Subacute disease involves similar, but less severe, clinical signs than the acute form. The subacute form is characterized by transitory thrombocytopenia, leukopenia, and numerous hemorrhagic lesions (Gómez-Villamandos et al. 1997). Other clinical signs include moderate to high fever, ascites, hydropericardium, edema in several organs (gallbladder or kidneys), abortion, or splenomegaly. Mortality rates range from 30 to 70%, and animals may recover after 3–4 weeks. This clinical form can be observed in endemic scenarios.

In Sardinia, surviving animals have been described with anti-ASFV antibodies, intermittent viremia, or subacute disease, as well as survivors with no clinical signs or unspecific signs (Mur et al. 2016a). Similar observations have been made under field conditions in the Russian Federation (Mur et al. 2016b) and under experimental conditions in animals inoculated with Eastern European isolates (Gallardo et al. 2016).

Chronic form

Chronic disease has been reported mainly on the Iberian Peninsula (Portugal and Spain) and countries infected with isolates from the Iberian Peninsula. Recently, chronic forms have been described in experimental animal inoculated with Eastern European isolates (Gallardo et al. 2018; 2016).

Lesions

A variety of lesions may be observed in animals infected with ASFV, depending on the virulence of the virus isolate. Acute and subacute ASF is characterized by extensive hemorrhaging and lymphoid tissue destruction. Conversely, lesions may be minimal or absent in subclinical or chronic disease (Mebus et al. 1983).

The principal gross lesions are observed in the spleen, lymph nodes, kidneys, and heart (Sánchez-Botija 1982). The spleen may be darkened, enlarged, infarcted, and friable (Figure 25.3). Lesions may be large infarcts with

Figure 25.3 Enlarged and darkened spleen from ASF acute form.

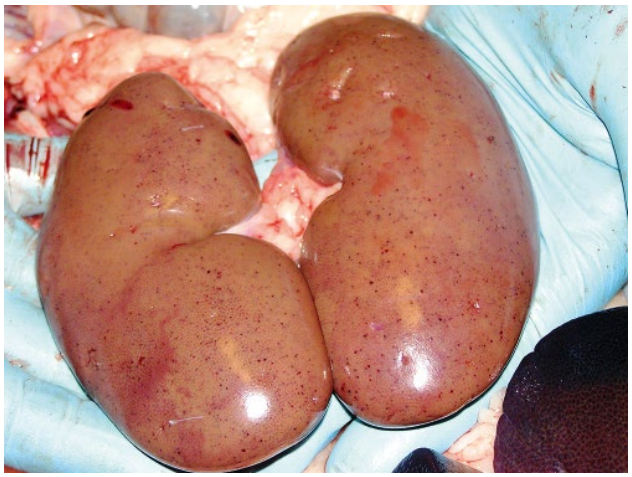

Figure 25.4 Kidneys from a pig infected with ASFV showing numerous petechiae on cortical surfaces.

subcapsular hemorrhages. Lymph nodes, especially the gastrohepatic and renal lymph nodes, are hemorrhagic, edematous, and friable and often resemble dark red hematomas. Because of congestion and subcapsular hemorrhage, cut sections of affected lymph nodes sometimes have a marbled appearance. Kidneys usually have petechial hemorrhages on cortical surfaces (Figure 25.4) and cut surfaces as well as in the renal pelvis. Intense hydropericardium with serohemorrhagic fluid is present in some cases. Petechial and ecchymotic hemorrhages may be observed in the epicardium and endocardium. Other lesions can also be observed in acute ASF, such as serohemorrhagic fluid in the abdominal cavity, with edema and hemorrhages throughout the gastrointestinal tract. Congestion of the liver and gallbladder may be observed, as well as petechial hemorrhages in the mucosa of the urinary bladder. Hydrothorax and petechial hemorrhages of the pleura are frequently found in the thoracic cavity, and lungs are usually edematous. Intense congestion is observed in the meninges, choroid plexus, and encephalon (Mebus et al. 1983).

Lesions in subacute ASF are similar to, but milder than, those in acute disease. Subacute disease is characterized by large hemorrhages in the lymph nodes and kidney. The spleen is enlarged and hemorrhagic. Congestion and edema can be observed in lungs, and, in some cases, interstitial pneumonia may be found.

In acute ASF, histopathological lesions are present in blood vessels and lymphoid organs. These lesions are characterized by hemorrhages, microthrombosis, and damage to endothelial cells, with accumulations of dead cells in the subendothelium (Gómez-Villamandos et al. 1995). The hemorrhagic splenomegaly characteristic of acute and subacute disease arises when viral replication leads to necrosis of splenic macrophages, destroying the splenic architecture. Lymphoid tissue destruction in acute ASF is observed mainly in the T area of lymphoid organs, but no evidence of virus replication in lymphocytes has been reported (Carrasco et al. 1996; Mínguez et al. 1988).

Chronic ASF is characterized by alterations in the respiratory tract, but lesions in the chronic form may be minimal or absent (Gómez-Villamandos et al. 1995; Mebus et al. 1983). Lesions include fibrinous pleuritis, pleural adhesions, caseous pneumonia, and hyperplasia of the lymphoreticular tissues. Fibrinous pericarditis and necrotic skin lesions are also common.

Diagnosis

Laboratory tests are essential for definitive diagnosis of ASFV because ASF clinical signs and lesions resemble those of other hemorrhagic diseases of pigs, such as classical swine fever (hog cholera), erysipelas, and septicemic salmonellosis. Thus, ASF cannot be diagnosed on the basis of clinical signs or gross lesions. In ASF-affected areas, it is also crucial to perform diagnostic evaluations of surviving animals that have recovered from infection, as well as animals showing only unspecific clinical signs.

Various laboratory tests are available for ASFV diagnosis (Arias and Sánchez-Vizcaíno 2002b). Samples recommended for laboratory analyses include the lymph nodes, kidney, spleen, lung, blood, and serum. When testing wild boar, bone marrow from leg is an excellent sample (Gallardo et al. 2015). Tissue samples are useful for virus isolation or detection; tissue exudates and serum samples may also be used for virus detection, though they serve primarily for antibody detection.

Identification of ASFV

The most convenient, safe, and frequently used techniques to detect and identify ASFV are the polymerase chain reaction (PCR) (Agüero et al. 2003; Fernández-Pinero et al. 2013; King et al. 2003) and the hemadsorption test (HAT) (Malmquist and Hay 1960). HAT is the reference standard test for ASF.

Several PCR-based methods have been assessed as consistent, analytically specific, and highly analytically sensitive for the detection of ASFV genotypes currently circulating, as well as for the detection of non-hemadsorbing and low virulence virus isolates. Primer sets and probes target sequences within a highly conserved region in the VP72 region of the genome. Some of them, when used in a real-time PCR system (Fernández-Pinero et al. 2013), provided the highest sensitivity for ASFV detection in chronically infected animals.

The diagnostic sensitivity and specificity of the HAT test makes it useful under a broad range of conditions. It should be used to evaluate suspected outbreaks,

especially when other tests are negative. HAT is based on the attachment of erythrocytes to the external (cytoplasmic) membrane of ASFV-infected porcine macrophages cultured *in vitro*. Typically, the erythrocytes form a rosette around the infected macrophages before the appearance of ASFV-induced cytopathic effects (Malmquist and Hay 1960). A few ASFV field strains have been isolated that induce cytopathic effects in macrophages without inducing hemadsorption (Sánchez-Botija 1982). These strains can be identified using PCR or direct immunofluorescence.

Serological tests

Several techniques have been adapted to the detection of anti-ASFV antibodies. ELISA (Sánchez-Vizcaíno 1986; Sánchez-Vizcaíno et al. 1979) is recommended for large-scale screening, while the indirect immunoperoxidase test, indirect immunofluorescence, and immunoblotting tests are recommended as confirmatory serological tests for positive or doubtful results (Gallardo et al. 2013, 2015; Pastor et al. 1987).

ELISA is well suited for control and eradication programs (Arias and Sánchez-Vizcaíno 2002a; Gallardo et al. 2015). Two indirect ELISAs described in the World Organization for Animal Health manual (OIE 2012) and several commercial competitive and indirect ELISAs have been validated for use under different epidemiological situations. These ELISAs may show lower diagnostic sensitivity when samples have been poorly preserved or when blood samples are used instead of serum, at least in the case of samples from wild boar (Arias et al. 1993; Gallardo et al. 2015). This limitation does not apply to "in-house" and commercial ELISAs based on new recombinant proteins (Gallardo et al. 2006, 2015).

The indirect immunoperoxidase and indirect immunofluorescence tests are highly diagnostically sensitive and specific as confirmatory assays following ELISA testing, as long as animals have been infected for at least 1 week (Arias and Sánchez-Vizcaíno 2002a). The immunoblotting test is recommended for confirming a clear positive for the presence of antibodies, which usually occurs at least 2 weeks post infection, and for confirming results when sera are suspected of being poorly preserved (Arias et al. 1993).

The serological diagnosis of ASF plays an important role in the surveillance program due to the fact that no vaccine is currently available against ASFV and, therefore, the presence of anti-ASFV antibodies in an animal indicates infection. This is particularly important for the detection of pigs that have recovered from subacute and inapparent ASF infection. These animals usually show high levels of ASFV-specific antibodies: IgM can be detected by 4 days post infection, and IgG by 6–8 days post infection. Antibody can circulate concurrently with virus for up to 6 months after infection (Arias and Sánchez-Vizcaíno 2002b; Wilkinson 1984) and remains detectable for years after the first exposure. The early appearance and subsequent persistence of anti-ASFV antibodies make them useful for detecting subacute and inapparent disease.

Immunity

Despite substantial progress toward an effective ASFV vaccine, no commercial vaccine is currently available. Pigs that survive ASFV infection develop efficient protective immunity against homologous viruses and, in certain cases, cross-protection against heterologous viruses (Boinas et al. 2004; Burmakina et al. 2016; King et al. 2011; Ruiz-Gonzalvo et al. 1981). The immune mechanisms involved in protection against ASFV are poorly understood, although both cellular and humoral immunities appear to be required (Takamatsu et al. 2013). The primary obstacles to protective immunity appear to be the absence of fully neutralizing antibodies and the great variability among virus isolates. Passive transfer of humoral immunity by administration of immune serum from ASFV-infected pigs or other infected animals can provide partial protection against ASFV, for example, a delay in the onset of clinical signs or mitigation of these signs, reduced levels of viremia, and higher survival rates (Onisk et al. 1994; Schlafer et al. 1984a,b; Wardley et al. 1985).

In vivo and *in vitro* studies have suggested a possible role for antibodies in complement-mediated cell lysis and antibody-dependent cell-mediated cytotoxicity (Rock 2017; Takamatsu et al. 2013). The innate immune response such as elevated activity of natural killer cells also plays an important role (Leitão et al. 2001) as well as the cytotoxic activity by a specific subset of CD8+ T lymphocytes (Martins and Leitão 1994; Oura et al. 2005).

Prevention and control

When ASF is suspected for any reason, pig movements should be restricted, and diagnostic testing performed immediately. It is important to remember that low virulence ASFV strains do not cause evident signs or lesions.

No treatment or effective vaccine against ASFV is available. Many attempts have been made to develop an efficacious ASF vaccine. The first trial with a live attenuated vaccine in 1963 in Portugal was unsuccessful (Manso-Ribeiro et al. 1963). Since then, some candidate vaccines based on attenuated ASFV have shown promising results (King et al. 2011; Leitão et al. 2001; O'Donnell

et al. 2016; Reis et al. 2016). However, there are still substantial shortcomings in regard to safety and efficacy.

Given the lack of an effective vaccine and the high costs associated with ASF, it is critical to protect ASF-free areas from the introduction of ASFV. Epidemiological studies have shown that contaminated garbage from international airports and ports is an important source of the virus (EFSA 2010). Therefore, all food leftovers from airplanes and ships should be incinerated.

In endemic European areas where mild or inapparent infections have been recognized, such as Sardinia, prevention measures include control of pig movements and pig products in combination with extensive serological surveys to detect carriers. In endemic areas of South and Est Africa, the most important prevention measure is the control of natural reservoirs, i.e. soft ticks (*O. moubata*) and wild African suids, with the objective of preventing their contact with domestic pigs. In Eastern Europe, it will be necessary to understand the role of biological vectors in the cycle and to control the movements of domestic pigs, wild boars, and pig by-products.

Methods to control ASF and eliminate ASFV from herds may differ depending on the region and continent, the specific epidemiological situation and circumstances, economic resources, and the situation in neighboring regions. Between 1985 and 1995, Spain carried out an extensive coordinated program to eradicate ASF, with the support of the European Community (Arias and Sánchez-Vizcaíno 2002a; Bech-Nielsen et al. 1995). Eradication of ASFV can be achieved without vaccination by the application of effective contingency programs. Every country should have an ASF contingency plan prepared and ready to implement in case of an ASF emergency.

Anelloviruses

Joaquim Segalés and Tuija Kekarainen

Relevance

In 1997, a previously unrecognized virus was detected in a Japanese patient with posttransfusion non-A-G hepatitis (Nishizawa et al. 1997). The virus was initially designated "TT virus" (TTV), referring to the initials of the patient. It was later renamed *Torque teno virus* from the Latin "torques" (necklace) and "tenuis" (thin) in reference to the organization of TTV DNA genome (Todd et al. 2005).

Human TTVs have been associated with liver and respiratory diseases, hematological disorders, and cancer. However, a causal role for TTV has not been established in any species, and therefore, these viruses are considered nonpathogenic commensal inhabitants of vertebrates (Simmonds et al. 1999).

Torque teno sus viruses (TTSuVs) are the TTV species infecting swine. Research on TTSuV is very recent, with the first epidemiological studies published in mid-2000s (Bigarré et al. 2005; McKeown et al. 2004). The link between TTSuVs and disease in swine has not been clearly established (Kekarainen and Segalés 2012).

Etiology

Increasing numbers of TTVs have been described and the nomenclature is changing rapidly. Among the 12 genera currently in the family *Anelloviridae*, 2 genera, *Iotatorquevirus* and *Kappatorquevirus*, include TTSuVs. Genus *Iotatorquevirus* includes two genetically distinct viral species, *Torque teno sus virus 1a* (TTSuV1a) (formerly *Torque teno sus virus 1* [TTSuV1]) and *Torque teno sus virus 1b* (TTSuV1b) (formerly *Torque teno sus virus 2* [TTSuV2]). Genus *Kappatorquevirus* also includes two species, namely, *Torque teno sus virus k2a* (TTSuVk2a) (formerly *Torque teno sus virus k2* [TTSuVk2]) and *Torque teno sus virus k2b* (TTSuVk2b) (Cornelissen-Keijsers et al. 2012; Kekarainen and Segalés 2012). The classification of TTSuVs is based on several tentative pairwise identity (PI) thresholds: variants (>95% PI), subtypes (85–95% PI), types (67–85% PI), species (55–67%), and genus (36–55%) (Huang et al. 2010). For simplicity, viruses in the genus *Iotatorquevirus* will be referred to as TTSuV1, and viruses in the genus *Kappatorquevirus* will be referred to as TTSuV2 in this chapter.

TTV virions are icosahedral and non-enveloped with a diameter of 30–32 nm. The buoyant density in cesium chloride is 1.31–1.33 g/cm^3 for TTV in serum and 1.33–1.35 g/cm^3 for TTV in feces (Okamoto et al. 1998).

The TTV genome is a single-stranded, negative-sense, circular DNA molecule of approximately 2.1–3.8 kb, depending on the host species (2.8 kb for TTSuVs) (Okamoto et al. 2002). The genomic organization and predicted transcriptional profile of TTSuVs resemble those of TTVs of humans, although the sequence similarity is less than 50% (Niel et al. 2005; Okamoto et al. 2002). The TTSuV genome contains untranslated region (UTR), occupying 24% of the viral genome (Okamoto et al. 2002), and three major ORFs: ORF1, ORF2, and ORF3. By analogy with circoviruses, ORF1 (635 amino acids) encodes the putative coat protein and presents sequence motifs that are characteristic of replication-associated proteins of circular ssDNA viruses. ORF2 (73 amino acids) contains sequences characteristic of tyrosine phosphatases (Kekarainen and Segalés 2012). The function of ORF3 (224 amino acids) is currently unknown. Splicing could be involved in generation of TTSuV mRNAs. For example, ORF3 mRNA is generated by splicing. Also, alternative splicing of TTSuV ORF1 could result in several mRNAs and different protein isoforms (Huang et al. 2012b; Martínez-Guinó et al. 2011).

The wide distribution of TTSuV in tissues (Aramouni et al. 2010) suggests that the virus can replicate in distinct cells, but no *in vitro* cell culture system has been identified (Kekarainen and Segalés 2012).

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Public health

There is no documented transmission of swine anelloviruses to humans. TTSuV DNA has been found in human drugs containing components of swine origin, but the biological significance is undetermined (Kekarainen et al. 2009). Also, TTSuV genome has been detected in pork meat and liver (Jiménez-Melsió et al. 2013; Leblanc et al. 2014; Monini et al. 2016), as well as in human feces (Jiménez-Melsió et al. 2013). The latter finding probably represents viral DNA coming from ingested contaminated pork products.

Epidemiology

TTVs have been found in humans, nonhuman primates, livestock species (pigs, sheep, cattle, camels, and poultry), companion animals (cats and dogs), wild boars, badgers, pine martens, tupaias, rodents, bats, sea turtles, and sea lions (Manzin et al. 2015). Each host has its own species-specific, genetically distinct TTV. However, human TTV can infect chimpanzees under experimental conditions (Luo et al. 2000).

No comprehensive study on geographic distribution has been done, but TTSuVs appear to be ubiquitous worldwide (Kekarainen and Segalés 2012). It is considered that the same TTSuV strains circulate among wild boars and domestic pigs. A retrospective study showed that TTSuVs were present as early as 1985 in Spain (Segalés et al. 2009).

TTSuVs can be detected in tissues, blood, semen, colostrum, nasal, and fecal samples (Aramouni et al. 2010; Kekarainen et al. 2007; Nieto et al. 2013; Sibila et al. 2009), indicating the potential for both horizontal and vertical transmission. As observed in human TTV, the rate of TTSuV detection in serum and nasal excretions increases with age (Sibila et al. 2009). Increasing prevalence and viral load in tissues with age (Xiao et al. 2012) suggests that transmission is very efficient, probably by the oral–nasal exposure.

The current inability to propagate virus *in vitro* precludes studies on the virus persistence in the environment or susceptibility to disinfectants. However, the physicochemical properties of TTSuVs are thought to be similar to those of other ssDNA viruses like members of the family *Circoviridae*.

Pathogenesis

The primary site of virus replication is unknown. In fetuses, the highest concentration of TTSuV is found in the lung, heart, spleen, and kidney, suggesting that these tissues contain a significant number of cells supporting viral replication (Aramouni et al. 2010). In older animals, high concentrations of virus are found in all tissues (Nieto et al. 2013). Whether this reflects actively replicating virus within these tissues or virus accumulated over time is uncertain. Recently, by using an *in situ* hybridization method, lymphoid tissues, including superficial inguinal, mesenteric, and hilar lymph nodes, tonsil, intestinal lamina propria of mucosa, and Peyer's patches, and sometimes spleen, were found to contain significant levels of positive signals and were suggested as target sites for TTSuV (Lee et al. 2014). T lymphocytes were speculated to be the major target cells for TTSuV (Lee et al. 2014).

TTSuVs may be found in a high proportion of apparently healthy animals (Kekarainen and Segalés 2012), which suggests that infection by itself does not produce clinical signs. However, TTSuVs have been associated with economically important diseases like porcine circovirus type 2 systemic disease (PCV2-SD) (classically known as post weaning multisystemic wasting syndrome) (Ellis et al. 2008; Kekarainen et al. 2006). Also, TTSuVs have been linked with a porcine dermatitis and nephropathy syndrome (PDNS)-like condition (Krakowka et al. 2008), weight gain reduction (de Menezes Cruz et al. 2016), inflammatory lung lesions (Aramouni et al. 2013b), porcine respiratory disease complex (PRDC) (Rammohan et al. 2012) and found in coinfection with many pathogens, including African (Luka et al. 2016) and classical (Aramouni et al. 2013a) swine fever. The association of TTSuV with disease is controversial, and it has been suggested that TTSuV species could differ genetically and in their role in clinical disease (Cornelissen-Keijsers et al. 2012; Rogers et al. 2017).

Clinical signs and lesions

At present, no clinical signs are specifically associated with TTSuV infection, and no clinicopathological experimental studies involving conventional pigs have been done due to the lack of readily available isolates. Inoculation of gnotobiotic pigs with TTSuV1-containing tissue homogenate caused mild interstitial pneumonia, transient thymic atrophy, membranous glomerulonephropathy, and modest lymphocytic-to-histiocytic liver infiltrates (Krakowka and Ellis 2008). One-half of gnotobiotic pigs inoculated intraperitoneally with TTSuV1 and 7 days later oronasally with PCV2 developed acute fatal PCV2-SD (Ellis et al. 2008). No PCV2-SD was observed when TTSuV or PCV2 was the only inoculum or if PCV2 preceded the inoculation with TTSuV inoculation. However, there are also contrary reports concerning the association of TTSuV infection with PCV2-SD

(Lee et al. 2010; McMenamy et al. 2013; Teixeira et al. 2015). Thus, TTSuV infection as a cofactor in the development of PCV2-SD is undetermined.

Diagnosis

No protocols for virus isolation have been described for TTSuVs. Therefore, diagnosis of TTSuV infection is based on the detection of viral DNA and/or antibodies against the virus. To date, the developed methods have been used for research purposes, and no commercial methods are available. Several PCR-based assays have been developed (Segalés et al. 2009), including a quantitative PCR (qPCR) for all TTSuV1 and TTSuV2 species in serum (Cornelissen-Keijsers et al. 2012; Gallei et al. 2009; Lee et al. 2010; Nieto et al. 2011) and a nonspecific qPCR that detects both TTSuV genera and bovine TTV (Brassard et al. 2010). A number of serological methods have been used in research, all of them based on ELISA (Huang et al. 2012a; Li et al. 2015; Nieto et al. 2015), with the exception of one report of a fluorescent microbead-based immunoassay (FMIA) (Giménez-Lirola et al. 2014).

Immunity

Few studies on immune responses against TTSuV have been reported. Both sows and piglets develop antibodies against TTSuV1 and TTSuV2 (Giménez-Lirola et al. 2014; Huang et al. 2012a; Nieto et al. 2015), although the kinetics are different for both viral genera (high levels in sows and pigs at early ages for TTSuV1, but low levels for TTSuV2) (Nieto et al. 2015). The high percentage of viremic, but antibody-positive, pigs reflects an inefficient anti-TTSuV immune response. Further, *in utero* infection prior to the gestational age at which the fetus becomes immunologically responsive and evidence of lifelong infection in pigs raise the possibility of immunotolerance (Aramouni et al. 2010). Further studies are needed to understand these observations.

The immunopathogenesis of swine anelloviruses is unknown. An *in vitro* study suggested that TTSuV1 does not have a significant immunosuppressive effect on antiviral immunity (Singh and Ramamoorthy 2016). In contrast, another study suggested that TTSuV1 natural infection has an adverse effect on the development of host immune responses, suppresses immunization by a porcine reproductive and respiratory syndrome (PRRS) attenuated vaccine, and exacerbates PRRS to a certain extent (Zhang et al. 2012). These preliminary results await confirmation.

Prevention and control

The impact of TTSuV infection and the consequences for herd health have not yet been established. Since a significantly higher TTSuVk2a load in serum has been described in PCV2-SD (Aramouni et al. 2011), measures to decrease the viral load might have an impact on disease outcome. One study reported that TTSuV viremia was controlled by a combined DNA and protein immunization (Jiménez-Melsió et al. 2015). PCV2 vaccination has also been tested as a potential measure to avoid TTSuV upregulation in the context of PCV2-SD. However, PCV2 vaccination did not alter TTSuV loads (Lee et al. 2012; Nieto et al. 2012).

Astroviruses

Gábor Reuter and Nick J. Knowles

Relevance

Astroviruses (AstV) have been identified in many mammalian and avian host species (Boujon et al. 2017). In some species, AstV have been linked to hepatic (e.g. duck), nephritic (e.g. chicken), gastroenteric (e.g. human, turkey, sheep), and/or neurologic (e.g. human, mink, cattle, sheep and pig) diseases (Arruda et al. 2017; Boros et al. 2017; De Benedictis et al. 2011; Mendez and Arias 2013; Reuter et al. 2018). AstV from different animal species are antigenically distinct (Mendez and Arias 2013). Porcine astroviruses (PAstVs) were first recognized by electron microscopy of diarrheic feces (Bridger 1980; Geyer et al. 1994; Shimizu et al. 1990; Shirai et al. 1985) and postulated to cause a mild, self-limiting diarrhea. Recently, PAstV-associated neurological disease was reported in pigs in Hungary and the United States (Arruda et al. 2017; Boros et al. 2017). But their causal role in enteric or other diseases in pigs still remains obscure.

Etiology

PAstVs are members of the family *Astroviridae*, which is divided into two genera, *Mamastrovirus* (AstV of mammals) and *Avastrovirus* (AstV of birds). Approximately 30 nm diameter and non-enveloped AstV particles are distinctive in appearance, with some particles showing a 5- or 6-pointed star surface pattern when viewed by negative stain electron microscopy (Figure 27.1; Bridger 1980; Shimizu et al. 1990). Not all particles show this distinctive appearance, and care is needed so as not to confuse them with the indistinct appearance of noroviruses, particularly in the presence of antibody.

The AstV genome is composed of positive-sense, single-stranded RNA 6.4–7.9 kb in length (excluding the poly[A] tail at the 3′ end) and consisting of three open reading frames: ORF1a, ORF1b, and ORF2 (Mendez and Arias 2013). The list of animal species susceptible to AstV infection has expanded in the last decade, and additional species will probably be identified. Studies of evolutionary genomic relationships, mainly based on ORF2 (capsid protein), showed that human and animal AstV belonged to phylogenetically distinct genomic clusters (Figure 27.2; Jonassen et al. 2001; Kapoor et al. 2009; Lukashov and Goudsmit 2002; Reuter et al. 2011). Multiple lineages (and serotypes) of AstV have been identified within the same host species, for example, humans (classical HAstV1-8, HAstV-MLB1, and HMOAstVs), bats, turkeys, and pigs. Thus, AstV are genetically highly diverse, with each lineage potentially representing an independent origin. The International Committee on Taxonomy of Viruses has officially classified 19 genotype species of mamastroviruses (*Mamastrovirus 1* through *Mamastrovirus 19*), but a number of AstV have not yet been classified. For example, up to five PAstV lineages (PAstV1 to PAstV5) have been identified (Laurin et al. 2011), but only PAstV1 has been classified under the species *Mamastrovirus 3*, and the taxonomic species of PAstV2–PAstV5 have not been officially classified.

The physicochemical and biological properties of PAstVs have not been fully characterized. Cytopathic PAstV1 from diarrheic pigs was successfully isolated on porcine kidney cell lines by incorporating trypsin into the medium (Indik et al. 2006; Shimizu et al. 1990). Immunofluorescent cells and AstV particles were also detected. A virus with a buoyant density of 1.35 g/ml was cloned, and a serum virus neutralization test was developed. The PAstV1 isolate was stable to treatment with lipid solvents and resisted heating at 56 °C (133 °F) for 30 minutes but showed some susceptibility to acid treatment at pH 3.0 for 3 hours. In most AstV, virion protein composition has not been established, but is generally thought to consist of three capsids ranging between 24 and 39 kD.

Public health

The zoonotic potential of AstV is unclear. The possibility of zoonotic transmission is suspected, but additional data is needed.

Epidemiology

PAstVs have been identified in pig feces in the United Kingdom (Bridger 1980), Japan (Shimizu et al. 1990), South Africa (Geyer et al. 1994), and Czech Republic (Indik et al. 2006) and recently in 12 more countries, indicating a worldwide distribution. The prevalence of PAstVs can be high in both diarrheic and clinically healthy swine. For example, PAstVs (PAstV1 to PAstV5), but predominantly PAstV4, were detected in 64% (326/509) of US porcine fecal samples (Xiao et al. 2013). Coinfections of a single pig with two or more PAstVs were observed (Xiao et al. 2013). One or more PAstVs were identified in 31.6% (25/79) of the suckling pigs sampled, 75.1% (136/181) of the nursery pigs, 72.3% (107/148) of the grow–finish pigs, and 28.6% (2/7) of mature pigs. PAstV prevalence was significantly higher in nursery pigs compared with suckling and mature pigs (Xiao et al. 2013). In a previous serological survey in Japan, 39% of 128 pigs in 8 herds had serum neutralizing antibodies to porcine astrovirus PAstV1 (Shimizu et al. 1990). All but one herd was antibody positive, and the in-herd prevalence ranged from 7 to 83%. PAstVs (PAstV4 and PAstV5) were also detected in wild boars (Cai et al. 2016; Reuter et al. 2012).

Transmission is presumed to be fecal–oral, but PAstV was also detected in nasal swab (Padmanabhan and Hause 2016) and blood samples (Brnic et al. 2013). Discoveries of novel AstV, in combination with genetic and evolutionary studies, support the hypothesis that cross-species transmission and natural recombination among AstV of humans, pigs, and other animal species, possibly through unknown intermediate hosts, may have occurred in the past. Given the diversity of AstV, interspecies transmission could be underestimated because no common molecular probes, antibodies, or oligonucleotide primers are available to identify AstV strains across different species (Mendez and Arias 2013).

