac+ik* [batɕik] (DIM), is a combined effect of Posterior and Stridency.

The various permutations of these constraints generate the outputs found in Slovak (51), Eastern Polish (52), and Standard Polish (53). The Russian example from (47) is repeated in (54) to clarify how the evaluation works once Posterior and Stridency have been added to the constraint set. To keep the tableaux within reasonable bounds, I ignore the faithfulness constraints in (46) and the candidates that would violate them (see the interaction displayed in (47) above).

(51) *Coronal Palatalization effects in Slovak*: advokat+ik 'lawyer (DIM)'
No affrication, so Ident[–strid] >> Stridency, but a change of the place of articulation, so Posterior>> Ident[+ant].

/advɔkat+ik/	Pal-*i*	Posterior	Ident[+ant]	Ident[–strid]	Strid
a. advɔkatik	*!				
b. advɔkatʲik		*!			*
c. advɔkatsʲik		*!			
☞ d. advɔkat̠ʲik			*		*
e. advɔkatɕik			*	*!	

[24] Since strident sonorants are universally unattested, GEN does not submit for evaluation candidates that contain such segments. That is, the prohibition against strident sonorants is a constraint on GEN.

(52) *Coronal Palatalization effects in Eastern Polish*: bac+ik 'whip (DIM)'

Affrication, so Stridency >> Ident[−strid], but no change of the place of articulation, so Ident[+ant] >> Posterior.

/bat+ik/	Pal-*i*	Ident[+ant]	Posterior	Strid	Ident[−strid]
a. batik	*!				
b. batʲik			*	*!	
☞ c. batsʲik			*		*
d. bat̠ʲik		*!		*	
e. batɕik		*!			*

(53) *Coronal Palatalization effects in Standard Polish*: bac+ik 'whip (DIM)'

Affrication, so Stridency >> Ident[−strid] and a change of the place of articulation, so Posterior >> Ident[+ant].

/bat+ik/	Pal-*i*	Posterior	Ident[+ant]	Strid	Ident[−strid]
a. batik	*!				
b. batʲik		*!		*	
c. batsʲik		*!			*
d. bat̠ʲik			*	*!	
☞ e. batɕik			*		*

(54) *Coronal Palatalization effects in Russian*: brat+ik 'brother (DIM)'

No affrication, so Ident[−strid] >> Stridency and no change of the place of articulation, so Ident[+ant] >> Posterior.

/brat+ik/	Pal-*i*	Ident[+ant]	Posterior	Ident[−strid]	Strid
a. bratik	*!				
☞ b. bratʲik			*		*
c. bratsʲik			*	*!	
d. brat̠ʲik		*!			*
e. bratɕik		*!		*	

Standard Polish challenges OT by admitting two contradictory patterns: Coronal Palatalization and Surface Palatalization. This is exemplified by near-minimal contrastive pairs in (55).

(55) *Polish Coronal Palatalization and Surface Palatalization*

a.	*but*	[t]	'shoe'		*buc+ik*	[tɕi]	(DIM)
				vs.	*but Iwana*	[tʲ#i]	'Ivan's shoe'
b.	*głos*	[s]	'voice'		*głos+ik*	[ɕi]	(DIM)
				vs.	*głos Iwana*	[sʲ#i]	'Ivan's voice'
c.	*kran*	[n]	'faucet'		*kran+ik*	[ɲʲi]	(DIM)
				vs.	*kran Iwana*	[nʲ#i]	'Ivan's faucet'

Classic OT cannot account for the contrast in (55) because of a ranking paradox. In order to generate /t/ → [tɕ] in (55a), POSTERIOR and STRIDENCY must dominate IDENT[+ant] and IDENT[−strid], respectively, as shown in (53). But, in order to generate /t/ → [tʲ], the ranking of the constraints must be exactly the opposite: IDENT[+ant] and IDENT[−strid] must outrank POSTERIOR and STRIDENCY, respectively.

The problem with classic OT is that it assumes strict parallelism as one of its fundamental governing principles. Strict parallelism forbids any form of derivationalism, so all evaluation must be carried out simultaneously (McCarthy and Prince 1995; Prince and Smolensky 2004). This tenet is rejected by Derivational Optimality Theory (DOT), a phonological framework developed in the work of Kiparsky (1997, 2000), Rubach (1997, 2000a, 2000b, 2003b, 2004) and others. DOT admits three derivational levels, which are defined morphologically: the stem level, the word level, and the post-lexical level.[25] (The latter takes constituents produced by syntactic operations as its domain, so these constituents are larger than words.) Each level constitutes a separate system with its own constraint ranking. This means that constraints can be reranked between levels, albeit the reranking must be minimal (Rubach 2000b). The winning candidate from an earlier level becomes the input to a later level, its "new underlying representation." The IDENT constraints take this new input as their point of reference for penalizing the disparity between the input and the output. In sum, each level in DOT constitutes a miniphonology with its own inputs and constraint ranking. These are exactly the assumptions that we need in order to account for the Polish data in (45). From the point of view of these data, the relevant distinction is between the word level and the post-lexical level. The input to the post-lexical level is the winner from the word level, and the constraints can be reranked. The ranking paradox encountered by classic OT is now easily resolved.

At the word level, the constraint ranking is as in (53), with POSTERIOR and STRIDENCY mandating the change of the place of articulation and affrication. The input /but+ik/ 'shoe' (DIM) has [butɕik] as its optimal output, exactly as in (53). At the word level, the phrase *but Iwana* 'Ivan's shoe' does not exist. Rather, we have a separate evaluation for each word: one for *but* and the other for *Iwana*, a tenet that DOT has inherited from Lexical Phonology. Since *but* and *Iwana* are not a constituent at the word level, /t/ is not before /i/, so PAL-*i* is not activated.

The situation is different at the post-lexical level. Now the rules of syntax have put together *but* and *Iwana*, which form a phrase and the phrase is subject to evaluation. The /t/ of *but* in *but Iwana* is before /i/, so PAL-*i* is activated. The faithful candidate [but#ivana] is excluded by PAL-*i* because [t] is hard, that is [+back], and [i] is front, that is [−back], so there is no agreement in the value for [±back]; we witness a violation of PAL-*i*. The candidate [butsʲ ivana] is eliminated by IDENT[−strid] >> STRIDENCY. These constraints have changed places at the post-lexical level, where affrication is not longer optimal. At the word level, they were ranked STRIDENCY >> IDENT[−strid] in order to obtain [tɕ] from /t/ in *buc+ik* 'shoe (DIM)'. The candidate [bu t̠ʲ ivana], with prepalatal [t̠ʲ], loses as well. It violates IDENT[+ant], which dominates POSTERIOR at the post-lexical level. This too is a case of reranking because POSTERIOR >> IDENT[+ant] derives [tɕ] from /t/ in *buc+ik* at the word level. To conclude, the word level ranking of the constraints is the

[25] The similarity between DOT and Lexical Phonology (see footnote 22) is not accidental. For discussion, see Kiparsky (1997, 2000), Rubach (1997, 2000a, 2000b), and Bermúdez-Otero (1999).

Classic OT is unable to solve the ranking paradox in (54) *vs.* (57).[27] In contrast, DOT has no difficulty dealing with these data. At the word level, the Russian response to PAL-*i* is Surface Palatalization, so IDENT-V[−back] is ranked above IDENT-C[+back], as in (54). At the post-lexical level, the response is Retraction, so the constraints are reranked to IDENT-C[+back] >> IDENT-V[−back], as in (57).

6 Conclusion

Slavic languages exhibit complex but regular patterns of palatalization, which uphold the bifurcation of the inventory into hard and soft segments, a bifurcation that is observed in numerous Slavic languages. The distinction between these classes of segments is necessary for morphology (assignment of declension paradigms), so it must exist at the underlying level. This view is supported by phonology since soft segments may occur in environments in which they cannot be derived from hard segments: before back vowels or at the end of the word.

Not all soft segments found in the surface representations come directly from underlying representations. There is solid evidence that in many instances soft segments are derived from hard segments via productive palatalization processes. These processes induce a variety of surface effects, ranging from palatalization as a secondary articulation to palatalization as a change in the place and/or manner of articulation.

Palatalization leads to much opacity in the surface representations, but this does not pose a serious analytical problem. Rather, it is a natural consequence of the interaction between independent generalizations.

OT can make excellent sense of the typological differences regarding both inventories and processes in various Slavic languages. The reason for the success is that OT uses universal constraints and claims that the permutation of these constraints generates different languages (factorial typology). The palatalization material discussed here upholds this claim and adds to it by showing that OT must admit derivational levels, making DOT rather than classic OT the better framework of analysis.

122 Slavic Yers

Tobias Scheer

1 Introduction

Yers is the name given to two vowels of Common Slavic (CS) that represent Indo-European short *i* (CS *vьdova = Lat. *vidua* 'widow') and short *u* (CS *dъva = Lat. *duo* 'two'), which is also the value that they had in CS. Textbook descriptions hold that by the end of the CS period, i.e. around the ninth century, ь and ъ first became centralized and extra short, before being lost altogether in certain positions. They appear in Old Church Slavonic documents, which have been available since the tenth century, but depending on the geographic origin (and invariably in more recent sources) there is evidence that the scribes no longer had access to their original forms (etymologically inconsistent use; confusion between ь and ъ). In modern Slavic languages, yers are represented by different vowels, which typically alternate with zero. This is due to the language-specific vocalization of yers that has occurred after the dialectal differentiation of CS into individual Slavic languages, which may (e.g. Eastern Slavic, Bulgarian) or may not (most of Western Slavic, Bosno-Croato-Serbian) continue to distinguish the original front–back opposition: in Russian for example, *e* represents ь, while *o* derives from ъ (CS dьnь, sъnъ > *d'en'* 'day', *son* 'dream'); and both yers have merged in Czech (> *den*, *sen*) and Bosno-Croato-Serbian (BCS) (> *dan*, *san*).

The diachronic situation is described at length in the traditional literature (e.g. Shevelov 1964: 432ff.; Carlton 1991: 165ff.), and we will not be concerned with it in any further detail in this chapter (except on the occasion of an excursus in §5 and §6.1). Rather, we will concentrate on the consequences of the loss of yers for the phonology of modern Slavic languages, and on their relevance for phonological theory. In the literature on Slavic, yers are typically associated with particular phenomena that are considered to be specifically Slavic. As a consequence, yer-related phenomena have been confined to the phonology of Slavic languages. For example, the literature often talks about yer vowels when describing vowel–zero alternations in Slavic; nobody would talk about yer vowels when it comes to the description of vowel–zero alternations in, say, French (on which see also CHAPTER 26: SCHWA): yers are a phenomenon specific to Slavic phonology.

We will see that the practice of considering yers to be Slavic-specific items is unwarranted, as it impedes phonological insight: Slavic vowel–zero alternations may have come into being on the grounds of vowels that have only existed in Slavic, but they are controlled by the same grammatical principles that are responsible for vowel–zero alternations and other processes in other languages. That is, the Lower rule, which has acquired some notoriety outside Slavic phonology, but is typically thought of as an analysis of a specifically Slavic phenomenon, is no more Slavic than, say, palatalization. The goal of this chapter is to show that Slavic vowel–zero alternations (i.e. yers) can contribute valuable insight into phonological theory, provided that the Slavic bias is abandoned.

2 Vowel–zero alternations: The basic pattern

2.1 *Alternating* vs. *non-alternating vowels, insertion* vs. *deletion*

A general property of Slavic vowel–zero alternations is that whether a vowel alternates with zero or not cannot be predicted from its phonetic or contrastive properties. Some illustration is given under (1) below.[1]

(1) *Alternating and non-alternating vowels of the same quality*

	alternating		*non-alternating*	
	CvC	CøC-V	CvC	CvC-V
Russian	ku'sok	kusø'k-a	ra'bot	ra'bot-a
	'piece (NOM SG/GEN SG)'		'work (GEN PL/NOM SG)'	
Polish	pies	pøs-a	bies	bies-a
	'dog (NOM SG/GEN SG)'		'devil (NOM SG/GEN SG)'	
Czech	lev	løv-a	les	les-a
	'lion (NOM SG/GEN SG)'		'forest (NOM SG/GEN SG)'	
BCS	tajac	tajøc-a	pajac	pajac-a
	'silence (NOM SG/GEN SG)'		'clown (NOM SG/GEN SG)'	

Whether a vowel alternates with zero or not must thus be somehow recorded in the lexicon. That is, analyses must be able to somehow distinguish "true" (i.e. stable) from "false" (i.e. alternating) vowels of the same quality. The occurrence of yers is thus unpredictable (just as their distribution as regular vowels in CS was), and this is also true at a broader level: alternating vowels freely occur across prefixes, roots, and suffixes in Slavic languages.

Another question that has been debated at length in the literature is whether alternating vowels are underlyingly absent and inserted, or present and deleted. Insertion-based analyses have been proposed by, among others, Laskowski (1975), Czaykowska-Higgins (1988), and Piotrowski (1992). They are convincingly

[1] Note that in this chapter the symbol "ø" indicates the absence of a vowel that alternates with zero. Data are presented in orthography (or transliteration for Russian) throughout. In most cases symbols are self-explanatory. Specifics are as follows: for Russian an apostrophe after a consonant indicates its palatality (as in *d'en'* 'day'). Polish *cz* and Czech *č* are [ʧ]; in (3), they are the palatalized version of the underlying suffixal /k/. Polish *ł* is [w], *y* is [ɨ] in Polish but [i] in Czech, and the diacritic on Czech *ě* indicates the palatality of the preceding consonant. In Czech (and Slovak), vowel length is noted by an acute accent or by a circle on *u* (*ů* is a long [uu]). In Polish, *ó* is pronounced [u] (just like *u*). Finally, Polish *ę*, *ą* are nasal vowels.

(3)

	a. *open syllable*		b. *closed syllable*	
	zero	vowel	vowel	vowel
	C __ C-V	C __ C-yer Cø	C __ C-ø	C __ C-CV
Russian	d'n'-a	d'e'n'-ok	'd'en'	d'en'-ø'k-a
Czech	dom-øk-u	dom-eč-ek	dom-ek	dom-eč-øk-u
Slovak	kríd-øl-o	kríd-el-iec	kríd-el	kríd-el-øc-e
Polish	buł-øk-a	buł-ecz-ek	buł-ek	buł-ecz-øk-a

The paradigms shown are fully regular in the languages in question, and the relevant distributional regularity is thus as in (4).[6]

(4) Alternation sites are vocalized in open syllables iff the following vowel alternates with zero.

Indeed, in all cases where an alternation site is vocalized in an open syllable (Pol. *bu.łe.czek*), the vowel of the following syllable alternates with zero itself (Pol. *bu.łe.czø.ka*). In other words, the existence of a vowel in *-ecz-* is a consequence of the fact that the vowel in *-ek* alternates with zero. Alternation sites are never vocalized in open syllables when the following vowel is stable.

For historical reasons that were discussed in the introduction, vowels which alternate with zero in Slavic languages are called yers. Following this tradition, the distributional generalization that covers all facts discussed identifies as the disjunction under (5) below that is rendered in *SPE*-type notation.

(5) *The yer context*

alternation sites show

V / __	{ C.CV	} in closed syllables	buł-ecz-k-a
	C#		buł-ek
	C ь,ъ }	before yers	buł-ecz-ek
ø / __	CV	iff V ≠ ь,ъ	buł-øk-a

The challenge raised by this distribution is its disjunctivity: vocalization occurs in closed syllables and in open syllables iff the following vowel is a yer. The question thus arises in which way closed syllables and yers constitute a natural class: i.e. what they have in common. We will see below that the syllable-based generalization can be maintained if certain assumptions are made regarding underlying representations and the cyclic (or phase-based) nature of the derivation.

3 Lower

3.1 *Original linear implementation*

If there is any chance to capture the distribution of vocalized and unvocalized alternation sites in terms of a non-disjunctive statement at all, the formulation must

[6] The yer literature typically talks about vocalized and unvocalized yers: yers are lexically present and thus may or may not appear on the surface. In the former case they are said to be vocalized, while in the latter they are unvocalized. The same goes for the more neutral (and less Slavo-centristic) term "alternation site." These vocabulary items are commonly used in the chapter.

The derivations under (7) show Lower and yer deletion at work, also in case several alternating vowels occur in a row. The example used is the Polish word for bread roll *bułka* (see (3); the rule that palatalizes *k* to *cz* is not represented).

(7) *Sample derivations showing the operation of Lower*

underlying	a.	buł-ĭcz-ĭk-a	b.	buł-ɨ̆k-ɨ̆
Lower		buł-ecz-ĭk-a		buł-ek-ɨ̆
yer-deletion		buł-ecz-k-a		buł-ek
surface		bułeczk-a		bułek
relevant yer occurs in		__C yer CV		__C yer #
underlying	c.	buł-ĭcz-ĭk-ɨ̆	d.	buł-ĭk-a
Lower		buł-ecz-ek-ɨ̆		buł-ĭk-a
yer-deletion		buł-ecz-ek		buł-k-a
surface		bułecz-ek		bułk-a
relevant yer occurs in		__C yer C yer #		__C V

Note that, under (7c), Lower must apply twice and from left to right, i.e. cyclically following the morphological structure [[[[buł] ɨ̆k] ĭk] ɨ̆], in order to transform /buł-ĭk-ɨ̆k-ɨ̆/ into [buł-ecz-ek-ɨ̆]. Were [buł ĭk ɨ̆k ɨ̆] interpreted in one go, it would not be clear to which yer Lower should apply first (more on this in §6.2). The traditional assumption is therefore that Lower is applied cyclically (e.g. Lightner 1965: 111f.; Pesetsky 1979; Rubach 1984: 184ff.). Based on Anderson (1974), however, Gussmann (1980, 2007) advocates a non-cyclic version of Lower whereby "the string is first scanned for the [alternating] segments; once these are identified, the change is implemented simultaneously" (Gussmann 1980: 30). That is, all yers are vocalized in one go, according to whether or not the following vowel is a yer in the underlying form.

4 Autosegmental analyses

4.1 *Autosegmentalized Lower*

In the 1980s, when the autosegmental idea was applied to all areas of phonological theory, Lower also evolved. The autosegmentalization of Lower was adopted by Hyman (1985: 58f.) and Rubach (1986) (see also Kenstowicz and Rubach 1987; Bethin 1998: 2[illegible]5 provides an informed overview). Rather than the rule itself, the autosegmentalization concerns the lexical identity of yers: recall that their distribution is unpredictable, and that they must be distinguished from non-alternating vowels of the same quality at the underlying level. In a non-autosegmental environment, the only way to express that two vowels are different is to make them contrast in quality. Hence, a six-vowel system such as the one encountered in Polish ([i u ɨ ɛ ɔ a]) will have to be augmented by two yers, whose melodic identity must not coincide with any of the existing vowels. The traditional solution since Lightner (1965) has been to assume that yers are high vowels, but ones which are assigned a [–tense] feature, which isolates them from the other three high vowels.

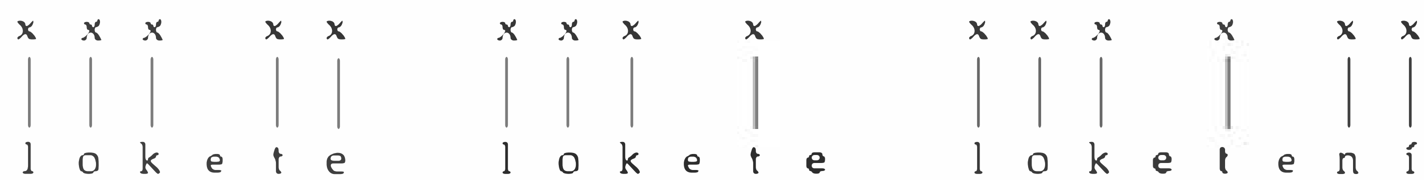
The result is a system where Polish possesses no fewer than five high vowels: /i u ɨ ĭ ɨ̆ ɛ ɔ a/.[8]

In autosegmental representations, a vowel that enjoys phonetic expression is defined as the association of a melodic unit with an x-slot, which in turn is dominated by a syllabic constituent. If there is an x-slot but no melody, nothing is heard (empty onset or nucleus); if there is a melody available but no x-slot, no phonetic trace will appear (e.g. floating consonants like in French liaison); finally, if both melody and x-slot are present but remain unassociated, nothing is heard either (see also CHAPTER 54: THE SKELETON).

Autosegmental representations thus offer an alternative way of making yers different from other vowels: their peculiar properties may be encoded structurally, rather than melodically. The alternative proposed by Rubach (1986) and Kenstowicz and Rubach (1987) therefore grants melodic, but no skeletal, properties to yers (see also Hyman 1985: 58f. along the same lines in a mora-based environment): yers are floating pieces of melody that do not possess any skeletal anchor in the lexicon, while stable vowels (which may be melodically identical) are lexically associated to an x-slot. The corresponding underlying representations are shown under (8) for the three relevant distributional situations, which are illustrated by Czech data from (2).

(8) *Yers are floating pieces of melody* (Rubach 1986)
Czech 'elbow'

a. loke̲t-e (GEN SG) b. loket (NOM SG) c. loket-ní (ADJ)



This option offers several advantages.[9] First, there is no longer any need to make yers high vowels, a solution whose only motivation was their historical CS properties. Also, extra features no longer need to be invoked: the choice of [–tense]

[8] The situation is actually more complicated than this; see Gussmann (1980: 63ff.) and Rubach (1984: 27ff., 139ff.).

[9] The autosegmentalization of Lower introduces representations as in (8), where syllabification is contrastive: two lexical items may be distinct only by the fact that a vowel either floats or is lexically attached. Two reviewers point out that contrastive syllabification may be viewed as a suspicious device from a general perspective. Note that since Hyman (1985) and Rubach (1986) it has been part-and-parcel of all (autosegmental) accounts of Slavic vowel–zero alternations across different theories (including OT). Also, apprehension regarding contrastive syllabification appears to be a bias that is introduced by theoretical preferences, rather than by fact: the general perspective inherited from the 1970s is that lexical entries are a linear sequence of pieces of melody, on which a syllabification algorithm superimposes syllable structure during phonological computation. In this perspective, therefore, syllable structure is absent from the lexicon. From this point of view, contrastive syllabification is indeed suspicious. This conception, however, is not without alternatives: there are theories like Government Phonology where lexical entries are fully syllabified, and the autosegmental analysis of Slavic yers is a step in this direction (although here only x-slots, not full syllable structure, are present in the lexicon). Also, the common practice of marking extrasyllabic consonants as <C> in lexical representations is nothing else than prespecifying the behavior of the item at hand during syllabification. Finally, the lexical association of melody with moras has been common practice in mora-based approaches to syllable structure since Hayes (1989). This option is represented by Yearley (1995) in the analysis of yers.

was entirely arbitrary. Any diacritic underlying representation for the two yers, such as /@/ and /%/, or any position in the vocalic triangle defined by whatever feature, would have done the job in the linear environment, provided that the two items are different from all other underlying vowels.

The alternative in (8) thus does away with absolute neutralization (i.e. a vowel that never appears on the surface in its underlying form) and its associated arbitrariness. Rather, alternating (yers) and non-alternating vowels are now identical as far as their melodic representation is concerned: the contrast is expressed in terms of association (compare the two *e*'s under (8a). There is thus a trade-off between an inventory that is expressed only by melodic contrast and an inventory where contrast is achieved both by melodic features and autosegmental structure. Of course, the number of objects that need to be contrasted remains the same – but the advantage of the autosegmental option is that no arbitrary contrast-achieving machinery ([–tense] vowels) needs to be used: the new way of expressing contrast only uses the tools that are provided by the autosegmental environment anyway.

Another advantage is that the rule of yer deletion can be dispensed with: the phonetic absence of unassociated melodic material is automatic in the autosegmental environment.

Finally, the autosegmentalization of Lower emancipates synchronic vowel–zero alternations from their diachronic affiliation, which also makes them a phenomenon that is not necessarily specific to Slavic languages (more on this in §8.2). That is, vowels which alternate with zero are no longer subject to any melodic restriction: in the linear system, two distinct vowels at most (i.e. the Eastern Slavic situation) could alternate with zero. Languages like Slovak, where more than two vowels alternate with zero, therefore begged the question. Rubach (1993: 139ff.) reports relevant evidence: *o*–zero *bahor* – *baho̲r-a* 'belly (NOM SG/GEN SG)', *e*–zero *šev* – *šo̲v-u* 'seam (NOM SG/GEN SG)', *a*–zero *jedo̲l-o* – *jedál* 'food (NOM SG/GEN PL)'.

In autosegmental terms, the relevant representations are straightforward: whatever vowel alternates with zero and whatever the number of different alternating vowels, their underlying representation is simply their floating melodic identity without a skeletal slot. Any alternating vowel will thereby be different from its melodically identical stable peer because it is associated to a skeletal slot. While every additional vowel that alternates with zero augments the inventory of underlying melodies in the linear system, the number of melodic identities is stable no matter whether a language possesses vowels that alternate with zero or not in the autosegmental environment.[10]

The autosegmentalized version of Lower is shown in (9).

(9) *Autosegmentalized Lower* (Rubach 1986; Kenstowicz and Rubach 1987)

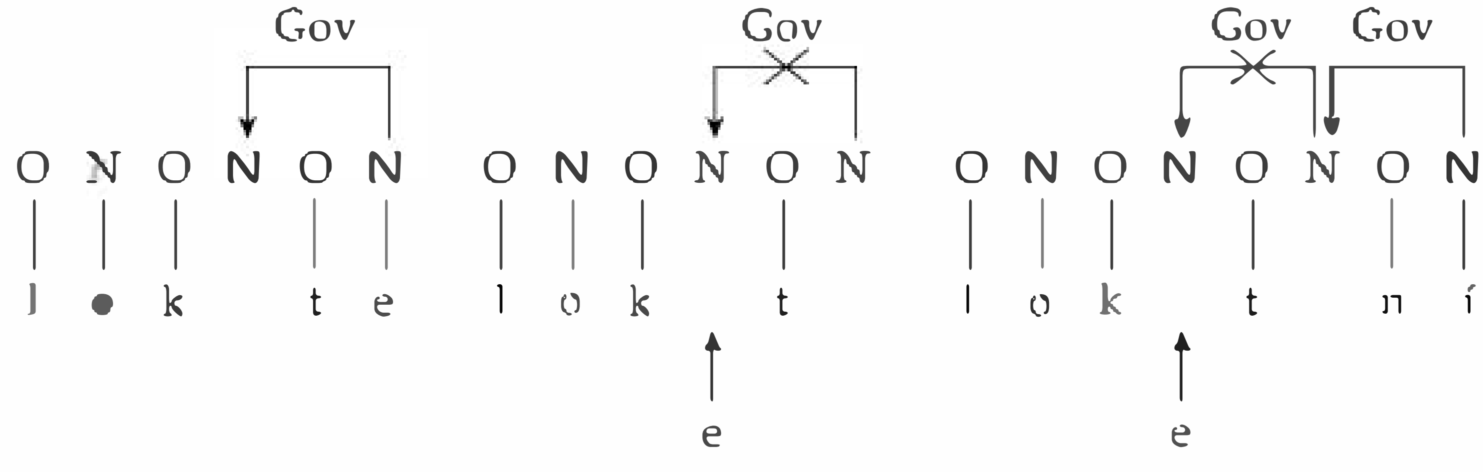
$$\text{ⓥ} \rightarrow \begin{array}{c} \text{x} \\ | \\ \text{V} \end{array} \;/\; \_\_\, C_0 \; \text{ⓥ}$$

[10] The number of alternating, i.e. lexically unassociated, vowels that a language possesses is thus a lexical and unpredictable property of the vocalic inventory: the reason why *e* and *o*, but not other vowels, are lexically floating in Russian, or why only *e* enjoys this status in Czech, is the same as the reason why Russian does not have, say, front rounded vowels.

In Government Phonology, Gussmann and Kaye (1993) apply the general distribution of empty nuclei that has no specific bond with Slavic to Polish vowel–zero alternations. In this perspective, alternating vowels (i.e. yers) have the opposite characteristics from those proposed by Rubach (1986): rather than melodies that lack lexical association (to an x-slot), they are represented as empty nuclei, i.e. a constituent that lacks melody. This option is shown in (12), where the Cezch data from (8) are used.

(12) *Yers are empty nuclei* (Gussmann and Kaye 1993)
Czech 'elbow'

a. lok$\underline{ø}$t-e (GEN SG) b. loket (NOM SG) c. loket-ní (ADJ)



In this perspective, *e* is epenthesized into empty nuclei that fail to be governed. Government is defined as a lateral relation whose head (origin) must be phonetically expressed: it relates the final and preceding nuclei in (12a) because the former is filled with the genitive case marker, but breaks down in (12b) when the final nucleus is empty (in classical terms: when the internal yer is followed by a final yer). When applying, government has thus the effect of silencing its target: the empty nucleus in (12a) remains unpronounced, but must appear on the surface when it fails to be governed as in (12b). Since government is a regressive lateral relation, strings that are subject to phonological computation are parsed from right to left. Thus the final filled nucleus first governs its left-hand neighbor in (12c), which therefore remains empty. Being phonetically unexpressed, this nucleus is then unable to act as a governor, a fact that causes the preceding empty nucleus to escape government and hence to vocalize.

Like the traditional analysis, the government-based version of Lower needs to recur to cyclic derivation in order to account for sequences of alternating vowels. In Polish *buł-ecz-ek* 'bread roll (DOUBLE DIM, NOM SG)' (see (7c)), the application of government to the entire string /buł$\underline{ø}_3$k$\underline{ø}_2$k$\underline{ø}_1$/ in one go would produce **buł$\underline{ø}$czek*: $\underline{ø}_1$ would be unable to govern $\underline{ø}_2$, which would therefore vocalize and govern $\underline{ø}_3$.

In order to derive the vocalization of all alternating vowels in a row, Gussmann and Kaye (1993) therefore apply government cyclically: *buł-ecz-ek* is divided into three cycles that are computed each in its own right: given [[[buł$\underline{ø}_3$] k$\underline{ø}_2$] k$\underline{ø}_1$],[15] nothing happens on the first cycle, [buł$\underline{ø}_3$], since there is only one domain-final empty nucleus. The second cycle involves [buł$\underline{ø}_3$k$\underline{ø}_2$], with two successive

[15] This underlying form is simplified for the sake of exposition: the suffix *-ek* is identified as /-$\underline{ø}$k$\underline{ø}$/ in Gussmann and Kaye (1993), but due to an operation called reduction loses its leftmost empty nucleus during the derivation.

empty nuclei, a situation that triggers the vocalization of $\underline{\emptyset}_3$ through the regular (non-)application of government ($\underline{\emptyset}_2$ is unable to govern $\underline{\emptyset}_3$, which therefore vocalizes). The input to the third cycle is thus [bułek$\underline{\emptyset}_2$k$\underline{\emptyset}_1$], and the presence of two successive empty nuclei again causes the leftmost to vocalize, producing the surface result *bułeczek*.

Gussmann and Kaye's (1993) analysis is an interesting blend of deletion- and insertion-based strategies: on the one hand the locus of alternating vowels is lexically specified by the presence of empty nuclei; these are pronounced by default but may be silenced when they are struck by government. In this sense we are talking about deletion. On the other hand, empty nuclei are (melodically) empty and therefore need to be filled in with melody that is lexically absent. In this sense the analysis is insertion-based.

Recall from §2.1 that insertion-based analyses were refuted mainly on the grounds of two arguments: (i) the locus of insertion cannot be predicted and (ii) the quality of the vowel that alternates with zero may be an idiosyncratic property of morphemes (like in Eastern Slavic, for example). While Gussmann and Kaye's (1993) system escapes the first criticism (empty nuclei determine the locus of alternation sites lexically), the second argument hits the target: in languages like Russian where more than one vowel alternates with zero, it cannot be predicted which vowel will be inserted into which morpheme.

The quality of alternating vowels must thus be recorded in the lexicon. Scheer (2004: §81f.) has therefore proposed to unify Rubach's original take, where yers are floating melodies that are recorded in the lexical make-up of morphemes with the government-based strand. That is, alternating vowels (yers) are nuclei that possess a melody, which however is not associated lexically (see also Gussmann 2007). By contrast, the melody of non-alternating vowels is lexically associated. The three options discussed are contrasted in (13), using the Czech word *pes* – *p*$\underline{\emptyset}$*s-a* 'dog (NOM SG/GEN SG)'.

(13) *Underlying representations of vowels that alternate with zero (yers)*

a. Rubach (1986) b. Gussmann and Kaye (1993) c. Scheer (2004,2005)

On the assumption of (13c), then, government acts as an association inhibitor: floating melodies associate by default except when their nucleus is governed. Or, in other words, melodies can only associate to ungoverned nuclei.[16] Another interesting property of (13c) is that it distinguishes between two kinds of "empty" nuclei: one that is really empty, and one that possesses an unassociated

[16] This analysis is along the lines of the behavior that is classically assumed for floating pieces of melody: for example, French liaison consonants (e.g. the final -*t* of *petit*, cf. *pet*[it] *enfant* 'small child' *vs. pet*[i] *café* 'small coffee') are traditionally taken to be lexically floating; they associate whenever an accessible, i.e. empty onset is available (e.g. Encrevé 1988). Hence association works in the absence of any explicit lexical relationship between the floater and the receiving constituent. The same is true for (13c): the floater associates whenever it can, and to the only nucleus that is available. The accessibility of this nucleus is defined by government (governed = inaccessible, ungoverned = accessible).

from all versions of the word in all possible donor languages (see also CHAPTER 95: LOANWORD PHONOLOGY).

A decision to break up a cluster by an epenthetic vowel or not thus needs to be made upon the lexicalization of new vocabulary items, and this produces random distribution of alternating vowels. Also, children when acquiring their native tongue have no way of knowing whether the cluster of something that they hear as *swetr-a* 'jumper (GEN SG)' in Polish or *metr-o* 'metro' in Czech will or will not break up until they have a chance to hear the word without the final vowel. Relevant mislexicalizations are indeed typical "mistakes" that are reported from children.

The arbitrary lexical distribution of alternating vowels in the modern language is also confirmed by the reverse evolution: there are numerous cases of vowels that were CS yers and thus alternated, but today are stable. Examples include *blech-a* < CS blъch-a 'flea (nom sg)', *bez* – *bez-u* 'elder (bot.) (NOM SG/GEN SG)' < CS bъzъ (e.g. Trávníček 1935: 48).

Let us now turn to alternating vowels without etymological basis that occur in native vocabulary. (14) provides some illustrations from Czech.

(14) *Non-etymological yers in native vocabulary*

a. *epenthesis in Old Czech*

CS	*Old Cz*	
ogn-ь	oheň	'fire (NOM SG)'
od-	od(e)-	'from'
orz-	roz(e)-	'separating, inchoative'
bez-	bez(e)-	'without'

b. *epenthesis in Modern Czech*

CS	*Old Cz*	*ModCz*	
vydr-ъ	vydr	vyder	'otter (GEN PL)'
sestr-ъ	sestr	sester	'sister (GEN PL)'
stьbl-ъ	stébl	stébel	'blade (GEN PL)'
kridl-ъ	křídl	křídel	'wing (GEN PL)'

(14) confirms that epenthesis was also active in native vocabulary, and throughout different stages of the evolution of the language: (14a) illustrates epenthetic alternating vowels that appeared between CS and Old Czech,[18] while (14b) shows epenthesis in Old Czech final clusters that occurred in Modern Czech.[19]

In sum, it may be said that while the initial spark for vowel–zero alternations in Slavic was the loss of CS yers, modern alternating vowels are entirely independent: it is true neither that they all go back to a CS yer, nor that all CS yers have produced modern alternating vowels.

[18] The three latter items under (14a) are prefixes/prepositions (whose behavior in Modern Czech is further discussed in §7.1). They show an alternating vowel in Old Czech despite the fact that there was no yer in CS: e.g. OCz *ote dne* 'from the day', *beze všeho* 'without all', *roze-hnal* 'dispel, scatter' (Trávníček 1935: 50). Isačenko (1979) describes the state of affairs in Russian prefixes.

[19] Unlike for the recent loans, epenthesis in (14a) and (14b) is predictable. Its conditions are discussed in Scheer *et al.* (2009).

[dom-Ek-Ek] without internal cyclic structure (in syntactic terms, it represents one single phase). The suffix *-ek* then became cyclic in diachronic evolution, which means that a cycle is created upon concatenation or, in syntactic terms, interpretation is triggered upon concatenation and the string has three phases: [[[dom] Ek] Ek]. By contrast, case markers such as GEN SG *-u* were non-cyclic in Old Czech and still are today: OCz = MdCz [dom-Ek-u] *domček* (Ziková 2008).

In other words, whether interpretation is triggered or not depends on a lexical property of affixes. This scenario contrasts with current syntactic phase theory, where a given class of arboreal nodes that is defined independently of lexical material (phase heads: CP, vP, and perhaps DP in Chomsky's original conception) determines when interpretation occurs. Affix classes in phonology (of which the Lower–Havlík contrast is an instance) thus call for what could be named piece-driven phases where lexical material is specified for triggering or not triggering interpretation, while current syntactic theory employs node-driven phases (see Scheer 2008 for further discussion).

7 Prepositions and prefixes

7.1 *The general picture*

Yers also occur after the final consonant of consonant-final prepositions and prefixes: e.g. Czech *v/ve* 'in', *nad/nade* 'over, above'. Since the vocalization of yers is decided by the right-hand context, the morpheme or word boundary that intervenes between the yer and the conditioning context plays a role: its greater or lesser transparency will impact on yer vocalization. This is the basic reason for the typically irregular vocalization patterns that are found in prefixes and prepositions. But there are also other factors that further complicate the picture: sensitivity to identical (or similar) preposition-/prefix-final and stem-initial consonants, sensitivity to stem-initial clusters and, in the case of prefixes, a good deal of analogical activity. Finally, lexicalized preposition–noun sequences also appear to occur.

As may be expected in such a case, there is a fair amount of variation among Slavic languages regarding the treatment of alternation sites in prepositions and prefixes. Relevant literature includes Zubritskaya (1995), Rubach (2000), Matushansky (2002), Gribanova (2008) on Russian, Rubach (1993) on Slovak, and Scheer (1996), Ziková (2008) on Czech (literature on Polish is mentioned below).

Let us first look at the stock of Slavic consonant-final prepositions and prefixes, which is more or less stable across Slavic languages. (18) below shows the Czech inventory (only basic, i.e. morphologically non-complex, items are displayed). It may be seen that prepositions and prefixes are by and large the same objects and have comparable meaning.

(18) *Czech prepositions and prefixes*

	prepositions	*prefixes*	
a.	v(e)	v(e)-	'in'
	s(e)	s(e)-	'with'
	z(e)	z(e)-	'from inside'
	k(e)	—	'towards'

b. *before unexpressed alternating vowels*

od-wszyć	wesz, wszy	'to de-louse, louse (NOM SG/GEN SG)'
od-pchlić	pchla, pcheł	'to de-flea, flea (NOM SG/GEN PL)'
bez-cłowy	cło, ceł	'duty-free, duty (NOM SG/GEN PL)'
nad-dniówka	dzień, dnia	'extra day's work, day (NOM SG/GEN SG)'
w-śnić się	sen, snu	'to start dreaming, dream (NOM SG/GEN SG)'
roz-łzawić	łza, łez	'to draw tears, tears (NOM SG/GEN PL)'

In these cases, the prefix boundary impacts on the vocalization of prefixes, which escape the influence of the root: the prefix does not "see" the root vowel.[23] Various implementations of this insight can be found in, among others, Rubach (1984: 18ff.), Szpyra (1989: 215ff., 1992b, 1995: 132f.), Cyran and Gussmann (1999), and Rowicka (1999a: 267ff.). Rubach (1984: 186ff.) develops a solution along the lines of Lexical Phonology: he captures the phonological autonomy of prefixes by feeding them into the derivation on the last cycle, which makes them immune to the action of Lower.

Whatever analysis is set up, though, it will face conflicting evidence since the same prefixes sometimes do – but at other times do not – vocalize in identical phonological environments.

8 The relevance of yers for phenomena other than vowel–zero alternations

8.1 *Within Slavic*

Yers usually draw attention because of their own behavior: we have seen how their alternation with zero is analyzed. The central empirical fact that led to the Lower rule and the view that yers entertain a lateral relation with the following vowel is the yer context (5): a yer appears on the surface in closed syllables and in open syllables iff the following vowel alternates with zero. Yers thus react to other yers or, looked at from the other end, a stable vowel triggers the phonetic absence of a preceding yer, while a yer triggers its presence. As conditioners, yers thus behave as if they were not there, although they are phonetically present.

Interestingly, this effect is not only observable on yers, but also on other vowels: the yer context also controls alternations beyond vowel–zero alternations, a fact that typically goes unnoticed in the literature. Scheer (2004: §428) has collected the following examples in Western Slavic.[24]

[23] Laskowski (1975: 34ff.) suggests that the strength or weakness of the prefixal boundary depends on the type of derivation: prefixes behave regularly in verbal forms, but produce the irregular pattern in nouns. This falls foul of fact in a number of cases in (20). Nykiel-Herbert (1985) contends that the vocalization of prefixes is a function of the number of morphological brackets that separate the prefix and the stem. This proposal also faces conflicting evidence; cf. Szpyra (1989: 211f.).

[24] Glosses: (a) 'frog' (NOM SG/DIM, GEN PL/GEN PL/DIM, NOM SG); 'name' (NOM SG/ADJ, GEN PL); (b) 'knife' (GEN SG)/'scissors' (i.e. DIM of 'knife'), GEN PL/'knife' (NOM SG)/'scissors' (NOM PL); (c) 'cow' (NOM SG/DIM, GEN PL)/GEN PL/DIM, NOM SG); (d) 'tooth' (GEN SG/DIM, NOM SG/NOM SG/DIM, GEN SG).

(21) *Alternations conditioned by the yer context "in closed syllables and in open syllables if the following vowel is a yer"*

		open syllable		closed syllable	
		C __ C-V	C __ C-yer	C __ C#	C __ C-CV
a.	Czech VV-V	žáb-a	žab-ek	žab	žab-øk-a
		jmén-o		jmen	jmen-ný
b.	Czech o-ů	nož-e	nůž-ek	nůž	nůž-øk-y
c.	Polish o-ó	krov-a	krów-ek	krów	krów-øk-a
d.	Polish ę-ą	zęb-a	ząb-ek	ząb	ząb-øk-a

Space restrictions hardly allow going into any more detail. For the sake of illustration, let us however consider the distribution of long and short vowels in Czech. These are restricted to a well-defined paradigm, feminine a-stems and neuter o-stems (a typical situation for Czech vowel length). At first glance the alternation looks like an instance of regular closed syllable shortening: short vowels occur in closed syllables (*žab* 'frog (GEN PL)', *žab-ka* 'frog (DIM, NOM SG)'), while long vowels appear in open syllables (*žáb-a* 'frog (NOM SG)'). Just as with vowel–zero alternations, however, this syllabic generalization is refuted by cases such as *žab-ek* 'frog (DIM, GEN PL)', where a short, rather than the expected long vowel appears in an open syllable. This only happens, though, if the following vowel alternates with zero, i.e. is a yer (its alternating character is established by *žab-ka*). In other words, the disjunctive yer context can be reduced to a simple non-disjunctive statement as before: short vowels (just as zeros) occur before yers, while long vowels are found before non-yers.

Before drawing conclusions from the fact that a number of other alternations are controlled by the same yer-based contextual conditions as vowel–zero alternations, a word is in order regarding the alternations in (21), whose non-productivity is notorious. There are many lexical items that do not undergo the alternations shown (which however are regular in case an item reacts). Diachronically, all four alternations amount to the same original Western Slavic process that manipulated vowel length.[25] The fact that the alternations are either not synchronically active (in Polish) or restricted to specific paradigms (in Czech) does not mean that they are less indicative, or do not witness a phonological process that once was synchronically active.

Therefore, if the yer context (5) is responsible for vowel–zero alternations as much as for other alternations, the Lower rule turns out to be but a specific subregularity of a much broader process whereby yers play the central role. That is, regarding the alternations in (21) as much as regarding vowel–zero alternations, the striking property of yers is that they behave as if they were not there even when they are phonetically expressed.

8.2 *Beyond Slavic*

We have already seen that the analysis of yers progressively turned away from a scenario where they are a specific property of Slavic languages. While linear

[25] Vowel length was lost in Modern Polish: alternations in this language are only witnessed by cases where original long and short versions of a vowel at some point also diverged in vowel quality. The diachronic and philological detail of the processes in (21) is discussed in Scheer (2004: §426).

approaches represented them as two idiosyncratic melodic items in the underlying vocalic inventory, they became regular and non-Slavic-specific phonological objects in the autosegmental era: only Slavic languages have [−tense] yers, but all languages can have floating pieces of melody. Government-based analyses have gone one step further: the lateral relation embodied by Lower identifies as government, and word-final consonants are followed by an empty nucleus, rather than by a yer with morphological value. Finally, it was shown in §5 that vowels which alternate with zero in modern Slavic languages may be completely independent from the Common Slavic vowels that are known as yers.

The insight that the phenomena at hand are not specifically Slavic, but phonological in nature, is also supported by the fact that the yer context in (5), which is rather specific, is found to control alternations beyond Slavic. Scheer (2004: §426, 2006) reports a number of relevant cases in point, among which two well-known alternations in French that concern schwa and [ɛ] on the one hand, and the ATR-ness of mid vowels on the other (e.g. Tranel 1987 for an overview). In French, the only vowel that alternates with zero is schwa [ə]. It has already been mentioned that, unlike in Slavic, the alternation is optional.

The schwa–[ɛ] alternation may be illustrated by the word *appeler* 'to call': [ɛ] appears in closed syllables (*j'appelle* [apɛl] 'I call', *il appellera* [apɛlʁa] 'he will call') and before a vowel that alternates with zero (*il appellera* [apɛləʁa] 'he will call'), while schwa is found in open syllables (*appeler* [apəle] 'to call'). Regarding the other alternation, French possesses six mid vowels that subdivide into two sets: [+ATR] [e o ø] and [−ATR] [ɛ ɔ œ]. In a number of Southern varieties, ATR-ness is distributed according to the yer context: [+ATR] versions occur in open syllables if the following vowel does not alternate with zero (*fêter* [fete] 'to party'), while mid vowels are [−ATR] in closed syllables (*je fête* [fɛt] 'I party', *perdu* [pɛʁdy] 'lost'), and in open syllables if the following vowel alternates with zero (*céleri* [sɛləʁi]/[sɛlʁi] 'celery').

The yer context also conditions consonants. The well-known alternation of the German velar nasal is a case in point (Scheer 2004: §480; relevant literature includes Dressler 1981 and Hall 1992: 199ff.). Like the English velar nasal, the underlying /Ng/ reduces to [ŋ] in closed syllables (*Ding* [dɪŋ] 'thing', *Angst* [ʔaŋst] 'fear'), but appears as [ŋg] before full vowels (*Ingo* [ʔɪŋgoo] (name), *evangelisch* [ʔɛfaŋgeelɪʃ] 'protestant'). Parting company with English (cf. Eng *finger* [fɪŋgə]), though, German also produces the reduced form before schwa (*Inge* [ʔɪŋə] (name), *Bengel* [bɛŋəl] 'rascal'). The same pattern, i.e. where consonants behave alike in coda position and before schwa, also occurs in Dutch (Kager and Zonneveld 1986).

Of course there is no point in trying to attribute these alternations to yer vowels or other Slavic-specific items. What we are facing is a truly phonological pattern that occurs in Slavic as much as in other languages, and whose key feature is the behavior of vowels that alternate with zero. Unlike other vowels, they behave as if they were not there even when they are phonetically expressed. Note that the quality of these vowels is entirely irrelevant: they may be peripheral, as in Slavic, or central ("true" schwas), as in French and German.

Analyses of so-called Slavic yers will therefore have to make sure that their instruments are not bound to Slavic, but can express more general phonological processes. Yers need to be extracted from their narrow Slavic context, where they have lived in a waterproof environment in much of the structuralist and the generative tradition. They can offer rich insight into phonological theory if they are placed in a broader context: "yers" condition processes that are different from vowel–zero alternations, and they are active beyond Slavic.

9 Handshape in Sign Language Phonology

Diane Brentari

1 Introduction

This chapter addresses the particular importance of the handshape parameter in sign language phonology, using evidence from a variety of sources: psycholinguistic and cross-linguistic, as well as system-internal evidence from phonological operations. The chapter is organized as follows. In §1, by way of introduction to this topic, some of the ways that handshape behaves differently in gesture and sign languages will be described. In §2, portions of basic handshape structure will be presented, the terms that will be used throughout the chapter will be defined, and some descriptive generalizations concerning handshape will be outlined. Further elaboration of the features of handshape is discussed in §3. A description on how handshape interacts with the other parameters of signs will be discussed in §4. In §5, several examples of the role of handshape at the grammatical interfaces will be described, and §6 will consist of some concluding remarks on the topic of handshape.

1.1 Handshape in gesture and sign language

Handshape includes the form that the hand(s) assume(s) during the articulation of a sign or gesture; however, handshape has been shown to behave differently in gesture and in sign languages in several important ways.

One notable difference concerning handshape in gesture and sign is the greater range of forms used by signers in comparison with gesturers. This has been demonstrated in a number of psycholinguistic studies using tasks in which signing and non-signing (gesturing) participants were asked to describe events using only signs or gestures (Singleton *et al.* 1993; Goldin-Meadow *et al.* 1996; Emmorey and Herzig 2003; Schembri *et al.* 2005). I will describe just one of these studies, that of Schembri *et al.* (2005). In this study the gesturers did not use their voices. A test that consisted of animated video stimuli of objects moving in space was used to elicit productions from three groups (Supalla *et al.* 1995): non-signing hearing gesturers from Australia, signers of Australian Sign Language, and signers of Taiwanese Sign Language. Properties of handshape, place of articulation (where the sign is articulated), and movement (displacement of the hands in space) were

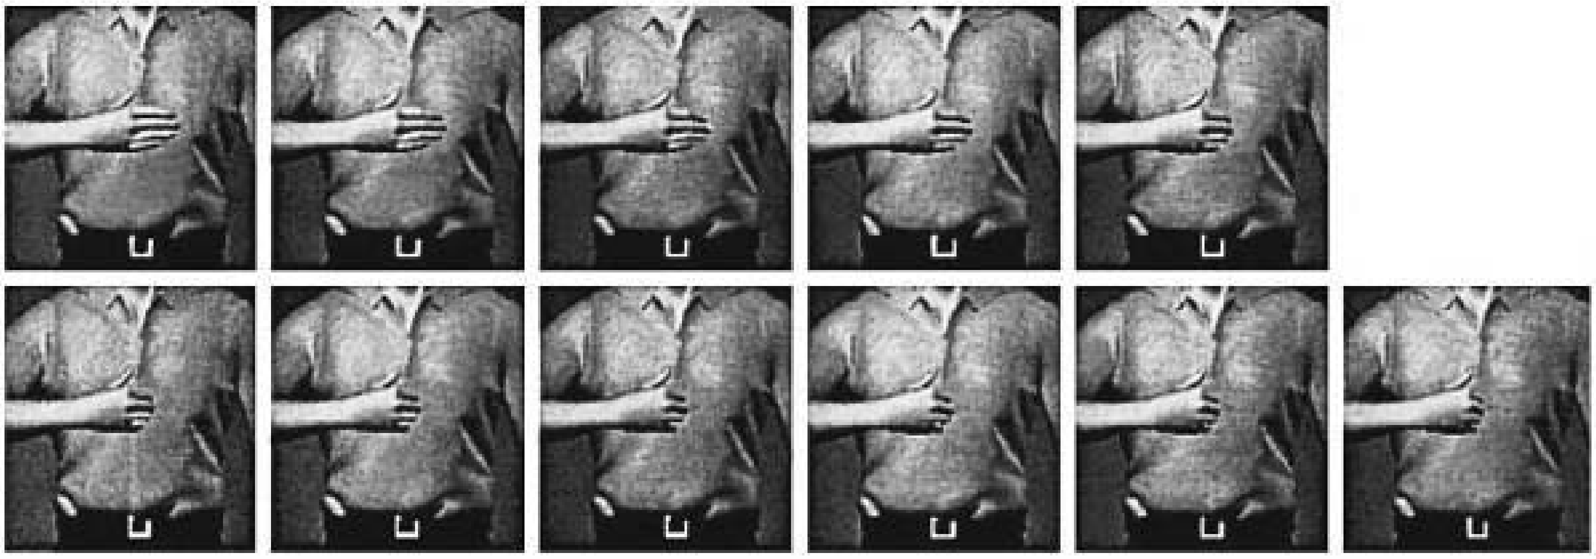

Figure 9.1 The eleven equal intervals between the two contrastive handshapes that were used in the categorical perception experiment presented in Emmorey *et al.* (2003): in the sign PLEASE (top left) and in the sign SORRY (bottom right)

counted for each subject and each group. I will describe only the results comparing the Australian gesturers and signers. The largest difference occurred in the handshape parameter. There was a 76 percent match on movement and place of articulation *vs.* a 44 percent match on handshape. The difference consisted in the greater number and complexity of the handshapes used by signers.[1]

Categorical perception is a second way that handshape in gesture and sign languages behaves differently; that is, native signers of American Sign Language (ASL) exhibit categorical perception for handshape (Emmorey *et al.* 2003; Baker *et al.* 2005), but gesturers do not. In Figure 9.1, 11 equal intervals between two handshapes are shown; static images were used in this study. These two handshapes are contrastive in ASL, and are seen here in the minimal pair PLEASE *vs.* SORRY . Categorical perception is described in the psycholinguistic literature as being present when performance on an identification task and a discrimination task produces a boundary between the categories that is in the same place along the continuum (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). In this case the identification task consisted of putting the images shown in Figure 9.1 into either the or group. The discrimination task consisted of taking images that are two intervals apart and asking participants to judge whether the two forms were the same or different.

In native signers the boundary between the and groups in the identification task and the strongest point of discrimination were in the same place, namely between intervals 4 and 6. Non-signers did not display categorical perception for these handshapes. Moreover, the native signers showed categorical perception for only the pairs of handshapes known to be contrastive; other pairs of stimulus handshapes that are not contrastive in ASL did not yield results indicating categorical perception. Handshapes that are considered allophonic and contrastive are described in detail in §2. The phenomenon of categorical perception does not demonstrate conclusively that a phenomenon is phonological in nature (Harnad 1987),

[1] A greater range of handshape forms is also seen in signers when compared with those of homesigners (Singleton *et al.* 1993; Goldin-Meadow 2001). Homesigners are deaf individuals who have not been exposed to a language model for a variety of reasons, and who have invented their own system of gestures to communicate with their family and acquaintances.

Figure 9.5 Two signs that are a minimal pair in ASL for joints. All properties of CANDY (a) and APPLE (b) are identical, except that CANDY has a straight index finger and APPLE has a bent index finger

is different because of the joint configuration of that finger: in CANDY it is straight; in APPLE it is bent (Figure 9.5). As mentioned previously, unselected fingers allow only extended and flexed specifications, but selected fingers allow for several more. The seven different positions that are contrastive in ASL are defined in (3) and shown in (4).

(3) *Definitions of joint configurations in handshape* (cf. Brentari 1998: 106–109)

a. Fully open: no joints of the hand are flexed.
b. Bent (closed): non-base joints flexed.
c. Flat-open: base joints flexed less than 90°.
d. Flat-closed: base joints flexed more than 90°.
e. Curved open: base and non-base joints flexed without contact.
f. Curved closed: base and non-base joints flexed with contact.
g. Fully closed: base and non-base joints fully flexed.

(4) *Contrastive positions of the joints in ASL*

(3a) (3b) (3c) (3d) (3e) (3f) (3g)

In addition to its ability to create minimal pairs, the joint position can change during the articulation of a single sign, as seen earlier in the HKSL sign SPECIAL

(Figure 9.3). These changes are called aperture changes, and they occur in a predictable fashion. Each joint configuration in (3) is assigned membership to either the open or the closed class, determined by its degree of closure and distribution in the system. If there are two handshapes in a sign, one must be from the open class and the other from the closed class. This was also observed by Mandel (1981) for ASL, first formalized in Sandler (1987) as the Handshape Sequencing Constraint, and further refined by Brentari (1990, 1998) as the Maximize Aperture Constraint. A recent formulation of this constraint is given in (5). This phonotactic constraint was also used in the word-segmentation task described in §1.1.

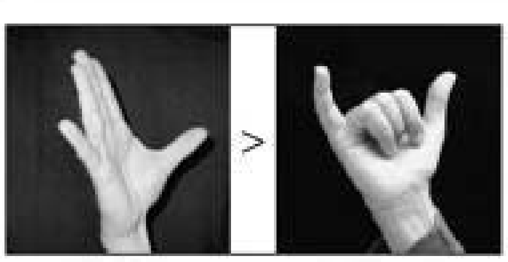
(5) *Handshape Sequencing Constraint* (Sander and Lillo-Martin 2006: 154)

If there are two joints positions in a sign, one must be [open] and the other [closed].

Examples of handshape sequences that are and are not permitted in a single sign are shown in (6) and (7). In (6a) the index, middle, and ring fingers change from open to closed, and in (6b) and (6c) all of the fingers change from closed to open in a way that conforms to the constraints in (2) and (5). Consequently, all things being equal, these sequences of handshapes should be perceived as single signs by signers of ASL. In contrast, the handshape sequences in (7) all violate the constraints in (2) or (5) in some way, and, all things being equal, such sequences ought to be perceived as two signs by ASL signers. The sequence in (7a) has a change in selected finger groups, violating the constraint in (2), and the sequence in (7b) and (7c) violates the constraint in (5) because the two handshapes in the sequence are either both closed (7b) or both open (7c). The Prosodic Model Notation System for handshape (Eccarius and Brentari 2008) is employed from now on in this chapter to underscore the differences and similarities among handshapes. This notation is explained in Appendix 9.1.

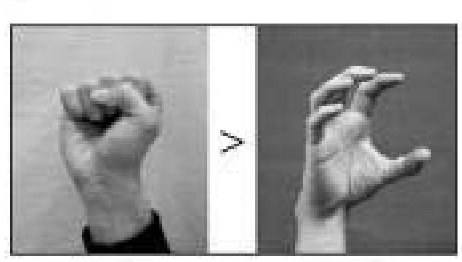
(6) *Permissible handshape changes within a sign*

a.



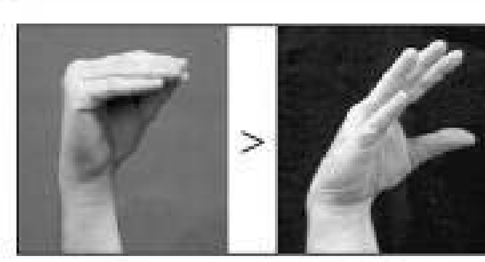
MT;/ > M@;/

b.



BT@ > BT^c

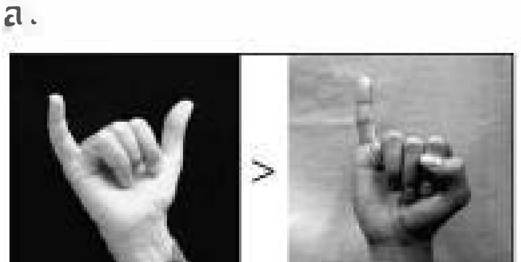
c.



BT> > BT^<

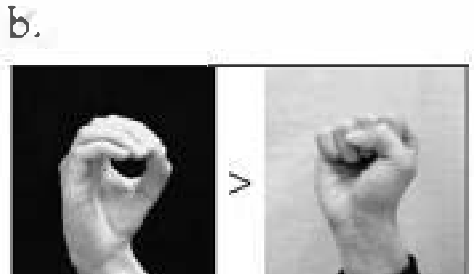
(7) *Impermissible handshape changes within a sign*

a.



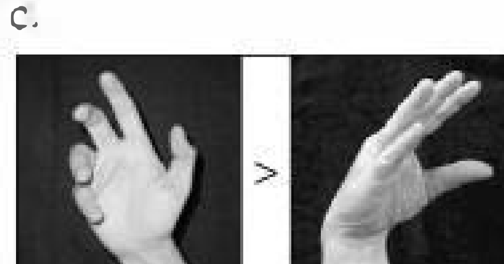
*M@;/ > BT@

b.



*BTo > BT@

c.



*BT-ĸc > BT^<

The different roles of joint features were formalized by van der Hulst (1995), who divided them into two different classes: those used for aperture change with their limited set of possibilities (i.e. "open" or "closed" variants of the underlying handshape) and joint selection for the seven distinctive joint contrasts.

In addition to selected fingers, unselected fingers, and joints, handshape can include other structures that will not be further discussed here due to space limitations. The thumb has the possibility of being a selected finger, and sometimes behaves differently than the other selected fingers in a sign. The arm can sometimes form a part of the larger articulatory structure. And two hands are sometimes used to articulate a sign; the dominant hand (H1) is the hand used to sign one-handed signs in a neutral linguistic context. The non-dominant hand (H2) is the other hand used in two-handed signs. This topic is covered in CHAPTER 10: THE OTHER HAND IN SIGN LANGUAGE PHONOLOGY. In addition, orientation of the hand in space is considered part of the handshape structure; this will be discussed in §3.

Based on the facts just presented, the areas of consensus among current models of sign language phonology about handshape are given in Table 9.1 (see Sandler 1989; Brentari 1990, 1998; van der Hulst 1993, 1995; Uyechi 1995; Channon 2002a, 2002b; van der Kooij 2002; Sandler and Lillo-Martin 2006). The generalizations in Table 9.1 extend to all sign languages studied thus far.

The hierarchical feature structure that includes the characteristics in Table 9.1 is given in (8). Notice the articulatory distinction between selected and unselected fingers, discussed in §2.1, as well as the feature distinction between the joints and fingers, discussed in §2.2.

Table 9.1 General characteristics of handshape

Structural property	*Description*
Feature geometry	The internal structure of handshape is best accounted for using a specific hierarchy of features that captures the relationships among the substructures of handshape.
H1/H2	An articulatory distinction of handshape that captures the roles of the two hands in a two-handed sign: the dominant hand (H1) and the other the non-dominant hand (H2) (see CHAPTER 10: THE OTHER HAND IN SIGN LANGUAGE PHONOLOGY).
Selected/ unselected fingers	An articulatory distinction of handshape that captures which fingers are foregrounded (selected) or backgrounded (unselected). Selected fingers can move during the articulation of a sign, and also can assume a larger range and more elaborate configurations of joints. Unselected fingers can assume only two joint configurations: fully open or fully closed.
Selected fingers/joints	A feature distinction within selected fingers capturing which fingers are selected and the disposition of their finger joints.

– but the index, middle, and ring fingers are selected in (10b): ASL WEIRD, and HKSL SUCCEED. In (11a) – HKSL NOT-HAVE and ASL INTERPRET – the index and thumb are selected, but in (11b) – HKSL NAME – the middle, ring, and pinkie fingers are selected.

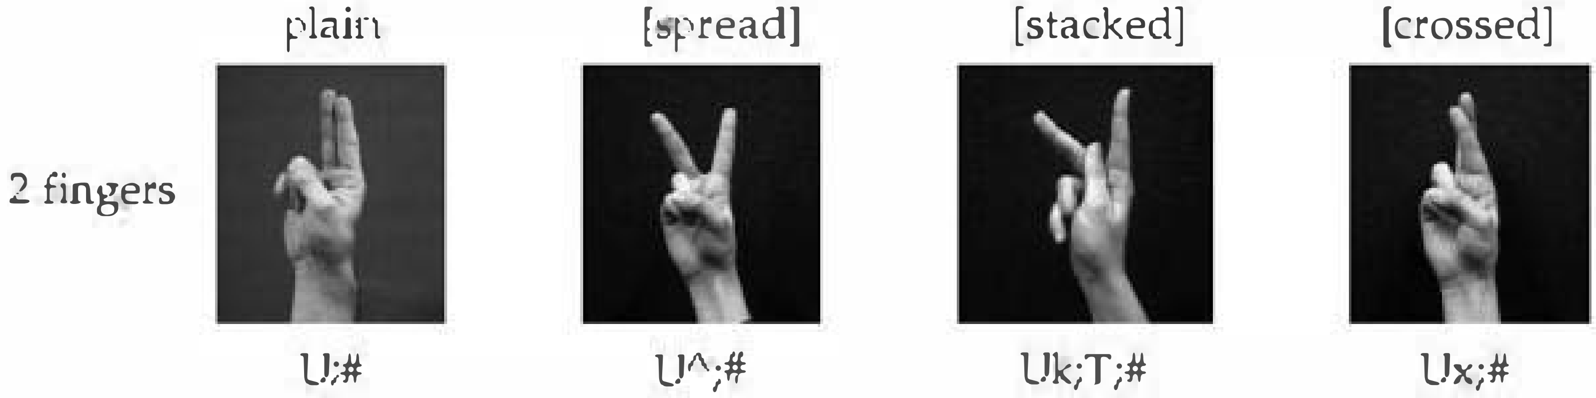
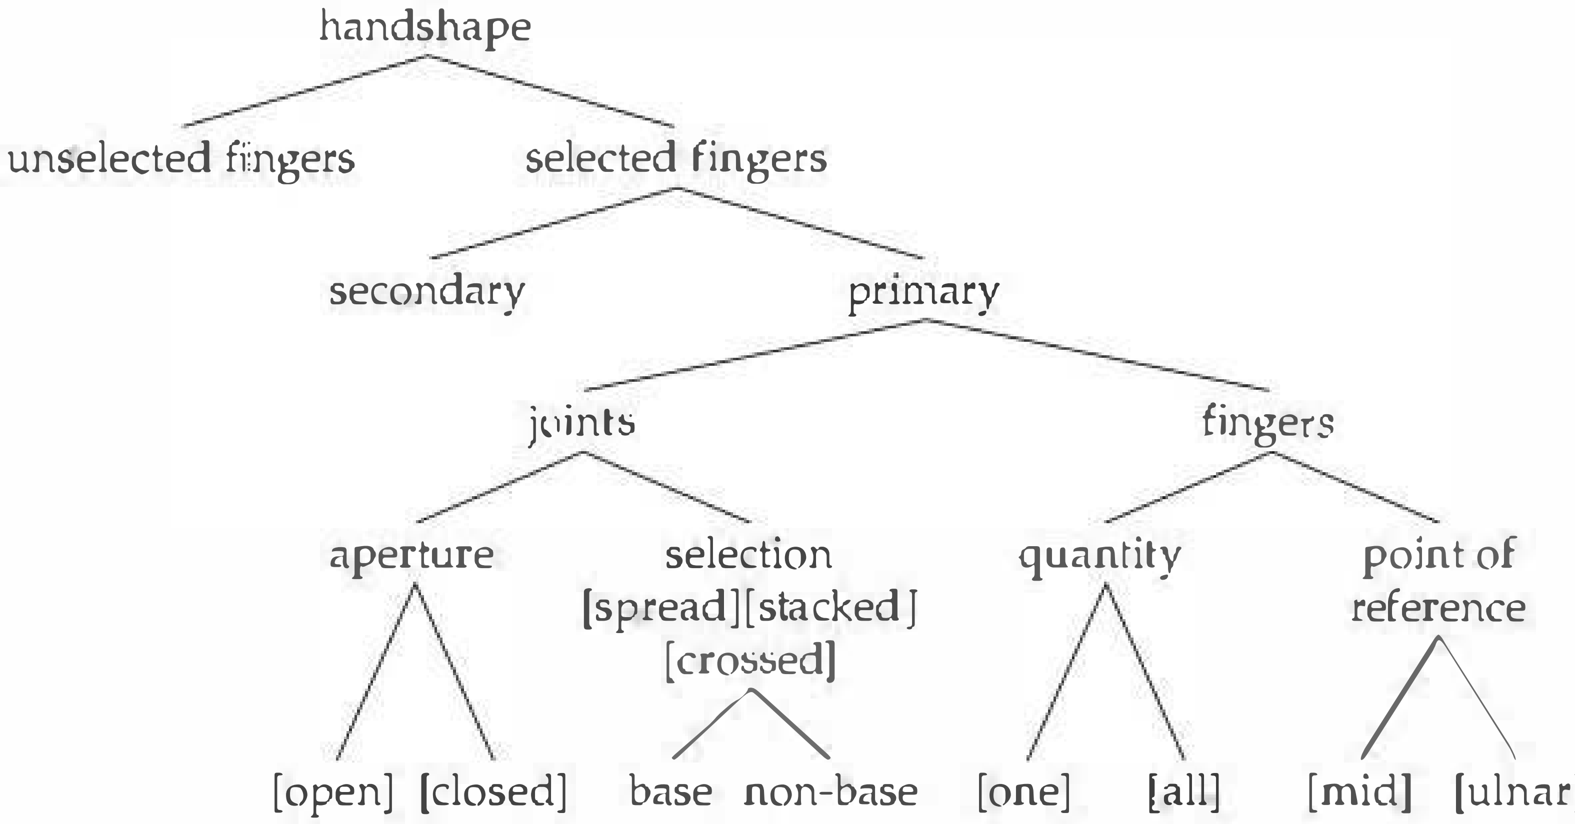
3.2 *Secondary selected fingers*

The distinction between selected and unselected fingers is sufficient to capture the majority of handshape contrasts in most sign languages, but there are a number of handshapes that require a third level of fingers, which has been called "secondary selected fingers" and can be distinguished from the "primary selected fingers" when necessary (Eccarius 2002). In such cases, the unselected fingers assume an unmarked open or closed joint position as described earlier, but the selected fingers have two different sets: one that is more marked, requiring the more elaborate specification (i.e. the primary selected fingers), and one that is less marked, but which still requires more specification than the unselected fingers (i.e. the secondary selected fingers). Cross-linguistic work – particularly from the sign languages of Asia – has demonstrated the need for this structure (Eccarius 2002, 2008; Fischer and Dong 2010). Some examples are given in (12)–(13). In (12), all three levels are represented: primary selected fingers, secondary selected fingers, and unselected fingers. The handshape in (12a) is from HKSL; (12b)–(12d) are from ASL.



If the elaborations of handshape structure described in §3 are added to the basic structure in (8), the full handshape structure is as in (16).

(16) *The structure of handshape with elaborations*



4 The role of handshape with respect to other parameters

The handshape structure in (16) is part of a larger feature hierarchy that includes Movement (M; see CHAPTER 24: THE PHONOLOGY OF MOVEMENT IN SIGN LANGUAGE), Place of Articulation (POA), and Orientation (OR). Models differ on how handshape should be represented with respect to the other parameters. Because of space, only three representative models are mentioned: the Hand Tier model (Sandler 1989; Sandler and Lillo-Martin 2006), the Prosodic Model (Brentari 1998), and the Dependency Model (van der Hulst 1995; van der Kooij 2002). Also because of space, only two points that bear on the issue of handshape (HS) and other phonological structures are raised: aperture change (ApChange; already discussed above) and orientation. A full discussion of the arguments for these structural differences is beyond the scope of this chapter, so the purpose of the representations below is simply to indicate where aperture change and orientation are represented in these different models. The differences arise from trying to best determine the simplest and most elegant analysis that can account for specific sets of forms. In addition, the Hand Tier Model adheres to the view that articulatory relatedness should

Table 9.2 Places of articulation internal to the hand (i.e. handparts). Each sign in the left column orientates the indicated handpart of the dominant hand toward the sign's place of articulation. Each sign in the right column uses the indicated handpart as a place of contact on the non-dominant hand during the production of the sign

	Role in orientation in ASL	Role in two-handed signs in ASL
1. finger fronts	LABEL	DISMISS
2. palm of hand	MY	LEARN
3. back of palm	LOVE (a thing)	NATIVE-AMERICAN
4. back of fingers	CHERISH	EASY
5. radial side of fingers	OLD	WOOD
6. ulnar side of fingers	BROKE ('no money')	TICKET
7. tip of fingers/thumb	COMPLAIN	TOP
8. heel of hand (wrist)	SLIP	CHEESE

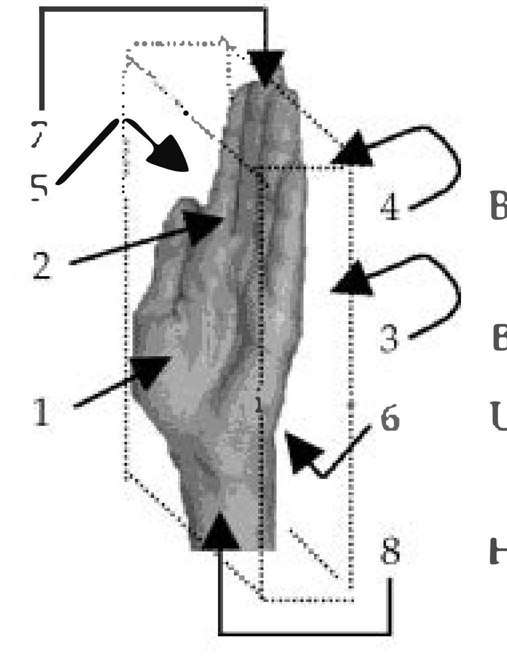


Figure 9.6 The eight surfaces of the hand used to indicate orientation

5 Handshape at the grammatical interfaces

Handshape has received a great deal of attention on purely phonological grounds, as we have seen in the previous sections. It has also been used to describe phenomena at the grammatical interfaces between phonology and other components of the grammar. Here we address handshape phenomena at the phonology–phonetics, phonology–morphology, and phonology–syntax interfaces. Each of the phenomena addressed in §5.2–§5.4 involves one or more of the phonological structures discussed earlier in this chapter. In order to understand how these phenomena are manifested in a sign language grammar, some background on the architecture of a sign language lexicon is needed.

5.1 Handshape in the core–periphery framework

Many sign languages have multiple origins, resulting in a lexicon divided into subcomponents according to the historical origins of signs, as well as their morphological and phonological behavior. For a model addressing similar facts for spoken languages, see Itô and Mester (1995a, 1995b); the sign language model is presented of these signs corresponds to the first letter of the English word (e.g. WATER, CAFETERIA, BACHELOR, and DIVORCE are all initialized signs). The spatial lexicon consists primarily of the classifier constructions, which are used to express events of motion and location. Classifier constructions are polymorphemic verbal complexes with a root – the movement – and affixes that involve place of articulation and handshape. The classifier morphemes that refer to the arguments of the predicate are the handshapes (Janis 1992; Benedicto and Brentari 2004). In classifier predicates, parts of the handshape structure can carry information about the size and shape of the object that may be phonological, morphological, and iconic at the same time. In Figure 9.7b examples of signs in each of the components using the same handshapes are shown: "F" , "O" , and "C"  handshapes.

5.2 *The phonology–phonetics interface and joint features*

A recent study was conducted to address whether the phonetic targets for joints were the same across the three lexical components described above (Eccarius 2008; Eccarius and Brentari, forthcoming). The stimuli consisted of video clips of core vocabulary, initialized signs from the foreign component, and classifier forms from the spatial component. Three handshape groups were tested ("O," "F," and "C"). Each item included three variants of the handshape (round, intermediate, and flat) at the same place of articulation using the same movement. The variants were designed to address the stability of joint specifications throughout the lexicon. A foreign item using the "C" handshape is given in Figure 9.8, with the round, intermediate, and flat forms. The round form is the sign for CAFETERIA and the flat form is the sign for BACHELOR (a minimal pair); the intermediate form could be interpreted as either sign or neither of them. Twelve Deaf signers who were native or early learners of ASL participated in this experiment.[10]

A total of 154 randomized stimulus video clips, balanced across lexical component (core, foreign, spatial), handshape group (O, F, C), and variant (round, intermediate, flat) were shown to each participant. Participants were asked to watch each clip and to respond to two questions presented immediately afterwards on the computer screen: "What is the best English meaning for this sign?" and "Please rate the handshape of this sign," from very bad to very good, on a five-point scale.

Figure 9.8 The round, intermediate, and flat variants of "C" used with the target signs CAFETERIA (left), BACHELOR (right), and an intermediate form (middle)

[10] A "native signer" is someone with two Deaf signing parents; an "early learner" is defined here as someone who learned ASL before age five.

Figure 9.9 (a) A whole entity and (b) a handling classifier handshape in ASL

of selected finger complexity.[12] Low-complexity handshapes have the simplest phonological representation (Brentari 1998), are the most frequent handshapes cross-linguistically (Hara 2003; Eccarius and Brentari 2007) and are the earliest handshapes acquired by native signers (Boyes Braem 1981). These three criteria converge on the set of handshapes represented in (18a): all fingers, index finger, and thumb. These three handshapes have also been found to be frequent in the spontaneous gestures that accompany speech (Singleton *et al.* 1993) and in child homesign (Goldin-Meadow *et al.* 1995). Medium-complexity handshapes include one additional elaboration of the finger representation of a one-finger handshape. The elaboration indicates that the single selected digit is not on the "radial" (thumb) side of the hand (the default specification) – e.g. in the finger is on the [ulnar] "pinkie" side of the hand and is [mid] "middle" – or that there is an additional finger selected, as in where two fingers are selected rather than one. High-complexity handshapes include all other handshapes, e.g. and.

(18) *Low- and medium-complexity handshapes* (Brentari 1998; Eccarius and Brentari 2007)

a. *low complexity*

- (B): fingers – quantity [all]
- (1): fingers – quantity [one]
- (T): selected fingers – thumb

b. *medium complexity*

- (I): fingers – quantity – (quantity [one], POR [ulnar])
- (8): fingers – quantity – (quantity [one], POR [mid])
- (U): fingers – quantity [one] – [all]

[12] Joint complexity has been set aside for future analysis and is not considered here.

Using both elicitation methods and grammaticality judgments, Eccarius (2008) and Brentari and Eccarius (2010) found that whole entity and handling classifiers differ systematically in their distribution of finger complexity. Whole entity classifiers have a larger set and a more complex set of finger contrasts than handling classifiers (see (19); the level of complexity is shown beneath each handshape).[13] Both types of classifier handshapes have the potential to use selected fingers to show the size and shape of an object, yet only whole entity classifiers do this extensively.

(19) *Number of finger contrasts for classifier handshapes in ASL, HKSL, and DSGS, with the finger complexity given for each*

	Finger contrasts						
Object CL-HSs	1	1	1	2	2	3	3
Handling CL-HSs	1	1	1	2			

This distribution is a part of the phonology–morphology interface for several reasons. First, the morphological categories for whole entity and handling classifiers are associated with a corresponding phonological pattern, but this state of affairs is not obligatory. For example, if a hypothetical morphological classifier type in a sign language comprised the following handshapes – – the set would also form a phonological class, because the handshapes in the set share a phonological property (their joints are all fully extended). New handshapes that enter the set would be predicted to be fully extended as well. If, instead, the hypothetical classifier type comprised this set of handshapes – – the set would not form a phonological class as there is no common property that the handshapes share. In this event, the handshapes would constitute a morphological class, but not a phonological one. In the case discussed here, finger complexity provides a unifying phonological property associated with whole entity and handling classifiers; high complexity is associated with whole entity classifiers and low complexity with handling classifiers. New forms entering the system are therefore expected to conform to this pattern. Second, the phenomenon is morphophonological because it is tied to specific morphological classes, similar to the way that Trisyllabic Laxing is tied to English words having specific Class 1 affixes (CHAPTER 94: LEXICAL PHONOLOGY AND THE LEXICAL SYNDROME). And third, this phenomenon is phonological because selected fingers are phonological throughout the system, as has been discussed earlier in this chapter, and whatever iconicity might exist in classifiers is subject to phonological pressures on the system as a whole, such as ease of articulation and ease of perception (Eccarius 2008).

This work expands the range of generalizations possible in sign language phonology, specifically with regard to handshape, which is important in its own right. In addition, it provides a new way to consider the emergence of phonology as it has evolved from gesture to homesign and from homesign to a sign language. Sign languages utilize iconicity, but it is not used in the same way by gesturers,

[13] Handshapes in (19) are abstract classes, so, for example, the handshape , with or without the thumb, represents any handshape with one selected finger, i.e. one finger active, e.g. , . The thumb is ignored in our analysis, except when it is the only finger selected.

The second diagnostic syntactic test is sensitive to objects/themes. The sign languages we have investigated have a form for the "distributive," with the meaning '. . . to each'. As above, sentences with verbs from the core lexicon are tested first (22). The sentence in (22a) with MELT, an unaccusative verb, is grammatical with the 'to-each' form. The sentence in (22b) with LAUGH, an unergative verb, obtains an ungrammatical result for the intended meaning 'Each woman laughed.' The only interpretation of this sentence that is acceptable is 'The woman laughed at each [of them].' As above, the sentences in (23) express a minimal difference in meaning and form (i.e. in both cases each book is moving onto its side). The form in (23a) contains the whole entity classifier and the one in (23b) contains the handling classifier, the same two forms discussed above. The results of this test determine that the sentences in both (23a) and (23b) are grammatical because both the whole entity (23a) and handling (23b) classifiers contain an object/theme. The whole entity classifiers are therefore intransitive since only an object is present, and the handling classifiers transitive because both an object and subject are present.

(22) *The Distributive Test applied to core lexical verbs*

a. BUTTER MELT+ 'to-each'
butter melt DISTRIBUTIVE
'Each butter melted.'

b. WOMAN LAUGH + 'to-each'
woman laugh DISTRIBUTIVE
\# 'Each woman laughed.'
'The woman laughed at each of them.'

(23) *The Distributive Test applied to classifiers*

a. BOOK B/+ MOVE + 'to-each'
book OBJECT CLASSIFIER + move + DISTRIBUTIVE
'Each of the books fell down (on its side).'

b. BOOK C/+ MOVE + 'to-each'
book HANDLING CLASSIFIER + move + DISTRIBUTIVE
'Each book was put on its side.'

This transitive–intransitive alternation concerns the phonology because it can be captured by a phonological analysis specifying which nodes of the feature tree are associated with this syntactic distinction. The phonological element involved in the transitive–intransitive alternation concerns the differential use of orientation of the hand.[15] In whole entity classifiers orientation is purely phonological and does not interact with the syntax. In handling classifiers, the parts of the hand shown in Figure 9.6 can be used morphologically, and these alternations also interact with the syntax to express an agent.

The studies presented here provide a few examples of how phonology interacts with the phonetic, morphological, and syntactic components. In the phonology–phonetics example, it was the joint features that were used. In the phonology–morphology example, it was the selected fingers that allowed for the generalization

[15] As stated in §4, orientation is represented differently in the phonological models available; however, these handpart features are part of the handshape structure in all models.

be searched for. This notation also captures the case of two handshapes that are very similar phonetically, but which belong to different handshape groups because of differences in their selected fingers, such as examples (10) and (11) in the text. A complex handshape meaning SPACE-SHUTTLE is transcribed below:

1. finger base symbol
2. thumb base symbol
3. thumb joint symbol
4. spread "stacked" and/or "crossed" joint symbol(s)
5. remaining joint symbol
6. secondary selected fingers symbols (4 are possible)
7. unselected fingers symbol

1	2	3	4	5		6					7
U			x		;	J	T			;	#

primary selected fingers (1–5); secondary selected fingers (6); unselected fingers (7)

See Eccarius and Brentari (2008) for full details of the notation system.

123 Hungarian Vowel Harmony

Miklós Törkenczy

1 Introduction

Vowel harmony is undoubtedly the best known and most studied aspect of Hungarian phonology. This is especially true if one has the international literature in mind: other Hungarian phonological phenomena have received relatively little attention. There is a host of analyses of Hungarian vowel harmony, pre-generative, "mainstream" generative (especially post-*SPE*), including optimality-theoretic approaches, and "non-mainstream" generative.[1] The reason for this attention is that Hungarian vowel harmony has been used as a testing ground for various theories and theoretical tools/devices of generative phonology. This is primarily due to (the coexistence of) a number of features displayed by Hungarian vowel harmony: long-distance effects, the transparency of neutral vowels and the variation in harmony associated with them, the intricate patterning of alternating and invariant suffixes, the existence of antiharmonic roots, and the combination and very different character of backness and roundness harmony. Attention increased especially with the advent of autosegmental phonology and underspecification theory (e.g. Clements 1976; Vago 1976, 1978, 1980a; Jensen 1978; Ringen 1978, 1980, 1988a; Booij 1984; van der Hulst 1985), and again with the recent shift of research towards phonetic motivation (e.g. Beňuš *et al.* 2003; Beňuš and Gafos 2005, 2007) and variation in phonology (e.g. Hayes and Londe 2006; Hayes *et al.* 2009). Because of this theoretical bias in the research into Hungarian vowel harmony, the linguist reading the literature may learn much, but also too little: the available analyses tend to focus only on some aspects of Hungarian vowel harmony[2] – typically those crucial to the theoretical issue at hand – and tend to disregard/ignore others, thus sometimes failing to do justice to the complexities and intricacies of Hungarian vowel harmony. Therefore, instead of surveying the analyses (which would not be useful or possible because of the sheer number of – often very different – competing analyses and the transitory nature of some

[1] For a bibliography of Hungarian vowel harmony, which is intended to be fairly exhaustive, see the further reading section below.

[2] Some comprehensive treatments are notable exceptions, e.g. Vago (1980c), Abondolo (1988), Olsson (1992), and Siptár and Törkenczy (2000).

of the theoretical problems some of them focus on), I will concentrate on the empirical aspect and the major analytic issues of Hungarian vowel harmony. In what follows, after a brief review of the Hungarian vowel system (§2), I will discuss in detail the properties of Hungarian vowel harmony in §3, attempting to give comprehensive descriptive coverage. I will pay special attention to areas where vowel harmony interacts with other, lesser-known (or rarely discussed) areas of Hungarian phonology. Finally, in §4 I will briefly survey the major analytic issues that a phonological treatment of Hungarian vowel harmony has to address. Throughout, I will try to be as theoretically neutral as possible and will take pains to highlight exceptional behavior or data/patterns not (sufficiently) understood.

2 Background: The Hungarian vowels

The phonological classification of the Standard Hungarian[3] vowels is given in (1) below, where the italicized characters that appear next to the IPA symbols are the vowel letters of Hungarian orthography. The vowel spelled <a> is transcribed as [ɔ], [ɒ], or [ɑ] in the literature. Phonetically, this vowel is more open than [ɔ] and less open than [aː ɑ]. It has considerably less lip rounding than [ɔ ɒ], but more than [ɑ]. As nothing hinges on this matter as far as vowel harmony is concerned, I will (arbitrarily) use the symbol [ɔ] for <a>.

(1)

	front		back	
	unrounded	rounded	unrounded	rounded
high	iː *í* i *i*	yː *ű* y *ü*		uː *ú* u *u*
mid	eː *é*	øː *ő* ø *ö*		oː *ó* o *o*
low	ɛ *e*		aː *á*	ɔ *a*

Although there are subtle phonetic differences between the heights of non-high long and short vowels, and [aː] is phonetically central, it is usually assumed that phonologically it is sufficient to distinguish only three vowel heights and two degrees of backness (see Siptár and Törkenczy 2000). The long–short pairs are established on the basis of length alternations like those in (2):[4, 5]

[3] It is also referred to as Educated Colloquial Hungarian (ECH), spoken in Budapest; see Nádasdy (1985). There is very little on Hungarian vowel harmony in dialects; see Rebrus (2000a), Ringen and Szentgyörgyi (2000), and Ringen and Vago (1998).

[4] There are sporadic cases of other pairings, e.g. [oː ~ ɔ]: *hó* ~ *hav-at* [hoː ~ hɔvɔt] 'snow (NOM ~ ACC)'.

[5] Hungarian consonant letters typically have transparent phonetic values, except for *sz* [s], *s* [ʃ], *zs* [ʒ], *cs* [ʧ], *c* [ts], *ny* [ɲ], *ty* [c], *gy* [ɟ], *j*, *ly* [j]. The doubling of a consonant letter or the first letter of a consonant digraph indicates a geminate consonant: *tt* [tː], *ggy* [ɟː]. As can be seen in (1), a single or a double acute accent above a vowel letter denotes length, not stress (which is always on the first syllable of the word). I will use capital letter abbreviations for harmonizing vowels in suffixes, as is customary in analyses of Hungarian vowel harmony (see §3.3.1). Wherever necessary, I will indicate roots by underlining and affixes in bold. The symbol "≈" will be used to indicate vacillation.

(2)

	nominative		*accusative*		
iː ~ i	*víz*	[viːz]	*viz-et*	[vizɛt]	'water'
yː ~ y	*tűz*	[tyːz]	*tüz-et*	[tyzɛt]	'fire'
uː ~ u	*kút*	[kuːt]	*kut-at*	[kutɔt]	'well'
øː ~ ø	*kő*	[køː]	*köv-et*	[køvɛt]	'stone'
oː ~ o	*ló*	[loː]	*lov-at*	[lovɔt]	'horse'
eː ~ ɛ	*kéz*	[keːz]	*kez-et*	[kɛzɛt]	'hand'
aː ~ ɔ	*nyár*	[ɲaːr]	*nyar-at*	[ɲɔrɔt]	'summer'

Given the classification in (1) the paired vowels differ in length only phonologically, except for *é* ~ *e* [eː ~ ɛ], which differ in height too, and *á* ~ *a* [aː ~ ɔ], which also differ in rounding. These predictable differences are often abstracted away from, and seen as the result of, late rules or phonetic interpretation.

3 Vowel harmony

Hungarian has both backness (palatal) and roundness (labial) harmony (see CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS and CHAPTER 118: TURKISH VOWEL HARMONY for more discussion of vowel harmony). Both are root-controlled or, more precisely, stem-controlled, i.e. the harmonic properties of the root/stem determine the harmonic properties of the affix(es). Directionality is left-to-right, but this does not have to be stipulated since all prefixes are outside the harmonic domain, which consists of root+ suffixes. Phonologically, prefix+ root combinations behave like compounds, in that each prefix forms its own harmonic domain, and thus does not harmonize with the root. Compare compound *fa* + *gyöngy* [fɔɟøɲɟ] 'mistletoe' (literally 'tree-pearl') and pre-verb + verb *át* + *köt* [aːtkøt] 'tie up' (literally 'across-tie'), where "+" indicates the morpheme boundary (see the discussion of the domain issue later in §4.1). Intervening consonants do not interact with Hungarian vowel harmony; they neither block nor initiate the harmonizing features.

Backness harmony, which in general requires that vowels should agree in backness within the harmonic domain, is based on the following groupings:

(3)

Back	B	u uː o oː ɔ aː
Front rounded	Fr	y yː ø øː
Neutral: front unrounded	N	i iː ɛ eː

Neutral vowels form a separate group, since they may in general interrupt a back harmonic span and may behave as transparent and/or opaque (see §3.4.1 for the details).

While backness harmony is pervasive in the phonology, roundness harmony is restricted. In general it requires that the *front* alternants of some suffixes should agree in roundness with the stem – in this sense it is parasitic on backness harmony (see §3.5 for details).

3.1 Roots

With respect to backness harmony, roots can be classified according to (a) the distribution of back, front rounded, and neutral vowels in them, and (b) the

3.2 The distribution of vowels in roots

(4) shows that Fr, B, and N vowels freely combine in (bisyllabic) monomorphemic roots, as all possible combinations exist. However, this picture is quite misleading, since the type frequency of some types of roots in the lexicon is strikingly lower than that of others. Notably, monomorphemic roots (bisyllabic or longer) in which Fr and B vowels combine in any order (types a.ii and b.i) are very rare (these are called "disharmonic stems"). For example, in a dictionary of about 80,000 lexical items I have found only 11 monomorphemic roots in which [ø] and [ɔ/aː] combine (e.g. *manöken* [mɔnøkɛn] 'model', *pönálé* [pønaːleː] 'penalty'), 12 in which [øː] and [ɔ/aː] combine (e.g. *amőba* [ɔmøːmɔ] 'amoeba', *amatőr* [ɔmɔtøːr] 'amateur'), and only one in which [øː] and [u] (*krőzus* [krøːzuʃ] 'very rich person') combine. That this is not due to the incompatibility of back and front vowels in monomorphemic roots can be seen if we examine the type frequency of "mixed" roots, i.e. roots in which B and N vowels combine in any order, namely types (b.iii) and (c.ii) in (4). There are many more mixed roots (of any length) than disharmonic roots. In the same search I found 1,084 monomorphemic roots in which [ɛ] and [ɔ/aː] combine (e.g. *ceruza* [tsɛruzɔ] 'pencil', *kráter* [kraːtɛr] 'crater'), and 149 in which [iː] and [ɔ/aː] combine (e.g. *papír* [pɔpiːr] 'paper', *hínár* [hiːnaːr] 'seaweed') in any order. Even though the frequency of [ɛ] or [eː] is known to be much higher than that of [ø] or [øː], the difference is telling. Thus, disharmonic roots, which are typically recent loans,[6] can be seen as special or irregular, while mixed roots – together with "simple roots" (roots not disharmonic or mixed) – are considered normal or regular (this is assumed in most analyses). Although (4) shows monosyllabic and bisyllabic roots only, as we have implied in the discussion above, the simple/mixed/disharmonic distinction carries over to longer roots as well: a root of any length is (a) simple if it contains Fr vowels only, B vowels only, N vowels only, or only Fr and N vowels, (b) mixed if *only B* and N vowels combine in it, and (c) disharmonic if it contains B and Fr vowels. A root that contains B, Fr, and N vowels is disharmonic (e.g. *manöken*). The frequency of the mixed type as compared to the disharmonic type is (part of) the lexical motivation for considering front unrounded vowels neutral. These are lexical classes independent of the harmonic behavior a root induces in a harmonizing suffix.

Roots are stable in their classes: there is typically no vacillation or allomorphy that involves harmony. If the root is subject to some alternation, the alternants are faithful in that they both belong to the same harmonic lexical class. This is true of vowel alternations, e.g. length alternations (see (2)), and vowel–zero alternations (*bokrot* [bokrot] 'bush (ACC)', *bokorban* [bokorbɔn] 'bush (INESS)', *epret* [ɛprɛt] 'strawberry (ACC)', *eperben* [ɛpɛrbɛn] 'strawberry (INESS)'), and trivially of all alternations that only involve consonants.

There are two kinds of exceptions to this generalization. "Vacillating disharmonic roots" (Vago 1978; van der Hulst 1985) are a marginal group of stems that are optionally either mixed or disharmonic. These roots are a special case of a phenomenon in which *some* syllables with [ɛ] in *some* roots have a free (or sometimes

[6] Intuitively, disharmonic roots "feel" foreign while mixed roots do not (by virtue of their mixed nature, other phonological properties may make them feel foreign too). To the best of my knowledge, this native speaker intuition about well-formedness has never been tested experimentally.

3.3 Suffixes

3.3.1 Suffix classes

Based on the quality of the alternating vowels involved and the number of suffix alternants, Hungarian suffixes fall into three alternating classes plus one in which the suffix vowel does not alternate (see Rebrus 2000a for an exhaustive list of suffixes). In the examples below I will use the same four roots whenever possible to facilitate comparison: *bot* [bot] 'stick', *fal* [fɔl] 'wall', *év* [e:v] 'year', *tök* [tøk] 'marrow'.[8]

(7) *Quaternary suffixes*
 [o~ɔ~ɛ~ø] *o~a~e~ö* (abbreviation: @)
 example: plural -@*k*
 botok [botok], ***falak*** [fɔlɔk], ***évek*** [e:vɛk], ***tökök*** [tøkøk]

There are 17 productive suffixes of this kind. Suffix-initial vowels that show vowel–zero alternation (traditionally called "linking" vowels) typically alternate in this way.[9]

(8) *Ternary suffixes*
 [o~ɛ~ø] *o~e~ö* (abbreviation: O)
 example: allative -*hOz* 'to'
 bothoz [bothoz], ***falhoz*** [fɔlhoz], ***évhez*** [e:fhɛz], ***tökhöz*** [tøkhøz]

There are nine productive suffixes of this kind.

Quaternary and ternary suffixes show the effect of backness and roundness harmony. The difference between quaternary and ternary suffix alternations (i.e. the occurrence of [ɔ] in the former) is due to Lowering, which is independent of harmony but interacts with it; see §3.5.1.

(9) *Binary suffixes*

a. [u~y] *u~ü* (abbreviation: U)
 example: -*Unk* 'our'
 botunk [botuŋk], ***falunk*** [fɔluŋk], ***évünk*** [e:vyŋk], ***tökünk*** [tøkyŋk]

b. [u:~y:] *ú~ű* (abbreviation: Ú)
 example: -*Ú* 'having'
 botú [botu:], ***falú*** [fɔlu:], ***évű*** [e:vy:], ***tökű*** [tøky:]

c. [ɔ~ɛ] *a~e* (abbreviation: A)
 example: inessive -*bAn* 'in'
 botban [bodbɔn], ***falban*** [fɔlbɔn], ***évben*** [e:vbɛn], ***tökben*** [tøgbɛn]

d. [a:~e:] *á~é* (abbreviation: Á)
 example: adessive -*nÁl* 'at'
 botnál [botna:l], ***falnál*** [fɔlna:l], ***évnél*** [e:vne:l], ***töknél*** [tøkne:l]

e. [o~ø] *o~ö* (no abbreviation)
 example: -*nok/nök* [nok/nøk] 'person acting in X capacity'
 látnok [la:tnok] 'visionary', ***mérnök*** [me:rnøk] 'engineer'

[8] The suffix counts are based on Rebrus (2000a) and Siptár and Törkenczy (2000); non-productive suffixes and semi/non-productive Latinate/Greek suffixes have been excluded.

[9] There are four exceptions: superessive -*n/on/en/ön* [n/on/ɛn/øn] 'on' (ternary); past -*t(t)/ott/ett/ött* [t(:)/ot:/ɛt:/øt:] (ternary); 1st plural possessive 'our' -*nk/unk/ünk* [ŋk/uŋk/yŋk] (binary); 1st personal plural (verb) -*nk/unk/ünk* [ŋk/uŋk/yŋk] (binary).

(13a) is not exceptionless: *-kor* is the only exception; it is productive, invariant and has a non-neutral vowel.

(14) *Non-neutral vowels*

a. Non-neutral vowels only exceptionally occur in productive invariant suffixes.
b. It is accidental which non-neutral vowels occur in a (productive or non-productive) invariant suffix (although some generalizations can be made: e.g. Fr vowels do not occur).

This asymmetrical distribution of vowels in alternating and invariant suffixes is (part of) the lexical motivation for considering front unrounded vowels neutral. Note that the neutrality of [ɛ] is questionable in this respect, since it does not occur in invariant suffixes (see §3.4.1).

The suffix analogue of disharmonic stems (in which Fr and B vowels would combine) does not exist.

3.4 Backness harmony

(4) above shows that the final vowel of the root (i.e. the one closest to the suffix) determines backness harmony if it is Fr or B (4a, 4b):

(15) If the closest vowel is Fr, the harmonizing suffix vowel will be front; if it is B the vowel will be back.

(15) also holds if the suffix is preceded by another suffix: *bot-Unk-bAn* = *botunkban* [botuŋgbɔn] 'in our stick', *év-Unk-bAn* = *évünkben* [e:vyŋgbɛn] 'in our year'.

If the final vowel is N, the preceding vowels determine backness harmony: *papír-bÓl* = *papírból* [pɔpi:rbo:l] 'of paper', *üveg-bÓl* = *üvegből* [yvɛgbø:l] 'of glass' (see (4c)). In fact, it is not exactly the final vowel that matters in this case but the final *uninterrupted sequence* of N-voweled syllables (one or more than one (N*)):

(16) If the closest vowel, not counting the final sequence of N-voweled syllables, is Fr (FrN*), the harmonizing suffix vowel will be front (4c.i).

Again, it does not matter if the final sequence of N-voweled syllables is contained in a monomorphemic root, or a polymorphemic stem: *kümité-tÓl* = *kümitétől* [kymite:tø:l] 'from kumite [sparring in karate]', *üd-ít-Ó* = *üdítő* [ydi:tø:] 'refreshing', *kövér-ít-i-tOk* = *kövérítitek* [køve:ri:titɛk] 'you (PL) make it/him/her fat'.

3.4.1 Variation

The remaining types of stems (4c.ii–iv) are in "zones of variation" (Hayes *et al.* 2009). Here vowel harmony is not (fully) predictable. Exactly what kind of harmonic behavior a given stem induces in harmonizing suffixes is the lexically arbitrary property of each stem. There are two types of behavior: (i) lexical variation and vacillation, and (ii) lexical variation, no vacillation.

(19) *Backness harmony after BNN stems*

	suffix behavior		
NN	back	back ≈ front	front
[iː i]		*analizisnak* ≈ *analizisnek* 'analysis' [ɔnɔliːziʃnɔk ≈ ɔnɔliːziʃnɛk]	
[iː i eː]		*klarinétnak* ≈*klarinétnek* 'clarinet' [klɔrineːtnɔk ≈ klɔrineːtnɛk]	*oxigénnek* 'oxigen' [oksigeːnːɛk]
[ɛ]			*novembernek* 'November' [novɛmbɛrnɛk]

Third, there are minor statistical patterns where backness harmony seems to be influenced by "unnatural" constraints independent of the height effect and the count effect. The following tendencies have been found by Hayes *et al.* (2009) to be statistically significant in the lexicon:[11]

(20) *Front harmonizing suffixes are preferred if the stem ends in a:*

a. bilabial non-continuant [p b m]
b. sibilant [s z ʃ ʒ ʧ ʤ]
c. coronal sonorant [n ɲ l r]
d. two-member consonant cluster

Ringen and Kontra (1989) found a preference for front harmonizing suffixes after BN stems which were longer than two syllables (but had just one N vowel) compared to two-syllable BN stems (e.g. *majonéz-Os* = *majonézes* [mɔjoneːzɛʃ] **majonézos* *[mɔjoneːzoʃ] 'with mayonnaise').

There seems to be a (potentially contrary) tendency for harmonizing suffixes to be back after BN stems in which the N vowel is stem-final: e.g. *parádé-bAn* = *parádéban* [pɔraːdeːbɔn] *?*parádében* [pɔraːdeːbɛn] 'in the parade'.

The height effect, the count effect, and these minor statistical effects combine to give the probability of the three types of suffix behavior after BN* stems. Consider, for instance, BN stems with stem-final [ɛ] (e.g. *dózse* 'doge'). In these stems the final [ɛ] lengthens to [eː] before most suffixes by Low Vowel Lengthening (LVL; see Siptár and Törkenczy 2000), a process that "upgrades" the vowel in the hierarchy of transparency, as [eː] is more transparent than [ɛ], thus *dózsé-nAk* = *dózsénak* ≈*dózsének* [doːʒeːnɔk ≈ doːʒeːnɛk] 'doge (DAT)', where the back-voweled suffix alternant is preferred, in accordance with Ringen and Kontra's findings. However, when we add the harmonizing suffix *-sÁg*, which does not trigger LVL, the vowel is not upgraded, and a back suffix alternant is less likely or impossible: *dózse-sÁg* = *dózseség* [doːʒɛʃeːg], *?*dózseság* *?[doːʒɛʃaːg] 'dogehood'.

Probability manifests itself in type frequency and native-speaker intuition. These were tested for some effects by Hayes and Londe (2006) and Hayes *et al.* (2009), using Google searches and a wug test, and by Ringen and Kontra (1989), using a sentence completion test with real BN stems.

Vacillation seems also to be sensitive to larger (phrasal) context (Kontra *et al.* 1989, 1991; Londe 2005). The choice between vacillating suffix alternants is

[11] These tendencies were found in all the zones of variation, i.e. in all-neutral stems as well.

of *Vígszínház* (Comic Theatre)), *Víg-bAn* = *Vígben* [vi:gbɛn], **Vígban* *[vi:gbɔn]. This also suggests that the antiharmonic pattern is not the regular/productive one. It is only roots that can be antiharmonic: there is no suffix that contains the relevant N vowels and, when added to an all-neutral non-antiharmonic (or Fr) root, would make the resulting stem antiharmonic.

(21) If in an all-neutral stem (N*) the closest vowel is [ɛ], the harmonizing suffix vowel will be *front*; if the closest vowel is [i: i e:], the harmonizing suffix vowel will be *front* after some stems and *back* after others.

Harmonic behavior is sometimes not only stem-specific, but also suffix-specific in the case of stems that show variation. The best-known example is *férfi* 'man' (see note 14), but there are others: e.g. *mágnes* [ma:gnɛʃ] 'magnet' vacillates in the dative *mágnesnek* ≈ *mágnesnak* [ma:gnɛʃnɛk ≈ ma:gnɛʃnɔk], but requires the front alternant of the adjective-forming suffix -(@)s: *mágneses* [ma:gnɛʃɛʃ], **mágnesos* *[ma:gnɛʃoʃ] 'magnetic', and *matek* [mɔtɛk] 'math' vacillates in the dative *mateknek* ≈ *mateknak*, [mɔtɛknɛk ≈ mɔtɛknɔk], but requires the back alternant of -(●)s *?*matekes* *?[mɔtɛkɛs], *matekos* [mɔtɛkos] if the meaning is 'person good at/interested/specializing in math'. The preference for one or another type of behavior may not be absolute. Very little is known about the suffix-specific aspect of Hungarian vowel harmony.

3.4.2 *Antiharmony*

Antiharmony occurs if an all-neutral stem takes the back alternant of a harmonizing suffix, a stem whose final vowel is Fr takes the back alternant of a harmonizing suffix, or a stem whose final vowel is B takes the front alternant of a harmonizing suffix. All three occur in Hungarian:

(i) *Antiharmonic roots*: this is the type of antiharmony we discussed in §3.4.1, which applies after a closed set of all-neutral roots.

(ii) *"Foreign" antiharmonic roots*: Some recent loans (from German and English) that are all neutral or whose final vowel is Fr take the back allomorph of the verb-forming suffix -(●)*l*, which otherwise harmonizes in the expected quaternary way (see (7), §3.5.1 and §4.3); cf. Kertész (2003). Compare (22a), where the suffix appears after "regular" Hungarian stems, with (22b), where it occurs after recent loans to form verbs:[15]

(22)	a.	*lábal*	[la:bɔl]	'wade'
		gombol	[gombol]	'button up'
		énekel	[e:nɛkɛl]	'sing'
		gőzöl	[gø:zøl]	'steam'
	b.	*(be)csekkol*	[ʧɛk:ol]	'check in'
		gründol	[gryndol]	'found (business)'
		risztol	[ristol]	'share (money)'
		dekkol	[dɛk:ol]	'wait (idly)'
		flémol	[fle:mol]	'flame' (in computing)

[15] Hungarian can borrow nouns, but not verbs, as bare roots. Verbs must be suffixed by verb-forming -(@)z or -(@)l: e.g. *sztrájk* [stra:jk] 'strike (N)', but *sztrájkol* [stra:jkol] 'go on strike'.

c.	*hekkel*	[hɛkːɛl]	'hack'
	printel	[printɛl]	'print'
	csetel	[ʧɛtɛl]	'chat (on the Internet)'
	netel	[nɛtɛl]	'use the Internet'

(22c) shows that recent verbal loans do not necessarily behave in an antiharmonic way. Kertész (2003) suggests that while it is not predictable which recent loan will behave antiharmonically with -(@)*l*, some regularities seem to obtain: foreign antiharmonic roots all end in a heavy syllable (in the stem containing the root and the suffix): ***dek**.kol*, ***flé**.mol* vs. ***cse**.tel*. Note that a heavy root-final syllable does not imply antiharmonic behavior: compare ***dek**.kol* and ***hek**.kel*. This can be seen as an "unnatural" constraint comparable to those in (20). This phenomenon is restricted to the verb-forming suffix -(@)*l*. The antiharmonic examples can be analyzed as containing a different, invariant -*ol* suffix (Siptár and Törkenczy 2000), in which case this type of antiharmony disappears. Then the problem becomes one of selection between the harmonizing verb-forming suffix -@*l* (22c) and the invariant -*ol* (22b) in recent loans.

(iii) *Systematic suffix-inconsistent antiharmony*: In Standard Hungarian the harmonizing conditional suffix -*nA*, which as a result of LVL becomes -*nÁ* before suffixes, appears in its *front* allomorph after stems with a final B vowel in the 1st singular indefinite present (Rebrus 2000b; Rebrus and Törkenczy 2005). Everywhere else the suffix harmonizes in a normal way. In the examples below I use the stems *vár* [vaːr] 'wait' and *tör* [tør] 'break' to show this.

(23) *Indefinite present conditional*

	vár		*tör*	
1SG	*vár-né-k*	[vaːrneːk]	*tör-né-k*	[tørneːk]
2SG	*vár-ná-l*	[vaːrnaːl]	*tör-né-l*	[tørneːl]
3SG	*vár-na*	[vaːrnɔ]	*tör-ne*	[tørnɛ]
1PL	*vár-ná-nk*	[vaːrnaːŋk]	*tör-né-nk*	[tørneːŋk]
2PL	*vár-ná-tok*	[vaːrnaːtɔk]	*tör-né-tek*	[tørneːtɛk]
3PL	*vár-ná-nak*	[vaːrnaːnɔk]	*tör-né-nek*	[tørneːnɛk]

The conditional suffix is not invariant, since it harmonizes in all other persons, and it is not the 1st singular morphosyntactic value that is associated with disharmony, since the same conditional suffix harmonizes in e.g. 1st singular definite present conditional: *várnám* [vaːrnaːm] vs. *törném* [tørneːm]. It is only before the 1st singular indefinite suffix -(@)*k* that the conditional suffix is invariably -*né*-. This inconsistent behavior with respect to backness harmony is exceptional: no other suffix behaves in this way. Otherwise, suffixes are stable in their classes: they are either always alternating (in the same way) or always invariant. In non-standard Hungarian and some regional dialects, this type of antiharmony does not occur and the conditional harmonizes in the usual way in the 1st singular indefinite present too: *várnák* [vaːrnaːk], *törnék* [tørneːk]. See §4.5 for further discussion of systematic suffix-inconsistent antiharmony.

3.4.3 -*ja/i* [jɔ/i]

The definiteness marker in the 3rd singular and 2nd and 3rd plural present indicative is peculiar because – although it alternates according to the harmonic type of the stem – the alternation is suppletive: the "front" alternant is *-i* [i] and the "back" alternant is *-ja/já*[16] [jɔ/jaː]: *töri* [tøri] *vs.* *várja* [vaːrjɔ] (3SG DEF PRES INDIC); *töritek* [tøritɛk] *vs.* *várjátok* [vaːrjaːtok] (2PL DEF PRES INDIC). Even though this alternation is suppletive, it does not violate backness harmony, since the vowel of *-ja/já* is back and *-i* is front. Interestingly, the *-i* alternant behaves in an opaque way: only a front suffix can follow it. This must be related to the fact that *-i* is the front alternant of a harmonizing suffix rather than an invariant one (compare invariant verb-forming *-ít* [iːt], which is transparent). Consider the following examples: *martini-z-i* [mɔrtinizi] and *martini-z-za*[17] [mɔrtinizːɔ] 'drink Martini (3SG DEF PRES INDIC)' are both possible due to the count effect. But when a harmonizing suffix e.g. *-tOk* (2PL) is attached to the first variant, only the front suffix alternant is possible *martini-z-i-tek* [mɔrtinizitɛk], **martinini-z-i-tok* *[mɔrtinizitok] 'drink Martini (3SG DEF PRES INDIC)' in spite of the fact that the count effect suggests both should be possible after a BN* stem.

However, vacillation *does* occur in similar examples with invariant *-ít*: consider *martini-s-ít-Om* ('treat as/turn something into Martini (1SG DEF PRES INDIC)'): *martini-s-ít-em* ≈ *martini-s-ít-om*, [mɔrtinisiːtɛm ≈ mɔrtinisiːtom] where both variants are possible. Furthermore, neutral-only invariant suffixes never change the harmonizing effect of the root and thus do not contribute to the count effect. Adding an invariant neutral-only suffix to a BN root or more than one to a B root never results in the count effect; the following harmonizing suffix will always be back without vacillation (as the root itself would require): *Martin-ék-hoz* [mɔrtineːkhoz], **Martin-ék-hez* *[mɔrtineːkhɛz] 'to the Martins'; *Márt-i-ék-hoz* [maːrtieːkhoz], *Márt-i-ék-hez *[maːrtieːkhɛz] 'to Martha (hypocoristic) and her group'. The vacillation in *martini-s-ít-em* ≈ *martini-s-ít-om* occurs because the root itself induces vacillation (as BNN) even without the invariant suffix: *martinitől* ≈ *martinitól* [mɔrtinitøːl ≈ mɔrtinitoːl]. This is a somewhat marginal phenomenon, because relevant examples are hard to come by, but it suggests that transparency is not only due to vowel quality or the rank of a vowel in the transparency hierarchy. It also shows that the association of transparency with invariance in suffixes manifests itself in very complex ways, which are unlikely to have a simple representational explanation.

3.5 Roundness harmony

Roundness harmony is relatively rarely discussed in the literature on Hungarian vowel harmony (see Polgárdi and Rebrus 1998; Ringen and Vago 1998; Rebrus 2000a; Siptár and Törkenczy 2000). Setting aside quaternary suffixes for the time being, roundness harmony can be stated as follows:

(24) If a ternary suffix is attached to a stem which is not antiharmonic and whose final vowel is front (N or Fr), the harmonizing suffix vowel will be front rounded if the final stem vowel is rounded and front unrounded if the final stem vowel is unrounded (e.g. *tökhöz, évhez*).

[16] The occurrence of [aː] in the alternant *-já* is due to LVL.

[17] The [j] of *-ja* assimilates to a preceding [z]; see Siptár and Törkenczy (2000).

The parasitic character of roundness harmony ((i) above) and its height sensitivity (ii) is typologically the most frequent state of affairs (Kaun 2004), although the restriction of *target* vowels to non-high while there are no height restrictions on the trigger seems atypical.

3.5.1 Quaternary and ternary suffixes: Lowering

Ternary suffixes, [o ~ ɛ ~ ø] *o* ~ *e* ~ *ö*, show the effect of backness harmony and roundness harmony in the way described above. Quaternary suffixes are different in that they show the usual ternary alternation after some stems and the *binary* alternation [ɔ ~ ɛ] *a* ~ *e* after others:

(25)	root			quaternary plural -@k suffix		ternary superessive -On suffix	
a.	*gáz*	[gaːz]	'gas'	*gázok*	[gaːzok]	*gázon*	[gaːzon]
	bot	[bot]	'stick'	*botok*	[botok]	*boton*	[boton]
	sün	[ʃyn]	'hedgehog'	*sünök*	[ʃynøk]	*sünön*	[ʃynøn]
	rög	[røg]	'clod'	*rögök*	[røgøk]	*rögön*	[røgøn]
b.	*gyep*	[ɟɛp]	'lawn'	*gyepek*	[ɟɛpɛk]	*gyepen*	[ɟɛpɛn]
	kép	[keːp]	'picture'	*képek*	[keːpɛk]	*képen*	[keːpɛn]
c.	*ház*	[haːz]	'house'	*házak*	[haːzɔk]	*házon*	[haːzon]
	fog	[fog]	'tooth'	*fogak*	[fogɔk]	*fogon*	[fogon]
	fül	[fyl]	'ear'	*fülek*	[fylɛk]	*fülön*	[fyløn]
	szög	[søg]	'nail'	*szögek*	[søgɛk]	*szögön*	[søgøn]

As can be seen in (25c), the vowel of the quaternary suffix shows up as [ɔ] instead of [o] after a final stem vowel and as [ɛ] instead of [ø] after a final front rounded stem vowel (i.e. roundness harmony does not apply). This is traditionally called Lowering, and the stems after which it happens are called lowering stems (25c). After non-lowering stems (25a) and stems whose final stem vowel is front unrounded, quaternary suffixes behave in the usual ternary way. In the standard dialect the lowering effect cannot be detected when the final stem vowel is front unrounded (25b), but in dialects that have a distinction between mid [e] and low [ɛ] it can, and there are other consequences of lowering in the standard dialect too (see Siptár and Törkenczy 2000).

All quaternary suffixes begin with a vowel that alternates with zero (a linking vowel), but not all suffixes with linking vowels are quaternary (see note 9).

It is a lexical property of a root whether it is lowering or not, but the frequency of lowering roots is different in different part-of-speech categories (verb roots are never lowering, most adjectives are lowering, and a closed set of about 200 nominal roots are lowering). In general, derivational suffixes do not turn a root or a stem into a lowering stem, but inflectional ones invariably do. Observe the behavior of the 1st singular definite suffix -(@)m: *üt-@m* = ***ütöm*** [ytøm] 'hit (1sg pres def)', *bánt-@m* = ***bántom*** [baːntom] 'hurt (1sg pres def)'; but *üt-@tt-@m* = ***ütöttem*** [ytøtːɛm] 'hit (1sg past def)', *bánt-@tt-@m* = ***bántottam*** [baːntotːɔm] 'hurt (1sg past def)'. The quaternary suffix lowers after the intervening past inflectional suffix -@tt: the roots are non-lowering, but the stems formed by the past suffix are (see Siptár and Törkenczy 2000).

4 Issues

Hungarian vowel harmony has been analyzed with binary features (both feature values active, or only one feature value active), unary features, or a mixture of binary and unary features. It has been given segmental and autosegmental treatments in derivational frameworks and in constraint-based ones, including Government Phonology and Optimality Theory (see further reading below). In this final section I briefly survey the most important or more interesting issues that an analysis of Hungarian vowel harmony must handle.

4.1 *Domains*

Hungarian vowel harmony applies within a domain that consists of a root plus suffixes, a domain which is often identified as the phonological/prosodic word. However, there are invariant suffixes that do not alternate. Most of these contain neutral (transparent) vowels, but there are a few with non-neutral vowels (see (10)). The former are usually analyzed as falling *within* the harmonic domain, and their invariance is seen as the consequence of their neutral character. The back invariant suffixes are either analyzed as falling outside the harmonic domain {*öt*}***kor*** [øtkor] 'at five' (where I use "{ }" to indicate the boundaries of the harmonic domain) or as being inside the harmonic domain {*öt**kor***}, but then the suffix vowel must be specified differently from the similar harmonizing ones (e.g. allative: -*hOz* = ***öthöz*** [øthøz] 'to five'). The first approach has been criticized on the grounds that if a harmonizing suffix follows the invariant back suffix, it shows up in its back alternant (Siptár and Törkenczy 2000). However, this hardly ever happens unambiguously, since the back invariant suffixes that *can* be followed by other suffixes are not (fully) productive, and as such they can be analyzed as part of the root (e.g. *cicus-hOz* = *cicushoz* [tsitsuʃhoz] 'to (a) kitten'). Also, the back invariant suffix could be analyzed as initiating its own harmonic domain in which the invariant suffix itself determines the harmonic properties of the following alternating suffix: {*cic*} {*ushoz*}. It can be seen as a drawback of the domain approach that it increases the proliferation of domains required by various processes whose domain boundaries do not line up; see Rebrus *et al.* (1996). Table 123.1 shows five suffixes (3rd plural possessive -*Unk*, -*Ul* 'in (a language)', -*ig* 'up to', -*sÁg* 'ness', -*ként* 'in the capacity of') and whether or not they obey backness harmony (VH), Low Vowel Lengthening (LVL), and the ban on adjacent identical vowels (${}^{*}V_aV_a$). For comparison I have included a pre-verb *le-* [lɛ] 'down' (since pre-verbs are known to be outside the harmonic domain).

As can be seen, various (types of) affixes delimit their own domains differently (there would be more types if more processes were included) and that invariant suffixes do not necessarily behave in the same way as prefixes (which are affixes that are not in the same harmonic domain as the stem).

4.2 *Harmony in roots*

Harmony obviously applies to suffixes as can be seen in the suffix alternations. There is sometimes disagreement about whether it applies in roots since there is no alternation evidence but only restrictions on co-occurrence (Kiparsky 1968;

Table 123.1 Domain mismatch

	VH	*LVL*	$*V_aV_a$
-Unk	+ *törökünk* 'our Turk' [tørøkyŋk] *dánunk* 'our Dane' [daːnuŋk]	+ *bembánk* 'our Bemba' [bɛmbaːŋk]	+ *bantunk* 'our Bantu' [bɔntuŋk]
-Ul	+ *törökül* 'in Turkish' [tørøkyl] *dánul* 'in Danish' [daːnul]	+ *bembául* 'in Bemba' [bɛmbaːul]	– *bantuul* 'in Bantu' [bɔntuul]
-ig	– *törökig* 'up to (a) Turk' [tørøkig] *dánig* 'up to (a) Dane' [daːnig]	+ *bembáig* 'up to (a) Bemba' [bɛmbaːig]	– *kocsiig* 'up to (a) car' [kotʃiig]
-sÁg	+ *törökség* 'Turkishness' [tørøkʃeːg] *dánság* 'Danishness' [daːnʃaːg]	– *bembaság* 'Bemba-ness' [bɛmbɔʃaːg]	X
-ként	– *törökként* 'as a Turk' [tørøkːeːnt] *dánként* 'as a Dane' [daːŋkeːnt]	– *bembaként* 'as a Bemba' [bɛmbɔkeːnt]	X
le-	– *ledob* 'throw down' [lɛdob]	– *ledob* 'throw down' [lɛdob]	– *leesik* 'fall down' [lɛɛsik]

Vago 1974; van der Hulst 1985). Disharmonic roots do exist, but they are clearly exceptional (see §3.2). While the answer is ultimately theory dependent and the motivation underlying the distinction between handling root-internal static regularities with Morpheme Structure Constraints (MSCs; see CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS) and suffix alternations with a rule of harmony has disappeared with the introduction of autosegmental representations and/or underspecification, it is notable that in OT treatments there is always a highly ranked IDENT-IO constraint relativized to the root that expresses the non-application of Hungarian vowel harmony in roots (see Ringen and Vago 1998; Hayes and Londe 2006). There are two points of interest:

(i) Vowel harmony seems to actively apply within a class of roots, called "epenthetic,"[20] which display vowel–zero alternations in their final syllable (see

[20] "Epenthetic" is only a convenient traditional label here; arguably, the vowel–zero alternation is neither epenthesis nor deletion; see Siptár and Törkenczy (2000). This has no bearing on the issue at hand.

§3.2 above). These roots all end in a VCVC string before consonant-initial suffixes and word-finally, but a VCC string before vowel-initial suffixes. Crucially, the vowel that alternates with zero behaves like the vowel of a ternary suffix [o ~ ɛ ~ ø]: its backness and rounding is determined by the preceding vowel:[21] *bokor* [bokor] 'bush', *bokorban* [bokorban] 'in (a) bush', *bokrok* [bokrok] 'bushes'; *eper* [ɛpɛr] 'strawberry', *eperben* [ɛpɛrbɛn] 'in (a) strawberry', *eprek* [ɛprɛk] 'strawberries'; *tükör* [tykør] 'mirror', *tükörben* [tykørbɛn] 'in (a) mirror', *tükrök* [tykrøk] 'mirrors'.

(ii) Root-internal and suffix harmony seem to be asymmetrical in that (a) there are no front rounded invariable suffixes, i.e. exceptions to vowel harmony that would be the equivalent of the *sofőr* type of disharmonic roots (4a.ii); and (b) unlike root + suffix combinations (e.g. *dzsungel-nÁl* = *dzsungelnál* ≈ *dzsungelnél* [ʤuŋgɛlnaːl ≈ ʤuŋgɛlneːl] 'near the jungle'), roots never vacillate between BN*[back] and BN*[front]: *mohamedán* ≈ **mohamedén* [mohɔmɛdaːn ≈ *mohɔmɛdeːn] 'Muslim'; *planéta* ≈ **planéte* [plɔneːtɔ ≈ *plɔneːtɛ] 'planet', *vanília* ≈ **vaníliе* [vɔniliɔ ≈ *vɔniliɛ] 'vanilla'. If vowel harmony is permitted to apply in roots, (i) is naturally explained, but (ii) will have to be seen as accidental unless some general principle (like Strict Cyclicity[22]; see also CHAPTER 85: CYCLICITY) can be used to distinguish the two cases.

4.3 *Harmony in suffixes*

All analyses have to address the question of how to distinguish suffixes that alternate in different ways (§3.3.1). This can be done in a fairly straightforward way with reference to vowel height. Some analyses assume that the alternating suffix vowels are fully specified and that the underlying identity of a suffix vowel is revealed when the suffix is used as a stem in pronominal forms (e.g. Vago 1980c; Ringen and Vago 1998): e.g. delative *-rÓl* in *botról/tökről* [botroːl/tøkrøːl] 'about (a) stick/marrow' has underlying /oː/ because of *rólam* [roːlɔm] 'about me', but ablative *-tÓl* in *bottól/töktől* [botːoːl/tøktøːl] 'from (a) stick/marrow' has underlying /øː/ because of *tőlem* [tøːlɛm] 'about me'. It is not clear why a phonological connection should hold between the suffixes and the corresponding pronominal forms: consider superessive *-On* in *boton/tökön* [boton/tøkøn] 'on (a) stick/marrow' and *rajtam* [rɔjtɔm] 'on me', where the same connection obviously does not obtain.