Pathogenesis, clinical signs, lesions, and immunity

In most mammalian species, AstV infections are associated with gastroenteritis. In humans, AstV were found to be the third to fourth most common cause of viral diarrhea in young children worldwide. PAstVs have been associated with severe diarrhea in natural infections, but only in the presence of other known enteric pathogens (Bridger 1980; Shimizu et al. 1990). Mild diarrhea developed in 4-day-old pigs after oral inoculation with PAstV1 grown in cell culture (Shimizu et al. 1990). Diarrhea commenced 1 day after inoculation and continued for 5–6 days. Cytopathic AstV was recovered from feces and pigs seroconverted. Similarly, PAstV-induced mild diarrhea was observed in 7-day-old gnotobiotic piglets in a per os experimental inoculation study in the Czech Republic (Indik et al. 2006).

Recent studies also demonstrated that extraintestinal consequences of PAstV infections may also be possible. PAstVs capable of causing viremia (RNAemia) (Brnic et al. 2013) were detected in nasal swabs collected from young pigs in unexplained acute respiratory disease (Padmanabhan and Hause 2016) and in brain tissues of piglets with congenital tremor (Blomström et al. 2014). More recently, neuroinvasive PAstV3-associated neurological disease (meningoencephalomyelitis, weakness, and paralysis) has been reported on swine farms in Hungary and the United States (Arruda et al. 2017; Boros et al. 2017). These recent results suggest that PAstV infections have a more complex pathogenesis and more serious disease outcome than previously thought (Reuter et al. 2018).

Nothing is known about antigenic differences between PAstVs and the immunity induced by infection with these viruses.

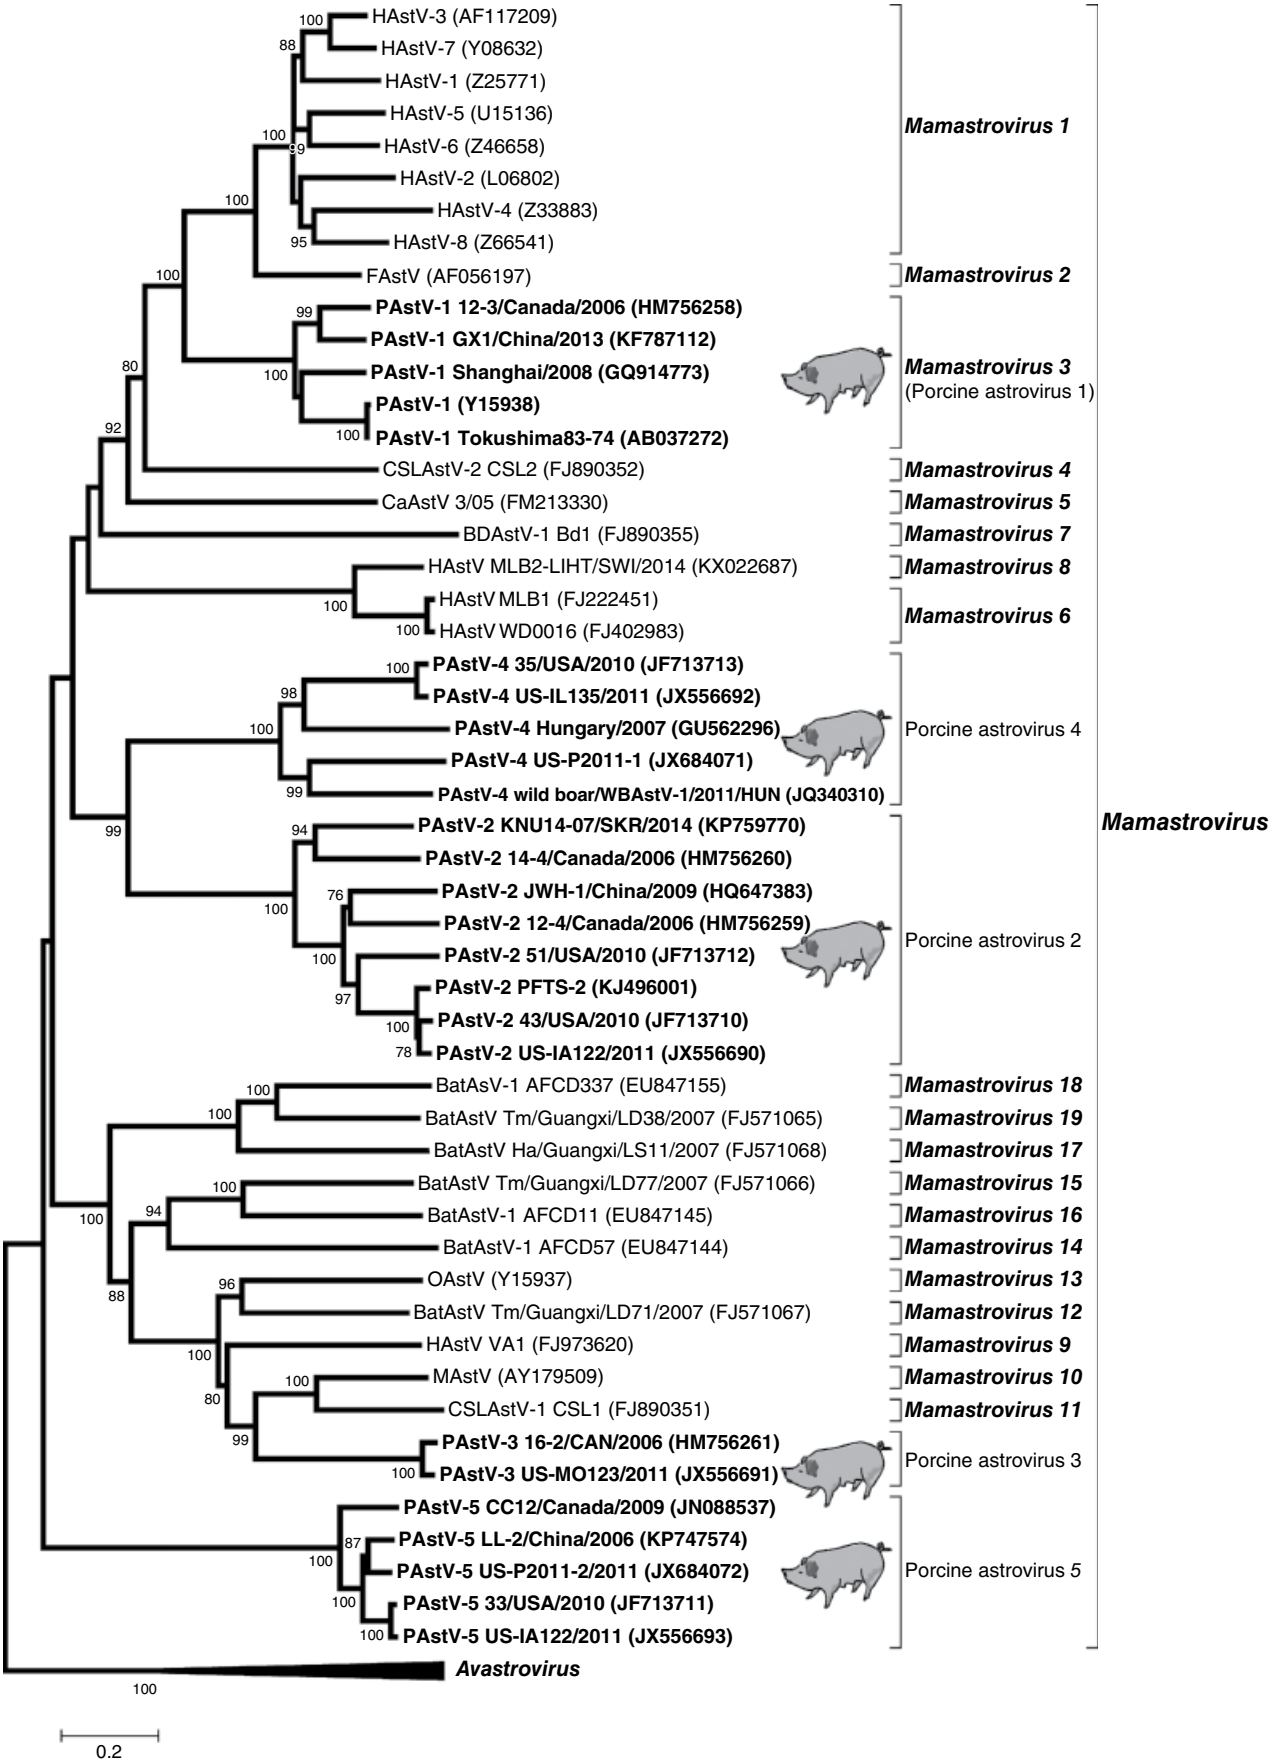

Figure 27.2 Midpoint-rooted neighbor-joining tree showing the relationships between the capsid proteins of porcine astroviruses and other representative members of the family in genera *Mamastrovirus* and *Avastrovirus*. Porcine astroviruses (PAstV1 to PAstV5) are in bold letters. BatAstV, bat astrovirus; BDAstV, bottlenose dolphin astrovirus; CaAstV, canine astrovirus; CSLAstV, California sea lion astrovirus; FAstV, feline astrovirus; HAstV, human astrovirus; MAstV, mink astrovirus; OAstV, ovine astrovirus.

Diagnosis

Assays have not been developed for routine diagnosis, but methods such as electron microscopy, isolation on cell culture, identification with immunofluorescence staining, detection of nucleic acids by reverse transcription polymerase chain reaction (RT-PCR) (Arruda et al. 2017; Boros et al. 2017), and next-generation sequencing methods using random primer-based amplification (Arruda et al. 2017; Shan et al. 2011) can be used to identify PAstV infection. Virus isolation for PAstVs has proven difficult. PAstV1 has been isolated on porcine kidney cells with the addition of trypsin (Indik et al. 2006; Shimizu et al. 1990), but there have been no reports of successful isolation of PAstV2–PAstV5. Virus neutralization and immunofluorescent antibody assays can be used to demonstrate PAstV1 seroconversion (Shimizu et al. 1990), but the diagnostic performance of these methods has not been established.

Prevention and control

PAstVs may be just one of several viruses that contribute to pre- and post weaning diarrhea and, perhaps, encephalomyelitis. Elimination of AstV from infected farms would be difficult because they are apparently widely distributed in swine populations and stable in the environment. Efforts to eliminate AstV would also be difficult to justify on the basis of their clinical effects. Assuming that lesions caused by infection with AstV are confined to the intestinal tract, oral rehydration would be expected to be effective in affected pigs. There are no commercially available vaccines.

Bunyaviruses

Chih-Cheng Chang

Relevance

Although more important in humans and ruminants, swine are nonetheless susceptible to several bunyaviruses, as supported by studies on Akabane, Oya, Lumbo, and Tahyna viruses (Arunagiri et al. 1991; Huang et al. 2003; Hubálek et al. 1993; Kono et al. 2002; Lim et al. 2007; Yadav et al. 2016). Bunyaviruses constitute a large and highly diverse group. Thus, it is possible that swine are susceptible to additional bunyaviruses. However, a consensus has not been achieved on the susceptibility of pigs to Gouléako virus and Herbert virus (Chung et al. 2014; Junglen et al. 2015). Similarly, Poskin et al. (2014) reported seroconversion, but no detection of viral replication in pigs inoculated with Schmallenberg virus.

Etiology

Bunyaviruses are single-stranded, negative-sense, enveloped viruses 80–100 nm in diameter. The genome is composed of three segments of negative-sense RNA that differ in size: large (L), medium (M), and small (S) (Elliott 1985, 1990). The L segment encodes a large polypeptide (L protein) with replicase and transcriptase activities (Jin and Elliott 1991, 1992). The M segment encodes two structural glycoproteins (G1 and G2) and a nonstructural protein (NSm) (Elliott 1985; Fazakerley et al. 1988; Fuller and Bishop 1982; Gentsch and Bishop 1979; Gerbaud et al. 1992). These glycoproteins, inserted into the membrane of the virion and projected onto the surface, are critical in viral virulence, attachment, cell fusion, and hemagglutination activity (Schmaljohn 1996). The nucleocapsid (N) and a nonstructural protein (NSs) are encoded by overlapping reading frames in the S segment (Elliott 1990).

Bunyavirus taxonomy underwent significant changes in 2016. Prior to 2016, the family *Bunyaviridae* was organized in five genera: *Hantavirus*, *Nairovirus*, *Orthobunyavirus*, *Phlebovirus*, and *Tospovirus*. In 2016, the International Committee on Taxonomy of Viruses created a new order, *Bunyavirales*, with nine families. Bunyaviruses known to be infectious for pigs are in the family *Peribunyaviridae*, genus *Orthobunyavirus* (Akabane, Oya, Lumbo, and Tahyna viruses). Traditionally, viruses in the genus *Orthobunyavirus* are divided into five serogroups: Bunyamera, Bwamba, California, Guama, and Simbu (Calisher 1996). Bunyaviruses of swine fall into the Simbu serogroup (Akabane, Oya, and Schmallenberg viruses) and California serogroup (Lumbo and Tahyna viruses) (Calisher 1996; Elliott 1997).

Public health

Humans are not susceptible to Akabane or Oya viruses (Bryant et al. 2005). Tahyna virus and the closely related Lumbo virus are widespread in some human populations, occasionally with clinical consequences (Gould et al. 2006; Vapalahti et al. 1996). Overall, the role of pigs in the complex ecology of bunyaviruses is largely undefined, but likely to be minor.

Epidemiology

Given the extensive global movement of people, animals, and goods, the geographical distribution of specific bunyaviruses is plastic and reflects each virus' ability to exploit available vector(s) and host(s). Akabane and Oya viruses are found worldwide, except Europe, and are transmitted to vertebrates by culicoid midges and mosquitoes (Calisher 1996). Lumbo (Africa) and Tahyna viruses (Asia, Africa, and Europe) are mosquito-borne viruses (Elliott 1997).

Akabane virus (Simbu serogroup) was first isolated from mosquitoes in Japan in 1968. Midges and mosquitoes are vectors of Akabane virus (Jennings and Mellor 1989; Kurogi et al. 1987; Oya et al. 1961), and herbivores, including cattle, sheep, giraffe, horses, and goats, are the natural vertebrate hosts (Al-Busaidy et al. 1988; Cybinski et al. 1978). Some work has shown that Akabane virus

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

may be prevalent in pig populations in Asia (Huang et al. 2003; Lim et al. 2007; Yanase et al. 2018), with biting midges (*Culicoides* spp.) serving as the primary vectors (Hsu et al. 1997; Huang et al. 2003). Akabane virus transmission in pigs may not be completely arthropod dependent. That is, infection occurred following experimental oronasal exposure (Huang et al. 2003).

In Korea, a survey found that 37% of pigs were seropositive for Akabane virus, with positive pigs on all of the 15 farms surveyed (Lim et al. 2007). In Taiwan, a national survey (Huang et al. 2003) found that approximately 75% of pigs were serum antibody positive for Akabane virus, with seropositivity rates in sow breeding herds reaching 99%. A high percentage of positive testing results in young pigs (98%) suggested the presence of maternal antibodies. Consistent with this interpretation, seropositivity declined to 17% in 20-week-old pigs and then returned to high levels (71%) in late finishers. Seropositivity rates for Akabane virus in cattle in Taiwan were also high (96%).

Sequential analysis of Taiwanese Akabane virus isolates from swine (NT-14) and cattle (PT-17) showed a high degree of homology (99.6%) for the small (S) RNA segment. Akabane virus was also identified in piglets with neurological disorders or congenital malformations in 2011 and 2013 in Japan, and the virus detected in piglets shared high nucleotide identity (99.02–99.83%) to the viruses detected in cattle at the same year (Yanase et al. 2018).

Serosurveys for other bunyaviruses have also been done in swine populations. A study of Oya virus (Simbu serogroup) in Malaysia found that 93% of 360 pigs sampled on 24 farms in 6 states were serum antibody positive (Kono et al. 2002). Hubálek et al. (1993) reported that 38% of wild boars (*Sus scrofa*) in the Czech Republic were seropositive for Tahyna virus (California serogroup). A serosurvey in China showed IgM and IgG antibodies against Tahyna virus in swine by indirect fluorescent antibody (IFA) assay (Li et al. 2010). Seroconversion of pigs to Lumbo virus, another member of the California serogroup, was reported in Sri Lanka (Arunagiri et al. 1991).

Pathogenesis

Little research on the pathogenesis of bunyaviruses in pigs has been reported. Huang et al. (2003) infected 4-week-old pigs with Akabane virus (isolate NT-14) under experimental conditions by oronasal exposure. Viremia occurred 1–6 days post inoculation (DPI). During this period, the virus was isolated from a variety of tissues (spleen, lungs, brain, small intestine, lymph node, thymus, and salivary gland) and persisted in the tonsil for 14 DPI. The virus was also isolated from oronasal discharge, but not feces. Naive pigs in direct contact with the inoculated pigs did not become infected.

Clinical signs and lesions

Akabane virus infection is inapparent in adult swine (Huang et al. 2003), but whether Akabane virus induces lesions in pregnant sows or their fetuses is not known. Under experimental conditions, Akabane virus (isolate NT-14) did not produce gross lesions, but mild lymphocytic encephalitis and cerebral vasculitis were observed (Huang et al. 2003).

Clinical signs and lesions have not been described for Tahyna and/or Lumbo viruses. Lesions caused by Oya virus in pigs have not been described, but Kono et al. (2002) suggested that Oya virus could cause clinical signs similar to Nipah virus infection.

Diagnosis

Bunyaviruses may be recovered in suckling mice or on susceptible cell culture systems, including hamster lung (HmLu-1), baby hamster kidney (BHK-21) cells, monkey kidney cells (Vero, MA-104, MARC-145), and mosquito cell lines (Bryant et al. 2005; Gerdes 2008; Huang et al. 2003; Kono et al. 2002). Techniques for bunyavirus detection and identification include transmission electron microscopy, serology (Huang et al. 2003), immunohistochemistry, reverse transcription–polymerase chain reaction (Bryant et al. 2005; Huang et al. 2003), and sequencing (Saeed et al. 2001).

Prevention and control

There are no effective treatments or vaccines available for bunyavirus infection in pigs. However, these viruses are inactivated by most common disinfectants, for example, hypochlorite, detergents, chlorhexidine, and phenols.

Caliciviruses

Nick J. Knowles and Gábor Reuter

Overview

The family *Caliciviridae* consists of five genera: *Lagovirus*, *Vesivirus*, *Norovirus*, *Sapovirus*, and *Nebovirus* (Clarke et al. 2012). The *Lagovirus* genus is composed of two species, *Rabbit hemorrhagic disease virus* and *European brown hare syndrome virus*, while the *Vesivirus* genus is composed of two species, *Vesicular exanthema of swine virus* and *Feline calicivirus*, plus a number of unassigned viruses. The *Norovirus*, *Sapovirus*, and *Nebovirus* genera each consist of a single species, *Norwalk virus*, *Sapporo virus*, and *Newbury-1 virus*, respectively. Some recently discovered caliciviruses are phylogenetically distinct from the existing genera and currently remain unclassified (although six novel genera have been proposed): Tulane virus detected from rhesus macaques (Farkas et al. 2008), St-Valérien virus detected from pigs (L'Homme et al. 2009b), chicken calicivirus (Wolf et al. 2011), turkey/chicken/goose calicivirus (Liao et al. 2014; Wolf et al. 2012), Atlantic salmon calicivirus (Mikalsen et al. 2014), and bat calicivirus (Kemenesi et al. 2016). Caliciviruses infecting pigs include VESV, Norwalk virus, Sapporo virus, and the unclassified St-Valérien virus.

Calicivirus virions are non-enveloped with icosahedral symmetry. They are 27–40 nm in diameter by negative stain electron microscopy (Wawrzkiewicz et al. 1968) and 35–40 nm by cryo-electron microscopy and X-ray crystallography (Prasad et al. 1999). The capsid is composed of 90 dimers of the major structural protein VP1 arranged on a $T = 3$ icosahedral lattice. In noroviruses, the VP1 forms a subunit composed of a shell and two protruding domains. A characteristic feature of calicivirus capsid architecture is the 32 cup-shaped depressions at each of the icosahedral fivefold and threefold axes. In negative stain virus preparations, some cup-shaped depressions appear distinct and well defined, while in others, these depressions are less prominent.

Caliciviruses have single-stranded, positive-sense genomic RNA organized into either two or three major open reading frames (ORFs). The nonstructural proteins are encoded in the 5′ part of the genome and the structural proteins in the 3′ part. Replication occurs in the cytoplasm, and two major positive-strand RNA species are found in infected cells: (1) the genome-sized, positive-strand RNA serves as the template for the translation of a large polyprotein that undergoes cleavage by a virus-encoded protease to form the mature nonstructural proteins, and (2) a subgenomic-sized, positive-strand RNA coterminal with the 3′ terminus of the genome is the template for the translation of the VP1 as well as the 3′ terminal ORF product VP2. A double-stranded RNA (dsRNA) corresponding in size to full-length genomic RNA has been identified in cells infected with feline calicivirus and San Miguel sea lion virus (SMSV), indicating that replication occurs via a negative-strand intermediate.

Virion molecular mass (Mr) is about 15×10^6. Virion buoyant density is 1.33–1.41 g/cm^3 in CsCl and 1.29 g /cm^3 in glycerol–potassium tartrate gradients. Virion S_{20w} is 160–187S (Wawrzkiewicz et al. 1968). Physicochemical properties have been established for some members of the family. Generally, caliciviruses are stable in the environment, and many strains are resistant to inactivation by heat and certain chemicals (ether, chloroform, and mild detergents) (Wawrzkiewicz et al. 1968). Enteric caliciviruses are acid stable, while vesiviruses are labile below pH 4.5–5.0 (Wawrzkiewicz et al. 1968).

Vesicular exanthema of swine virus

Relevance

Vesicular exanthema of swine (VES) is an acute, highly infectious disease characterized by fever and formation of blisters on the snout, oral mucosa, soles of the feet, the coronary band, and between the toes. In pigs, the clinical disease is indistinguishable from foot-and-mouth disease,

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

vesicular stomatitis, swine vesicular disease, and vesicular disease caused by Seneca Valley virus.

Originally confined to California, VES became widespread in the United States during the 1950s, but a vigorous campaign to eradicate the disease was successful. In 1959, the United States was declared free of VES, and the disease was designated a foreign animal disease; it has never been reported as a natural infection of pigs in any other parts of the world.

Since 1972, a virus indistinguishable from vesicular exanthema of swine virus (VESV), designated as SMSV, has been isolated from throat and rectal swabs from premature and 4-month-old California sea lion pups, dead and weanling northern fur seal pups, and nursing northern elephant seal pups. It has also been isolated from vesicular lesions on marine mammals, commercial seal meat produced in Alaska, and perch-like fish collected from tidal pools off the southern California coast. SMSV isolated from both fish and marine mammals is capable of producing vesicular exanthema in pigs and humans (Smith et al. 1998b). In addition, caliciviruses isolated from throat and rectal swabs from dairy calves cause clinical vesicular exanthema in exposed pigs.

Etiology

The genus *Vesivirus* is composed of two species: *Vesicular exanthema of swine virus* and *Feline calicivirus*. A number of other vesiviruses, isolated from dogs and mink and as cell culture contaminants, are distinct from the two species and remain unclassified. Viruses in the species *Vesicular exanthema of swine virus* are classified into more than 40 serotypes (although not all have been serologically compared) (Neill et al. 1995). Thirteen are known as VESV (VESV-B34, VESV-101-43, VESV-A48, VESV-B51, VESV-C52, VESV-D53, VESV-E54, VESV-F55, VESV-G55, VESV-H54, VESV-I55, VESV-J56, VESV-K54), 17 as SMSV (SMSV-1, SMSV-2, SMSV-4 to SMSV-7, SMSV-9 to SMSV-11, SMSV-13 to SMSV-17, SMSV-FADDL 7005, SMSV-693 M, SMSV-3709), and the remainder named after the hosts from which they were first isolated, that is, California sea lion virus 02012181, Steller sea lion virus (SSLV) V810, SSLV-V1415, bovine calicivirus (BCV) Bos-1, BCV Bos-2, cetacean calicivirus Tur-1, primate calicivirus Pan-1, reptile calicivirus Cro-1, walrus calicivirus, skunk calicivirus, rabbit calicivirus, and human calicivirus. Seven VESV serotypes isolated during the 1930s and 1940s have since been lost or destroyed and have not been compared with later serotypes. SMSV-3 was found to be a mixture of SMSV-1 and SMSV-2. Complete genome sequencing of SMSV-8 and SMSV-12 shows them to be distinct from other members of the species *Vesicular exanthema of swine virus* (Neill 2014; N.J. Knowles et al., unpublished data). Members of the species *Vesicular exanthema of swine virus* all replicate in mammalian cell cultures (e.g. monkey kidney or porcine kidney) usually causing a rapid and destructive CPE.

Public health

These viruses are not thought to be of public health significance; however, human infection by two different marine mammal serotypes has been reported. SMSV-5 was recovered from vesicular lesions on the palms and soles of a researcher working with the virus (Smith et al. 1998b). In a separate incident, an individual who handled diseased Steller sea lions (*Eumetopias jubatus*) in the Bering Sea developed blistering of the hard palate, upper lip, and facial area. A novel vesivirus (strain McAll) was isolated from throat washings sampled 30 days post onset (Smith et al. 1998b).

Epidemiology

VESV/SMSV and related viruses have been found along the Pacific Coast of North America as far north as the Bering Sea. Outbreaks of VES occurring between 1932 and 1951 in pigs in the United States were limited to California. However, in 1951, one serotype (B51) spread to 41 states and the District of Columbia. Two further serotypes appeared in New Jersey in 1954 and 1956.

Natural infections have been found in pigs, pinnipeds, cetaceans, cattle, horses, skunk, primates (including humans), reptiles, and fish (Smith et al. 1998a). SMSV-7 and SMSV-17 have been isolated from a sea lion liver fluke (*Zalophatrema* sp.) and a mussel (*Mytilus californianus*), respectively (Smith et al. 1998a). Experimentally, at least six of the SMSV serotypes have been shown to cause vesicular disease in pigs indistinguishable from that caused by VESV (Berry et al. 1990; Bresse and Dardiri 1977; Gelberg and Lewis 1982; Smith et al. 1974, 1980; Van Bonn et al. 2000).

The principal form of transmission during outbreaks of vesicular exanthema in the United States was thought to be by feeding untreated contaminated garbage. However, spread by direct contact of infected animals occurs readily (Madin 1975).

Clinical signs and lesions

Following an elevated temperature, vesicles appear at one or more of the following sites: snout, lips, tongue, mucosa of the oral cavity, and on the sole, interdigital space, and coronary band of the foot (Madin 1975). Lesions may also appear on the teats, particularly in nursing sows.

Diagnosis

Presumptive diagnosis in pigs is based on fever and the presence of typical vesicles, which normally rupture within 24–48 hours to form erosions. Laboratory

differentiation of VESV from other vesicular disease-causing viruses, such as foot-and-mouth disease virus (*Aphthovirus*, *Picornaviridae*), swine vesicular disease virus (*Enterovirus*, *Picornaviridae*), Seneca Valley virus (*Senecavirus*, *Picornaviridae*), and vesicular stomatitis virus (*Vesiculovirus*, *Rhabdoviridae*), is essential.

Virus may be detected by a variety of serologically based laboratory tests, including complement fixation (Bankowski et al. 1953), virus neutralization (Bankowski et al. 1953; Holbrook et al. 1959), and enzyme-linked immunosorbent assay (ELISA) (Ferris and Oxtoby 1994). However, the serologically based tests rely on specific antisera for each serotype.

Electron microscopy may be performed on epithelial tissue suspensions or after passage in swine tissue cultures. Various reverse transcription polymerase chain reactions (RT-PCRs) have been developed for the identification of vesiviruses (McClenahan et al. 2009; Reid et al. 1999, 2007).

VES viruses may be isolated in cell cultures (usually pig or monkey kidney cell lines). Once the serotype involved in an outbreak has been confirmed, serological assays can be used for the detection/diagnosis of infected herds.

Immunity

Animals that have recovered from VESV develop a strong immune response and are protected against the same serotype for at least 6 months (Madin 1975). Neutralizing antibody may be detected 10–12 days post infection and peak at 21–28 days post infection.

Prevention and control

No specific treatment is available for VESV infection. Vaccines are not available, and the number of serotypes would probably preclude their development. Suspected cases of vesicular exanthema should be reported immediately to the proper authorities. Garbage and fish should be cooked before being fed to pigs. Despite VES having not appeared since its eradication in the 1950s, VES-like viruses are widespread in the Pacific Ocean and periodically appear in domesticated and captive wildlife along the Western United States. The potential for vesicular disease to appear in pigs remains an ever-present threat.

Porcine caliciviruses (noroviruses and sapoviruses)

Relevance

Porcine caliciviruses (noroviruses and sapoviruses) were first recognized when diarrheic feces from post weaning and nursing pigs in the United Kingdom and the United States were examined by electron microscopy (Bridger 1980; Saif et al. 1980). Porcine caliciviruses have not been widely studied, and much is unknown concerning their role in naturally occurring swine disease. This is in contrast to the recognized role of caliciviruses in sporadic and epidemic acute gastroenteritis in humans.