Perhaps the most vexing problem (other than the representation of neutral vowels; see §4.4) is how to distinguish ternary alternations from quaternary ones (§3.3.1). Recall that the difference is that quaternary suffixes show the effect of Lowering, but ternary ones do not. The analytic problem is that mid and low vowels (specifically the low vowel [ɛ]) are involved in both so it is not possible to distinguish them on the basis of surface height. [ɛ] is two-faced: it patterns with the *low vowels* in length alternations (e.g. LVL) and in binary suffixes like *-bAn* 'in', but with the *mid vowels* in ternary alternations. This is usually analyzed by

[21] The details are more complicated: there are a handful of exceptional "epenthetic" stems whose alternating vowel is not [o ~ ɛ ~ ø], and there are some vowel-initial suffixes before which the alternating vowel is retained; for details see Siptár and Törkenczy (2000).

[22] Presumably, Strict Cyclicity can only block vowel harmony within the root if it is a structure-changing operation (cf. Kiparsky 1982), thus only if root vowels are fully specified for the harmonizing feature.

assuming that the vowel of ternary alternations (and the alternating vowel of "epenthetic" roots) including *e* is underlyingly mid, and that it becomes low as a result of phonetic interpretation. By contrast, the vowel involved in quaternary alternations is specified in such a way that it becomes low by Lowering after lowering stems. Thus the reason why roundness harmony does not apply after lowering stems is that the resulting vowel would be a *low* front rounded vowel, which does not exist in Hungarian (see Siptár and Törkenczy 2000). This kind of analysis is problematic for surface-oriented frameworks unless some special provisions are made to handle opacity.

4.4 Transparency, neutral vowels, and variation

The behavior of neutral vowels is perhaps the main reason why Hungarian vowel harmony has received so much attention in phonology. Virtually all available theoretical approaches and analytic tools have been applied to Hungarian neutral vowels. In these analyses the fact that (some) neutral vowels are transparent is either representationally or procedurally expressed, i.e. it is either coded in the way these vowels are represented (e.g. Ringen 1988a, 1988b) or the way these vowels are "calculated" by the rules/constraints (e.g. Ringen and Vago 1998; Siptár and Törkenczy 2000). If the representational analysis is chosen, the vowel harmony rule(s)/constraint(s) can be formulated in a general way; if the procedural analysis is adopted, no special representations have to be assumed for transparent vowels. Note that the behavior of BN* stems, specifically the count effect, is a serious problem for the representational view if the transparency of vowels is analyzed as a consequence of the fact that they are not specified for the harmonizing feature. Given the usual autosegmental assumptions, the B trigger and the target of harmony are adjacent no matter how many transparent vowels intervene: there is no reason why behavior should change depending on the number of vowels, but it does.

Until very recently, variation, vacillation, and gradience in Hungarian vowel harmony (§3.4.1) – although they were noted and sometimes dealt with in the analyses – were seen as less important than the "overall" pattern of Hungarian vowel harmony, which was considered to be essentially categorical. Accordingly, a great deal of attention was paid to the exact identity of neutral/transparent vowels, specifically to whether [ɛ] is transparent (e.g. Siptár and Törkenczy 2000) or opaque (e.g. Ringen and Kontra 1989). Even if gradience in transparency was sometimes recognized, it was not built into the models (derivational, OT, etc.), which were categorical by nature. Accordingly, variation/vacillation was handled representationally, by setting up more than one underlying form for the vacillators or procedurally, by optional rules or variable constraint ranking (see Siptár and Törkenczy 2000). Hayes and Londe (2006) propose an analysis in which gradience is directly built into the model, in the form of stochastic OT, where the constraints referring to the various neutral vowels can be independently and stochastically ordered in the hierarchy of constraints. In such an analysis the categorization problem concerning [ɛ] disappears.

Some recent experimental studies (Benus *et al.* 2003; Benus and Gafos 2007) suggest that transparent vowels also participate in backness harmony *phonetically*, contrary to what all other analyses assumed. They claim that transparent vowels in the front-selecting stems (e.g. *bili-vAl* = *bilivel* [bilivɛl] 'with the chamber pot') are produced with more advanced tongue body than the corresponding vowels that occur in back-selecting stems (e.g. *buli-vAl* = *bulival* [bulivɔl] 'with the party'). Crucially, it is also claimed that the relative retraction of the [i] in *bulival* is *not* a co-articulation effect due to the neighboring back vowels, since it also shows up in *isolated* forms of antiharmonic roots like *híd* [hi:d] 'bridge' and *cél* [ʧe:l] 'aim' (as opposed to *víz* [vi:z] 'water' and *szél* [se:l] 'wind'). Beňuš and Gafos (2007) also connect the differential phonological behavior of [ɛ] compared to [i: i e:], with their different articulatory and acoustic properties, a difference which is completely arbitrary or a lexical effect in most other analyses. (For a discussion of transparent vowels see CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS.)

4.5 *Antiharmony*

The problem with antiharmonic roots (§3.4.1) is how to distinguish them from non-antiharmonic ones. They are typically assumed to have some kind of arbitrary lexical marking (in the form of abstract vowels, floating features expressing "backness" or explicitly arbitrary diacritics/full listing; see e.g. Vago 1980c; Siptár and Törkenczy 2000; Hayes and Londe 2006). Beňuš and Gafos (2007) suggest that antiharmonic roots are phonetically distinguishable from harmonic ones, thus their phonological patterning is phonetically motivated (see the discussion above). Hayes *et al.* argue that there are non-categorical biases for antiharmony based on the statistics of the lexicon, which are phonologically "unnatural" but nevertheless are accessed by native speakers.

The systematic suffix-inconsistent antiharmony of conditional *-nÁ* (§3.4.2.iii) is usually either not discussed in the literature or it is treated as entirely arbitrary (Vago 1976, 1980c). Rebrus and Törkenczy (2005) argue that the antiharmony of the conditional in the 1st singular present indefinite after back roots (e.g. *tudnék* [tudne:k] 'I would know (INDEF)') is a paradigm contrast effect. The "regular" form with the back allomorph of the conditional suffix **tudnák* *[tudna:k] 'I would know (INDEF)' would result in homophony with the present 3rd plural definite conditional form *tudnák* [tudna:k] 'they would know (DEF)'. What is interesting is that Hungarian vowel harmony can be shown to be active in spite of antiharmony. There *is* homophony between the present 1st singular indefinite conditional forms and the present 3rd plural definite conditional forms of front stems (*ölnék* [ølne:k] 'I would kill (INDEF)'), but this cannot be avoided through antiharmony, since the hypothetical antiharmonic form **ölnák* *[ølna:k] would violate Hungarian vowel harmony more than *tudnék* [tudne:k], where the suffix has a neutral vowel.

4.6 *Backness harmony* vs. *roundness harmony*

The central problem about roundness harmony is its restricted character (§3.5). This is rarely addressed in the literature, but some authors argue that it is not harmony at all, but a form of (local) licensing of the feature expressing roundness in suffixes and that accounts for some of its properties, specifically, its strictly local nature and its dependence on backness harmony (§3.5); see Polgárdi and Rebrus (1998) and Ringen and Vago (1998). The restriction of targets to non-high vowels makes Hungarian roundness harmony an interesting problem for phonetically based theories that make the prediction on perceptual grounds that the preferred targets of rounding harmony are high vowels (Kaun 2004).

5 Conclusion

The complexities of Hungarian vowel harmony – especially the long-distance effects involving neutral vowels, the numerous classes of harmonic and invariant suffixes, and the class of antiharmonic roots – made Hungarian vowel harmony an especially interesting phenomenon, a "hot" topic when the nature of representations was the central issue in phonological theory. Now that the focus of phonological research has shifted to other areas, such as variation, gradience, phonetic motivation, the role of the statistics of the lexicon, the role of paradigms in phonological phenomena, and the analysis of opacity in surface-oriented constraint-based theories (such as OT), there is every reason for Hungarian vowel harmony to receive just as much attention, since some aspects of it are crucially relevant to these new issues, specifically the gradient transparency of neutral vowels as manifested in the statistics of variation (§4.4), the phonetics of neutral vowels and the connection between surface vowel quality and transparency (§4.4), the role of the paradigm in antiharmony (§4.5), the statistics of the lexicon and the antiharmonic behavior of some all-neutral roots (§4.5), the restrictions on roundness harmony (§4.6), and the opacity of the distinction between ternary and quaternary alternations, both involving [ɛ] (§4.3). Some of these issues have recently been addressed in the literature (Rebrus 2000b; Beňuš *et al.* 2003; Rebrus and Törkenczy 2005; Hayes and Londe 2006; Beňuš and Gafos 2007; Wanlass 2008; Hayes *et al.* 2009), and it is clear that the intricacies of Hungarian vowel harmony will continue to contribute to the development of phonological theory.

ACKNOWLEDGMENTS

I would like to thank Péter Rebrus and Péter Siptár for their comments on various issues discussed here. I am grateful to Keren Rice, Paul de Lacy, Marc van Oostendorp, and an anonymous reviewer for their comments on an earlier version of this chapter.

124 Word Stress in Arabic

JANET C. E. WATSON

1 Introduction

Within phonological theory, Arabic word stress has received arguably more attention than the word stress of any language other than English; and within Arabic linguistics, more work has been devoted to stress-related phenomena than any other single topic. This chapter addresses some of the reasons behind this phenomenon.

The chapter is structured as follows: §2 considers the characteristics of Arabic word stress, discussing general features common to different varieties and basic ways in which modern Arabic dialects differ both from Classical Arabic and from each other. §3 provides a historical overview of the treatment of Arabic word stress within generative paradigms, focusing on major contributions in the analysis of Arabic stress, and cases where data from Arabic has contributed to the development of stress theory. §4 considers stress in Classical Arabic, and then examines in more detail word stress in three modern dialects – Cairene, San'ani (Yemen), and Levantine – focusing particularly on phenomena that pose a challenge for metrical phonology.

2 Characteristics of Arabic word stress

With over 250 million speakers, Arabic is the official language of 18 sovereign states from Mauritania in the west to Iraq in the east. It is also spoken in parts of southern Turkey, by Maronite Christians in northern Cyprus, and in parts of sub-Saharan Africa. Arabic language enclaves are found in the Balkh region of Afghanistan, parts of Iran, and Uzbekistan. All Arabic dialects exhibit word stress; however, the socially and geographically diverse area over which Arabic is spoken leads to differences in the mechanics of word stress assignment. In all cases stress location is a function of both syllable weight and syllable position, but dialects differ in the distribution of syllable types, the leftmost extent of stress (third or fourth syllable from the right), the rhythmic grouping of syllables, the interaction of stress, syncope and epenthesis, and the degree to which lexical information may affect stress.

Arabic recognizes three weights of syllable: light, heavy, and superheavy. Light syllables are always open, heavy syllables are open or closed, and superheavy syllables are closed or doubly closed. Examples of these syllable types from Classical Arabic are given below:

(1)

	open		*closed*		*doubly closed*	
light	CV	wa 'and'				
heavy	CVV	sā.fara 'he traveled'	CVC	min 'from' ka.tab.tu 'I wrote'		
super-heavy			CVVC	bāb# 'door'	CVCC	bint# 'girl'
					CVVGG[1]	mādd# 'stretching'
			CVVG	mād.dun 'stretching (NOM)'		

CV and CVC are unrestricted, although unstressed short vowels in open syllables are often deleted in modern dialects. CVCC and CVVGG are restricted to word- or utterance-final position.[2] In the distribution of other syllable types, however, dialects vary. Levantine, Sudanese, some Peninsular, and North African dialects allow CVGG and/or CVVC in derived environments word internally, as in: /māsik-īn/ > [māskīn] 'holding (MASC PL)', /ʃāf-ha/ > [ʃāfha] 'he saw her', /muʕallim-īn/ > [mʕallmīn] 'teachers'. Cairene allows CVVC syllables word finally only, as in: [kitāb kibīr] 'a big book', but /kitāb-na/ > [kitabna] 'our book'; Cairene restricts CVCC to utterance-final position, breaking up word-final non-utterance-final CVCC syllables through epenthesis, as in: /bint ṭawīla/ > [bint[i] ṭawīla] 'a tall girl'; CVV occurs only when stressed in Cairene: initial CVV in ['ʃāfit] 'she saw' and ['ʕālam] 'world' contrast with initial CV in [ʃa'fitu] 'she saw him' and [ʕa'lamu] 'his world'.

Stress falls on one of the last three syllables, in some dialects one of the last four syllables, with assignment dependent on the weight and position of the stressed syllable. Modern dialects follow the assumed rules of Classical Arabic (§3.1) whereby stress is assigned to a final superheavy (CVVC, CVCC, or CVVGG) syllable, as in Cairene: [fi'luus] 'money', [ma-xa'bazʃ] 'he didn't cook', and Palestinian: [ja'waab] 'answer', [bi-'ḥuṭṭ] 'he puts'. In the absence of a final superheavy, stress is assigned to a heavy penult (CVV or CVC), as in Cairene: [ka'tabtu] 'you (PL) wrote', [fih'muuha] 'they understood her', and Palestinian: [mus'taʃfa] 'hospital', [mu'naafis] 'competitor'. In the absence of either a final superheavy or a heavy penult, the dialects differ. In words with a heavy antepenult, Cairene stresses the light penult, while most other dialects stress the antepenult: Cairene [mad'rasa] 'school' contrasts with Beirut/Damascene ['madrase].

Modern Arabic dialects differ in their rhythmic grouping of light syllables. Western and Bedouin-type dialects tend to group light syllables into weak–strong

[1] GG denotes *geminate*.

[2] In Classical Arabic, superheavy syllables occur pre-pausally only, resulting from pre-pausal deletion of short final vowels or case endings.

pairs (iambs): Cyrenaican Bedouin stresses the penult in forms such as: [kitab-at] > [ik'tibat] 'she wrote', [ingital-aw] > [inig'tilaw] 'they were killed', and the final syllable in [ki'tab] 'he wrote', [nu'xal] 'palm-trees' (Mitchell 1960); eastern urban dialects group light syllables into strong–weak pairs (trochees), stressing the antepenult in forms such as Cairene: ['katabit] 'she wrote', [in'kasarit] 'it (FEM) broke', and the penult in ['katab] 'he wrote', ['walad] 'boy' (SEE CHAPTER 44: THE IAMBIC–TROCHAIC LAW).

All modern dialects differ from Classical Arabic in at least optionally deleting short vowels in unstressed open syllables (Birkeland 1954). Some dialects delete short high vowels only, as in Damascene: /fihim-u/ > ['fihmu] 'they understood', /fihim-na/ > [f'himna] 'we understood' but /katab-u/ > ['katabu] 'they wrote' (Cowell 1964). Other dialects delete short vowels irrespective of their quality, as in Lebanese Kfar-Ṣġāb: /ḍarab-ak/ > ['ḍarbak] 'he hit you' and /samak-i/ > ['samki] 'one fish' (Fleisch 1974).

Several dialects differ from the assumed predictable quantity-based system of Classical Arabic in that certain morphemes affect stress placement. In Cairene and Tunisian the 3rd feminine singular perfect inflectional suffix *-it* attracts stress on suffixation: Cairene ['ramit] 'she threw' becomes [ra'mitu] 'she threw it (MASC)', contrasting with other CVCVCV forms, such as 'katabu 'they wrote', where the antepenult is stressed. In Iraqi, the dual suffix *-een* retracts stress, although all other cases of word-final CVVC attract stress: ['ʧalbeen] 'two dogs' contrasts with [taʕ'baan] 'tired' (Erwin 1963: 43). In Muslim Mosul Iraqi, stress always falls on the final syllable of a verbal or nominal stem when it takes a suffix, as in: [nəx'ləṭ-u] 'we mix it (MASC)' (Jastrow 2007). In some western dialects and dialects of Oman, word stress is phonemic in disyllabic noun–verb pairs: initial stress in ['fihim] 'understanding' contrasts with final stress in [fi'him] 'he understood' (Janssens 1972).

Finally, modern dialects differ as to whether or not epenthetic vowels count for stress purposes. In Cairene, a penultimate post-CVC syllable with an epenthetic vowel is stressed like any other penultimate post-CVC syllable: compare [bin'tina] 'our daughter' with [mad'rasa] 'school' and [fih'mitu] 'she understood him'. In Iraqi and Levantine, by contrast, stress is assigned as if the epenthetic vowel were not there: penultimate stress in Muslim Mosul [ka'tabit] 'I wrote' contrasts with initial stress in ['katabət] 'she wrote' (Jastrow 2007).

3 Theoretical accounts of Arabic word stress

This section provides a historical overview of theoretical accounts of Arabic word stress, focusing on ways in which research on Arabic has contributed both to the development of metrical theory and to a deeper understanding of Arabic prosodic structure and cross-dialectal differences.

3.1 *Pre-generative approaches*

Concepts upon which generative studies of Arabic word stress draw have their roots in early pre-generative approaches. The older traditional studies of Erpenius (1656), Brockelmann (1908), and Wright (1971) recognized the role of the syllable and syllable weight in stress assignment, distinguishing between light (CV) and heavy (CVV and CVC) syllables (see CHAPTER 57: QUANTITY-SENSITIVITY). The analyses of stress in Cairene by Harrell (1957) and Cairene and Cyrenaican Bedouin by Mitchell (1956, 1960) are based on the position and relative weight of syllables.

The Prague School (Jakobson 1971) describes stress assignment not in terms of syllables, but in terms of moras. Moraic accounts of stress in Arabic include Cantineau (1960: 240), for whom stress in El-Hamme of Gabes (Tunisia) is placed: "on the third mora of the word . . . on the fourth if the third corresponds to a consonant," accounting for penultimate stress in: [k'tibtu] 'you (PL) wrote', and antepenultimate stress in: ['madrasa] 'school'. The mora is referred to in the informal expression of Abdo's (1969) post-*SPE* (Chomsky and Halle 1968) account, where Classical Arabic stress is assigned to the vowel preceding the last two moras (the third or fourth mora from the right-edge). Within metrical theory, it later returns as a full-fledged element of the representation, firmly embedded within the prosodic hierarchy.

3.2 *Generative approaches*

Generative approaches to stress in Arabic have followed contemporary approaches in generative phonology, with a few landmark changes in orientation. In the *SPE* segment-based approach adopted by Abdo (1969), Brame (1970, 1973, 1974), Broselow (1976), Johnson (1979), and Weldon (1980), stress is encoded as a phonological distinctive feature, [+stress], assigned to a [+syllabic] segment in a particular segmental context. Essential variables are included in the vocabulary of phonological rules. Take Palestinian as an example, for which the basic stress rules are:

(2) a. Stress a final superheavy syllable: [ba-'ʃūf] 'I see', [bi-'ḥuṭṭ] 'he puts'.
 b. Otherwise stress the rightmost non-final heavy syllable: [ba-'ʃūfiʃ] 'I don't see', [ka'tabti] 'you (FEM SG) wrote', ['miktaʃif] 'discovering'.
 c. Otherwise stress the first syllable (up to the antepenult): ['katab] 'he wrote', ['zalama] 'man'.

Under this approach, stress is assigned by the following rule (Brame 1974), where C_0 indicates an arbitrary number of consonants, including zero, and C_0^1 either zero or one consonant.

(3) *Stress assignment*
 $V \rightarrow [+\text{stress}] \; / \; \_\_ \; C_0((VC)VC_0^1)]$

This rule abbreviates three disjunctively ordered sub-rules:

(4) $V \rightarrow [+\text{stress}] \; / \; \_\_ \; C_0VCVC_0^1]$ e.g. ['zalama], ['miktaʃif]
 $V \rightarrow [+\text{stress}] \; / \; \_\_ \; C_0VC_0^1]$ e.g. [ka'tabti], ['katab]
 $V \rightarrow [+\text{stress}] \; / \; \_\_ \; C_0]$ e.g. ['ḥaṭṭ] 'he put', [ba-'ʃūf]

3.2.1 *The interaction of morphology and word stress*

Brame noted that the basic stress rules and their formalism in (2) fail to account for data such as [ka'tabit] 'I/you (MASC SG) wrote' (cf. ['katabit] 'she wrote'),

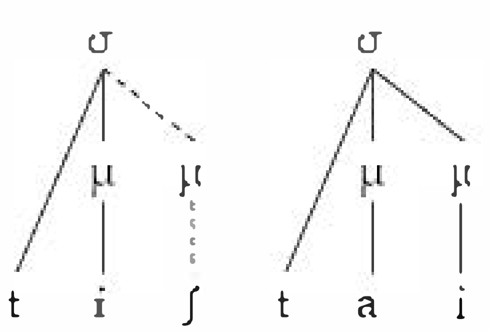
[ˈʔabilna] 'before us' (cf. [ʔˈbilna] 'we accepted'). These forms are derived from underlying /katab-t/ and /ʔabl-na/ through epenthesis (see CHAPTER 67: VOWEL EPENTHESIS), and are explained by Brame as the assignment of stress prior to epenthesis, giving intermediate [kaˈtab-t] and [ˈʔabl-na]. Epenthesis does not undo stress assignment, leading to opaque assignment of stress to a light penult in [kaˈtabit], and opaque non-assignment of stress to the heavy penult in [ˈʔabilna] (§3.2.3). These cases of opaque assignment, or lack of assignment, of stress were attributed initially by Brame (1970, 1973, 1974) and later by others (e.g. Kenstowicz and Abdul-Karim 1980; Kiparsky 1982, 2000, 2003) to the cycle and the preservation of metrical structure assigned in earlier cycles ((54); CHAPTER 85: CYCLICITY). The *SPE*-type approach to word assignment has since been superseded, but recognition of the role of the cycle and of the interaction of syncope and epenthesis with word stress assignment has not. As we shall see below (§4.2.3), within the stratal version of Optimality Theory (OT), opaque stress is attributed to inter-level constraint masking: if α is the constraint system of domain Y (e.g. stem), and β is the constraint system of a larger domain Z, then β's markedness constraints can render α opaque (Kiparsky 2000). Thus, opacity in dialects such as Levantine is attributed to word-level assignment of stress and postlexical epenthesis, which renders stress opaque.

3.2.2 *The prosodic hierarchy and representation of the syllable*

The post-*SPE* period formed an asyllabic interlude in the analysis of Arabic word stress. Most pre-generative and non-generative accounts made reference to the syllable, and within generative phonology there was increasing recognition that sounds grouped into syllables of differing prosodic weights, and that the syllable formed part of the prosodic hierarchy (Fudge 1969; Kiparsky 1979; McCarthy 1979; Selkirk 1980, 1982; Halle and Vergnaud 1987).

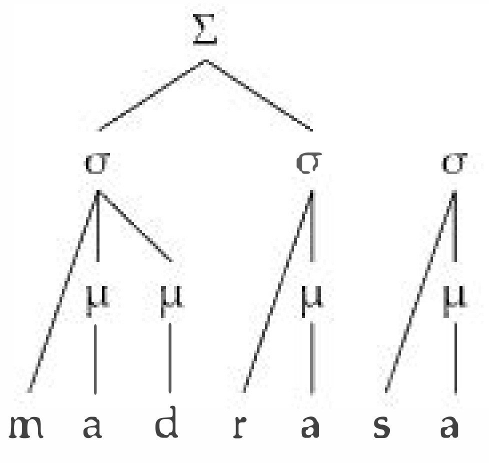
At this time it came to be recognized that the syllable formed a unit within a prosodic hierarchy, a hierarchy that recognized units of prosodic structure above the syllable – the foot (see CHAPTER 40: THE FOOT) and the prosodic word (see CHAPTER 51: THE PHONOLOGICAL WORD) – and a unit of prosodic structure below the syllable: the mora. Weight-based, rather than segment-based, models of the syllable representing the prosodic tier as a series of moras (e.g. McCarthy 1980; Angoujard 1990; McCarthy and Prince 1990) provide a model that reflects the role of prosodic weight in stress assignment by accounting for phonological positions, and by distinguishing between light (monomoraic) and heavy (bimoraic) syllables (Hayes 1989): short vowels contribute one mora, long vowels two moras, geminate consonants one mora, and coda consonants are assigned a mora through Weight-by-Position in languages such as Arabic, where CVC syllables count as heavy (quantity-sensitivity). In San'ani [tiʃtai] 'you (FEM SG) want', for example, the vowels contribute moras and /ʃ/ receives a mora through Weight-by-Position (indicated by a dashed line):

(5)



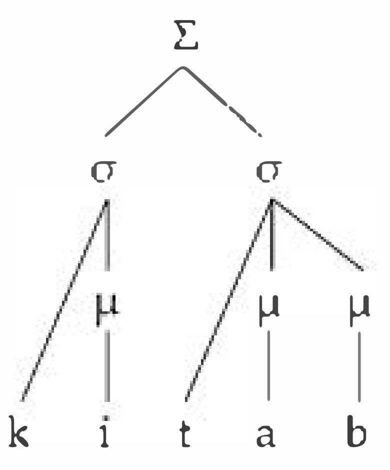
from the stressed syllable to the right-edge of the word, placing a word like ['madrase] 'school' within a single foot. McCarthy (1979, 1980) restricted the foot by measuring it in moras: in Damascene, the stressed mora plus, at most, two following moras. A word comprising three light syllables, such as ['darasu] 'they learnt', exhausts the foot, giving ['(darasu)], but in a word comprising a heavy plus two light syllables, such as ['madrase] 'school', the final light syllable is excluded from the foot: ['(madra)se].

(8)



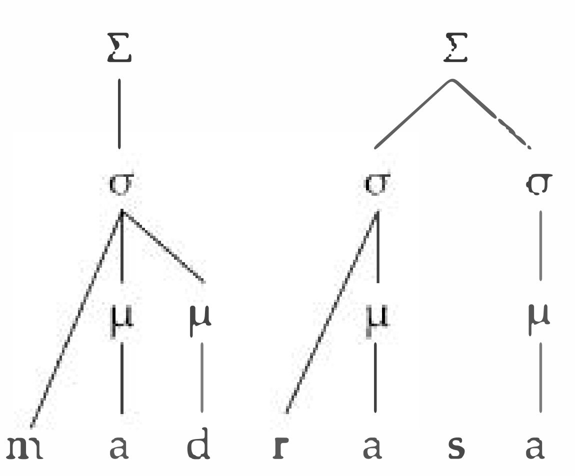
Since these accounts, bounded foot inventories have often excluded feet that require counting higher than two (but cf. e.g. Burzio 1994). Hayes (1989, 1995) argues for absolute binarity: the maximal and canonical iamb consists of a light syllable followed by a heavy syllable, as in Cyrenaican Bedouin [ki'tab] 'he wrote':

(9)



Trochees comprise two equal elements: syllables in the syllabic trochee, moras in the moraic trochee. In a moraic trochee dialect, [madrasa] 'school' comprises two moraic trochees; cf. (8):

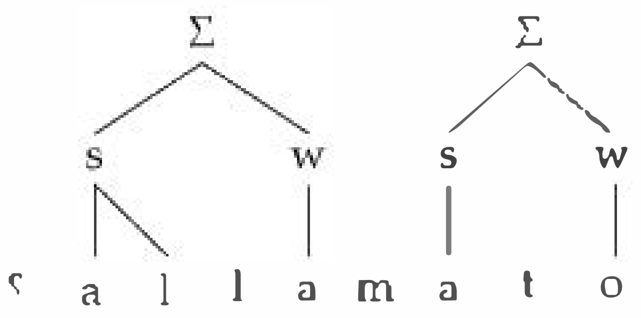
(10)



The uneven trochee, which comprises a heavy and a light syllable in moraic trochee systems, is ruled out by Hayes. It is, however, invoked by Irshied and Kenstowicz (1984), Angoujard (1990), and Kager (2009) to account for penultimate stress in

HLLL forms in trochaic Arabic dialects, as in Jordanian Bani-Hassan [ʕalla'mato] 'she taught him':

(11)



3.2.5 Constituency and the metrical grid

Metrical trees reflect constituency through sister nodes, but fail to represent in any transparent way typical stress characteristics of stress clash or alternating rhythm between strong and weak syllables. Prince (1983) and Selkirk (1984) argued that the metrical grid could better capture the rhythmic characteristics of stress, and that constituency into feet could be eliminated. Compare the pure grid representation of Cairene [mux'talifa] 'different (FEM SG)' below with the metrical tree representation in (6):

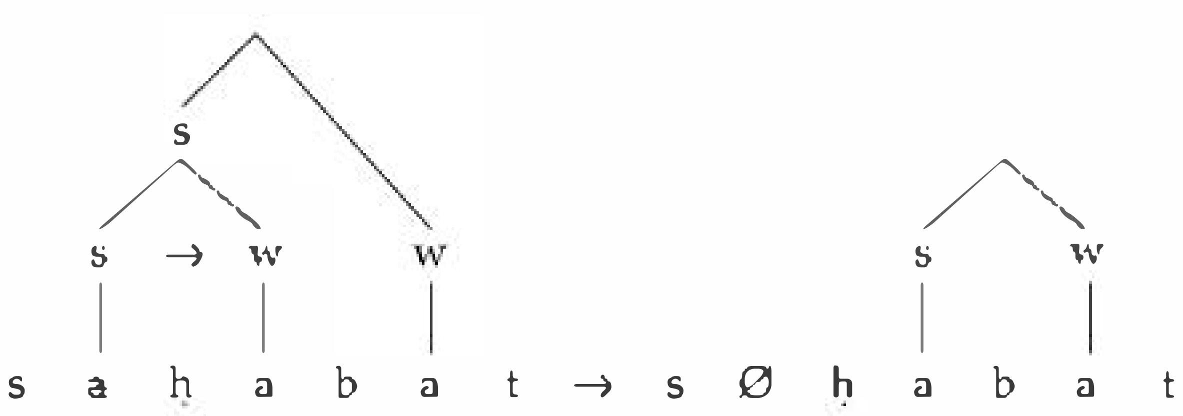
(12)

In 1985, data from an Arabic dialect appeared to challenge the effectiveness of the pure grid. In an account of Bedouin Hijazi Arabic (BHA), Al-Mozainy *et al.* (1985) analyzed alternations such as those in (13) as resulting from low vowel deletion and stress shift.

(13)	'saḥab	'he pulled'	s'ḥabat	'she pulled'
	'naxal	'palm trees'	n'xalah	'a palm tree'
	'salag	'hunting dogs'	s'ligah	'a hunting dog'

They argued the direction of shift was governed by constituent structure and that vowel deletion in BHA induces left-to-right stress shift to the sister node within the metrical tree:

(14)



Through eliminating constituency, the pure grid provided no explanatory account for the direction of stress shift in data such as these. The introduction of brackets within the grid (Halle and Vergnaud 1987; Halle and Kenstowicz 1991;

Hayes 1995), however, enabled the grid to handle such data, showing that on vowel deletion stress shifts within the bracketed constituent (in this case to the right):

```
(15) a.  (*       )      b.   (     *       )    word
         (*    .)             (     *)           foot
          *    *                    *            syllable
        s  a  ḥ  a  b        s  Ø  ḥ  a  b  a  t
```

Further work on BHA showed the initial findings to have been based on an incorrect analysis of the foot-type: essential paradigms had not been considered (Angoujard 1992; Paoli 2008), and BHA feet were re-analyzed as iambs rather than moraic trochees (McCarthy 2003); motivated by the tendency of iambic feet to maximize quantitative differences between the head and dependent syllables, deletion targets the unstressed vowel of an iambic foot. The basic conclusions that stress is preserved on deletion of stressed vowels and that the direction of stress shift is predictable from constituency remain valid, however, and are supported by data from other Arabic dialects: Cyrenaican Bedouin (Hayes 1995, data from Mitchell 1960) and San'ani (Watson 2002: 116) both exhibit stressed vowel deletion and stress shift[4] within the foot: leftwards in Cyrenaican, which exhibits iambic stress, and rightwards in San'ani, which exhibits trochaic stress.

```
(16) a. Cyrenaican [ki'tib] 'books' > ['kitbih] 'his books'
        (        *  )    (  *                )    word
          (.     *)      (  *          )          foot
           *     *          *                *    syllable
        k  i  t  i  b  >  k  i  t  Ø  b  i  h

     b. San'ani ['xaʃab] 'wood' > [x'ʃabih] 'a piece of wood'
        (  *        )    (        *          )    word
          (*     .)         (     *    )          foot
           *     *                *          *    syllable
        x  a  ʃ  a  b  >  x  Ø ʃ  a  b   i  h
```

3.2.6 *Unparsed syllables*

The findings of many researchers suggest metrical structure need not exhaust the string of syllables. Hayes (1995) claims syllables left over after foot construction are either unfooted or form degenerate feet. Degenerate feet are not optimal, but languages differ as to whether they impose a strong or a weak ban on them. Languages that permit words smaller than the canonical foot (a single mora in a moraic trochee system, or a single syllable in an iambic or syllabic trochee system) tend to invoke the weak ban, while languages that do not permit sub-minimal words invoke the absolute ban.

Sub-minimal content words are generally unattested in Arabic and sub-minimal grammatical words are expanded on suffixation to provide a minimal bimoraic base, as in Cairene:

[4] Optional in the case of San'ani: ['xaʃabih] ~ [x'ʃabih].

(17)	/min-u/	>	[minnu]	'from him/it (MASC)'
	/ʕan-kum/	>	[ʕannukum]	'about you (PL)'
	/fi-h/	>	[fī(h)]	'in it, there is'

Sub-minimal loanwords are typically expanded through vowel lengthening to match the minimal prosodic word, as in: [bār] 'bar' and [bāṣ] 'bus'. Some dialects, such as San'ani, however, do have stressable monomoraic content words, including [ab] 'father', [ax] 'brother', [yad] 'hand', [dam] 'blood', and a few sub-minimal function words that contrast with comparable bimoraic words in Cairene, and never lengthen, including [kam] 'how many' (cf. Cairene [kām]), [man] 'who' (cf. Cairene [mīn]), and [maʕ] 'with' (cf. Cairene [maʕa]) (Watson 2002: 88–89). Further evidence that degenerate feet are allowed in strong position in San'ani includes the exceptional stressing of peripheral light syllables, giving optional initial stress in forms such as ['tamām] 'good', and optional final stress in forms such as [ʃik'mih] 'party for parturient' (§4.2.2).

3.2.7 *Weak parsing*

Many languages stress the third syllable from the word edge. Hayes (1982, 1989, 1995) argues such systems can be accounted for not by expanding the universal inventory to include ternary feet, but by resorting to the independently motivated devices of extrametricality at the edge, destressing in clash, and the non-exhaustivity of foot construction. Non-exhaustivity of foot construction means syllables can be skipped through a device known as weak local parsing, potentially creating ternary alternation in longer strings (Hayes 1995: 308):

```
(18)  (x  .)    (x  .)    (x  .)
       ˘  ˘  ˘  ˘  ˘  ˘  ˘  ˘  ˘
```

This device enables Hayes to provide an account of Arabic dialects which dispenses with the uneven trochee. Bani-Hassan [ʕalla'mato], seen above in (11), is analyzed in moraic trochees with weak local parsing (Hayes 1995: 366):

```
(19)    (x)          (x     .)
         ¯       ˘     ˘     ˘
      ʕ  a  l  l  a  m  a  t  o
```

3.2.8 *Final consonants, syllables, and feet*

The right-edge of the word prompts exception in many languages: extra-long syllables are often restricted to the right-edge, and syllables that act as heavy non-finally often fail to attract stress in final position. In Cairene, the sequence [.tab.] is stressed penultimately in [ka.'tab.tu] 'you (PL) wrote', but not finally in ['ka.tab] 'he wrote'. To account for the asymmetric behavior of closed syllables and the invisibility of peripheral elements to stress rules, Liberman and Prince (1977) introduced the notion of extrametricality (see CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY), the rules for which were developed by Hayes (1979, 1982, 1989). Thus, rather than specify for relevant languages that CVC is light finally, but heavy non-finally, and that only CVCC and CVVC syllables are heavy finally, the rightmost consonant is analyzed as invisible to stress rules through extrametricality, making final CVC equivalent in weight to non-final CV (Hayes 1995: 57):

(20)	*Final*	*Non-final*
	CV	CV
	CV<C>	CV
	CVC<C>	CVC
	CVV	CVV
	CVV<C>	CVV

In several Arabic dialects, final pairs of light syllables also appear to be invisible to stress rules. In Palestinian, for example, stress is assigned to the rightmost bimoraic sequence in these words:[5]

(21)	'ʔana	'I'
	'katabu	'they wrote'
	bara'kitna	'our cow'
	ka'tabna	'we wrote'

However, in words comprising a heavy syllable followed by two light syllables, or four light syllables, stress is assigned to the initial syllable:

(22)	'barakito > 'bakarto	'his cow' (with High Vowel Deletion)
	'madrasa	'school'
	'ʃajaratun (Classical)	'tree (NOM)'

Hayes (1995) analyses such patterns as resulting from foot extrametricality, subject to the non-exhaustivity condition. Thus, ['madrasa] is parsed as [(mad)(rasa)], with two bimoraic feet; by not exhausting the word the peripheral foot is eligible for extrametricality, giving [(mad)<(rasa)>]. Stress is assigned to the rightmost visible (non-extrametrical) foot: ['(mad)<(rasa)>]. The characteristic Cairene pattern of stressing a light penult after a heavy antepenult, by contrast, is analyzed as resulting from lack of foot extrametricality: the rightmost visible foot is stressed in all dialects, but only in Cairene is the peripheral foot visible to stress rules: Cairene [(mad)'(rasa)] contrasts with Palestinian ['(mad)<(rasa)>].

3.2.9 CVXC syllables

Stress patterns in several languages, including Arabic, indicate that an extrametrical consonant does not deprive the rightmost foot of peripherality: by being contained within the peripheral foot, the peripheral consonant does not intervene between the foot and the right-edge. In San'ani ['katabatih] 'she wrote it (MASC)', for example, extrametrical /h/ falls within the rightmost foot, itself deemed extrametrical. Stress assignment to the rightmost visible foot gives ['(kata)<(bati<h>)>]. An analysis of extrametricality in the case of CVVC and CVCC strings, however, predicts the wrong results: extrametricality would render final C invisible to stress rules; as an extrametrical element it would fall in the adjacent foot, failing to deprive the foot of peripherality; as peripheral feet, CVCC and CVVC syllables would be invisible to stress rules in dialects such as Palestinian for which foot extrametricality holds, but not in dialects where foot extrametricality fails to apply. Such an analysis would predict a stress difference in words of the pattern CVVCVCC

[5] Data from Brame (1973, 1974), Abu-Salim (1980), and Kenstowicz and Abdul-Karim (1980).

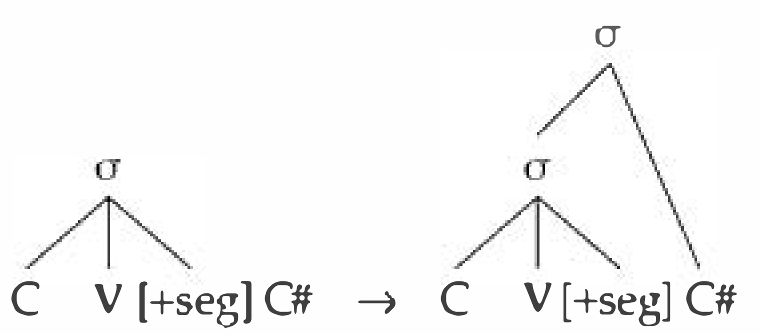
and CVCCVCC between dialects that exhibit foot extrametricality (23a), and dialects such as Cairene, which do not (23b):

(23) a. Consonant extrametricality: darrast → darras<t>
Foot extrametricality: (dar)(ras<t>) → (dar)<(ras<t>)>
Stress rightmost visible foot: *'(dar)<(ras<t>)> (= dar'rast)

b. Consonant extrametricality: darrast → darras<t>
Foot extrametricality: *n/a*
Stress rightmost visible foot: (dar)'(rast)

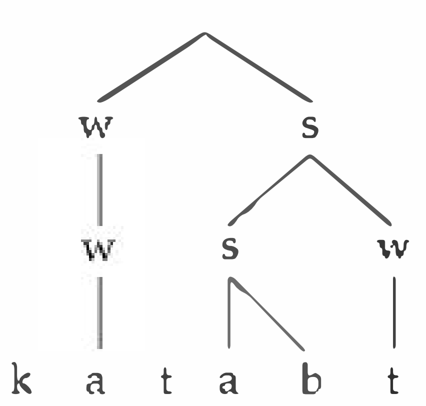
A significant step in research on Arabic stress concerns the analysis of these so-called "superheavy" syllables. Superheavy syllables are exceptional on two counts: they are the only syllable types that are always stressed in final position (although cf. §4.2.2), and they are restricted to domain-final position (at least in morphologically simple forms). Thus, in terms of stress rules, they behave like penultimate CVV or CVC (as do CVVC/CVCC syllables in English; Burzio 1994; Harris and Gussmann 2002). Several analyses of CVVC/CVCC strings have been proposed around the basic analysis of heavy syllable + element. This was expressed initially by McCarthy (1979: 453) through Chomsky-adjoining a word-final consonant to a heavy syllable:

(24)



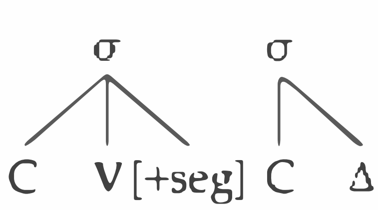
Halle and Vergnaud (1979) analyze final C in CVXC as the weak element in a branching foot:

(25)



In later accounts (Aoun 1979; Angoujard 1981, 1990; Selkirk 1981;[6] Burzio 1994), the rightmost C forms a degenerate syllable, i.e. a syllable with an empty nucleus or null vowel:

(26)



[6] Only for CVCC syllables. See §4.2.2.

For Hayes (1995: 126), final C in CVXC is not syllabified at the initial stage: CVXC is analyzed as heavy syllable + stray consonant, while CVC is analyzed as light syllable + extrametrical consonant:

(27) CVX.C
 CV<C>

Within OT, Al-Mohanna (2004) analyses final C of word-final CVXC as attached directly to the prosodic word node. Essentially, then, all accounts show that the rightmost C in CVXC sequences intervenes between the right edge and the heavy syllable, depriving the foot formed by the heavy syllable of peripherality. Thus, *darrast* (23) in both Cairene- and Palestinian-type dialects is analyzed as [(dar)'(ras).t].

This section has examined key approaches to Arabic stress within the generative paradigm, with particular focus on challenges raised by Arabic data for stress theory. §4 will provide sketches of the stress systems of Classical Arabic and three modern Arabic dialects, focusing on core similarities and differences between the dialects, and examining approaches invoked to account for cross-dialectal differences and apparent exceptions to the stress algorithms.

4 Stress algorithms

4.1 *Classical Arabic*

The early Arab grammarians provided detailed descriptions of segments and melodic phonological processes characteristic of readings of the Qur'an and certain Peninsula dialects; however, word stress is never mentioned. This led some researchers to believe that Classical Arabic exhibited no word stress (Birkeland 1954; Ferguson 1956; Garbell 1958), and others to assume it to have been similar to the rather fluctuating word-stress system found today in western dialects of the Arabian Peninsula.

The Classical Arabic stress patterns have since been reconstructed through comparison of modern dialect stress patterns (Janssens 1972), versification (Weil 1954; Wright 1971), and observation of the non-dialectal pronunciation of Classical Arabic in some regions (Abu-Fadl 1961; Mitchell 1993). There is now general consensus that Classical Arabic exhibited predictable stress. Disagreement exists, however, as to the leftmost limit of stress. It is agreed that penultimate CVC or CVV bore stress, or, if the penult was light, antepenultimate CVC or CVV. Where both the penult and antepenult were light, as in /masʔalat-un/, researchers differ: Erpenius (1656), Abdo (1969), Brame (1970), Bohas and Kouloughli (1981), and Angoujard (1990) argue that stress did not retract beyond the antepenultimate syllable, giving, in this case, [mas'ʔalat-un] 'problem (NOM)'. Brockelmann (1908), Wright (1971), Janssens (1972), and McCarthy (1979), by contrast, claim stress is assigned to the initial syllable in such cases, giving ['masʔalatun]. If this latter holds, this would mean Classical Arabic, in contrast to the modern dialects, exhibited unbounded metrical feet, constructing feet from one heavy syllable up to, but not including, the next heavy syllable. Under both analyses, lexical exceptions exist: dialect comparison and the non-dialectal pronunciation of Classical Arabic suggest stress was not assigned to the initial heavy syllable in derived verb forms VII and VIII, but to the light antepenult, giving: [in'faʕala] and [if'taʕala] rather than *['infaʕala] and *['iftaʕala].[7] Similarly, most particle prefixes are unstressed irrespective of their relative position (Mitchell 1960: 371, 1975: 77), leading to antepenultimate or penultimate stress in forms such as: [al-'walad-u] 'the boy (NOM)' (cf. Wright's ['madrasat-un] 'school (NOM)'), [al-'yad-u] 'the hand (NOM)', (cf. ['maktab-un] 'office (NOM)'), [wa-'yad-un] 'and a hand (NOM)' (cf. ['katabat] 'she wrote').

The stress algorithm for Classical Arabic is given in (28) (bracketed elements included in case stress retraction is limited to the antepenult):

(28) *Classical Arabic stress*

a. Stress a pre-pausal superheavy (CVVC, CVVCC, or CVCC) syllable: [ki'tāb] 'book', ['mādd] 'stretching (MASC SG)', [ʃa'ribt] 'I/you (MASC SG) drank'.

b. Otherwise, stress the rightmost non-final heavy (CVV, CVC, or CVVG) syllable (up to the antepenult): [da'rasnā] 'we learnt', [ṣā'būnun] 'soap (NOM)', ['maktabah] 'library', ['māddun] 'stretching (NOM)', ['maktabatun] 'library' (non-pause) (or [mak'tabatun]).

c. Otherwise, stress the leftmost CV syllable (or antepenult): ['kataba] 'he wrote', ['katabatuhu] 'library' (or [kata'batuhu]).

4.2 Arabic dialects

This section presents the basic stress algorithms for Cairene, San'ani, and Levantine, three dialects analyzed as exhibiting moraic trochaic stress. Each subsection considers some of the most significant data that has impacted on metrical theory and approaches invoked to handle this data. The section is concluded by a table summarizing the main stress and stress-related typological characteristics of each dialect and of Cyrenaican Bedouin, aspects of which we considered in §3.

4.2.1 Cairene

More generative accounts of word stress have been provided for Cairene than any other Arabic dialect. Cairene attracted attention due to its characteristic avoidance of a heavy antepenult in favor of a light penult, deletion of unstressed high vowels but, with few exceptions (Woidich 2006), not unstressed low vowels, reduction of unstressed long vowels, and its exceptions.[8] An initial stress algorithm for Cairene was provided by Harrell (1957, cf. also Mitchell 1956):

(29) *Cairene stress*

a. Stress-final CVV(C) or CVCC: [ka'tabt] 'I wrote', [ʔa'bū(h)] 'his father', [saka'kīn] 'knives', [ṭala'bāt] 'demands'.

b. Otherwise, stress the antepenult when the penult and antepenult are light, unless the pre-antepenult is light: ['ʔabadan] 'never', [mux'talifa] 'different (FEM SG)'. Cf. [kata'bitu] 'she wrote it (MASC)' with pre-antepenultimate CV.

c. Otherwise, stress the penult: [yik'tibu] 'they write', [ʕa'malti] 'you (FEM SG) did', [mar'taba] 'mattress', ['bētak] 'your (MASC SG) house'.

[7] An exception for Wright (1971), etc., but not for Angoujard (1990).

[8] Descriptive accounts of Cairene in the theoretical literature include Mitchell (1952, 1956, 1960, 1975), Harrell (1957, 1960), Tomiche (1964), Behnstedt and Woidich (1985), and Woidich (2006).

In /ʕālam-u/ > [ʕa'lamu], unstressed CVV is reduced to CV. In /ʔābil-u/ > ['ʔablu], the high vowel in the weak position of the foot is deleted, resulting in a CVVC syllable, impermissible in Cairene. The long vowel is subject to Closed Syllable Shortening (CSS) to prevent word-internal CVVC, giving ['ʔablu] 'they met'. Watson (2002), who follows Hayes (1995) in disallowing the uneven trochee, analyses forms such as /sāfir-it/ > ['safrit] as assignment of metrical structure prior to syncope, with re-assignment of metrical structure after the application of each phonological rule:

(37) a. Construction of moraic trochees from left to right: (sā)(firit).
b. Assignment of stress to the head of the rightmost foot: (sā'(firit)).
c. Reduction of unstressed CVV to CV: (sa'(firit)).
d. Refooting: ('(safi)rit).
e. Syncope of the high vowel: '(safrit).

Both these approaches deal with this data, but they miss the generalization that, with the exception of CiCiCa/CuCuCa plurals and the *-it* morpheme, all short high vowels in the position CVCVCV(C) are subject to syncope, even if they would be stressed by the normal stress algorithm (Kenstowicz 1980; Teeple 2009), namely: /kanakit-u/ > [ka'naktu] 'his coffeepot', /kanabit-u/ > [ka'nabtu] 'his sofa'. This data suggests word-internal short high vowels are subject to syncope prior to assignment of metrical structure, as long as the resulting syllable is permissible (cf. Broselow 1992: 36–37): /kanakit-u/ gives [kanaktu], but /mudarris-a/ fails to give *[mudarrsa] because word-internal [.darr.] (CVGG) is impermissible in Cairene.

Syncope is not restricted to the phonological word in Cairene; it also occurs within the phonological phrase: high vowels in word-initial CV syllables are subject to phrasal syncope after a word-final vowel, as in:

(38)	/ʔana fihimt/	>	'ʔana f'himt	'I understood'
	/ṭardi kibīr/	>	'ṭardi k'bīr	'my parcel is big'

Deletion fails to occur in (39), however, even though word-initial CV follows word-final CV:

(39)	/huwwa fihim/	>	'huwwa 'fihim	(*fhim)	'he understood'
	/huwwa wiḥiʃ/	>	'huwwa 'wiḥiʃ	(*w'ḥiʃ)	'he is bad'

In (38), the high vowel falls in an unstressed syllable in the citation form ([fi'himt] 'I understood', [ki'bīr] 'big'). By contrast, in (39), the high vowel falls in a stressed syllable in the citation form (['fihim] 'he understood', ['wiḥiʃ] 'bad'). Taken with data such as [ka'naktu] 'his coffeepot', this suggests two types of syncope occur in this dialect: lexical syncope, which targets word-internal CV-flanked high vowels prior to the assignment of metrical structure, and phrasal syncope, which targets unstressed word-initial CV-flanked high vowels after the assignment of metrical structure.

4.2.2 *San'ani*

The main interest in San'ani, the dialect of the old city of San'a, Yemen, lies in its stressing of peripheral light syllables, and the patterning of CVV syllables with syllables ending in the left leg of a geminate (CVG), but not with CVC syllables.[9]

The basic stress algorithm for Classical Arabic (28) applies to most word-types:

(40) a. Stress a final CVCC or CVVC syllable: [gi'rīt] 'I/you (MASC SG) read/learnt', [gam'bart] 'I/you (MASC SG) sat', [ki'tāb] 'book'.

b. Otherwise, stress the rightmost non-final heavy syllable (CVV or CVC) up to the antepenult: ['madrasih] 'school', [miǧ'sālih] 'launderette', [da'rastih] 'I/you (MASC SG) recited it'.

c. Otherwise, stress the leftmost CV syllable: ['libisat] 'she put on, wore', [mak'tabatih] 'his library', ['katabatih] 'she wrote it (MASC)'.

(40) fails to apply in San'ani, however, when the penult or antepenult is CVV or CVG. Here the rightmost non-final CVV or CVG syllable attracts stress from final CVCC or CVVC (Watson 2002: 81):

(41)	'ṣābūn	'soap'
	'xuṭṭāf	'clasp'
	mu'darrisīn	'teachers (MASC)'
	'xārijīn	'going out (MASC PL)'

Similarly, while the rightmost non-final CVC syllable is stressed iff in penultimate or antepenultimate position, CVV and CVG are stressable in pre-antepenultimate position:

(42)	mak'tabatī	'my library'
	mu'sajjilatī	'my recorder'
	'hākaḏahā	'like this'

(40) often fails to apply in post-pausal position: San'ani exhibits contextually fluctuating stress (Rossi 1939; Naïm-Sanbar 1994); post-pausally the initial syllable is usually stressed, irrespective of its weight or that of following syllables. Where initial CV is stressed before CVXC, this is analyzed in Watson (2002) as a degenerate syllable (§3.2.6):

(43)	'tamām	'okay'
	'katabt	'I/you (MASC SG) wrote'
	'ʔusbūʕ	'week'
	'baladīyāt	'municipality'

The following revised algorithm accounts for the data:

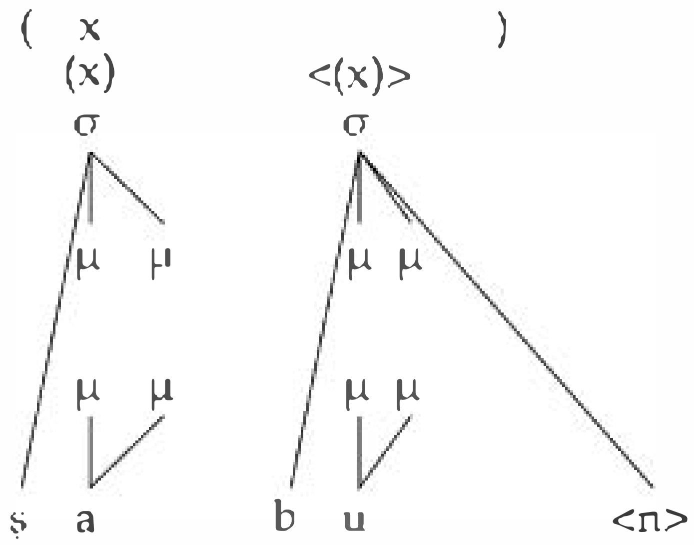
(44) *San'ani stress*

a. Stress the rightmost non-final CVV or CVG syllable: [ma'kātib] 'offices', [ba'sātīn] 'gardens', ['xārijīn] 'going out (MASC PL)', [mit'ʔaxxirāt] 'late (FEM PL)', ['hākaḏahā] 'like this', ['sāfart] 'I/you (MASC SG) traveled', ['dawwart] 'I/you (MASC SG) looked for'.

[9] Data cited in the theoretical literature include Rossi (1939), Goitein (1970), Naïm-Sanbar (1994), and Watson (2002).

'soap', two bimoraic feet are constructed on the upper moraic layer; the peripheral foot is extrametrical, and stress is assigned to the rightmost visible foot:

(49)



word layer construction (ERR)
foot extrametricality
consonant extrametricality

4.2.3 *Levantine*

Levantine has attracted a great deal of attention within generative phonology, due principally to its complex interactions between the morphology and stress assignment.[12] The dialects basically exhibit the Latin stress rule (McCarthy 1980: 79), with the exception of (50a), which Latin lacks:

(50) *Levantine stress*

a. Stress final CVCC or CVVC: [bi-t-'ḥuṭṭ] 'she/you (MASC SG) put', [ja'wāb] 'answer'.
b. Otherwise, stress a heavy penult: [ka'tabti] 'you (FEM SG) wrote', ['bārak] 'he blessed'.
c. In disyllables ending in CV or CVC, stress the initial syllable: ['ḍarab] 'he hit', ['bana] 'he built', ['ʔana] 'I'.
d. Otherwise, stress the antepenult: ['darasu] 'they learnt', [mut'taḥida] 'united', ['ʕallamat] 'she taught', ['madrasa] 'school'.

Hayes (1995: 128) accounts for Palestinian stress as follows:

(51)	a.	Consonant extrametricality	C → <C> /__]word
	b.	Foot construction	Form moraic trochees from left to right. Degenerate feet are forbidden absolutely.
	c.	Foot extrametricality	Foot → <Foot> /__]word
	d.	Word layer construction	ERR

These rules generate the following metrical structure:

```
(52)      (*                    )       word layer construction: ERR
          (*)    <(*         .)>        foot construction: moraic trochees, L > R,
                                        foot extrametricality
           μ  μ     μ       μ
       m   a  k  t  a   b   a   <k>     consonant extrametricality
```

[12] The many traditional descriptive-analytical accounts of Levantine include Feghali (1919), Bauer (1926), Cantineau (1939, 1946, 1960), El-Hajjé (1954), Cowell (1964), Jiha (1964), Grotzfeld (1965), Blanc (1970), Fleisch (1974), and Naim-Sanbar (1986).

Levantine-like opacity has continued to attract considerable interest within constraint-based models. Optimality-theoretic approaches towards opacity include: invoking constraints on the stressing of epenthetic vowels, maximizing paradigmatic contrasts,[13] and translating the notion of the cycle into lexical and postlexical strata. Within parallel OT, Kager (1999) accounts for Levantine opacity by invoking the constraint Head-Dep(O/I) ('every vowel in the output prosodic head has its correspondent in the input'), which prohibits stress on epenthetic vowels. By dominating constraints responsible for stress, Head-Dep(O/I) rules out penultimate stressed *[fi'himna] (input ['fihm-na]) and *[yi'kitbu] (input ['yiktib-u]), and other constraints select ['fihimna] and ['yikitbu]. Kiparsky, however, raises two objections to this constraint: first, its only remit is to prevent epenthetic vowels from being stressed, but epenthetic vowels are not simply unstressable, they are *invisible* to stress: words of the form CVCVCV(C) receive antepenultimate stress unless the final vowel is epenthetic, in which case the penult is stressed, acting as if the epenthetic vowel were not there, as in: [ka'tabit] 'I/you (masc sg) wrote'. Second, Head-Dep(O/I) fails to relate the opacity of stress to other word-level prosodic processes, thus missing the generalization "that *all* processes of word phonology ignore epenthetic vowels" (Kiparsky 2000: 353). For example, word-level closed CVVC syllables are shortened even though they are opened by postlexical epenthesis:

(55) /ʃāf-it/ > ʃāfit 'she saw'
/ʃāf-t/ > 'ʃifit (*ʃāfit) 'I saw'

Brame's insight (§3.2.1) that syncope is ordered before epenthesis in dialects such as Levantine is captured in stratal OT by allowing different constraint rankings in the lexical and postlexical strata (Kiparsky 2000, 2003). The relevant constraints here are the faithfulness constraint Max-'V, requiring the stressed vowel of the input to have a correspondent in the output, and the markedness constraints Reduce, which minimizes the number of non-final light syllables, and License-μ, which requires all moras to be licensed by syllables. Syncope takes place at the word level because Reduce outranks License-μ. At the post-lexical level, epenthesis is prompted by the promotion of License-μ, and Max-'V rules out candidates in which stress is assigned to the epenthetic vowel. Kiparsky's stratal OT analysis of /yiktib-u/ > ['yikitbu] is given in (56) and (57):

(56) VC *dialects: Word level*

Input: ['(yik).(ti.bu)]	Reduce	License-μ	…
☞ a. '(yik).tμ.bu	*	*	
b. '(yik).(ti.bu)	**!		

[13] Broselow (2008), for example, argues that the invisibility of epenthetic vowels in Iraqi Arabic is motivated by maximization of contrast between stems of different grammatical types.

10 The Other Hand in Sign Language Phonology

Onno Crasborn

1 Introduction

Signed languages used by Deaf communities use the visual channel for communication. Multiple articulators are involved in producing all phonological material, including the head (its rotation around all three axes), many if not all aspects of facial expression (including eye gaze), the position of the upper body, and of course the two hands. It is only slowly becoming clear how linguistic the use of some articulations, e.g. eye gaze, really is (Metzger 1998; Meurant 2008). For most articulators and their phonological representations in the lexicon, we still have a very limited view on their actual use across the sign languages of the world (Eccarius and Brentari 2007).

The linguistic status of the two hands has been argued for from the very start of research on sign phonology, together with the features that make up their shape, rotation, location, and movement (CHAPTER 9: HANDSHAPE IN SIGN LANGUAGE PHONOLOGY; CHAPTER 24: THE PHONOLOGY OF MOVEMENT IN SIGN LANGUAGE; CHAPTER 56: SIGN SYLLABLES): Stokoe's (1960) ground-breaking analysis of the lexicon of American Sign Language (ASL) showed that some signs only have specifications for one hand, while others have a specification for two hands. That is, the distinction between one-handed and two-handed signs plays a role in the lexicon and needs to be specified there. While this has not been contested in any phonological analysis since, researchers have proposed different models of the two hands. This chapter will primarily focus on the possible phonological representations in the lexicon (§2 and §3), yet will also look beyond the lexicon to see to what extent the two hands can function independently in expressing separate morphemes simultaneously (§4). An overview of open questions is presented in §5.

1.1 *The two hands and the modality difference*

All sign languages that have been described so far show a lexical distinction between one-handed and two-handed signs, as a quick look through any (picture) dictionary will show. Some examples from NGT (*Nederlandse Gebarentaal*; Sign Language of the Netherlands) are presented in Figure 10.1.

Figure 10.1 Examples of one-handed and two-handed signs from NGT. (a) One-handed signs: TIRED, HOLIDAY, DOG; (b) two-handed signs: TEA, GIFT, PROCESS

In principle, the fact that there are two symmetrical articulators in the visuo-spatial modality used in signed languages is one of the most salient differences between sign and speech. Humans have one mouth, but two hands. The fundamental question one would like to answer is whether this does or does not have an impact on the linguistic structure of the two types of languages. It is clear that deaf signers do not "speak with two tongues" – their left and their right hand do not continuously convey independent messages. At a phonetic level, aside from the motoric difficulty of permanently controlling the two symmetrical limbs completely independently, it would be impossible to visually perceive two completely independent movements (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY). At a higher cognitive level of processing as well, it is not easy to express two independent thoughts at the same time, and the same holds for parsing two information streams in perception. In social interaction between humans, there might be great advantages to being able to utter statements on a primary level while commenting on them on a "meta" level. One could thus communicate along two independent paths simultaneously, but this is clearly not how human interaction works in daily life, even though "tone of voice" may reveal some of our attitudes toward what is being said. The impact of having two symmetrical articulators on the linguistic structure of signed languages is thus likely to be more subtle in nature.

This chapter summarizes the different proposals that have been made to describe the lexical phonology of two-handed signs and their relation to one-handed signs, but it will also look at some of the other roles that can be played by the "other hand" outside the lexicon. The overall conclusion will be that, given the many possibilities for simultaneous activities of the two hands, primarily at the grammatical and discourse levels, many questions remain open for investigation. Thus we cannot yet give a satisfactory answer to the question of the possible impact

(1953) and Stokoe (1960) were devoted to making the case for signed languages as real languages. In phonology, this involved the investigation of the extent to which the structure of lexical signs could be characterized with the same types of structures proposed for spoken language phonology. While it is clear that the phonetic content of signed and spoken languages differs, the hypothesis was tested that grammars, as more abstract properties of phonological structure, are highly similar, if not identical. Thus, for example, Stokoe (1960) proposed the decomposition of the form of lexical items in terms of phonemes (giving them a different name, "cheremes," to emphasize the differences in phonetic content and the fact that they were structured simultaneously rather than sequentially), similar to the phonemic analysis of that time (see CHAPTER 11: THE PHONEME). Later, Sandler (1989) proposed a model of ASL phonology in terms of feature trees, similar to Clements's (1985) feature geometry model for spoken language phonology (see CHAPTER 27: THE ORGANIZATION OF FEATURES). In each of these models, the role of the second hand did not require any specific theoretical concept. It was one of the parameters or one of the features – but not something outside the spectrum of phonological constructions found up to that time. As Sandler and Lillo-Martin (2006) summarize, the grammars of signed languages studied so far strongly resemble those of spoken languages when one abstracts away from the concrete phonetic substance of the two modalities. For this reason, there is no doubt that signed languages are "true languages," whatever definition one likes to use. Still, it remains an interesting question how the particular phonetic substance of a second symmetrical articulator finds a place in a phonological model.

Stokoe (1960) considered the main phonological parameters of a lexical sign to be handshape ("dez"), location ("tab"), and movement ("sig"). Orientation was regarded as "minor parameter," because it typically does not fulfill any distinctive function and its phonetic form is predictable in many signs. Interestingly, although one-handed signs were clearly set apart from two-handed signs in the notation (using one *vs.* two handshape symbols), something like "handedness" was not explicitly considered to be a distinctive property of the phonology of the sign. Whether a sign has one or two hands needs to be specified, but this parameter was not assigned the status of the basic aspects, handshape, location, and movement. The lack of a large set of minimal pairs involving orientation may have been the reason for this choice.

In all studies since, whether on ASL or other signed languages, there has never been a claim that one- *vs.* two-handedness is predictable on the basis of other phonological properties, or of semantic (or iconic) properties of the sign. Thus it needs to be lexically specified, and as such is a distinctive phonological feature of lexical items (see CHAPTER 2: CONTRAST; CHAPTER 17: DISTINCTIVE FEATURES). In the languages studied to date, very few minimal pairs have been identified in support of this distinctive nature of two-handedness. A rare example from NGT is presented in Figure 10.2.

Stokoe introduced a basic distinction among two-handed signs that has been taken over by most phonological models since then: in some signs both hands move, while in others one hand appears to function as the location of the other hand ("double dez" and "tab-dez," respectively, in Stokoe's terminology). Some examples of such more symmetric and less symmetric signs from NGT are presented in Figures 10.3 and 10.4. When both hands move, this can be fully symmetric (Figure 10.3a), or in an alternating fashion (Figure 10.3b, c). Various

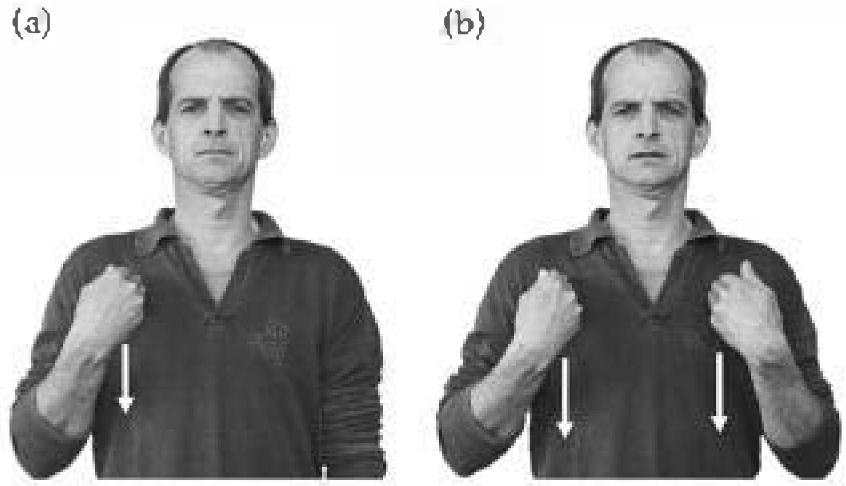

Figure 10.2 Minimal pairs in NGT based on number of hands: (a) HUMAN-BEING and (b) BEHAVIOR

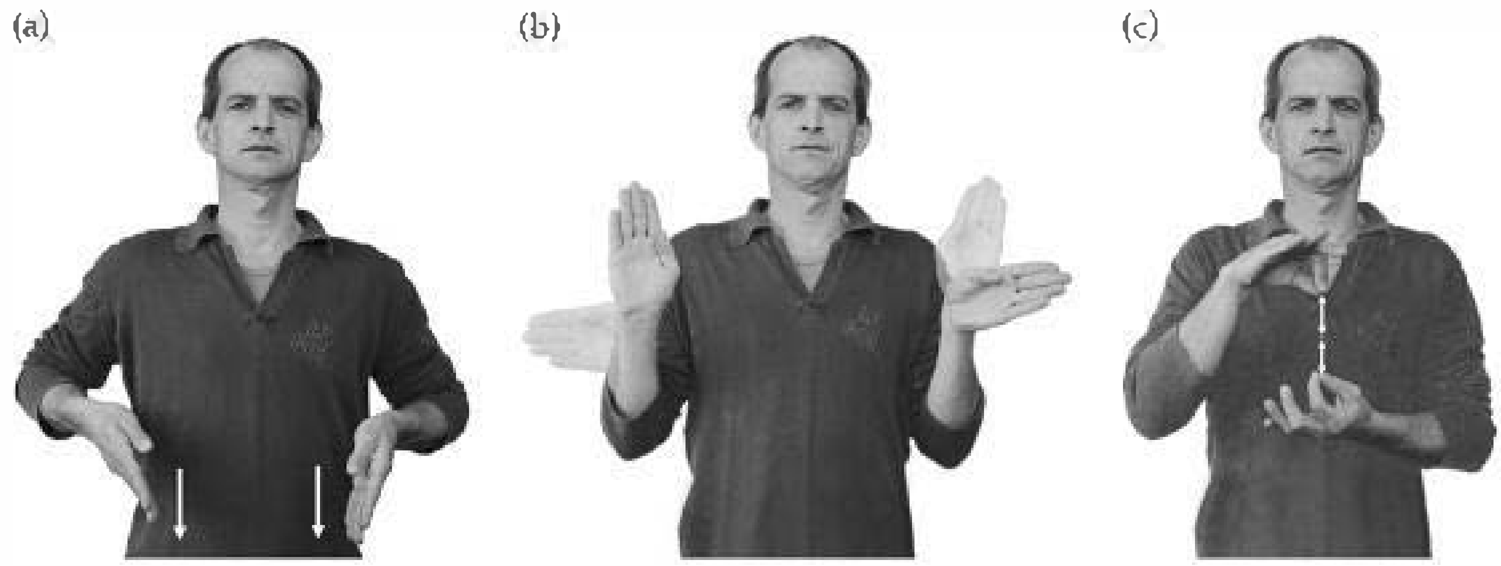

Figure 10.3 Examples of symmetrical signs: both hands move: (a) STAND, (b) TRAFFIC, (c) WEAKLING

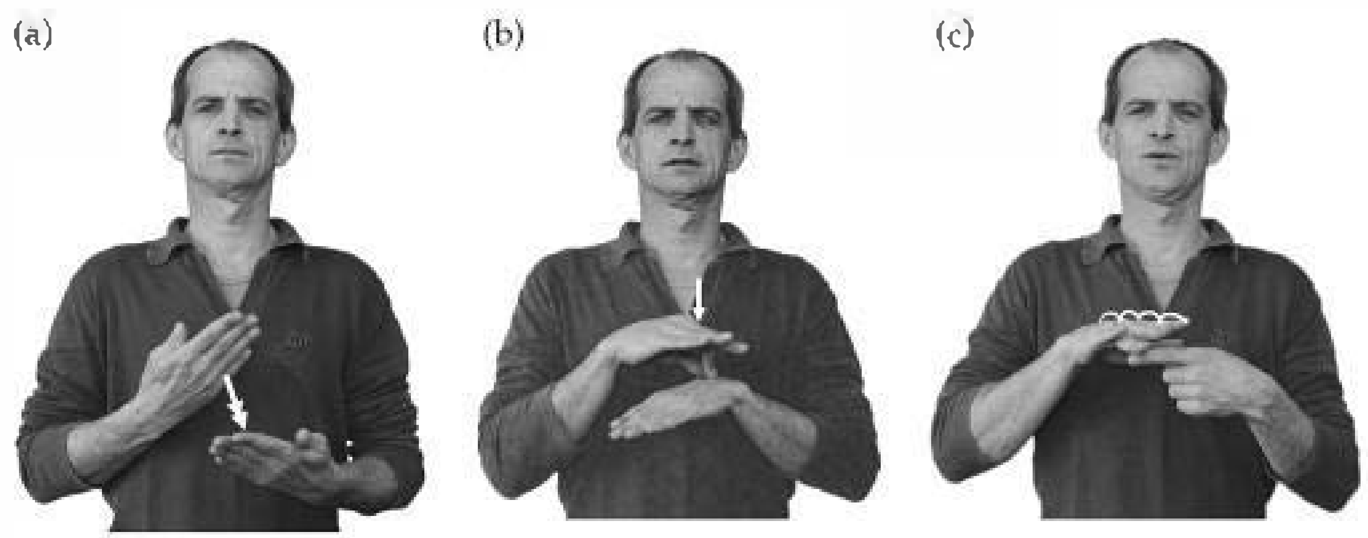

Figure 10.4 Examples of asymmetrical signs: one hand acts as the location for the other hand: (a) EVIDENCE, (b) ILL, (c) PHONOLOGY

types of asymmetry are further discussed in Padden and Perlmutter (1987) and Crasborn (1995).

2.2 *Battison's conditions*

Battison (1974, 1978) elaborated on the basic distinction between symmetric and asymmetric signs by observing two phonological regularities in the set of two-handed signs, which he characterized as morpheme structure constraints. They are the Symmetry Condition and the Dominance Condition, given in (1).

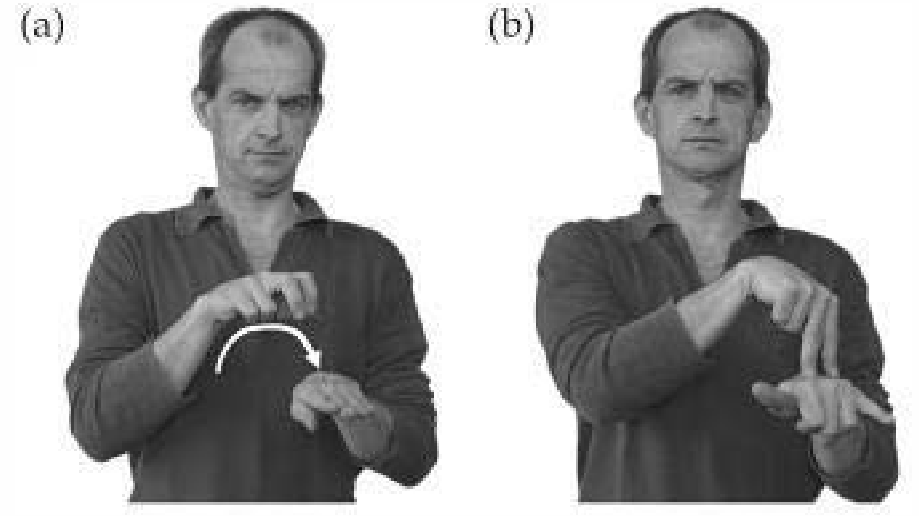

Figure 10.6 Classifier constructions from NGT. (a) 'Human or animal jumps onto a flat surface'; (b) 'Human stands on an airplane'

two-handed classifier constructions in many signed languages. These complex morphological constructions feature classifier hand configurations that each represent a separate morpheme, and (typically) the location and movement of each involves additional morphemic material. Two examples are presented in Figure 10.6.

While the example of a classifier construction from NGT in Figure 10.6a obeys the Dominance Condition for lexical items in (1b), the example in Figure 10.6b would be ruled out for monomorphemic signs, in ASL as well as in NGT: the Y handshape found in the non-dominant hand in Figure 10.6b does not occur on the weak hand in asymmetric signs in these languages. Eccarius and Brentari (2007) focus on this type of sign and classifier construction, to which Battison's Dominance Condition applied: the handshapes are different. Rather than looking at the two handshapes as a whole, they compare the selected fingers and their configuration within the handshapes. Each feature class can have marked or unmarked values (see CHAPTER 9: HANDSHAPE IN SIGN LANGUAGE PHONOLOGY). This allows the revision of the Dominance Condition as in (2), quoted from Eccarius and Brentari (2007: 1187), which also covers constructions such as the one in Figure 10.5b (italics in the original):

(2) *Revised Dominance Condition*
(a) If the two hands do not share the same specification for *both selected fingers and joints* (i.e., *the handshapes* are different), then (b) one hand must be passive while the active hand articulates the movement, and (c) *the form as a whole* (i.e., *selected fingers and joints for both hands*) *is limited to two marked phonological structures, only one of which can be on the passive hand.*

In terms of handshape features, the construction in Figure 10.6b shows a marked finger selection for the dominant hand (index and middle finger) and on the non-dominant hand (thumb and pinkie), making for a total of two marked structures in the whole form. All selected fingers are extended (unmarked), and thus do not add to the complexity beyond what the Revised Dominance Condition allows. A combination of the two hands where the dominant hand shows curved fingers, as in Figure 10.6a, is thus predicted to be unacceptable (a prediction that has yet to be tested for NGT). Thus, it would appear that the phonological complexity allowed for monomorphemic two-handed signs within the lexicon is not exceeded in morphologically complex forms.

Figure 10.9 The poem "Hope," by Wim Emmerik. Left hand: GUN, SHOOT-GUN, HUMAN-FALL; right hand: HOPE, DO, LIFE

finger for a certain time span ("theme buoy"). In an analysis of NGT poetry by Wim Emmerik, Crasborn (2006) shows that various types of buoy constructions occur in addition to the simultaneous realization of unrelated lexical items; this happens so frequently that one-handed articulations are virtually absent. When they are present, or when the two hands take turns in articulating a string of one-handed signs, this has a marked poetic effect. Figure 10.9 shows one of Emmerik's poems, in which each hand articulates three signs in sequence, the two hands articulating two different phrases at the same time. In this case, the left hand signs the optimistic Dutch expression *hoop doet leven* ("where there's hope, there's life"), while the other hand is pointing a gun at the head and shooting someone. Emmerik (1993) explains that this poem aims to express the two sides of the coin of a medical development (cochlear implants that promise to make deaf people hear) that was starting to gain popularity at the time. Similarly, Brentari (1998) discusses an example from a poem by the ASL poet Clayton Valli in which the hands act independently to express two different phrases simultaneously.

While this chapter mostly focuses on the phonological analysis of one-handed *vs.* two-handed lexical items, it is clear that the non-dominant hand also plays a role outside the lexicon, and that the uses of the two hands beyond the lexicon have been understudied. On the basis of the review of phonological representations in §3 and the discussion of some phonetic and phonological processes in §4, some of these open questions will be discussed in §5.

5 Conclusion

In summary, the striking modality difference of having two symmetrical articulators in signed but not in spoken languages does not appear to lead to wildly different lexical structures. Although in the signed languages that have been studied there is no prominent distinctive role in the lexicon for one-handedness *vs.* two-handedness, it is also clear that two-handedness has to be specified in the lexicon for each lexical item: whether one or two hands are involved in the articulation is not predictable from other properties of a sign. The actual phonological role of the second hand is rather restricted: it can be a copy of the dominant hand, or a place of articulation. The possibility of independence of the two hands is, however, exploited at the prosodic level, where spreading of the non-dominant articulator across one or more lexical items on the dominant hand can visually mark the size of certain prosodic units. In addition, the prolonged presence of certain morphemes can be exploited by the syntactic and discourse levels of the grammar, often yielding complex structures that await further investigation and analysis. These "simultaneous constructions," including the classifier constructions, reveal new questions about the relation between the lexical form of one and two-handed signs and their appearance in discourse. I briefly discuss some of these and related questions in the rest of this section.

While in the introduction it was stated that many signers by default use their preference hand as the dominant hand, it has also been observed that people can quite easily switch the left and the right hand. It is not yet clear when exactly this "dominance reversal" occurs in different languages, and to what extent its occurrence interacts with the lexical distinction between symmetric and asymmetric signs discussed in this chapter. Can some types of one-handed or two-handed sign perhaps block dominance reversal, or force it to occur at a different point in the discourse? Also, to what extent is the choice of dominant articulator influenced by the use of spatial locations on the left *vs.* on the right? Referents and parts of discourse can be localized by employing a left–right contrast (e.g. Friedman 1975; Lillo-Martin and Klima 1990); a question that arises is to what extent this triggers left-handed *vs.* right-handed articulations of sentences.

Several researchers have noted that classifier morphemes, as well as other types of articulations of the non-dominant hand, can be held at their (final) location for not just one Phonological Phrase (as with "meaningless," purely prosodic, spreading of the non-dominant hand), but for a number of sentences (Liddell 2003; Sandler 2006). How can we analyze such structures in terms of prosodic units? The largest unit in the prosodic hierarchy proposed by Nespor and Vogel (1986) is the Utterance, which can encompass several connected Intonational Phrases (or in syntactic terms, several clauses or even whole sentences joined by connectives). But is this unit large enough for the types of constructions that we are discovering in signed languages? Or is there a larger, discourse-level unit that simply forms a "Discourse Phrase," say, that can join several prosodic Utterances?

Longer simultaneous constructions at a morphosyntactic and discourse level also open up a new area of evidence for the study of Weak Drop: which types of signs block weak hand spreading because they do not allow for a one-handed articulation, and which do not? Are there circumstances where the process of weak hand spreading is so dominant that all two-handed signs are affected? The arrival of large corpora of semi-spontaneous signed language interaction promises to provide an important source of evidence for the investigation of these types of topics (Crasborn *et al.* 2007; Crasborn 2010; Johnston and Schembri, forthcoming).

Finally, as in other domains of sign language research, questions about linguistic typology remain largely open in the field of phonology. Although we have a reasonable number of elementary sign language dictionaries available from many non-Western signed languages, it is clear that most signed languages have not yet been analyzed in great detail, even at a lexical level. How universal are the (revised) Symmetry and Dominance conditions, for example? Eccarius and Brentari (2007) looked at Hong Kong Sign Language in addition to the Western languages ASL and Swiss German Sign Language, but this study is quite exceptional in this respect. The similarities across unrelated languages found so far, together with the strong phonetic origin of the phonological symmetry patterns,

11 The Phoneme

B. Elan Dresher

1 Introduction

The concept of the phoneme was central to the development of phonological theory. In the early twentieth century, phonological theory was all about the phoneme: how to define it, how to recognize it, how to discover it (see, for example, the articles selected for inclusion in Joos 1957 and Makkai 1972). The American structuralist term for phonology, phonemics, indicates to what extent the field was considered to be about the phoneme.

Things have now changed. The phoneme, to all appearances, no longer holds a central place in phonological theory. Two recent and voluminous handbooks devoted to phonology, edited by Goldsmith (1995) and by de Lacy (2007), have no chapter on the phoneme. It is barely mentioned in the indexes. This does not mean that the phoneme plays no role in modern phonology; closer inspection reveals that the phoneme is far from dead. However, it is not much talked about, and when it is, it is more often to dispute its existence than to affirm it.

Such a dramatic change in fortunes for a concept bears some looking into, and this chapter will be devoted to trying to understand what has happened to the phoneme in its journey into the twenty-first century, and what its prospects are for the future.

2 Origins of the term

S. R. Anderson (1985: 38) cites Godel (1957) and Jakobson (1971) as locating the origin of the term *phoneme* in the French word *phonème*, coined in the early 1870s by the French linguist Dufriche-Desgenettes. He proposed the term to substitute for the German *Sprachlaut* ("speech sound"), so it did not have the modern sense of phoneme, but rather corresponded to what we would now call "speech sound" or "phone." The term was taken up by Saussure (1879), who used it in yet a different sense, and from Saussure it was taken up by the Polish Kazan school linguists Jan Baudouin de Courtenay and Mikołaj Kruszewski.

S. R. Anderson (1985: 60–68) traces how the meaning of the term evolved from Saussure's use to the one that ultimately emerged from the Kazan school (for detailed accounts of the history of the phoneme see also Krámský 1974; Fischer-Jørgensen 1975). Saussure (1879) used it in his historical work on Indo-European to refer to a hypothesized sound in a proto-language together with its reflexes in the daughter languages, what we might call a "correspondence set." For example, if a sound that is reconstructed as *g in the proto-language has reflexes *g*, *h*, and *k* in three daughter languages, then the set {*g*, *h*, *k*} would constitute a "*phonème*" for Saussure.

Kruszewski recast the notion in synchronic terms to refer to a set of alternating elements; for example, if the same morpheme has a final [g] before suffixes beginning with a back vowel, a palatalized [g^j] before suffixes beginning with a front vowel, and a [k] when it is word-final, the alternation "[g] before a back vowel, [g^j] before a front vowel, and [k] when final" would constitute a "phoneme." Subsequently, Baudouin reinterpreted the term "phonemes" as referring to the abstract, invariant psychophonetic elements that alternate; in the above example, one could posit a phoneme /g/ that participates in the alternations that cause it to be realized as [g], [g^j], or [k], depending on the context.

In a final step, the term was extended also to sounds that do not alternate, thereby arriving at a conception of the phoneme as "the psychological equivalent of a speech sound" (Baudouin de Courtenay 1972: 152). It is in this sense that the phoneme entered phonological theory in Europe and North America.

3 General concept of the phoneme

The general concept of the phoneme preceded the term or its exact definition, which is a more difficult enterprise. The basic concept is that of the unity of sounds that are objectively different but in some sense functionally the same. As Twaddell (1935: 55) observes, this concept is not new: if a special term was not needed before the late nineteenth century, it is because in the absence of close phonetic observation, it is not necessary to distinguish between "phoneme" and "speech sound." Alphabetic writing systems tend to have separate letters only for sounds that have a distinctive function, though deviations from this principle occur (Krámský 1974: 10; Fischer-Jørgensen 1975: 4). In ordinary parlance one talks of the sound "d" or "k" as if each of these represents a single sound, rather than, as is the case, a range of sounds.

Parallel to the development of the phonemic concept as part of phonological theory mentioned above, British and French phoneticians who laid the foundations for what became the International Phonetic Association (IPA) arrived at a similar notion motivated by more practical concerns. According to Jones (1967: 256), Henry Sweet (1877) was the first to draw a distinction between "narrow" and "broad" transcription: narrow transcription aims (in principle) to record sounds in as much detail as possible, whereas broad transcription records only distinctive differences in sound. It was recognized early on that the goal of assigning a unique symbol to every sound in every language, even if it could be realized, would lead to transcriptions for particular languages that would be impractical and virtually illegible. Therefore, Paul Passy insisted in 1888 that only distinctive differences should be recorded, and called this principle *une règle d'or* ("a golden rule") from which one should never depart (cited in Jones 1967: 256). Thus, while the IPA is popularly known for developing a universal phonetic alphabet that is associated with phonetic ("narrow") transcription, its founders insisted on "broad" (i.e. phonemic) transcription for purely practical reasons. The practical strain remained influential in phonological theory, as attested by the subtitle of Pike's (1947) *Phonemics: A technique for reducing languages to writing.*

It is hard to imagine what linguistic description would be like without a phoneme concept of some sort. To take one entirely typical example, the Australian language Pitta-Pitta (Pama-Nyungan) is said to have three vowels, *i*, *a*, and *u* (Blake 1979: 187). In describing their pronunciation, Blake writes that they "are similar to the vowels of 'been', 'balm', and 'boot' respectively" (presumably [i], [ɑ], and [u]). Further reading reveals that this is only true in open syllables, and when stressed, and when near certain consonants. In a closed syllable, "they are similar to the vowels of 'bin', 'bun', and 'put'" ([ɪ], [ʌ], and [ʊ]). Further, the vowel *a* is pronounced [æ] in the vicinity of a palatal consonant, and unstressed *a* has a schwa-like pronunciation, [ɐ]. Objectively, then, Pitta-Pitta has at least eight different vowel sounds, and probably many more if we were to attend to further distinctions in different segmental and prosodic contexts, and in different situations and for different speakers.

This variation does not detract from the fact that there is an important sense in which this language has three vowels. In the distribution given above, we recognize that the variation is a consequence of the influence of context, and has no contrastive function: [i] and [ɪ] are variants of a phoneme we can designate as /i/, [u] and [ʊ] are variants of /u/, and [ɑ], [ʌ], [æ], and [ɐ] are variants of /a/. Put differently, in every slot where a vowel belongs we have only three choices in this language. If we are told that a word begins with the sequence *m*-vowel-*rr*-, we know that the vowel must be one of the variants of /a/ (e.g. *marra* 'open'), /i/ (e.g. *mirri* 'little girl'), or /u/ (e.g. *murra* 'stick').

4 Defining the phoneme

In the 1930s many linguists came to share the intuition that a concept like the phoneme is needed in phonological description.[1] Pinning down the definition of this concept proved to be difficult. Like other linguistic notions, such as "sentence," "syllable," and "topic," what starts out as a relatively unproblematic intuitive concept inevitably gets caught up in theory-internal considerations. In the case of the phoneme, three issues have been particularly contentious: (i) what sort of entity is the phoneme (physical, psychological, other); (ii) what is the content of the phoneme; and (iii) how does one identify phonemes?

4.1 *What type of entity is the phoneme?*

Twaddell (1935) surveyed the various definitions of the phoneme that were then in circulation, and classified them as being of two main types. One type assumes that the phoneme is a physical reality, and the other assumes that it is a psychological notion.

[1] Acceptance of the phonemic principle was by no means universal, however, particularly among traditional grammarians and writers of historical grammars. The phoneme does not appear in Campbell's (1959) *Old English grammar*, to the general applause of reviewers (see Dresher 1993 for discussion); its first appearance in a traditional-style Old English grammar is Hogg (1992).

be empirically tested. While it is no doubt correct that appealing to a vague and unknown "mind" cannot serve as an adequate explanation (*explanans*) of any phenomenon, the cognitive revolution that began in the 1950s has shown the fruitfulness of studying mental representations and processes as things to be explained (*explananda*).

4.1.3 The phoneme as a fiction

The consequence of rejecting both physical and psychological reality for the phoneme is that Twaddell (1935) is forced to conclude that the phoneme, though an "eminently useful" term, is a fictitious unit. There exist philosophies of science in which useful, indeed indispensible, units can be fictions, but most linguists since the 1950s have taken a "realist" view of linguistics (Chomsky 1980: 104–110). From this perspective, a unit that is required to give an adequate account of some phenomenon must be real at some level. Once we abandon empiricist assumptions about science and psychology, there is no obstacle to considering the phoneme to be a psychological entity.

4.2 *What is the content of the phoneme?*

It is one thing to locate the phoneme as a psychological (or physical) concept; it remains to try to characterize the content of the phoneme. What are phonemes made of? How are they represented? In this section I review some different approaches to these questions.

4.2.1 The phoneme as a set of contrastively underspecified features

Sapir's "point in the pattern." A particularly influential psychological conception of the phoneme was that of Sapir (1925, 1933). For Sapir (1925), each phoneme occupies a particular point in the sound pattern of a language. For example, he proposes that the hypothetical languages he calls C and D have the identical pattern, even though phonetic details differ. What is important is that each consonant in C has a corresponding consonant in D that occupies the same point in the pattern (the inventories in (1) maintain Sapir's arrangement, though I have updated his notation to modern IPA symbols).

(1) *Phonemes with identical patterning* (Sapir 1925)

a. *Pattern of C*

h		w	j	l	m	n
p	t		k	q		
b	d		g	c		
f	s		x	χ		

b. *Pattern of D*

h		v	ʒ	r	m	ŋ
pʰ	tʰ		kʰ	qʰ		
β	ð		ɣ	ʁ		
f	ʃ		ç	ħ		

In other terms, Sapir's "point in the pattern" refers to the contrastive status of a phoneme, and the way it relates to other phonemes in the system. Though Sapir did not assume a theory of distinctive features (CHAPTER 17: DISTINCTIVE FEATURES),

some such notion appears to be needed to make this notion explicit (Dresher 2009: 38–39). Thus, the series /b d g ɢ/ in language C can be characterized as being contrastively obstruent and voiced, properties it shares with the series /β ð ɣ ʁ/ in language D.

Sapir points out further that the sound pattern of a language is guided by the phonetics but may deviate from it. For example, /ʒ/ in language D is not classified with the voiced obstruents, but rather with the sonorants, corresponding to /j/ in language C. Thus, this sound is physically an obstruent, but psychologically and functionally a sonorant.

Sapir (1933) goes further in characterizing the phoneme as a psychological unit, arguing that "the phonemic attitude is more basic, psychologically speaking, than the more strictly phonetic one," setting off a debate about the psychological reality of phonemes that is still ongoing. He argues that perception in terms of phonemes accounts for difficulties native speakers have in grasping certain phonetic facts about their language, or perceiving "correctly" the objective sounds before them (see §6). Sapir's interpretation of these "errors" has been disputed over the years, but his work did much to establish the phoneme, and the "-emic attitude" more generally, as an important psychological and symbolic unit.

Prague School: Phonemic make-up or content. We observed that an explication of Sapir's notion of "point in the pattern" benefits from thinking of phonemes as possessing contrastive properties. This idea was carried further by phonologists of the Prague School, notably Jakobson and Trubetzkoy. The notion of opposition (or contrast between two phonemes) was central to their conception (CHAPTER 2: CONTRAST). Analysis of the nature of oppositions requires that phonemes be characterized as possessing features. The contrastive features necessary to distinguish a phoneme from others in the same system contribute to the phonemic make-up (Jakobson) or phonemic content (Trubetzkoy) of the phoneme.

Jakobson (1962) cites the observation of Hála that the simple vowels of Slovak are almost identical to the vowels of Standard Czech except for an additional short front vowel, /æ/, that occurs in dialects of Central Slovak (2).

(2) *Czech and Slovak vowel systems* (Jakobson 1962: 224)

a. *Standard Czech*			b. *Standard Slovak*	
i		u	i	u
e		o	e	o
	a		æ	a

Jakobson notes (1962: 224) that the presence of /æ/ in Slovak, though "a mere detail from a phonetic point of view . . . determines the phonemic make-up of all the short vowels." Thus all the short vowels in Standard Slovak come in pairs that contrast in the frontness/backness dimension, so that the vowels /i e æ/ are contrastively front (acute, in terms of Jakobson's features), and /u o a/ are contrastively back (grave). Lip rounding, though present phonetically in /u/ and /o/, is not contrastive and therefore does not enter into the phonemic make-up of these vowels.

In Czech the low vowel /a/ is not opposed to another low vowel. Therefore, even though it is almost identical to the Slovak /a/, Jakobson considers it to be neutral with respect to tonality, having no contrastive value except for its height.

Trubetzkoy (1969: 66–67) uses the term "phonemic content" to refer, like Jakobson, to those contrastive properties that characterize phonemes:

b. *Underlying representations*

$$\underset{\begin{bmatrix}+\text{high}\\-\text{round}\end{bmatrix}}{/\text{I}/} \quad \underset{[-\text{high}]}{/\text{A}/} \quad \underset{\begin{bmatrix}+\text{high}\\+\text{round}\end{bmatrix}}{/\text{U}/}$$

c. *Some realization rules*

i. $[\;\;] \rightarrow [+\text{tense}]$ / __ in an open syllable

ii. $[\;\;] \rightarrow [-\text{tense}]$ / __ in a closed syllable

iii. $\begin{bmatrix}-\text{high}\\ \alpha\text{tense}\end{bmatrix} \rightarrow \begin{bmatrix}\alpha\text{low}\\+\text{back}\\-\text{round}\end{bmatrix}$

iv. $\begin{bmatrix}+\text{high}\\ \alpha\text{round}\end{bmatrix} \rightarrow [\alpha\text{back}]$

v. $\begin{bmatrix}-\text{high}\\-\text{stress}\end{bmatrix} \rightarrow$ ɐ

d. *Sample derivations*

	'open'	'little girl'	'stick'
Underlying	/mAr.rA/	/mIr.rI/	/mUr.rA/
Stress	'mAr.rA	'mIr.rI	'mUr.rA
Rules (i)–(v)	'mʌr.rɐ	'mɪr.ri	'mʊr.rɐ

Other versions of underspecification theory have been proposed within generative grammar. In the 1980s, the most notable were Radical Underspecification (Kiparsky 1982, 1985; Archangeli 1984; Pulleyblank 1986) and Contrastive Specification (Steriade 1987). In the 2000s, a number of theories were proposed in which notions of contrast and phonological activity play key roles. Besides MCS, these include the minimalist theories of phonological representation of Hyman (2001a, 2001b, 2003) and Morén (2003, 2006), the theory of feature economy of Clements (2001, 2003, 2009), and the representational economy and underspecification proposal for laryngeal systems of Avery and Idsardi (2001). Other versions of phonological minimalism can be found in Dependency Phonology (Anderson and Ewen 1987; J. M. Anderson 2005; some of the papers in Carr *et al.* 2005) and Radical CV Phonology (van der Hulst 1995, 1996, 2005).

4.2.2 *The fully specified basic variant phoneme*

The model in (4), with each phoneme represented in the lexicon by a single underspecified representation, is not the only view of phonemic representation. S. R. Anderson (1985) traces it to subsequent interpretations of Saussure's notion that what is important in language is differences. Anderson (1985: 43f.) argues that this view, which he calls the "incompletely specified" theory of the phoneme, is not the only, or even the best, interpretation of what Saussure intended. He presents two alternative views. One is what he calls the "fully specified basic variant" phonemic theory. On this approach, one of the surface allophones of a phoneme is chosen as the basic underlying representation. That is, the representation of a phoneme is a full-fledged segment, with all its properties. A set of rules then changes the basic variant to its allophones in the appropriate contexts. Some on underlying representations, a principle known as Richness of the Base. In Pitta-Pitta, for example, the grammar would be required to derive the correct vowel allophones no matter what input vowels are presented to the grammar. A simplified set of constraints governing the Pitta-Pitta high vowel allophones is given in (6) and a sample evaluation is shown in (7).

(6) *Pitta-Pitta in OT*

Some constraints for high vowels

TnsOpen	Vowels are tense in open syllables.
LaxClosed	Vowels are lax in closed syllables.
Ident[high]	Preserve underlying values of [high].
Ident[round]	Preserve underlying values of [round].
Rd=Bk	The value of [back] must be the same as [round].
Ident[back]	Preserve underlying values of [back].
Ident[tense]	Preserve underlying values of [tense].

(7)

/mɨrrɪ/	TnsOp	LaxCl	Id[hi]	Id[rd]	Rd=Bk	Id[bk]	Id[tns]
a. mɨrrɪ	*!				*		
b. mɨrri					*!		*
c. murri				*!			*
d. mirri		*!				*	**
☞ e. mɪrri						*	*

The input in this example is /mɨrrɪ/, an impossible surface form in which both vowels are "wrong": the first vowel, /ɨ/, is not a possible surface vowel in Pitta-Pitta, according to the description above; the second vowel is possible in a closed syllable, but not in an open one. Therefore, the "faithful" candidate (a), which preserves both input vowels, violates two constraints, one for each vowel. Candidate (b) has a legal vowel in the open syllable but the back unrounded vowel is illicit. Candidate (c) repairs the unattested /ɨ/ by making it correspond to [ʊ], a possible sound in this context, but not in correspondence with an underlying [−round] vowel. Candidate (d) changes both vowels to [+tense], incurring a fatal violation of LaxClosed. Candidate (e) is the winner because it alone respects all the constraints in the highest tier, though violating the two lower-ranking constraints.

In this kind of grammar there is no representation of a phoneme /I/ or /i/, nor is there any statement to the effect that [i] and [ɪ] are allophones of a single phoneme. The latter is a consequence of the constraints and the way they interact, ensuring that any input vowel bearing the feature specifications [+high, −round] will surface as [i] in an open syllable and as [ɪ] in a closed syllable, whatever other specifications they start with.

This view of the phoneme has certain affinities with Exemplar Theory and related proposals (Johnson 1997; Bybee 2001; Pierrehumbert 2001; Välimaa-Blum 2009), whereby multiple copies of lexical items are stored in great detail, forming exemplar "clouds" of remembered episodes of individual experience. On this view, speech sounds, too, are stored in terms of exemplar clouds. Some exemplar theorists posit that there are exemplar clouds of phonemes as well as of words

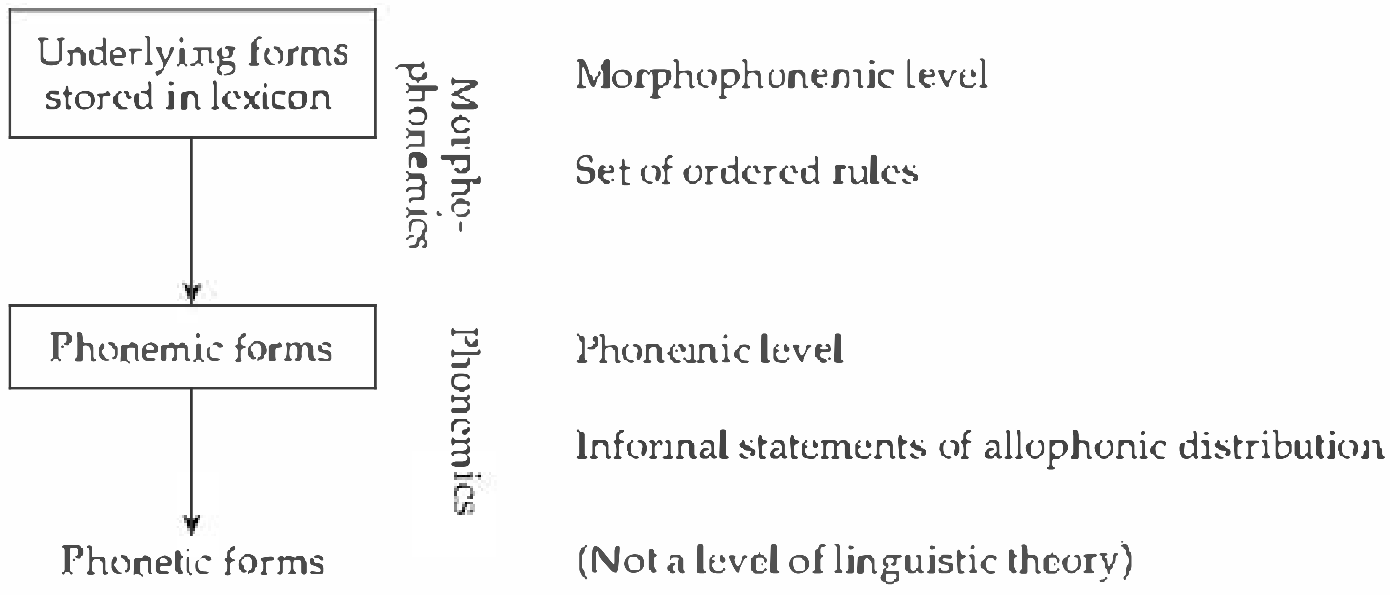

Figure 11.1 Levels in post-Bloomfieldian American structuralist phonology

final obstruent. Voicing is a contrastive feature in Russian that distinguishes pairs of obstruent phonemes: /t/ and /d/ have opposite specifications for the feature [voiced], as do /k/ and /g/, /s/ and /z/, and so on. Since RVA mainly turns one phoneme into another, it must apply in the morphophonemic component:

(13) *Russian regressive voicing assimilation*

a.	*Morphophonemic component*		
	Morphophonemes	//'mok bi//	//'mok lʲi//
	RVA	'mog bi	—
	Phonemes	/'mog bi/	/'mok lʲi/
b.	*Allophonic component*		
	Phonemes	/'mog bi/	/'mok lʲi/
	Other rules	'mog bɨ	—
	Phonetic form	['mog bɨ]	['mok lʲi]
		'were (he) getting wet'	'was (he) getting wet?'

In (13), the phrase 'were (he) getting wet' is realized as ['mog bɨ], where underlying /k/ voices to /g/ before voiced obstruent /b/ (compare [mok lʲi] 'was (he) getting wet?', with a /k/ preceding the sonorant /lʲ/). The rule that changes /k/ to /g/ changes one phoneme to another, and so it must be a morphophonemic rule. This result is forced in any phonemic theory that observes the constraint that allophones of different phonemes may not overlap: in this case, [k] may not be an allophone of both /k/ and /g/.

Halle (1959: 22–23) points out that there are Russian obstruents that do not have voiced counterparts, /ts ʧ x/ (that is, there are no contrasting phonemes /dz ʤ ɣ/). He observes that these phonemes participate in voicing alternations in the same way as other obstruents; in particular, they trigger and undergo RVA (14). Thus, we have ['ʒeʤ bɨ] 'were one to burn', where [ʤ] is the voiced counterpart of [ʧ] (compare ['ʒeʧ lʲi] 'should one burn?', with voiceless [ʧ] before [lʲ]). Because [ʤ] is not a phoneme in its own right, but exists only as an allophone of /ʧ/, this application of voicing is an allophonic rule, and must be assigned to the component that maps phonemic forms into phonetic forms.

Sapir's (1933) arguments for the phoneme as a unit of perception are early examples of this type. Fromkin (1971, 1973) argues that slips of the tongue are a window on linguistic representations and processes. Errors like *teep a cape* for *keep a tape* and [fuwt mijving] for *feet moving* show transpositions of individual segments cut out of the speech stream. Fromkin argues that errors where only one segment in a cluster is involved provide further evidence that individual segments are units of speech performance: examples are *fish grotto* > *frish gotto* and *sticky point* > *spicky point*.[8]

Language games exist in many languages and involve manipulations of various kinds of linguistic units (see Sherzer 1982 and Bagemihl 1995 for overviews). Games that pick out individual segments appear to presuppose a linguistic analysis in which such units are represented. For example, some games involve the exchange of segments: Tagalog /'dito/ > /'doti/ 'here', or Javanese /satus/ > /tasus/ '100' (cited in Bagemihl 1995: 704). Again, much of this does not specifically show evidence for phonemes as opposed to segments.

Neurolinguistic evidence is becoming increasingly influential in finding out about the sort of representations speakers have. Kazanina *et al.* (2006) report that magneto-encephalographic brain recordings reveal that Russian and Korean speakers react differently to tokens of [d] and [t]. In Russian, these sounds are contrastive, members of different phonemes, /d/ and /t/; in Korean, both sounds exist, but they are not contrastive and map into a single phoneme /T/. Russian speakers showed evidence of separating the sounds into two categories, whereas Korean speakers did not. Kazanina *et al.* (2006) conclude that a speaker's perceptual space is shaped not only by the phonetic distribution of sounds, but also by a more abstract phonemic analysis of speech sounds.

6.3 *Evidence from synchronic and diachronic patterning*

The most pervasive sort of evidence for phonemic representations comes from synchronic and diachronic phonological processes, which typically target individual segments, or classes of segments. It is hard to see how phonology could operate without some representations of the affected units. Of course, whether or not a phonemic representation is required depends on what alternate units are posited. Thus, some processes that apply to initial or final consonants could be recast as applying to syllable onsets or codas (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE). Even in such cases, it may still be necessary to be able to identify individual phonemes, apart from their positions in syllables. As Idsardi (2010) points out, Russian /ivan/ 'Ivan' and /k ɨvanu/ 'to Ivan' have no syllables in common: 'Ivan' is syllabified /i.van/ and 'to Ivan' is syllabified /ki.va.nu/ (cf. Halle and Clements 1983: 149). A representation in which syllables are primitives would have difficulty showing how these words are related.

[8] As mentioned in the previous section, these types of tests are often ambiguous as to whether they target phonemes or just segments. Most of these speech errors show that individual segments can be isolated, but do not necessarily require a phonemic analysis. One interesting example Fromkin (1971: 31) cites is *split pea soup* becoming *plit spea soup*. The fact that *pl* (presumably [pʰl], though Fromkin does not explicitly say) surfaces rather than *bl* when the *s* is transposed could suggest that the speaker groups unaspirated stops following *s* with voiceless stops, rather than with voiced stops.

7 The phoneme in the twenty-first century

As the above survey shows, the phoneme has not disappeared from phonological theory. The fact that recent handbooks of phonology have no chapters devoted to it is not a sign of its demise; rather, it is a function of the development of phonological theory. The time is past when one can attempt to provide an exhaustive definition of the phoneme and its properties apart from elaborating a complete theory of phonology. Many current topics in phonology can be viewed as being about aspects of the phoneme, even though the phoneme is not invoked. For example, the content of the phoneme is studied in distinctive feature theory (CHAPTER 17: DISTINCTIVE FEATURES), feature organization ("geometry"; CHAPTER 27: THE ORGANIZATION OF FEATURES), underspecification (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION), markedness theory (CHAPTER 4: MARKEDNESS) and notions of contrast (CHAPTER 2: CONTRAST). Constraints on the relations between phonemes and phonetics on one side, and lexical representations on the other, are bound up with the question of the organization of the phonological grammar, whether parallel or derivational, or divided into lexical and post-lexical components, and the relation between lexical storage and production and perception.

When one reads the pioneering works of phonology in the late nineteenth and early twentieth centuries, one is struck at their sense of excitement and revelation when discussing the phoneme. This same feeling continues to exist in introductory courses, where the phoneme retains a central place. That phonological theory has subsumed it into more specialized issues and sub-theories does not detract from the fact that it remains, in the words of Krámský (1974: 7), "one of the most magnificent achievements of linguistic science."

ACKNOWLEDGMENTS

I would like to thank Ewan Dunbar, Liisa Duncan, Daniel Currie Hall, Bill Idsardi, and an anonymous reviewer for discussion and suggestions. This work was partially supported by research grant 410-08-2645 from the Social Sciences and Humanities Research Council of Canada.

12 Coronals

T. A. Hall

1 Introduction

Numerous studies in the past two decades have argued that coronals like /t/ and /n/ have properties that differentiate them from labials like /p/ and /m/ and dorsals like /k/ and /ŋ/ (e.g. Paradis and Prunet 1991b). For example, in many languages coronals are the only sounds that undergo place assimilation or rules of epenthesis. Sounds like /t/ and /n/ are likewise often the output of rules neutralizing place contrasts. The present chapter summarizes the special properties of coronals and evaluates a number of theoretical and empirical claims made in the literature concerning these sounds.

In (1) I provide some background information for readers unfamiliar with the term "coronal." We can observe here several common IPA symbols for coronal consonants for four manners of articulation. Note that there are four major places, namely labial, coronal, dorsal, and glottal. The present chapter concerns itself with the sounds in the box in (1).

(1)

	labial		coronal				dorsal		glottal
stops	p b		t d		ʈ ɖ	c ɟ	k g		ʔ
fricatives		f v	s z	ʃ ʒ	ʂ ʐ		x ɣ	χ ʁ	h
nasals	m		n		ɳ	ɲ	ŋ		
liquids			l r						

From the point of view of phonetics, coronal consonants include at least the following four places of articulation: (denti-)alveolar (e.g. /t d/), post-alveolar (e.g. /ʃ ʒ/), retroflex (e.g. /ʈ ɖ/) and palatal (e.g. /c ɟ/).[1] From the perspective of

[1] Coronals also uncontroversially include (inter)dentals like /θ ð/. A lesser-known coronal place of articulation is alveolo-palatal (e.g. /ɕ ʑ/, as in Polish and Mandarin). Palatal stops like /c ɟ/ are considered to be coronal, although there is some controversy concerning whether or not palatal fricatives like /ç ʝ/ are coronal or dorsal (or both). For various views on this issue the reader is referred to Hume (1992), Hall (1997), and Robinson (2001). In addition to the coronal consonants like the ones in (1), a number of linguists have argued that front vowels like /i e/ are coronal, e.g. Clements (1976), Hume (1992), and Clements and Hume (1995). I use the term "coronal" in this chapter to refer only to consonants.

phonology there is general consensus that the boxed sounds in (1) form a natural class that is captured with the privative feature [Coronal]. Within that class, it is often useful to draw a distinction between "anterior coronals" like /t d s z n l/ and "non-anterior coronals" like /ʈ ɖ c ʃ ʒ ʂ ʐ ɳ ɲ/.[2]

As noted above, a number of studies have argued that coronals like the ones in (1) display a unique set of properties not shared by labials or dorsals. Put simply, the properties of sounds like /t/ have led many linguists to the conclusion that coronal is the least marked major place of articulation (e.g. Kean 1975; Paradis and Prunet 1991a). By contrast, much recent work has argued that the unmarked major place is glottal (e.g. Lombardi 2002; de Lacy 2006), dorsal (e.g. Trigo 1988, who uses the term "velar") or even labial (Hume and Tserdanelis 2002; see also CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION). In light of these apparently conflicting claims, it is natural to ask whether or not coronals are indeed endowed with special properties, or if coronal is simply another place on par with dorsal and labial (Blevins 2004). It is the purpose of the present chapter to evaluate the special status of coronals and to show where the areas of controversy lie.

The special status of coronals is clearly connected to the question of how markedness is defined in general and in phonology in particular (see Hume 2003, de Lacy 2006, and Rice 2007 for recent discussion). Rice draws a distinction between properties of "natural markedness" and those of "structural markedness," where the former term refers specifically to non-phonological criteria, e.g. frequency, acquisition, and saliency, and the latter term to phonological criteria.

The present chapter focuses only on phonological arguments for markedness (i.e. structural markedness). According to Rice (2007), three of these criteria are assimilation, neutralization, and epenthesis. This means that coronals like /t/ are unmarked if they undergo place assimilation, if they are the output of place neutralization, or if they can be epenthesized.[3]

The remainder of this chapter is organized as follows. In §2 I summarize some of the general questions concerning the status of coronals that are currently in dispute. All of these questions will be referred to extensively in the following sections. The following three sections concentrate on the role of coronals with respect to the three properties of structural markedness referred to above, namely assimilation (§3), epenthesis (§4), and place neutralization (§5). In §6 and §7 I consider two additional properties of structural markedness, namely the role of coronals in syllable structure and the transparency of coronals in place spreading. In §8 I provide a brief summary of each of the main theoretical and empirical issues addressed in the preceding sections.

[2] From the point of view of articulatory phonetics, coronals are usually defined as sounds produced with the tip blade (including the tip) of the tongue (see Keating 1991: 30). I adopt the definition proposed by Halle and Stevens (1979: 346), according to which coronal sounds involve the raising of the "central" portion of the tongue, i.e. the part of the tongue connecting the blade with the tongue body. In referring to the "central" part of the tongue, this revised definition is therefore able to include palatals as coronal sounds. From the point of view of acoustic phonetics, coronals are characterized by a concentration of energy in the upper frequencies of the spectrum (Jakobson *et al.* 1952).

[3] For reasons of space, I do not discuss the other two diagnostics for structural markedness mentioned by Rice (2007), namely coalescence and deletion. Put simply, it is typically assumed that unmarked features are more prone to coalescence or deletion than marked features. A property of structural markedness not mentioned by Rice (2007) is dissimilation. For an argument that coronals are unmarked in place dissimilation in Tashlhiyt Berber the reader is referred to Alderete (2004: 400ff.).

2 General research questions

In the following sections I discuss the five very general questions in (2) pertaining to coronals, all of which are open to debate.

(2) a. Markedness: Are coronals endowed with special properties that differentiate them from the other major places and, if so, what are they?
b. Universality: Are the properties characterizing coronals (or other places of articulation) universal or language-specific?
c. Representations: To what extent do the properties of coronals (or other places of articulation) require unique phonological representations?
d. Manner: Why do unmarked coronals belong to certain manner categories and not to others?
e. Coronal subplaces: Why do unmarked coronals belong to certain subplaces and not to others?

While the unmarkedness of coronals (i.e. (2a)) is the position usually taken in the literature, this question is still a controversial one. It also needs to be clarified whether or not the special properties for coronals can vary within a single language. For example, if coronals are unmarked relative to labials and dorsals in Language A with respect to assimilation, will they also be unmarked in Language A with respect to epenthesis or neutralization? If not, how does one account for this asymmetry? One of the most controversial questions concerning markedness in linguistics pertains to universality (i.e. (2b)): are coronals less marked than labials and dorsals in all languages without exception? It is sometimes assumed that this is the case, but much current work has questioned this assumption. If the unique properties of coronals are language-specific, does this imply that there are no constraints on possible targets for place assimilation and outputs of place neutralization?

Regardless of what one's answer is to the question of markedness and universality, one needs to provide a formal analysis for the unmarkedness of coronals with respect to other major places of articulation in at least some languages (i.e. (2c)). Many phonologists argue that the special status of coronals in such languages requires that they have a particular representation that makes them unique from other major places of articulation. By contrast, much recent work in Optimality Theory (OT) has denied the role of representations. It will be clear below that many adherents of OT argue that the special properties of coronals (i.e. their unmarkedness) should be captured not with representations, but instead with a markedness hierarchy. Is the rejection of unique representations for coronals warranted?

It will be clear below that for those languages in which coronals are unmarked, it is only certain sounds within that class that display these properties. For example, many languages have place assimilations that affect coronals, but these assimilations will only apply to nasals but not to fricatives (i.e. (2d)), and only to alveolars and not to palatals (i.e. (2e)). What kind of cross-linguistic variation is attested with respect to manner and coronal subplaces? And how should generalizations concerning manner and coronal subplaces be captured theoretically?

3 Coronals as the target for place assimilation

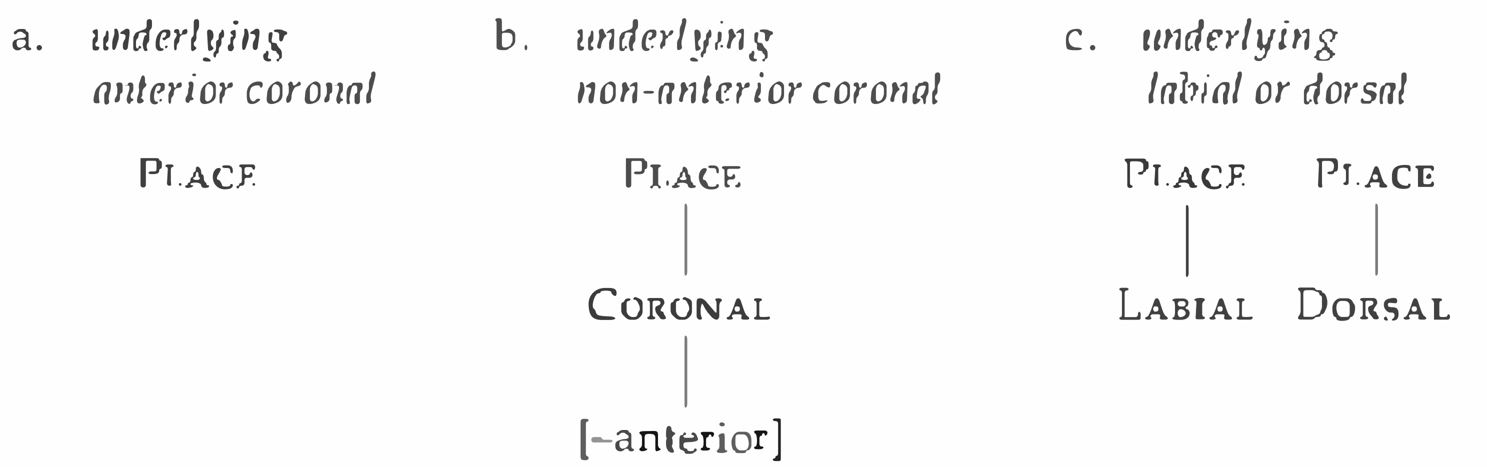
A number of linguists have argued that sounds like /n/ and /t/ are more prone to place assimilation than the corresponding labials or dorsals (e.g. Kiparsky 1985; Avery and Rice 1989). Consider the Catalan data in (3) below from Kiparsky (1985: 95), whose source is Mascaró (1976).

(3) a. *so*[n] *amics* 'they are friends'
so[m] *pocs* 'they are few'
so[ŋ] *grans* 'they are big'
b. *so*[m] *dos* 'we are two'
ti[ŋ] *pa* 'I have bread'
a[ɲ] *feliç* 'happy year'

In (3a) we can observe in the second and third example that the /n/ in the morpheme 'they' assimilates to the place of articulation of a following labial or dorsal. By contrast, none of the other three underlying nasals (i.e. /m ŋ ɲ/) assimilates to the place features [Labial] or [Dorsal]; see (3b).

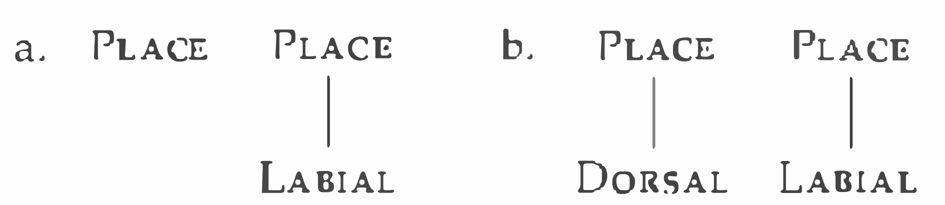
One way of capturing the special status of /n/ is to posit a representation for that segment which is underspecified for all place features (e.g. Kiparsky 1985: 97–99). This idea is captured in the representations in (4), where (4a) is the structure for /n/ and (4c) for labials and dorsals, and (4b) for non-anterior coronals like /ɲ/. I refer to (4) henceforth as the "coronal underspecification" approach, although it should be clear from (4) that it is only anterior coronals that are underspecified.[4]

(4)



An important assumption made in the coronal underspecification approach is that nasal assimilation in Catalan involves the spreading of a feature to a segment lacking that feature. Given the structure-building nature of nasal assimilation, the rule can spread [Labial] to the left in (5a) but not in (5b).

(5)



[4] Kiparsky (1985) assumes that palatals like /ɲ/ are dorsal, but I follow the consensus view that they are coronal. His representations differ slightly from the ones in (4) because he does not assume the existence of a [Place] node. Structures like the ones in (4) are endorsed by several of the authors in Paradis and Prunet (1991b), although opinions differ on whether or not anterior coronals like /t/ and /n/ lack [Coronal] as in (4a), or [Place] as well as [Coronal].

The model in (7) can account for the pattern of assimilation in Korean in (6). Unmarked coronals like /t/ assimilate to a following labial or dorsal. Significantly, labials can assimilate to dorsals (by the spreading of [DORSAL]), but dorsals cannot serve as the targets of place assimilation.

Mohanan (1991), McCarthy and Taub (1992) and Hall (1995) all point out a potential problem with the coronal underspecification approaches in (4). It will be clear below that these criticisms also hold for (7). In many of the languages in which sounds like /n/ are argued to be underspecified for place features, we also find rules that crucially require /n/ to be marked for place features. For example, like Catalan, English and German /n/ assimilates to a following labial or dorsal. Since this assimilation is post-lexical, it would be necessary to analyze /n/ as underspecified for place features at that late stage in the derivation. The problem is that there are lexical rules (or static constraints) that require that coronal sounds like /n/ be specified for place features. For example, in German there is a lexical rule of schwa epenthesis that inserts a schwa only between a coronal stop and a coronal obstruent in verbs (e.g. *arbeit-et* [aɐbaitət] 'works' *vs. lern-t* [lɛɐnt] 'learns'). Clearly, the rule of schwa epenthesis can only go into effect if sounds like /t/ are [CORONAL]. In American English, initial coronal consonant plus [ju] is prohibited. Thus the constraint banning '[CORONAL] [ju]' sequences must make reference to the feature [CORONAL].

The pattern of place assimilation in Sri Lankan Portuguese Creole is problematic for both of the representational models discussed above because labials and dorsals but not coronals serve as the target. Consider the data from that language (from Hume and Tserdanelis 2002) in (8), which illustrate the pattern of place assimilation across morpheme boundaries:

(8)		*nom. sg.*	*gen. sg.*	*dat. sg.*	*verbal noun*	
	a.	[vaːrzim]	[vaːrzin-su]	[vaːrzim-pə]	[vaːrsiŋ-ki]	'harvest'
		[maːm]	[maːn-su]	[maːm-pə]	[maːŋ-ki]	'hand'
		[miːtiŋ]	[miːtin-su]	[miːtim-pə]	[miːtiŋ-ki]	'meeting'
	b.	[bataan]	[bataan-su]	[bataan-pə]	[bataan-ki]	'button'
		[siːn]	[siːn-su]	[siːn-pə]	[siːn-ki]	'bell'

In the first column of (8a) we can observe monomorphemic words in the nominative singular ending in a labial or dorsal nasal. Before the genitive singular suffix /-su/ in the second column, both the labial and dorsal assimilate to the place of articulation of the following /s/. The third column is important because it illustrates that the dorsal nasal assimilates to the place of the following /p/. Finally, we can see in the fourth column that /m/ assimilates to dorsal before /k/. The data in (8a) can be contrasted with the examples in (8b), which show that the coronal nasal /n/ resists place assimilation to both a labial and a dorsal.

What the data in (8) tell us is that in Sri Lankan Portuguese Creole, labials and dorsals undergo place assimilation but that coronals do not. Hume and Tserdanelis (2002) argue that the pattern of assimilation in (8) poses a serious problem for the coronal underspecification approach in (4). The reason is that coronal underspecification presupposes that only the marked features (e.g. the ones that resist place assimilation) are underlyingly specified for place features, while the unmarked features (e.g. the ones that undergo place assimilation) are the ones a list of other languages in which palatals fail to undergo place assimilation, but impressionistically, this generally appears to be the case.[7] If the constraint ranking approach taken in (8) were to be extended to include the constraints referring to the subplaces within the coronal range, then one would expect there to be a language in which the palatal stop /c/ or the retroflex stop /ʈ/ undergoes place assimilation, while the alveolar stop /t/ does not. To the best of my knowledge, such a pattern of assimilation is not attested, but the question of whether or not "everything goes" among coronal subplaces clearly needs to be left open for further research.