Human caliciviruses belong to two genera, *Norovirus* (formerly Norwalk-like viruses) and *Sapovirus* (formerly Sapporo-like viruses), in the family *Caliciviridae* (Mayo 2002). Viruses in both genera (porcine noroviruses and porcine sapoviruses) are now accepted as common infectious agents on pig farms, and it seems possible that caliciviruses may have a significant role in porcine enteric disease. Public health concerns over potential cross-species transmission and animal reservoirs for caliciviruses have been raised (Mattison et al. 2007; Reuter et al. 2010; Wang et al. 2005a). However, the question is still open. Based on limited data, there is no clear evidence that known porcine caliciviruses pose a threat to human health.

Porcine noroviruses

Etiology

Noroviruses, possessing a 27–32 nm non-enveloped capsid and an indistinct morphology, were reported in swine in 1980 (Bridger 1980) (Figure 29.1). The genome is composed of positive-sense, single-stranded RNA of 7.3–7.7 kb in length, excluding the poly(A) tail at the 3′ end. It is composed of three ORFs. ORF1 encodes a polyprotein that undergoes protease processing to produce several nonstructural proteins, including an RNA-dependent RNA polymerase (RdRp). ORF2 and ORF3 encode a major capsid protein (VP1) and a minor capsid protein (VP2), respectively (Green 2007).

Noroviruses are genetically highly diverse. Phylogenetic analysis of the virus capsid has been used to designate seven genogroups (G) named GI–GVII (Vinjé 2015).

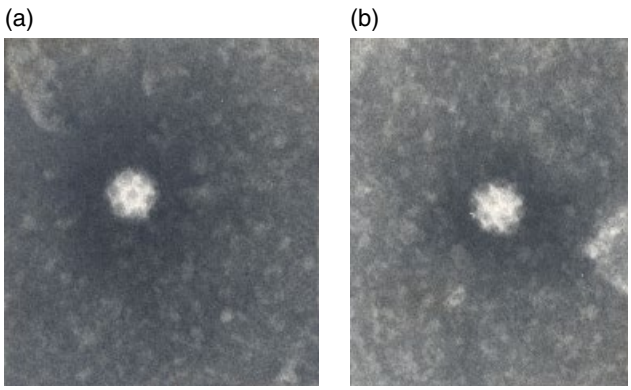

Figure 29.1 Negative stain electron microscopy. Panels (a) and (b): The sapovirus virion has typical calicivirus morphology with clear cup-shaped depressions and measures approximately 35 nm in diameter.

Viruses within each genogroup have been grouped into genotypes: 1–9 in GI, 1–22 in GII, 1–3 in GIII, 1 in GVII, and 2 each in GIV, GV, and GVI (Vinjé 2015; Wang et al. 2005a; Zheng et al. 2006). Due to the high sequence diversity between these genogroups (up to 60% amino acid difference), it has been suggested that they may represent distinct virus species (Zheng et al. 2006). GI has been found in humans and possibly pigs (Sisay et al. 2016a,b), GII in humans (genotypes 1–10 and 12–22) and pigs (genotypes 11, 18–19), GIII in cattle and sheep, GIV in humans and lion, GV in rats and mice, and GVI and GVII in dogs (Figure 29.2). Porcine norovirus sequences, including the prototype porcine norovirus strain Sw918/1997/JP (AB074893), grouped with the GII human noroviruses but formed three separate genotypes (11, 18, and 19) distinct from human noroviruses (Sugieda et al. 1998). Homologous recombination probably also occurs between porcine norovirus genotypes (Wang et al. 2005a).

Porcine norovirus genomes have been identified in pigs from Japan, the Netherlands, the United States, Hungary, Belgium, Canada, China, Korea, Slovenia, and Brazil (Cunha et al. 2010; Keum et al. 2009; L'Homme et al. 2009a; Mauroy et al. 2008; Mijovski et al. 2010; Reuter et al. 2007; Shen et al. 2009; Sugieda et al. 1998; Sugieda and Nakajima 2002; van der Poel et al. 2000; Wang et al. 2005a). Interestingly, virus-like particles (VLPs) of Sw918/JP (genotype 11) and QW101/2003/US (genotype 18) cross-react with antibodies against human GII noroviruses (Farkas et al. 2005; Wang et al. 2005a). In addition, human recombinant norovirus VLP binds specifically to histo-blood group antigens (HBGAs) in epithelial cells of pig gastrointestinal tissue (Tian et al. 2007). More data are required to determine whether human and porcine noroviruses are antigenically distinct or related and whether humans and pigs might share noroviruses.

Porcine noroviruses have not been cultured *in vitro*, and nothing is known about their physicochemical and other biological properties. In general, noroviruses are characterized by stability in the environment and relative resistance to inactivation.

Public health

The close genetic and antigenic relationships between human and porcine noroviruses raise public health concerns regarding their potential for cross-species transmission and as reservoirs for noroviruses. However, there is no evidence for the direct threat of porcine noroviruses to human health.

Epidemiology

Noroviruses have been identified in humans, swine, cattle, sheep, mice, dogs, and lion. It is assumed that natural norovirus transmission is fecal–oral.

Norovirus RNA was detected relatively infrequently (0.4–6%) in pigs by RT-PCR in 4 of 1017 normal slaughtered pigs collected in 1997 from 26 Japanese farms (Sugieda et al. 1998), 2 of 100 pooled fecal samples from fattening pigs (3–9 months of age) on 100 farms in the Netherlands (van der Poel et al. 2000), 6 of 275 fecal samples from normal adult swine in the United States, and 1 of 17 fecal samples from normal swine under the age of 2 years in Hungary (Reuter et al. 2007). These figures are likely to be an underestimate of porcine norovirus prevalence as PCR primers designed for human noroviruses were used, and pre- and post weaning diarrheic piglets were not examined.

The geographical distribution indicates the worldwide occurrence of porcine noroviruses among pigs in farms. Little is known about the association of porcine noroviruses with natural disease. It is not established if porcine noroviruses are species specific, but it has been postulated that the close genetic similarity of porcine noroviruses and human noroviruses may mean that porcine noroviruses are a reservoir of human infection (Sugieda and Nakajima 2002; van der Poel et al. 2000).

Pathogenesis, clinical signs, lesions, and immunity

All porcine noroviruses were detected from pigs with no clinical signs. Subclinically infected pigs may be natural reservoirs for noroviruses. The isolate QW101/2003/US (genotype 18) replicated in gnotobiotic pigs with fecal shedding coincident with mild diarrhea (Wang et al. 2005a).

In an experiment using GII.4 human norovirus, 48 (74%) of 65 gnotobiotic piglets developed mild diarrhea (Cheetham et al. 2006). Histopathological examination showed mild lesions in the proximal small intestine of only one of the seven pigs. Evidence was found for replication of the virus in intestinal enterocytes in 18 of 31 cases. Seroconversion after 21 days post inoculation was detected by antibody ELISA in 13 of 22 virus-inoculated pigs, indicating human norovirus replication in pigs.

Seroprevalence of GII norovirus in swine was 97% in the United States and 36% in Japan (Farkas et al. 2005). Immune responses against porcine noroviruses, protective immunity, and/or the role of maternal antibodies have not been assessed. It may be assumed that protective immune mechanisms are similar to those for other enteric virus pathogens. Porcine norovirus infections in pigs may potentially provide useful insights into protective immunity of the equivalent viruses of humans.

Diagnosis

No diagnostic tests for porcine noroviruses have been developed for use outside the research laboratory. Porcine noroviruses have been detected using electron

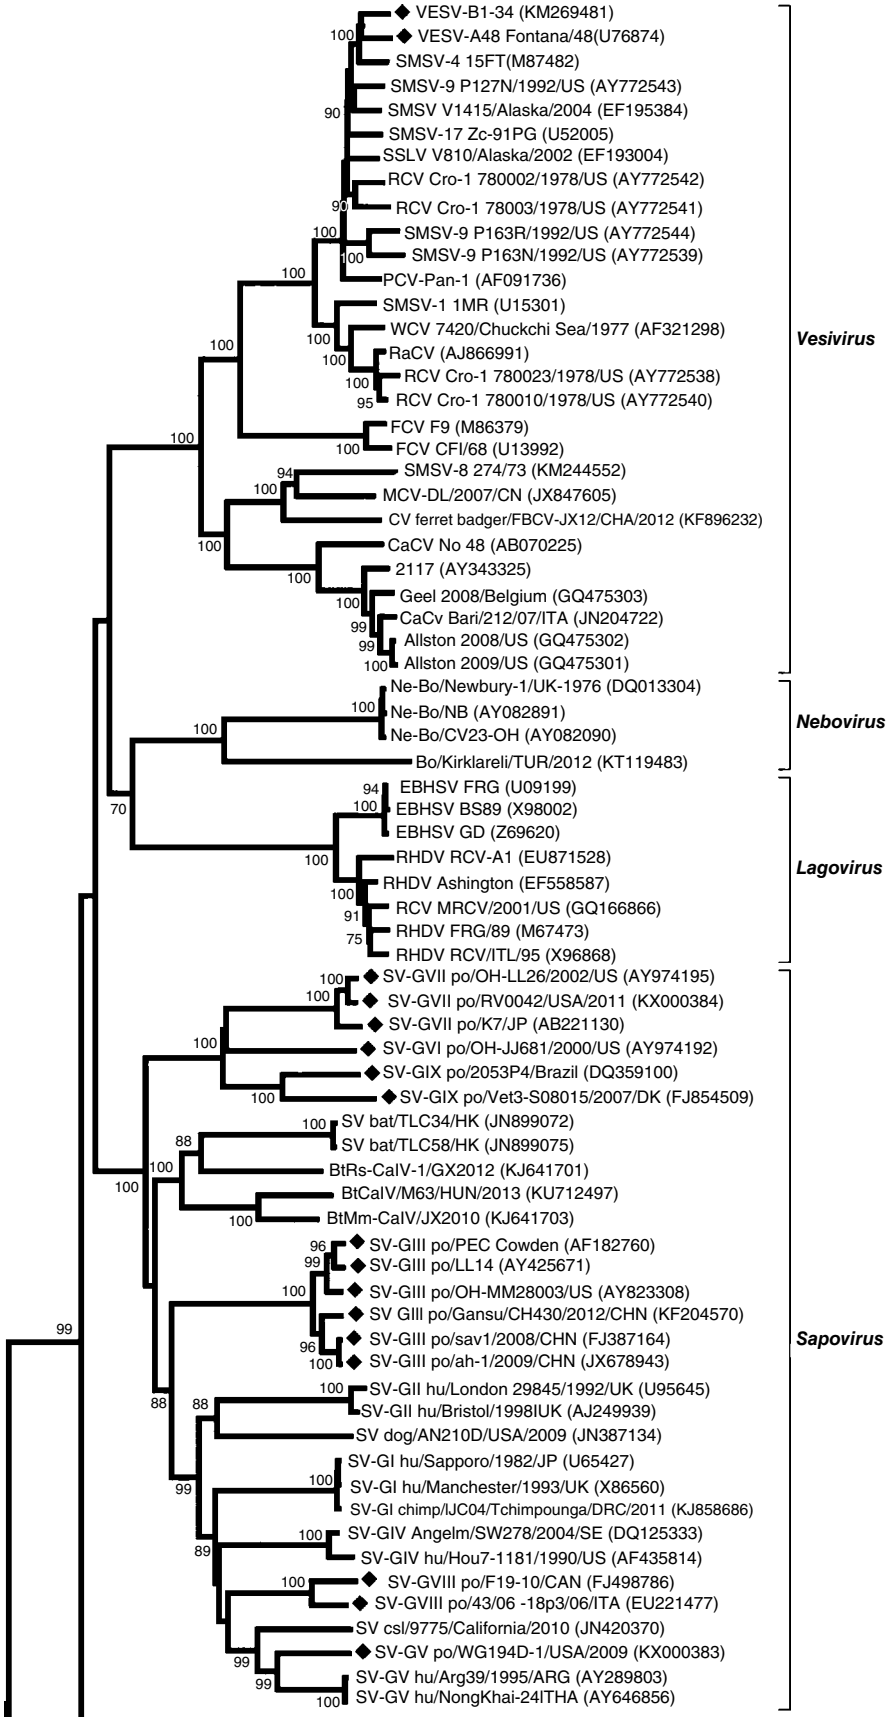

Figure 29.2 Unrooted neighbor-joining tree showing the relationships between the capsid proteins of caliciviruses in swine and other members of the family. Swine caliciviruses are indicated by ◆ (black diamond). Members of the five accepted calicivirus genera (*Lagovirus*, *Nebovirus*, *Norovirus*, *Sapovirus*, and *Vesivirus*) and candidate genera (names in quotation marks) are represented.

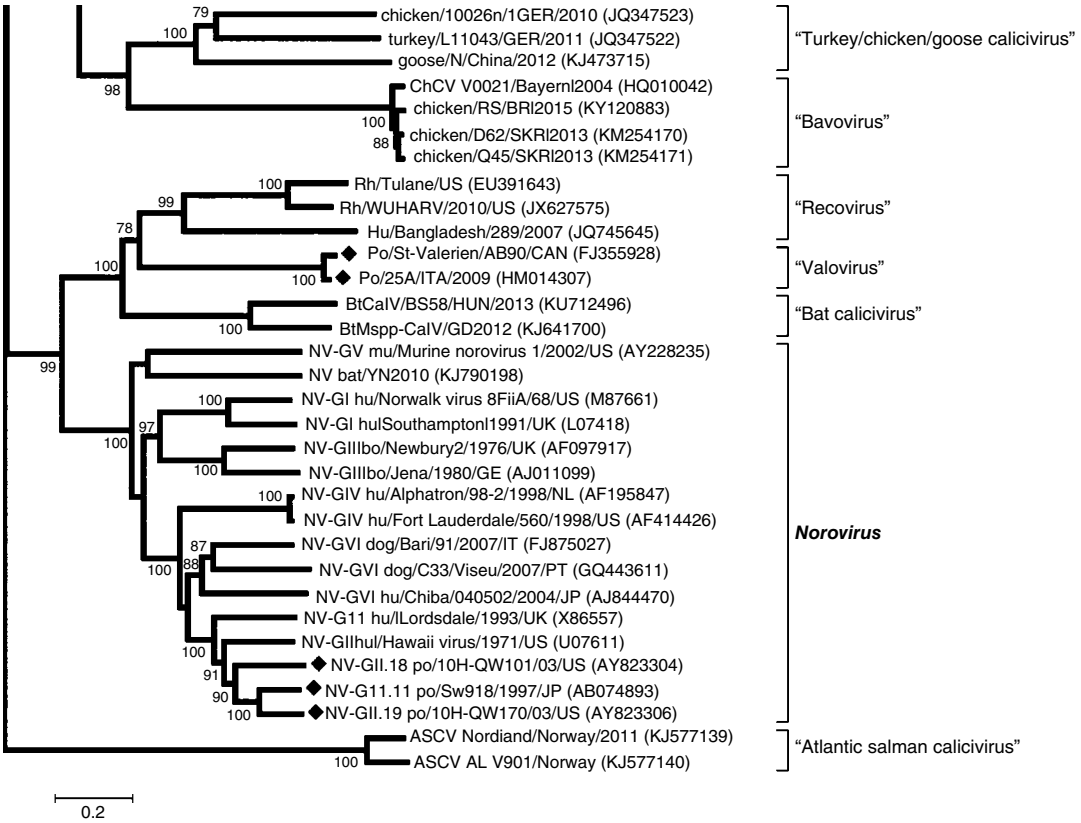

Figure 29.2 (Cont'd)

microscopy, RT-PCR, and real-time RT-PCR (Reuter et al. 2007; Sugieda et al. 1998; Sugieda and Nakajima 2002; van der Poel et al. 2000; Wang et al. 2005a). However, the sensitivity of molecular tests for laboratory diagnosis of porcine norovirus infections has not been evaluated.

Prevention and control

Assuming that porcine norovirus epidemiology and immunology are similar to porcine rotaviruses, it is likely that these viruses persist in the environment, and it may be impossible to eliminate the infection from pig herds and prevent natural infection of piglets. However, the persistence of porcine enteric viruses in animal waste depends on the waste treatment technology (Costantini et al. 2007). It is also likely that sows pass on maternal antibody in colostrum and milk and thus limit infection and damage in the gut of nursing piglets. Treatment with oral rehydration fluids is likely to be successful.

Porcine sapoviruses

Etiology

Sapoviruses, possessing a 30–35 nm non-enveloped capsid and typical calicivirus morphology with clear cup-shaped depressions, were reported in swine in the United States in 1980 (Saif et al. 1980) and genetically characterized as sapovirus in 1999 (Guo et al. 1999). The genome is composed of positive-sense, single-stranded RNA of 7.3–7.5 kb in length, excluding the poly(A) tail at the 3′ end. It is composed of two ORFs. ORF1 encodes a polyprotein that undergoes protease processing to produce several nonstructural proteins including an RdRp, and a major capsid protein (VP1). ORF2 is predicted to encode the minor capsid protein (VP2) (Green 2007).

Sapoviruses are genetically highly diverse. Phylogenetic analysis of the major virus capsid protein has been used to designate five official genogroups (G) named GI–GV (Green 2007). However, further novel sapovirus genogroups (GVI–GX) identified in swine were also proposed (Reuter et al. 2010; Wang et al. 2005b). Within each genogroup, viruses have been grouped into genotypes: 1–3 in GI, 1–3 in GII, and 1 each in GIII–GX (Green 2007; Reuter et al. 2010). Due to the extremely high sequence diversity between these genogroups, it has been suggested that they may represent distinct virus species. Human sapoviruses belong to genogroups GI, GII, GIV, and GV. Porcine sapovirus belongs to genogroups GIII, GVI, GV, GVII, GVIII, GIX, and GX (Figure 29.2). GIII strains were detected the most frequently in pigs.

Double infections with different porcine sapoviruses are common among pigs (Reuter et al. 2010). Recombination

probably also occurs between porcine sapovirus genotypes (Hansman et al. 2005; Wang et al. 2005b). By phylogenetic analysis, a higher degree of genetic diversity was seen among porcine sapoviruses than among the known human sapoviruses, indicating that the coevolution of sapoviruses in swine was longer (Reuter et al. 2010). On the other hand, GVIII is genetically more closely related to human sapoviruses (especially those of GV and GI) than to other sapovirus genogroups in swine (Martella et al. 2008; Reuter et al. 2010; Wang et al. 2005b).

Porcine sapoviruses (historically called porcine enteric calicivirus [PEC]) have been studied more extensively than porcine norovirus. PEC/Cowden, a prototype porcine sapovirus (GIII), has been studied in detail (Flynn and Saif 1988; Flynn et al. 1988; Guo et al. 1999, 2001a; Parwani et al. 1990; Saif et al. 1980). The PEC/Cowden sapovirus was cultured in primary porcine kidney cells and the continuous porcine kidney cell line (LLC-PK) but only by inclusion of intestinal contents in the culture medium (Flynn and Saif 1988; Parwani et al. 1991). Interestingly, bile acids were identified as the factor that allowed cultivation by affecting the protein kinase A cell signaling pathway (Chang et al. 2002, 2004).

Public health

Public health concerns over potential cross-species transmission and animal reservoir for sapovirus have been raised. However, there is no evidence for the direct threat of porcine sapoviruses to human health.

Epidemiology

Porcine sapovirus RNA has been identified frequently in pigs (8–67%) and pig farms (7–88%) by RT-PCR in several countries, including Belgium (Mauroy et al. 2008), Brazil (Barry et al. 2008), Canada (L'Homme et al. 2009a), China (Shen et al. 2009), Ethiopia (Sisay et al. 2016b), Hungary (Nagy et al. 1996; Reuter et al. 2007), Italy (Martella et al. 2008), Japan (Shirai et al. 1985; Sugieda et al. 1998; Sugieda and Nakajima 2002), the Netherlands (van der Poel et al. 2000), South Korea (Kim et al. 2006), the United Kingdom (Bridger 1980), the United States (Guo et al. 1999; Saif et al. 1980), and Venezuela (Martinez et al. 2006), and in six European countries (Reuter et al. 2010). The geographical distribution indicates the worldwide occurrence and endemic circulation of porcine sapoviruses among pigs and in pig farms. Pigs are infected with porcine sapovirus early in life (Reuter et al. 2010). The one study conducted to examine the prevalence of porcine sapoviruses related to PEC/Cowden showed that at least 83% of 30 sow serum samples from Ohio pig herds with PEC-associated post weaning diarrhea had antibodies reactive to PEC/Cowden (Guo et al. 2001b).

It has not been established whether porcine sapoviruses are species specific. At present, sapoviruses have been identified only in humans, swine, and mink. It is assumed that the main natural transmission mode is fecal–oral. In general, sapoviruses are characterized by stability in the environment and relative resistance to inactivation.

Pathogenesis

Experimental infections with the porcine sapovirus PEC/Cowden produced enteric lesions and disease (Flynn et al. 1988; Guo et al. 2001a). Unusual for viral enteric pathogens, disease and small intestinal lesions in the duodenum and jejunum resulted from intravenous inoculation of PEC/Cowden, as well as by oral exposure. Viral replication in enterocytes was demonstrated by immunofluorescence with anti-PEC/Cowden antiserum. Sapovirus particles were demonstrated in intestinal contents and in the bloodstream, the first time viremia has been associated with an enteric calicivirus. The mechanism by which the virus reached the small intestine and villous enterocytes from the bloodstream was not determined. When infected by the oral route, fecal shedding of the sapovirus PEC/Cowden occurred for up to 9 days. When infected by the intravenous route, fecal shedding was observed for at least 8 days.

Clinical signs

Porcine sapoviruses are one of the viral agents that cause diarrhea in swine. With PEC/Cowden, the incubation period ranged from 2 to 4 days after oral inoculation, and clinical signs of anorexia and diarrhea persisted for 3–7 days (Flynn et al. 1988; Guo et al. 2001a). All inoculated pigs became infected and developed clinical signs ranging from mild to severe diarrhea. Control pigs and pigs infected with the tissue culture-adapted PEC failed to develop clinical signs, although intestinal lesions were observed in the exposed pigs.

Lesions

Infection with PEC/Cowden produced lesions indistinguishable from those produced by other enteric viral pathogens (Flynn et al. 1988; Guo et al. 2001a). Lesions included shortening, blunting, fusion or absence of duodenal and jejunal villi, and, by scanning electron microscopy, an irregular microvillus coat on enterocytes. Crypt cell hyperplasia and a reduction of villus/crypt ratios occurred with cytoplasmic vacuolation and infiltration of polymorphonuclear and mononuclear cells into the lamina propria.

Diagnosis

No diagnostic tests for porcine sapoviruses have been developed for use outside the research laboratory. Porcine sapoviruses have been detected using electron

microscopy, RT-PCR, and real-time RT-PCR (Reuter et al. 2010; Sugieda et al. 1998; Sugieda and Nakajima 2002; van der Poel et al. 2000; Wang et al. 2005a). However, the sensitivity of molecular tests for laboratory diagnosis of porcine sapovirus infections has not been evaluated. An antigen and antibody ELISA was developed and used to study PEC/Cowden (Guo et al. 2001b).

Immunity

Immune responses, protective immunity induced by porcine sapoviruses, and the role of maternal antibodies have not been assessed. It may be assumed that protective immune mechanisms are similar to those for other enteric virus pathogens. However, the finding of an extraintestinal phase to the pathogenesis of a porcine sapovirus may mean that other immune strategies might be used for their control.

Prevention and control

Assuming that porcine sapovirus epidemiology and immunology are similar to porcine rotaviruses, it is likely that these viruses persist in the environment, and it may be impossible to eliminate the infection from pig herds and prevent natural infection of piglets. However, the persistence of porcine enteric viruses in animal waste depends on the waste treatment technology (Costantini et al. 2007). It is also likely that sows will pass on maternal antibody in colostrum and milk and thus limit infection and damage in the gut of nursing piglets. Treatment with oral rehydration fluids is likely to be successful.

St-Valérien virus

In 2009, a report described a novel calicivirus from pigs in Quebec, Canada (L'Homme et al. 2009b). Genomic analysis revealed a positive-sense RNA genome of 6409 nucleotides encoding two major ORFs. Phylogenetic analysis showed that these viruses form a unique cluster with a common root with the noroviruses and the Tulane virus isolated from captive juvenile rhesus macaques. The genus name *Valovirus* has been suggested with the St-Valérien virus as the prototype (Di Martino et al. 2011). The virus has also been found in the United States (Wang et al. 2011), Italy (Di Martino et al. 2011), and Japan (Sato et al. 2014). In a study in Italy, 10.3% of 614 pigs had antibodies to St-Valérien virus (Di Martino et al. 2012). The role of St-Valérien virus in swine disease is unknown.

Circoviruses

Joaquim Segalés, Gordon M. Allan, and Mariano Domingo

Relevance

In the late 1990s, a porcine circovirus (PCV) distinct from a known PCV contaminant of PK-15 cell cultures (Tischer et al. 1974, 1982) was detected in North America and Europe (Allan et al. 1998; Ellis et al. 1998). The original cell culture contaminant was designated porcine circovirus type 1 (PCV1), and the new pathogenic virus was named porcine circovirus type 2 (PCV2) (Allan et al. 1999b). Subsequently, the term "porcine circovirus diseases" (PCVDs) was proposed to group diseases or conditions linked to PCV2 (Allan et al. 2002b). In North America, the term "porcine circovirus-associated diseases" (PCVAD) is used (Opriessnig et al. 2007). PCVD can have different clinical manifestations: PCV2 systemic disease (PCV2-SD), which was historically known as post weaning multisystemic wasting syndrome (PMWS) (Clark 1996; Harding 1996); PCV2 reproductive disease (PCV2-RD) (West et al. 1999); porcine dermatitis and nephropathy syndrome (PDNS) (Rosell et al. 2000b); and subclinical infection. PCV2 has also been linked to respiratory (Kim et al. 2003) and enteric (Kim et al. 2004a) diseases, but both have shown to be part of PCV2-SD (Baró et al. 2015; Ticó et al. 2013). Among PCVDs, PCV2-SD and the subclinical infection have a worldwide impact on swine production. Commercial PCV2 vaccines have been available since 2006, and economic losses attributed to PCVDs, including subclinical PCV2 infections, have been markedly reduced (Segalés 2015). PCV2 is also an important coinfecting agent, and vaccination against PCV2 can assist in the control of clinical disease associated with polymicrobial infections (Chae 2016). Porcine circovirus type 3 (PCV3) has recently been described and is thought to be linked to PCVD-like scenarios (Palinski et al. 2016; Phan et al. 2016), although no experimental evidence is currently available to support this association. Also, a recent limited study does not support disease association with PCV3 (Franzo et al. 2018a). Further studies will be warranted to establish the potential pathogenicity of PCV3.

Etiology

PCVs belong to the genus *Circovirus* in the family *Circoviridae* (Rosario et al. 2017). Three PCV types have been described: PCV1, PCV2, and PCV3. It should be noted that PCV3 has not been yet officially listed in the genus *Circovirus*. PCV1 was first described as a PK-15 cell contaminant (Tischer et al. 1974, 1982) and was not pathogenic for swine (Allan and Ellis, 2000). PCV2 has been the most commonly studied species because of its link to PCVDs (Segalés 2012). PCV3 has recently been identified (Palinski et al. 2016; Phan et al. 2016), but little is known about PCV3 beyond its genomic sequence.

PCVs are non-enveloped and 12–23 nm in diameter (Figure 30.1) (Tischer et al. 1982). Based on studies of PCV2, the nucleocapsids exhibit icosahedral symmetry, and three-dimensional studies have shown a polygonal outline containing 60 capsid (Cap) protein elements arranged in 12 slightly protruding pentameric units, giving an overall diameter of about 20.5 nm (Crowther et al. 2003). The circular, covalently closed single-stranded DNA (ssDNA) genome contains 1759 (PCV1), 1767–1768 (PCV2), and 2000 (PCV3) nucleotides (Hamel et al. 1998; Meehan et al. 1997, 1998; Palinski et al. 2016; Phan et al. 2016). PCV1 and PCV2 may have a common evolutionary origin, but a common ancestor has not been identified (Olvera et al. 2007).