4 Coronals as epenthetic segments

There is general agreement in the literature that epenthesis is a valid markedness diagnostic. Glottals ([ʔ h]) are the most common epenthetic consonants from a cross-linguistic point of view, but coronals have been argued to be less marked than labials or dorsals in terms of epenthesis. For example, in their defense of the claim that coronal is the least marked place, Paradis and Prunet (1991a: 20) write: "In initial and intervocalic positions, coronals (including fricatives) are inserted more often than noncoronals." The language most often cited with coronal epenthesis (i.e. the unmarked voiceless stop /t/) is Axininca Campa, although sometimes other languages are cited as well (e.g. Gokana and Amharic).

Consider first languages with epenthetic glottals (i.e. [ʔ]). According to the survey provided in Lombardi (2002), there are languages attested in which [ʔ] is epenthesized initially (presumably to avoid vowel-initial syllables), medially (as a means of resolving hiatus), or finally. In many languages with an epenthetic glottal, the sound being epenthesized is not phonemic, but there are languages attested in which a glottal is epenthesized even if that sound belongs to the underlying consonants (e.g. Selayarese; Lombardi 2002). Some of the languages with epenthetic glottal include Arabic (word-initial) and Selayarese (between identical vowels). The coda context for glottal epenthesis is illustrated in the Cupeño examples in (13) from Lombardi (2002: 229), who cites Crowhurst (1994).

(13)	/ʧi/	[ʧiʔ]	'gather'
	/kʷa/	[kʷaʔ]	'eat'

According to the sources cited above, epenthesis of a consonant in final position in Cupeño is necessary to satisfy a bimoraic minimal word requirement. The reason [ʔ] is epenthesized, as opposed to some other consonant, is that glottal is seen as the least marked place. The unmarkedness of place of articulation is accomplished with constraints similar in function to the Preserve constraints discussed in (9)–(11) above. In particular, the constraints penalize the relevant major place category (i.e. *Lab, *Cor, *Dors, *Phar). Lombardi (2002) assumes

7 Hungarian is yet another example of a language in which palatals fail to undergo place assimilation (Siptár and Törkenczy 2000: 207). Interestingly, these authors remark that Hungarian /ɲ/ assimilates to [ŋ] before dorsals in certain dialects (2000: 211). In the literature on Korean it is usually assumed that "palatal" /c/ assimilates to a following dorsal (i.e. /ck/ → [kk]), but not to a following labial; however, an anonymous reviewer points out that Korean /c/ is closer to a strident affricate (IPA /tɕ/) than a palatal stop.

that the constraint penalizing glottals is *Phar, because in her system glottals have pharyngeal place features (i.e. [Phar, +glottal]). Lombardi (2002) also operates under the assumption that glottals are obstruents and not sonorants. As I point out below, the treatment of glottals as obstruents is not universally accepted.

Lombardi's (2002) markedness hierarchy is presented in (14). In contrast to the markedness hierarchy posited in the previous section, the one in (14) is assumed to be universally fixed. See de Lacy (2006) for a similar markedness hierarchy.

(14) *Dors, *Lab >> *Cor >> *Phar

According to the hierarchy in (14), glottals are the optimal epenthetic consonants because their place markedness is even lower than that of the relatively unmarked coronals. Consider the evaluation of the first example in (13), given the hierarchy in (14):

(15)

Input: /ʧi/	MinWd	*Dors	*Lab	*Cor	*Phar
a. [ʧi]	*!				
☞ b. [ʧiʔ]					*
c. [ʧit]				*!	
d. [ʧik]		*!			
e. [ʧip]			*!		

In this tableau, candidate (15b) is selected over candidates (15c–15e) because the latter three insert consonants that have a place of articulation other than glottal.

In other languages a coronal is epenthetic. The intuition behind the ranking in (14) is that coronal is the next best place in terms of epenthesis. Thus, if there is some independent reason for why a glottal cannot be epenthesized, then a coronal (and not a labial or a dorsal) will be.

Consider now the Axininca Campa examples in (16) from Lombardi (2002), who cites McCarthy and Prince (1993) and Payne (1981). This example is usually considered to be a paradigm case for a language with an epenthetic [t]. /N/ represents a nasal consonant unspecified for place features.

(16) /i-N-koma-i/ [iŋkomati] 'he will paddle'
/i-N-koma-aa-i/ [iŋkomataati] 'he will paddle again'

These examples illustrate that [t] is epenthesized intervocalically in order to ensure that every syllable has an onset. Given the markedness hierarchy in (14), the challenge posed by these examples is that they require that a coronal rather than a glottal be epenthesized.

Both Lombardi (2002) and de Lacy (2006) argue that a coronal, rather than a glottal, is epenthesized for reasons of sonority. The generalization is that onsets with a stop are more harmonic than those with a fricative, nasal, or liquid, because stops are the least sonorous segment type on the sonority hierarchy. Assuming that de Lacy (2006) is correct in his analysis of glottals as sonorants, [t] is selected over glottals because the latter make worse onsets than the former. This intuition is captured in the following tableau:

For example, de Lacy (2006) discusses languages with an epenthetic rhotic [r], e.g. English and Southern Tati, and shows that this process applies only in the context of low vowels. Consider the latter language. In Southern Tati the approximant [r] is epenthesized after low vowels, but after non-low (unrounded) vowels (e.g. /i e/) the epenthetic segment is [j], and after non-low (rounded) vowels (e.g. /y u/) it is [w]. In this language, epenthetic consonants copy the place and manner features of the preceding vowel; hence, [j] appears after /i e/ because all of these sounds have the same value of [sonorant] and [approximant] (and the place feature [Coronal]). The sound [w] likewise appears after sounds like /y u/, because all of these segments share the same manner and place features. After /a/ the epenthetic consonant is the approximant [r], because the latter sound copies the preceding vowel's manner features (i.e. [sonorant] and [approximant]). Significantly, the epenthetic consonant cannot copy the preceding vowel's place features because /a/ is neither [Labial], [Coronal], nor [Dorsal] (de Lacy 2006: 101–102, after Clements and Hume 1995).

Since there appear to be no languages in which a non-anterior coronal like [j] can be freely epenthesized regardless of the quality of an adjacent vowel, I conclude that the approach described by de Lacy (2006) makes the correct predictions. This approach could potentially be falsified by a language in which [j] (or some other non-anterior coronal) is epenthesized in the context of any vowel (and not simply in the neighborhood of /i e/). Whether or not there are such languages is a question that clearly needs to be left open for further study.

5 Coronals as the output of place neutralization

Many languages are attested in which a multiple place of articulation contrast is neutralized in coda position, but these languages can vary concerning the output sound. Some languages have been argued to involve a place neutralization to coronal, thereby providing evidence for the claim that coronal in these languages is less marked than labials or dorsals. Some of the languages cited with a place neutralization to coronal are Finnish (Yip 1991), Greek, Italian, Croatian dialects, as well as Fante (Kiparsky 1995: 669), Castilian Spanish, and Koyukon (Rice 1996). Many well-known languages are attested in which the output of place assimilation is glottal, i.e. debuccalizations converting sounds like /s/ to [h] (in dialects of Spanish) or /t/ to [ʔ] (in dialects of English). More interesting for purposes of the present chapter are languages reported to neutralize place contrasts to dorsal (Selayarese) or labial (Manam).

Languages referred to above which debuccalize sounds like /s/ or /t/ to glottal are unproblematic given the markedness hierarchy in (14). Given an input like /tat/, the most harmonic output is [taʔ], because the candidates [tak], [tap] and [tat] incur violations of the high-ranking markedness constraints *Dors, *Lab and *Cor. If the faithfulness constraint militating against the change from /t/ to some other sound is ranked lower than *Phar, then the output [taʔ] will be selected as optimal. An approach to neutralizations that accepts coronal underspecification would need to explain why the output of /tat/ is [taʔ] and not [tat]: since debuccalization is usually assumed to delete all and only place features, one might expect the output to be a coronal if coronals lack place features. However, the problem might be solvable if glottals are analyzed as having even less structure than

In Rice's (1996) representational approach, final nasals in Selayarese – like the final coronals in languages like Finnish – have the representation in (7a), which lacks [Place]. In Finnish a default rule applies specifying that consonants unspecified for [Place] are [Coronal]. Unlike Finnish, Selayarese does not have the default rule assigning [Coronal] to placeless consonants, and thus the consonant that lacks [Place] is interpreted phonetically as velar.

Languages that neutralize place of articulation to dorsal can be captured in an OT approach with a freely rankable markedness hierarchy. The correct output can be achieved by ranking the constraint militating against dorsals lower than the constraints militating against coronals or labials. By contrast, in approaches to OT with a fixed markedness hierarchy (as in (14)), it is not clear how the examples in (20) can be accounted for. De Lacy (2006) ultimately argues that place neutralizations can have only two possible outputs, namely coronal and glottal. He argues that the cases of neutralization to dorsal can be explained in other ways; recall from §4 that he re-analyzes dorsals that are apparently epenthetic as being morphological in nature. In the case of Selayarese in (20) (and other languages), de Lacy (2006) argues that the dorsal nasal is really glottal. In Oceanic languages the neutralization of /t/ to [k] is a common historical process, but de Lacy (2006) claims that there are no languages in which such neutralizations can be motivated as synchronic processes on the basis of alternations. Whether or not de Lacy's (2006) re-analysis of apparent cases of neutralization to dorsal can be extended to other languages is – in this writer's view – doubtful. See also Rice (2008) for criticisms. Rice also points to Manam as a language that neutralizes a multiple place contrast to labial, but it is not clear how these data can be accounted for with the fixed markedness hierarchy in (14).

Not much attention seems to have been paid in the literature to questions (2d) and (2e). Given that there are languages in which the output of place neutralization is a coronal, why is the subplace anterior and why is the manner a stop or nasal? Could a language with /p t c k/ neutralize the four-way contrast to the palatal stop [c]? While it is conceivable that such a neutralization might occur in the neighborhood of a front vowel (since front vowels are often assumed to be [Coronal] and (redundantly) [−anterior]), there appear to be no attested cases of this type of a neutralization that are not assimilatory. Could a contrast among fricatives /f s x/ be neutralized to [s]? Again, this type of neutralization appears not to be attested.

6 Coronals and syllable structure

A number of linguists have observed that there are languages in which coronal obstruents have a privileged position in syllable structure in the sense that they can occur in contexts where labial and dorsal obstruents cannot. Examples like the ones to be discussed below can be thought of as a particular type of neutralization to coronal, although they do not involve active neutralizations like the one discussed above for Pawnee. In this section I discuss a familiar case study from German and English syllable structure illustrating the special status of coronals.

Many writers have made the following observation for German and English: if a syllable ends in a sequence of two obstruents and if the first one is a stop, then the second one must be a coronal obstruent (see Hall 2002 and references representation as in (22a). Thus, on this view, all words are fully syllabified, as in (22b). In order to explain the apparent SSG violations in (21), Hall restates the SSG as follows: "A sonorant consonant in the syllable coda may only be preceded by segments of higher sonority." Given this constraint (which Hall refers to as SON), the final sequences in (21) have a well-formed sonority profile because SON does not refer to sequences of adjacent obstruents.

One way of capturing the fact that the underlined sounds in (21) are coronal is to adopt the following context-sensitive markedness constraints (modified slightly from Hall 2002: 47):

(23) *Context-sensitive markedness constraints*

a. *TP/TK: $\begin{bmatrix} -\text{son} \\ -\text{cont} \\ \text{CORONAL} \end{bmatrix} \begin{bmatrix} -\text{son} \\ \text{PERIPHERAL} \end{bmatrix}]_\sigma$

b. *PK/KP: *[PERIPHERAL] [PERIPHERAL]]$_\sigma$

The constraint *TP/TK in (23a) is necessary to rule out sequences like [atk] and [atp], and the constraint *PK/KP in (23b) likewise rules out sequences like [apk] and [akp]. Note that (23a) and (23b) cannot be combined into a single constraint (i.e. *[−son, −cont] [PERIPHERAL]]$_\sigma$), because the first segment referred to in (23a) is a stop only (cf. [sk] clusters, e.g. *ask*), but the two segments referred to in (23b) can be any peripheral segment.

The constraints in (23) are advantageous because they are also able to account for the fact that sequences like [tk tp] are repaired in other languages by processes like epenthesis, deletion, or metathesis. A typical example is discussed by Kenstowicz (1994: 300), who shows that in Lebanese Arabic word-final sequences like /tk db/ are split up by vowel epenthesis (see (24b)), but the mirror image sequences /kt bd/ are not (see (24a)). Lebanese Arabic also provides evidence that sequences of two peripheral obstruents are marked as well, since they are separated by an epenthetic vowel (see (24c)).

(24)	a.	/sakt/	[sakt]	'act'
		/ʕabd/	[ʕabd]	'slave'
	b.	/fatk/	[fatik]	'eradicating'
		/nadb/	[nadib]	'wailing'
	c.	/ʕakf/	[ʕakif]	'leaning to the letter'
		/rikb/	[rikib]	'riding'
		/ħabk/	[ħabik]	'weaving'

Consider now the data in (25) from German and English, which illustrate a slightly different generalization than the ones in (21): after VXC, where X = a short vowel or a consonant, i.e. after a short vowel plus two consonants, a long vowel plus one consonant or a diphthong plus one consonant, the only type of consonant that can follow is a coronal obstruent. In (25a) the coronal and the preceding consonant are tautomorphemic and in (25b) they are heteromorphemic. Generalizations similar to the ones in final position also hold in initial position as well, but I concentrate below only on data like the ones in (25). As in (21), the word-edge sounds in (25) subsume anterior coronals and non-anterior coronals.

In at least three languages (Guere, Fula, and Mau), vowel harmony has been shown to apply across coronals but not across labials and dorsals (or non-anterior coronals), thereby implying that coronals are less marked than the latter two major places (Paradis and Prunet 1989). Paradis and Prunet argue that the aforementioned languages require coronal underspecification: only coronals lack [Place] (and hence [Coronal]), but labials and dorsals are specified for [Place] and their dependent articulator features [Dorsal]/[Labial]. Given representations like the ones described, only coronals should allow vowel harmony to apply across them, because vowel harmony is argued to spread [Place] (and the dependent feature [Dorsal]). Vowel harmony is blocked when a dorsal or a labial (or non-anterior coronal) intervenes, because these segments all have [Place], which inhibits spreading. A potential problem for this representational approach would be a language in which labials or dorsals but not coronals are transparent to spreading. Paradis and Prunet (1991c, 1994) discuss apparent examples of languages with transparent dorsals (e.g. Choctaw, Chinook, Ennemor) and re-analyze the data in ways that are compatible with coronal underspecification. A question that clearly needs to remain open is whether or not the same strategy holds for all languages with transparent dorsals. A second question is whether or not there are languages in which labials are transparent, but not coronals or dorsals. Finally, it remains to be seen how an OT analysis might account for languages with transparent coronals.

8 Conclusion

The present chapter has examined a number of theoretical and empirical issues with respect to the special status of coronals. Emphasis was placed on the behavior of coronals from the point of view of structural markedness, in particular epenthesis, assimilation, neutralization, syllable structure, and transparency. In (2) I posited five general research questions, which I repeat in (26) for convenience:

(26) a. Markedness: Are coronals endowed with special properties that differentiate them from the other major places and, if so, what are they?
  b. Universality: Are the properties characterizing coronals (or other places of articulation) universal or language-specific?
  c. Representations: To what extent do the properties of coronals (or other places of articulation) require unique phonological representations?
  d. Manner: Why do unmarked coronals belong to certain manner categories and not to others?
  e. Coronal subplaces: Why do unmarked coronals belong to certain subplaces and not to others?

Concerning point (26a), the examples discussed in the preceding sections have demonstrated that there are undeniably languages in which coronals have a special status, e.g. languages like Catalan, in which only /n/ and not other nasals undergo place assimilation. However, one cannot conclude that coronals are unique in all languages (i.e. (26b)). I draw this conclusion in light of some of the examples discussed above. For example, in Sri Lankan Portuguese Creole labials are unmarked with respect to place of assimilation. It also appears to be the case

13 The Stricture Features

Ellen M. Kaisse

The late 1980s and early 1990s saw the publication of a large number of articles treating features and feature geometry, following on the highly influential article by Clements (1985) that had argued for the organization of features into a hierarchically arranged tree. But if one takes a look at the features whose position and organization were so often debated, they fall into only a few groups: first, the vocalic features typically involved in vowel harmony – features of height, backness, rounding, or tongue root position; second, laryngeal features such as glottalization, voicing, and aspiration; and third, the place features labial, dorsal, and coronal and their dependents, especially those of coronal (see CHAPTER 27: THE ORGANIZATION OF FEATURES; CHAPTER 21: VOWEL HEIGHT; CHAPTER 19: VOWEL PLACE; CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION; CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION; CHAPTER 12: CORONALS). Such a concentration can be traced back in part to the material covered in Clements's seminal article. But it also reflects those features that seem most often and most unequivocally involved in assimilation, or, to follow McCarthy's (1988) diagnostics, the trio of assimilation, dissimilation, and reduction or deletion. There was also notable interest in the position and behavior of [lateral] (CHAPTER 81: LOCAL ASSIMILATION; CHAPTER 60: DISSIMILATION; CHAPTER 79: REDUCTION; CHAPTER 31: LATERAL CONSONANTS). But most of the traditional manner and major class features – [continuant], [consonantal], [sonorant] – received short shrift.[1] These three, along with the less widely adopted feature [approximant], are sometimes called stricture features (Kenstowicz 1994: 480ff.), because they specify how the articulators are brought together but are not themselves inherently associated with any one articulator. They are "articulator-free," in the terminology of Clements and

[1] Chomsky and Halle (1968: 299–300) distinguish five kinds of features: major class, cavity, manner of articulation, source, and prosodic. The major class features are [sonorant] and [consonantal] (and the quickly eliminated [vocalic]). The manner features are [continuant], [delayed release], [tense], and several features related to suction and ejection. Major class features, they explain, mainly have to do with closing and opening and with pressure buildup and release. While [continuant] was not categorized as a major class feature by Chomsky and Halle, it is the one manner feature that strongly relates to how closely the articulators are approximated. Padgett (1991) and Kenstowicz (1994), amongst others, thus group [consonantal], [sonorant], and [continuant] together as stricture features.

Hume (1995) and must be associated with some articulator to be fully interpreted. The major class features [consonantal] and [sonorant] do not participate often, if at all, in the archetypical phonological processes of spreading and delinking, and they do not form nice bundles of features that beg to be organized under a node of the feature geometry. The other major class features of Chomsky and Halle (1968), [syllabic] and [vocalic] (the latter already tentatively withdrawn in a footnote in Chomsky and Halle 1968: 302), have over the decades been subsumed in representations, with [syllabic] coming to mean head or nucleus of the syllable and not being specified as a distinctive feature of any segment.[2] As early as 1974, Hankamer and Aissen suggested that the major class features might be superfluous, and in a more elaborated proposal, Selkirk (1984) proposed doing away with both [consonantal] and [sonorant] by replacing them with a multivalued sonorancy feature (see also CHAPTER 8: SONORANTS). Nonetheless, the consensus view seems to be that these features are still needed. Their necessity is taken for granted in many significant works on feature theory of the last decade or two, such as Clements (2003), to mention one representative example. As an independent issue, the proper definition of [continuant] has always been problematic: it has not been obvious exactly what natural classes should be delineated by this feature, nor how it should be placed on the feature tree (see also CHAPTER 28: THE REPRESENTATION OF FRICATIVES).

In this chapter I will review some of the proposals to keep, redefine, or locate on the feature tree the problematic stricture features [consonantal], [sonorant], and [continuant], or to do away with them altogether. In the spirit of the *Companion*, we will spend most of the time looking at the phonological and phonetic phenomena upon which these various proposals rested. The chapter is organized as follows. We begin with a discussion of the arguments for and against the existence of [consonantal]. In the second section, we turn a similar spotlight upon [sonorant]. The third section considers arguments that bear on the need for both features, hinging on the sonority sequencing principle, weight, and lenition. The final section treats the definition and feature geometry of [continuant].

1 The major class feature [consonantal]

Chomsky and Halle (1968: 301–302) distinguished a group of binary "major class features" that segregate segments into the large groups of consonants and vowels, sonorants and obstruents, glides and liquids, and syllabic and non-syllabic sounds. The binary feature [consonantal] makes the most obvious cut among segments, capturing the distinction between vowels and consonants.

> Consonantal sounds are produced with a radical obstruction in the midsagittal region of the vocal tract; nonconsonantal sounds are produced without such an obstruction. (Chomsky and Halle 1968: 302)

[2] Padgett (2008) argues that [vocalic] should be reinstated to describe the difference between vowels, which have no frication, and the type of glide that shows some frication. For Padgett, both [consonantal] and [vocalic] should be employed so as to capture a fine hierarchy of degree of stricture.

(1) a. *Cypriot Greek consonantalization*
The glide [j] becomes a voiceless palatal stop [c] after a consonant.
b. *Bergüner Romansh consonantalization*
The glides [j] and [w] are realized as the voiced stop [g] before a consonant.
c. *Uyghur vowel consonantalization*
Devoiced high vowels become syllabic fricatives before a consonant. /i/ is realized as [ʃ̩], /u/ as [ɸ̩ʷ] and /y/ as [ɸ̩ᶣ].
d. *Ahtna vocalization*
Certain consonants become vowels before a consonant. /b/ and /χʷ/ are realized as [u], while /ɣ/ and /c/ appear as [i].
e. *Halland Swedish vocalization*
The uvular fricative /ʁ/ is realized as the offglide [ɑ̯] before any consonant.

Kaisse (1996) adds the debuccalization of [s] to [h] in Argentinian Spanish, which only takes place when a coda /s/ is preceded by a vowel or glide. Thus the rule appears to be a rightward spreading of the feature [−consonantal].

Let us consider the first two examples, Modern Cypriot Greek and the Bergüner dialect of Romansh, in a little more detail. These two have mirror-image environments that make it unlikely that alternative analyses will succeed by identifying a specific position in the syllable, be it onset or coda, as the cause for consonantalization. On the other hand, Cypriot also shows the sorts of complications that offer a wedge to alternative analyses that do not use the spread of [consonantal].

Newton (1972a) describes a defining characteristic of all Cypriot dialects: what would appear as the glide [j] in other dialects is realized as a voiceless palatal stop after most consonants or as a voiceless velar stop after [r]. Numerous alternations in Cypriot support this consonantalization as a productive process. (The cognate form in non-consonantalizing dialects is the intermediate form shown to the right of the first arrow in the examples below.)

(2)	a.	aðerfi	'brother'
		/aðerfi+a/ → aðerfja → aðerfca	'brothers'
	b.	vari	'heavy'
		/vari+ume/ → varjume → varkume	'I am bored'
	c.	mati	'eye'
		/mati+a/ → matja → matca *or* maθca	'eyes'

This last example shows the continuancy adjustment that complicates the phenomenon, and which Kaisse regards as orthogonal to it. In virtually all dialects of Modern Greek (Newton 1972b), sequences of obstruents are adjusted so that the first is a fricative and the second a stop (see also CHAPTER 28: THE REPRESENTATION OF FRICATIVES). Though spread of [consonantal] seems the most obvious approach to the Cypriot alternation, J. Harris (1996) points out that the case is not straightforward, since we must devoice and obstruentize the glide, not merely turn it into a consonant.

Bergüner Romansh (Kamprath 1986) displays a process of "glide hardening" that is practically the mirror image of the Cypriot case: glides become velar stops before any consonant. Unlike Greek, Romansh has a [w] as well as a [j]. Both glides become [g], which may then devoice before voiceless consonants.

(3) a. kreja /krej+a/ 'believes'
krekr̩ /krej+r/ 'to believe'
b. /skrejver/ → skregver̥ 'to write'
c. /lavowra/ → lavogra 'works'

Note that both for Cypriot and Romansh, there is no place, continuancy or sonorancy assimilation. Thus the most likely first analysis is that this is a simple spread of the feature [consonantal], which is indeed how Kamprath formalizes the rule.

Since onsets tend to favor strengthening of consonants (CHAPTER 55: ONSETS), the Romansh case is useful in showing that position in onset is not a necessary condition for consonantalization of glides. The Greek case shows it is not sufficient, either, since a word-initial or post-vocalic glide does not strengthen, lacking as it does a preceding consonant.

(4) jerakos 'falcon'
lojazo 'pay attention to'

Cho and Inkelas (1993) attempt to re-analyze Cypriot and Romansh without [consonantal] spreading, and object that all the examples cited by Kaisse must refer to structural information in addition to features. This seems a peculiar objection, as many voicing and place assimilations, for example, affect only segments in coda position. Moreover, it is not true of all Kaisse's examples: Ahtna and Uyghur involve only features, not position in the syllable. And we have just seen that the Cypriot Greek case involves segments in the onset, while its mirror image in Romansh involves those in the coda. Nonetheless, with so few examples in the literature, there is indeed a danger that they can all be accounted for either by referring to syllabic position without [consonantal] or by replacing [consonantal] with some other active feature, and allowing consonantality to come along as a side-effect. Cho and Inkelas suggest that in Cypriot, consonantalization is a side-effect of the imposition of the [+cont][–cont] template that Kaisse argues must be imposed on all Modern Greek consonant clusters.

Hume and Odden (1996) take a more ambitious and thoroughgoing approach in attempting to dispose of Kaisse's examples. Their ultimate goal is to remove [consonantal] from the inventory of features altogether, by demonstrating that it is superfluous. They give three types of arguments.[4] First, no segments are distinguished only by the one being [+consonantal] and the other [–consonantal]. Thus, the difference between [w] and [β] is not only one of consonantality but also one of sonority, the difference between [j] and [ʎ] lies in laterality as well as consonantality, and so forth. Second, [consonantal] is never employed crucially to describe a natural class. (The class would be vowels, glides, and possibly

[4] Hume and Odden's line of attack follows from the same sort of reasoning as that given in Harris (1996). He argues that we can motivate the need for a particular distinctive feature in four ways: features code lexical contrasts, define natural classes of segments, determine syllabification, and guarantee phonetic interpretability.

Hume and Odden discuss two classes of phenomena where the class [−consonantal] does seem at first glance to be required. These are nasalization and the calculation of sonority. The first is exemplified by Arabela and several other languages, where nasality spreads to vowels, glides, and laryngeals (CHAPTER 78: NASAL HARMONY). However, Hume and Odden point out that the general hierarchy of segments able to be nasalized parallels the sonority hierarchy (see CHAPTER 49: SONORITY), so that in some languages, liquids are added to the class of nasalizable segments, in others voiced stops, and so forth. We will see in the next section that later research has suggested that the sonority hierarchy may in fact be a derivative notion. Hume and Odden anticipate this line of attack, arguing that the sonority hierarchy need not refer to [consonantal]; it can be unified with the nasalizability scale using the notion of impedance, "the resistance offered by a sound to the flow of air through the vocal tract above the glottis." Since laryngeals have no impedance, they are vowel-like and nasalizable, but they are inadequate syllable peaks, because some impedance is required for a syllable peak.

The remaining cases of consonantal spread offered in Kaisse (1992) are re-analyzed by Hume and Odden as fortitions involving other features: continuancy in the case of Cypriot Greek, voicing in the case of Uyghur, and perhaps some combination of structural position and continuancy dissimilation for Romansh.

J. Harris (1996) also proposes to eliminate the major class features and takes on a re-analysis of the Cypriot case as his major example. His argument is that the Cypriot process specifically targets a glide in the onset position of a coda-onset cluster. I do not think this particular solution will work, since the rule applies word-initially:

(7)	a.	/θios/ → θjos → θcos	'uncle'
	b.	pi	'drink'
		/na pi+o/ → na pjo → na pco *or* na fco	'that I drink'

Greek is particularly coda-averse and accepting of complex onsets, as judged by the intuitive syllabifications of native speakers and the wide variety of complex onsets *vs.* the very strict restrictions on coda consonants. Consequently, native speakers do not judge that a word-initial consonant like the [f] in [na.fco] is syllabified into the coda of a preceding vowel-final word (Joseph and Philippaki-Warburton 1987: 241ff.).

In conclusion, the cases of consonantal spread advanced by Kaisse (1992) constitute a reasonable body of data that suggest that [consonantal] may be an active feature that is useful in describing cases of consonantalization of glides and vowels and vocalization of consonants. But there are not enough cases that are immune from re-analysis to allow phonologists to rest comfortably in the knowledge that the feature is required in our theory. The rest of this section considers other evidence for the superfluity or redundancy of [consonantal].

Clements and Hume (1995) and Levi (2004) contain excellent demonstrations that [consonantal] in itself is inadequate to account for phenomena involving the transparency of consonants to vowel harmony and the distinction between underlying vowels and true underlying glides; what we need is a feature-geometric distinction between vowels, which have a vocalic place node, and consonants, which do not (unless they happen to have a secondary vowel-like feature such as palatalization). Levi (2004; CHAPTER 15: GLIDES) shows that if basic are best described using a multivalued [sonorant] feature, dispensing with the other major class features altogether.

Parker (2002) takes on the frequent complaint that [sonorant] has vague or conflicting phonetic definitions; he shows that the traditional feature (for which he ultimately supports a scalar rather than a binary-valued feature) and the traditional sonority hierarchy have regular phonetic correlates, namely intensity and, to a lesser extent, intra-oral pressure.

Sonority certainly does seem to be an important concept in speech perception, as one would expect if it is based in loudness. Recall that Stevens and Keyser (1989) pick it out as one of three perceptually salient features that can be expected to be used and enhanced in many segment inventories. This perceptual argument is reinforced from another angle in more recent work by Bates *et al.* (2007), who show that the feature [±sonorant] plays an important role in modeling pronunciation for speech recognition. Whether these perceptually based observations constitute arguments that impinge on the actual universal inventory of phonological features, however, is not entirely obvious. As we have noted already, the gold standard for motivating a phonological feature is its activity in one or more processes of assimilation, dissimilation, or deletion. Even less than [consonantal], [sonorant] does not seem to behave actively in such phonological processes. For this reason, McCarthy's (1988) survey article likewise locates it as an annotation on the root node. Furthermore, [sonorant] is subject to the same critique as [consonantal] when it comes to its use in defining the position of a segment in the sonority hierarchy and in sonority sequencing. We shall see in the next section that many phoneticians have argued that universals of segment ordering are derivative from perceptual factors. If that argument is accepted, the feature [sonorant] may be superfluous.

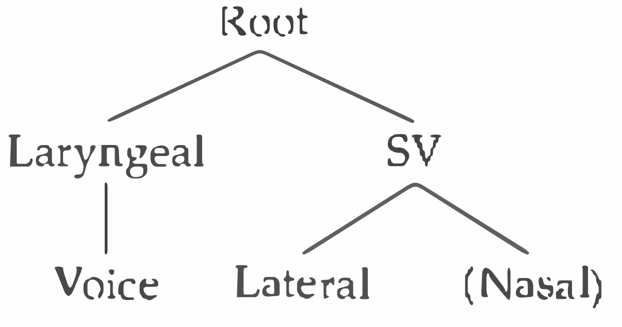
I am aware of only two direct defenses of [sonorant] as an active feature that participates in an assimilation process. Milliken (1988) suggests that flapping in North American English (see CHAPTER 113: FLAPPING IN AMERICAN ENGLISH) can be seen as the spread of [+sonorant]. In this process, a coronal stop becomes a voiced flap, roughly in inter-sonorant position. Olson and Schulz (2002) bring forward a much less familiar case, which thus bears presenting in some detail: the alternation of the 3rd person singular suffix /-ɲa/ in the Nilo-Saharan language Bilaala. This suffix appears as [ɲa] after nasals, liquids, glides, and vowels. That is, it is a nasal sonorant when adjacent to a sonorant. However, it appears as an obstruent following an obstruent, but maintains its place of articulation, ruling out spread of the entire root node. As the data below show, the process is not simply spread of [−sonorant]; the suffix also takes on the voicing and continuancy of the preceding obstruent, suggesting possible if unwieldy lines of re-analysis for someone attempting to dispose of this case.

(9)	a.	mon-ɲa	'his child'
		ɓɛr-ɲa	'his slave'
		kuhul-ɲa	'his hip'
		kaw-ɲa	'its length'
		ʧe-ɲa	'his mother'
	b.	got-ʧa	'his place'
		bob-ʤa	'his father'
		gurus-ʃa	'his money'

Olson and Schulz have certainly found a very relevant case for the question of whether [sonorant] is an active feature. Still, this process is a morphologically circumscribed one in Bilaala. It applies only to this pronoun; the nasal-initial 1st person singular, /-ma/, is invariant. One would like more robust cases on which to base a decision. As Olson and Schulz themselves say, until more cases are found, the question of the cross-linguistic phonological activity of [sonorant] remains unresolved. They offer and argue against a less elegant solution, where [−nasal] rather than [−sonorant] spreads. Such a solution is hardly ideal, requiring that nasal be a binary, not a privative feature, but it would allow a way out of the current case.

Rice (1993) attacks the traditional definition of [sonorant] from another direction. Summarizing and expanding work by Piggott (1990) and by Rice and Avery (1989), she proposes eliminating [sonorant] as an annotation on the root note and replacing it with a feature [spontaneous (or sonorant) voice], with dependents [lateral] and (predictable) [nasal].

(10)



Rice's proposal is based on the fact that even voiced obstruents in some systems, such as that of Southern Barasano (Piggott 1992) and Rotokas, can act like sonorants, take their voicing from sonorants or alternate with sonorants. These obstruents possess a spontaneous voicing node. In such languages, the basic division between consonants seems to fall not between the class of obstruents and the class of sonorants but rather between voiceless obstruents and everything else. Rice's proposal also encompasses the well-known fact that in many languages the voicing of obstruents acts very differently phonologically from that of sonorants. For instance, in Japanese, voiced obstruents block the voicing process known as Rendaku, but voiced sonorants do not block voicing. Rice shows that the familiar way of explaining such facts – namely that sonorant voicing only becomes available post-lexically – is not empirically adequate, motivating her alternative proposal.

3 The features [sonorant] and [consonantal] in sonority sequencing, weight, and lenition

Another strong motivation for retaining the features [consonantal] and [sonorant] may be that they are critical in describing sonority sequencing, the general tendency of syllables to have the most obstructed, consonant-like segments at the margins (the onset and the coda) and to progress to more vowel-like segments at the peak or nucleus. Clements (1990: 292) adds up the major class features [consonantal], [sonorant], and the less generally recognized [approximant] to give a sonority value for non-syllabic segments, resulting in the widely known scale.

of segments maximizes the robustness of each segment's cues. The phonotactics of human language are arranged to maximize redundancy of cues, strong auditory impact of each cue and resistance of cues to masking by surrounding noise. Since some segments contain internal cues that do not depend on their flanking segments, they are expected to figure in apparent exceptions to segment sequencing generalizations. Noisy (strident) fricatives, for instance, can be recognized without a following vowel or sonorant consonant because the noise of frication allows them to be uniquely identified. Thus /s/ figures repeatedly in clusters where sonority plateaus or is reversed (CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS). Similarly, nasal consonants contain nasal poles and zeros that allow their manner of articulation, though not their place, to be reconstructed without a flanking vowel. Thus, sonority-reversing onset clusters like [nd] are frequently found in the world's languages, and not all can be explained away as prenasalized stops.

Stops, on the other hand, do not contain internal cues – their formant transitions and noise bursts are best perceived if a vowel or sonorant follows. Therefore, strings of stops not flanked by vowels or liquids are hard to recover (CHAPTER 46: POSITIONAL EFFECTS IN CONSONANT CLUSTERS). The ideal encoding for all segments results from the alternation of vowels and consonants. This is not only for the sake of the consonants. Though cues to vowels are the formants of the vowel itself, in natural speech, where a steady state is frequently not achieved, the formant transitions from a preceding consonant can add valuable information. CV is an optimal syllable not only because the V maximizes the cues to the C's identity but also because the C maximizes the cues for the V.

Clements (1990) encodes the naturalness of CVCV sequences with his construct of the "demisyllable": a sequence of adjacent tautosyllabic consonants + vowel or of adjacent tautosyllabic vowel + consonants (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE). When conjoined with his Dispersion Principle, which favors maximal changes in sonority between adjacent segments in a syllable, the alternation of consonants and vowels becomes optimal. But without perceptual underpinning (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY), we are still short of an explanation of why demisyllables with large sonority jumps are preferable.

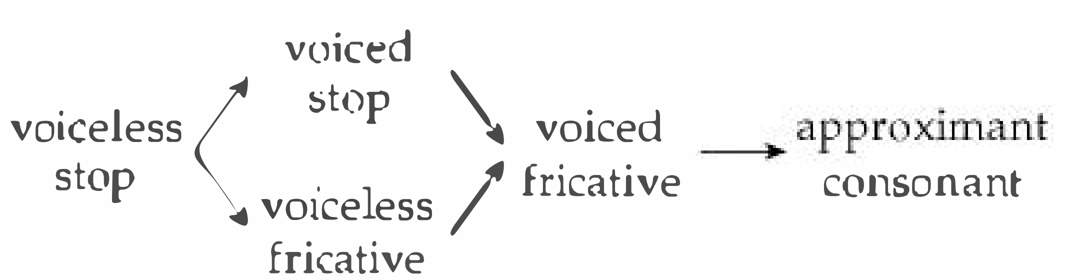
A cue-based theory can also offer an explanation for the preference which languages demonstrate for onsets over codas, for obstruent onsets over sonorant onsets, and for sonorant codas over obstruent codas, tendencies that do not fall out from the sonority sequencing principle without additional stipulations. Clements (1990) stipulates that steep dispersion in the CV demisyllable and shallow dispersion in the VC demisyllable are favored. And indeed this observation was a significant step forward. But it need not be a stipulation. Wright (2004) explains that the response pattern of the auditory nerves favors CV sequences over VC because of the perceptual boost that occurs at the beginning of a stimulus. An onset consonant, especially an obstruent, receives a boost but a coda consonant tends to be masked because the nerve fibers are already saturated by the sound of the vowel. (The nerve fibers recover quickly, in a matter of a few milliseconds, so that even the brief silence that occurs during a stop closure allows for the whole boost phenomenon to re-set; see Moore (1989). Therefore, even the burst and transitions of a medial C in a CVCV sequence get a boost, due to the silence created by the closure of that consonant.) Nasals are not particularly boosted in onset position, because the nerve fibers are saturated before the nasal ends, so nasals are less favored in onsets than obstruents are, yielding an apparent favoring of steep sonority dispersion in CV onsets and a shallow one in VC codas. Codas should be sonorous, because only sonorant consonants and fricatives, but not stops, can encode their own cues without needing release into a vowel. Cue-based sequencing explanations thus also cover the "Syllable Contact Law" (Murray and Vennemann 1983), which prefers a large fall in sonority between the coda of one syllable and the onset of an adjacent syllable. Even the tendency of nasals to lose their place of articulation in codas is encompassed in the cue-based view, since nasals have good voicing and manner cues internal to their realization, but not good place cues. The apparent preference for gradual sonority slopes from nucleus to coda is thus a by-product of the poorness of the internal cues of stops.

To summarize our discussion of the relation between the major class features and phonotactic constraints, the current view of many phonologists is that [consonantal] and [sonorant] are needed to describe sonority sequencing. The sonority feature may be binary (Clements 1990; Zec 2007) or multivalued (Selkirk 1984; Parker 2002). But there are also strong arguments that sonority sequencing is epiphenomenal, and that cue robustness covers the empirical ground better (Wright 2004). The last view, if accepted, undercuts one of the major arguments that we need [sonorant] or [consonantal] as a distinctive feature.

One might also think that the feature [sonorant] would be required to define syllable weight in languages where this concept is needed to describe the distribution of stress or contour tone or to define the minimal word. Zec (1995), for instance, makes major strides in demonstrating how something like sonority can operate in defining what constitutes a heavy syllable in a given language. However, Gordon (2002, 2004) argues that weight is a non-uniform, phonetically driven concept, not best captured with a feature. The definition of a heavy syllable can differ within even a single language, with the stress system, for instance, treating one kind of syllable as heavy while the tone system employs a different definition. Gordon finds that the energy within the syllable rhyme correlates with the tendency of a stress system to treat it as heavy, while the portion of the rhyme characterized by sonorant energy best determines whether it can bear contour tone. (For more on this discussion see CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE and CHAPTER 57: QUANTITY-SENSITIVITY.) So once again, the issue of whether [sonorant] is required remains without complete consensus.

Finally, the features [sonorant] and [consonantal], along with [continuant] and [voice], have been repeatedly argued to participate in weakening or lenition processes, especially those occurring intervocalically (CHAPTER 66: LENITION). The typical lenition pattern is summarized by Lass and Anderson (1975) as follows:

(13)



For instance, the pre-Old English phoneme /g/ weakens to /ɣ/ in Old English and to /w/ in Middle English before being lost altogether in late Middle English. While such developments are both common and intuitively natural, they are difficult to describe in a unified or coherent fashion using the binary distinctive features. Voicing and continuancy are kinds of manner features, while sonorancy and consonantality are major class features. Dependency phonologists (see for instance van der Hulst and Ewen 1991) have proposed that what is going on is the gradual addition of a |V| component, a sonorancy feature that is more present in voiced sounds than voiceless ones, more in fricatives than stops, more in sonorants than obstruents, and more in vowels and approximant consonants than in non-approximants. A similar solution has been proposed within Government Phonology by J. Harris (1990), which sees lenition as a loss of the elements representing occlusion and noise.[7]

4 The manner feature [continuant]

Three major issues dog the discussions of [continuant] in the literature (see also CHAPTER 16: AFFRICATES; CHAPTER 28: THE REPRESENTATION OF FRICATIVES). First, there is debate on the proper definition of the feature and thus about its values for laterals. Second, there is the question of what kinds of processes [continuant] participates in and what these tell us about where is it located on the feature tree. In particular, is it a direct and independent daughter of the root node, or is it somehow implicated in a daughter relation with Place? Or is it, perhaps, the organizing node of the tree, as proposed by Steriade (1993)? The last issue deals with the structure of affricates: are they a sequence of [−continuant] and [+continuant] features characterizing a single root (Sagey 1986), an unsequenced complex containing both values (Hualde 1987; Lombardi 1990), or basically stops whose release is fricated rather than strictly open (Steriade 1993)?

The definition of [continuant] is intimately bound up with an empirical question: do lateral consonants form a natural class with stops, which are [−continuant], or with fricatives and other [+continuant] sonorants such as rhotics? (See also CHAPTER 30: THE REPRESENTATION OF RHOTICS; CHAPTER 31: LATERAL CONSONANTS.) Chomsky and Halle (1968: 317) adopt the following definition:

(14) In the production of continuant sounds, the primary constriction in the vowel [sic] tract is not narrowed to the point where the air flow past the constriction is blocked; in stops the air flow through the mouth is effectively blocked.

Since laterals have airflow along one or both sides of the tongue, they are [+continuant] by this definition, and we will want to adopt it if it can be demonstrated that the great majority of phenomena bearing on the question categorize laterals with fricatives rather than with stops.

Halle and Clements (1983: 7), on the other hand, consider laterals to be noncontinuants, and therefore modify the definition.

(15) Continuants are formed with a vocal tract configuration allowing the airstream to flow through the midsagittal region of the oral tract; stops are produced with a sustained occlusion in this region. (Vowels, glides, *r*-sounds, fricatives *vs.* nasal and oral stops, laterals.)

7 Within Optimality Theory, Kirchner (2004) proposes that lenition is not a phonological process of spreading that refers to distinctive features at all. Rather it is achieved through the high ranking of a constraint LAZY, which penalizes biomechanical effort and works on a highly detailed phonetic scale of such effort.

as well as obvious strengths. In a survey of some 6,000 languages, it is not practical to investigate each case in anything approaching the detail I was able to lavish on twelve cases. But sometimes the devil is in the details.

In Harris and Kaisse (1999: 142) we analyzed this process as spread of the feature [−continuant]:

(17) X [COR, −son, +voice]
[−cont]

Navarro Tomás (1965) describes virtually the same process for Castilian Spanish. Since this example manifestly involves a change from [+continuant] to [−continuant], Kaisse (2000) considered it to be the best kind of evidence for the continuancy of /l/. Mielke's Finnish case is not so obviously related to continuancy. It could, for instance, have to do with the unmarked status of /t/. Nonetheless, it seems unlikely that such a stance could successfully dispose of all 30 of Mielke's examples. But since Finnish is the only [+continuant] case he reports in any detail, the matter cannot yet be fully resolved.

Mielke also discusses a different and intriguing kind of ambiguous behavior on the part of laterals. As has been much discussed, in Catalan, Spanish, and Basque, the lateral acts as [+continuant] before consonants at some places of articulation and [−continuant] before other places. In a related but distinct kind of case, some speakers of Hungarian add /l/ to the class of palatalizable non-continuants while others do not (Abondolo 1988: 64, cited in Mielke 2005). Again, let us consider the Spanish version of this phenomenon, as it is both well-known and frustratingly complicated. The process in question distributes the voiced obstruents, which come in stop and fricative variants. (J. W. Harris 1985; Kenstowicz 1994). But the case is really too vexed to draw any firm conclusion from. The judgments for these alternations are unstable – the same speaker can produce the stop and the fricative variant in the same environment – there are variations amongst idiolects and dialects that are not understood, and the theoretical bases for some of the analyses that have been proposed are shaky. Almost every analysis of the phenomenon one could think of has been vigorously defended by an excellent phonologist, and no consensus has emerged. The process works as follows. Spanish has no underlying contrast between voiced stops and voiced fricatives. Descriptions generally simplify the distribution as follows: after vowels, fricatives, and *r*, the voiced fricative allophones [β ð ɣ] appear. The voiced stops appear initially, after a pause, and after stops and nasals.

(18)	tu βeso	'your kiss'	besos	'kisses'
	los βesos	'the kisses'	um beso	'a kiss'
	por βesos	'through kisses'	futbol	'football'

The behavior of *l* as a trigger is more complex: following the lateral, we find the stop [d] but the fricatives [β ɣ].

(19)	el βeso	'the kiss'
	el dinero	'the money'
	el ɣato	'the cat'

Exactly what one is to make of even these simplified facts has been the subject of some debate, well summarized in Kenstowicz (1994: 487–489) Apparently, the process involves the spread of [continuant]. If this is so, is the lateral showing its true colors in contact with the homorganic obstruent [d] or with the non-homorganic [β ɣ]? We saw in the affrication process described earlier that some speakers may require homorganicity in order for a consonant to spread its continuancy to a palatal fricative. This suggests that it is in clusters with coronals that /l/ shows its continuancy – it is [-continuant] – and that fricatives are the underlying members of the voiced obstruent phoneme, emerging unscathed after *l* when not homorganic with it. On the other hand, the mixed environments in which the stop variants occur (after pause as well as after nasals and stops) suggests that the stops are underlying and the voiced fricatives are derived by spread of [+continuant]. Following that line of reasoning would suggest that /l/ is [+continuant].

But the facts are actually even more complicated. The rule is highly variable, and even utterance-initial fricatives are occasionally produced. I have had the same speaker produce a fricative and a stop in the same context, one after the other, in elicitation. Technically, the proposal of spread of [+continuant] is hard to execute in theories where non-contrastive features are not present in the lexical phonology, because vowels would have to be represented as [+continuant] at the point in the derivation where spreading occurs, while voiced obstruents were still [0 continuant] at that point (so as to be able to take on the continuancy of the preceding segment). The upshot is that we would do better to base our decision on the continuancy of laterals on less daunting cases. Mielke in fact uses this case to argue that even within a single process of a single language, the continuancy of a lateral may differ. But one stands on shaky ground at this point in drawing conclusions from this phenomenon. Similar comments can be made about two other Iberian languages, Catalan (Mascaró 1984, 1991) and Basque (Hualde 1991), whose continuancy alternations are remarkably similar to those of Spanish, probably due to areal influences. (See also CHAPTER 28: THE REPRESENTATION OF FRICATIVES.)

An appealing recent proposal is that features are emergent, rather than innate (Pulleyblank 2003; Mielke 2004, 2005, 2008). Speakers are not born with a definition for continuant and a categorization of segments according to that feature (see also CHAPTER 17: DISTINCTIVE FEATURES). Rather, they may group sounds together as a phonological category because those sounds have acoustic and articulatory similarities or because in the language they are learning, they act as a natural class. As Mielke puts it, stops and fricatives are archetypically and unmistakably [–continuant] *vs.* [+continuant]. So we almost always find them patterning as such in phonological processes, whatever language they occur in. But laterals and nasals have ambiguous cues and may be categorized as [+continuant] in one language and as [–continuant] in another. Even more iconoclastically, perhaps, Mielke's survey of 571 languages found 6,077 phonologically active classes of sounds, only 71 percent of which were describable by any set of distinctive features at all.

We turn now to the question of where the feature [continuant] should be located in the feature geometry. Kenstowicz (1994) contains an excellent summary of the issues. As mentioned at the beginning of this chapter, there are comparatively few phonological processes which make use of the feature [continuant], so while the need to employ it to differentiate contrasting segments has not been challenged, On the other hand, a rule like Zoque post-nasal voicing, which is looking at the left edge of the affricate, would treat it as a [−continuant] and class it with the stops, which voice after nasals, rather than with the fricatives, which do not:

(21)	min-pa	→	minba	'he comes'
	pʌn-ʧʌki	→	pʌn-ʤʌki	'figure of a man'
	winsaʔu	→	winsaʔu	'he received'

Unfortunately, it turns out that there are also phonological processes that class affricates and stops together even if they are looking at the wrong edge of the affricate, such as a deletion rule in Basque (Hualde 1987) that deletes a stop before another stop but turns an affricate to a fricative in the same environment, as it were deleting the [−continuant] portion of the affricate:

(22)	bat paratu	→	ba paratu	'put one'
	hots bat	→	hos bat	'a cold'

Kenstowicz (1994: 499–503) contains an excellent summary of the various moves theoreticians made after Hualde's demonstration that affricates were not simply contour segments with the [−continuant] segment ordered first. The most comprehensive solution yet proposed is that of Steriade (1993). As mentioned above, Steriade treats affricates as a species of stop whose release feature has the same degree of stricture as a fricative's. Thus affricates are generally expected to pattern with stops, as in the Basque and Zoque cases. However, the adjacent fricative releases that would result in English if the [s] or [z] allomorph was employed after an affricate prevent affricates from acting with the stops in this case.

To summarize this section, a number of proposals for the proper position of [continuant] in the feature geometry have been proposed, many with positive empirical consequences. However, no consensus has been reached which would allow us to say that one of them has been the most widely adopted by the phonological community. On a similar note, the proper extension of the feature to laterals remains troubled and may be a reflection of the emergent nature of features, which have no universal or innate definition. Finally, the behavior of affricates is not well explained by regarding them as segments with ordered minus and plus [continuant] values (see CHAPTER 16: AFFRICATES).

14 Autosegments

William R. Leben

1 Tonal autosegments

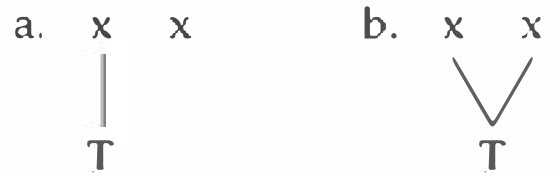
Autosegments are the central unit of representation in what generativists came to call non-linear phonology, an area described in earlier linguistic models under rubrics such as suprasegmentals (Trager and Bloch 1941), simultaneous components (Harris 1944), and prosodic analysis (Firth 1948). At the time autosegments were introduced by Goldsmith (1976), phonological and phonetic representations in the standard model of generative phonology were challenged for lack of adequate ways to express traditional prosodic features with the strictly segmental framework of Chomsky and Halle (1968; *SPE*). Even stress – widely regarded outside the generative school as a property of syllables – was treated as a feature on vowels in *SPE* (see CHAPTER 40: THE FOOT for more discussion), which in fact had no use for the syllable as a unit of representation, though it did posit a feature [syllabic] on individual segments (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE).

If one of the early reasons for *SPE*'s huge success was the scope of what it promised to describe and explain, the framework's formal precision quickly made it apparent where to look for problems. Thus Woo (1969) hypothesized that contrastive lexical tones were level tones, like High, Mid, and Low, rather than contour (or "dynamic") tones like Rising and Falling, and that tones were expressed as features on vowels or on sonorants following the vowel in the same syllable. Together these two hypotheses made a dramatic prediction: "no dynamic tone can occur on a short vowel distinctively." After re-analyzing a few potential counterexamples to this generalization, she concluded that her prediction was essentially correct. New counterexamples to Woo's prediction arose in Leben (1971). That study provided independent support for Woo's analysis of rising and falling tones as level tone sequences and thus concluded that what must be wrong was Woo's hypothesis that each level component of a contour tone was assigned to its own unique segment.

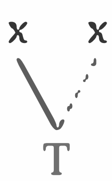
A simple sign that contour tones are decomposed into level tone sequences comes from downstep, the gradual change in register that is triggered in many languages by a Low tone following a High tone (CHAPTER 35: DOWNSTEP). Leben (1971) noted that in a falling tone, the High component is subject to the same downstep effect as any level High tone, while the Low component triggers downstep just like any level Low tone. The same of course is true of the components of rising and rising–falling tones. Interestingly, this is true even in languages like Mende, where falling, rising, and rising–falling can all occur on single monosyllables. The conclusion is that contour tones do indeed behave like sequences of level tones, yet these level tones can be in a many-to-one relationship with a tone-bearing unit (TBU).[1]

Goldsmith (1976) supplies an equally elegant argument for one-to-many relationships between tones and tone-bearing units. The familiar case of tone spreading (Hyman and Schuh 1974), in which a toneless syllable is assigned the tone of an adjacent syllable, creates a one-to-many relationship between a tone and a set of tone-bearing units. Following Goldsmith, rightward tone spreading consists in the change from (1a) to (1b) and is schematized as in (2).

(1)



(2)



One-to-many and many-to-one relations among tones and tone-bearing units provided early motivations for the autosegmental model. Also persuasive were linguistically significant tone melodies going well beyond the individual tone-bearing unit. Drawing on work in some tone languages of West Africa by Welmers (1949), Rowlands (1959), and Edmondson and Bendor-Samuel (1966), Leben (1973) argued that word-length tone melodies motivated a level of representation in which tones were not represented on individual segments but on whole words or morphemes. A striking example is Mende, in which nouns exhibit the tone melodies H, HL, LH, L, and LHL. The fact that these melodies all occur on nouns of one, two, and three syllables argues that at some level the melody is independent of the number of syllables or segments in a word. Further, the non-occurrence of the melody HLH in words of any length strengthens the point. For Mende forms illustrating this point, see CHAPTER 45: THE REPRESENTATION OF TONE.

Hyman (1987) discusses a case "more like Mende than Mende" in a language from a very different group and region, namely Kukuya, analyzed by Paulian (1975). In the example below from Hyman (1987: 313–314), words of varying lengths are grouped by tone melody, given in the left-hand column. Like Mende, Kukuya has words of one, two, and three syllables, and attested tone melodies are combinations of High and Low. As in Mende, the melody HLH is not found. The second column shows the surface mappings schematically. A hyphen separates tones on adjacent syllables, e.g. L-L shows that an L appears

[1] Duanmu (1993, 1999) argues that Woo's original insight can be preserved by positing the mora as the universal TBU. For cases like Kukuya, where contour tones are assigned to syllables lacking phonological length, he suggests that *phonetic* length may suffice. Optimality Theory, with violable constraints, offers other alternatives for rescuing Duanmu's suggestion, even in the face of cases like Kukuya, with more tones than moras to bear them.

on the first and second syllable. Where two tones are not separated by a hyphen, they appear on the same syllable, e.g. LL-H indicates that both moras of the first syllable are L and the second syllable is H.

(3) *Kukuya* (Bantu, Congo)

underlying	*mapped*	*example*	
/L/	L	(ki).ba	'grasshopper killer'
	LL	(ki).baa	'jealousy'
	L-L	(kì).bala	'to build'
	LL-L	(kì).baala	'to cleave'
	L-L-L	(kì).balaga	'to change route'
/H/	H	(mà).ba	'oi. palms'
	HH	(mà).baa	'cheeks'
	H-H	(mà).baga	'show knives'
	HH-H	(lì).baama	'liana'
	H-H-H	(lì).balaga	'fence'
/LH/	LH	(mò).sa	'weaving knot'
	LH	(mò).saa	'seed necklace'
	L-H	(mò).sami	'conversation'
	LL-H	.saabi	'roofing'
	L-L-H	.m^{w}arəgi	'younger brother'
/HL/	HL	(ki).kaa	'to pick'
	HL	(ki).kaa	'to grill'
	H-L	(kì).kara	'paralytic'
	HL-L	(kì).kaara	'to be just right'
	H-L-L	(kì).karaga	'to be entangled'
/LHL/	LHL	(.ndí).bvi	'he falls'
	LHL	(.ndi).kaaj	'he loses weight'
	L-HL	(.ndí).pali	'he goes out'
	LH-L	(.ndí).baami	'he wakes up'
	L-H-L	(.ndí).kaləgi	'he turns around'

2 Compound segments

In another case that antedates and to some extent anticipates autosegments, Anderson (1974, 1976) explicitly questioned the adequacy of *SPE*-type segments in complex cases involving phenomena like nasality, aspiration, and intrusive stop formation. The essential insight was that they functioned as single segments, yet comprised a sequence of articulations like contour tones above. Illustrated below are prenasalized, postnasalized, and "medio-nasalized" stops (see CHAPTER 23: PARTIALLY NASAL SEGMENTS). The last-mentioned are alternants of prenasalized stops occurring between vowels in Kaingáng, a language of Brazil (Wiesemann 1972):

(4)

a. *prenasalized consonant* [^{m}b]	b. *postnasalized consonant* [b^m]	c. *"medio-nasalized" consonant* [^{m}b^m]
C	C	C
[+nas] [−nas]	[−nas] [+nas]	[−nas] [+nas] [−nas]

Drawing on a parallel between the level tone sequences making up rising and falling tones, autosegmental analyses began to represent prenasalized, post-nasalized, and "medio-nasalized" segments like the above as single consonants associated with sequences of autosegments with contrasting values for the feature [nasal].

It is easy to see parallels with other segments that phonology treats as single units even though they consist of sequence articulations, and by the late 1970s this two-tiered approach spread to affricates, which *SPE* had analyzed with the implicit sequence feature [delayed release].

3 The autosegmental formalism

The core of the autosegmental model is a set of multi-tiered linear sequences of feature bundles (segments), each tier linked to others by association lines. The "auto" of *autosegment* designates the relative autonomy or independence of the "segments" on one tier from those on another. Linking between one autosegmental tier and another is carried out by a general convention, the Well-Formedness Condition, supplemented by language-particular rules. Goldsmith's (1976: 48) version of the Well-Formedness Condition linked autosegmental tones to the segmental tier as follows, leaving aside a variety of possible adjustments:

(5) *Well-Formedness Condition* (WFC)[2]

a. All vowels are associated with at least one tone; all tones are associated with at least one vowel.
b. Association lines do not cross.

The WFC interacts with a set of language-specific rules and general operations linking one tier with the other. In the earliest analyses, the first tone of a melody would be assigned by a (possibly language-specific) rule linking a single tone with a single tone-bearing unit). Then, as we can see by inspection, the WFC would guarantee that all remaining tones and TBUs were linked. This elegant solution quickly became messier once it was applied to a variety of languages.

The first complication involved initial tone assignment. Since Williams (1976, circulated in 1971), the unmarked case in tone languages seemed to be that the first tone in a melody was assigned to the first TBU. But Goldsmith's (1977) analysis of English intonation, circulated in 1975, showed that an accented TBU would tend to attract a tone, whether or not the accented TBU or the tone it was to be paired with was leftmost in the string. Haraguchi (1975) established a similar result for lexical accents in Japanese, with additional complications (CHAPTER 120: JAPANESE PITCH ACCENT). The pairing of tones with accents was widely recognized by pre-generative traditions, as shown by the traditional term *pitch accent*, but the generative phonologist's need to account for this pairing in explicit terms led to new investigations of what aspects of tone association were and were not universal (CHAPTER 42: PITCH ACCENT SYSTEMS).

2 As McCarthy (2004) reminds us, (5) was one of the original generativist constraints, expressing a set of requirements to be satisfied rather than specifying an operation (see also Bird and Ladd 1991).

Kahn's (1976) dissertation explored the consequences of expressing the syllable as an autosegmental unit, with segments assigned to syllables by autosegmental association lines. Up to that time, syllable constituency had been represented through the placement of syllable boundaries among a linear string of segments. Kahn argued that the many-to-one associations typical of autosegmental phonology predicted the possibility of the ambisyllabic segment, a single segment simultaneously belonging to two adjacent syllables. This insight led to even more highly structured approaches to the syllable; see §8 and CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE.

Autosegmental association was also enlisted early on to account for phonological length (Leben 1977, 1980; McCarthy 1979; Hayes 1980; Ingria 1980; Clements and Keyser 1983; see also CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH; CHAPTER 37: GEMINATES). The basic idea, associating one length unit with a short segment and two with a long one, was incorporated into moraic theory (Prince 1983; Hyman 1985; McCarthy and Prince 1986; Itô 1989).

By applying autosegmental notions to vowel harmony in Akan, Clements (1977) accounted for some of the defining properties of vowel harmony. These included the one-to-many relationship between a phonological feature and the feature-bearing units of a phonological string and the tendency of such a feature to spread automatically to neighboring segments unspecified for that feature (CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY).

These developments would eventually lead to a theory of feature geometry assigning structure to what had been "bundles" of unordered distinctive features in the *SPE* theory. The structure was a hierarchical arrangement into groups, reflecting ways in which one feature set affects others. In effect, as McCarthy (1988: 89) noted, feature geometry "constitutes a model of the phonologically relevant characteristics of the human vocal tract." We return to feature geometry in §6.

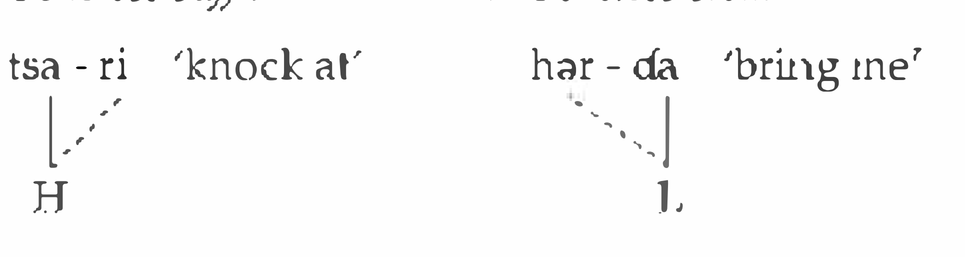
5 Autosegmental linking and spreading

As autosegmental analyses accumulated, conceptions altered about what the Well-Formedness Condition could capture as truly universal. As noted in §3, initial tone linking was found to differ quite a bit from language to language. The same is true of tone spreading, for which Pulleyblank (1986) observed three basic situations: some languages don't allow spreading at all, while others spread tone only to a single adjacent TBU and still others apply spreading to an unbounded sequence of TBUs.

Pulleyblank (1986) shows that in Margi, stems and suffixes can bear either High or Low tones or, as in the examples below, one or the other can be toneless. When either is toneless, it gets its tone from its neighbor, whether on the right or on the left. The dotted line indicates the change:

(7) *Margi* (Chadic, Nigeria)

a. *Toneless suffix* b. *Toneless stem*



Goldsmith's original formulation of the WFC accounted for this spreading automatically, but Pulleyblank (1986) proposed several modifications, observing that languages differ in how they treat tone spreading. Some don't allow spreading at all, while others spread tone only to a single adjacent TBU, and still others apply spreading to an unbounded sequence of TBUs. Pulleyblank (1986: 11) consigns spreading to language-specific rules and is left with (8) and (9) as the assumed universals. In the new formulation the only part of the process that is a constraint rather than an operation is (9).

(8) *Association conventions* (Pulleyblank 1986)

Map a sequence of tones onto a sequence of tone-bearing units,
a. from left to right;
b. in a one-to-one relation.

(9) *Well-Formedness Condition* (Pulleyblank 1986)
Association lines do not cross.

Here is how these two principles apply in Kukuya examples drawn from (3):

(10) *Kukuya*

a. baami 'he wakes up'
LHL

b. kaara 'to be just right'
HL

c. ɪnwarəgi 'younger brother'
LH

d. kaaj 'he loses weight'
LH L

In (10a) left-to-right mapping assigns a tone to each TBU. The fact that two tones are assigned to the bimoraic vowel /aa/ suggests that the mora is the TBU. In (10b) H is assigned to the first mora and L to the second. Kukuya-specific tone spreading needs to extend L to the final vowel. In another language, spreading might not happen, in which case Pulleyblank's approach would place a Low tone on the final vowel by default if no other rule assigned a tone beforehand.

In (10c) the first two tones are assigned to the first two TBUs. As in (10b), the rightmost TBU receives its tone by spreading from the left. However, this predicts the mapping LHH instead of the correct LLH. Another Kukuya-specific rule must be invoked – a very natural one, according to Hyman and Schuh (1974), which moves the transition from L to H in the sequence LHH one TBU to the right, giving LLH. An alternative that has received some attention would be to first associate the tones at the left and right edges of the melody with the TBUs closest to the corresponding edges of the segmental string, with later adjustments for any remaining TBUs or tones. Edge-In Association is illustrated in connection with example (16) below.

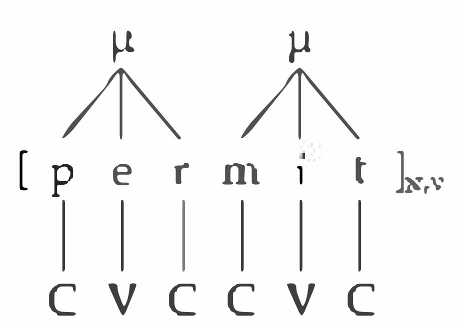
In (10d) the first Low tone is assigned to the first mora of /aa/ and High is assigned to the second. A Kukuya-specific process needs to assign the Low floating on the right to a TBU. This process is subject to the WFC, preventing the rightmost Low from going to the leftmost mora. As a result, the WFC guarantees that the last tone will go on the last TBU. For more detail on the WFC and autosegmental association, see Hammond (1988).

6 Non-concatenative morphology

Another significant outgrowth of autosegmental phonology was the extension of multi-tiered representations to morphology, beginning with McCarthy's (1979, 1981) templatic analysis of Arabic, applying the notion of long components (Harris 1951) to morphemes in general, and using autosegmental notation instead of the boundary symbols used by *SPE* to delimit morphemes. The examples in this section illustrate some developments in templatic morphology that fed back into phonology, including the addition of a CV tier and some new principles for linking one autosegmental tier with another (see also CHAPTER 105: TIER SEGREGATION; CHAPTER 108: SEMITIC TEMPLATES).

McCarthy illustrates the basic idea with this informal autosegmental representation of the English noun and verb *permit*:

(11)



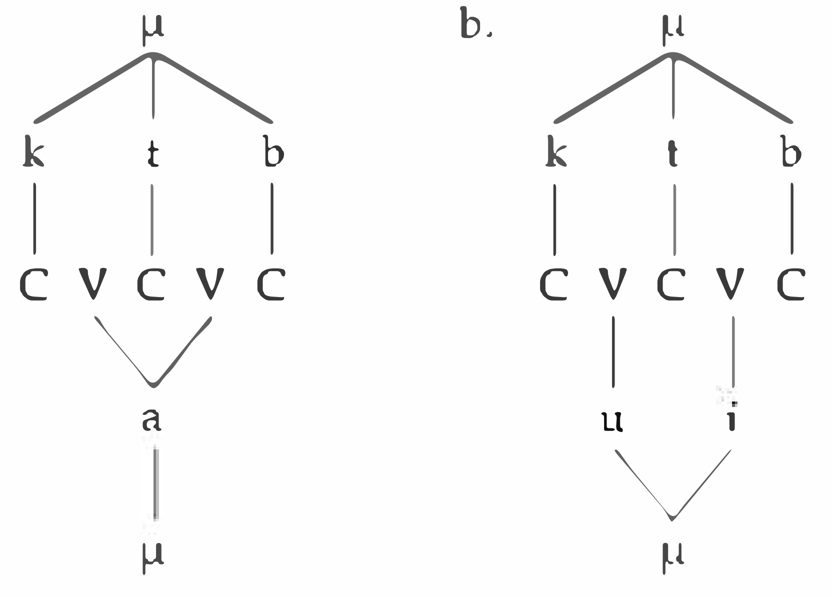
where μ is an autosegmental node representing a morphemic constituent lined by association lines to the sequences *per* and *mit*, which stand for the feature bundles that spell out the prefix *per-* and the root *mit*. The Cs and Vs at the bottom – shorthand for [–syllabic] and [+syllabic] segments respectively – represent the form's overall syllable pattern and are called the prosodic template.[4] In templatic morphology Cs and Vs are the analog of the TBUs in autosegmental representations of tone, while the morphemes – segment sequences like *per* and *mit* – are the analog of tonal melodies in our earlier examples.

This approach provides a simple way for McCarthy to represent the phonological and morphological structure of forms in a language like Arabic, where roots typically consist of consonants, and vowel patterns are used to differentiate inflectional categories like active/passive and perfective/imperfective. In the example

[4] This model was adapted and put to a variety of new uses by Halle and Vergnaud (1980) and by Clements and Keyser (1983). Halle and Vergnaud referred to the prosodic template as the CV skeleton, and Clements and Keyser called it the CV tier.

below, the triliteral root /ktb/ 'read' combines with the vowel pattern /aa/ to form the perfective active stem /katab/ and the perfective passive stem /kutib/.

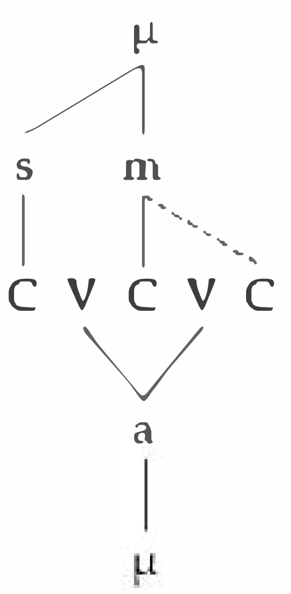
(12) a. b.



The tiered analysis expresses each stem's two discontinuous morphemes and at the same time its resulting phonological form. Not only are the separate tiers and the association lines borrowed from autosegmental phonology; to some extent, so too are the mapping principles. Note that the links between the morphemes in (12) and the C- and V-slots are consistent with principles (5), (8), and (9) above, as long as we require that [−syllabic] segments map onto C and [+syllabic] segments onto V. McCarthy makes a number of significant adjustments for more complicated cases, but the basic autosegmental framework provides an elegant start.

The need to associate every C position with a melody element leads to some interesting predictions. In (13) the bilateral root /sm/ combines with the vowel pattern /aa/ to form the perfective active stem /samam/. The structure is sketched in (13):

(13)

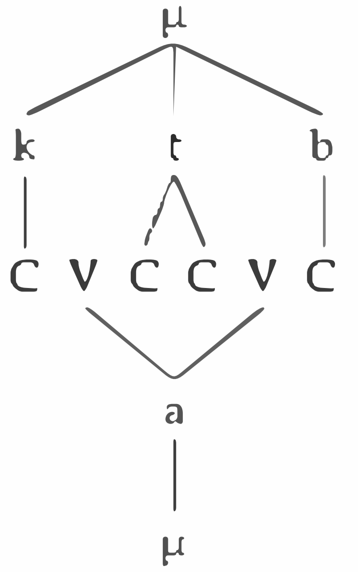


Surprisingly, the mapping procedure employed in (12) suffices for (13). Because the root contains only two consonants, and because the mapping procedure goes from left to right, we might expect the rightmost C position to remain empty. But the WFC requirement that all C positions must be filled will automatically add a link, and the prohibition against crossing association lines guarantees that the link will go to the second root consonant and not to the first.[5]

[5] As McCarthy notes, the absence of stems like */sasam/ is correctly predicted by this account, which maps from left to right. Another key component in this prediction is the Obligatory Contour Principle (see §9), which prohibits adjacent copies of a phonological element. This is yet another parallel between autosegmental accounts of phonological and morphological structure.

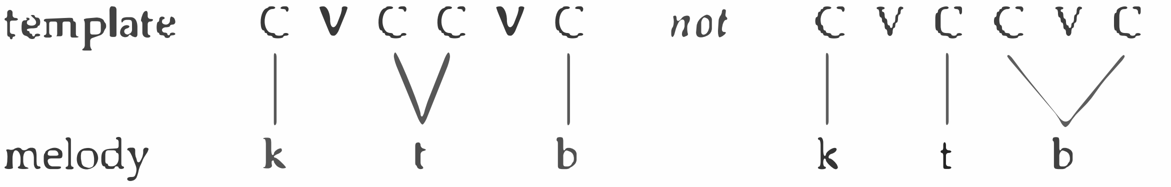
One complication in the autosegmental representation of morphological structure has led to a possible modification later applied to phonology. Consider how the proposal sketched in (12) would apply to the Arabic stem /kattab/, Form II of the active perfective Form I stem /katab/. Forms I and II have the same morphemic content and differ only in their prosodic template, CVCVC for Form I and CVCCVC for Form II (McCarthy 1981: 385–386). The second is shown in (14), after applying the mapping principles form above. Note that we get */katbab/ instead of the desired /kattab/.

(14)



For this purpose McCarthy devises a rule that results in a change from /katbab/ to /kattab/. This is fine, but one wonders whether a more general solution can be found. As an alternative, Yip (1988) proposes abandoning the left-to-right mapping principle for Arabic in favor of Edge-In Association, which would associate the leftmost and rightmost melody elements with the leftmost and rightmost Cs of the prosodic template:[6]

(15)



(16) gives a version of Yip's Edge-In Association:

(16) *Edge-In Association* (Yip 1988: 571)

a. *Anchoring*
Associate the outermost melodic elements to the outermost skeletal slots, one-to-one.

b. *Filling*
Associate the remaining melodic elements and the remaining slots in the same way.

c. *Template satisfaction*
Language-specific.

Yip goes on to mention tonal cases where (16) would be an improvement over left-to-right mapping, while allowing for the possibility that mapping tones

[6] As Yip notes, this rules out McCarthy's elegant analysis of /samam/ *vs.* */sasam/, and the account she offers in its place is unfortunately less general than the original one.

onto TBUs is governed by different principles from these (see also Archangeli and Pulleyblank 1994; Zoll 1997, 2003). Back in templatic morphology, Buckley (1990) shows that Edge-In Association predicts the correct mapping of Tigrinya roots onto noun and verb templates, for example in the key case of mapping triliteral roots onto the quadrilateral plural template, where other approaches fail.

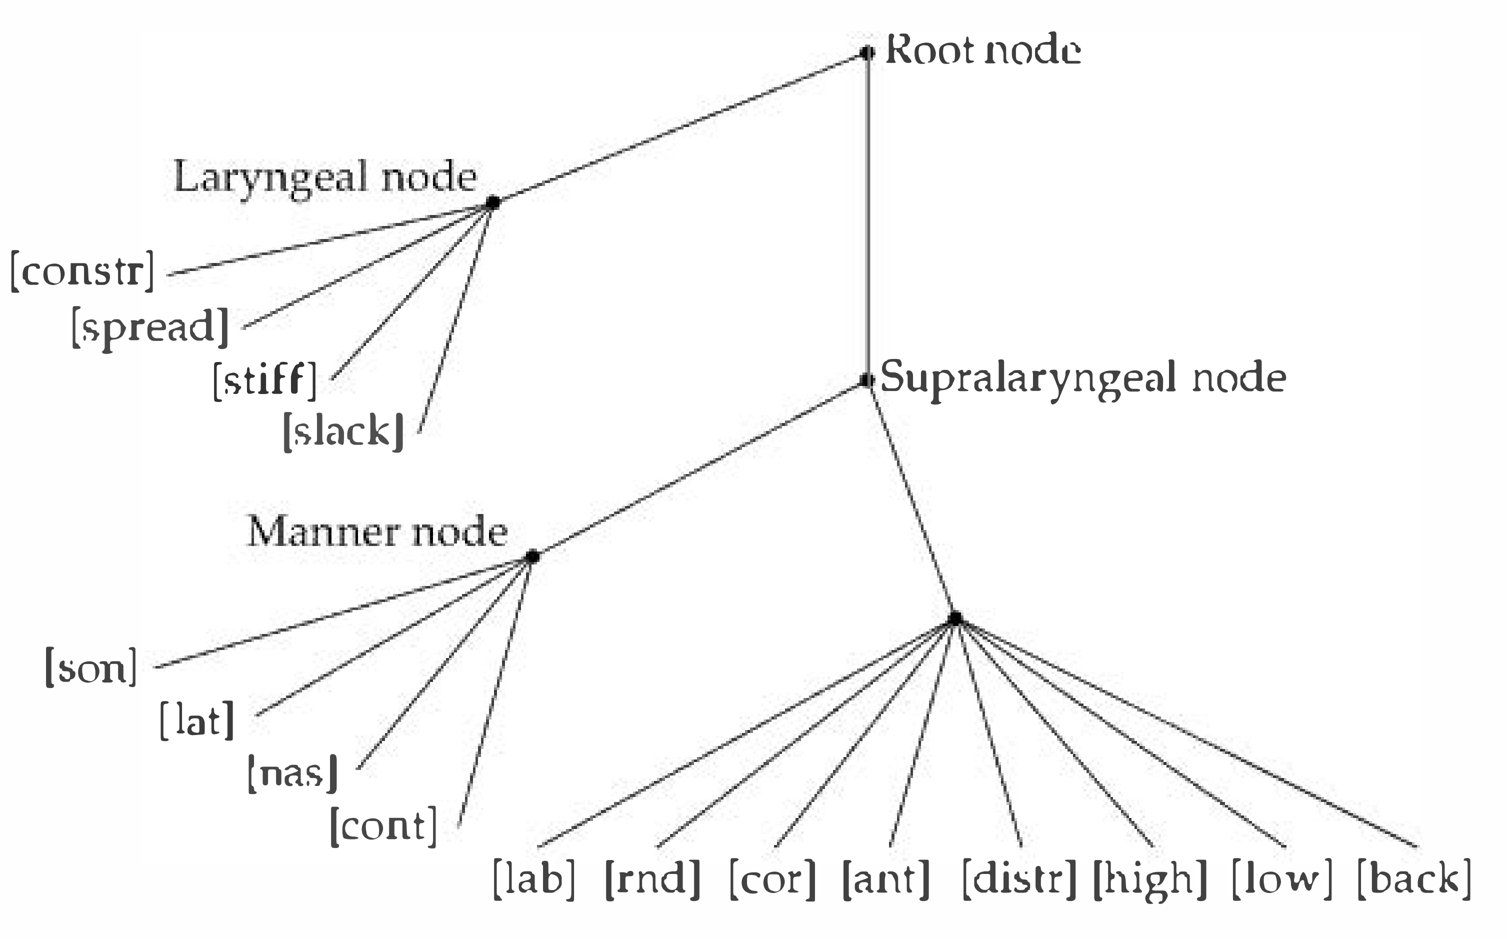
7 Feature geometry

In light of the autosegmental treatment of tone spreading and vowel harmony, which spread a given element across a string of feature-bearing units, consider now the standard assimilations of segmental phonology, such as voicing assimilation or nasal assimilation.

Phenomena like these could profit greatly from the autosegmental formalism if motivation could be found for abstracting features like [voice] and [nasal] from the segments.

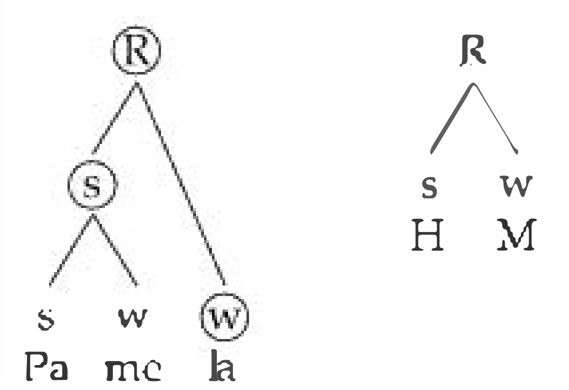
This is exactly what Goldsmith (1981) proposed, and the idea was pursued in rigorous detail by Clements (1985) and Sagey (1986). Clements (1985) noted that distinctive features grouped into neat classes, including place, manner, and supralaryngeal, which could be naturally represented by branching tree structures with phonological features as terminal nodes dominated by nodes representing feature classes (CHAPTER 27: THE ORGANIZATION OF FEATURES). Subclasses like place and manner could in turn be dominated by other classes, like supralaryngeal. In Clements's system, each feature and feature class was an autosegmental tier, and this tier in turn was linked to the tier above. (17) is a sketch adapted from McCarthy (1988: 89):

(17)



The motivation for each grouping lies in the cross-linguistic tendency of features within a group to behave together. For example, the place node above groups together features that tend to undergo assimilation together. Independent motivation postulating a metrical structure for autosegmental tunes[7] (illustrated on the right in (20)) and a procedure using this structure to fit the tune to metrically congruent parts of the text (illustrated on the left in (20)). The binary metrical feet can be related to early work in generative metrics, e.g. Halle and Keyser (1972). (The nodes labeled R are root nodes of metrical trees for text and tune.)

(20)



Liberman also included what he called a metrical grid to account for rhythmic structure. Across a fairly rich range of cases, these two additions enabled an English intonational melody to be linked to the right places in the intonational phrase. Liberman retained the autosegmental notion that complex tones were resolved as sequences of level ones, an idea pursued even further by others, beginning with Pierrehumbert (1980), as described in the following paragraphs.

On the right in example (20) above is an early autosegmental intonational "tune." To Liberman and Sag (1974), these tunes were meaningful – Liberman (1975) called them morphemes and stored them in a lexicon. This notion soon led to work on the internal structure of the melodies, beginning with Pierrehumbert (1980), Beckman and Pierrehumbert (1986), and Pierrehumbert and Beckman (1988). The constituents of intonational melodies included pitch accents, phrase accents, and boundary tones. Each constituent is a sequence of one or more autosegments, with a few enhancements to designate which autosegment was assigned to an accented syllable or to a given position in the phonological or intonational phrase. (An intermediate phrase was also posited for some languages, e.g. Japanese in Pierrehumbert and Beckman 1988.) This framework served as the basis for the widely used ToBI intonation transcription system (Beckman and Ayers 1994; Jun 2005).

In the example below, from Pierrehumbert and Hirschberg (1990), the instances of H* are pitch accents, each associated with the accented element in the text just above it. The symbols H and L not followed by an asterisk are called phrase tones: H is the phrase tone for the first phrase, and L is the phrase tone for the second. The L% at the end marks the utterance boundary (see also CHAPTER 32: THE REPRESENTATION OF INTONATION; CHAPTER 116: SENTENTIAL PROMINENCE IN ENGLISH; CHAPTER 50: TONAL ALIGNMENT).

(21) The train leaves at seven or nine twenty-five.
H* H* H* H H* H* L L%

[7] Such tunes are familiar from earlier American, British, Dutch, and other traditions, but the decomposition of tunes into sequences of level tones, drawn from the same inventory as the tones of lexical tone languages, was novel, if similar in some respects to earlier American approaches, notably Pike (1948).

point out, every intonational contour obeys the OCP, i.e. consists only of sequences of unlike tones.

Jun (2005: 434–435) provides a table summarizing the ToBI analyses of intonation in a sample of 11 languages that are typologically quite diverse. Listed in the table are all of the attested ToBi tone sequences for pitch accents, phrase tones, and boundary tones in these languages. Jun's table includes 22 cases of pitch accents comprising two or more tones, such as L+H*, H+↓H*, and H*+L. Three of Chickasaw's four pitch accents violate the OCP: LHHL, LL, and LHH. The German pitch accent H*↓H either conforms or does not conform, depending on whether we regard the downstep ↓ as a break between the adjacent H tones.[10] Aside from these cases, the remaining 18 sequences feature only unlike tones in adjacent positions. For phrase tones and boundary tones, the pattern is clear. The two bi-tonal phrase accents and 13 multi-tonal boundary tones all conform to the OCP.[11]

However, the literature is rife with examples of tone languages violating the OCP in one way or another (see Myers 1997). Some of the most enduring results on the question were captured in Odden (1986), with additional details in Odden (1995). One of these is that languages differ in how they deal with sequences of identical tones across prosodic boundaries. Odden (1995: 462) suggests that Kipare fuses High tones across phrase boundaries into a single High tone. The evidence is that a prepausal sequence of High tones is realized as Low after a floating Low tone, even if they are from different prosodic words. Here is one of his examples:

(27) *Kipare* (Bantu, Tanzania)

vá↓ná vékíjílá nkhúku ndórí nkhúndú jángú
'while the children eat those little red chickens of mine'

The change that applies to this string is that *all* of the High tones following the downstep marker (↓) become Low, despite the fact that this expanse crosses many word boundaries.

A related observation comes from Hausa (Inkelas and Leben 1990), where emphatic intonation raises High tone to the extra-High register. Once the extra-High register is triggered, all remaining High tones in the phrase are pronounced extra-High, even on words not emphasized. In (28), the leftmost two syllables have a Low tone, marked with a grave accent, and the remaining ones are lexically High-toned. /neemoo/ 'look for', is emphasized in (28b) but not in (28a). In (28b), when the register shifts up for /neemoo/, it stays up for the remaining High-toned words, even though they are not emphasized.

(28) *Hausa* (Chadic, Nigeria)

a. *Normal*
Bà mù | neemoo awarwaron Maanii ba
'We didn't look for Maanii's bracelet.'

b. *Emphatic*
Bà mù | *neemoo* awarwaron Maanii ba
'We didn't *look for* Maanii's bracelet.' (*neemoo* is emphasized)

[10] Similar cases arise in African languages: see example (28) below and the surrounding discussion.
[11] But see Ladd's (2008) review, cautioning against generalizing across languages or even across varieties of one language based on ToBI analyses.

Odden's other seemingly inescapable result is briefly that in some languages the sequence HH can contrast with a single H. He analyzes Shambaa (Bantu, Tanzania) as having two types of High-toned sequence: one type that surfaces as level High, as in (29a), and another surfacing with a downstepping pattern, as in (29b):

(29) *Shambaa* (Odden 1986, 1995)

```
a. /njoka/  'snake'        b. /ngoto/  'sheep'
      \/                          |  |
      H                           H  H

   Surface patterns
      njóká                      ngó↓tó
     [   ¯  ¯ ]                 [  ¯  – ]
```

Odden argues that the OCP ought to reduce H and HH to the same melody, yet clearly H in (29a) contrasts with HH. Here then is a lexical tonal contrast that contradicts the OCP.

However, it should not be missed that Shambaa also exemplifies the principle underlying the OCP – avoidance of sequences of identical tones – since wherever two High tones come together, they are broken up by a downstep. The same happens in some other Bantu languages, e.g. Namwanga (Bickmore 2000: 302), and in some non-Bantu languages, e.g. the Chadic language Miya (Schuh 1998). Cassimjee and Kisseberth (2001: 329–331) offer examples of closely related languages that differ in the conditions for inserting downstep between adjacent High tones, if downstep is inserted at all.

Subsequent work, beginning with Myers (1997), has gotten considerable mileage from regarding the OCP as a violable constraint – reasonably enough, since most constraints can be violated. Again, see Myers (1997). We return briefly to Shambaa in §10.1 in connection with the tonal foot.

As with Yip's (1988) proposal for edge-in mapping, it is still an open question whether the OCP for tone is the same constraint as the OCP applied to other features. McCarthy's (1986) suggestion to apply the OCP to antigemination in general met with a prompt retort from Odden (1988), who wrote on anti-antigemination. The matter is still unresolved.

10 Prosodic groupings of autosegments

Two areas of current exploration concerning autosegments are groupings of autosegments into "foot-like" structures (van Oostendorp and Revithiadou 2005) and the possibility of deriving the results of autosegmental theories of harmony from connectionist accounts.

10.1 Tonal feet

From the beginning, some of the basic units of prosodic phonology – notably prosodic words in the case of harmony processes and phonological phrases in the case of intonation – were found to form natural domains for sequences of autosegments. The pioneering autosegmental accounts of intonation grouped tones into tunes, while the enhanced autosegmental strings pioneered by Pierrehumbert (1980) and Pierrehumbert and Beckman (1988) went with phrase-like prosodic units.

Groupings of lexical tones into prosodic constituents came next. Rice (1987) and Goldsmith (1987) discussed cases in which High tone was attracted to a metrically strong position. Another early instance was Kenstowicz and Kisseberth's (1990) demonstration that metrical feet in Zigula (Bantu, Tanzania) determine where High tones shift to – in general, to the penult, the head of a disyllabic trochee. While Zigula lacks word stress phonetically, the TBU designated as the head typically attracts lexical High tones as well as intonational tones, and this has come to be regarded as a characteristic of feet in tonal languages.

For example, the Zigula 3rd person subject prefix /a-/ contributes a High tone to the verb. This High tone is realized on the penultimate syllable of the verb in the example below, where the other morphemes in the verb are toneless. The situation becomes more complicated when other morphemes contribute a High tone.

(30) *Zigula* (Kenstowicz and Kisseberth 1990: 167)

a- hugusahug(usa) 'he/she shells repeatedly'

H

Duanmu (1999) portrays a more complex interrelationship between metrical structure and tone in his account of the differences between Mandarin and Shanghai, illustrated here in the way the two languages deal with tone for the foreign name *Chicago*:

(31) a. *Mandarin* (transcribed in Pinyin)
H-H-H → H-H-H
zhi-jia-ge 'Chicago'

b. *Shanghai* (transcribed in phonetic symbols)
H-H-H → H-L-L
tsz-ka-ku 'Chicago'

In Mandarin, which contrasts full and light syllables, (31a) has three full syllables, and by foot constraints which Duanmu motivates independently, each syllable is stressed. This in turn guarantees, again by an independent constraint, that each syllable retains its High tone. Shanghai, on the other hand, does not contrast full and light syllables underlyingly (Duanmu 1993), and so the three syllables of (31b) group into a single foot, preserving only the tone of the head, the first syllable. The two remaining syllables are realized as Low by default.

Zec (1999) shows that in the neo-Štokavian dialect of Serbo-Croatian, stress and tone are both critical factors in the definition of the *foot*. This can be seen from the following foot inventory.

(32) *Serbo-Croatian* (Zec 1999)

without tone

a. $[\ \sigma_{\mu\mu}\ ]_{Ft}$ b. $[\ \sigma_{\mu}\sigma_{\mu}\ ]_{Ft}$

with tone

c. $[\ \sigma_{\mu\mu}\ ]_{Ft}$ d. $[\ \sigma_{\mu}\ ]_{Ft}$
H H

If a High tone (Zec's interpretation of a pitch accent; see CHAPTER 42: PITCH ACCENT SYSTEMS) is present, then a foot can be either one or two moras in length. In the absence of a High tone, the foot must be bimoraic – either a long syllable or two short ones.

Foot structure has also figured in recent accounts of African tone languages. For example, in Kera (Pearce 2006) the metrical foot, grounded phonetically, is the key to explaining the distribution and behavior of tone. She presents evidence (2006: 260) that when a word consists of exactly one foot, each syllable can carry a tone, but in words with two feet, each foot can only have one tone.

Leben (2002) offers a tonal foot reinterpretation of Odden's (1986) Shambaa data from (29) above. Odden proposes the underlying tonal contrast H *vs.* HH for the respective phonological representations in (29a) and (29b). But the only evidence for the underlying sequence HH is its surface realization [H$^{\downarrow}$H], the pattern that obtains in a phrase when a word ending in High directly precedes another High tone. This evidence is hardly conclusive. Suppose that some language inserts an epenthetic [t] between words ending in [n] and words beginning in [s]. This would not necessarily mean that word-internal [nts] has to be analyzed phonologically as /ns/. Leben (2002), agreeing that there is an important contrast in (29), suggests that (29a) has one foot, while (29b) has two:

(33) a. /njoka/ b. /ngoto/
(H) (H)(H)

He suggests that this contrast is analogous to the familiar one in stress languages, between one foot (as in English *attic*) and two (as in English *Aztec*).

Pearce (2006: 260–261) offers a summary, with a dozen references, of ways in which tones interact with metrical feet:

(34) *Types of interaction between tones and metrical feet* (Pearce 2006)

a. In the association of tones to heads.
b. In the deletion of tones on non-heads.
c. In the spreading of tones within the foot.
d. In the preference for certain tones on heads and non-heads.
e. In associating certain melodies with certain foot types.

Taken together, Pearce's references offer consistent cross-linguistic evidence for the tone-bearing unit as either the entire metrical foot or its head.

10.2 Tonal complexes

Akinlabi and Liberman (2001) argue for a similar entity. Their tonal complex is a grouping of lexical tones into a structure broadly described as the "tonal analog of the syllable." The basic claim is that constraints involving tonal complexes "can motivate deletion, epenthesis, spreading or reordering of tonal features, just as constraints on syllable or foot structure may motivate such processes in well-known cases of segmental phonology."

Tonal complexes help Akinlabi and Liberman explain why tone spreading in a schematic example like (35a) typically results in (35b) rather than (35c). (See Hyman 2007 for this observation.)

(38) a. *spreading* b. *shifting*

Cassimjee and Kisseberth's insight is that spreading and shifting are similar in expanding the H domain. The difference is that on the surface H comes to cover the entire domain, while shifting results in a single link at a domain edge.

The example below shows how closely spreading and shifting are related in three Nguni languages:[12]

(39) *Nguni languages* (Cassimjee and Kisseberth 2001)

	Swati	*Durban Zulu*	*Phuthi*
a.	[ba̲-já]naːtsa	[ú̲-kú]-ʧu-la	[kú̲-límí]siːsa
	'[cl.2] are drinking'	'to sing'	'to cultivate intensively'
b.	[ba̲-ja-khilikí]dzeːla	[bá̲-já-límá]liːma	[bá̲-já-límé]laːma
	'[cl.2] are stumbling'	'[cl.2] are cultivating (REP)'	'[cl.2] cultivate for one another'
c.	si-ja-[sɛ̲bé:]nta	si-ja-[la̲lé:]la	si-ja-[bɔ̲́ní:]sa
	'we are working'	'we listen'	'we show'

The H domains in these three languages are all constructed according to the same principles (see Cassimjee and Kisseberth 2001: 333–337). The surface tonal differences in the bracketed domains result from whether the underlying High tone (the underlined mora at the left edge of the bracketed expression) shifts or spreads or both. Cassimjee and Kisseberth informally represent a surface TBU that arises from underlying H with an underline – [ba̲] in the left column of (39a) – and surface H with an acute accent – [já] in the left column of (39a) – but this is purely a matter of notation, not a formal difference from the standard autosegmental representation. The differences among the three languages are summarized in (40).

(40) a. In Swati, input H *shifts* to the final syllable of the H domain.
b. In Durban Zulu, input H *spreads* from prefixes to the final syllable of the H domain and *shifts* from input stems to the final syllable of the H domain.
c. In Phuthi, input H *spreads* to the final syllable of the H domain.

Thus Swati involves shifting, Phuthi involves spreading, and Durban Zulu involves both. The ODT analysis makes this difference – which leads to tonal strings that sound very different among the three languages – a highly natural, yet rather superficial one. What recommends their representation of High domains is that it captures a basic fact about these three related languages, namely that the initial and final locations of Nguni High tones are all determined by the same principles, despite the superficial differences.

[12] The Durban Zulu forms are from Laura Downing, as cited by Cassimjee and Kisseberth (2001); the Phuthi forms are from Donnelly (1997).

(47) m a w a s a

\|/ V

[+nas][−nas]

McCarthy opts for the format in (47) for the convenience of using just one line per candidate in an OT tableau. Autosegments are not being abandoned here but are acquiring more structure – namely, heads.[13]

McCarthy's approach is extended to tone with revisions by Key (2006). Volk (2008) observes that ODT differs from Headed Span Theory in a least one important respect: the former but not the latter sanctions representations in which a TBU is linked with several non-contiguous surface tones. This is also a key difference between ODT and standard autosegmental practice.

Another question that requires further study, attributed to Lee Bickmore (McCarthy 2004: 5, fn. 5), is floating features. The version of FAITHHEADSPAN(●F) in (46) does not apply to floating elements in the input, but the fix may be simple, as McCarthy suggests: a reformulation along the lines suggested by Zoll (1996) and Lombardi (1998).

However, for output floating elements the solution is not so easy: a revision of any analyses that appear to require them. But any revisions would need to capture generalizations that floating tones famously have made so transparent. For example, tone assignment in Tiv normally places no more than one tone on any given TBU (Pulleyblank 1986). But in phrase-final position, a falling tone can appear on a single TBU, as shown by the two variants in (48), from Arnott (1964) (the arrow denotes downstep):

(48) *Tiv* (Arnott 1964)

mbá$^{\downarrow}$ kásév 'there are women'

[‾ – –]

kásév mbâ 'there are women'

[– – \ ]

A floating Low tone at the end of /mba/ accounts naturally for its downstepping effect on the following word and is motivated independently by the high fall on /mba/ before pause.

A more complex case for surface floating tones comes from Asongwed and Hyman's (1976) analysis of Ngamambo (Cameroon, Grassfields Bantu). They show that the five surface tone levels of Ngamambo, shown in (49), correspond to two surface tones, High and Low, which can be either docked on TBUs or floating in output forms. The hyphens at the beginning and end of the forms indicate whether they are a prefix or a root.

(49) *Ngamambo's five tone levels* (Asongwed and Hyman 1976)

High	mə́-
Mid	ʌ̄-
Lower Mid	ʌ-
Unreleased Low	-bàp˺
Low	ʌ̀-

[13] Finlay (2008) notes a similar approach, the Headed Feature Domains Theory of Smolensky (2006), which "makes slightly different restrictions on the representations of feature spans."

The Mid tone above is the alternant of High tone that appears on vowel-initial prefixes. The unusual number of floating tones in outputs helps to explain the complex morphotonemics of this language. For example, there are two types of High-toned noun. In isolation, both have the same tonal realization, but they differ systematically when a noun possessor follows:

(50) a. mə́ɲíp 'water' mə́ɲíp Àbò 'water of slave'
b. mə́fɔ́m 'fat' mə́fɔ̂m Àbò 'fat of slave'

Asongwed and Hyman account for this by positing a High tone sequence for roots like (50a), while the High tone sequence in (50b) is followed by a floating Low.[14]

Larry Hyman (personal communication) adds that floating tones are also a problem in ODT, again due to faithfulness requirements. Clearly, floating tones have a special role to play in this discussion. Their existence is practically predicted by autosegmental theory in assigning tone to an independent tier. And we have seen clear parallels between standard autosegmental phonology and the newer domain-based alternatives. The problem seems to be in formulating a version of faithfulness that will allow tone either to be associated with a position or to float. See also CHAPTER 45: THE REPRESENTATION OF TONE.

ACKNOWLEDGMENTS

Thanks to the editors and to two anonymous reviewers for essential help in revising and reshaping this chapter from the ground up. Special mention to Larry Hyman for dozens of specific suggestions and corrections based on an early draft of this chapter and to Chuck Kisseberth for corrections under severe time pressure to the account of Optimal Domains Theory.

[14] Example (50) simplifies the facts, and a fuller account makes an even stronger case for output floating tones. The floating tone in (50b) appears to show up directly on the corresponding syllable in the possessed–possessor forms, but in fact the situation is more complex. In between the two nouns is an associative marker which itself may be a floating tone. That tone in turn is determined by what precedes, and notably by the final tone of the preceding noun, whether that tone is floating or not. See the charts in Asongwed and Hyman (1976: 48, 50) for examples of the dozens of possible combinations of disyllabic N_1, associative marker, and disyllabic N_2. Without floating tones in the output, it might be necessary to posit a set of arbitrary declension-like classes to account for the possibilities.

15 Glides

Susannah V. Levi

1 Introduction

The division of sounds into two major classes – consonants and vowels – is challenged by a set of sounds that exhibits characteristics of both categories. Variably referred to as "glides," "semi-vowels," or "semi-consonants," these *intermediate* segments require an examination of those properties that differentiate vowels and consonants.[1] Glides have appeared problematic for phonological theories because of their (apparent) variable behavior. Glides can pattern with vowels – even alternating with them in some languages – and can also pattern with consonants. This variable behavior has fueled a debate over the existence of glides as distinct phonemes that contrast with vowels. This chapter will present a typology of vowel-glide systems in which glides can exist both as distinct phonemes and as allophonic variants of vowels (hereafter "phonemic glides" and "derived glides," respectively). Glides derived from vowels behave phonologically like vowels, while phonemic glides pattern with consonants to the exclusion of vowels (Levi 2004), eliminating the *variability* in behavior. Herman (1994) and Hume (1995) argue for a distinction between "consonantal" and "vocalic" glides based on these different behaviors. In this chapter, the distinction between glides will be grounded in their phonological status as allophones of vowels or as distinct phonemes. The major questions surrounding glides relate to their phonological status.

i. Can glides be distinct phonemes different from vowels or do they exist only as allophones of vowels, based on their phonological environment and/or position in the syllable?
ii. If glides can be phonemic, do they behave like vowels or consonants, or do they instead form a distinct third category of segments that has a unique behavior different from either vowels or consonants?
iii. If they can be phonemic, how should they be represented? Is this representation more similar to vowels or consonants? Is the representation universal?
iv. How does the phonological status (phonemic or derived) relate to the surface phonetic realization? What does it mean to be a glide on the surface? What does it mean to be a glide phonologically?

[1] In some frameworks, glides form part of the class of approximants, along with liquids (Ladefoged 2006). As this term refers to a larger class of sounds, it will not be used here.

Answering questions (i)–(iii) is crucial to all theories of phonology. Whether using a derivational *SPE*-style analysis (Chomsky and Halle 1968), a feature-geometric representation, a government phonology approach, or an Optimality Theory (OT) approach, it is necessary to establish the featural make-up of glides to determine whether phonological processes can or should apply or whether constraints – often formulated in relation to a particular phonological feature – are violated. Question (iv) will be discussed briefly in §4.

An example of predictable glide behavior will illustrate some of the issues surrounding the status of glides. Latin is a classic example of a language in which surface glides and vowels are found in predictable phonological environments. High vowels surface as glides in word-initial position when they occur before another vowel (1a) and intervocalically (1b) (Steriade 1984). High vowels surface as vowels after consonants (2).

(1) *Glide realization*

a.	/iecur/	[je.kur]	'liver'
	/uenio/	[we.ni.oː]	'I come'
b.	/ouis/	[o.wis]	'sheep'
	/auus/	[a.wus]	'grandfather'
	/iuuenis/	[ju.we.nis]	'young'

(2) *Vowel realization*

/mulier/	[mu.li.er]	'woman'
/dies/	[di.eːs]	'day'
/mutuus/	[mu.tu.us]	'mutual'

Languages such as Latin that show this type of predictable behavior have been used to argue that glides are merely positional variants of vowels (see §3.1 and §3.2). §3.4 presents a typology of vocoid systems that include both derived and phonemic glides. Before examining the debate and typology, we first provide an overview of how glides have been discussed in the phonetic and phonological literature (§2). Following the typology section (§3), we conclude in §4 with a brief discussion of the issues that remain.

2 A brief history of glides: Phonetics and phonology

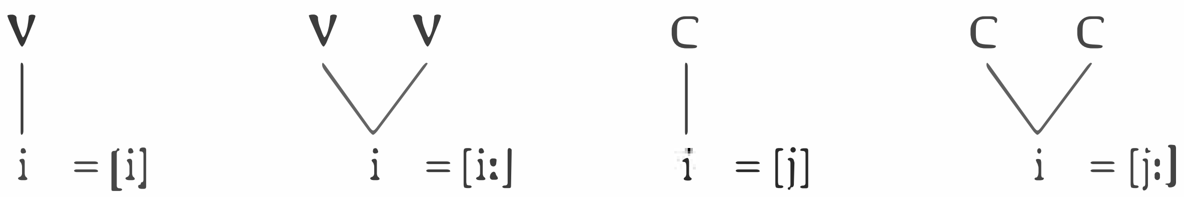
2.1 *Phonetics*

As with all issues involving glides, there is little consensus as to how they should be characterized phonetically. The most commonly discussed phonetic properties of glides – and how they compare to vowels – are degree of constriction, duration, amplitude, and even syllable position. Discussion of constriction as a distinguishing phonetic correlate of glides dates back over 100 years. Whitney (1865: 239) describes glides in English as "vowels of so close a position that they verge upon the consonants" (see also CHAPTER 21: VOWEL HEIGHT). Sweet (1877, 1907) targets constriction as the defining difference between consonantal and vocalic sounds which eventually provides the basis for the features [consonantal] and [vocalic]

With the reintroduction of the syllable in phonological theory came a push to eliminate the feature [syllabic]. Kaye and Lowenstamm (1984) argue that syllabification processes, not features such as [syllabic], determine syllable position. In their view, glides and vowels are featurally identical ([−consonantal, +vocalic]) and should *never* be distinct segments. They use the symbols /I/ and /U/ to highlight that syllabification determines whether they surface as a glide or a vowel.

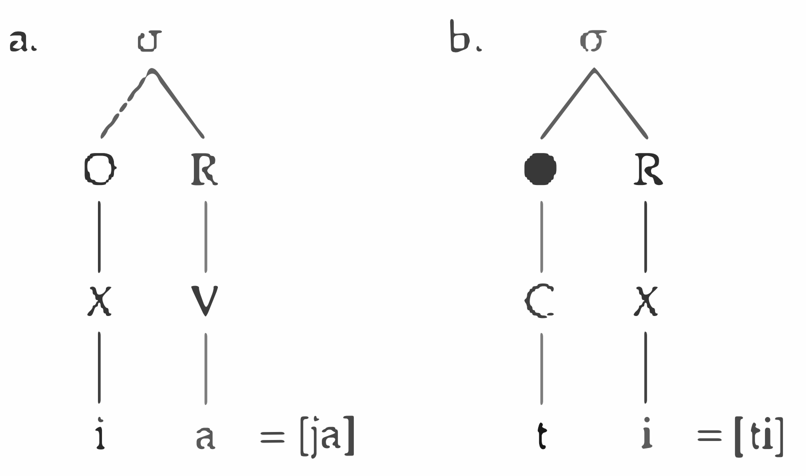
In theories that target the syllable, it is structure, not features, that distinguishes glides from vowels. Clements and Keyser (1983) introduce the CV tier between the segmental tier and the syllable tier, and eliminate the feature [syllabic]. The difference between vowels and glides is thus determined by whether the segment is dominated by a C or a V node, as in (4).

(4)



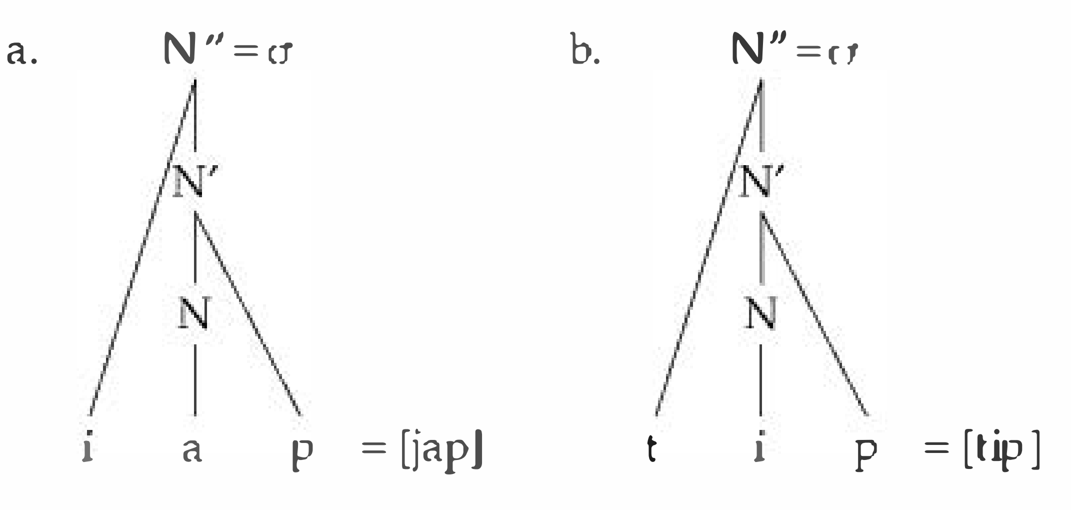
One criticism of CV theory was that it neglected to capture the empirical generalization that syllable position is largely predictable, making the CV tier redundant (Levin 1985). In a move to eliminate some of this redundancy, Steriade (1984) added X as a possible element to the CV tier to account for the predictability of glide/vowel alternations in Latin. This representation allows high vowels to alternate between peak and non-peak elements in the syllable without requiring rules that change skeletal slots (e.g. C → V). In Steriade's proposal, vowels and glides surface as in (5).

(5)

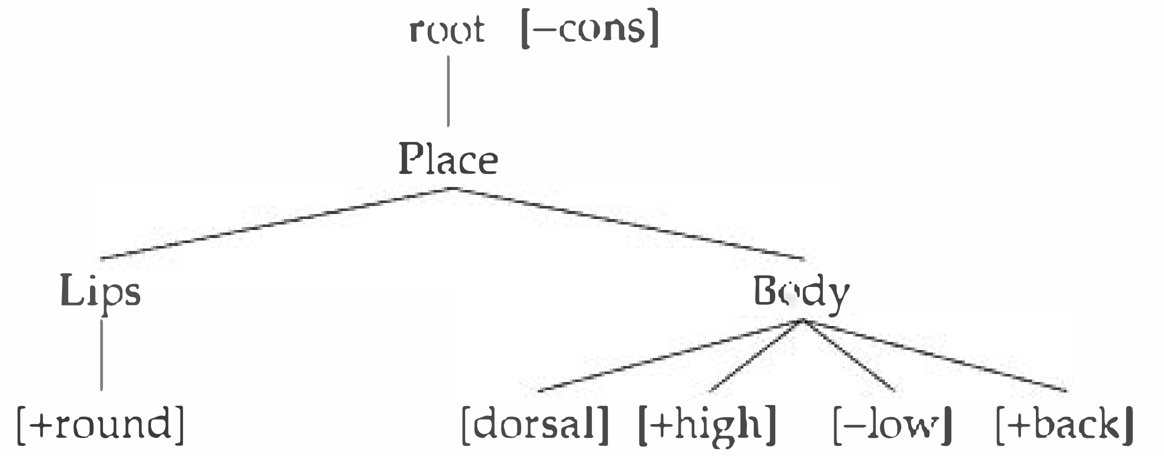


Noting the redundancy of the CV tier in general, Levin (1985) eliminated CV in favor of X for all skeletal positions. Non-peak elements are linked either to N″ (onsets) or to N′ (codas). The difference between vowels and glides thus remains on a higher structural level.

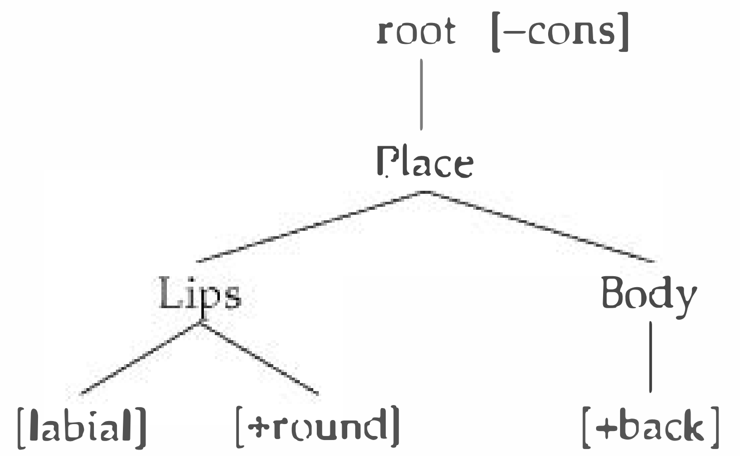
(6)



(10) a. /u/ (*and derived* [w])



b. /w/



3 The debate: Is there evidence for a phonemic distinction between vowels and glides?

Despite abundant work on glides, vowels and their alternations, there remains no consensus on the existence of glides as distinct phonemes (CHAPTER 11: THE PHONEME). There are two common ways glides are treated in the literature. The first is to assume that phonemic glides do not exist and that glides are only allophones of vowels. In this view, glides are treated as "high vowels in a non-syllabic disguise" (Durand 1986), and are only distinct on a syllabic level (e.g. Jakobson *et al.* 1952; Clements and Keyser 1983; Kaye and Lowenstamm 1984; Durand 1986; Deligiorgis 1988; Rosenthall 1994). The second treatment of glides has been to remain agnostic about their phonological status. Despite the rather prominent view that glides are only positional variants of vowels, many works include glides in consonant inventories.

As will be shown below, the confusion surrounding glides (i.e. their phonological status and the conflicting phonological evidence) can be attributed to the existence of two distinct types of glides. Specifically, glides can either be derived from vowels and thus be positional variants of vowels ("derived glides") or they can exist as distinct phonemes ("phonemic glides"). One reason glides have not been understood and have been viewed as behaving differently from other segments (e.g. forming the class of [0 consonantal] segments; see CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION) is that their *variable* behavior has been attributed to a single class of segments. Recognizing that glides can be derived from two distinct sources eliminates the variable behavior and the "duality" of glides.

3.1 Predictable alternations between glides and vowels

A common type of language is one in which glides surface in predictable environments, and are thus positional variants of underlying vowels. Latin (discussed in §1)

The large proportion of predictable cases compared to the small proportion of lexically nuclear vowels is expected in an analysis that treats the "special" vowels as marked (Harris and Kaisse 1999: 185).

Data from Korean also provide evidence for both predictable glide/vowel alternations and unpredictable vowels. Unmarked, underlying high vowels surface as vowels between consonants (e.g. [ʧi-ta] 'lose') and as glides intervocalically (e.g. [moj-ət-ta] 'gathered') (Yun 2003). In C __ V environments there is variability; some lexical items allow a glide while others require a vowel, generating hiatus as in (16). Forms that surface with a vowel in gliding environments (16b) are rare; only six out of 428 stems exhibit this pattern (Yun 2003). Here C' represents a fortis consonant (CHAPTER 111: LARYNGEAL CONTRAST IN KOREAN).

(16) a. *Gliding allowed*

/p^{h}i-/	[p^{h}i.ta]	[p^{h}jət.ta]	*[p^{h}i.ət.ta]	'straighten'
/ʧi-/	[ʧi.ta]	[ʧjət.ta]	*[ʧi.ɔt.ta]	'lose'
/ʧ'i-/	[ʧ'i.ta]	[ʧ'jət.ta]	*[ʧ'i.ət.ta]	'boil'

b. *Gliding disallowed*

/pi.-/	[pi.ta]	[pi.ət.ta]	*[pjət.ta]	'be empty'
/p'i.-/	[p'i.ta]	[p'i.ət.ta]	*[p'jət.ta]	'sprain'
/p^{h}i.-/	[p^{h}i.ta]	[p^{h}i.ət.ta]	*[p^{h}jət.ta]	'bloom'

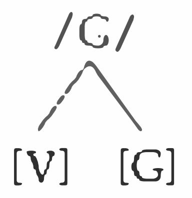
Analyses of these "vocalic" languages represent alternating vocoids like those from predictable languages in the previous section. Vowels that surface in *unexpected* environments are considered to be lexically marked as nuclear (e.g. Guerssel 1986; Roca 1997; Harris and Kaisse 1999). Levin (1985) argues that the property of being a syllable head could be specified underlyingly. In this chapter, this lexical marking is represented as /i=N/ or /u=N/, indicating that they must surface as syllabic. Because these segments are lexically marked, they are expected to be less numerous than those that exhibit the basic alternating pattern. Indeed, this marginal status is confirmed by Spanish and Korean.

Evidence suggesting that alternating segments and lexically marked vowels are featurally identical (though structurally distinct) comes from the Pasiego dialect of Spanish. In Pasiego, stressed high vowels cause harmonic raising of preceding mid vowels (Penny 1969a, 1969b; Hualde 1989), as in [be'ber] 'to drink' – [bi'bi:s] 'you (PL) drink (INDIC)'. Raising is also triggered by derived glides in stressed syllables, as in [amfi'θjon] 'infection' (cf. [amfes'tar] 'to infect') (Kaisse and Levi 2004). Finally, lexically nuclear vowels, also trigger harmony, as in [bi'bi.a] 'he was drinking (INDIC)' (Penny 1969b) and [kuxi'ri.a] 'I would take' (Hualde 1989). That derived glides, plain high vowels, and lexically marked high vowels trigger raising suggests a featural identity between these segments. Recognizing that surface glides are derived from vowels, and that the unusual vowels have marked structure but identical features unifies the analysis of vowel harmony to a single feature bundle associated with high vowels.

3.3.2 *"Glide" languages*

The previous sections provided evidence for languages with predictable realization of vowels and glides, as well as unpredictable distributions in which vowels occur in unexpected environments. There are also languages that exhibit glides in environments where vowels are expected. These languages with phonemic glides will be

(23) *Type IV*

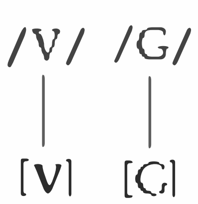


Thus far, no Type IV languages have been identified. As discussed in §3.4.2, languages that lack underlying high vowels are rare. The lack of Type IV (and also Type VII) suggests a possible implicational relationship: if phonemic glides alternate, there must also be underlying vowels that alternate. Determining whether a language is Type III or IV would require an examination of the phonology to consider whether other phonological processes could adjudicate between these two possible systems. For example, a Type III language with vowel harmony should show participation of both vowels and glides (as discussed for Pasiego), while a Type IV language should show transparency of vowels and glides. Other phonological phenomena that target featural, rather than syllabic distinctions, would also establish a difference between Type III and Type IV languages.

3.4.5 *Type V: Non-alternating underlying vowel and glide*

Type V languages contain both phonemic glides and vowels that do not alternate. Type V is the second type of language with phonemic glides. Yawelmani, Tahltan, and Turkish are languages of this type (Levi 2004).

(24) *Type V*



Yawelmani syllabification provides evidence for the absence of alternations between vowels and glides. Vowel hiatus is banned and repaired by [ʔ]-insertion and vowel deletion, as in (25). That gliding is not a legal repair for hiatus shows that high vowels cannot surface as glides (data from Newman 1944).

(25)	a.	[ʔ]-*insertion*		
		/ṣaṣa:-in/	[ṣaṣa:-ʔ-in]	'eye-ross'
		/pana:-it̪*'/	[pana:-ʔ-it̪*']	'one who is arriving'
	b.	*Vowel deletion*		
		/wili:l-d̪a:-ihni:/	[wilal-d̪-ihniʔ]	'one always preparing to depart'
		/paxju:-ila:-hin/	[paxj-ula:-hin]	'caused something to scatter'

Consonant clusters are also prohibited. Thus, in clusters involving glides, the only legal repair is vowel epenthesis as in (26), and vocalization is prohibited.

(26)	/ʔutj-t/	[ʔutj-u-t]	'fall-AORIST'	*[ʔuti-t, ʔutu-t]
	/logw-k'a/	[logiw-k'a]	'pulverize-IMP'	*[logu-k'a]

Two other types of evidence suggest an underlying contrast between vowels and glides in Yawelmani. First, all consonants and glides have plain and glottalized series (represented as [C']) (see (27)), whereas vowels do not.

(27) ṭ'ojix 'applying medicine' (Newman 1944: 19)
ṭ'oj'ix 'getting rusty' (Newman 1944: 19)
ṭ'aw' 'throw' (Archangeli 1984: 285)

A second type of evidence for a phonological contrast between vowels and phonemic glides comes from vowel harmony. In Yawelmani, glides are transparent to vowel rounding harmony (see CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS).

(28) *Glide as a non-trigger*

/boːwn-/	[bown-iṭ]	'trap-PASS AORIST'	(Archangeli 1984: 263)
	*[bown-uṭ]		
/joloːw-/	[joloːw-hin]	'assemble-AORIST'	(Kisseberth 1969: 24)
	*[joloːw-hun]		

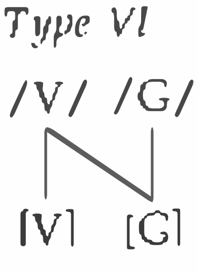
Evidence from hiatus and cluster resolution, sonorant series, and vowel harmony indicates the presence of contrasting segments (vowel and phonemic glide) which do not show surface alterations.

Several other languages exhibit Type V patterns. In Tahltan, glides participate in consonant harmony (Hardwick 1984; Shaw 1991) while vowels do not, suggesting that vowels and glides are phonologically distinct (see also CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS and CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). Additionally, there is no evidence from syllabification to suggest that these two segments should be treated as a single phoneme. In Turkish, vowels and consonants with secondary articulations participate in vowel harmony (CHAPTER 118: TURKISH VOWEL HARMONY), showing that vowel harmony is not based on syllable position (Levi 2001). In contrast, glides do not participate in vowel harmony, suggesting that they must be featurally distinct from vowels. Furthermore, phonemic glides in clusters force epenthesis (e.g. /mejl/ → [mejil] 'tendency'; Lewis 1967). Like Yawelmani and Tahltan, there is no evidence in Turkish suggesting alternations between vowels and glides.

3.4.6 *Type VI: Alternating underlying vowel and non-alternating underlying glide*

Type VI languages contain a vowel that alternates similar to Type III languages. In addition, Type VI languages contain a phonemic glide that only surfaces as a glide. Languages of this type include Karuk, Sundanese, Pashto, and Pulaar (Levi 2004).

(29) *Type VI*



In Karuk, the realization of an underlying vowel as a vowel or a glide is predictable based on syllabification parameters in the language. Tautosyllabic consonant clusters are banned, making the maximal syllable template CVC (Bright 1957). Thus, all medial CC sequences must be syllabified as VC.CV. The absence of sequences

The difference between phonemic and derived glides is also apparent in their behavior before vowel-initial suffixes. Phonemic /w/ patterns with /r/ and surfaces before vowel-initial suffixes as in (33a) and (33b). In contrast, morpheme-final derived glides pattern with other vocalic segments, exhibiting deletion and coalescence before vowel-initial suffixes, as in (33c).

(33)	a.	*Phonemic glide /w/*				
		/ikiiw/	→	[ikjiw]	'to fall'	
				[ikjíw-iʃ(rih)]	'to fall down'	
				[ikjiw-ûɪr]	'to fall for a long time'	
		/iw/	→	[ʔiw]	'to die'	
				[ʔíw-apuh]	'dead'	
			cf.	[ʔíːm-kara]	'to drown'	
	b.	*Other consonants*				
		/isʧur-ahi/	→	[iʃʧur-ahi]	'to be cracked'	
		/paθrih-a/	→	[paθrih-a]	'rain (N)'	
	c.	*Final* /u/ → [w]				
		/ikriu/	→	[ikriw] 'to sit'		
				/ikriu-is(rih)/ →	[ikrîːʃ(rih)]	'to sit down'
					*[ikriw-iʃ(rih)]	
				/ikriu-at/ →	[ikrêːt]	'lived'
					*[ikriw-at]	
		/ihiiu/	→	[ihjiw] 'to shout'		
				/ihiiu-unis/ →	[ihjûːniʃ]	'to shout at'
					*[ihjiw-uniʃ]	

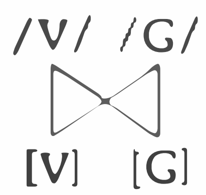
Other Type VI languages include Sundanese, Pashto, and Pulaar. In Sundanese, segments are divided into those that undergo nasal harmony and those that do not (Robins 1957; Cohn 1990, 1993). As expected, derived glides pattern with vowels in undergoing nasal harmony (e.g. /ɲiar/ → [ɲĩj̃ãr] 'seek-ACTIVE'). In contrast, phonemic glides block nasal harmony (e.g. /ŋajak/ → [ŋãjak] 'sift-ACTIVE'). An analysis of Sundanese that recognizes a distinction between two types of glides and the relationship between derived glides and their vowel source on the one hand and phonemic glides on the other simplifies the harmony system (Levi 2008a). In Pashto, glides surface in reverse sonority clusters (e.g. [wradz] 'day' (Penzl 1955); see also CHAPTER 49: SONORITY), where they would otherwise be unexpected if they were derived from vowels (Levi 2004). In other environments, glides and vowels surface predictably, suggesting that vowels can surface as either vowels or glides. In Pulaar, glides differ in how they behave in consonant alternations (Paradis 1992); one set of labial glides alternates with labial stops while another set alternates with velar stops, suggesting a distinction between two types of glides. Similarly, palatal glides are divided into two sets: those that alternate with velars and those that alternate with palatal stops. Using evidence from consonant gradation, vowel harmony, vowel epenthesis, and gemination, Levi (2004) argues that glides that alternate with labial or palatal stops are phonemic, while those that alternate with velar stops are derived.

French is another language that is often cited as including both derived and phonemic glides (Spence 1971; Valdman 1976; Walter 1977; Noske 1996; Hannahs (i.e. glides surfacing as vowels) as different from underlying vowels (CHAPTER ##: DERIVED ENVIRONMENT EFFECTS).