After PCV infects a cell, the ssDNA is converted to a double-stranded DNA (dsDNA) intermediate known as the "replicative form" (RF) (Mankertz et al. 2004). The RF is ambisense, with genes encoded by both the viral (positive) and the complementary (negative) strand. PCV2 genes are arranged in 11 putative open reading frames (ORFs) (Hamel et al. 1998), but protein expression

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

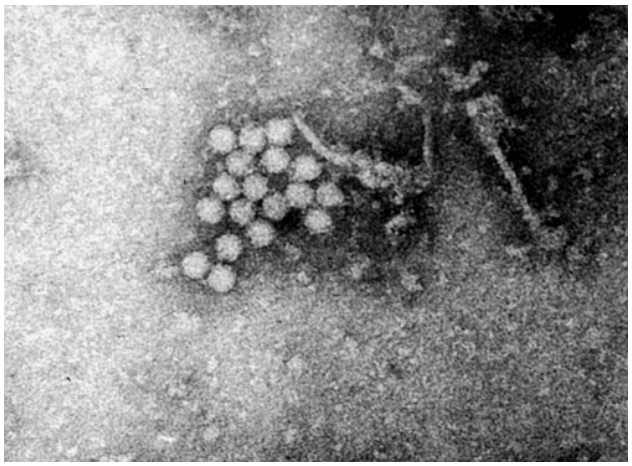

Figure 30.1 PCV2-SD-affected pig. Electron microscopy of PCV2 particles isolated from an affected pig. Virion particles are 15–20 nm in diameter. Transmission electron photomicrograph of negatively stained virions.

has been described for only four. ORF1 (Rep gene) is located on the positive strand in clockwise orientation. It codes for the nonstructural replicase proteins Rep and Rep', 314 and 178 amino acids (aa) in length, respectively (Cheung 2003; Mankertz et al. 1998). ORF2 (capsid gene) is on the complementary strand and oriented counterclockwise. It encodes for the capsid, the only structural protein (233–234 aa) (Mankertz et al. 2004; Nawagitgul et al. 2000). ORF3 is located on the complementary strand, oriented counterclockwise, and completely overlaps the ORF1 gene. ORF3 codes for a nonstructural protein 105 aa in length. *In vitro*, the ORF3 protein induces apoptosis in PK-15 cells (Liu et al. 2005), and an ORF3-defficient PCV2 mutant was shown to be less virulent in pigs compared with wild type PCV2 (Karuppannan et al. 2009). An ORF4, located also on the complementary strand and oriented counterclockwise, encodes a protein with a role in suppressing caspase activity and regulation of $CD4^+$ and $CD8^+$ T lymphocytes (He et al. 2013).

PCV2 genotypes

Analyses have shown close phylogenetic relationships and nucleotide sequence identities >93% among PCV2 viruses from around the world (Franzo et al. 2016; Xiao et al. 2015). PCV2 genotype definitions based on pairwise sequence comparisons (PASC) was proposed in 2008 (Segalés et al. 2008), and five genotypes (PCV2a, PCV2b, PCV2c, PCV2d, and PCV2e) have since been identified. However, the growing number of the PCV2 sequences reported since 2008 have made it apparent that the 2008 PASC thresholds for PCV2 genotyping do not apply to all PCV2 strains (Franzo et al. 2015a) and a new PCV2 genotyping method is needed. A PCV2 genotyping method based on marker positions was proposed (Franzo et al. 2015a), but has not been widely used.

PCV2a was the most prevalent genotype in clinically affected pigs from 1996 to the early 2000s, after which PCV2b predominated ("genotype shift"). The emergence of PCV2b in North America and Europe was associated with the appearance of a more severe clinical disease (Carman et al. 2006; Cortey et al. 2011; Timmusk et al. 2008; Wiederkehr et al. 2009). PCV2d (also called mutant PCV2b by some research groups) was first reported in China (Guo et al. 2010), and a second "genotype shift" (from PCV2b to PCV2d) may be currently occurring globally (Franzo et al. 2016; Xiao et al. 2016), perhaps driven by the worldwide use of PCV2 vaccines. PCV2c has been detected in archival material in Denmark (Dupont et al. 2008), in wild pigs from Brazil (Franzo et al. 2015b), and in domestic swine in China (Liu et al. 2016). PCV2e has been identified in swine samples collected in the United States and Mexico (Davies et al. 2016; Harmon et al. 2015). The clinical significances of PCV2c and PCV2e are unknown.

PCV2 strains of the same or different genotype may coinfect the same pig (Cheung et al. 2007; de Boisseson et al. 2004; Gagnon et al. 2007; Grau-Roma et al. 2008; Hesse et al. 2008). *In vivo* and *in vitro* studies provided evidence of viral recombination (Cheung 2009; Hesse et al. 2008; Lefebvre et al. 2009; Olvera et al. 2007). Thus, the emergence of new genotypes could have been the result of recombination between strains infecting the same animal. At least three circulating recombinant forms (CRF) have been found in pigs in different parts of the world (Franzo et al. 2016). A recombinant virus containing PCV1 ORF1 and PCV2a ORF2 was identified in Quebec (Canada), apparently derived from a chimeric killed vaccine strain that was not effectively inactivated (Gagnon et al. 2010).

Antigenic variability

Initially, similarities in reactivity to monoclonal and polyclonal antibodies led to the conclusion that no major antigenic differences existed among PCV2 strains (Allan et al. 1999b; McNeilly et al. 2001). Subsequent work revealed antigenic variability among PCV2 genotypes (Guo et al. 2010; Lefebvre et al. 2008a; Saha et al. 2012; Shang et al. 2009). Despite genotypic and antigenic differences, it is considered that PCV2 exists as a single serotype.

Physicochemical and biological properties

PCV1 has a buoyant density of 1.37 g/mL in CsCl, does not hemagglutinate erythrocytes from a wide range of species, is resistant to inactivation at pH 3 and by chloroform, and is stable at 70 °C (158 °F) for 15 minutes (Allan et al. 1994b). The biological and physicochemical prop-

erties of PCV2 are not well characterized. Infectivity decreases somewhat in an acid buffer, but PCV2 remains viable even at pH < 2. Infectivity is markedly decreased at pH 11–12 (Kim et al. 2009). PCV2 resists inactivation at high temperatures 56 °C (133 °F) for 1 hour and 75 °C (167 °F) for 15 minutes, which suggests that the virus is able to remain infectious in the environment at high ambient temperatures (e.g. summer) (Kim et al. 2009; O'Dea et al. 2008). Exposure of PCV2 (10 minutes to 24 hours) at room temperature to a number of commercial disinfectants (chlorhexidine, formaldehyde, iodine, oxidizing agents, and alcohols) leads to a significant reduction in virus titers (Kim et al. 2009; Martin et al. 2008; Royer et al. 2001).

Laboratory cultivation

Replication of PCVs *in vitro* is best achieved by inoculation of semi-confluent monolayers of PCV-free PK-15 cells. Since PCVs do not produce cytopathic effect, viral replication is monitored by immunofluorescence or immunoperoxidase staining (Allan and Ellis 2000). PCV1 has been shown to replicate in other porcine-derived cell lines and Vero cells (Allan et al. 1994a; Tischer et al. 1982). PCV2 has also been shown to replicate in IPEC-J2 (Yan et al. 2014) and lymphoblastoid L35 (Rodríguez-Cariño et al. 2011) cell lines. PCV DNA replication seems to be dependent on cellular enzymes expressed during the S phase of growth (Tischer et al. 1987) or perhaps cell repair (Sánchez et al. 2003) and has been reported to be dependent on the porcine cyclin A (CycA) as an important regulator of the PCV2 life cycle (Tang et al. 2013). Viral yields may be enhanced by cell treatment with glucosamine, but care must be taken because glucosamine is cytotoxic (Allan and Ellis 2000). Glutamine starvation of PK-15 cultures has been shown to increase PCV2 replication by promoting p38 MAPK activation, which was associated with the downregulation of intracellular glutathione levels (Chen et al. 2015). There have been no reports on successful PCV3 isolation in cell culture yet.

Public health

PCVs are not zoonotic. PCV DNA has been detected in vaccines produced for use in humans and swine (Kuehn 2010; Quintana et al. 2006; Victoria et al. 2010). These findings reflect quality control issues in vaccine production.

Epidemiology

PCV1 and PCV2 are ubiquitous in both domestic and feral swine (Allan and Ellis 2000; Calsamiglia et al. 2002; Segalés and Domingo 2002; Vicente et al. 2004). Nucleotide sequence analysis grouped PCV1 detected in wild boar with PCV1 from domestic swine (Csagola et al. 2008). Likewise, the nucleotide identity of PCV2 isolates from wild boars was almost identical to isolates from domestic swine and included both PCV2a and PCV2b genotypes (Ellis et al. 2003; Schulze et al. 2004; Sofia et al. 2008). PCV3 DNA has been detected in domestic swine in the United States, China, Italy, Poland, South Korea, Brazil, the United Kingdom, Denmark, Spain, and Germany (Collins et al. 2017; Franzo et al., 2018b; Fux et al. 2018; Ku et al. 2017; Li and Tian 2017). Interestingly, it was reported that PCV3 DNA was detected in archived clinical samples as far back as in 2002 in the United Kingdom and in 1996 in Spain (Collins et al. 2017; Klaumann et al. 2018a). Currently the transmission, duration of virus shedding, and other epidemiological data of PCV3 mainly remain unknown.

With the exception of mice and rats, non-porcine species are not susceptible to PCV2 infection (Allan et al. 2000b; Ellis et al. 2000, 2001; Rodríguez-Arrioja et al. 2003). PCV2 can replicate in and transmit between mice to a limited degree (Kiupel et al. 2001; Opriessnig et al. 2009a). PCV2 has been found in mice and rats from pig farms, suggesting a possible role as alternate hosts or mechanical vectors, but not in rodents collected outside swine herds (Lorincz et al. 2010) or houseflies (Blunt et al. 2011). PCV2 sequences were also found in buffalo meat in China (Zhai et al. 2014), although their origin was unclear.

Oronasal exposure is the primary route of transmission, but PCV2 has been found in nasal, tonsillar, bronchial, and ocular secretions, feces, saliva, urine, colostrum, milk, and semen (Rose et al. 2012). Pigs can become infected by eating raw tissues from viremic animals (Opriessnig et al. 2009c). Transplacental infection occurred in pregnant sows intranasally exposed to PCV2 3 weeks prior to farrowing (Ha et al. 2008, 2009; Park et al. 2005). Naïve sows inseminated with semen contaminated with PCV2 exhibited reproductive failure, and their fetuses became infected (Madson et al. 2009a; Sarli et al. 2012). However, it is believed that the quantity of PCV2 naturally shed in semen is not sufficient to infect sows or their fetuses (Madson et al. 2009a).

Transmission of PCV2 among pigs can occur by mixing susceptible with infected animals (Albina et al. 2001; Bolin et al. 2001). Direct contact is more efficient than transmission between animals in separate pens (Andraud et al. 2008). Longitudinal studies quantifying PCV2 in serum, nasal excretions, and feces found that most pigs became infected at 4–11 weeks of age, depending on the farm (Carasova et al. 2007; Grau-Roma et al. 2009). A variable percentage of sows and piglets may be viremic during lactation (Grau-Roma et al. 2009; Shen et al. 2010), suggesting the possibility of transmission from sows to nursing piglets through respiratory secretions, colostrum, and milk (Rose et al. 2012).

PCV2 persistence in individuals or groups of pigs has not been studied extensively, but Bolin et al. (2001) isolated virus or detected viral DNA in tissues from experimentally inoculated pigs for up to 125 days post inoculation (DPI). In the field, viral DNA has been detected in serum from pigs for up to 22 weeks (Rodríguez-Arrioja et al. 2002). PCV2 DNA was repeatedly found in sera from pigs 7–70 days of age (Grau-Roma et al. 2009), providing further evidence that some animals remain persistently infected despite the presence of high levels of PCV2-specific antibodies (McIntosh et al. 2006; Rodríguez-Arrioja et al. 2002).

Pathogenesis, clinical signs, lesions, and diagnosis

PCV1 is nonpathogenic to swine. PCV3 has been reported to be found in cases of PDNS, reproductive failure, and cardiac and multisystemic inflammation (Palinski et al. 2016; Phan et al. 2016), but its pathogenesis and clinical significance are still under debate (Franzo et al. 2018a; Klaumann et al. 2018b). The remainder of this section focuses on pathogenesis, clinical signs, lesions, and diagnosis of PCV2-SD, PCV2-RD, and PDNS.

Porcine circovirus type 2 systemic disease

Pathogenesis

PCV2-SD is characterized by severe impairment of the immune system, and clinical signs and lesions are often the result of the additive effect of co-infectious pathogens in different organs. Thus, PCV2-SD is a multifactorial disease in which PCV2 infection is the necessary cause. Genotypes PCV2a, PCV2b, and PCV2d are all considered pathogenic, that is, able to cause PCV2-SD (Allan et al. 1999a; Lager et al. 2007; Opriessnig et al. 2017). Differences in virulence among genotypes or strains has been postulated, but not adequately addressed (Segalés et al. 2013).

PCV2 viremia is first detected around 7 DPI and peaks at 14–21 DPI (Allan et al. 1999a; Opriessnig et al. 2008; Rovira et al. 2002). Under field conditions, seroconversion usually occurs at 7–12 weeks of age, and antibodies last until at least 28 weeks of age (Rodríguez-Arrioja et al. 2002).

There is little information regarding the target cells for initial viral replication, the early events of PCV2 infection, or the cell type(s) that supports PCV2 replication *in vivo*. PCV2 does not code for its own DNA polymerases, and cells in the S phase are presumed necessary for the virus to complete its infectious cycle (Tischer et al. 1987). If so, cells with a high mitotic rate should be the most efficient for viral replication. Lymphoid tissues contain the highest concentration of PCV2 (Quintana et al. 2001; Rosell et al. 1999), but virus may also be detected in epithelial cells from the kidney and respiratory tracts, endothelial cells, lymphocytes, enterocytes, hepatocytes (including Kupffer's cells in the liver), smooth muscle cells, and pancreatic acinar and ductal cells (Opriessnig and Langohr 2013).

The role of monocytes and lymphocytes in sustaining PCV2 replication is still unresolved (Meng 2013). Initial work suggested that macrophages and lymphocytes did not play a significant role in PCV2 replication (Gilpin et al. 2003; Vincent et al. 2003), but later studies found that they (mainly macrophages) may support replication (Hamberg et al. 2007; Pérez-Martín et al. 2007; Rodríguez-Cariño et al. 2010; Yu et al. 2007). Characterization of PCV2-infected leukocyte subpopulations from peripheral blood mononuclear cells (PBMCs) showed that circulating T lymphocytes ($CD4^+$ and $CD8^+$), and to a lesser extent B lymphocytes, supported PCV2 replication, but not PBMC-derived monocytes (Lefebvre et al. 2008b; Lin et al. 2008; Yu et al. 2007). In PCV2-SD-affected pigs, the highest concentration of virus is found in the cytoplasm of monocyte–macrophage lineage cells (Rosell et al. 1999; Sánchez et al. 2004). *In vitro* studies have shown that PCV2 infects these cells, after which they become persistently infected with little or no virus replication (Gilpin et al. 2003; Vincent et al. 2003). For this reason, it has been suggested that monocytic cells facilitate dissemination of PCV2 within the host, rather than being a primary target for PCV2 replication (Vincent et al. 2003).

Although PCV2-SD has been reproduced under experimental conditions, a definitive, consistently repeatable disease model is lacking. Horizontal transmission of PCV2-SD by commingling affected and healthy pigs and between affected and naïve pigs in adjacent pens has been reported (Kristensen et al. 2009), but both infectious and noninfectious factors are believed to play a role in PCV2-SD (Rose et al. 2012).

Reasons for inconsistency in the experimental reproduction of PCV2-SD are not known, but may be related to the origin of pigs, age of the animals at inoculation, immunological status, genetic predisposition, PCV2 strain, type of inoculum, infectious dose, and/or route of administration. Meta-analysis suggested that the experimental reproduction of PCV2-SD was most probable in colostrum-deprived pigs <3 weeks of age inoculated with high doses ($>1 \times 10^5$ $TCID_{50}$ per pig) of PCV2b in combination with another pathogen (Tomás et al. 2008).

Field observations suggested that certain genetic lines of pigs might be more susceptible to PCV2-SD. This observation was supported by experimental studies in which Landrace were shown to be more likely to develop PCV2-SD than Duroc, Large White, and Pietrain pigs (Opriessnig et al. 2006, 2009b). However, field studies have reported contradictory results, with the Pietrain

boar line showing no effect in one study (Rose et al. 2005) and lower general post weaning and PCV2-SD-associated mortalities in another (López-Soria et al. 2011).

The most repeatable PCV2-SD models are based on PCV2 inoculation in combination with other infectious and/or noninfectious cofactors (Allan et al. 2004). Noninfectious risk factors for PCV2-SD are summarized in Table 30.1. Infectious agents considered potential PCV2-SD triggers include infection with porcine parvovirus (PPV), porcine reproductive and respiratory syndrome (PRRS) virus, and/or *Mycoplasma hyopneumoniae* (Opriessnig and Halbur 2012). Stimulation and/or activation of the immune system of PCV2-infected pigs by other viral infections or noninfectious factors upregulates PCV2 replication and increases viral loads in tissues and serum (Allan et al. 1999a, 2000a; Harms et al. 2001; Kennedy et al. 2000; Krakowka et al. 2001; Rovira et al. 2002). This suggests that PCV2 infection and immunostimulation may be pivotal events in the development of PCV2-SD, although the mechanism by which coinfection or immunostimulation triggers the development of PCV2-SD in PCV2-infected pigs is unknown (Allan et al. 2012).

Conversely, regular features of PCV2-SD in severely affected pigs are suggestive of immunosuppression, such as microscopic lymphoid lesions (Clark 1997; Rosell et al. 1999), the association of PCV2-SD with opportunistic pathogens (Grau-Roma et al. 2011), and changes in immune cell subpopulations in lymphoid tissues and PBMCs (Darwich and Mateu 2012). The most striking evidence of immunosuppression are the extensive lesions in lymphoid tissues of PCV2-SD-affected pigs (i.e. depletion of B and T lymphocytes), an increase in the number of macrophages, and loss or redistribution of interfollicular dendritic cells (Chianini et al. 2003). In lymphoid tissues, depletion of T lymphocytes primarily involved $CD4^+$ cells and, to a lesser extent, $CD8^+$ cells (Sarli et al. 2001).

Another feature suggestive of immunosuppression in PCV2-SD-affected pigs is the alteration of PBMC subsets, mainly lymphopenia (Darwich et al. 2002; Nielsen et al. 2003). Depletion of B and T lymphocytes was experimentally observed only in PCV2-inoculated pigs that later developed PCV2-SD. Changes in T-cell subsets involved mainly $CD4^+CD8^+$ memory T cells. In PCV2-inoculated pigs that did not show clinical signs, the number of cytotoxic ($CD4^-CD8^+$) and γδ ($CD4^-CD8^-$) T lymphocytes was increased in comparison with that of control pigs, suggesting an active response to PCV2 infection.

Although lymphoid depletion and lymphopenia are consistent features of PCV2-SD-affected pigs, it is not known whether the loss of lymphocytes is a direct or an indirect effect of PCV2 infection. PCV2-infected PBMCs

Table 30.1 Noninfectious risk factors for post weaning multisystemic wasting syndrome (PMWS).

	Factors increasing the risk of PMWS	Factors decreasing the risk of PMWS
Animals	• Gender (male) • Litter of origin • Low birth weight • Low weaning weight • Low weight at the beginning of fattening period	• Gender (female)
Facilities	• Large number of sows • Large pens at nursery and growing ages • Proximity to other pig farms	• Separate pit for adjacent fattening rooms • Shower facilities
Management practices	• High level of cross-fostering • Short empty periods at weaning and fattening • Large range in age and weight entering the nursery • Continuous flow nursery • Purchase of replacement gilts • Sows with neck injuries due to poor injection technique • Early weaning (<21 days of age)	• Sorting pigs by sex at nursery stage • Greater minimum weight at weaning • Group housing sows during pregnancy • Visitors with no pig contact for several days before visiting farm • Use of semen from an insemination center
Vaccination/treatment/nutrition	• Vaccination of gilts against PRRSV • Vaccination of sows against *Escherichia coli* • Use of separate vaccines against erysipelas and porcine parvovirus on gilts	Vaccination of sows against atrophic rhinitis Regular treatment for ectoparasites Use of oxytocin during farrowing Use of spray-dried plasma in initial nursery ration

PRRSV, porcine reproductive and respiratory syndrome virus.

undergo morphological changes typical of cellular degeneration (Lefebvre et al. 2008b), and B and T lymphocytes, albeit a low proportion, support PCV2 replication (Pérez-Martín et al. 2007; Yu et al. 2007). Alternatively, lymphoid depletion might be the result of virus-induced apoptosis, but this is controversial (Ren et al. 2016).

Clinical signs

PCV2 is ubiquitous and most PCV2 infections are subclinical. In the field, the proportion of PCV2-infected pigs and their viral load increases gradually from lactation onward, coincident with the decline in maternal immunity. Only a variable proportion of PCV2-infected pigs develop PCV2-SD, typically at 2–4 months of age (Segalés 2012). At that time, clinically affected pigs have a higher concentration of virus in serum, shed higher levels of virus, and demonstrate a weaker antibody response compared with subclinically infected pigs (Fort et al. 2007; Grau-Roma et al. 2009). Morbidity in affected farms is commonly 4–30% (occasionally 50–60%), and mortality 4–20% (Segalés 2012). PCV2-SD is characterized clinically by wasting (Figure 30.2), pallor of the skin, respiratory distress, diarrhea, and, occasionally, icterus (Harding and Clark 1997). Enlarged subcutaneous lymph nodes are a common finding in the early clinical phases of PCV2-SD.

Experimental infections comparing PCV2-inoculated groups with negative controls rarely detected significant differences in production parameters (Fernandes et al. 2007). However, the evaluation of production records on farms without clinical disease showed that the use of PCV2 vaccines reduced mortality and increased average daily gain (ADG) (Segalés 2015).

Figure 30.2 PCV2-SD-affected pig (left) compared with an age-matched healthy pig (right). Note the severe growth retardation and the marked spinal cord of the affected animal.

Lesions

PCV2-SD lesions are primarily found in lymphoid tissues, and enlargement of lymph nodes is the most prominent feature of the early clinical phase of PCV2-SD (Clark 1997; Rosell et al. 1999). Normal sized, or even atrophied, lymph nodes are usually seen in more advanced phases of PCV2-SD (Segalés et al. 2004), and the thymus is frequently atrophied in diseased pigs (Darwich et al. 2003a). Characteristic histopathological lymphoid lesions in PCV2-SD-affected pigs include lymphocyte depletion with infiltration by large histiocytic cells and giant multinucleate cells (Figure 30.3) (Clark 1997; Rosell et al. 1999). In the thymus, cortical atrophy is a prominent finding (Darwich et al. 2003a). Cytoplasmic viral inclusions may be found in histiocytes or dendritic cells (Figure 30.4).

Lungs may be enlarged, non-collapsed, and rubbery in consistency, in a diffuse or patchy distribution, with fluid-distended interlobular septa. These findings correspond microscopically to interstitial pneumonia, with thickening of alveolar septa, pneumocyte type II hyperplasia, and the presence of macrophages and few neutrophils in alveolar spaces. Peribronchial fibrosis and fibrinous bronchiolitis occur in advanced cases (Clark 1997; Segalés et al. 2004).

In a few cases of PCV2-SD, the liver is enlarged or atrophied, pale, and firm, with a fine granular surface that corresponds microscopically to widespread cytopathic changes and inflammation (Clark 1997; Segalés et al. 2004). Pigs may show generalized icterus at this latter stage. Microscopic lesions in the liver may vary from mild lymphohistiocytic hepatitis to massive inflammation,

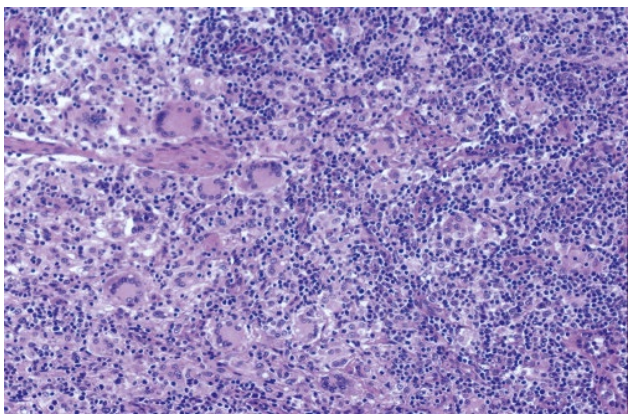

Figure 30.3 Histological appearance of a mesenteric lymph node from a PCV2-SD-affected pig. Note the lack of lymphoid follicles together with a change in cell subpopulations, which are dominated by macrophages and multinucleate giant cells with a marked loss of lymphoid cells. Hematoxylin and eosin stain.

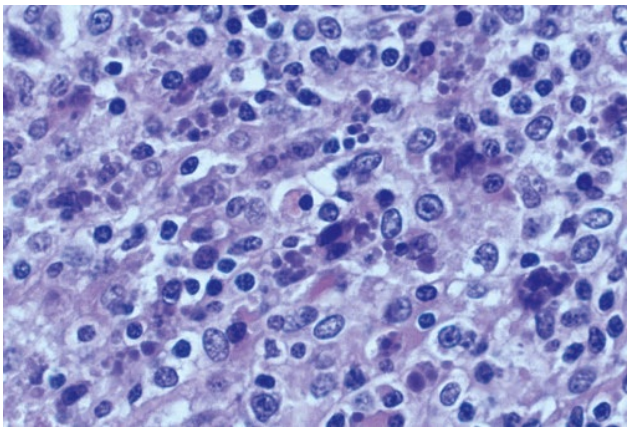

Figure 30.4 Inguinal superficial lymph node. Presence of various intracytoplasmic rounded inclusion bodies characteristics of porcine circovirus type 2 infection in a PCV2-SD-affected pig. Hematoxylin and eosin stain.

with apoptotic bodies, disorganization of hepatic plates, and perilobular fibrosis. Some hepatocytes may show large prominent nucleus and apoptosis (Resendes et al. 2011; Rosell et al. 2000a). PCV2 antigen may be found in periportal inflammatory infiltrates, in Kupffer's and endothelial sinusoidal cells, and in the nucleus and cytoplasm of hepatocytes.

Some pigs show white spots in the kidney cortex that correspond to mononuclear interstitial nephritis. PCV2 antigen may be found in renal epithelial tubular cells and infiltrating mononuclear cells. Foci of lymphohistiocytic inflammatory infiltrates may be seen in many tissues of pigs affected by PCV2-SD (Segalés et al. 2004). Brain lesions, consisting primarily of vasculitis, have occasionally been described (Correa et al. 2007; Seeliger et al. 2007). Vasculitis and lymphangitis have been found as relatively regular findings in PCV2-SD-affected pigs (Resendes and Segalés 2015).

Diagnosis

A diagnosis of PCV2-SD in a pig or group of pigs is warranted if the following criteria are fulfilled (Sorden 2000):

1) Growth retardation and wasting, frequently with dyspnea and enlargement of inguinal lymph nodes and occasionally with jaundice.
2) Moderate to severe characteristic histopathological lesions in lymphoid tissues.
3) Moderate to high amounts of PCV2 within the lesions in lymphoid and other tissues of affected pigs.

This case definition does not exclude the concomitant presence of other diseases together with PCV2-SD. Neither clinical signs nor gross lesions observed in suspected PCV2-SD-affected pigs are sufficient to diagnose the disease. In particular, the respiratory form of PRRS virus infection and all diseases and conditions that cause wasting must be differentiated from PCV2-SD (Harding and Clark 1997).

A herd diagnosis of PCV2-SD is based on the occurrence of a clinical process characterized mainly by wasting and mortality in excess of the expected and/or historical level for the farm and the individual diagnosis of PCV2-SD, as described above, in a number of pigs (Grau-Roma et al. 2012). This case definition is very useful in an epidemic situation, but the evolution of PCV2-SD to a more chronic, milder form with lower mortality makes more difficult establishing a diagnosis in farms suspected of PCV2-SD that subsequently responded to PCV2 vaccination.

Several methods have been developed to detect PCV2 in tissues. *In situ* hybridization (ISH) and immunohistochemistry (IHC) are the most widely used tests for the diagnosis of PCV2-SD (McNeilly et al. 1999; Rosell et al. 1999). PCV2 nucleic acid or antigen is usually found in the cytoplasm of histiocytes, multinucleate giant cells, and other monocyte–macrophage lineage cells, as well as in other cell types (Segalés et al. 2004).

A strong correlation has been observed between the quantity of PCV2 seen in tissues and the severity of microscopic lymphoid lesions in PCV2-SD (Figure 30.5) (Rosell et al. 1999). Since the amount of PCV2 in damaged tissues is the primary difference between PCV2-SD-affected and PCV2 subclinically infected pigs, techniques that allow PCV2 quantification in tissues and/or serum could potentially be used to diagnose PCV2-SD (Brunborg et al. 2004; McNeilly et al. 2002; Olvera et al. 2004). However, while quantitative polymerase chain reaction (PCR) shows potential for the diagnosis of PCV2-SD on a population basis, histopathology in combination with the detection of PCV2 in tissues is required for the diagnosis of PCV2-SD in

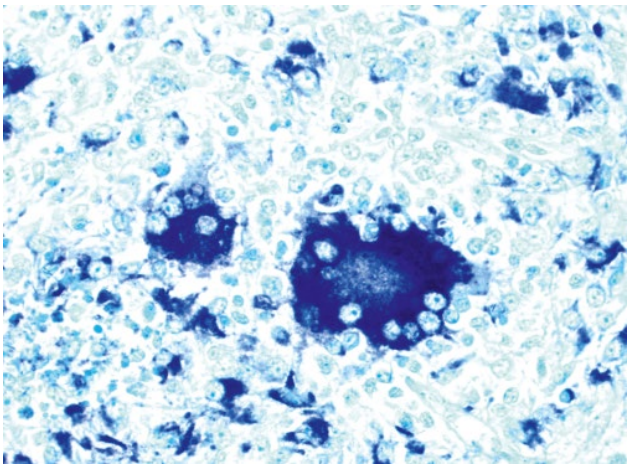

Figure 30.5 Mesenteric lymph node. Marked presence of PCV2 nucleic acid in the cytoplasm of multinucleate giant cells and macrophages (blue-stained cells) in a PCV2-SD-affected pig. *In situ* hybridization to detect PCV2; fast green counterstain.

individual pigs (Grau-Roma et al. 2009). Qualitative PCR techniques should not be used to diagnose PCV2-SD because the virus is ubiquitous and positive results in the absence of clinical disease are common.

Serologic assays for the detection of antibodies to PCV2 have been developed (Segalés and Domingo 2002), but diagnosis of PCV2-SD using serological techniques is problematic because PCV2 is ubiquitous and seroconversion patterns are relatively similar in affected and non-affected farms.

Porcine circovirus type 2 reproductive disease

Pathogenesis

Porcine embryos are susceptible to PCV2 infection, and their susceptibility increases with developmental stage (Mateusen et al. 2004). PCV2 replicates in *in vivo* produced zona-pellucida-free morulae and blastocysts (Mateusen et al. 2004, 2007), which might lead to embryonic death and eventually return to estrus. However, the relevance of this finding to naturally occurring reproductive disease is unknown.

Direct intra-fetal inoculation with PCV2 at 57, 75, and 92 days of gestation showed that PCV2 replicated in all inoculated fetuses, with significantly higher replication in fetuses inoculated at 57 days of gestation (Sánchez et al. 2001). PCV2-susceptible cells in fetuses include myocardiocytes, hepatocytes, and cells of the monocyte–macrophage lineage (Sánchez et al. 2003). Myocarditis-like lesions were observed in the heart, and cardiac tissues contained the highest virus titer and the highest proportion of infected cells.

Pensaert et al. (2004) reported mummification in fetuses inoculated at 57 days of gestation, with transmission of PCV2 to neighboring non-inoculated fetuses. At farrowing, fetuses inoculated at 75 days of gestation were stillborn, whereas fetuses inoculated at 92 days of gestation showed no lesions. In both cases, cardiac tissues were virus positive, and pigs were PCV2 antibody positive at birth.

Intranasal inoculation of pregnant sows with PCV2 or artificial insemination with PCV2-contaminated semen produced infection in fetuses/newborn piglets and/or reproductive failure (Madson et al. 2009a; Park et al. 2005; Sarli et al. 2012). Park et al. (2005) intranasally inoculated six sows with PCV2 3 weeks before the expected farrowing date. Subsequently, three sows aborted and three farrowed prematurely. PCV2 antigen and nucleic acid were detected in lymphoid and non-lymphoid tissues from stillborn and live-born piglets, but no PCV2-SD-like or cardiac lesions were observed. Madson et al. (2009a) artificially inseminated three sows with PCV2a-contaminated semen and three with PCV2b-contaminated semen. Sows that received semen with PCV2b became pregnant and maintained pregnancy to term, but most of the fetuses were mummified with myocardial lesions associated with PCV2 antigen. Sows inseminated with PCV2a-contaminated semen failed to become pregnant. Whether this was due to early embryonic death caused by PCV2a or another factor was undetermined.

Clinical signs

PCV2 has been linked to late-term abortions and stillbirths (West et al. 1999), but the contribution of PCV2 infection to reproductive failure in the field is unclear. Some reports suggest that its occurrence is rare (Ladekjaer-Mikkelsen et al. 2001; Maldonado et al. 2005; Pensaert et al. 2004; Sharma and Saikumar 2010), while others suggest that 13–46% of aborted fetuses and/or stillborns are infected with PCV2 (Kim et al. 2004b; Lyoo et al. 2001). Mummification is also an outcome of late reproductive problems caused by PCV2 infection (Madson et al. 2009a).

Based on experimental data, it is feasible to conclude that return to estrus would be the outcome of PCV2 infection at early gestation, since the virus is able to replicate and cause death of zona-pellucida-free embryos (Mateusen et al. 2007). However, the real impact of early gestation infection is currently unknown.

PCV2 infections can be found in clinically normal live-born piglets, indicating intrauterine infection (Eddicks et al. 2016; Shen et al. 2010). The viability and performance of these animals may not be overtly affected, although a subclinical impact of transplacental infection cannot be ruled out.

Lesions

Stillborn and nonviable neonatal piglets show chronic passive hepatic congestion and cardiac hypertrophy with multifocal areas of myocardial discoloration (West et al. 1999). The primary microscopic lesion corresponds to a nonsuppurative, fibrotic, and/or necrotic myocarditis (Mikami et al. 2005; West et al. 1999).

Diagnosis

The diagnosis of PCV2-RD at late gestation includes three criteria (Segalés 2012):

1) Late-term abortions and stillbirths, sometimes with evident hypertrophy of the fetal heart.
2) The presence of heart lesions characterized by extensive fibrosing and/or necrotizing myocarditis.
3) The presence of high amounts of PCV2 in myocardial lesions and other fetal tissues.

In aborted and mummified fetuses, PCV2 is mainly found in the myocardiocyte (Madson et al. 2009a; West et al. 1999). Recent studies suggested that this case definition is useful for the diagnosis of acute reproductive failure, whereas quantitative PCR is an appropriate diagnostic method across a wider time span (Hansen et al.

2010). Serology is not useful for the detection of intrauterine infection with PCV2 (Hansen et al. 2010). This is reinforced by the recent evidence that small amounts of PCV2 antibodies are able to cross the placenta in some fetuses coming from sows with very high serological titers (Saha et al. 2014), probably related to small lesions in the placental barrier during gestation. PCV2-RD at late gestation is clinically indistinguishable from other swine diseases that cause late-term abortions and stillbirths. In addition, the presence of mummies of different sizes must be differentiated from the infection by PPV.

The putative diagnosis of PCV2-RD at early gestation has been suggested based on two criteria (Segalés 2012):

1) Regular return to estrus.
2) PCV2 seroconversion following the return to estrus and/or PCV2 PCR positivity around return-to-estrus occurrence.

PCV2-RD at early gestation should be clinically differentiated from other infectious and noninfectious conditions causing return to estrus in sows.

Porcine dermatitis and nephropathy syndrome (PDNS)

Pathogenesis

PDNS is classified as an immune-mediated disease, although the specific antigen triggering this condition is unknown. In principle, the nature of such an antigen could be diverse, but the clinical and epidemiological data supports PCV2 as the most likely suspect. It has been suggested that excessive PCV2 serum antibody titers may somehow be involved with triggering the condition (Wellenberg et al. 2004); however, this hypothesis awaits experimental confirmation.

Clinical signs

PDNS affects nursery, growing, and adult pigs (Drolet et al. 1999). The prevalence of PDNS is usually <1% (Segalés et al. 1998), although higher frequency has been described (Gresham et al. 2000). Mortality approaches 100% in pigs older than 3 months versus approximately 50% in younger pigs. Severe, acutely affected pigs die within a few days after the onset of clinical signs. Surviving pigs tend to recover and gain weight 7–10 days after the beginning of the syndrome (Segalés et al. 1998).

PDNS-affected pigs are anorexic and depressed, with little or no pyrexia (Drolet et al. 1999). They may be prostrate, reluctant to move, and/or stiff-gaited. The most obvious sign of PDNS is the presence of irregular, red to purple macules and papules in the skin, primarily on the hind limbs and perineal area (Figure 30.6), but sometimes more generally distributed. With time, the lesions become covered by dark crusts. The lesions gradually fade, sometimes leaving scars (Drolet et al. 1999). Serum BUN and creatinine are markedly elevated, indicating acute renal failure.

Figure 30.6 PDNS-affected pig. Presence of necrotizing cutaneous lesions of generalized distribution, which tend to be more numerous and coalescent on the hind limbs.

Lesions

Macules and papules from the skin are seen microscopically as necrotic and hemorrhagic tissue associated with necrotizing vasculitis (Segalés et al. 1998). Necrotizing vasculitis is a systemic feature. Studies on tissue sections from pigs with PDNS have failed to consistently demonstrate PCV2 antigen or nucleic acid associated with PDNS vascular lesions.

Pigs that die acutely with PDNS have bilaterally enlarged kidneys with a fine granular cortical surface, small reddish pinpoint cortical lesions, and edema of the renal pelvis (Segalés et al. 2004). These lesions correspond to a fibrinonecrotizing glomerulitis with fibrin and neutrophils filling and occluding Bowman's spaces and a non-purulent interstitial nephritis. Pigs with prolonged disease may show chronic glomerulonephritis (Segalés et al. 1998). Normally, both skin and renal lesions are present in PDNS, but in few occasions, skin or renal lesions may occur alone. Lymph nodes may be enlarged and red in color. Splenic infarcts may be also present (Segalés et al. 1998). Microscopically, lymphoid lesions like those of PCV2-SD but milder are frequently observed in PDNS-affected pigs (Rosell et al. 2000b).

Diagnosis

Since the triggering antigen for PDNS is unknown, detection of PCV2 is not a diagnostic requirement. Instead, the diagnosis of PDNS is based on two criteria (Segalés 2012):

1) The presence of hemorrhagic and necrotizing skin lesions, primarily on the hind limbs and perineal area, and/or swollen and pale kidneys with generalized cortical petechiae.
2) The presence of systemic necrotizing vasculitis and necrotizing fibrinous glomerulonephritis.

PCV2 nucleic acid or antigen is usually found in PDNS-affected pigs, mainly in the cytoplasm of histiocytes, multinucleate giant cells, and other monocyte–macrophage lineage cells, as well as in some epithelial cell types (Segalés et al. 2004).

Differential diagnoses for PDNS include any condition that causes red to dark discoloration of the skin, as well as conditions that cause petechial hemorrhages in the kidneys (Segalés 2012). Special note should be made of the similarity of gross lesions between PDNS, classical swine fever (CSF), and African swine fever.

Immunity

In vitro studies demonstrated that PCV2 modulates the immune system. The addition of PCV2 to cultured alveolar macrophages altered the production of certain cytokines and/or chemokines (Chang et al. 2006). The altered functionality of PCV2-infected alveolar macrophages may favor the spread of PCV2, as well as render pigs more susceptible to opportunistic and secondary pulmonary infections.

PCV2 infection of myeloid dendritic cells did not interfere with dendritic cell maturation or their ability to process and present antigen to T lymphocytes (Vincent et al. 2003, 2005), but PCV2 interaction with plasmacytoid dendritic cells (natural interferon-producing cells) impaired their responsiveness to danger signals (Vincent et al. 2007). PCV2-induced impairment of dendritic cell function does not require viral replication, but is mediated by viral DNA in a dose-dependent manner (i.e. a minimum concentration of dsDNA (RF) is necessary to mediate inhibition) (Vincent et al. 2007).

The addition of PCV2 to PBMCs from either healthy or clinically affected pigs altered their cytokine profiles (Darwich et al. 2003a) and seemingly modulated the specific immune responses to other pathogens as well (i.e. PCV2 downregulated the cytokine recall antigen response) (Kekarainen et al. 2008). Inhibition of some of cytokine responses was mediated by the release of PCV2-induced interleukin-10 (IL-10) by monocytic cells. *Ex vivo*, increased serum levels of this cytokine in PCV2-infected pigs were associated with the development of PCV2-SD (Darwich et al. 2003b; Stevenson et al. 2006). It has been suggested that IL-10-producing cells are of myeloid and lymphoid origin, but they are rarely, if ever, infected with PCV2 (Crisci et al. 2010; Doster et al. 2010).

Most current knowledge on PCV2 immunity was generated under PCV2-SD and PCV2 vaccination scenarios in piglets.

Under field conditions, colostral antibodies decline during the lactating and nursery periods, followed by active seroconversion during the growing–finishing period (Carasova et al. 2007; Grau-Roma et al. 2009; Larochelle et al. 2003). PCV2-SD is very rarely observed in pigs younger than 4 weeks of age (Segalés and Domingo 2002), suggesting that certain levels of maternal immunity protect against the development of PCV2-SD (Allan et al. 2002a; Calsamiglia et al. 2007).

Specific immune responses to PCV2 develop 2–3 weeks after inoculation. In the field, seroconversion occurs in both subclinically infected and PCV2-SD-affected pigs (Grau-Roma et al. 2009). Some field studies found no difference in total anti-PCV2 antibody titer levels between non-PCV2-SD- and PCV2-SD-affected pigs (Larochelle et al. 2003; Sibila et al. 2004), but others have reported weaker humoral immune responses in PCV2-SD-affected pigs (Grau-Roma et al. 2009; Meerts et al. 2006).

An insufficient humoral response (Bolin et al. 2001; Okuda et al. 2003; Rovira et al. 2002) and, in particular, a poor neutralizing antibody response (Fort et al. 2007; Meerts et al. 2006) is associated with increased viral replication, severe lymphoid lesions, and the eventual development of PCV2-SD. During infection, antibodies are produced especially against the capsid protein, but also against nonstructural replication-associated proteins (Pérez-Martín et al. 2010; Pogranichnyy et al. 2000). All current commercial PCV2 vaccines elicit anti-capsid antibodies only, as they are all based either on capsid protein or on non-replicative viruses (Segalés 2015).

Pigs with subclinical PCV2 infections develop specific humoral and T-cell responses, although relatively slowly (Fort et al. 2009a; Steiner et al. 2009). The kinetics of the helper and cytotoxic T-cell responses, as measured by the number of IFN-γ secreting cells (SC), are dependent on the individual animal and the time post inoculation at which the cells are assayed.

PCV2-SD-affected pigs show B- and T-cell lymphopenia induced by PCV2 infection. Most notably, B and $CD3^+CD4^+CD8^+$ memory/activated T lymphocytes are depleted in PCV2-SD-affected animals (Nielsen et al. 2003). Both vaccination and infection elicit memory/activated T cells. These cells persist long term post infection/vaccination and are able to expand rapidly after recall antigen recognition (Ferrari et al. 2014). More specifically, it has been suggested that PCV2-specific IFN-γ/TNF-α-co-producing CD4+ cells, produced upon vaccination/infection, play a pivotal role in controlling and clearing PCV2 infection (Koinig et al. 2015).

Overall, current data on the adaptive immune response against PCV2 infection/vaccination suggest that the cell-mediated response, as measured by IFN-γ-SC, together with a significant neutralizing antibody response, is responsible for viral clearance in infected animals and protection (Fort et al. 2009a; Kekarainen and Segalés 2015). It has been hypothesized that a failure in one or

both responses could result in PCV2-SD development (Kekarainen et al. 2010).

Prevention and control

PCV2-SD is a multifactorial disease that can be controlled by the use of PCV2 vaccines, but prior to the advent of vaccines, prevention and control focused on eliminating environmental and infectious cofactors and triggers believed to trigger PCV2-SD (e.g. "Madec's 20-point plan") (Ellis et al. 2004; Madec et al. 2000; Segalés et al. 2005). These issues are still pertinent.

Most current vaccines worldwide are based on PCV2a strains (Segalés 2015). Although vaccines are effective in reducing clinical signs of PCVDs, their efficacy against mixed infection of PCV2a and PCV2b and the recently emerged PCV2d is less clear (Jeong et al. 2015; Opriessnig et al. 2014; Rose et al. 2016; Shen et al. 2010) and requires further study (Afghah et al. 2017).

Vaccination of both sows and piglets has been shown to be beneficial in the continuous control of PCVD (Segalés 2015). In this protocol it is important to take into account the possible interference of maternally derived immunity upon PCV2 vaccine efficacy in piglets.

Vaccination of sows has two potential objectives: (1) to prevent PCVDs in offspring or (2) to protect against PCV2-RD. To prevent PCVDs in offspring, vaccination should take place during late gestation. PCV2 infection and/or low serological titers to PCV2 in sows at farrowing increased the overall mortality of their offspring to PCV2-SD (Allan et al. 2002a; Calsamiglia et al. 2007). Measures that increase maternal immunity and decrease sow viremia at farrowing should diminish piglet PCV2-SD mortality in problem herds (Pejsak et al. 2010).

If the objective is to prevent PCV2-RD, vaccination may be done during the acclimatization of gilts, prior to mating, during lactation, or at weaning. Sow vaccination has been shown to increase fertility, farrowing rate, number of piglets born alive, birth weight of piglets, and number of piglets weaned per a litter (Pejsak et al. 2012). However, one study using a PCV2 commercial subunit vaccine (Madson et al. 2009b) found that vertical transmission of PCV2 could occur in PCV2-vaccinated dams exposed at 56 days of gestation, although clinical protection was achieved. To date, minimal data exist regarding the benefits of the continuous vaccination of the breeding stock and its effects on PCV2-RD.

Piglet vaccination to control PCV2-SD in affected farms is faster than sow vaccination because vaccine administered to piglets elicits protective immunity in the animal at risk of the disease. Low antibody responses, or even lack of detectable antibody after vaccination, do not necessarily indicate lack of protection. High levels of maternally derived antibodies interfere with active seroconversion following vaccination (Fort et al. 2009b; Fraile et al. 2012; Opriessnig et al. 2010), although vaccine efficacy under field conditions seems not to be jeopardized in spite of moderate to high antibody titers (Fachinger et al. 2008; Feng et al. 2016). Cell-mediated immunity is also assumed to be important for protection (Fenaux et al. 2004; Pérez-Martín et al. 2010). Development of cell-mediated immunity was demonstrated by production of PCV2-specific IFN-γ-SC in piglets vaccinated with a PCV2 subunit vaccine (Fort et al. 2009b).

Coronaviruses

Linda J. Saif, Qiuhong Wang, Anastasia N. Vlasova, Kwonil Jung, and Shaobo Xiao

Overview

The family *Coronaviridae* within the order *Nidovirales* consists of two subfamilies: (1) *Coronavirinae* comprising the genera *Alphacoronavirus*, *Betacoronavirus*, *Gammacoronavirus*, and *Deltacoronavirus* and (2) *Torovirinae* comprising the genera *Torovirus* and *Bafinivirus* and an unassigned genus.

Five swine coronaviruses (CoVs) have been identified: transmissible gastroenteritis virus (TGEV) first described in 1946; porcine respiratory coronavirus (PRCV), a spike (S) gene deletion mutant of TGEV isolated in 1984; porcine epidemic diarrhea virus (PEDV) isolated in 1977; porcine hemagglutinating encephalomyelitis virus (pHEV) isolated in 1962; and porcine deltacoronavirus (PDCoV) detected in 2012. In addition, a TGEV/PEDV recombinant virus (TGEV backbone but with PEDV spike gene) has been identified in swine in Europe (Akimkin et al. 2016; Belsham et al. 2016; Boniotti et al. 2016), and a bat-HKU2-like alphacoronavirus has been identified in swine in China (Gong et al. 2017; Pan et al. 2017; Zhou et al. 2018). In pigs, CoVs and toroviruses (ToVs) affect a variety of organs, including the gastrointestinal and respiratory tracts, the peripheral and central nervous systems (CNS), and the mammary glands. Most ToVs and PRCV induce mainly subclinical infections in pigs, whereas TGEV, PEDV, PDCoV, and pHEV infections can result in fatal enteric or nervous diseases.

Swine CoVs comprise three distinct genera – *Alphacoronavirus*, *Betacoronavirus*, and *Deltacoronavirus* (Figure 31.1) – and share replication strategies common to *Coronaviridae*. TGEV and PRCV belong to the *Alphacoronavirus 1* species that also contains closely related CoVs of domestic cats and dogs. PEDV and two human CoVs (229E and NL63) are separate species in the same genus *Alphacoronavirus*. The newly identified bat-HKU2-like swine enteric alphacoronavirus also belongs to the genus *Alphacoronavirus*, but its taxonomic name has not been defined. pHEV and PDCoV are genetically distinct, and they belong to the *Betacoronavirus and Deltacoronavirus* genera, respectively. Together with bovine, human OC43, equine, and canine respiratory CoVs, pHEV is a member of the *Betacoronavirus 1* species. PDCoV is most closely related to other mammalian deltacoronaviruses from Asian leopard cats and Chinese ferret badgers (Ma et al. 2015). For each swine CoV, only a single serotype is recognized.

CoVs are enveloped and pleomorphic, with an overall diameter of 60–160 nm as viewed by negative staining electron microscopy (EM) (Figure 31.2). Most have a single layer of club-shaped spikes (S protein) 12–25 nm in length, but pHEV and some other betacoronaviruses have a second shorter layer of surface spikes, the hemagglutinin-esterase (HE) protein.

Genomic organization and gene expression: TGEV prototype

Swine CoVs contain one large, polyadenylated, single-stranded, genomic RNA (25–30 kb) of positive-sense polarity. The genome organization, replication strategy, and expression of viral proteins are similar to those of other human and animal CoVs (Enjuanes and Van der Zeijst 1995; Gonzalez et al. 2003; Laude et al. 1993). The complete genomes of the Purdue and Miller strains of TGEV are 28,546–28,580 nucleotide (nt) long and share 96% overall identity (Penzes et al. 2001; Zhang et al. 2007). Most CoVs have buoyant densities in sucrose of 1.18–1.20 g/mL. The phospholipids and glycolipids incorporated into the virus envelope are derived from the host cell, and thus, the envelope composition is host cell dependent (Enjuanes and Van der Zeijst 1995).

Most CoVs contain four structural proteins: a large surface glycoprotein (spike or S protein visible as the corona; Figure 31.2), a small membrane protein (E), an integral membrane glycoprotein (M), and a nucleocapsid protein (N). However, pHEV also contains an HE protein (de Groot et al. 2008).

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

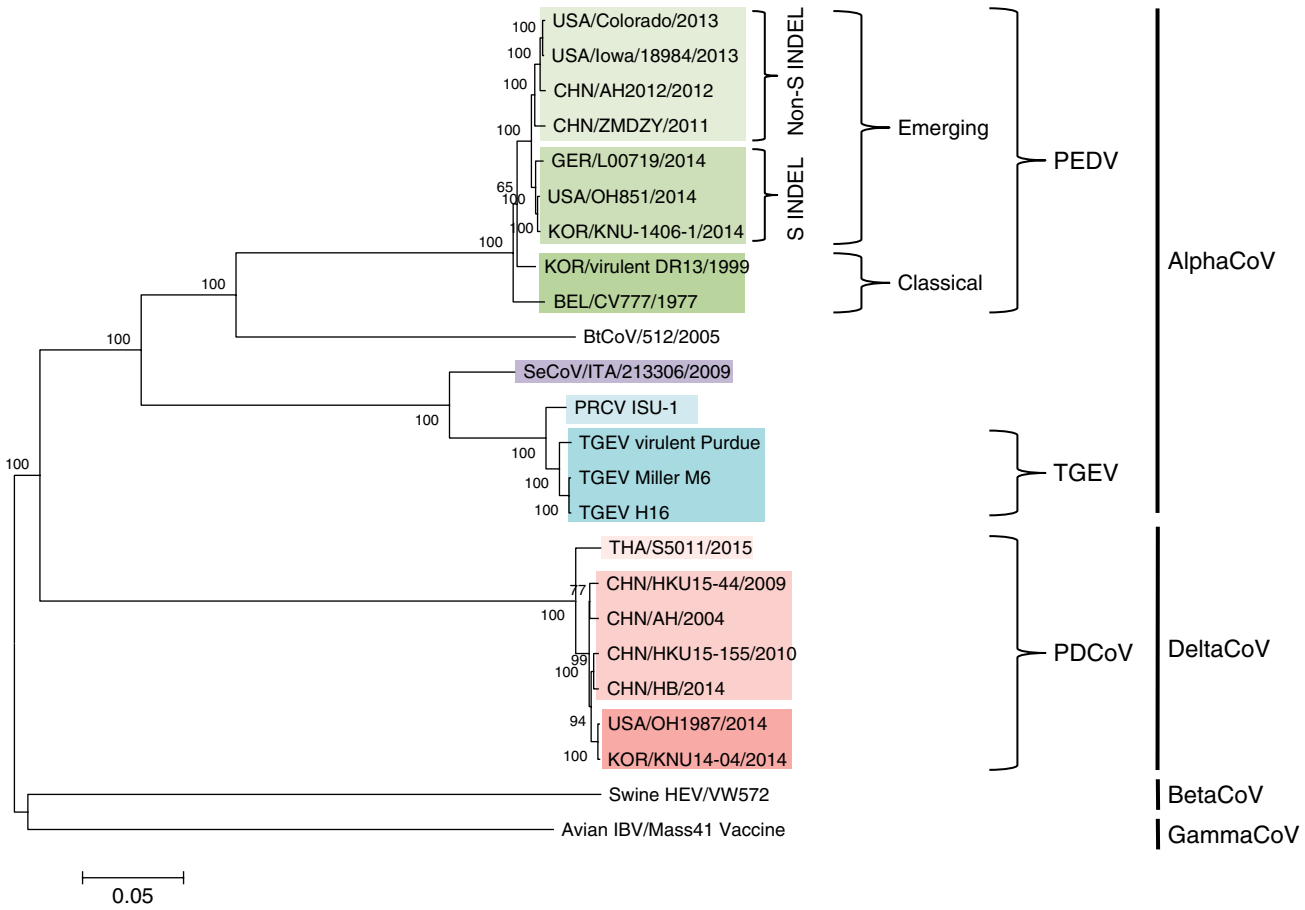

Figure 31.1 Phylogenetic tree of coronaviruses. The complete genomes of TGEV, PEDV, and PDCoV strains, closely related PRCV and a bat alphacoronavirus, a porcine HEV strain, and an avian IBV strain were selected. Multiple sequence alignments were performed using ClusterW, and a neighbor-joining phylogenetic tree supported with a bootstrap test of 1000 replicates was constructed using MEGA 6.0 software. The number on each branch indicates the bootstrap value. The scale represents the nucleotide substitutions per site. Color-shaded areas denote different swine virus clusters.

The N protein (47 kDa) interacts with viral RNA to form a helical ribonucleoprotein complex. This structure, in association with M protein, forms an internal icosahedral core in TGEV. The 29–36 kDa M glycoprotein is embedded in the viral envelope by 3–4 membrane-spanning regions. In TGEV, the hydrophilic N-terminus with a single accessible glycosylation site is responsible for interferon (IFN) induction (Charley and Laude 1988). Epitopes on protruding N- and C-terminal ends of the M protein of TGEV bind complement-dependent neutralizing monoclonal antibodies (MAbs) (Laude et al. 1992; Woods et al. 1988).

The TGEV S glycoprotein (220 kDa) occurs as trimer complexes (Delmas and Laude 1990) and functions in virus neutralization (complement independent), virus-cell attachment, membrane fusion, and hemagglutination. The large deletion in the S gene of PRCV results in a smaller S protein (170–190 kDa) (Figure 31.3). During fusion of TGEV with host cell membranes, two highly conserved heptad repeat regions (HR1 and HR2) of the S protein undergo conformational changes important for fusion (Ma et al. 2005). Entry of TGEV into the cell is likely associated with cholesterol-rich membrane microdomains (Ren et al. 2008), since exogenous cholesterol rescued virus infectivity.

Epitope mapping of the S glycoprotein of TGEV revealed four antigenic sites (A, B, C, D) (Figure 31.3). Site A–B, the conserved immunodominant epitope, is recognized strongly by neutralizing MAbs (Correa et al. 1990; Delmas and Laude 1990; Simkins et al. 1992, 1993), although other sites (D, C) can also induce virus-neutralizing (VN) antibodies (Delmas and Laude 1990). The S protein mutations in attenuated TGEV strains or the natural TGEV deletion mutant PRCV include a serine/alanine mutation at amino acid (aa) 585 position associated with induction of VN antibodies, as well as receptor (aminopeptidase N) binding (Zhang et al. 2007).