3.4.8 *Type VIII: Alternating underlying vowels and glides*

Type VIII languages show a balanced pattern where both phonemic glides and vowels can surface as vowels or glides. Type VIII languages fit the generalization mentioned in §3.4.4 that a phonemic glide can only alternate if the vowel also alternates. Imdlawn Tashlhiyt Berber is an example of this type of language (Levi 2004).

(36) *Type VIII*



Evidence for predictable realization of underlying vowels comes from syllabification, as in (37) (Elmedlaoui 1985: 27).

(37)	/i-kti/	[i-kti]	'he remembered'
	/i-ura/	[j-ura]	'he wrote'

Evidence from syllabification of other segments and from sonority plateaux suggests a systematic pattern (Dell and Elmedlaoui 1985), where the first member of a plateau surfaces as syllabic (38) (Elmedlaoui 1985: 39).

(38)	/i-sui/	[i-suj]	'he passed'
	/t-ikiu-t/	[t-ikiw-t]	'kind of plant'

Some words contradict this pattern. In these cases, the second of two vocoids surfaces as syllabic. Following Dell and Elmedlaoui, Levi (2004) analyses the first high vocoid of these sequences as a phonemic glide, making the sequence a sonority rise, rather than a plateau. Thus, the difference between the forms in (38) and (39) is that the former contain /CVV/, while the latter contain sequences of /CGV/ (Elmedlaoui 1985: 42).

(39)	/i-swi/	[i-swi]	*[isuj]	'excrement'
	/aˁ-kˁjˁuˁdˁ/	[aˁ-kˁjˁuˁdˁ]	*[aˁkˁiˁwˁdˁ]	'braid (hair)'

Imdlawn Tashlhiyt Berber is especially interesting because it allows any segment to surface as syllabic, including phonemic glides (Elmedlaoui 1985). Data in (39) and (40) show that phonemic glides can surface as glides or vowels.

(40)	/nw/	'be cooked'	[nwa]	PERFECTIVE
			[nwi]	NEGATIVE
			[nu]	AORIST

Taken together, these data provide evidence for a high vowel that surfaces as either a vowel or a derived glide and for a phonemic glide that surfaces as a glide or

16 Affricates

Yen-Hwei Lin

1 Introduction

An affricate is a single segment that has a complete closure with a fricative or delayed release. Like stops, affricates consist of a closure phase followed by a release phase, but unlike stops, the release of affricates contains additional supra-laryngeal properties. Phonological evidence based on phonotactics and sonorancy is often used to distinguish affricates from homorganic bisegmental stop + fricative sequences. For example, in English no stop + fricative sequences can occur in word-initial or syllable-onset position, but [ʧ] and [ʤ] can, and hence are treated as affricates. Kehrein (2002: 5–6) groups affricates into four types as in (1), but considers them to be stops phonologically.

(1) *The phonetic class of affricates*

   a. Orally centrally released strident affricates: e.g. [ts], [ʧ], [tɕ]
   b. Orally centrally released non-strident affricates: e.g. [pɸ], [tθ], [kx]
   c. Orally laterally released affricates: e.g. [tɬ]
   d. Nasally released affricates: e.g. [pm], [tn], [kŋ][1]

In phonological theory, the formal characterization of affricates has been a much-debated issue (Clements and Hume 1995: 256; see Kim 1997: 23–38 and Kehrein 2002: 11–15 for reviews of different proposals). What is at issue is how affricates should be represented to account for the way they pattern in phonological processes and segmental contrasts. More specifically, what phonological feature(s) should be adopted to represent affricates and how do affricates behave in phonological patterning? First, if affricates are represented as consisting of a stop component followed by a fricative component, one expects affricates to pattern with stops at their left edges and with fricatives at their right edges. Second, if the two components are unordered phonologically, affricates can pattern with stops or fricatives at either edge in phonological processes. Third, if affricates are phonologically just stops, they are expected to form a natural class with stops,

[1] Due to space limitation, I will not discuss nasally and laterally released affricates specifically, and for ease of reference, I will refer to affricates as segments with a fricative release.

but crucially not with fricatives. If affricates are phonological stops, how are they to be differentiated from simple stops? Under the first approach, affricates have the same representation in phonology and phonetics, whereas under the second and third approaches, the phonological and phonetic representations are different, which leads to the question of when the stop–fricative sequence becomes linearly ordered or the fricative release projected.

This chapter describes different positions with respect to these questions and issues through presentation of relevant data and arguments. In terms of the phonological representation of affricates, I classify the approaches to affricates into three major categories: (i) the *Stop Approach*, (ii) the *Affricate Approach*, and (iii) the *Complex Segment Approach*. The Stop Approach can be traced back to Jakobson *et al.* (1952: 24), where affricates are treated as strident stops, specified as [−continuant, +strident]. One problem with this proposal is that not all affricates are strident. Chomsky and Halle (1968: 329) therefore propose to represent all affricates as [−continuant, +delayed release]. This then accords affricates an independent phonological status, contrasting with stops, which are [−continuant, −delayed release], and fricatives, which are [+continuant, −delayed release]. This is the Affricate Approach (see Kehrein 2002: 11). The feature [delayed release] was later replaced by [+continuant] (Campbell 1974), leading to the Complex Segment Approach, in which affricates form a natural class with stops and with fricatives. Since [delayed release] has not been in common use in recent phonological literature, I focus in this chapter on proposals within the Complex Segment Approach and the Stop Approach since the early 1980s.

The proposals within the Complex Segment Approach differ in (i) how the stop and fricative components of affricates are organized and represented, and (ii) whether or not there is an asymmetrical relationship between the two components, and if there is, which component is the head. Within the Stop Approach, affricates are treated as stops with some additional feature(s) (e.g. [+strident]) manifested as part of the fricative release in articulation, and the proposals differ in what those additional features are in distinguishing affricates from simple stops, and whether the fricative release is projected in the phonological or phonetic component.

Some of the proposals also make different predictions regarding *edge effects*, i.e. cases where affricates pattern with stops with regard to rules sensitive to their left edges and with fricatives with regard to rules sensitive to their right edges. The general assumption is that if or when the stop and fricative components are ordered or when the fricative release is projected, affricates are expected to exhibit edge effects.

In what follows, §2 reviews the proposals and data supporting the Complex Segment Approach, §3 presents the evidence and proposals for the Stop Approach, and §4 addresses the question regarding the point in the derivation at which the stop and fricative components are ordered or the fricative release is projected. In §5, additional data relevant to the debate are discussed, and the final section concludes with brief remarks on remaining issues.

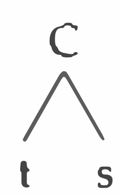
2 The Complex Segment Approach

What I refer to as a complex segment is defined as a single segment with multiple articulations in manner or place features, and hence covers both *contour segments*, such as affricates and prenasal stops, and *complex segments*, such as labial-velars, as proposed by Sagey (1986: §2.4). For Sagey, the multiple articulations in a contour segment are phonologically ordered, but those in a complex segment are not (see also CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION). For our purposes, I make a distinction between complex segments with internal ordering and those without.

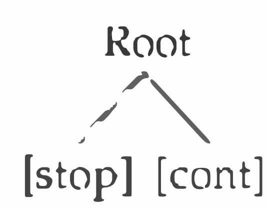
The major proposals under the Complex Segment Approach are summarized in (2) and (3). The *contour segment* analysis in (2a), in which the ordered stop and fricative are linked to one single skeletal slot, and the *contour feature* analysis in (2b), in which the ordered [stop] and [cont] features[2] are linked to a single segmental root node, are analogous to the analysis of contour tones in autosegmental phonology (Goldsmith 1976; CHAPTER 14: AUTOSEGMENTS; CHAPTER 45: THE REPRESENTATION OF TONE); e.g. a falling tone consists of a high tone at the left edge and a low tone at the right edge and is linked to one single tone-bearing unit. Evidence supporting this position comes from data showing edge effects for affricates.

(2) *Affricates as complex segments with internal ordering*

a. Clements and Keyser (1983)



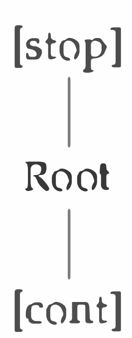
b. Sagey (1985)



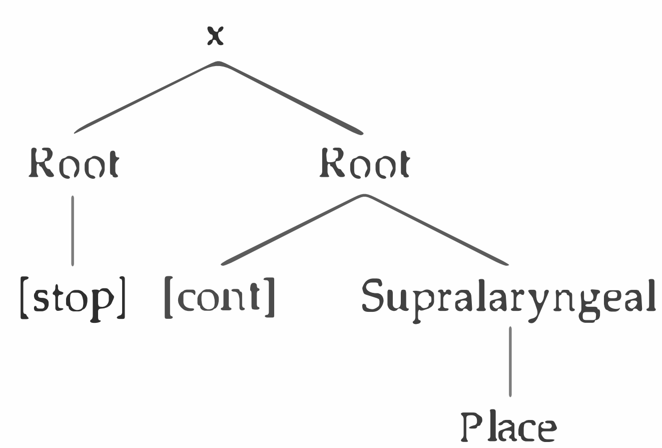
With [stop] and [cont] on separate tiers, the two stricture features are phonologically unordered in the *unordered feature* analyses in (3). Affricates thus do not exhibit edge effects, and can pattern with stops or fricatives on either edge.

(3) *Affricates as complex segments without internal ordering*

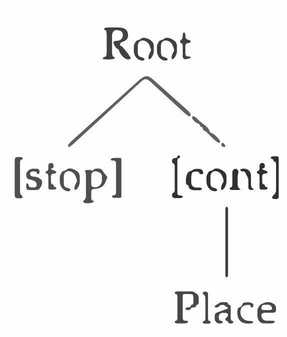
a. Lombardi (1990)



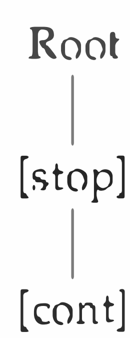
b. Hualde (1991)



c. van de Weijer (1992, 1996)



d. Schafer (1995)



[2] For the rest of this chapter, I use [stop] for [−continuant] and [cont] for [+continuant] for ease of unified exposition in discussing different proposals. See also CHAPTER 13: THE STRICTURE FEATURES; CHAPTER 28: THE REPRESENTATION OF FRICATIVES.

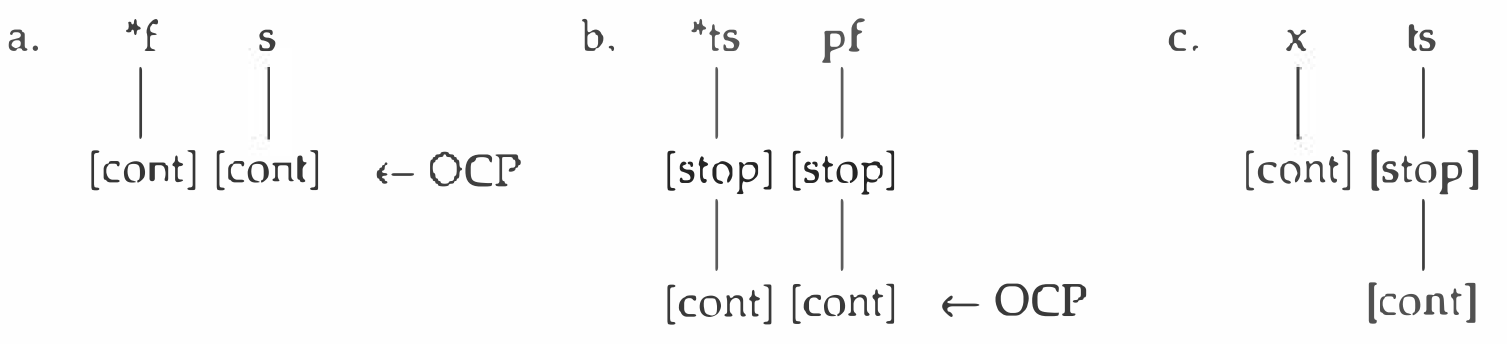
phonemic inventory of Nisgha and the rule is blocked by Structure Preservation (Kiparsky 1985).

Strengthening also shows that affricates pattern with stops. For example, in Tswana, continuants are turned into stops or affricates after a specific nasal morpheme (Schafer 1995: 71): /N+βona/ → [mpona] 'see me', /N+sixa/ → [ntshixa] 'cut me', which is analyzed as spreading [stop] from the nasal to the continuants, resulting in stops or affricates.

Concluding that stops and affricates spirantize, and fricatives strengthen, Schafer argues that encoding the [stop] feature as the head stricture accounts for the patterning of stops and affricates in both strengthening and spirantization, whereas a principled explanation of such patterning is not available in a non-configurational representation.

The second piece of evidence comes from the restrictions on German morpheme-internal consonant clusters (Schafer 1995: 80–84). Fricative clusters are disallowed (e.g. *[f–s], *[s–v], *[ʃ–z]), as are affricate clusters (e.g. *[ts–pf]); however, fricative–affricate clusters are permissible (e.g. [f–ts] in *seufzen* [zoiftsən] 'sigh' and [x–ts] in *jauchzen* [jauxtsən] 'cheer'). As illustrated in (10a) and (10b), the OCP on [cont] can apply only to those [cont] features on the same tier. Since the [cont] feature of the affricate is secondary, it is not on the same tier as the [cont] feature of the fricative (10c). I will come back to the German data in §5.1.

(10)



Schafer demonstrates that affricates persistently pattern with stops phonologically. Assigning [stop] as the head stricture of the affricate means that the proposal actually shares some similarities with the Stop Approach. The main difference is that the [cont] feature is still retained in the representation of the affricate as a secondary stricture feature, and can be referred to by a rule or constraint.

2.3 *Summary and predictions of the Complex Segment Approach*

The different proposals under the Complex Segment Approach share the claim that both [stop] and [cont] are contained in the phonological representation of affricates, but they differ in the relationship between the two stricture features. The major prediction made by the Complex Segment Approach is that affricates can pattern with either stops or fricatives phonologically. If the two features are ordered (§2.1), affricates are expected to show edge effects. If the two features are unordered with equal status (§2.2.1–§2.2.2), affricates can pattern with stops or fricatives on either edge. Under the unordered approach, there are two proposals that claim an asymmetrical relationship between the two stricture features. The first maintains that [cont], but not [stop], dominates place features, which predicts that a rule that targets a [stop] segment with place features does not affect affricates (§2.2.3.1).

(15) *Polish strident assimilation*

a.	[−son, Cor, +ant] → [αPlace] / __ [+strid, αPlace]		
b.	*rozszerzyć*	[s ʃ] ~ [ʃ ʃ]	'broaden'
	okaz cierpliwości	[s tɕ] ~ [ɕ tɕ]	'example of patience'
	podczas działań	[z dʑ] ~ [ʑ dʑ]	'during the action'
c.	*chłopiec szukał*	[ts ʃ] ~ [ʧ ʃ]	'the boy was seeking'
	occie	[ts tɕ] ~ [tɕ tɕ]	'vinegar (LOC SG)'
d.	*twardszy*	[t ʃ] ~ [ʧ ʃ]	'harder'
	oddzielić	[d dʑ] ~ [dʑ dʑ]	'separate'

This can be viewed as an anti-edge effect, in which affricates and fricatives pattern together as triggers in a rule referring to the left-edge context, and hence as a counterexample to the ordered version of the Complex Segment Approach (cf. §2.2.1). This patterning of affricates with fricatives, however, can be attributed to shared [+strident] rather than [cont].

Additional examples illustrating the patterning of affricates with fricatives in terms of stridency include (i) strident dissimilation in Baztan Basque (Kim 1997: 49, 54–55), in which a strident affricate dissimilates to [−strident] after a strident fricative (e.g. /as+tsen/ → [asten] 'to raise'), (ii) vowel insertion between strident fricatives/affricates and -s under English plural formation (§2.2.2; Kehrein 2002: 55–56), and (iii) Hungarian strident coronal place assimilation (Kim 1997: 66–67), which assimilates coronal strident fricatives/affricates in place with the following coronal strident segment: e.g. /egeːs+ʃeːg/ → [ʃ+ʃ] 'health', /egeːs#ʧaːlaːd/ → [ʃ#ʧ] 'entire family', /nolts+ʃaːg/ → [ʧ+ʃ] 'eightness', /makaʧ#tsitsa/ → [ts#ts] 'obstinate kitten'.

3.2 *Re-analyses of cases where affricates are specified as* [cont]

One major obstacle for the Stop Approach is the presence of cases where affricates are claimed to be specified as [cont]. The first type of evidence for specifying affricates as [cont] is based on morpheme structure constraints and consonant harmony involving fricatives and affricates to the exclusion of stops. Recall that for Modern Yucatec Maya morpheme structure restrictions, Lombardi (1990: 389–390) proposes an OCP constraint on [cont] that affects both fricatives and affricates (§2.2.2), arguing that affricates must be specified as [cont]. Kehrein (2002: 46–51; cf. Rubach 1994: 141, fn. 24) suggests that the feature [strident] or Coronal (if coronal stops are unspecified for place) can be used instead to replace [cont] for the analysis, a solution also applicable to cases of sibilant/coronal harmony in languages like Tahltan (Shaw 1991; §3.4 below) and Basque (Hualde 1991; van de Weijer 1996; see §2.2.2).[9]

The second type of evidence comes from stop deletion/debuccalization (§2.2.1). For example, in Basque (5), a stop deletes before a stop, but an affricate loses the [stop] feature and becomes a fricative, and in Yucatec Maya, a stop becomes

[9] As shown in (10) in §2.2.3.2, Schafer (1995) also makes use of the OCP on [cont] to account for German consonant cluster restrictions. However, the feature [+strident] or Coronal cannot be used since the affricate [pf] has neither, and non-permissible affricate clusters such as [ts-pf] cannot be ruled out. I will come back to the German case in §5.1.

[h] and an affricate becomes a fricative before a homorganic stop. A unified account of stop deletion/debuccalization and affricate fricativization involves the deletion of the [stop] feature so that the stop becomes deleted or debuccalized, leaving the affricate with the [cont] feature. Kehrein (2002: 51–55; cf. Rubach 1994: 141, fn. 24) proposes to treat the situation with two independent rules: simple stops delete (or debuccalize), but strident stops (i.e. affricates) spirantize. He also points out that if [stop] deletion were the correct unified generalization, one could imagine a logically possible process of [cont] deletion in which fricatives delete and affricates become stops, and yet such a process is unattested.[10] In addition, the fact that in Yucatec Maya stops become [h] seems to suggest a general spirantization account: stops → fricative [h] and affricates → fricatives. Kim (1997: 46–59) analyzes stop deletion in Baztan Basque as a unified process of spirantization motivated by the OCP constraint on [stop]: both simple stops and strident stops become fricatives through dissimilation or spirantization, but the fricatives derived from simple stops, e.g. [x] from [k], [ð] from [d], and [θ] from [t], are deleted due to Structure Preservation (Kiparsky 1985; CHAPTER 76: STRUCTURE PRESERVATION: THE RESILIENCE OF DISTINCTIVE INFORMATION), i.e. the language does not have these fricatives.

The third type of potential problem concerns the affrication of stops before high vowels, which is typically analyzed as spreading [cont] from the vowel to the preceding stop, creating an affricate with both [stop] and [cont]: e.g. /tat+i+mas+u/ → [tatʃimasu] 'to stand (POLITE PRES)', /tat+u/ → [tatsu] 'to stand (PRES)' in Japanese (Clements 1999: 287; Kim 2001: 90). Under the Stop Approach, processes of affrication are argued to be feature insertion of [+strident] or addition of fricative noise between the stop and the vowel due to a phonology–phonetics mismatch (Kim 1997: 39, 2001: 102; Clements 1999: 289; see also CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). This re-analysis is based on the observation that the release transition from a simple stop to a high vowel has the turbulence and spectral properties similar to the noise of a strident fricative, and can be interpreted as the release of a strident affricate (Kim 1997: chs. 3–4, 2001; Clements 1999: 287–289 and references therein).

In sum, for all three types of data that seem to require the [cont] specification for affricates, proponents of the Stop Approach offer re-analyses claiming that affricates need not bear [cont].

3.3 *Phonological contrasts*

One common argument against treating affricates as strident stops is the fact that not all affricates are strident (Chomsky and Halle 1968: 329; Lombardi 1990: 409), e.g. [tθ] in Tahltan (Shaw 1991) and [pf] in German. Under the Stop Approach, place features such as [distributed], [laminal], or Labial are typically used to specify non-strident stops (e.g. Shaw 1991: 146; Kim 1997: 39; Kehrein 2002: 9–10). A labio-dental affricate like [pf] has sometimes been proposed to be a [+strident] stop, in contrast to a bilabial stop (Kim 1997: 106–108).[11]

[10] An anonymous reviewer comments that fricativization in Basque (Hualde 1991: 134f.; van de Weijer 1992: 142–143), where affricates become stops after fricatives/affricates, comes close to this. This process, however, does not delete fricatives after fricatives/affricates.

[11] This of course raises the question of how the feature [strident] should be defined, which I will not pursue here.

Examination of cross-linguistic phonological contrasts among affricates and stops leads Clements (1999) and Kehrein (2002) to argue that (i) affricates are phonological stops which bear no [cont] feature and are distinguished from non-affricated stops by place features or manner features such as [strident], [lateral], [nasal], and (ii) affrication or fricative release is best accounted for at the phonetic level when the phonological feature combinations are spelled out as sequential phonetic events, which Kehrein (2002: ch. 2) proposes to be a phonetic strategy for increasing the perceptibility of phonological contrasts.

The main finding is that strident, lateral, and nasal affricates contrast with stops, but non-strident affricates do not. Coronal affricates can contrast with stops at the same place of articulation in terms of stridency in languages, e.g. the contrast of simple stop, strident affricate, and strident fricative: /t ts s/ in Hamer and /t ʈʂ ʂ/ in Burushaski (Kehrein 2002: 17; cf. Clements 1999: 278–279), as can lateral and nasal affricates, e.g. the contrast of simple stop, lateral affricate, and lateral sonorant /t tɬ ɬ/ in Navajo and the contrast of simple stop, nasal affricate, and nasal sonorant /b bm m/ in Zing Mumuye (Kehrein 2002: 18–19).

On the other hand, non-strident affricates occur as allophones of stops, or as phonetic realizations of aspirated stops or of stops contrasting within a major place category (Kehrein 2002: 21). That is, languages do not contrast stops and non-strident affricates. Examples of allophonic variation include free variation of [k] and [kx] for some speakers of Thai, and allophonic derivation of bilabial affricates from bilabial stops before [u], e.g. /p/ → [pɸ] /__ /u/ in Lahu (Kehrein 2002: 22). In addition, the aspirated stops in those languages with laryngeal contrasts are likely to show affrication; e.g. in Navajo, the three-way /k k' k^h/ contrast is realized phonetically as [k k' kx^h]. Finally, apparent contrasts between stops and non-strident stops (e.g. /p/ *vs.* /pf/ in German, and /t/ *vs.* /tθ/ in Chipewyan) are contrasts at minor places of articulation, e.g. bilabial *vs.* labio-dental within the major category of Labial in German,[12] and apical [t] *vs.* laminal [tθ] in Chipewyan within the category of Coronal (Kehrein 2002: 23, 25; cf. Clements 1999: 275). Additional examples include palatal /cç/ *vs.* /k/ in Irish and /k/ *vs.* uvular /qx/ in Wolof within the Dorsal category (Kehrein 2002: 25; cf. Clements 1999: 283–285). In some cases, what were claimed to be palatal non-strident affricates in contrast with palatal stops are actually alveo-palatal strident affricates, e.g. /cç/ should be /t̠ɕ/ in Komi (Kehrein 2002: 28–29; Clements 1999: 281–282). Kehrein (2002: 29–30) thus concludes that (i) a stop and its homorganic non-strident affricate are never in contrast, (ii) non-strident affricates are phonetic realizations of their corresponding stops, and (iii) a stop is often realized as an affricate when it is in contrast with another stop within the same primary articulator with small place differences.

3.4 *Natural classes*

In all the analyses of affricates considered above, affricates have a stop component, and hence form a natural class with stops. Many of the examples we have seen earlier fall into this category. The Stop Approach differs from the Complex

[12] As pointed out by an anonymous reviewer, it is unclear which feature should be used to differentiate /p/ and /pf/. If the traditional feature [strident] is not used, an alternative must be considered (Clements 1999: 283).

suggesting an edge effect (cf. Piro §5.2 below). The solution offered by Schafer is that *affricate–affricate clusters are ruled out in the phonology when [stop] and [cont] are still unordered, but the lack of the *affricate–fricative clusters occurs in the phonetic component when the secondary [cont] stricture becomes ordered after [stop]. It is not specified, however, whether there is independent evidence in German suggesting that some restrictions must be phonological and some must be phonetic.

5.2 *Piro obstruent co-occurrence restrictions*

Following up on Steriade's (1989) initial analysis of consonant clusters in Piro (see also Kenstowicz 1994: 502–503), Lin (2005) conducts a comprehensive examination of Piro consonant co-occurrence restrictions, based on the data in Matteson (1965). Excluding a couple of minor restrictions and accidental gaps, the major generalizations held for obstruents are given in (17). The obstruents in Piro include /p t k ts tʃ tç s ʃ ç/, with /tç/ and /ç/ as non-strident palatal segments specified as both Coronal and Dorsal. The restrictions apply in underlying representation and/or during the derivation. When non-permissible clusters occur through morpheme concatenation and boundary vowel deletion, the first consonant of the cluster deletes, with compensatory lengthening of the preceding vowel (Matteson 1965: 33–34; Lin 1997).[16]

(17) *Piro obstruent co-occurrence restrictions*

a. *[p–p] *[t–t] *[k–k] *fricative–fricative *affricate–affricate
underlying morpheme and derivational restrictions (33)
e.g. nika 'he eats' – ka 'passive' → nikka → ni:ka 'he is eaten'
kose 'to pull' – çe 'always' – ta → kosçeta → ko:seta 'to always pull'
çitçi-tʃi → çitçtʃi → çi:tʃi 'foot'

b. *[t]–affricate
underlying morpheme and derivational restrictions (33)
e.g. hitsrukate-tʃi → hitsrukattʃi → hitsruka:tʃi 'chief'

c. affricate–[t] allowed
e.g. hajehitçtokota 'to hate secretly' (433)

d. fricative–affricate allowed
e.g. kaʃtʃa-ta 'to grab and eat' (350)
wanestsi 'approximation' (383)
stʃeha 'curl' (423)

e. *strident affricate–strident fricative
underlying morpheme restrictions

f. [tç]-fricative and [ç]–affricate allowed
e.g. haʃitçʃima 'a kind of fish' (256)
hitççetyawaka 'custom' (273)
hiçtçipaka 'to sway, reel' (393)

The interests and challenges of the data are: (i) *affricate–affricate clusters are ruled out as a class (17a), suggesting that these affricates may either be Coronal stops to be ruled out together with *[t–t] or have unordered stricture features similar to Schafer's (1995) analysis of German (§2.2.3.2); (ii) however, the edge

[16] The numbers after the examples in (17) indicate the page numbers in Matteson (1965).

effects exhibited by *[t]–affricate *vs.* affricate–[t] (17b) and (17c) and by fricative–affricate *vs.* *strident affricate–strident fricative clusters (17d) and (17e) suggest that [cont] must be present in the affricate and ordered at the right edge; (iii) affricate–fricative clusters are prohibited only when both are strident (17e) and (17f), which suggests the patterning of affricates and fricatives in term of stridency (Rubach 1994; Kim 1997), but this patterning involves edge effects, since strident fricative–strident affricate clusters are allowed (17d). As in Schafer's analysis of German consonant clusters (§5.1), one single affricate representation coupled with only one level of constraint evaluation seems impossible. If affricates are represented as ordered [stop–cont], the OCP on [cont] that rules out *fricative–fricative clusters would also rule out well-formed [tç]–fricative clusters. If the two features are unordered, the OCP on [cont] would rule out well-formed fricative–affricative and [tç]-fricative clusters. If affricates are just stops, the OCP on homorganic [stop] that rules out *[t–t] and *[t]–affricate, together with *[p–p] and *[k–k], would also incorrectly rule out well-formed affricate–[t] clusters.

Lin (2005) proposes an optimality-theoretic (Prince and Smolensky 1993) account in which (i) affricates are stops underlyingly and in the lexical phonology but have fricative release at the right edge post-lexically, and (ii) different constraints are active at these two different levels.[14] The independent evidence provided for the lexical–post-lexical division in Piro comes from cyclic boundary vowel deletion followed by cluster simplification, which shows that fricative clusters such as [s–ç] are simplified to [ç] cyclically in the lexical phonology but stop clusters such as [k–k] are allowed lexically but prohibited and simplified to [k] post-lexically (Lin 1997, 2005: 133–134).

The relevant constraints and lexical *vs.* post-lexical constraint rankings proposed by Lin (2005: 131–133) are given in (18).

(18) *Constraints and constraint rankings*

a. *Relevant constraints*
C-Faith
The corresponding consonants in the input and output are identical.
OCP-[cont]
Adjacent [cont] features are prohibited.
OCP-[stop] & OCP-Pl
Adjacent [stop] and identical major place features are prohibited.
OCP-aff
Adjacent [stop, cont] segments are prohibited.[15]
OCP-[cont] & OCP-[+strid]
Adjacent [cont] and [+strident] features are prohibited.

b. *Lexical constraint ranking*
OCP-[cont] >> C-Faith >> OCP-[stop] & OCP-Pl, OCP-aff, OCP-[cont] & OCP-[+strid]

c. *Post-lexical constraint ranking*
OCP-[stop] & OCP-Pl, OCP-aff, OCP-[cont] & OCP-[+strid] >> C-Faith >> OCP-[cont]

[14] See Lin (2005: 137–139) for an alternative analysis that makes use of Schafer's (1995) [stop]-as-head model, which, as in the German case (§5.1), also requires two levels of evaluation.

[15] This can be interpreted as an OCP effect against more than one marked segment within a local domain (Alderete 1997; Ito and Mester 2003).

(19) *Piro phonetic transitional vowel and syllabic consonant*

a.	stop–stop	[t^{ə}po]	'curve'
	stop–fricative	[k^{ə}su]	'. . .'s house'
	fricative–stop	[s̩kota]	'low abdomen'
b.	stop–affricate	[p^{ə}ʧowi]	'an edible root'
	fricative-affricate	[joçtçita]	'he changes course'
c.	affricate–stop	[ʧ^{ə}kotu]	'cebus monkey'
	affricate–fricative	[peʧiʧ^{ə}çeta]	'he always lies in wait'

This looks like an unexpected case of anti-edge effects, because the process refers to the right-edge context of the first consonant, and yet affricates pattern with stops rather than fricatives.

The process applies also to sonorants, which always show up as syllabic consonants when followed by any consonant, and a transition from a fricative to a sonorant leads to transitional vowel insertion (e.g. [smota] → [s^{ə}mota] 'blunt point'), unlike the syllabic fricatives in (19a) and (19b). Transitional vowel insertion always applies between a stop/affricate and any consonant. Lin (2005) gives a generalized sonority-based analysis in which (i) stops and affricates as a group are less sonorant than fricatives, which in turn are less sonorant than sonorants, (ii) a transitional vowel is inserted when the first consonant is a stop/affricate or it is less sonorant than the second consonant, and (iii) the first consonant becomes syllabic if it is a sonorant or it is more sonorous than the second consonant. It is concluded that if stricture properties determine relative sonority of segments, as is commonly assumed, the fact that affricates and stops belong to the same sonority class suggests that the stop part of the affricates is primary and the fricative part is secondary even at the phonetic level.

Alternatively, it is also likely that affricates, like stops but unlike fricatives and sonorants, have release positions (Steriade 1993; (12) in §3), so stops and affricates behave in the same way when the releases are not masked by the next consonant and thus perceptually interpreted as transitional vowels. Whatever the analysis and interpretation of the data, this phonetic patterning of affricates with stops in Piro may indicate the fundamental nature of affricates as being stops.

6 Concluding remarks

The Stop Approach has put forward cogent arguments and appears to have acquired a strong following in recent years. Some studies from child language acquisition, such as Menn (1973) on English and Cook (2006) on Chipewyan, seem to provide additional support to the affinity between stops and affricates by showing that stops and affricates are acquired earlier than fricatives and that fricatives are often replaced by stops or affricates in children's speech (cf. Jakobson's 1941 claim that stops and fricatives are acquired before affricates). Moreover, some studies exploring the interaction between phonetics and phonology indicate that the fricative component of the affricate is phonetic in nature. For example, as mentioned in §3.2, Clements (1999) and Kim (1997, 2001) provide a phonetically based explanation for high vocoid conditioned phonological assibilation (e.g. /t/ → [ʧ] / __ [i]): the affricate is not created by assimilating [cont] from the vowel

17 Distinctive Features

Jeff Mielke

1 Introduction

Distinctive feature theory is an effort to identify the phonetic dimensions that are important for lexical contrasts and phonological patterns in human languages. The set of features and its explanatory role have both expanded over the years, with features being used to define not only the contrasts but the groupings of sounds involved in rules and phonotactic restrictions, as well as the changes involved in rules. Distinctive features have been used to account for a wide range of phonological phenomena, and this chapter overviews the incremental steps by which the feature model has changed, along with some of the evidence for these steps. An important point is that many of the steps involve non-obvious connections, something that is harder to see in hindsight. Recognizing that these steps are not obvious is important in order to see the insights that have been made in the history of distinctive feature theory, and to see that these claims are associated with differing degrees of evidence, despite often being assumed to be correct.

The structure of the chapter is as follows. §2 describes the series of non-obvious claims that led to modern distinctive feature theory, and §3 briefly describes the particular features that have been proposed. §4 reconsiders some of the earlier claims, and §5 looks at some ongoing investigations.

2 Building a model of phonological behavior

Distinctive feature theory began largely as a model for reducing the number of phonological contrasts in a language, and the feature system that was developed for this purpose was gradually embellished in order to provide an account for more and more facts about sound patterns and typology. Trubetzkoy (1939: 66–89) developed the study of oppositions between speech sounds, which grew into the study of distinctive features. After Trubetzkoy's death in 1938, the early years of distinctive feature theory were associated most with Roman Jakobson.

2.1 Reducing contrasts with (mostly) binary features

Jakobson (1942: 235) hypothesized that differences that on their own are not meaningful, such as the differences between phonemes, are very demanding on perception and memory, and he concluded that the number of "primordial and unmotivated values" should be minimized. For example, the eight-vowel inventory of Turkish (/i ɨ y u e ɑ ø o/) involves 28 binary relations, as illustrated in Figure 17.1. Jakobson observed that many of these relations are essentially the same, e.g. the difference between /i/ and /y/ is basically parallel to the difference between /e/ and /ø/. Both relate an unrounded vowel and a rounded vowel which are otherwise largely the same. In the figure, solid lines with black circles at the end are used to represent independent contrasts. The contrasts between the eight vowels can be reduced to three orthogonal dimensions (height, backness, and rounding), and any of the 28 binary relations can be represented as differences along one or more of these three dimensions (see CHAPTER 2: CONTRAST). In this way, 28 binary oppositions can be captured by three binary distinctive features. The vowel inventory of Turkish is a particularly clean example, because it happens to be "cubic," fully exploiting three features, but any inventory containing pairs of segments that differ from each other along similar phonetic dimensions is reducible in this way to some extent.

The assumption of binarity for these features since the early days of feature theory can be attributed in part to the influence of Information Theory (Shannon and Weaver 1949). Jakobson *et al.* (1952) argued that Information Theory provides a sequence of binary selections as the most reasonable way to analyze communication, and that language is not merely amenable to such an analysis, but is inherently structured in this way. Some pairs of words, such as *bill/pill* and *bill/dill*, involve a difference of one feature, while pairs like *bill/fell* can be treated as a difference of more than one binary feature (since the difference between /b/ and /f/ can be reduced to two independently motivated dimensions, and the difference between /ɪ/ and /ɛ/ can be reduced to one). Jakobson *et al.* (1952) noted that each of the phonetic dimensions related to a distinctive feature is continuous, but features consistently pick out two polar points. Since the dichotomous scale was believed to be the optimal code, they saw no reason why language would be organized according to a more complicated system. Some features, such as [compact/diffuse] (see next section) were considered to be equipollent, having three values (compact, diffuse, or neither), based on the fact that there seem to be three degrees of vowel height along the same dimension (e.g. /i/–/e/–/æ/).

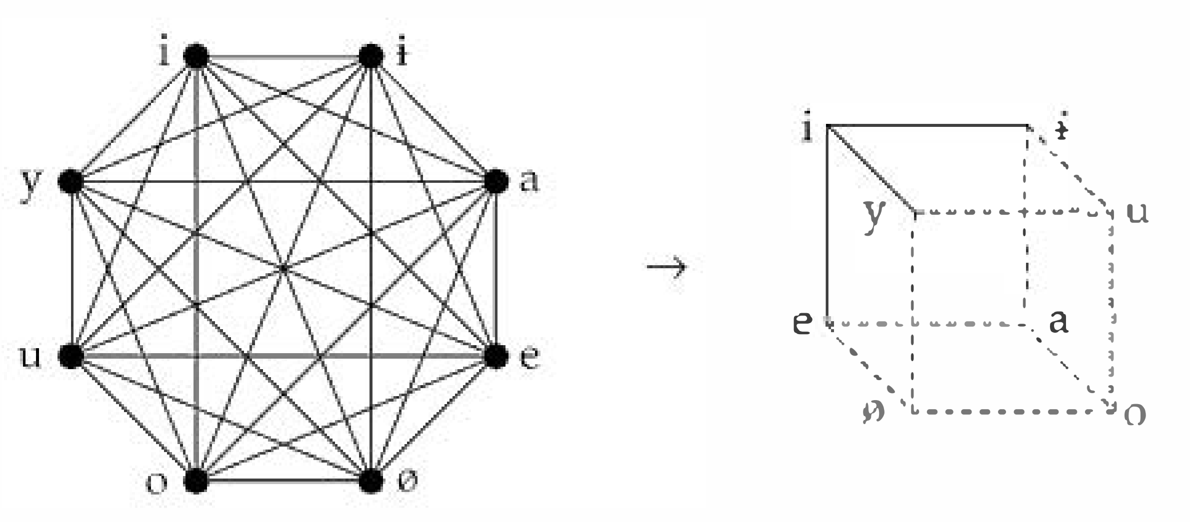


Figure 17.1 Reducing 28 binary relations to 3

The advances up to this point are summarized in (1).

(1) a. Claim: Segmental contrasts can be reduced to a smaller number of featural contrasts.
 b. Claim: Features are (mostly) binary.

Miller and Nicely (1955) provided some phonetic evidence in support of the idea that contrast between segments is divided into discrete channels. They showed that the distinctions between different consonants occupy different parts of the speech signal, and can be interfered with through different techniques for signal degradation. Miller and Nicely adopted voicing, nasality, affrication, duration (which could also be called "stridency") and place as features to distinguish /p t k f θ s ʃ b d g v ð z ʒ m n/. The oppositions associated with these features are affected differently by random masking noise, high-pass filtering, and low-pass filtering. The idea is that the information content of a message is distributed among different acoustic channels, and can consequently be selectively and independently degraded. Random masking noise degrades affrication, duration, and place distinctions more than it degrades voicing and nasality. Duration, on the other hand, is more resistant to high-pass filtering. These results are relevant to the design of telephone communication systems, but also supportive of the idea that different phonological contrasts are manifested in different parts of the speech signal. This provides evidence consistent with consolidating phonetic differences as in the Turkish example above in Figure 17.1. Although the dimensions investigated by Miller and Nicely are not the same dimension that distinguish the Turkish vowels, oppositions that are treated as parallel in phonological analyses were shown to be degradable in transmission, independent of other oppositions.

2.2 *Abstractness, universality, and innateness*

The reduction of segmental contrasts to a smaller number of distinctive features can be a purely language-particular endeavor. Jakobson (1942: 241) asserted that "[t]he description of a system of values and the classification of its elements can be made only from that system's own perspective, that is, from the perspective of the tasks that the system fulfills." He observed, though, that languages often make use of the same phonetic dimensions for contrasts (Jakobson 1942: 239). If two languages use the same phonetic dimension, then a distinctive feature in one language is fundamentally similar to the "same" feature used in the other. Jakobson contrasted this with the difference between similar-sounding phonemes in different languages. Since phonemes are treated as bundles of distinctive feature values, the phonological content of a phoneme depends on the segmental oppositions it is involved in. It was the *features*, then, that could be treated as basic building blocks, comparable across languages.

Jakobson *et al.* (1952: 40) reported that they detected only 12 distinctive features (Table 17.1) in the languages of the world "which underlie their entire lexical and morphological stock," but left open the possibility of adding more. These features were defined primarily in acoustic terms.

The universality of this kind of feature set can be interpreted as a fact about the phonetic dimensions that are available to the human vocal tract and the human auditory system rather than a claim about the features themselves. That is, if humans

Table 17.1 *Preliminaries* (Jakobson *et al.* 1952): Acoustically defined features

Fundamental source features:		
Vocalic (periodic voice source with non-abrupt onset)	*vs.*	Non-vocalic
Consonantal (acoustic zeros across the spectrum)	*vs.*	Non-consonantal
Envelope features:[a]		
Interrupted (abrupt onset)	*vs.*	Continuant
Checked (abrupt decay)	*vs.*	Unchecked
Strident (irregular waveform)	*vs.*	Mellow
Voiced	*vs.*	Voiceless
Resonance features:		
Compact (predominance of one formant region)	*vs.*	Diffuse
Grave (low end of spectrum dominates)	*vs.*	Acute (high end dominates)
Flat (formants shifted down)	*vs.*	Plain
Sharp (F2 and other formants shifted up)	*vs.*	Plain
Tense (longer and more energetic)	*vs.*	Lax
Nasal	*vs.*	Oral

[a] The term *envelope* in the feature categories refers to the "temporal envelope of sound intensity" (Jakobson *et al.* 1952: 21), i.e. how abruptly the sound starts or ends, and how smooth the intensity remains in between.

are physically limited to 12 phonetic dimensions for distinguishing sounds, then language is similarly limited in the range of distinctive features it can involve. The limiting factors are physiology and acoustics, not features. Jakobson *et al.* (1952: 31) argued that the feature [flat] (defined acoustically as downwardly shifted formants) could apply to both pharyngealization and labialization, since the two articulatory gestures have similar acoustic effects, since they appear never to be used contrastively in the same language, and since Bantu languages and Uzbek substitute labialized consonants for Arabic pharyngealized consonants in loanwords. This can be treated as an observation about acoustic and perceptual similarity or as the effects of a universal abstract feature. In later approaches, the features themselves were taken to be the basic limiting factor. While this practice of drawing explanations from (potentially innate) features themselves has been attributed to the influence of Chomsky's approach to syntax (e.g. Chomsky 1957, 1965), Halle (1983) reports that it was present all along:

> Considerations [that languages apparently do not make use of acoustic or articulatory correlates of features alone] were in our minds thirty years ago when Jakobson, Fant and I were working on *Preliminaries to Speech Analysis*, and it was these considerations that led us to draw a sharp distinction between distinctive features, which were abstract phonological entities, and their concrete articulatory and acoustic implementations. Thus, in *Preliminaries* we spoke not of "articulatory features" or of "acoustic features," but of "articulatory" and/or "acoustic correlates" of particular distinctive features. The model we had in mind was, therefore, of the type . . . where the abstract distinctive features constitute the link between specific articulatory and acoustic properties of speech sounds.

Quantal Theory (Stevens 1972, 1989) attributes the phonological oppositions used by languages to the non-linear relationships between articulatory and acoustic

2.3 *Features for alternations*

While Jakobson *et al.* (1952) focused on identifying the distinctive features used for contrasting sounds, these features have since been put to other uses in describing phonological phenomena. For example, it was discovered that the features used to define lexical contrasts could also be used to formulate phonological rules. Halle (1959: 65) describes the assimilation pattern in Russian in (3) in terms of features as follows: "Before acute compact (palatal) consonants, strident acute noncompact (dental) consonants become compact (palatal)" (see CHAPTER 71: PALATALIZATION and CHAPTER 121: SLAVIC PALATALIZATION).

(3) *Russian sibilant assimilation* (Halle 1959: 65)

/bez-ˈʧestʲij-o/	bʲiʃˈʧʲesʲtʲijə	'dishonor'
/bez-ˈʒalostʲn-o/	bʲiʒˈʒaəsnə	'pitiless'
/s-ˈʃum-om/	ˈʃʃuməm	'with noise'

This rule can be formulated in the *SPE* rule format (using *Preliminaries* features) as in (4).

(4) $$\begin{bmatrix} \text{consonantal} \\ \text{strident} \\ \text{acute} \\ \text{non-compact} \end{bmatrix} \rightarrow [\text{compact}] \;/\; \_\_ \begin{bmatrix} \text{consonantal} \\ \text{acute} \\ \text{compact} \end{bmatrix}$$

Here the feature [compact] is being used not simply to distinguish sounds from each other, but for two additional purposes. First, along with other features, it is being used to define the classes of sounds involved in a sound pattern, namely the class of sounds that become palatal in the context of the rule, and the class of sounds that trigger this change. Second, the feature [compact] is being used to define the change described by the rule. As a member of the set of distinctive features, [compact] can define contrasts, classes, and changes. These multiple functions mean that multiple types of evidence can be used to motivate a feature. Since there are often multiple ways to define the same class or the same segmental contrast, spreading of a single property is taken as particularly strong evidence for the existence of a feature.

The set of possible changes is identified with the set of possible contrasts, and the set of classes that are predicted to be involved in rules (or later, constraints) are defined as those classes of segments that share one or more feature values, to the exclusion of all other sounds in the inventory. Using the same features that define contrasts to describe classes of sounds involved in rules or to describe changes involved in rules is not a necessary step, and it interacts with the earlier claim that there is a particular feature set available to all languages.

(5) a. Claim: The distinctive features that define segmental contrasts also define changes in alternations.
    b. Claim: The same features also define classes of sounds that may be involved in alternations.

Halle (1972: 62) summarizes the goals of feature theory as follows:

> I take it that a study of the speech sounds of a given language must account for, among others, the following three sets of facts: it must yield insights into the articulatory aspects of the sounds; it must concern itself with the acoustic and psychoacoustic character of the sounds, and, finally, it must allow us to make sense of various regularities that can be observed in the behavior of different speech sounds and sets of speech sounds, regularities that have traditionally been referred to as phonological or morphophonological. The task of the student of speech sounds then is to discover a theory that will do justice to these different aspects of speech.

A further development of feature theory that was motivated in part by the account of alterations involve the number of values possessed by features. For example, Sagey (1986) argued that place features are privative (have only one value). This claim helps account for the observation that the negative values of these features do not seem to be involved in sound patterns. Dependency Phonology and Element Theory (Harris 1994; Harris and Lindsey 1995) take this further. See also CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION.

2.4 *Characterizing functional subgroupings of features*

A further development of the feature model was the hierarchical organization of features, in a way that is consistent both with the interdependence of their phonetic correlates and with the way they are grouped together in phonological patterns. In motivating constituency among distinctive features, Clements (1985: 229) observed that at least four articulatory parameters show considerable independence from each other: (a) laryngeal configuration, (b) degree of nasal cavity stricture, (c) degree and type of oral cavity stricture, (d) pairing of an active and a passive articulator:

> For example, one can maintain a certain oral tract configuration constant, say the one appropriate for producing the vowel [a], while varying the type of laryngeal configuration, or the position of the velum. Or one can hold the laryngeal configuration constant while varying the internal geometry of the oral tract.

However, within each category, it is diffiicult or impossible to vary one gesture while maintaining another. Clements observes that with the exception of laryngeal, which seems to be completely independent, there is limited mutual dependence between these parameters. Clements emphasizes that the justification for a model of feature organization must come from observed sound patterns rather than physiology, even if there is an apparent physiological basis to the organization. This move to features organized hierarchically was accompanied by a move to autosegmental rules, in which assimilation is treated as an association between a set of features forming a constituent in the hierarchy and the representation of a segment undergoing assimilation. Since there are assimilatory patterns that spread only laryngeal features, these features are grouped together as a constituent in the hierarchy, and such patterns are formalized as spreading of the laryngeal node, which dominates these features. Spreading of place features independently of other features is handled similarly. After the addition of feature organization and [vocalic], changing the definitions from acoustic to articulatory without changing much in the way of segments they apply to. In both cases, phonetic definitions were chosen to match the traditional understandings of consonants and vowels. Clements and Hume (1995) later advocated rebranding [consonantal] as its opposite [vocoid]. Chomsky and Halle (1968: 302) also added the feature [sonorant], and later entertained the idea of dropping [vocalic] in favor of [syllabic] (1968: 353–355). The difference between these two is that [+vocalic] includes both syllabic and non-syllabic liquids and excludes nasals, while [+syllabic] includes syllabic liquids and nasals, but excludes their non-syllabic counterparts. The motivation for making this change is accounting for truncation phenomena occurring before foreign words in French, whereby vowels truncate before vowels, while consonants truncate before consonants (including liquids and glides), so there is no elision in *le yogi* and no liaison in *les yogis*, as in (8). When the following word is part of the native vocabulary, glides pattern with vowels.

(8) *Elision in French native and foreign words* (Chomsky and Halle 1968: 353)

a. Native vocabulary: Glides pattern with vowels
le garçon
l'oiseau
l'enfant

b. Foreign vocabulary: Glides pattern with consonants
le yogi
**l'yogi*

The feature [syllabic] is needed to capture the distinction between the classes involved in truncation before foreign words (Chomsky and Halle 1968: 355):

> This example is, thus, of the greatest importance for our feature framework. If, as it now appears to us, [(9)] is indeed the correct formulation of the phonetic facts just discussed, and if, moreover, this example is shown to be more than an isolated instance, the feature framework will have to be revised along the lines [of replacing [vocalic] with [syllabic]].

(9) $$\begin{bmatrix} -\alpha\text{syll} \\ \alpha\text{cons} \end{bmatrix} \rightarrow \emptyset \ / \ \_\_\# \begin{bmatrix} -\alpha\text{syll} \\ +\text{foreign} \end{bmatrix}$$

History has shown that this example is indeed more than an isolated instance, and that the distinction between vowels and consonants is referred to by rules. [syllabic] is not typically necessary to contrast the segments in inventories, because [vocalic] does basically the same work, but the issue is capturing classes of sounds that pattern together. More recently, the feature [syllabic] has been mostly abandoned as a segmental feature, because its work (distinguishing segments that are or are not syllable nuclei) is done by prosodic structures (see e.g. Anderson 1981). But there are two important points here. First, the distinction made by the feature [syllabic] turned out to be supported by cross-linguistic evidence, showing that the initial proposal was on the right track. Second, though, the feature [vocalic] is automatically jettisoned as a consequence. The problem is that subsequent work in phonology has shown a need for this distinction too, but a one allomorph is treated as basic and the other derived, there is no way to characterize a derived class in terms of traditional distinctive features, or to describe it in terms of shared phonetic properties. The most straightforward reason for the unnaturalness of this class is the fact that the dental nasal patterns with the retroflex stops and not with the dental stops.

(12) *Kolami plural* /-(u)l/ *allomorphy* (Emeneau 1961: 46–50)

a. [-l] after /ʈ ɖ n̪ i i: e e: a a:/

singular	*plural*	
d̪uʈ	d̪uʈl	'hips'
eɖ	eɖl	'bullock'
to:ren̪	to:ren̪l	'younger brothers'
sir	sid̪l	'female buffalo'
kaje	kajel	'fish'
bi:-am	bi:l	'rice'
kala	kalal	'dreams'

b. [-ul] after /p t̪ k d̪ g s v z m ŋ j/

nenjeŋ	nenjeŋul	'meat'
poj	pojul	'hearth'

An alternative to a universal feature set as an explanatory force in phonology is that inventories and sound patterns are limited by phonetic and historical factors (factors often invoked to explain "crazy" phenomena), and the appearance of a single feature set responsible for disparate phonological phenomena may be due to the role of phonetics in all of these phenomena. This is consistent with Blevins's (2004) approach to sound patterns in general and Mielke's (2008) approach to feature effects. A move away from a small feature set is also seen in some approaches to Optimality Theory, such as Flemming (1995), Kirchner (1997), and Boersma (1998).

4.1 Segmental contrasts

The idea that features play a limiting role in determining possible contrasts in inventories has for the most part not been accompanied by a null hypothesis about what segmental contrasts would be like in the absence of features. Mielke (2008) argues that the record of sound patterns does not support the literal interpretation of a restricted universal set of features. The main criticism is that the similarity between sound patterns in unrelated languages can be accounted for in terms of shared historical and phonetic factors.

An example of this type of argument is final devoicing, which is documented in a wide range of unrelated languages (see CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION). Blevins (2006: 136–140) describes the sources of these final devoicing patterns in detail. To summarize briefly, the phonetic sources of phrase-final devoicing include the use of laryngeal spreading and closing gestures to mark phrase boundaries in many languages, phrase-final lengthening, and difficulty perceiving phrase-final consonant release. Further, since children are typically exposed to a high number of single-word utterances, there is a tendency for them to generalize phrase-final phenomena to the word-final context. Since final voicing does not have the same phonetic sources, it is not widely observed. Mielke (forthcoming) shows that uses of the feature [voice] to characterize sound patterns are dominated by a small number of phonetically motivated patterns that are mostly assimilatory. As long as there are phonetic and historical explanations for the recurrence of certain sound patterns, feature theory can be interpreted as a model of these historical and phonetic effects (and this is how it is interpreted by many linguists), but the nature of sound patterns does not support features as a primary source of explanation or the restrictive nature of a small universal feature set.

If features are not universal as a part of Universal Grammar, then there is no need to explain how they could have emerged in the human genome over a short period of time, or why signed and spoken languages appear to have completely different features (or how signed language features could have developed in the human genome at all). See CHAPTER 9: HANDSHAPE IN SIGN LANGUAGE PHONOLOGY, CHAPTER 10: THE OTHER HAND IN SIGN LANGUAGE PHONOLOGY and CHAPTER 24: THE PHONOLOGY OF MOVEMENT IN SIGN LANGUAGE on features in sign language phonology. There is, however, a need to show how features are learned, and this is a topic of ongoing research (Lin 2005; Lin and Mielke 2008; Mielke 2010).

Also, if features are not innate, then there are consequences for other arguably universal primitives, such as constraints in Optimality Theory (Prince and Smolensky 1993). Many of these constraints refer to features, so if the features are not innate, the constraints referring to them cannot be innate either. Some approaches to Optimality Theory, such as Hayes (1999), involve universal constraints that are induced from phonetics. Features referred to by these constraints would need to be either innate or similarly induced from available data. See CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS and CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS.

Crucial evidence for features as the basis of segmental contrasts would be contrasts that appear to be ruled out by features but not by phonetics, such as (perhaps) the unattested apical retroflex *vs.* sub-apical retroflex contrast. However, it remains to be shown whether the cross-linguistic frequency distribution of both types of retroflex is such that they would be expected to co-occur in the same language anyway.

On the other hand, proposed features predict a wide range of unattested contrasts, and overdetermine the representation options for many attested ones. As discussed above, it has been possible to maintain the claim that there are only three vowel heights by making use of auxiliary "height" features like [ATR]. This is possible in part because it is difficult to falsify without articulatory imaging. While there is X-ray evidence for English to support the use of [ATR] to distinguish, e.g.

The last definition requires reference to a feature theory:

(15) *Natural class: Feature theory-dependent definition*

A group of sounds in an inventory that share one or more distinctive features within a particular feature theory, to the exclusion of all other sounds in the inventory.

The reason for breaking the definition down in this way is that natural classes and phonologically active classes are implicitly treated as the same thing in many approaches to phonology. It is worthwhile to seriously ask whether these definitions all refer to the same thing. The identification of natural classes with phonologically active classes is an explicit working assumption in some approaches, e.g. Halle (2002), who argues that the position that phonologically active classes are featurally natural has led to improvements in analyses of phonological phenomena. Mielke (2008) collected a database of phonologically active classes in the world's languages based on grammars of 549 languages and conducted feature analyses on the 6,077 resulting phonologically active classes involved in alternations, using *Preliminaries* (Jakobson *et al.* 1952), *SPE* (Chomsky and Halle 1968), and Unified Feature Theory (Clements and Hume 1995) features. Chomsky and Halle (1968) does the best, but still leaves a residue of about 29 percent of the unnatural classes, which is not easily handled using feature proposals subsequent to *SPE* (e.g. the Kolami example above and hundreds of others).

The way in which natural classes are traditionally defined (conjunction of distinctive feature values, yielding the intersection of the classes defined by each feature value individually) is also non-obvious. This technique has allowed many phonologically active classes that are not defined by a single feature to be represented, providing support for the idea that features used for contrast are also accounting for phonologically active classes, but it also massively overpredicts the range of phonologically active classes. It is not obvious that phonologically active classes defined by more than one feature are less atomic than classes defined by one feature. For instance, the class defined by [+voice, −sonorant] (voiced obstruents) is more frequently active than the class defined by [+voice] alone, and the class of glides (which requires reference to syllabicity and something like [−consonantal] or [+vocoid]) is more frequently active than the class defined by [−consonantal]/[+vocoid] alone. The fortunate fact that these active classes can be defined in terms of features needed to define contrasts has made it unnecessary to propose features for them, but their reasons for being involved in sound patterns may have more to do with the phonetic properties of the sounds involved in a way that is not directly related to the features used to describe them.

If there is a mismatch between phonologically active classes and the features used for lexical contrast, an alternative is a separate model predicting classes that are likely to be involved in sound patterns, perhaps in terms of common sound changes affecting more than one segment (Blevins 2004; Mielke 2008, forthcoming). The phonetic parameters defining these classes would not necessarily correspond directly to the parameters needed to contrast segments from one another. The class of voiced obstruents can be defined atomically in terms of non-spontaneous voicing – consistent with feature analyses by Rice and Avery (1989) and Rice (1992) that use the feature [sonorant voice], distinct from [voice] – which is relevant for many of the sound patterns this class is active in;

moreover, the class of glides is frequently involved in sound changes resulting in vocalization/devocalization alternations.

Flemming (2005) argues for another type of phonologically active class that is a consequence of constraint interaction. In this view, classes of sounds that pattern together can do so as a result of separate constraints, each targeting a different featurally natural class. The resulting (apparent) phonologically active class is not necessarily featurally natural, since it is determined by constraint interaction, not directly by features. See also Yip (2004, 2005) for a constraint-based approach to the cross-linguistic variability of laterals.

Mielke (2005) argues that examining a large sample of phonologically active classes shows that they range quite continuously from phonetically natural to phonetically unnatural, and that there does not appear to be evidence for a distinct cut-off between natural and unnatural classes. In cases where phonetic correlates are less clear, phonological patterning is also less clear, indicating that it is the phonetic properties in which features are grounded that are important, and features themselves do not make more specific predictions about sound patterns. For example, the feature [continuant] appears to be categorical for segments such as stops and fricatives, which strongly display its phonetic correlates, but laterals – whose specification has been controversial and whose phonetic cues are ambiguous – pattern with continuants about as often as with non-continuants. See CHAPTER 31: LATERAL CONSONANTS for more on this issue.

4.3 *Defining alternations*

If the features needed for defining the change in alternations do not match the features needed for other purposes, they could be accounted for by a model of likely alternations. For example, it is known that not all features appear to spread. This observation was addressed within feature geometry by placing non-spreading features such as [consonantal] and [sonorant] in the root node. If assimilation is the result of phonologized co-articulation (Baudouin de Courtenay 1972 [1895]; Ohala 1993; Blevins 2004), then an account of co-articulation and its phonologization could possibly account more directly for sound patterns interpreted as feature spreading. Mielke (forthcoming) surveys the behavior of classes defined by various features, and concludes that the phonological behavior of particular features can be attributed to the phonologization of phonetic effects. Features that are frequently spread in assimilatory patterns are features whose phonetic correlates are believed to be easily co-articulated. Features that rarely or never spread seem to be those that are not easily involved in co-articulation without involving the correlates of other features. Feature values that are frequently involved in dissimilation ([−voice] and [−nasal]) are the opposite values of the feature values that assimilate most frequently, consistent with Ohala's (1981) claim that dissimilation is the result of mistakenly undone assimilation (see CHAPTER 60: DISSIMILATION). As such, dissimilation is dependent on the phonologized co-articulation of an opposite value.

5 New types of experimental evidence

Regardless of whether features are needed to account for the typology of contrasts and sound patterns, behavioral studies such as Studdert-Kennedy *et al.*

(1972) indicated that features are involved in representations used in language processing. More recently, advances in brain imaging technology have opened new lines of research into the mental organization of phonology, building on earlier behavioral research (see CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY). Two big questions here are whether brain activity provides evidence for abstract features in adults, and the separate issue of whether this organization is a consequence of language exposure or a consequence of innate aspects of the language faculty.

In a magneto-encephalography (MEG) study, Phillips *et al.* (2000) report evidence for the feature [voice] in the left-hemisphere auditory cortex of adult English-speaking participants. This is similar to Studdert-Kennedy *et al.*'s (1972) dichotic listening experiment. Since acoustic similarity is similarly controlled for, an abstract feature can be motivated over acoustic similarity. Acoustically distinct but featurally identical stimuli were treated as identical in the auditory cortex. Other MEG studies report evidence of abstract vowel features (Obleser *et al.* 2004) and featural underspecification in the mental lexicon (Eulitz and Lahiri 2004). Dehaene-Lambertz and Pena (2001) report electrophysiological evidence that newborns distinguish [pa] and [ta] in a way that they do not distinguish repetition of the same syllable produced by different speakers. Studies with infants have the potential to address more directly the questions about whether these abstract representations are rooted in innate features or in exposure to language data.

These are a few examples of types of evidence that were not available in the early years of distinctive feature theory. New techniques for studying phonetics and phonology – such as brain and vocal tract imaging, new behavioral methodologies and computer modeling, and electronic databases of inventories, sound patterns, and sound changes – stand to improve our understanding of sound patterns and our understanding of how features are involved in accounting for them.