Porcine aminopeptidase N (pAPN) has been identified as the TGEV cell receptor (Delmas et al. 1992). The receptor-binding and major neutralizing site (site A) on the S

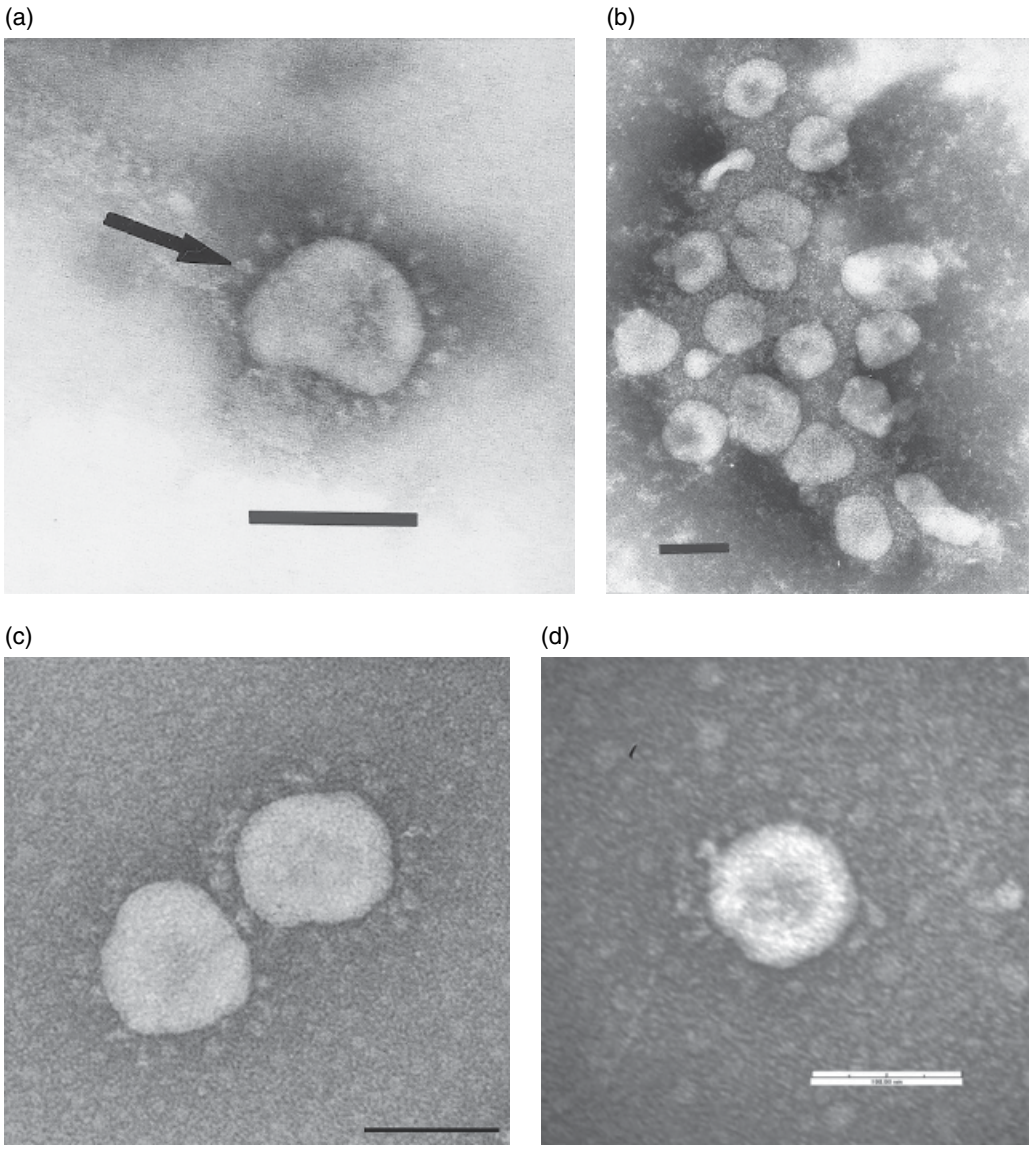

Figure 31.2 Electron micrographs. (a) A TGEV particle showing typical coronavirus morphology. Arrow points to the virus peplomers or spikes. Bar = 100 nm. (b) Typical virus–antibody aggregates observed by immunoelectron microscopy of TGEV and gnotobiotic pig anti-TGEV serum. Bar = 100 nm. (c) Two particles of emerging non-S INDEL PEDV PC22A strain, bar = 100 nm. *Source:* Oka et al. (2014). Reproduced with permission of Elsevier. (d) A PDCoV particle, bar = 100 nm. *Source:* Jung et al. (2015b).

protein of TGEV are located within the same domain (Figure 31.3) (Godet et al. 1994). TGEV binding to sialic acid residues on glycoproteins of target cells was proposed to initiate infection of intestinal enterocytes (Schwegmann-Wessels et al. 2002). Treatment of TGEV with sialidase enhanced hemagglutinating activity (Noda et al. 1987; Schultze et al. 1996). The hemagglutinating activity resides in the N-terminal region of the TGEV S protein, a region that is missing from the PRCV S protein; thus, determination of hemagglutinating activity (Schultze et al. 1996) could potentially differentiate PRCV and TGEV strains.

TGEV and PEDV as well as PDCoV also encode 1–2 accessory proteins encoded by open reading frame (ORF) 3 (TGEV and PEDV), ORF6 (PDCoV), and ORF7 (TGEV and PDCoV). The overall genome organization is 5′UTR-ORF1ab, S, ORF3, E, M, ORF6, N, ORF7-3′UTR.

Contrasts and comparisons

Seven CoVs are related antigenically or by their genomic sequences (Enjuanes and Van der Zeijst 1995): TGEV, PRCV, canine coronavirus (CCoV), feline infectious peritonitis virus (FIPV), feline enteric coronavirus (FECoV), PEDV, and human CoV 229E. CoVs within the species *Alphacoronavirus 1* (TGEV, PRCV, CCoV, FIPV, FECoV) are antigenically related, based on cross-reactivity in VN and immunofluorescence (IF) tests and with MAbs to the S, N, or M proteins, and all share the antigenic subsite

Ac on the S protein (Enjuanes and Van der Zeijst 1995). As members of the same species, these viruses likely represent host range mutants of an ancestral virus strain (de Groot et al. 2008). TGEV and CCoV could be distinguished *in vitro* by two-way cross-neutralization tests and other biological differences (Reynolds et al. 1980), i.e. both TGEV and CCoV grow in canine kidney cells and a feline cell line, whereas TGEV, but neither CCoV nor FIPV, grows in swine cells.

For the S glycoprotein that confers host range specificity, the 300 aa residues at the N-terminus are the most variable. In this domain, CCoV and FIPV are more similar to each other than to TGEV (Wesseling et al. 1994). Differentiation of the TGEV-related CoVs is possible using specific MAbs to the S glycoprotein of TGEV that recognize TGEV but not PRCV, FIPV, or CCoV strains (Callebaut et al. 1989; Laude et al. 1993; Sanchez et al. 1990; Simkins et al. 1992, 1993).

Interestingly, outbreaks of fatal acute gastroenteritis associated with TGEV-related CCoV type II (CCoV-II) were reported in European dogs (Decaro et al. 2009; Erles and Brownlie 2009). The close genetic relatedness (>96% aa identity) in the key replicase domains suggested that the recently emerged CCoV-II strains are host range variants of TGEV that infect dogs (de Groot et al. 2008). Based on the S protein, the CCoV-IIb strains (TGEV-like) (Decaro et al. 2010) may represent novel recombinant viruses of mixed (TGEV/CCoV) origin.

Several researchers reported that the severe acute respiratory syndrome (SARS) CoV cross-reacts with antibodies to *Alphacoronavirus 1* species (TGEV, PRCV, CCoV, FeCoV) through the N protein (Ksiazek et al. 2003; Sun and Meng 2004) and that this cross-reactivity mapped to the N-terminal region (Vlasova et al. 2007). This discovery led to use of SARS CoV-specific N peptide fragments in serologic assays to detect SARS CoV antibodies in animal sera (Vlasova et al. 2007). One-way cross-reactivity with the N protein has also been reported for PEDV, FIPV, CCoV, TGEV, and a putative mink CoV (Have et al. 1992; Zhou et al. 2010). Although no cross-reactivity between PEDV and TGEV-related CoVs was initially reported (Enjuanes and Van der Zeijst, 1995), one-way cross-reactivity between TGEV Miller and several PEDV strains (classical CV777, emerging non-S INDEL and S INDEL US strains) was recently confirmed (Lin et al. 2015b).

In vivo biological differences in pathogenicity for neonatal pigs are evident among TGEV, CCoV, and FIPV strains. Whereas virulent FIPV caused diarrhea and intestinal lesions similar to those of virulent TGEV, CCoV caused no clinical signs and only slight villous atrophy. CCoV shed by acutely infected dogs, infected baby pigs, and induced serum VN antibodies to CCoV and TGEV (Woods and Wesley 1992). However, baby pigs and pregnant gilts infected with FIPV did not produce TGEV VN antibodies, but did develop some immunity to TGEV challenge.

PRCV strains have been characterized and sequenced (Britton et al. 1991; Costantini et al. 2004; Kim et al. 2000b; Rasschaert et al. 1990; Vaughn et al. 1995; Zhang et al. 2007). Two striking features characterize the PRCV genome: (1) a large deletion (621–681 nt) near the N-terminus of the S gene producing a smaller S protein (Figure 31.3) and (2) a variable region with deletions that compromise ORF3 downstream of the S gene. These genetic changes may account for the altered tissue tropism of PRCV (Ballesteros et al. 1997; Sanchez et al. 1999). An overall nucleotide and aa sequence identity of 96–98% between TGEV and PRCV suggests that PRCV evolved from TGEV (Zhang et al. 2007) and that this occurred on a number of independent occasions.

Disease outbreaks caused by swine CoVs are endemic or variable in swine-producing countries. Nevertheless, the diseases induced by these CoVs have resisted eradication

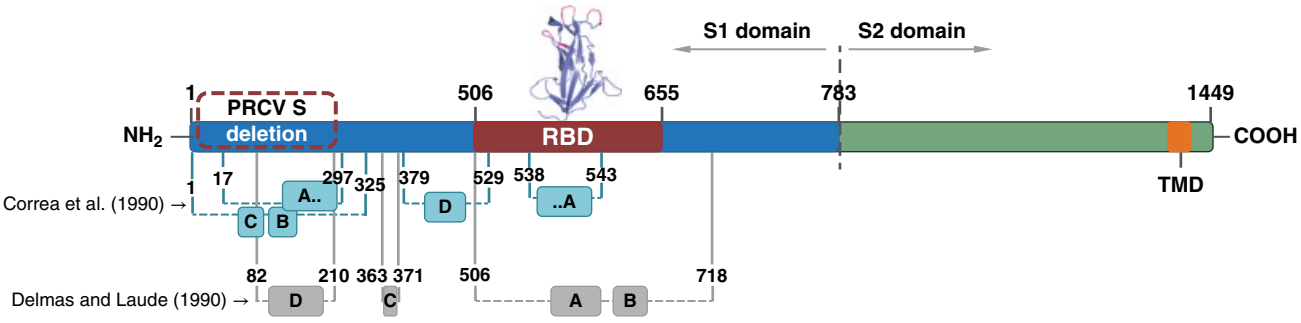

Figure 31.3 Schematic diagram of TGEV S protein. RBD, receptor-binding domain (shown in red); TMD, transmembrane domain (shown in orange). According to Correa et al.'s (1990) classification (light blue boxes), site A is discontinuous and located around positions 17 and 297 and 538 and 543, site B is located between amino acids 1 and 325, and site D is located between 379 and 529. The relative order of sites C and B and part of site A is not determined. According to Delmas and Laude's (1990) classification (light gray boxes), S protein antigenic sites D, C, and A/B are located between amino acids 82 and 210, between 363 and 371, and between 506 and 718, respectively. Dotted red box indicates a 227 aa deletion in the PRCV S protein. *Source:* Adapted from Correa et al. (1990) and Delmas and Laude (1990).

efforts, and the viruses may continue to evolve in domestic pigs, wild boars, and other potential reservoir (bats) or secondary hosts, such as carnivores, via interspecies transmission.

Transmissible gastroenteritis virus and porcine respiratory coronavirus

Relevance

TGE is a highly contagious enteric viral disease of swine characterized by vomiting, severe diarrhea, and high mortality (often 100%) in piglets less than 2 weeks of age. TGE was first described by Doyle and Hutchings (1946) in the United States and subsequently reported worldwide. Although swine of all ages are susceptible to TGEV or PRCV infection, the mortality in TGEV and/or PRCV seropositive herds and in swine over 5 weeks of age is generally low.

The appearance and widespread prevalence of PRCV, a naturally occurring deletion mutant of TGEV, lessened the clinical impact of TGE (Brown and Cartwright 1986; Laude et al. 1993; Pensaert et al. 1986, 1993; Pensaert 1989; Yaeger et al. 2002). However, sporadic outbreaks of severe diarrhea in piglets caused by TGEV in TGEV/PRCV seronegative herds are still reported in North America, Europe, and Asia. Currently, TGEV and PEDV co-circulate in Asia, Europe, and the United States, and recently, pathogenic recombinant TGEV/PEDV variants (swine enteric coronavirus [SeCoV]) were identified and characterized in Europe (Akimkin et al. 2016; Belsham et al. 2016; Boniotti et al. 2016). SeCoV that contains PEDV S gene on a TGEV backbone reportedly causes disease clinically indistinguishable from that caused by TGEV and PEDV. This epidemiological situation requires frequent monitoring and development of reliable tools for differential diagnosis (Kim et al. 2001; Masuda et al. 2016).

Etiology

TGEV antigen can be demonstrated by IF staining in the cytoplasm of infected cells 4–5 hours post infection (Pensaert et al. 1970). Maturation of virus occurs in the cytoplasm by budding through the endoplasmic reticulum, and viral particles (65–90 nm in diameter) are observed within cytoplasmic vacuoles (Figure 31.4a) (Pensaert et al. 1970; Thake 1968). Virus may line host cell membranes after exit from infected cells (Figure 31.4b). A similar intracellular replication scenario has been described for PEDV (Figure 31.4c). TGEV glycoproteins are also evident on the surface of infected ST cells (Laviada et al. 1990).

TGEV is stable when stored frozen, but labile at room temperature or higher. Infectious virus persisted in liquid manure slurry for more than 8 weeks at 5 °C (41 °F), 2 weeks at 20 °C (68 °F), and 24 hours at 35 °C (95 °F) (Haas et al. 1995). In recent studies that used TGEV as a surrogate for SARS CoV (Casanova et al. 2009), it remained infectious in water and sewage for several days at 25 °C (77 °F) and for several weeks at 4 °C (39 °F).

TGEV is highly photosensitive. Fecal material containing 1×10^5 pig infectious doses (PID) was inactivated within 6 hours when exposed to sunlight or to ultraviolet light (Cartwright et al. 1965; Haelterman 1962). TGEV is inactivated by exposure to 0.03% formalin, 1% Lysovet (phenol and aldehyde), 0.01% beta-propiolactone, 1 mM binary ethylenimine, sodium hypochlorite, NaOH, iodines, quaternary ammonium compounds, ether, and chloroform (Brown 1981; VanCott et al. 1993). TGEV field strains are trypsin resistant, relatively stable in pig bile, and stable at pH 3 (Laude et al. 1981), allowing virus to survive in the stomach and small intestine. However, properties of attenuated and field strains of TGEV vary.

Public health

Pigs are the main species naturally susceptible to TGEV and PRCV. No infection of humans has been reported.

Epidemiology

On a herd basis, two epidemiologic forms of TGE are recognized: epidemic and endemic. Infections with the TGEV deletion mutant PRCV present a different pattern, greatly complicating seroprevalence studies of the epidemiology of TGEV (Pensaert 1989).

Epidemic versus endemic TGE

Epidemic TGE occurs when most of the animals in a herd are TGEV/PRCV seronegative and susceptible. After introduction, the disease spreads rapidly to swine of all ages, especially during winter. Inappetence, vomiting, or diarrhea occurs in most animals. Suckling pigs show marked clinical signs and rapidly dehydrate. Mortality is very high in pigs under 2–3 weeks of age but decreases in older pigs. Lactating sows often develop anorexia and agalactia, with reduced milk production, which further contributes to piglet mortality.

Endemic TGE refers to the persistence of the virus and disease in a herd perpetuated by the continual or frequent influx of susceptible swine. Endemic TGE is a common sequel to a primary outbreak and occurs in seropositive herds that have frequent farrowings (Stepanek et al. 1979), herd additions, or commingling of susceptible pigs. In endemically infected herds, TGEV

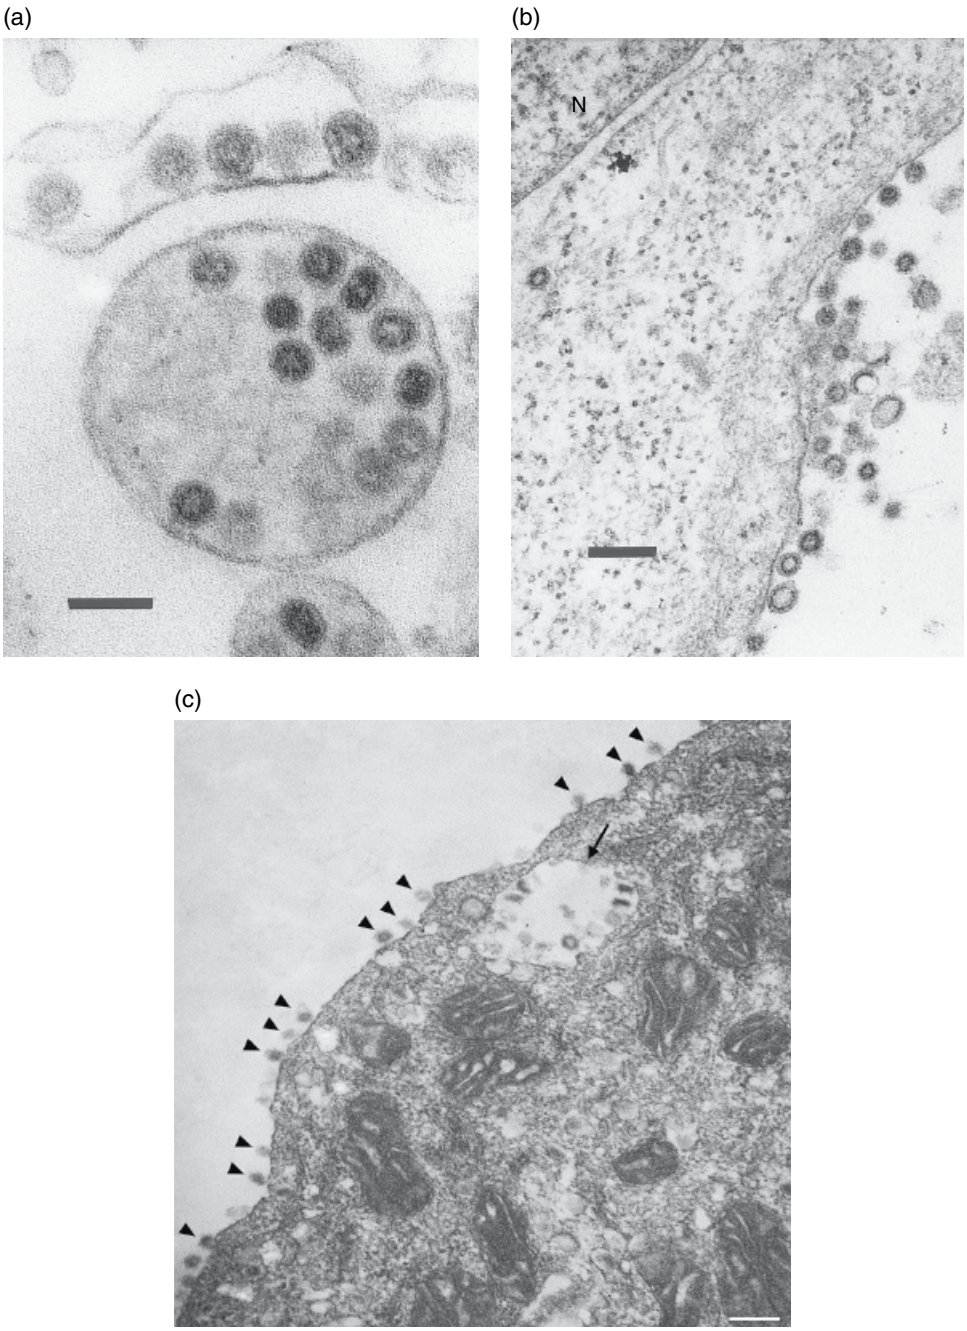

Figure 31.4 Electron micrographs. (a) TGEV in vesicles of the endoplasmic reticulum of a pig kidney cell (36 hours post infection). Bar = 100 nm. (b) TGEV lining the cell membrane of a pig kidney cell (36 hours post infection). N = nucleus; bar = 200 nm. (c) A PEDV-infected Vero cell. Reproduced with permission of Elsevier.

spreads slowly among adult swine (Pritchard 1987). Sows are frequently immune and asymptomatic and will transfer a variable degree of passive lactogenic immunity to their progeny. In these herds, mild TGEV diarrhea occurs, and mortality is usually under 10–20% in pigs from approximately 6 days of age until approximately 2 weeks post weaning. The age-related effects are influenced by the management system and the degree of passive immunity from the sow.

Endemic TGE in suckling or recently weaned pigs can be difficult to diagnose and must be differentiated from other types of endemic diarrheal pathogens common in young pigs, such as PEDV, PDCoV, rotavirus, and *Escherichia coli*. Endemic TGE persists in the herd as long as susceptible or partially immune swine are exposed to TGEV. It is unclear whether the source of virus is from reactivation of virus shedding in carrier swine or reintroduction of virus into the herd from an external source.

Porcine respiratory coronavirus

PRCV is a TGEV variant that infects the respiratory tract with limited or no shedding in feces (Pensaert 1989). However, PRCV-infected pigs produce antibodies that neutralize TGEV. The first isolation of PRCV was in Belgium in 1984 (Pensaert et al. 1986). In 1989, PRCV was detected in two herds in the United States with no history of TGEV vaccination or clinical disease (Hill et al. 1990; Wesley et al. 1990).

Swine population density, distance between farms, and season influence PRCV epidemiology (Have 1990; Pensaert 1989). PRCV infects pigs of all ages by contact or airborne transmission. PRCV infections are often subclinical. The risk of PRCV spread increases in areas of high swine density, where the virus can travel several kilometers. The virus has spread rapidly and extensively in pigs in Europe (Brown and Cartwright 1986; Have 1990; Laude et al. 1993; van Nieuwstadt et al. 1989) and became endemic even in TGEV-free countries (Laude et al. 1993; Pensaert 1989; Pensaert et al. 1993). A limited serological survey in 1995 in the United States suggested that many asymptomatic herds in Iowa were seropositive for PRCV (Wesley et al. 1997).

PRCV circulates in the herd, infecting pigs before the age of 10–15 weeks after passively acquired maternal antibodies have declined. Introduction of pigs into fattening units and commingling of PRCV-negative and PRCV-positive pigs from diverse sources result in seroconversion to PRCV in pigs shortly after introduction into most units.

Susceptible pigs experimentally infected with PRCV shed virus from nasal secretions for less than 2 weeks (Onno et al. 1989; VanCott et al. 1993; Wesley et al. 1990). There is no evidence for the fecal–oral transmission of PRCV. PRCV persists in closed breeding farms by regularly infecting newly weaned pigs, even in the presence of maternal antibodies (Pensaert et al. 1993). PRCV can persist in the herd throughout the year, or it can disappear in summer and reappear in the nursery and fattening units in winter. Coincident with the widespread dissemination of PRCV, the seroprevalence of TGEV in Europe has decreased, to a low prevalence (Brown and Paton 1991; Pensaert et al. 1993).

Transmission and reservoirs

An epidemiological feature of TGE is its seasonal appearance during winter. Haelterman (1962) suggested that this is because the virus is stable when frozen and more labile when exposed to heat or to sunlight. This would allow virus transmission between herds in winter on fomites or animals. He proposed at least three possible reservoirs for TGEV between seasonal epidemics: (1) pig farms in which the virus spreads subclinically, (2) hosts other than swine, and (3) carrier pigs. There is evidence for the existence of TGEV in non-porcine hosts. Cats, dogs, and foxes have been suggested as possible carriers of TGEV from one herd to another, since they can shed virus in their feces for variable periods (Haelterman 1962; McClurkin et al. 1970) and virus excreted by dogs was infectious for pigs (Haelterman 1962; Reynolds and Garwes 1979).

The concentration of starlings (*Sturnus vulgaris*) in winter in feeding areas of swine may foster mechanical spread of TGEV among farms. Pilchard (1965) reported that TGEV was detected in the droppings of starlings for up to 32 hours after feeding TGEV. Houseflies (*Musca domestica*) have also been proposed as possible mechanical vectors for TGEV. TGEV antigen was detected in flies within a swine herd, and experimentally inoculated flies excreted TGEV for 3 days (Gough and Jorgenson 1983). According to surveys conducted in Central Europe, antibodies against TGEV are also present in approximately 30% of the feral pig population (Sedlak et al. 2008).

The third possibility relating to TGE transmission is the duration of TGEV shedding and the role of the carrier pig. Nasal shedding of PRCV in experimentally infected pigs occurs through 10 days post infection (DPI) (Onno et al. 1989; Wesley et al. 1990). However, how long pigs clinically recovered from TGEV and PRCV infection in the field remain infectious is unknown. One report indicated chronic and/or persistent TGEV fecal shedding for up to 18 months, suggesting a possible role for the long-term carrier hog in transmitting TGEV (Woods and Wesley 1998). Although TGEV has been detected in the intestinal and respiratory tracts for periods of up to 104 DPI (Underdahl et al. 1975), it is unknown whether infectious virus is shed or transmitted. Addition of sentinel pigs to a herd at 3, 4, and 5 months after a previous TGE outbreak resulted in no infections in the introduced pigs, as determined by serologic tests (Derbyshire et al. 1969).

Pathogenesis

Intestinal and extraintestinal replication of TGEV

Jejunal enterocytes undergo massive necrosis within 12–24 hours after infection, resulting in marked reduction in enzymatic activity (alkaline phosphatase, lactase, etc.) in the small intestine. This disrupts digestion and cellular transport of nutrients and electrolytes (including sodium), thereby causing an accumulation of liquid in the intestinal lumen and acute malabsorptive diarrhea (Moon 1978) that leads to severe and fatal dehydration in piglets (Butler et al. 1974) and loss of extravascular protein. Dehydration is also related to metabolic acidosis coupled with abnormal cardiac function due to hyperkalemia.

The severe villous atrophy in the jejunum (Figure 31.5a and b) and to a lesser extent in the ileum of TGEV-infected pigs is often absent in the proximal duodenum (Hooper and Haelterman 1966a). Villous atrophy is more

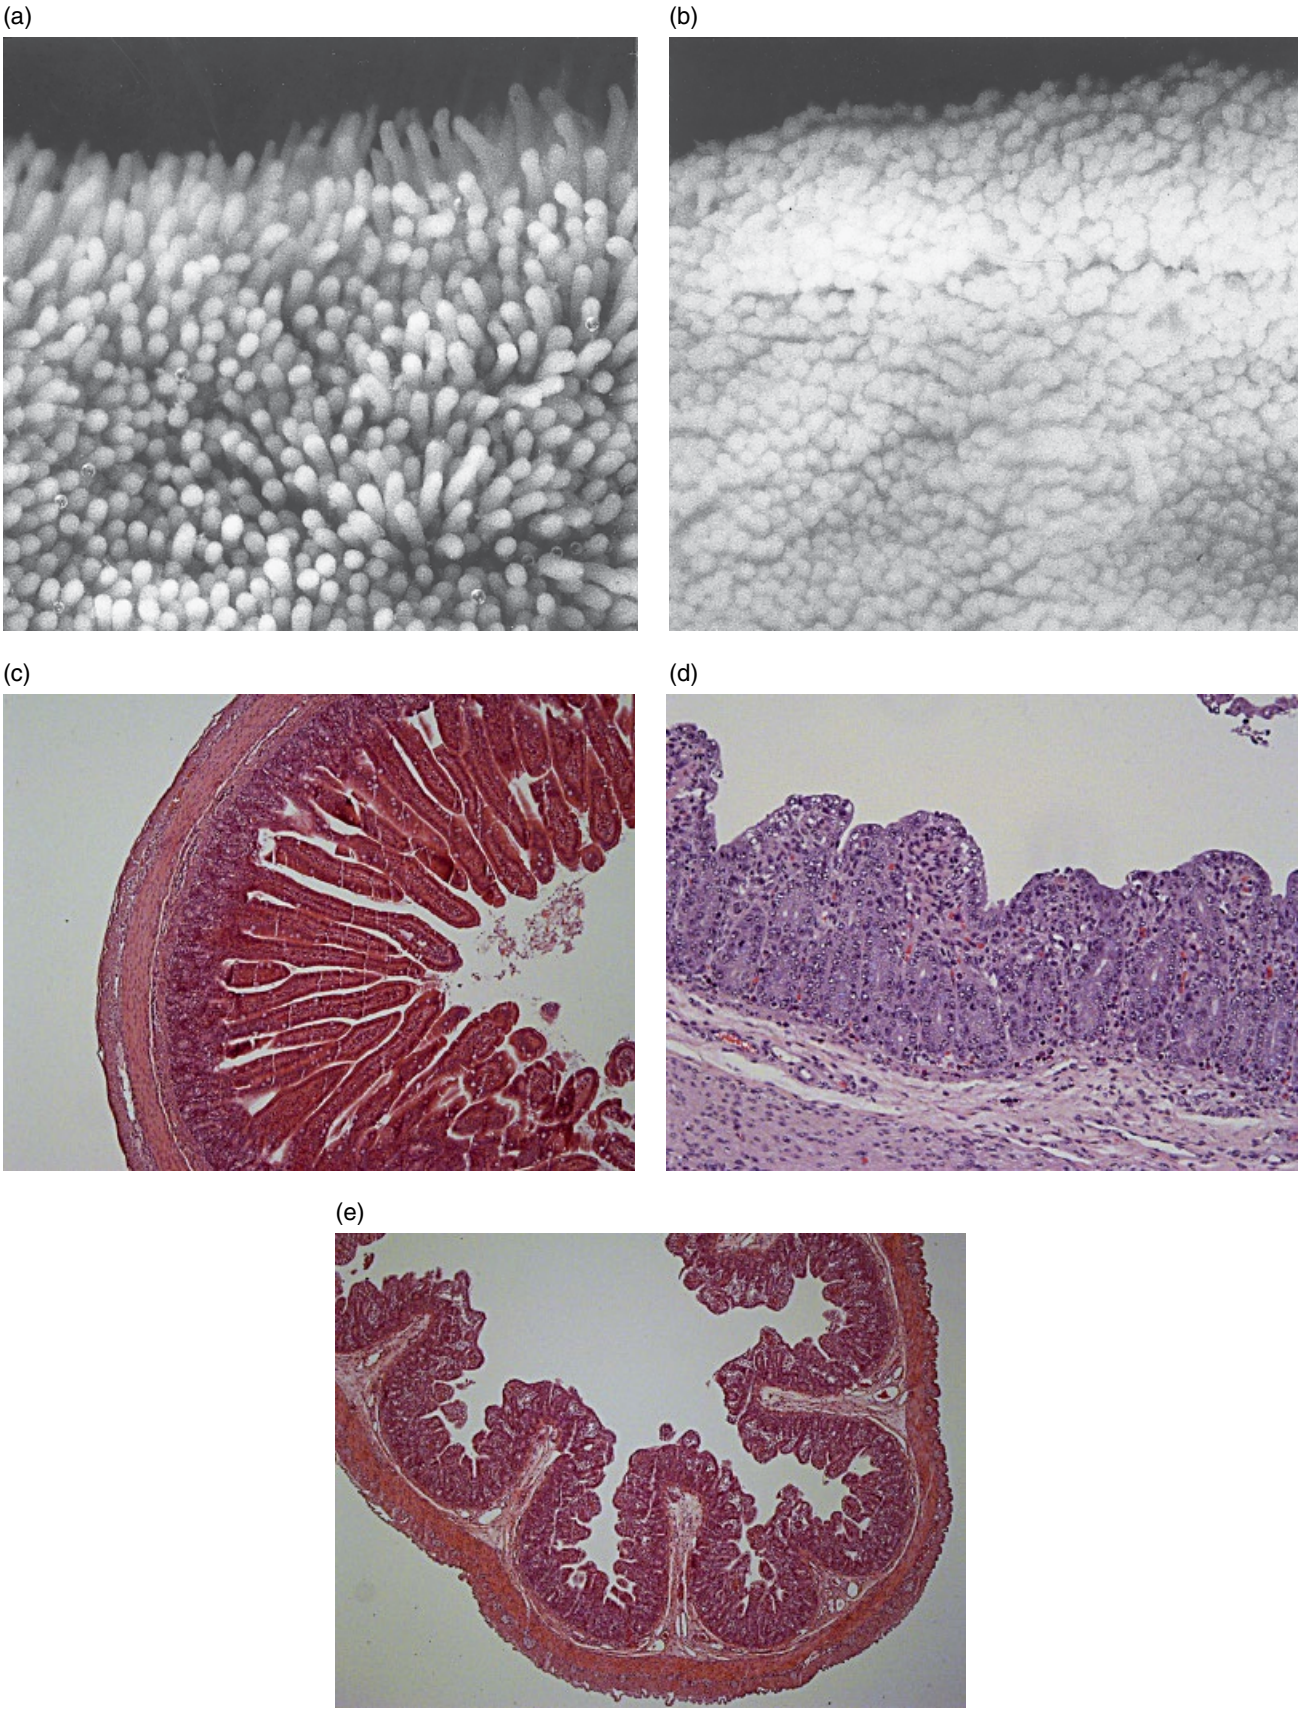

Figure 31.5 Villi of the jejunum from a normal pig (a) and from a TGEV-infected pig (b), as viewed through a dissecting microscope (approximately ×10). Hematoxylin and eosin (H&E)-stained jejunum of a normal gnotobiotic pig (17 days of age), showing normal villi (×80) (c) (*Source:* Jung et al. 2015b); of a PEDV-infected gnotobiotic pig (26 days of age) at 46 hours post inoculation (at onset of clinical signs), showing acute diffuse, severe atrophic jejunitis (×200) (d) (*Source:* Jung et al. 2014); and of a PDCoV-infected gnotobiotic pig (17 days of age) at 3 days post inoculation (×40) (e) (*Source:* Jung et al. 2015b).

severe in newborn pigs than in 3-week-old pigs (Moon 1978), suggesting higher susceptibility of neonates to TGEV infection. A similar degree and distribution of small intestinal villous atrophy is also evident for PEDV (Figure 31.5c and d) and PDCoV (Figure 31.5c and e).

Mechanisms to account for age-dependent susceptibility to clinical disease include the slower replacement in newborn pigs of infected villous epithelial cells by migration of cells from crypts (Moon 1978). These newly replaced villous enterocytes are reportedly resistant to TGEV infection, possibly due to induction of innate immunity and intestinal IFN (Abou-Youssef and Ristic 1972) or the inability of the regenerating cells to support virus growth.

The exposure dose of infectious virus plays a major role in age-dependent susceptibility. The infectious dose of TGEV needed to infect a 6-month-old market hog was 10^4 times greater than that needed to infect a 2-day-old piglet (Witte and Walther 1976). Moreover, the severity of clinical signs due to TGEV increased when pigs were injected with a synthetic corticosteroid, dexamethasone (Shimizu and Shimizu 1979), similar to dexamethasone-aggravated lung pathology in PRCV infection (Jung et al. 2007; Zhang et al. 2008), indicating the possible effect of stress on TGEV/PRCV disease severity. In addition, TGEV in combination with other enteric pathogens, such as *E. coli* or porcine rotavirus, caused more severe enteritis than either infection alone (Underdahl et al. 1972). Likewise, PRCV respiratory infection and lung lesions were exacerbated by preexisting porcine reproductive and respiratory syndrome virus (PRRSV) infection (Jung et al. 2009; van Reeth et al. 1996).

Extraintestinal sites for TGEV replication include lungs (alveolar macrophages) and mammary tissues (Kemeny et al. 1975). Oronasal infection of pigs with TGEV caused pneumonia (Underdahl et al. 1975). Cell culture-attenuated but not virulent TGEV replicated in cultures of alveolar macrophages *in vitro*, suggesting a possible role for these cells in lung infection (Laude et al. 1984). Moreover, TGEV was detected in nasal secretions of infected piglets (VanCott et al. 1993) and lactating sows exposed to infected piglets (Kemeny et al. 1975). Cell-cultured strains of TGEV generally showed reduced virulence in pigs, with less replication in the gut and higher levels of replication in the upper respiratory tract compared with virulent TGEV (Frederick et al. 1976; VanCott et al. 1993).

TGEV replicated in mammary tissues of lactating sows (Saif and Bohl 1983) and infected sows shed virus in milk (Kemeny and Woods 1977). The clinical or epidemiological significance of mammary gland infection with TGEV under field conditions is unclear, but agalactia is often seen in TGEV-infected sows and TGEV spreads rapidly among pigs.

Replication of PRCV in the respiratory tract

PRCV has a tropism for the respiratory tract. It replicates to high titers in porcine lungs (1×10^7–10^8 $TCID_{50}$) in type 1 and 2 pneumocytes and infects epithelial cells of the nares, trachea, bronchi, bronchioles, alveoli, and, occasionally, alveolar macrophages (Atanasova et al. 2008; Jung et al. 2007, 2009; O'Toole et al. 1989; Pensaert et al. 1986). PRCV induces necrosis of infected cells, increasing innate immune responses at the infection sites, including high levels of IFN-α and nitric oxide in lungs (Jung et al. 2009, 2010). Innate cytokines inhibit initial viral replication and modulate Th1/Th2 responses with the latter enhancing B-cell responses, leading to secretion of VN antibodies.

Virus shedding in nasal secretions lasted for 4–6 days after experimental PRCV infection. The severity of PRCV-induced pneumonia and viral replication in lung peaked at 8–10 DPI, coinciding with increased numbers of T and B cells and frequency of lymphocytic inflammation. Thereafter, pulmonary lesions and clinical signs resolved concurrently with increased VN antibody titers (Atanasova et al. 2008; Jung et al. 2009).

Depending on the experimental conditions and the virus strains used, PRCV may be detected in blood, tracheobronchial lymph nodes, and occasionally the small intestines of infected pigs. However, virus in infected enterocytes does not spread to adjacent cells (Cox et al. 1990a,b), and fecal shedding is low or undetectable. The limited intestinal replication of PRCV may be related to the deletion in the S gene. When fecal and nasal isolates of PRCV from the same pigs were compared genetically, only point mutations, but not additional deletions, were noted in the S gene (Costantini et al. 2004).

Clinical signs

Epidemic TGE

Typical clinical signs of TGE in seronegative piglets are vomiting and profuse watery, yellowish diarrhea, with rapid loss of weight, dehydration, and high morbidity and mortality in pigs under 2 weeks of age. The severity of clinical signs, duration of disease, and mortality are inversely related to the age of the pig. Most pigs under 7 days of age will die in 2–7 days after onset of clinical signs. Most suckling pigs over 3 weeks of age will survive, but may remain stunted. Clinical signs of TGE in finishing swine and in sows include inappetence, transient diarrhea, and vomiting.

The incubation period is short, usually 18 hours to 3 days. Infection generally spreads rapidly through the entire group, and most swine are affected in 2–3 days, but this is more likely to occur in winter than summer (Haelterman 1962).

Endemic TGE

Endemic TGE occurs in large herds that farrow frequently and in TGEV or PRCV seropositive herds. Clinical signs are usually less severe than those in seronegative pigs of the same age. Mortality is low, especially if pigs are kept warm. The clinical signs in suckling pigs can resemble rotavirus, PEDV, or PDCoV diarrhea (Bohl et al. 1978; Pensaert and de Bouck 1978; Wang et al. 2014a). In some herds, endemic TGE is manifested primarily in weaned pigs and may be confused with PEDV (Madson et al. 2014), *E. coli*, coccidia, or rotavirus infections (Pritchard 1987).

Porcine respiratory coronavirus

Experimentally, PRCV infection of pigs is mostly subclinical with self-limiting respiratory infection. The early antiviral effects of innate immune responses to PRCV infection, followed by cell-mediated and antibody responses, likely effectively control the infection (Atanasova et al. 2008; Jung et al. 2007, 2009, 2010; Zhang et al. 2008). Clinical signs include (1) respiratory signs (e.g. coughing, abdominal breathing, dyspnea), (2) depression and/or anorexia, and (3) slightly decreased growth rates (Lanza et al. 1992; van Reeth et al. 1996; Wesley and Woods 1996).

The severity and frequency of clinical signs are influenced by the presence of other bacterial or viral pathogens in the herd. For example, coinfection with PRRSV can alter the severity of either PRCV or PRRSV infections. Inoculation with PRRSV followed by PRCV resulted in prolonged fever with respiratory disease, reduced weight gain, and prolonged severe pneumonia (Jung et al. 2009; van Reeth et al. 1996). Ongoing or preexisting PRRSV infection significantly suppressed innate immune responses (reduced IFN-α levels in lung and blood natural killer [NK] cell cytotoxicity) during early PRCV infection, which may exacerbate PRCV pneumonia (Jung et al. 2009).

TGEV lesions

TGE gross lesions are confined to the gastrointestinal tract. The stomach is distended with curdled milk and may have petechial hemorrhages (Hooper and Haelterman 1966b). The small intestine is distended with yellow fluid and curdled, undigested milk. The wall is thin and transparent, due to villous atrophy. A major lesion of TGE is markedly shortened villi of the jejunum and ileum (Figure 31.5a and b), similar to PEDV and PDCoV lesions (Figure 31.5c–e) (Debouck et al. 1981; Jung et al. 2015b), but usually more severe and extensive than that seen in rotavirus diarrhea (Bohl et al. 1978). Infections with some strains of *E. coli* and coccidia may produce similar lesions (Hornich et al. 1977). Transmission EM of TGEV-infected villous enterocytes has revealed alterations in the microvilli, mitochondria, endoplasmic reticulum, and other cytoplasmic components. Virus particles, primarily in cytoplasmic vacuoles, were observed in villous enterocytes and in M cells, lymphocytes, and macrophages in the dome regions of Peyer's patches (Chu et al. 1982; Thake 1968).

Pathologic findings and the extent of villous atrophy are highly variable in pigs from endemically infected herds (Pritchard 1987). Moxley and Olson (1989) showed that the level of passive immunity in TGEV-infected pigs influenced both the degree of villous atrophy and its segmental distribution. Villous atrophy was minimal in pigs nursing sows previously infected with virulent TGEV, compared with pigs nursing seronegative sows or sows given live attenuated vaccines. In partially protected pigs, villous atrophy was primarily in the ileum and not the jejunum. Similar observations were noted in pigs from herds with endemic TGE.

PRCV lesions

PRCV primarily causes upper and lower respiratory tract disease. The PRCV-induced lesions are generally limited to the lungs and commonly observed as consolidation of the lung and bronchointerstitial pneumonia, with frequent peribronchiolar and perivascular lymphohistiocytic cuffing (Atanasova et al. 2008; Cox et al. 1990a; Halbur et al. 1993; Jabrane et al. 1994; Jung et al. 2007, 2009). PRCV-induced bronchointerstitial pneumonia is characterized by (1) thickening of the alveolar septa by infiltration of inflammatory leucocytes, principally macrophages and lymphocytes; (2) type 2 pneumocyte hypertrophy and hyperplasia; (3) accumulation of necrotic cells and inflammatory leucocytes in alveolar and bronchiolar lumina due to airway epithelial necrosis; and (4) peribronchiolar or perivascular lymphohistiocytic inflammation. Within 10 days of PRCV infection, the virus simultaneously induces inflammatory (cell necrotizing) and proliferative (alveolar septal thickening) chronic-active bronchointerstitial pneumonia (Jung et al. 2007, 2009).

Diagnosis

The collection and preservation of appropriate clinical specimens is necessary for reliable diagnosis. Because clinical signs and atrophic enteritis caused by TGEV are frequently observed in other enteric infections (rotavirus, PEDV, PDCoV, and coccidia), laboratory diagnosis of TGE must be accomplished by one or more of the following procedures: detection of viral antigen or nucleic acids in feces or lesions, virus isolation from specimens, or detection of TGEV antibodies.

Diagnosis of PRCV requires similar procedures, but with a focus on respiratory specimens. Evaluation of

clinical signs, histologic lesions, and tissue distribution of viral antigen may provide a presumptive diagnosis. PRCV does not cause diarrhea or villous atrophy and replicates almost exclusively in respiratory tissues (Pensaert 1989). Thus, PRCV is suspected if there is antigen in lung tissues, seroconversion to TGEV/PRCV, and no signs of enteric disease.

Detection of viral antigens or nucleic acids

Detection of TGEV antigen in small intestinal enterocytes is commonly used to diagnose TGE. Either IF (Pensaert et al. 1970) or immunohistochemical (IHC) (Shoup et al. 1996) techniques using MAb against the highly conserved N protein of TGEV may be used in frozen or formalin-fixed tissues (Figure 31.6a), but they require pigs in the early stage of infection. A similar viral antigen distribution is seen in the small intestine of PEDV- (Figure 31.6b) and PDCoV-infected pigs (Figure 31.6c). An exception for PEDV and PDCoV is the occasional detection of viral antigens in the crypt epithelial cells and the colon.

An enzyme-linked immunosorbent assay (ELISA) using MAb or polyclonal antibodies to TGEV is used to detect TGEV antigens in cell culture, feces, and intestinal contents (Lanza et al. 1995; Sestak et al. 1996, 1999a; van Nieuwstadt et al. 1988) or PRCV antigen in cell culture, nasal swabs, or lung homogenates (Lanza et al. 1995).

RT-PCR or real-time RT-PCR is currently used for diagnosis of TGEV and differentiation of TGEV, PRCV, PDCoV, and PEDV (Costantini et al. 2004; Kim et al.

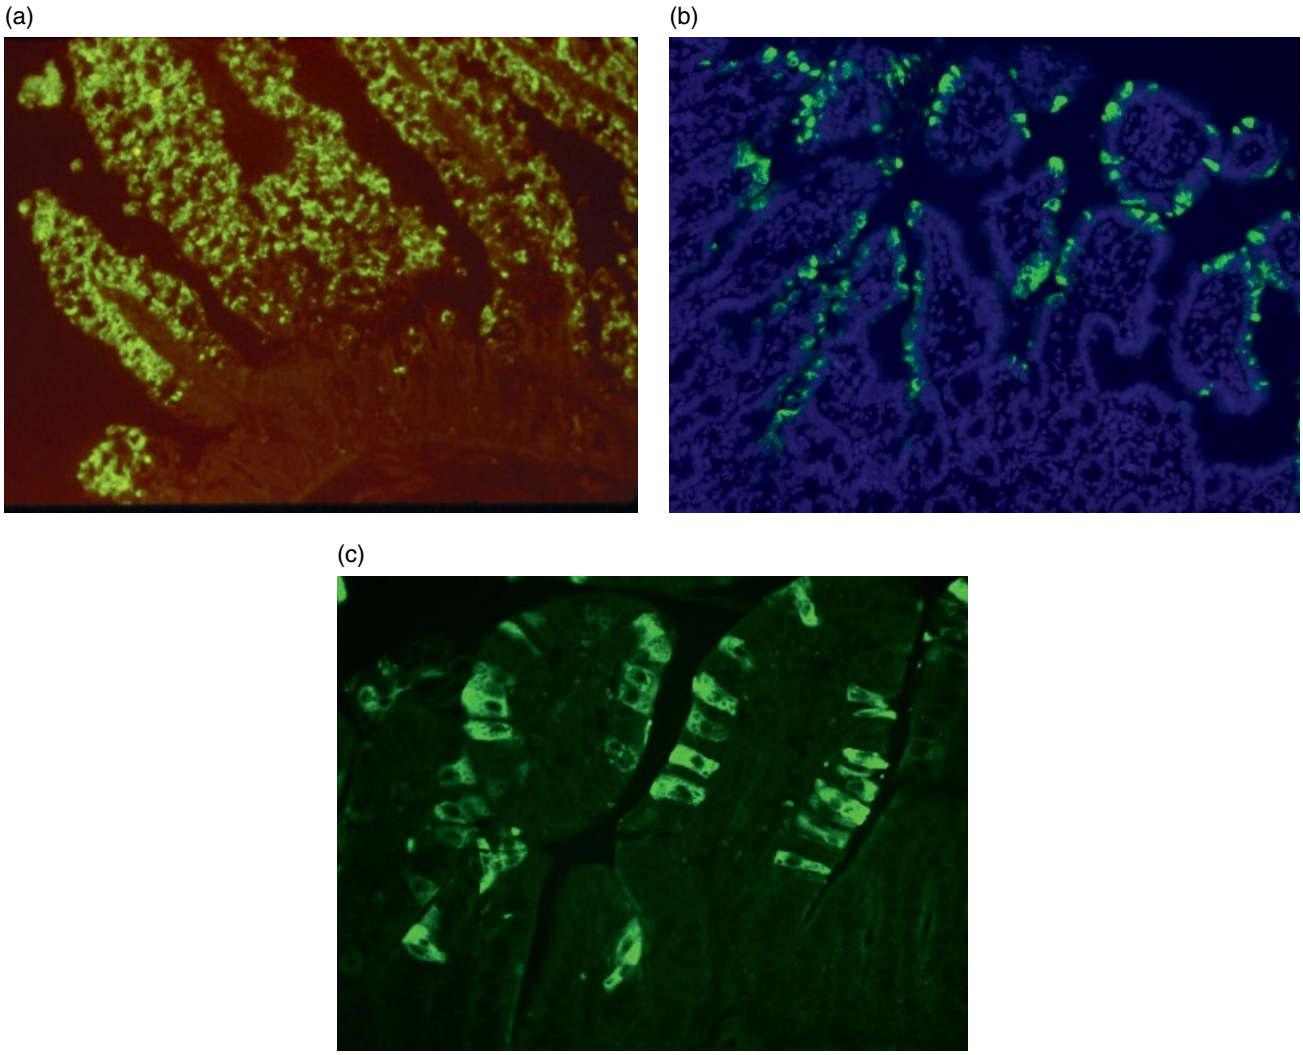

Figure 31.6 Immunofluorescent staining (green) of (a) TGEV antigens in almost 100% of the ileal enterocytes lining the villi of a TGEV-infected piglet. Note absence of TGEV antigens in the crypt epithelial cells. (b) PEDV antigens in the enterocytes of the jejunum of a piglet at 67 hours post inoculation with the emerging non-S INDEL PEDV strain PC21A (37–41 hours after onset of clinical signs), indicating that the epithelial cells lining atrophied villi are positive for PEDV (×200). *Source:* Jung et al. 2014. (c) PDCoV antigens in the jejunum of a gnotobiotic pig at 3 days post inoculation with PDCoV strain OH-FD22, showing similar localization of PDCoV antigens in the cytoplasm of villous epithelial cells (×400).

2000a, 2001, 2007; Masuda et al. 2016; Ogawa et al. 2009). PRCV/TGEV differentiation is accomplished using PCR primers targeting the S gene deletion region in PRCV strains. Multiplex RT-PCR and real-time RT-PCR assays have been developed for the simultaneous detection of major porcine viruses associated with diarrhea including rotavirus, TGEV, PDCoV, and PEDV (Masuda et al. 2016; Ogawa et al. 2009). These assays permit detection of up to nine viruses in a sample. Moreover, multiplex microarray hybridization was employed for the rapid differential diagnosis of eight CoVs including TGEV (Chen et al. 2005).

Electron microscopy (EM)

TGEV can be demonstrated in the intestinal contents and feces of infected pigs by negative contrast transmission EM (Figure 31.2a). Immune electron microscopy (IEM) has advantages over conventional EM in being more sensitive for detecting TGEV and distinguishing it from PEDV, PDCoV, and enveloped membranous debris, as well as concurrently detecting the presence of other enteric viruses (Figure 31.2b) (Saif et al. 1977).

Virus isolation

Primary and secondary pig kidney (PK) cells (Bohl and Kumagai 1965) or cell lines (Laude et al. 1981), porcine thyroid cells (Witte 1971), and the McClurkin swine testicle (ST) cell line (McClurkin and Norman 1966) are recommended for the isolation of TGEV from feces or gut contents of infected pigs. Distinct cytopathic effects (CPE) may be negligible upon primary isolation of field strains, requiring additional passages. The CPE consists of enlarged, rounded cells with a balloon-like appearance (Bohl and Kumagai 1965). For detecting viral CPE or plaques, the sensitivity of ST cells can be further enhanced by adding pancreatin or trypsin to cell culture media (Bohl 1979) and using older cells.

Pig kidney and ST cells are preferred for isolating PRCV from nasal swab fluids or lung tissue homogenates. PRCV- and TGEV-induced CPE are similar, with syncytia frequently observed as also reported for PEDV and SARS CoV grown in Vero cells (Hofmann and Wyler 1988; Ksiazek et al. 2003). Identification of cell culture virus can be done by VN, IF staining, or IEM using specific TGEV antiserum or differential MAbs (Garwes et al. 1988) and RT-PCR using virus-specific primers (Enjuanes and Van der Zeijst 1995; Kim et al. 2000a; Laude et al. 1993).

Serology

TGEV antibodies can be detected by several serologic tests. However, TGEV serology is complicated by the fact that both TGEV and PRCV induce VN antibodies that are qualitatively and quantitatively similar (Pensaert 1989). A blocking ELISA test can differentiate between these antibodies based on using MAbs to TGEV antigenic sites that are absent on the PRCV S protein (Bernard et al. 1989; Callebaut et al. 1989; Delmas and Laude 1990; Garwes et al. 1988; Sanchez et al. 1990; Sestak et al. 1999b; Simkins et al. 1992, 1993). Blocking ELISAs should only be applied on a herd basis because some pigs with low TGEV or PRCV antibody titers may not be detected (Callebaut et al. 1989; Sestak et al. 1999b; Simkins et al. 1993) and the accuracy of commercial ELISAs for differentiating US strains of PRCV and TGEV is low (Sestak et al. 1999b). ELISA tests were used to differentiate not only between TGEV and PRCV antibodies but also between TGEV and TGEV-like CCoVs or classical CCoV-II antibodies (Elia et al. 2010; Lopez et al. 2009).

A rise in antibody titer between acute and convalescent serum samples provides retrospective evidence for TGEV or PRCV infection. To determine the presence of endemic TGE or PRCV, serum samples from 2- to 6-month-old swine (often free of passively acquired antibodies at this age) can be tested for antibodies (Derbyshire et al. 1969). The VN test using cell culture-adapted viruses has been the most widely used (Bohl 1979; Bohl and Kumagai 1965). VN antibodies to TGEV are detectable in serum by 7–8 DPI and persist for at least 18 months. Little is known regarding the persistence of VN antibodies to PRCV within a herd. Antibody ELISA tests (Bernard et al. 1989; Berthon et al. 1990; Callebaut et al. 1989; Garwes et al. 1988; Sestak et al. 1999a, b; van Nieuwstadt et al. 1989) have been reported, but they require concentrated purified virus or S or N protein for coating ELISA plates.

Immunity

Active immunity to TGEV

The duration of active immunity in swine after oral infection with virulent TGEV has not been well characterized. Intestinal infection of breeding-age swine results in detectable serum antibodies that persist for at least 6 months and possibly several years (Stepanek et al. 1979). Although serum antibodies provide serologic evidence of TGEV or PRCV infection, they afford little indication of the degree of active immunity to TGEV. Swine that have recovered from TGE are immune to subsequent short-term challenge, presumably due to local immunity within the intestinal mucosa (Brim et al. 1995; Saif et al. 1994; VanCott et al. 1993, 1994). The age and immune status of the animal at initial infection and the severity of the challenge influence the completeness and duration of active immunity.

The mechanism of active immunity in the gut relates to stimulation of the secretory IgA (sIgA) immune system with production of sIgA antibodies by intestinal plasma cells (Saif et al. 1994; VanCott et al. 1993, 1994). IgA TGEV antibodies and antibody-secreting cells (ASCs)

have been detected in the intestine and serum of pigs after oral, but not parenteral inoculation with TGEV (Kodama et al. 1980; Saif et al. 1994; VanCott et al. 1993, 1994). Kodama et al. (1980) proposed that detection of IgA antibody in the serum, presumably intestinally derived, might serve as an indicator of active immunity to TGE. Enzyme-linked immunospot (ELISPOT) assay was used to investigate the kinetics of IgA and IgG TGEV antibody production by the pig's systemic and local gut-associated lymphoid tissues (GALT). High numbers of IgA ASCs were induced in GALT only by virulent TGEV. In contrast, live attenuated (vaccine) TGEV or PRCV strains induced significantly fewer IgA ASCs (Berthon et al. 1990; Saif et al. 1994; VanCott et al. 1993, 1994). Besides local antibody-mediated immunity, cell-mediated immunity (CMI) may also be important in active immunity against TGEV infections. However, only indirect evidence exists concerning the role of CMI in resistance to TGEV infection. CMI was demonstrated with lymphocytes obtained from GALT of swine orally infected with virulent TGEV (Brim et al. 1995; Frederick et al. 1976; Shimizu and Shimizu 1979), whereas swine parenterally or oronasally inoculated with attenuated TGEV or PRCV developed CMI mainly in systemic sites. Lymphoproliferative responses to TGEV persisted within GALT, but not systemic lymphocytes, for at least 110 days after oral infection of 6-month-old swine (Shimizu and Shimizu 1979), but for only about 14–21 days after infection of younger (7- to 11-day-old) pigs (Brim et al. 1995). CD4 T helper cells are involved in lymphoproliferative responses to TGEV (Anton et al. 1995). Potent production of antiviral IFN-α by plasmacytoid dendritic cells (DCs) derived from TGEV-infected swine was observed upon stimulation of these cells *in vitro* with TGEV antigens (Calzada-Nova et al. 2010).

A correlation between lymphoproliferative responses and lactogenic immunity to TGEV was described in sows vaccinated with attenuated or recombinant TGEV vaccines (Park et al. 1998). Although T-cell epitopes were identified by lymphoproliferation studies for each of the three major proteins of TGEV, a dominant functional T helper epitope was defined on the N protein (N321) (Anton et al. 1995). The N321 peptide-induced T cells collaborated in the *in vitro* synthesis of TGEV VN antibodies specific for the S protein. Maximal responses were induced by native S protein combined with recombinant N protein. Such findings have important implications for design of CoV subunit or other recombinant CoV vaccines.

Because lymphocyte cytotoxicity was absent in newborn piglets and decreased in parturient sows, it was proposed that a lack of NK cell activity against TGEV-infected cells might correlate with the increased susceptibility of newborn piglets and parturient sows to TGEV infection (Cepica and Derbyshire 1984). Thus, CMI or innate immunity may play a role in either recovery from TGEV infection or resistance to reinfection via the rapid elimination of TGEV-infected epithelial cells. Some TGEV strains can also downregulate host immune responses. A virulent (SHXB) but not attenuated (STC3) TGEV strain impaired the ability of porcine intestinal DCs or monocyte-derived DCs to recognize antigen, migrate, and induce T-cell proliferation *in vivo* and *in vitro* (Zhao et al. 2014).

PRCV-induced active immunity to TGEV

The dramatic decline in epidemic outbreaks of TGE in Europe following the widespread dissemination of PRCV prompted researchers to examine if respiratory PRCV infection could induce protective intestinal immunity against TGEV. The consensus from several studies was that prior infection of nursing or weaned pigs with PRCV provided partial immunity against TGEV challenge, as evidenced by a reduced duration and level of virus shedding and diarrhea in most pigs studied (Brim et al. 1995; Cox et al. 1993; VanCott et al. 1994; Wesley and Woods 1996).