18 The Representation of Clicks

Amanda Miller

1 Introduction

Click consonants are a type of complex segment. Complex segments are defined as single segments that have two oral constrictions that are nearly simultaneous (Sagey 1990). Click consonants have an anterior constriction, which is either labial or coronal, and a posterior constriction, which is uvular in those Khoesan languages in which posterior place of clicks has been investigated with articulatory methods. The posterior place of clicks in Zulu starts out as velar in the closure, and releases at a uvular place of articulation. Clicks are unique in that they are produced with an ingressive lingual (also known as velaric) airstream mechanism, which is produced by trapping air between a lingual or linguo-labial cavity formed between the two oral constrictions. The tongue moves, in different ways for different clicks, to expand this oral cavity and thus to rarefy, or decompress, the air within it. When the anterior constriction is released, air rushes in to make the characteristic popping sound. The lingual ingressive airstream differentiates clicks from pulmonic stop consonants, which are produced on an outward flow of air from the lungs, and from other complex segments, such as labial-velars and labial-coronals, which are produced using a pulmonic or glottalic airstream.

Clicks have played an important role in phonological theory because of the phonological complexity that they exhibit, and the large number of click contrasts found in Khoesan language inventories. Clicks exhibit at least three major areas of complexity that are not found in most other consonants: (1) the double place of articulation features; (2) the overlap of the two constrictions for the length of the segments; and (3) the non-pulmonic airstream mechanism. In early representations of clicks, the suction used to form the airstream was recognized. However, later proposals capture the two places of articulation features in clicks, and assume that the non-pulmonic airstream is a redundant feature that is predictable from having two simultaneous oral places of articulation. Recent representations incorporate features capturing the unique airstreams involved in clicks.

In order to capture the phonological representation of clicks, there are five major dimensions that must be accounted for. First, there are the four major dimensions used for all stop consonants: place of articulation, manner of articulation (including lateral contrasts), laryngeal setting, and nasality (see CHAPTER 22: CONSONANTAL

Table 18.1 Recognized and unrecognized click types

Click	Symbol	Source
bilabial	[ʘ]	IPA (2006)
dental	[ǀ]	IPA (2006)
alveolar (Nǀuu), postalveolar (Juǀ'hoansi)	[!]	IPA (2006)
lateral alveolar	[ǁ]	IPA (2006)
palatal	[ǂ]	IPA (2006)
retroflex	[‼]	Doke (1925), Snyman (1997), Miller *et al.* (2009c)

PLACE OF ARTICULATION, CHAPTER 13: THE STRICTURE FEATURES, CHAPTER 31: LATERAL CONSONANTS, and CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION for more discussion). In addition, clicks involve a non-pulmonic airstream, referred to as velaric (Beach 1938; Ladefoged and Traill 1984, 1994; Ladefoged and Maddieson 1996) or lingual (Miller *et al.* 2007; Miller *et al.* 2009a), which is unique to these consonants. Click languages exhibit a range of inventory sizes, and the languages exhibit a range of complexity on each of these five dimensions.

Place of articulation features for clicks are complicated, because both the anterior and posterior places of articulation must be accounted for, as well as the relative timing of these features. Historically, researchers thought that all clicks had a velar posterior place of articulation (Doke 1923; Beach 1938; Traill 1985; Ladefoged and Maddieson 1996). Thus it was thought that posterior place was not contrastive. Click types are therefore named according to the anterior place of articulation. Recent phonetic and phonological studies have provided evidence that the posterior constrictions of clicks are post-velar, and that some of the clicks involve tongue root retraction.

Six distinct click types have been attested in Khoesan languages. These are provided in Table 18.1. The bilabial click occurs only in the related Tuu languages !Xóõ (Traill 1985) and Nǀuu (Miller *et al.* 2009a), and in the Ju-ǂHoan language ǂHoan (Bell and Collins 2001).[1] Other languages with a bilabial click, such as ǀXam, are now extinct. The retroflex click has been described phonetically by Doke (1925) and Miller *et al.* (2009c) in Grootfontein !Xung. Snyman (1997) provides a survey of !Xung languages, and transcribes the retroflex click in several !Xung-speaking areas surrounding Grootfontein. Heine and König (2010) describe a different click in Ekoka !Xun as retroflex, but phonetic description of this click is lacking. Sands (2007) suggests that it may be a retracted lateral, based on preliminary acoustic analysis of a few tokens. The click corresponds historically to the palatal click in other Ju-ǂHoan languages, and behaves synchronically similarly to the palatal click with respect to the Back Vowel Constraint, described in §4.1.

Language inventories display a wide range of variation in the number and types of clicks. Table 18.2 lists the languages that contain one-, three-, four-, and five-click inventories. The Cushitic language Dahalo and the Bantu languages Rumanyo

[1] Ju-ǂHoan is the name of a language family, Juǀ'hoan or Juǀ'hoansi the name of a language.

Table 18.2 Number of click types in consonant inventories of languages

One-click inventories	Dahalo, Rumanyo, Southern Sotho, Mbukushu
Two-click inventories	—
Three-click inventories	Hadza, Xhosa, Zulu, Sandawe
Four-click inventories (all coronal clicks)	Ekoka !Xung, G|ui, Ju|'hoansi, Khoekhoe, Khwe, Mangetti Dune !Xung, Naro, Yeyi
Five-click inventories (including the labial click)	ǂHoan, Nluu, !Xóõ
Five-click inventories (all coronal clicks)	Grootfontein !Xung

Mbukushu has only one click type – the dental click.[2] Southern Sotho contains only the alveolar click type. There are no languages exhibiting two click types. The Bantu languages Xhosa and Zulu, and the isolates Hadza and Sandawe, each have three-click inventories, containing the dental, central alveolar, and lateral alveolar click types. Many languages have four-click inventories, containing the four coronal click types recognized by the IPA. These languages contain all languages of the Khoe-Kwadi group, as well as most of the members of the Ju branch of the Ju-ǂHoan family. The Ju-ǂHoan language Ekoka !Xung has four click types, but with the retracted lateral click type in place of the central palatal click type [ǂ].

Most of the languages that have five-click inventories are Tuu languages, but ǂHoan also has five click types. These languages include the four coronal click types recognized by the IPA, as well as the labial click type. However, Grootfontein !Xung has the four coronal click types recognized by the IPA, as well as a retroflex click type, [‼], yielding five coronal click types in all (Miller *et al*. 2009c).

Clicks also occur paralinguistically in many languages throughout the world. For example, a lateral click is used in English to encourage a horse to trot (Ladefoged 1982), and a dental click is used to express disapproval, commonly represented as *tsk-tsk*. Clicks are also used as discourse markers in English (Wright 2007), and have been reported to occur in an auxiliary language of Lardil, Damin, which has bilabial, dental, apico-alveolar, and apico-domal nasal clicks (Dixon 1980; Hale and Nash 1997). Clicks are also found in Chinese nursery rhymes (Nathan 2001). Extremely weak clicks have also been shown to occur in German, when alveolar–velar stop sequences overlap at word boundaries (Fuchs *et al*. 2007).

The phonetic characteristics of the retroflex click and the laterally released palato-alveolar click are still being explored, but Miller *et al*. (2009c) describe the retroflex click as a postalveolar click in Grootfontein !Xung. One of the speakers produced this click with a sub-apical contact, but there was both inter-speaker and intra-speaker variation. Grootfontein !Xung is a centrally located lect. Ju|'hoansi, spoken to the east, has an alveolar click in cognate words, and Mangetti Dune !Xung and other northern lects have a lateral alveolar click in the same words (Miller-Ockhuizen and Sands 1999).

[2] Both Rumanyo and Mbukushu clicks exhibit a lot of variation, and can be realized as dental, alveolar, or lateral alveolar click types.

The manner of articulation of clicks is relatively complex. All clicks involve two complete constrictions, and are thus non-continuants. Clicks contrast in the manner of articulation of their release properties. They can have either a release with a complete constriction or a fricated release, as in pulmonic affricates. Thus clicks can be either stops or affricates. The stop and fricative portions of the releases are mostly uvular, though there are additional release properties that may be epiglottal (Miller 2007). The affricates are also airstream contour segments, and will be discussed with the airstream contrasts in §6. There is clear phonological evidence from positional distribution that all click consonants, including nasal clicks, behave phonologically as obstruents. Thus clicks only occur in initial position of roots in the Ju-ǂHoan, Khoe-Kwadi, and Tuu language families.

Click languages display a large range of variation in terms of the complexity of laryngeal contrasts. Table 18.3 lists the languages according to the number of voice onset time (VOT) contrasts contained in the oral click inventories. Languages of the Ju branch of the Ju-ǂHoan language family, and the Tuu language !Xóõ, display the most complexity on the laryngeal dimension, with four-way VOT contrasts. The voiced aspirated clicks are parallel to the voiced aspirated pulmonic stops in Ju|'hoansi in exhibiting a voiceless interval, which Miller-Ockhuizen (2003) attributes to a larger glottal opening gesture than is found in Hindi voiced aspirates. The Bantu language Mbukushu has a simple two-way VOT contrast. The laryngeal settings are independent from the click mechanism. Eleven out of the 19 languages included in this survey contain a three-way VOT contrast.

The fourth dimension that must be accounted for in clicks is the airstream dimension. Miller *et al.* (2007) and Miller *et al.* (2009a) introduce the term "lingual airstream" to replace the term "velaric airstream." They note that the term "velaric" suggests that this airstream is somehow initiated by the velum or that it involves a velar stop, and provide evidence that the posterior release in clicks is uvular not velar. The term "lingual" reflects the anatomical source of air. The tongue is used to create a low-pressure cavity, the anterior release of which initiates the ingressive flow of air. Sagey (1990) argues that airstream is a matter of phonetic implementation, and does not need to be specified in the phonological representation of clicks. I provide evidence that N|uu contains sounds that differ solely in terms of airstream. There are stops that are produced fully with a lingual airstream mechanism, with the shift from ingressive lingual airstream to pulmonic egressive airstream occurring at the CV boundary between a click and a following vowel. These stops contrast solely with a class of stops that involve a shift from lingual ingressive airstream to a

Table 18.3 A subset of VOT contrasts found in click languages[a]

No voicing contrast	Dahalo, Hadza,[b] Khoekhoe
Two-way VOT contrast	Mbukushu
Three-way VOT contrast	Grootfontein !Xung, G|ui, ǂHoan, Xhosa,[c] Zulu, Khwe, Mangetti Dune !Xung, Naro, N|uu, Sandawe, Yeyi
Four-way VOT contrast	Ekoka !Xung, Ju|'hoansi, !Xóõ

[a] Rumanyo is not included in this table.
[b] Hadza has a three-way VOT contrast in pulmonic consonants, but no voicing or aspiration contrasts in the click inventory.
[c] Ladefoged and Traill (1994) refer to the Xhosa voiced click as murmured.

2 Background

Clicks occur primarily in southern African and east African languages in seven language families. The east African click languages, Hadza and Sandawe, are both spoken in Tanzania, and there has thus far been little diachronic evidence to link them genealogically to southern African Khoesan languages, or to each other (Sands 1998), though see Güldemann and Elderkin (2010) for evidence that Sandawe is related to the Khoe-Kwadi language family. Hadza is currently thought to be a language isolate. Dahalo is a Cushitic language with clicks (Maddieson *et al.* 1993) which is spoken in Kenya. Dahalo has thus far not been shown to be related to the geographically closest click languages, Hadza or Sandawe. However, Ten Raa (1969) has suggested that there might be a common substratum between Dahalo and Sandawe.

The majority of click languages are spoken in southern Africa. The non-Bantu southern African click languages were described by Greenberg (1966) as belonging to one language family called Khoisan. They were grouped together as the Northern, Southern, and Eastern Southern African Khoisan branch of the Khoisan family, along with Hadza and Sandawe. The southern African Khoesan languages are currently spoken mainly in Namibia, Botswana, and South Africa, but related languages were historically present in Zimbabwe, Zambia, and Angola, and there are still small pockets of speakers in these countries today (Brenzinger 2001).

Güldemann (2006) argues that the non-Bantu southern African click languages belong to at least three distinct families: the Khoe-Kwadi family, the Ju-ǂHoan family, and the Tuu family. He has demonstrated that similarities in the number of clicks in the inventories of Tuu and Khoe-Kwadi languages can be attributed to a substrate, rather than a genealogical relationship between these languages. I follow Güldemann in using the term "Khoesan" as a neutral way of referring to click languages that do not belong to the well-established Bantu or Cushitic families, with no implied genealogical relationship. I use "Khoesan" rather than"Khoisan" because the spelling matches the orthographies of the languages involved.

In southern Africa, clicks also occur in a number of Bantu languages, most notably southern Bantu languages of the Nguni group, including Zulu and Xhosa. These languages have been shown to have adopted clicks through the process of Hlonipa and regular borrowing (Herbert 1990), but they are now a fully functional part of the language inventories. Clicks also occur in the Namibian Bantu languages Rumanyo (Gciriku), Mbukushu, Mbalan'we, and Fwe (Baumbach 1997) as well as Yeyi, spoken in both Namibia and Botswana (Fulop *et al.* 2003), and Tumbuka, spoken in Malawi.

In this chapter, I focus mainly on phonological patterns found in Khoesan languages, though I also refer to evidence from Zulu. Many of the Khoesan languages are underdocumented and underdescribed. The patterns discussed in this chapter all come from a subset of languages that contain sufficient description of phonological patterns. The languages discussed, and their sources, are listed in Table 18.6.

3 Unit *vs.* cluster analyses of clicks

The presence of clicks in a consonant inventory increases the size of the inventory. However, there is a large range in inventory sizes among the different languages

Table 18.6 Click languages discussed in this chapter and their sources

Language	*Family*	*Source(s) of phonological description*
Dahalo	Cushitic	Maddieson *et al.* (1993)
Ekoka !Xung	Ju-ǂHoan	Heine & König (2010)
Grootfontein !Xung	Ju-ǂHoan	Doke (1925)
G|ui	Khoe-Kwadi	Nakagawa (2006)
Hadza	Isolate	Sands *et al.* (1993)
ǂHoan	Ju-ǂHoan	Bell & Collins (2001)
Ju|'hoansi	Ju-ǂHoan	Snyman (1970, 1975); Miller-Ockhuizen (2003)
Khoekhoe	Khoe-Kwadi	Beach (1938); Brugman (2009)
Khwe	Khoe-Kwadi	Kilian-Hatz (2003)
Mangetti Dune !Xung	Ju-ǂHoan	Miller *et al.* (2008)
Naro	Khoe-Kwadi	Visser (2001)
N|uu	Tuu	Miller *et al.* (2009a); Miller (2010a)
Rumanyo (Gciriku)	Bantu	Mölig & Shiyaka-Mbereme (2005)
Sandawe	Isolate	Wright *et al.* (1995); Hunziker *et al.* (2008)
!Xóõ	Tuu	Traill (1985, 1994)
Xhosa	Bantu	Ladefoged & Traill (1994)
Yeyi	Bantu	Fulop *et al.* (2003)
Zulu	Bantu	Doke (1926); Thomas-Vilakati (2010)

containing clicks. Güldemann (2006) provides inventory size, as well as the proportion of non-clicks to clicks in the inventories of Tuu and Khoe languages, showing a range of inventory sizes within each of these families. The Bantu language Zulu has 45 segments, 12 of which are clicks (Thomas-Vilakati 2010). The Tuu language !Xóõ has the largest number of segments that has been documented so far, with a total of 119 contrastive segments, 83 of which are clicks. N|uu has 73 segments, 45 of which are clicks. G|ui is described by Nakagawa (2006: 259) as having 53 segments and a number of clusters involving clicks, but he notes that under a unit analysis it would have 89 segments. Ju|'hoansi has 89 contrastive segments, 47 of which are clicks. ǂHoan has 55 clicks, and Khwe 32.

Traill (1993), Güldemann (2001), and Nakagawa (2006) argue that a click containing a pulmonic release should be represented as a consonant cluster comprised of a sequence of a lingual segment and a pulmonic segment. Güldemann's (2001) and Nakagawa's (2006) arguments for a cluster interpretation of clicks are that the interpretation decreases the size of the consonant inventory, and that under a cluster interpretation all of the second members of the cluster exist as independent segments in the inventory. Further, Güldemann (2001) argues that the simple stop types that are contained in the clusters are more frequent than the cluster types.

Ladefoged and Traill (1984: 11) note that cluster analysis of clicks for !Xóõ would result in clusters of segments that differ in voicing, which was a language type not known to exist at the time.

Miller *et al.* (2009a) argue that not all click release types in N|uu occur as single segments in that language. This is problematic for cluster analyses of clicks, because segments that occur in clusters almost always occur as single segments as well. Further, Miller *et al.* (2009a) argue that if airstream contours are represented as consonant clusters with clicks as their first members, then languages such as G|ui would be the only languages in the world with obstruent–obstruent clusters but not obstruent–sonorant clusters. A survey of cluster types by Kreitman (2008) found no languages with obstruent–obstruent clusters that did not also have obstruent–sonorant clusters. Kreitman's study did find languages with clusters of mixed voicing – most notably Modern Hebrew. I argue that large inventories arise in languages with clicks, because these languages make full use of airstream as a contrastive dimension. Miller-Ockhuizen (2003) shows that pulmonic stop–sonorant clusters that occur in loanwords from English and Afrikaans into Ju|'hoansi are broken up by epenthesis, providing phonological evidence that Ju|'hoansi does not allow stop–sonorant clusters.

(1) lists the inventory of G|ui consonants, including the interpretation of all of the clicks as single units, in the spirit of Miller *et al.* (2009a), and Nakagawa's (2006) interpretation of some of the clicks as clusters. Nakagawa's analysis transcribes a distinction between "velar" clicks and "uvular" clicks, and transcribes all clicks with either a "k" or a "q," following Ladefoged and Maddieson (1996). Miller *et al.* (2009a) and Miller (2010a) have shown, using ultrasound imaging of the tongue during click production in N|uu, that the posterior release of [ǂ] and [ǂ͡q], on the one hand, and [!] and [!͡q], on the other, occurs at the same location, and that in all four clicks the location is uvular. In [ǂ] and [ǂ͡q], the posterior release location is back uvular and does not involve tongue-root retraction, while in [!] and [!͡q], the posterior release location is front uvular and involves a ballistic tongue-root retraction movement. Miller *et al.* (2009a) argue that the glottal stop in N|uu is allophonic in vowel-initial words, and thus does not occur as a single segment in the language. Furthermore, the glottal fricative in N|uu and most Khoesan languages is voiced, and thus does not correspond to the voiceless aspiration found in the voiceless nasal aspirated click.

(1)

a. *Unit analysis*	*Cluster analysis*	b. *Unit analysis*	*Cluster analysis*
!	/k!/	$!^{χ}$	/k!/ + /χ/
$^{g}!$	/g!/	$!^{χ'}$ or $!^{H}$	/k!/ + /qχ'/[4]
$^{ŋ}!$	/ŋ!/	!q	/k!/ + /q/
$!^{h}$	/k!ʰ/	ɢ!	/k!/ + /ɢ/
$!^{ʔ}$	/k!'/	$!q^{h}$	/k!/ + /qʰ/
		!q'	/k!/ + /q'/
		$^{ŋ}!^{ʔ}$	/k!/ + /ʔ/
		$^{ŋ}!^{h}$	/k!/ + /h/

[4] Nakagawa notes that this click and the similar pulmonic consonant [qχ'] are both realized with a lateral release. However, he notes that this click does not spread the lateral feature to a medial consonant the way that lateral clicks do. He thus claims that the lateral release is phonetic detail.

4.1 *The Back Vowel Constraint*

The Back Vowel Constraint is a CV co-occurrence restriction that blocks the co-occurrence of front vowels with a class of consonants, including labial and alveolar clicks (see also CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). In this section, I discuss the BVC patterns in G|ui (Nakagawa 2006), Ju|'hoansi (Miller-Ockhuizen 2003), N|uu (Miller 2010a), and !Xóõ (Traill 1985; Sagey 1990), and provide different analyses of the BVC. Most authors (Traill 1985; Sagey 1990; Clements and Hume 1995; Miller 2010a) analyze the BVC as assimilation between the posterior place of articulation of clicks and following front vowels. Earlier analyses viewed the posterior constrictions in clicks as velar, based on early phonetic studies. Miller (2010a) views the posterior constrictions of clicks as uvular, based on her ultrasound investigations of the posterior constrictions in clicks (Miller *et al.* 2007; Miller *et al.* 2009a; Miller 2010a), and she states the BVC as assimilation to an [RTR] feature of clicks. Nakagawa (2006) analyzes the BVC as assimilation between the anterior tongue shape of clicks and following front vowels. Miller's (2010a) and Nakagawa's (2006) analyses capture different patterns of linguo-pulmonic contour segments (Miller *et al.* 2009a) in N|uu and the phonetically similar clicks that are analyzed as clusters of clicks followed by uvular pulmonic segments in G|ui. The two analyses also make different predictions about the patterns found with non-click consonants, particularly labials.

Previous phonetic literature has described the posterior constriction in all clicks as velar (Doke 1923; Beach 1938; Ladefoged and Traill 1984, 1994; Traill 1985; Ladefoged and Maddieson 1996), and phonological representations of clicks have captured the posterior constriction with the phonological feature [+back] (Chomsky and Halle 1968; Sagey 1990) or the feature [dorsal] (Traill 1993; Clements and Hume 1995). The initial description of the BVC (Traill 1985) in !Xóõ treats all clicks, as well as velar stops, as being subject to the constraint. The BVC, stated in (4), changes a front vowel to a [+back] vowel by assimilation to the [+back] feature of the click.

(4) *Back Vowel Constraint* (Traill 1985)

if:	C_1	V_1
	<+back>	
then:	C_1	V_1
	<+back>	<+back>

A second process, Dental Assimilation, changes back vowels following dental [|] and palatal [ǂ] clicks to front vowels, in effect undoing the BVC. Chomsky and Halle (1968) and Sagey (1990) use the feature [+anterior] to classify the dental and palatal clicks separately from the central and lateral alveolar clicks. The Dental Assimilation rule in Sagey (1990) crucially requires palatal clicks to be [+anterior], in keeping with the fact that the palatal click has a long laminal constriction stretching from the dental place of articulation to the post-alveolar place of articulation (see Sands *et al.* 2007 and references therein).

Miller-Ockhuizen (2003) argues that there are two classes of clicks: those that are subject to the BVC, and those that are not. She proposes that the central alveolar [!] and lateral alveolar [||] clicks that are subject to the BVC have a uvular posterior constriction, which is specified for a [pharyngeal] feature. She proposes the BVC in (5), using Clements and Hume's (1995) feature theory (see CHAPTER 27: THE ORGANIZATION OF FEATURES):

(5) *Back Vowel Constraint* (Miller-Ockhuizen 2003)

*{[pharyngeal]$_{\text{Vplace}}$ [coronal]$_{\text{Vplace}}$ }$_{\sigma}$

[pharyngeal] and [coronal] cannot be specified on the same or different V-place within a syllable.

She argues that front vowels are underlyingly present in Ju|'hoansi following dental and palatal click types, and dental and palatal clicks are unspecified for the feature [pharyngeal].

Traill (1997) proposes the acoustic feature [+grave] to account for BVC patterns in !Xóõ, which also contains the labial click. His analysis captures the fact that labial and alveolar clicks pattern together with respect to the BVC. However, Miller-Ockhuizen (2000) shows that pulmonic labial consonants and labial clicks pattern differently in !Xóõ, and thus this feature is problematic. Traill (1985) considered initial labial consonants to be only found in loanwords in !Xóõ. Labial consonants are low frequency in root-initial position, but extremely frequent in root-medial position in most Khoesan languages (see Miller-Ockhuizen 2003: 131 for Ju|'hoansi and Miller (2010a) for N|uu).

Miller (2010a) provides the results of a database study over the N|uu lexicon. The phonological patterning of N|uu consonants with respect to the BVC is summarized in Table 18.7. Miller (2010a) analyzes the BVC as assimilation of a front vowel to an [RTR] feature on the consonant.

Table 18.7 Patterning of N|uu consonants with respect to the BVC

	Occur with front and back vowels	*Occur with back vowels and the [əi] and [æ] allophones of /i/ and /e/*
Pulmonic stops	Labial [b β] Alveolar [s z ɾ] Palatal [c ɟ ʃ ʒ] Velar [k g]	Uvular [q χ kχ']
Clicks	Dental click [ǀ] Palatal click [ǂ]	Labial click [ʘ] Central alveolar click [!] Lateral alveolar click [ǁ]
Clicks with airstream contours (stops)	Dental clicks [ǀ͡q] Palatal clicks [ǂ͡q]	Labial click [ʘ͡q] Central alveolar click [!͡q] Lateral alveolar click [ǁ͡q]
Clicks with airstream contours (affricates)		Uvularized labial click [ʘ͡χ] Uvularized dental click [ǀ͡χ] Uvularized central alveolar click [!͡χ] Uvularized lateral alveolar click [ǁ͡χ] Uvularized palatal click [ǂ͡χ]

The patterning of dental and palatal linguo-pulmonic stops, [ǀq͡] and [ǂq͡], in Nǀuu provides evidence that these clicks are unspecified for [RTR] (see CHAPTER 25: PHARYNGEALS). Herzallah (1990), Elorietta (1991), McCarthy (1994), and Rose (1996) have shown that both uvulars and pharyngeals cause retraction of front vowels in Semitic languages. Uvular and pharyngeal sounds are thus generally characterized as all being specified for the feature [RTR]. The Nǀuu click patterns suggest that there are uvular constrictions that don't involve the feature [RTR]. Phonetically, the posterior place of articulation in Nǀuu palatal clicks is back uvular, at the point where the oral tract and pharynx meet, and it does not involve tongue-root retraction (Miller *et al.* 2009a; Miller 2010a). The posterior constriction in dental and palatal clicks is more like the production of [u] (Miller *et al.* 2009b), which involves tongue-root raising (Esling 2005), not tongue-root retraction. Miller (2010a) notes that these differences in articulation are consistent with their differences in featural specification. The alveolar click is specified for the feature [RTR], while the palatal click is unspecified for the feature.

Nakagawa (2006) describes the patterning of Gǀui consonants with respect to the BVC. The patterns seen in Gǀui largely mirror those found in Nǀuu, except that the click clusters with uvular offsets, [ǀq !q ǁq ǂq] (Miller *et al.*'s 2009a linguo-pulmonic stops), are all subject to the BVC in this language. Nakagawa accounts for the BVC in Gǀui using the two constraints in (6). One constraint accounts for the click patterns, and the other for the non-click patterns. Nakagawa notes that Cq represents a non-click uvular consonant, i.e. /q ɢ q^h q' qχ' χ/, whether it occurs as an independent consonant or as a cluster offset, and "!/ǁ" stands for an apical click. The alveolar clicks would thus be captured with his feature [+apical], and the uvulars would be captured with the feature [+grave], though this would predict that velar and labial pulmonic consonants are also subject to the constraint. However, Nakagawa (2006: 229) notes that there are 17 words in Gǀui that have a velar consonant followed by a [−back] vowel. Nakagawa attributes the presence of front vowels following some velars to the phonetic ambiguity of velars.

(6) a. *Cq V[−back]
    b. *!/ǁ V[−back]

Miller-Ockhuizen (2003) notes that the velar stops [k] and the velar fricative "x" (Snyman 1970, 1975; Dickens 1994) pattern differently in Juǀ'hoansi, and she re-analyzes the fricative as uvular [χ] and the velarized clicks [ǀx !x ǁx ǂx] as uvularized clicks [$ǀ^χ$ $!^χ$ $ǁ^χ$ $ǂ^χ$], based on the raised F1 values in vowels following these sounds. The place difference accounts for the different BVC patterns, as the uvular fricative and the uvularized clicks are [RTR]. This same disparity in [k] and "x" is found in Gǀui (Nakagawa 2006: 231), although Nakagawa maintains the traditional description of the dorsal fricative as "velar" and the [ǀx !x ǁx ǂx] clicks as velarized. As a result, he describes velars as patterning ambiguously. The velar stop [k] in !Xóõ is phonologically ambiguous (Traill 1985). There are both forms with the [əi] allophone of /i/, as in *kəi* 'grow', and the [e] allophone of [e] as in the word *kèhn* 'being' in Traill's (1994) dictionary. Further, Traill (1985) notes that the concordially determined forms *ki* (class 1) and *ke* (class 3) are often realized in speech as [ti] and [te], due to the BVC, and Afrikaans loanwords containing [k] are realized with [t] in !Xóõ. The dorsal fricative "x" occurs only with

Table 18.8 Distribution of segments in Khoekhoe (Brugman 2009)

Segment	*Root-initial*	*Clitic-initial*	*Root-medial*

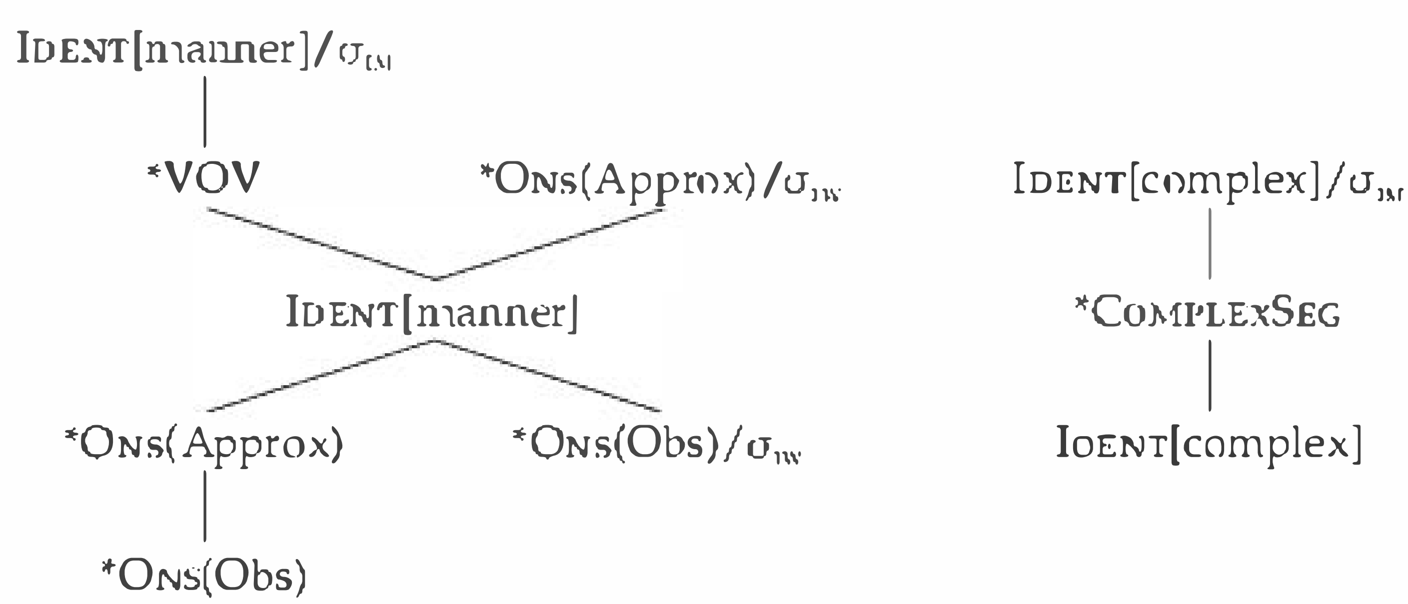
[m n]	✓	✓	✓
[ɾ]		✓	✓
[β]			✓

(9) *ONS(Approximant) >> *ONS(Nasal) >> *ONS(Obstruent)

These constraints are ranked with IDENT[manner] constraints, and the constraints are relativized to different positions. In order to capture the unique positioning of clicks, she uses the constraint *COMPLEXSEG. The complete ranking of constraints that accounts for the Khoekhoe patterns is provided in (10), where "IW" is "initial" and "IM" is "medial."

(10) *Constraint ranking for Khoekhoe segment distribution* (Brugman 2009)



Additional evidence for *COMPLEXSEG comes from the distribution of clicks in three different forms of pronouns found in N|uu. Table 18.9 provides a list of three forms of all of the pronouns found in N|uu, which Collins and Namaseb (2007) describe as the simple form, the click form, and the "a" form.

The distribution of these forms of pronouns is syntactically determined (Collins and Namaseb 2007). The simple forms occur in subject position (for non-questions), object position, and possessor position. Collins and Namaseb note that they are not syntactically weak in the traditional sense, since they can appear in coordinate structures, can be modified by numerals and "only," and can be clefted. The click forms of the pronouns appear obligatorily as the subject in yes–no questions

Table 18.10 !Xóõ onsets in different morpho-prosodic positions (Brugman 2009)

[p t k s]	✓	✓	
[m n]	✓	(n)	✓
[ɾ]		✓	✓
[b j ɲ]			✓

Table 18.11 Featural specification of guttural consonants and vowels

Value for [pharyngeal]	[pharyngeal]		*Unmarked for* [pharyngeal]	
[spectral slope] *value*	[high]	[low]	[high]	[low]
aspirated consonants/breathy vowels			✓	
glottalized consonants/glottalized vowels				✓
uvularized consonants	✓			
epiglottalized consonants/epiglottalized vowels		✓		

A constraint, ALIGN([spectral slope]$_V$, L; μ_1, L), is proposed by Miller-Ockhuizen (2003: 138) to account for the distribution of guttural vowels within the first syllable of a root. Given the recent advances in positional augmentation, we can capture the distribution of both guttural consonants and vowels in the first syllable of a root by ranking the constraint *GUTTURAL below IDENT[Guttural]/σ_{1W}, and above IDENT[Guttural].

G|ui limits the medial consonants to the set of /b w r j m n/ (Nakagawa 2006: 114), and allows the full set of 89 consonants (or 53 segments plus all possible clusters) initially. Thus, G|ui seems also to have a constraint licensing obstruents in initial position, and sonorants in medial position, just like the other Khoesan languages. However, Nakagawa (2006) reports monomoraic non-root words that contain clicks in G|ui. It is possible that these words may have the same prosodic status as roots, similar to the post-positions and complementizers in Khoekhoe (Brugman 2009: 202). It is also possible that the constraints are ranked differently in G|ui. Clicks are limited to root-initial position in all of the other documented Ju-ǂHoan, Khoe-Kwadi, and Tuu languages, though their distribution in non-roots is unexplored.

a re-analysis in either of these languages. The diachronic evidence from click change provided in §3 suggests that, at least historically, these segments may have also differed in posterior place phonologically. Without further phonetic studies, we do not know if these clicks may also differ, or have differed in the past, in speakers' productions or in listeners' perceptions. Any theory that accounts for clicks needs to account for airstream contour segments in N|uu.

7 Conclusion

I have provided an overview of the types of evidence that are available for place of articulation, manner of articulation, and airstream of clicks. I have given an overview of unit analysis and cluster analysis of click consonants. I have noted that the unit analysis of clicks results in larger click inventories. Cluster analyses of clicks, on the other hand, result in smaller segment inventories. This comes at a cost, as it results in Khoesan languages being the only languages in the world that allow obstruent–obstruent clusters without also allowing obstruent–sonorant clusters.

There are three main sources of evidence for the phonology of clicks. The Back Vowel Constraint and nasal assimilation provide evidence as to the place of articulation in clicks. The positional distribution of clicks provides evidence that clicks are obstruents, and that their status as complex segments makes them more marked. The existence of airstream contour segments in Nluu provides evidence that airstream is an independent dimension of sound structure. All of these types of evidence must be accounted for by any phonological theory that accounts for clicks.

19 Vowel Place

Bruce Morén-Duolljá

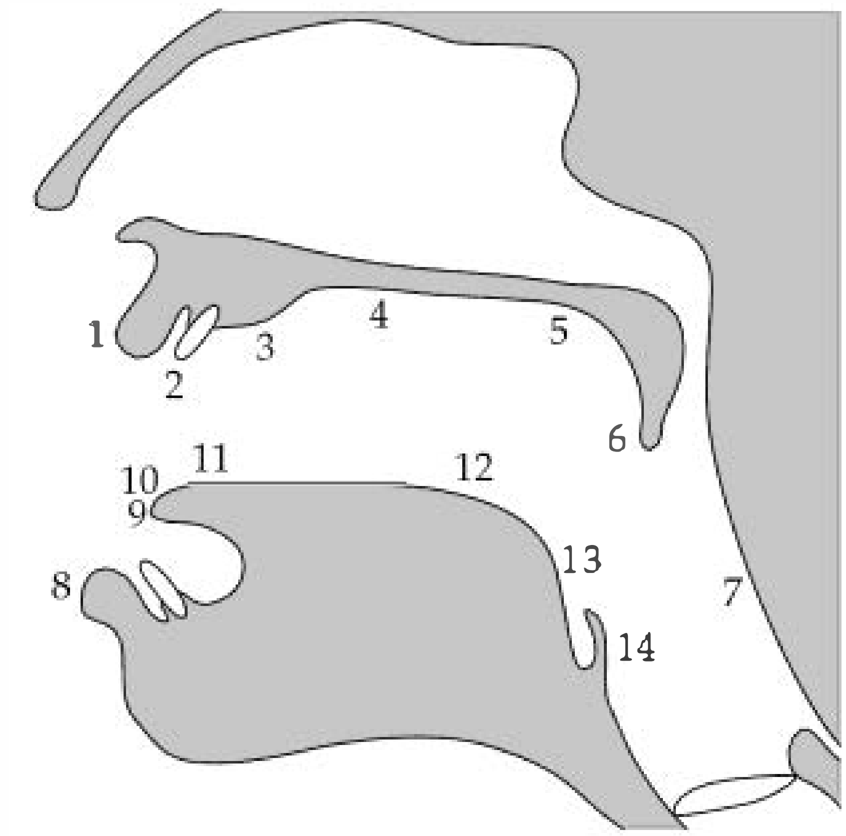
What is vowel place and what role does it play in the sound patterns of language? The term "vowel place" means different things to different people. There are two main reasons for this. First, the relationship between the articulation and the acoustics of "place of articulation" is complex and multifaceted. Second, phonological features have a range of model-specific definitions. The purpose of this chapter is to give a general introduction to the phonetic and phonological issues necessary to understand vowel place.

1 The phonetics of "place"

At its most basic, "the behavior of the vocal tract in speech can be described as an alternation of closing and opening" (Chomsky and Halle (*SPE*) 1968: 301). These closings and openings result in a complex set of aerodynamic and acoustic effects. Depending on the amount of the contraction or expansion, combined with language-particular phonotactics, a resulting acoustic signal is interpreted as a consonant and/or a vowel. The type and degree of the vocal tract openings and closings on the articulatory side of things corresponds roughly (but, as we will see, not directly) to what are commonly and descriptively referred to as phonological major class features, consonant manner features, and vowel height features (CHAPTER 21: VOWEL HEIGHT).[1] However, it is not enough to look at sound patterns only in terms of constriction. One must also attend to the precise location at which constrictions occur within the vocal tract.

We have known since the groundbreaking work of Chiba and Kajiyama (1942) that constrictions and expansions along the vocal tract have particular acoustic effects that can be explained in terms of tube acoustics. Depending on the proximity of a constriction or expansion to a node (i.e. point of minimal air displacement) or a loop (i.e. point of maximal air displacement) associated with a tube's resonance frequency, there will be different effects on that resonance frequency. A constriction at a loop causes a decrease in frequency, and a constriction at a node causes an increase. It is the location along the length of the vocal tract where articulatory gestures take place, combined with their acoustic correlates, that corresponds to

[1] I will not discuss openings and closings of the glottis.



Passive articulators
1 upper lip
2 upper teeth
3 alveolar ridge
4 hard palate
5 velum (soft palate)
6 uvula
7 pharyngeal wall

Active articulators
8 lower lip
9 tongue tip
10 tongue blade
11 tongue front
12 tongue dorsum
13 tongue root
14 epiglottis

Figure 19.1 Vocal tract diagram

a large extent (but not absolutely) to what is commonly known as phonological place of articulation.

From an articulatory perspective, place involves passive and active articulators (see Figure 19.1). The former are static landmarks along the upper surface of the vocal tract. The latter are mobile articulators along the lower surface of the vocal tract that move nearer to or further from the static landmarks during speech.

If one looks at the documented combinations of active and passive articulators found cross-linguistically, one sees evidence of all physically felicitous combinations. Further, neither active nor passive articulator seems to be privileged in having primary responsibility for defining place across contexts. For example, the passive uvula articulator can be used to single out the set of uvulars, and the active epiglottis articulator can be used to single out the set of epiglottals. However, the active tongue dorsum articulator is used for both dorsals and uvulars, whereas the passive pharyngeal wall articulator is used for both pharyngeals and epiglottals.

Combinations of active and passive articulators result in particular shapes of the vocal tract and cause the general acoustic effects described by Chiba and Kajiyama. To illustrate this in simplified terms, we can look at the schematized vocal tract in Figure 19.2. Here we see a tube closed at one end by the larynx and open at the other end by the lip orifice. The first three formants (F1, F2, and F3) are indicated by sine waves, and loops and nodes associated with these formants are indicated by solid and dashed vertical lines, respectively. The F1/F2/F3 loop labeled A corresponds to the labial region, the F3 node labeled B corresponds to the alveolar region, the F2 node C and F3 loop D correspond to the velar region, and E, F, and G correspond to the pharyngeal region.

The acoustic results of contractions at the various loops and nodes in the vocal tract are seen most clearly in F2 transition targets associated with stops. These correspond quite nicely to what are commonly described as the primary consonant places. This is illustrated in Figure 19.3 for labial, alveolar, and velar stops in particular vowel contexts. We see that labial constrictions have a low F2 target

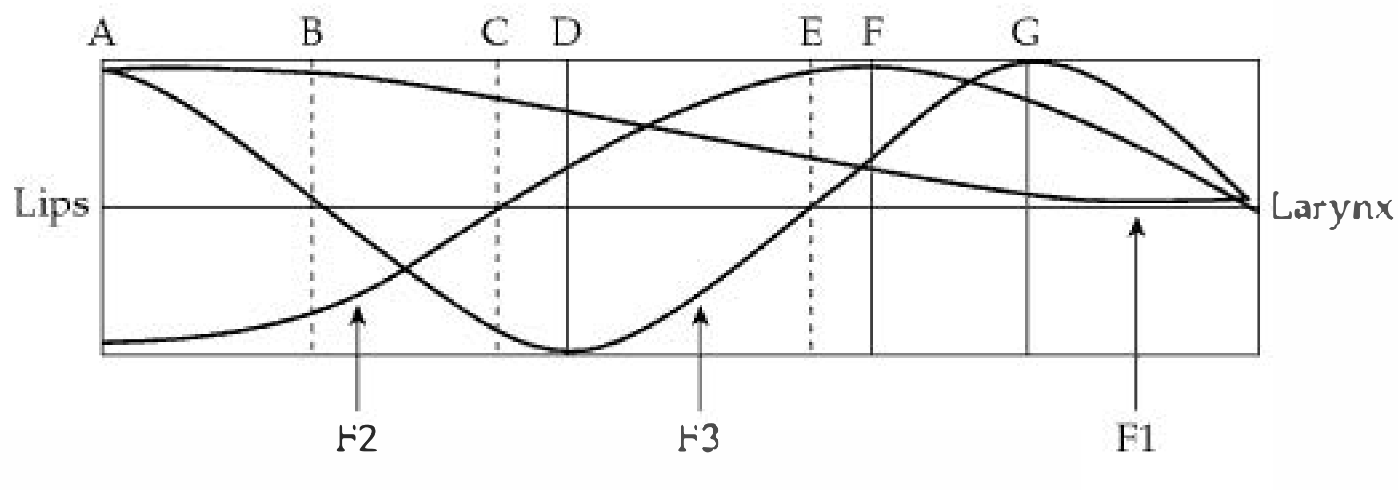


Figure 19.2 Illustration of vocal tract tube acoustics

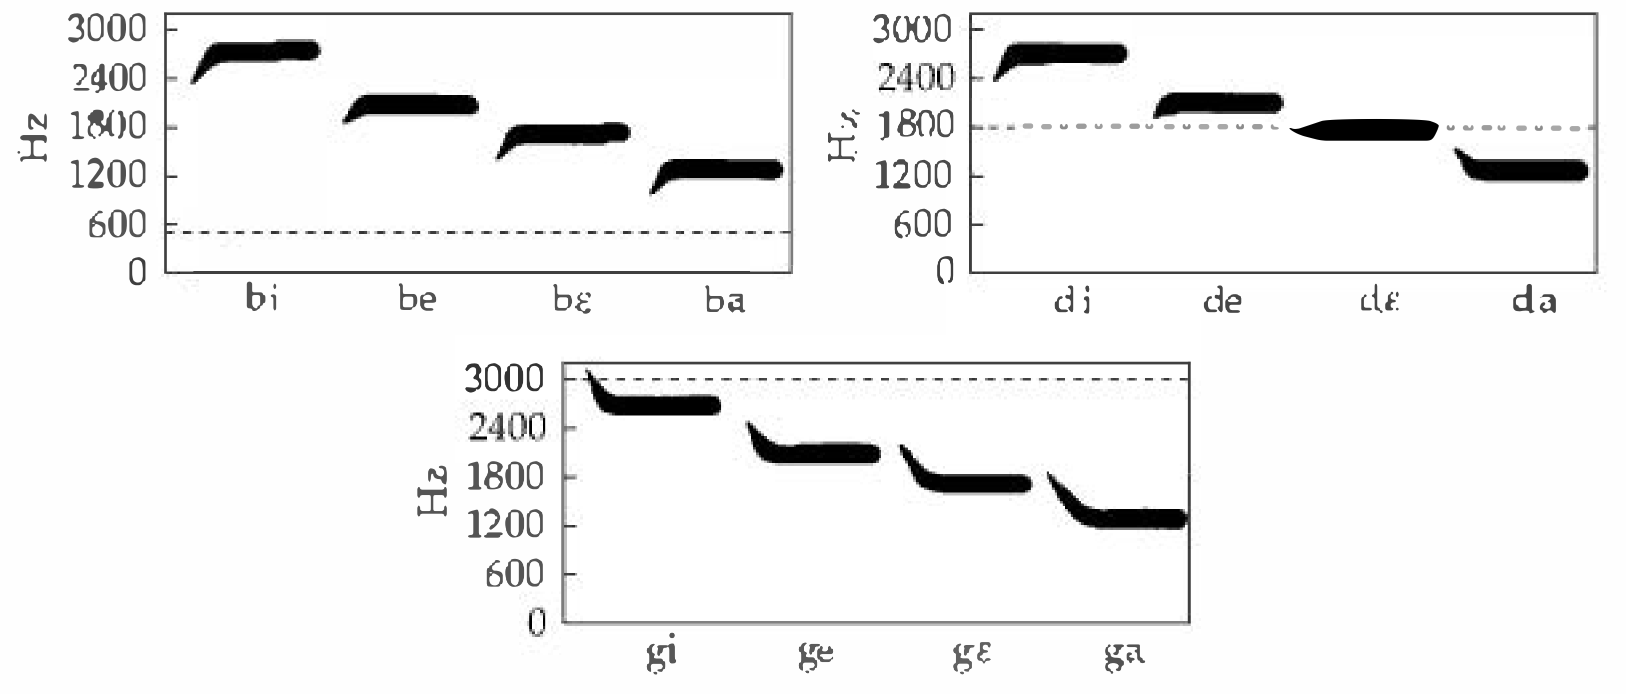

Figure 19.3 F2 schematics for several consonant–vowel combinations. Dashed lines indicate stop transition targets (modified from Delattre *et al.* 1955)

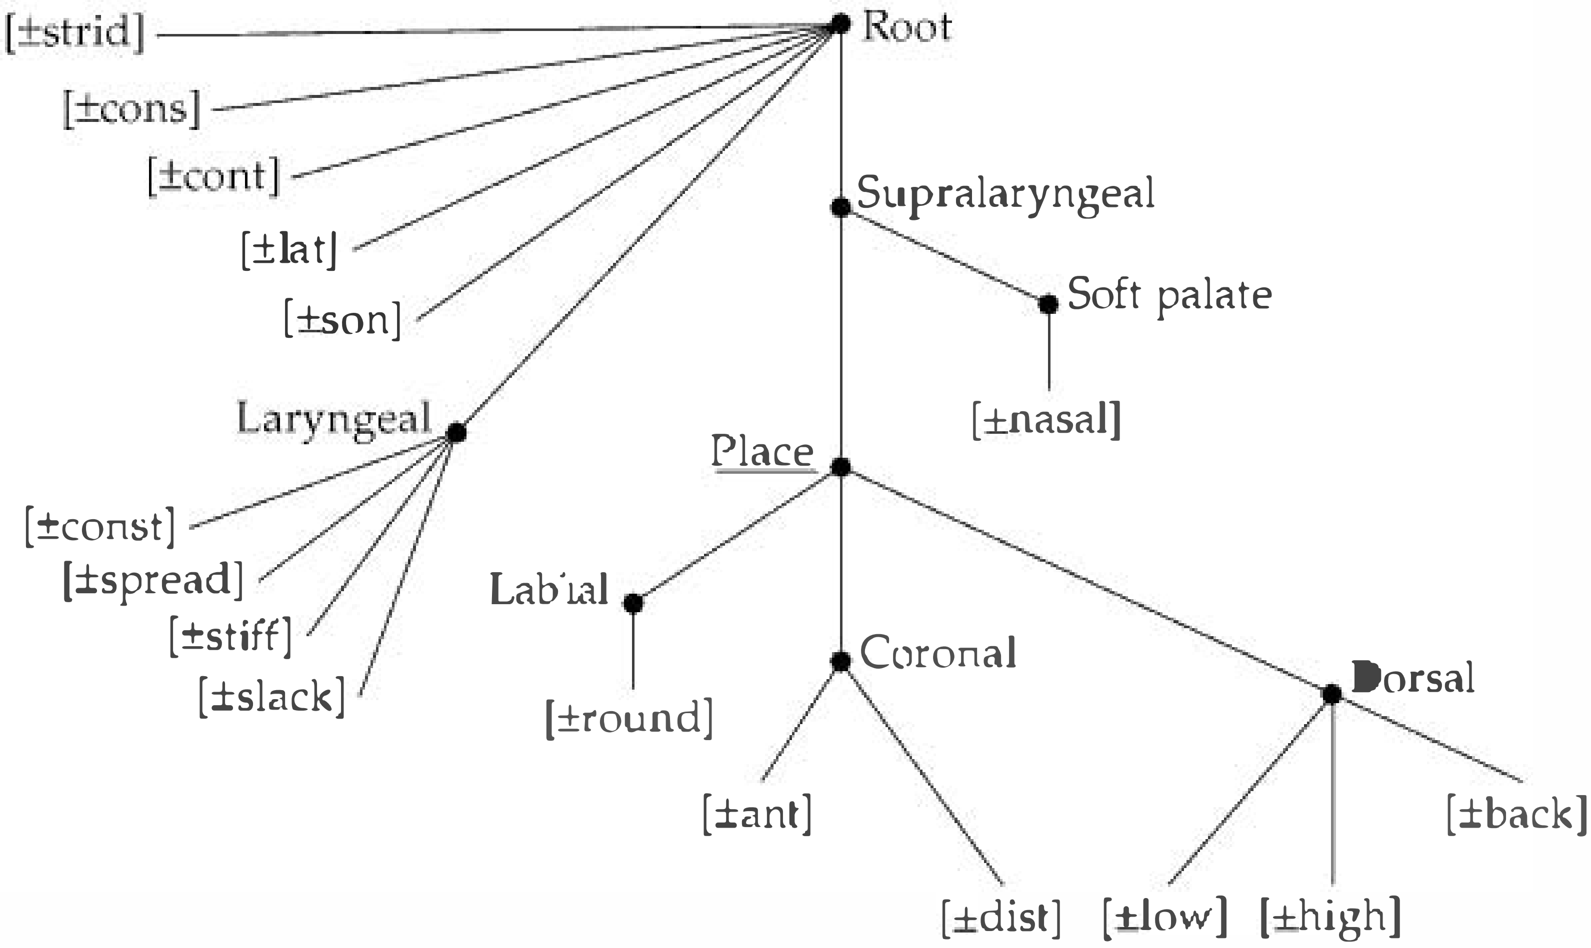
(below 600 Hz). This is because the labial region is a loop for F2. Alveolar constrictions have a mid-range F2 target (approximately 1800 Hz), because this region is neither a loop nor a node for F2. Velars have a high F2 target (above 2500 Hz), because this is a node for F2.[2]

Although there are complications to this story when one looks carefully at particular contexts and at combinations of articulations in running speech, there is general consensus in the literature with respect to the relationship among some consonant articulations, acoustics, and phonological place features. This is in no small part due to the rather extreme constrictions that consonants require for their production. These allow for a robust and precise articulatory and acoustic characterization of consonants. Further, these extreme articulations and their natural proximity to resonance nodes and/or loops also produce "quantal effects" (Stevens 1972, 1989), where relatively large movements along some regions of the vocal tract produce only small acoustic results, while small movements along other regions produce large acoustic results. Thus it is not surprising that certain consonant places are quite common across the world's languages. It is also not

[2] Although not shown in Figure 19.3, the close proximity of an F2 node and F3 loop in the velar region results in the well-known "velar pinch" typical of velar consonant formant transitions in some contexts – i.e. F2 is high and F3 is low (Stevens 1989).

[dorsal]) are dependent. This idea has been modified a number of times over the years, for example in (1).

(1) *Feature geometry of Sagey (1990)*



It is important to note that this type of geometry groups traditional place features and non-place features under "place" organizing structures. For example, Sagey uses place, labial, coronal, and dorsal organizing "place" nodes that have dependent [±round], [±anterior], and [±back] "place" features and dependent [±distributed], [±low], and [±high] "non-place" features.

Although there are language-particular phonetic and phonological facts that have led to this proposal, there are a number of unanswered questions that must be asked. For example, what is the formal difference between a place node and a place feature? Why can some structures, such as [coronal], be both a feature and an organizing node for dependent features, while other structures, such as C-place, V-place, and aperture, can only be an organizing node? Is there a formal reason for this? What is "place" in a model where both place features and non-place features are dependent on the same "place" nodes? It is beyond the scope of this chapter to answer these questions, but it is important to think about what "place" really means and how it might be modeled.

To summarize, we have to contend with at least three meanings of the term "vowel place" in the literature. It can be a descriptive term for related articulatory and/or acoustic characteristics. It can be a descriptive term for related phonological features. It can be a formal term for segment-internal organizing structure.

4 The phonology of vowel place

If we assume there is phonological vowel place from a featural and/or an organizational perspective, we have to ask ourselves what it is used for. There are seven major types of phenomena that are relevant here:

(2) a. Vowel contrasts
 b. Consonant contrasts
 c. Vowel interactions
 d. Consonant–vowel interactions
 e. Consonant–vowel alternations
 f. Vowel neutralizations
 g. Consonant interactions

The first five will be discussed below.

4.1 *Vowel place contrasts*

The most obvious use of vowel place features is to establish contrasts among vowels (see CHAPTER 2: CONTRAST). However, given the interactions among vowel articulations and acoustics discussed above, it is difficult to establish absolute and precise articulatory or acoustic characteristics for vowel place and translate these directly to phonological structures. It is thus common to describe vowel inventories via a combination of articulatory configuration and relative position along F1 and F2 continua in charts such as that in Figure 19.5. The vertical axis represents F1 and relative openness of the oral cavity (see CHAPTER 21: VOWEL HEIGHT). The horizontal axis represents F2 and relative location along the front–back dimension of the oral cavity, where there is a constriction or expansion.

What is important for our purposes is the number of differences along the horizontal axis if relative F1/openness/tongue height is controlled for. It is also important to relate those differences to articulator configurations and phonological patterns. As we see in Figure 19.5, there seem to be six major categories along the F2 acoustic dimension for most vowel heights[3] – [i y ɨ ʉ ɯ u], [e ø ɘ ɵ ɤ o], and [ɛ œ ɜ ɞ ʌ ɔ], and these divide articulatorily into three main areas based on tongue position (i.e. front, central, and back), with a further split based on lip configuration (i.e. rounded and unrounded).

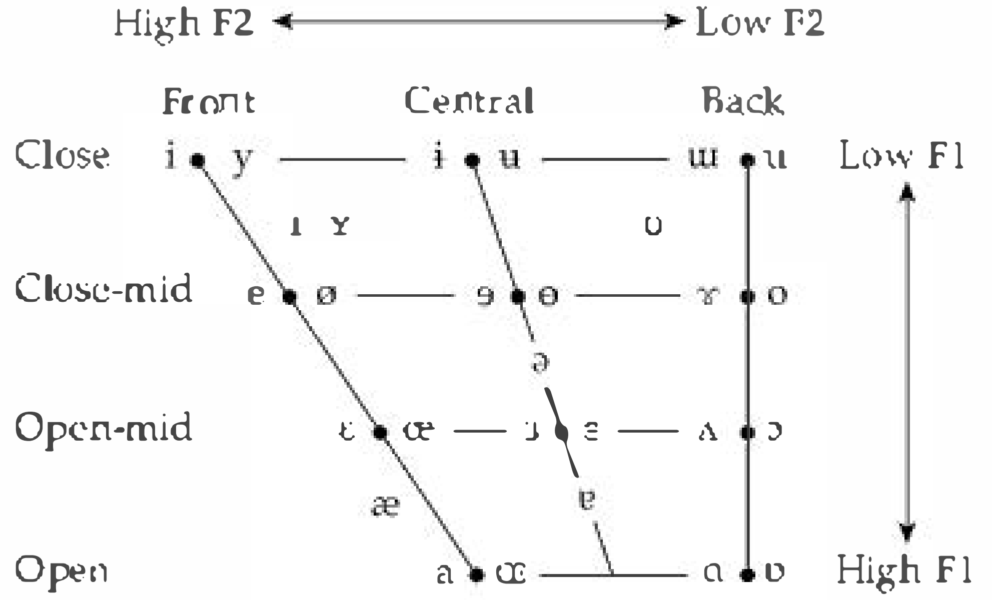


Figure 19.5 Standard vowel chart (IPA)

[3] I do not discuss here the important work of Lass (1984), which claims that there is evidence for ten place distinctions. This claim is not based on contrasts within the speech of individual speakers, but on what he calls "dialect distinguishability." Because there is no evidence that so many contrasts are needed within a given phonological grammar, I take this to indicate fine-grained phonetic distinguishability that does not translate into phonological feature specifications. This is also the conclusion of Rice (2002).

There are four interpretations for the fact that lip rounding can combine with tongue configuration to produce contrasts along the F2 continuum. First, vowel features are defined acoustically, rather than articulatorily. After all, one cannot claim that Figure 19.5 represents articulatorily defined vowel features having to do with tongue position (i.e. "front–back") and height, and then include labial characteristics. The second is to claim that [round] is not a vowel place feature, but some other type of feature. This leaves vowel place as defined solely via tongue position – this is the position taken by Chomsky and Halle (1968). The third is to suggest that vowel features are not defined purely on acoustic or articulatory characteristics, but different features are acoustically or articulatorily defined. This seems to be the position taken by most generative phonologists, even if they do not state so explicitly. Finally, one could claim that vowel place features are articulatorily defined via the location along the vocal tract where constrictions or expansions occur. This is essentially the position of Articulatory Phonology (Browman and Goldstein 1986, 1992; see also CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS).

While it is fairly uncontroversial that the vowel space is divided roughly into six phonetic regions along the F2 dimension when one looks at cross-linguistic inventories, there is considerable debate about how these phonetic regions should be classified from a phonological perspective. Clements (1991) suggests that three distinct, unary, place features/nodes are needed to capture six contrastive vowel places – two features/nodes for tongue position along the front–back dimension (i.e. [coronal] and [dorsal])[4] and one feature/node for lip rounding (i.e. [labial]). This is a minor modification of *SPE*-based feature theory. There are, of course, a number of ways to implement this system, depending on one's assumptions about underspecification/full specification, feature co-occurrence markedness, etc. (CHAPTER 4: MARKEDNESS; CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION). (3a) and (3b) show two possible implementations for high vowels.[5]

(3)

a.	[labial]	[coronal]	[dorsal]	b.	[labial]	[coronal]	[dorsal]
[ɨ]				—			
[ʉ]	✓			—	✓		
[i]		✓		[i]		✓	
[ɯ]			✓	[ɯ]			✓
[y]	✓	✓		[y]	✓	✓	
[u]	✓		✓	[u]	✓		✓
—		✓	✓	[ɨ]		✓	✓
—	✓	✓	✓	[ʉ]	✓	✓	✓

As we see in (3a), the central unrounded vowel [ɨ] is placeless, three vowels ([ʉ i ɯ]) have one place feature specified, and two vowels ([u y]) have two places. Interestingly, factorial combination predicts two additional vowels that seem to

[4] These labels make use of two aspects of the phonetics. Descriptively, "coronal" refers to the passive articulator (i.e. the crown of the oral cavity) and "dorsal" refers to the active articulator (i.e. tongue dorsum). It is unclear what the advantage is of having this mixed set of labels.

[5] This is an illustration, and it is not meant as an endorsement of this over other approaches.

Thus the fact that Wolof and Nimi'ipuu non-RTR/RTR vowel pairs differ in both F1 and F2 does not automatically justify dismissing a pharyngeal place hypothesis. More evidence is needed. One might fruitfully compare the subtle F2 differences here with those between the labial and non-labial vowel pairs discussed in §4.1 (e.g. [i] and [y]). What makes labiality an obvious candidate for a phonological place distinction for vowels, but not pharyngeality?

Finally, there is evidence from some Arabic varieties that vowels can have contrastive pharyngeal place. For example, Cairene Arabic is usually described as having just three contrastive vowels, /i u a/; however, recent studies show that there are four contrastive vowels in this language – /i u a ɑ/ (Youssef 2006, 2007). The vowel [ɑ] is a contrastive "emphatic" vowel that triggers what is called emphasis spread and is also the result of spreading emphasis to /a/. If the descriptive term "emphasis" is interpreted as involving a phonological pharyngeal feature (as is commonly done), then this language has a contrastive pharyngeal and non-pharyngeal low vowel. As one might expect from looking at Wolof and Nimi'ipuu, the difference between pharyngeal and non-pharyngeal vowels in Cairene Arabic is realized acoustically by both F2 and F1 differences, where the pharyngeal vowel has a higher F1 and a lower F2.

To summarize, there are at least five vowel places from an articulatory perspective: labial, coronal, velar, pharyngeal, and retroflex. The first four primarily involve passive articulators, while the fifth primarily involves a particular active–passive articulator combination. Further, the acoustic correlates of the first three involve almost exclusively variation in F2, while the fourth involves both F1 and F2, and the fifth F3. There is currently disagreement in the literature on vowel place contrasts with respect to how many vowel place features are needed to establish cross-linguistically possible and language-particular phonological contrasts. This is in no small part due to the fact that different theories use different aspects of phonetics (and their relationship to phonology) to define phonological place features.

4.2 *Consonant place contrasts*