This partial immunity presumably is related to the rapid increase in TGEV VN antibodies (Cox et al. 1993; Wesley and Woods 1996) and numbers of IgG and IgA ASCs in the intestines of PRCV-exposed pigs after TGEV challenge (Saif et al. 1994; VanCott et al. 1994). The altered tissue tropism of PRCV was also linked to a shift in antibody responses; that is, in TGEV-infected pigs, more IgA ASCs were found in gut, whereas PRCV predominantly induced IgG ASCs in the lung (VanCott et al. 1994). Migration of PRCV IgG and IgA ASCs from the bronchus-associated lymphoid tissues (BALT) to the gut of the PRCV-exposed pigs after TGEV challenge might explain the rapid anamnestic response and the partial protection induced (VanCott et al. 1994). However, neonatal pigs required at least 6–8 days after PRCV exposure to develop partial immunity to TGEV challenge (Wesley and Woods 1996).

Passive immunity to TGEV

Passive lactogenic immunity is critical to provide newborn piglets with immediate protection against TGEV infection. Circulating passive antibodies, acquired after absorption of colostral immunoglobulin (primarily IgG), protect the neonate against systemic but generally not intestinal infection (Hooper and Haelterman 1966a; Saif and Sestak 2006). Mechanisms of passive immunity to TGEV infections have been reviewed (Chattha et al. 2015; Saif and Bohl 1979; Saif and Jackwood 1990; Saif and Sestak 2006). Swine recovered from TGE transmit passive immunity to their suckling pigs by the frequent ingestion of colostrum or milk (lactogenic immunity) that contains TGEV VN antibodies (Hooper and Haelterman 1966a). Such antibodies in the lumen of the

intestine neutralize the ingested TGEV and protect the susceptible small intestinal enterocytes. This is accomplished naturally when piglets suckle immune sows frequently or by continuous feeding of antiserum to piglets. During the first week of lactation, IgA becomes dominant in milk and IgG decreases.

TGEV IgA antibodies in milk are stable in the gut and provide the most effective protection, but IgG antibodies are also protective if high titers are maintained in milk after vaccination (Bohl and Saif 1975) or by artificial feeding of colostral IgG antibodies (Stone et al. 1977). TGEV IgG antibodies are produced in the sow's milk after parenteral or systemic immunization, whereas TGEV IgA antibodies occur in milk after intestinal infection. It is postulated that IgA immunocytes migrate to the mammary gland after antigenic stimulation in the gut where they localize and secrete IgA antibodies into colostrum and milk that play a key role in passive intestinal immunity of suckling pigs (Bohl and Saif 1975; Saif and Bohl 1979; Saif and Jackwood 1990; Saif and Sestak 2006). The "gut–mammary" immunologic axis, first proposed in relation to TGEV infections in swine (Bohl et al. 1972; Saif et al. 1972), provided the initial concept for a common mucosal immune system. This concept continues to be important in the design of maternal vaccines that are capable of providing effective lactogenic immunity against enteric pathogens.

PRCV-induced passive immunity to TGEV

The incidence and severity of TGE in countries with PRCV has declined since PRCV has become widespread (Schwegmann-Wessels and Herrler 2006). This suggests that prior exposure of swine to PRCV imparts partial immunity to TGEV (Laude et al. 1993; Pensaert 1989).

Prior natural exposure of sows to PRCV induced a variable degree of passive protection (44–53% mortality) against experimental TGEV challenge of suckling pigs (Bernard et al. 1989; Paton and Brown 1990). Variable protection in the field during TGE outbreaks was also noted among litters of PRCV-exposed sows (Pensaert 1989; Sanchez et al. 1990). Similar variable levels of protection (30–67% mortality) were reported after TGEV challenge of piglets suckling sows that had been experimentally infected or reinfected with PRCV during pregnancy (De Diego et al. 1992; Lanza et al. 1995; Sanchez et al. 1990; Sestak et al. 1996; Wesley and Woods 1993). In the latter two studies, litter mortality was lowest (range = 0–27%), and IgA and IgG milk antibody titers were highest in sows multiply exposed to PRCV during two subsequent pregnancies. These experimental findings agreed with field reports that naturally PRCV-exposed sows reinfected with PRCV during pregnancy secreted PRCV IgA antibodies in milk and provided a high degree of protection (0–12.5% mortality) to TGEV challenge (Sanchez et al. 1990). Besides PRCV IgA antibodies in milk, a hallmark of protection in these and other studies (Wesley and Woods 1993) was induction of active immunity to TGEV in the sow preventing clinical disease or agalactia.

Besides quantitative differences in the levels of IgA antibodies induced in milk of sows after exposure to TGEV or PRCV, researchers have investigated potential differences in virus epitopes recognized by the milk IgA antibodies (De Diego et al. 1992, 1994). In TGEV-infected sows, antigenic subsite A (Aa, Ab, Ac), followed by antigenic subsite D, was the best inducer of IgA antibodies, while after PRCV infection, antigenic site D and subsite Ab were immunodominant (Figure 31.3). Thus, only IgA recognizing at least antigenic sites A and D conferred protection *in vivo*, whereas any immunoglobulin isotype reactive to one antigenic site neutralized virus *in vitro*.

Prevention and control

Treatment

No antiviral drugs have been developed for treatment of TGE. After the discovery of SARS CoV, studies were conducted with various surrogate viruses, including TGEV, to develop anti-CoV agents. Ortego et al. (2007) used TGEV deletion mutants to show that absence of the E protein blocks virus trafficking in the endoplasmic reticulum and prevents virus maturation. RNA interference (RNAi) targeting the viral RNA polymerase was studied *in vitro* as a strategy to prevent TGEV infection (Zhou et al. 2007). Although protective *in vitro*, the results of analogous *in vivo* experiments were less convincing (Zhou et al. 2010).

Studies suggest that IFN may activate NK cells in newborn pigs, contributing to resistance to challenge with TGEV (Lesnick and Derbyshire 1988; Loewen and Derbyshire 1988). In addition, during a field outbreak of TGE, 1- to 12-day-old piglets treated orally for 4 days with 1–20 IU of human IFN-α had significantly greater survival rates than placebo-treated piglets (Cummins et al. 1995).

The only available treatment for TGE is to alleviate starvation, dehydration, and acidosis. Parenteral treatment with fluids, electrolytes, and nutrients are effective in treating young pigs, but not practical under farm conditions. Oral therapy with balanced electrolyte or glucose solutions is contraindicated in young pigs (Moon 1978). The following measures are suggested: provide a warm (above 32 °C [90 °F]), draft-free, dry environment and provide water or nutrient solutions freely to TGEV-infected pigs. Such measures reduced mortality in pigs that were infected at more than 3–4 days of age. Antibacterial therapy is beneficial in 2- to 5-week-old pigs if there is concurrent infection with bacterial pathogens. Cross-fostering of infected or susceptible litters

onto TGE-immune sows was useful in some field outbreaks (Stepanek et al. 1979).

Management

Biosecurity

Swine in the incubative or viral shedding stage of the disease or possibly carriers can transmit TGEV. To introduce swine into a herd, precautions are needed to assure that swine originate from herds free of TGE, are serologically negative, and/or have been placed in isolation on the farm for 2–4 weeks before being added to the herd. After a TGE outbreak, at least 4 weeks should elapse from the last sign of disease before introducing such animals into a "clean" herd. Feces from TGEV-infected swine can be carried on boots, shoes, clothing, truck beds, feeds, and so on and can be a source of infection to other herds, requiring strict disinfection regimes, especially in winter.

After onset of TGE and endemic TGEV

When TGE occurs on a farm and pregnant animals have not yet been exposed, two procedures may minimize losses of newborn pigs: (1) If the sows are due to farrow in at least 2 weeks, use feedback methods to orally expose them to virulent autogenous virus, such as a slurry of minced intestines of acutely infected pigs, so that they will be immune at farrowing. (2) If the sows will farrow in under 2 weeks, attempt to provide facilities and management procedures to avoid exposure to TGEV until at least 3 weeks post farrowing.

Some success has been achieved in elimination of TGEV from epidemically infected closed breeder herds without depopulation by the following procedures (Harris et al. 1987): (1) bring in breeding stock replacements for the next 4–6 months; (2) in the face of an outbreak, feedback TGEV acutely infected minced piglet intestines simultaneously to all pigs in the herd (including replacement stock) to eliminate susceptible hosts, shorten the time the disease progresses through the herd, and ensure more uniform exposure levels in all pigs; (3) maintain strict all-in/all-out production in farrowing and nursery units; and (4) add sentinel seronegative pigs about 2 months after clinical signs of TGE disappear and monitor these pigs for seroconversion to TGEV. Potential hazards associated with feedback control of TGE include possible spread of other pathogens to pregnant sows and throughout the herd.

Other approaches to control or terminate endemic TGE include the following. First, pregnant seropositive sows can be vaccinated intramuscularly late in gestation or shortly after farrowing with live attenuated TGEV vaccine to boost immunity, increase milk antibody levels, and maintain longer passive immunity in suckling pigs (Saif and Sestak 2006; Stepanek et al. 1979). Although this procedure may only delay onset of TGE in exposed pigs, the delay itself can reduce mortality. Second, break the cycle of infection by eliminating reservoirs of susceptible pigs in a unit: prevent the continual influx of susceptible animals into the herd temporarily (alter farrowing schedule as possible), utilize other facilities, and create smaller farrowing and nursing units to achieve an all-in/all-out system.

Immunoprophylaxis

Vaccines and vaccinations

There are several licensed TGEV vaccines. All contain inactivated or live attenuated TGEV and are approved for use in pregnant or neonatal swine. These vaccines and their efficacy have been reviewed (Saif and Sestak 2006) but will be briefly summarized.

Many variables complicate the evaluation of both experimental and commercial TGEV vaccines, resulting in conflicting data. These include the challenge dose and strain of TGEV, the age of the pig at challenge, environmental conditions (especially temperature), the health status and milking efficiency of the vaccinated sow, and the immune status (for TGEV or PRCV antibodies) of the dam at vaccination. If previously infected sows were unknowingly used in vaccine challenge studies, this could account for discrepant results seen in immune responses and piglet protection. This possibility can only be eliminated by using sensitive tests (such as VN) to measure TGEV/PRCV antibodies and by knowing the herd history of test animals since occurrence of PRCV in herds further complicates TGEV vaccine studies.

TGE vaccination of the seronegative pregnant dam

A variety of viral vaccines (virulent, attenuated, inactivated, and subunit) and routes of administration (oral, intranasal, intramuscular, subcutaneous, and intramammary) (Bohl and Saif 1975; Moxley and Olson 1989; Saif and Bohl 1979; Saif and Jackwood 1990; Saif and Sestak 2006) have been tested for induction of lactogenic immunity. Only oral administration of live virulent virus to pregnant sows consistently stimulated high levels of protective immunity for the sow and persisting TGEV IgA antibodies in milk that passively protected piglets.

The generally poor results for oral or intranasal vaccination of sows using attenuated TGEV strains (Moxley and Olson 1989; Saif and Bohl 1979; Saif and Sestak 2006) may be attributed to the limited replication of most attenuated strains in the sow's intestine (Frederick et al. 1976). This results in little antigenic stimulation of intestinal IgA immunocytes and correspondingly little IgA antibody secretion in milk. Thus, the dilemma is how to develop commercial TGEV vaccines that are capable of stimulating IgA in the gut of sows, but sufficiently attenuated so as not to produce disease in newborn pigs.

Parenteral TGEV vaccines induced even lower or inconsistent protection rates in TGEV/PRCV seronegative swine. They have two major disadvantages: (1) Vaccinated swine develop little or no gut immunity and often get sick when exposed to TGEV, depriving their suckling pigs of milk. (2) The low titer IgG and no IgA TGEV antibodies in milk of vaccinated sows fail to provide optimal passive protection to suckling pigs. Currently available parenterally administered TGEV vaccines may be more effective in boosting immunity in pregnant swine previously infected with TGEV or PRCV than in initiating immunity in seronegative pregnant swine. These vaccines may be especially useful in herds in which endemic TGE is a problem (Stepanek et al. 1979).

TGE vaccination of neonatal or weaned pigs

Active immunization of suckling or feeder pigs could be important for control of endemic infections, especially in newly weaned pigs, in which TGEV infections result in increased mortality. Live attenuated and inactivated TGEV vaccines have been licensed in the United States for oral or intraperitoneal administration, respectively, shortly after birth. However, the presence of maternal antibodies in vaccinated pigs decreased or completely suppressed (Furuuchi et al. 1978; Hess et al. 1982; Lanza et al. 1995; Sestak et al. 1996) active antibody production following oral administration of attenuated TGEV vaccines. Other approaches using recombinant TGEV proteins (reviewed in next section) have been used in attempts to actively immunize young pigs against TGEV.

Recombinant vaccine approaches

Among the major structural proteins of TGEV, the S protein contains immunodominant epitopes recognized by VN antibodies. Epitopes for continuous domains (Delmas and Laude 1990) were incorporated into synthetic peptides derived from the S protein (Posthumus et al. 1991). However, a peptide containing the major T helper cell epitope derived from the N protein has been reported to cooperate with the S protein for *in vitro* induction of TGEV antibody (Anton et al. 1996).

To express the TGEV S (or S epitopes), M, or N proteins, several prokaryotic and eukaryotic systems such as *E. coli*, *Salmonella*, adenovirus, vaccinia virus, pox virus, baculovirus, DNA vectors, and plants were used (Enjuanes et al. 1992; Godet et al. 1991; Gomez et al. 2000; Meng et al. 2013; Park et al. 1998; Shoup et al. 1997; Smerdou et al. 1996; Torres et al. 1996; Tuboly et al. 2000; Yuan et al. 2015). In some studies (Torres et al. 1996), but not others (Gomez et al. 2000; Smerdou et al. 1996; Tuboly et al. 2000), protective antibodies were induced in inoculated animals correlating with partial protection (Park et al. 1998; Shoup et al. 1997). A novel approach to passive immunization was suggested by feeding the recombinant immunoproteins capable of inducing TGEV VN antibodies to sows to confer passive immunity to piglets (Bestagno et al. 2007). The approach may be cost effective by expressing these proteins in plants (Monger et al. 2006).

Various levels of VN antibodies and protection were induced using eukaryotic vectors to express the TGEV S glycoprotein encoding the glycosylation-dependent antigenic determinants (sites A and B) with or without sites C and D (Figure 31.3). The baculovirus- or vaccinia virus-expressed S glycoprotein of TGEV induced low titers of VN antibodies in serum, colostrum, and milk, but low or no protection (Godet et al. 1991; Hu et al. 1985; Shoup et al. 1997; Tuboly et al. 1995). Only S glycoprotein constructs containing antigenic site A induced high VN antibody titers. Sites C and D induced only low titer VN antibodies, but interestingly, they primed pigs for secondary serum antibody responses after challenge (Shoup et al. 1997).

Similar findings were evident in studies using the same baculovirus-expressed S constructs administered IM to boost antibody responses in sows vaccinated orally with attenuated TGEV vaccines: the partial protection rates were comparable with IM boosting with attenuated TGEV vaccine (Park et al. 1998). Baculovirus-expressed TGEV structural proteins (S, N, and M) coadministered IP with *E. coli* mutant LT adjuvant induced TGEV IgA antibody responses associated with reduced TGEV shedding in challenged pigs (Sestak et al. 1999b).

Recent studies have used molecular approaches to develop vectored TGEV vaccines and test them in porcine and murine models. A human adenovirus engineered to express the TGEV or PRCV S proteins (Callebaut et al. 1996; Torres et al. 1996; Tuboly and Nagy 2001) elicited variable protection against TGEV mortality and little protection against TGEV or PRCV infection. An oral *Lactobacillus casei*-based vaccine expressing repetitive (20X and 40X) peptides of the antigenic D site of TGEV S protein induced humoral and T-cell-based immune responses and Th17 polarization in mice (Jiang et al. 2014, 2016). Additionally, an attenuated *Salmonella typhimurium* vector expressing TGEV N or M proteins and a recombinant *Bacillus subtilis* strain expressing TGEV S protein induced T-cell proliferation, antibody and cytokine responses in mice, and antibody responses in pigs, respectively (Mou et al. 2016; Qing et al. 2016; Zhang et al. 2016a). Yuan et al. (2015) expressed the A epitope of the S protein in swinepox virus and demonstrated that this vaccine administered to sows was immunogenic and protected piglets against clinical disease. DNA plasmids were generated for PEDV and TGEV for the development of DNA vaccines that were immunogenic in mice, but not tested in pigs (Meng et al. 2013).

An effective TGEV vaccine should primarily elicit an intestinal immune response (Saif and Jackwood 1990; Saif and Sestak 2006; VanCott et al. 1993). Further improvements of TGEV vaccines might be achieved by the use of mucosal adjuvants/delivery systems such as immunostimulating complexes (ISCOMs), vitamin A, probiotic bacteria, biodegradable microspheres, or infectious recombinant TGEV clones engineered to enhance TGEV immunogenicity and reduce pathogenicity (Chattha et al. 2015; Enjuanes et al. 2005). Studies of TGEV infectious cDNA minigenomes indicate that this approach also can be used for targeted delivery of immunogens derived from other pathogens to the intestine or respiratory tract.

Porcine epidemic diarrhea virus

Relevance

In 1971, acute outbreaks of diarrhea in feeder and finishing pigs were observed in England (Oldham 1972). The disease spread to other European countries, and the name "epidemic viral diarrhea" (EVD) was adopted. In 1976, similar outbreaks were observed, but in swine of all ages, including suckling pigs (Wood 1977) and, in 1978, a CoV-like agent was associated with the outbreaks in piglets (Chasey and Cartwright 1978; Pensaert and de Bouck 1978). Experimental inoculations with the Belgian isolate (CV777) revealed its enteropathogenicity for piglets and growing pigs (Debouck and Pensaert 1980), and the names "porcine epidemic diarrhea" (PED) and PED virus (PEDV) were adopted (Debouck et al. 1982). In the 1970s and 1980s, PEDV caused widespread epidemics in Europe, with severe losses in suckling pigs. Since then, PEDV has been associated more often with isolated outbreaks and recurrent diarrheic problems in weaned and feeder pigs. However, epidemics also occurred, as in Italy in 2005–2006.

In Asia, PEDV epidemics were first reported in 1982 and outbreaks continued through the 1990s and 2000s. The situation changed in 2010 when PED outbreaks in China caused by highly virulent PEDV strains resulted in the loss of >1 million piglets in 1 year (Sun et al. 2012). In 2013, PEDV outbreaks were reported in the United States, likewise with severe losses (Stevenson et al. 2013).

The initial PEDV strains are referred to as classical PEDV strains (Chen et al. 2013). The strains identified since 2010 are considered emerging PEDV strains. Variants of the emerging PEDV strains containing insertions and deletions in the S gene ("S INDEL" strains) were first detected in the United States (Lin et al. 2016; Wang et al. 2014b). By the end of 2016, the emerging PEDV strains, both non-S INDEL and S INDEL, had spread throughout North and South America, Asia, and Europe.

The situation continues to evolve. For example, recombinant enteric CoVs between TGEV and PEDV have been detected in Italy (2009–2012), in Germany (2012), and in Eastern Europe (2016) (Akimkin et al. 2016; Belsham et al. 2016; Boniotti et al. 2016).

Etiology

Morphologic and physicochemical properties of PEDV (Figure 31.2c) are similar to those of other members of the family *Coronaviridae* (Figure 31.2). Based on genetic and antigenic criteria, PEDV is included in the genus *Alphacoronavirus* together with bat coronavirus (BtCoV)/512/2005, TGEV, PRCV, FECoV, FIPV, CCoV, and HCoV 229E. Based on phylogenetic analysis of the complete genomes, the global PEDV strains are divided into two major groups: the classical PEDV strains that first emerged in the 1970s in Europe and the PEDV strains appeared after 2010 (Lin et al. 2016) (Figure 31.1). The emerging PEDV strains are further divided into "non-S INDEL" (mainly highly virulent) and "S INDEL" subgroups (Figure 31.1) because the former and latter cause severe and mild PED, respectively, in the field and in experimental pig challenge studies (see "Pathogenesis"). The S INDEL strains contain insertions and deletions similar to the classical PEDV strains in the S1 subunit of the S protein (Vlasova et al. 2014). They likely resulted from multiple recombination events between the classical and emerging PEDV strains in Asia, perhaps related to widespread use of live classical PEDV vaccine strains in swine. Other minor PEDV variants have been reported, e.g. US TC-PC177, USA/OK10240-8/2017, and Japanese TTR-2 strains, bearing large deletions (194–200 aa) in the N-terminal domain (NTD) of the S protein (Oka et al. 2014; Suzuki et al. 2015; Zhang et al. 2018). The 197-aa deletion (residues 34–230) of PC177 strain occurred during Vero cell adaptation, whereas the 194-aa deletion (residues 23–216) of the TTR-2 strain and the 200-aa deletion (residues 31–230) of the OK10240-8 strain were detected in clinical swine samples in Japan and the United States, respectively. Unlike the altered tissue tropism seen for PRCV (enteric to respiratory), the two PEDV strains (PC177 and TTR-2) retained their enteric tropism, but with reduced virulence (Lin et al. 2016; Suzuki et al. 2016).

Although PEDV variants have different insertions or deletions in the S glycoprotein and variation in the S glycoprotein of PEDV may be related to pathogenesis and cross-neutralizing activity, there appears to be only one PEDV serotype (Choudhury et al. 2016; Lin et al. 2016). There is no cross-neutralization between PEDV and TGEV or between PEDV and PDCoV (Lin et al. 2015b; Ma et al. 2016). However, a low degree of cross-reactivity

was observed between PEDV and other animal alphacoronavirus antibodies. For example, a TGEV MAb recognized PEDV N protein (Lin et al. 2015b), TGEV Miller antiserum reacted with PEDV N protein (Gimenez-Lirola et al. 2017), TGEV and PRCV antisera reacted with PEDV M protein (Gimenez-Lirola et al. 2017), and mink alphacoronavirus antiserum reacted with PEDV M and N proteins (Have et al. 1992).

Vero (African green monkey kidney) cells support the growth of PEDV in culture medium supplemented with trypsin (Figure 31.4c). CPE consists of vacuolation and large multinucleated syncytia (Hofmann and Wyler 1988). PEDV also grows in various swine cell lines, including bladder and kidney cells (Shibata et al. 2000; Wang et al. 2016b), ST cells (Liu et al. 2015a), alveolar macrophage cell line 3D4 (Park and Shin 2014), and small intestinal epithelial cells (IECs) (Cao et al. 2015; Cong et al. 2015). As reviewed by Teeravechyan et al. (2016), PEDV can also replicate in bat lung cell line Tb1-Lu (Liu et al. 2015a), duck IEC line MK-DIEC (Khatri 2015), and human liver cell line HuH-7 (Wang et al. 2016b).

pAPN, the cell receptor used by TGEV, was initially considered to be the putative receptor of PEDV with some supporting evidence (Cong et al. 2015; Li et al. 2007; Nam and Lee 2010); however, some recent studies argue that pAPN may not be a functional receptor for PEDV (Li et al. 2017; Shirato et al. 2016).

Public health

PEDV is only infectious for swine and does not play a known role in public health.

Epidemiology

Classical PEDV regularly caused epidemics in Europe from 1971 until the late 1980s, but reports after 2000 are rare. An epidemic in Italy (2005–2006) affected 63 herds, but mortality was largely restricted to suckling piglets (Martelli et al. 2008). Until the emergence of new PED outbreaks in 2014, PEDV was not considered important, and therefore, the prevalence of classical PEDV in Europe is unknown. Except for an outbreak associated with the emerging non-S INDEL strain in Ukraine in 2014, subsequent outbreaks in France, Germany, Belgium, Slovenia, and the Netherlands were due to the emerging S INDEL strains (Lin et al. 2016).

In Asia, classical PED appeared in China in the late 1970s, causing serious losses in many provinces (Wang et al. 2016a; Xuan et al. 1984). PED was recognized in Japan in 1982 (Kuwahara et al. 1988; Sueyoshi et al. 1995; Takahashi et al. 1983) and Korea in 1993 (Chae et al. 2000; Hwang et al. 1994; Kweon et al. 1993), but is known to be present in India (Barman et al. 2003) and Thailand (Puranaveja et al. 2009). In 2010, despite the widespread use of PEDV strain CV777 vaccines, severe PEDV outbreaks due to non-S INDEL strains occurred in China (Sun et al. 2012, 2016; Wang et al. 2016a). Later, emerging S INDEL strains were also detected in China (Wang et al. 2016a).

Since 2013, the emerging non-S INDEL PEDV strains have been detected in other Asian countries/regions outside of China, including Japan (Masuda et al. 2015), South Korea (Kim et al. 2015), Vietnam (Vui et al. 2014), Thailand (Cheun-Arom et al. 2015), Taiwan (Lin et al. 2014), and the Philippines (Kim et al. 2016). The S INDEL PEDV was also detected in Japan in 2013 (Suzuki et al. 2015) and Korea in 2014 (Lee et al. 2014).

The first highly virulent PED outbreak caused by non-S INDEL PEDV occurred in swine farms in the United States in April 2013 (Stevenson et al. 2013), followed by the detection of milder PED outbreaks caused by the S INDEL PEDV in January 2014 (Wang et al. 2014b). From 2013 to 2014, PEDV killed approximately 7 million piglets in the United States. In January 2017, PEDV had spread to 39 US states and to Puerto Rico. PEDV has also spread to other countries (e.g. Canada and Mexico) in the Western Hemisphere (Lin et al. 2016). PEDV has not been reported in Africa or Australia.

Direct or indirect fecal–oral transmission is the main route of PEDV transmission. Contaminated equipment, feed and feed ingredients, transportation, or personnel may serve as vehicles for PEDV transmission (Dee et al. 2014, 2016; Schumacher et al. 2016). Evidence of PEDV aerosol transmission has been reported in some (Alonso et al. 2014), but not other studies (Niederwerder et al. 2016). In emerging non-S INDEL PEDV experimentally infected 4-week-old pigs, infectious virus excretion assessed by PEDV transmission to susceptible sentinel pigs lasted 14–16 days (Crawford et al. 2015). However, at 42 days post-initial oral exposure, some pigs still shed PEDV RNA in feces, illustrating discordance between prolonged detection of PEDV RNA in feces and the transmission of infectious PEDV to susceptible pigs.

After an outbreak on a breeding farm, PEDV can become endemic through a cycle of infection of consecutive litters as they lose lactogenic immunity at weaning. Although a study from South Korea showed a PEDV infection rate of 9.75% in wild boars (Lee et al. 2016a), their role in the maintenance and transmission of PEDV is unknown.

Pathogenesis

The pathogenesis of PED is related to the age of pigs at the time of infection, virus strain virulence, inoculation routes, and doses.

The PEDV pathogenesis was first studied in piglets (3 days of age) orally inoculated with the classical PEDV

CV777 isolate (Coussement et al. 1982; Debouck et al. 1981) (Table 31.1). Clinical signs were observed after 22–36 hours. Viral replication occurred mainly in the cytoplasm of villous epithelial cells throughout the small intestine as early as 12–18 hours post inoculation (PI), peaking at 24–36 hours. Infection resulted in degeneration of enterocytes, leading to a reduction in the villous height/crypt depth (VH/CD) ratios from the normal 7 : 1 to ≤4 : 1. The pathogenic features of classical PEDV in the small intestine of piglets were very similar to those of TGEV, but somewhat less pronounced (Figure 31.5). PEDV replication was also observed in the colonic epithelium where slight cell degeneration was seen (Ducatelle et al. 1982). Occasionally, PEDV-positive crypt cells were also observed by IHC or IF staining, but the enterocyte regeneration capacity was preserved (Debouck et al. 1981; Sueyoshi et al. 1995). Shibata et al. (2000) showed that SPF pigs inoculated with field PEDV between the ages of 2 days and 12 weeks developed age-dependent resistance. That is, mortality was only observed in 2- to 7-day-old piglets. Pathogenic features of PED caused by classical PEDV strains described in Korea and Japan are very similar to those reported in Europe (Kim and Chae 2003; Sueyoshi et al. 1995).

Lohse et al. (2016) studied PEDV pathogenicity in 5-week-old pigs using classical PEDV strain (TC Br1/87, P3), an emerging S INDEL strain in Germany, and a non-S INDEL strain in the United States. Unfortunately, the S INDEL PEDV failed to infect pigs. Compared with the classical PEDV-infected pigs, the non-S INDEL PEDV-infected pigs had more severe clinical signs and histopathological changes, higher peak viral RNA shedding titers in feces, and longer detection of viral RNA in serum. These results suggested that the emerging non-S INDEL PEDV was more virulent than classical PEDV. However, concerns related to data interpretation include the following: (1) The Br1/87 inoculum was the Vero cell culture-adapted virus at passage 3, whereas the non-S INDEL was the wild-type virus from pigs and its infectious dose was not determined, so the disease outcomes may be due to different infectious doses. (2) The non-S INDEL inoculum contained a low amount of rotavirus by conventional RT-PCR. Therefore, coinfection with PEDV and rotavirus may influence disease severity. Generally, the pathogenesis and the age-dependent resistance of the emerging non-S INDEL PEDV strains were similar to those of the classical PEDV strains (Table 31.1) (Jung et al. 2014, 2015a; Madson et al. 2014; Niederwerder et al. 2016; Pensaert and Martelli 2016; Stevenson et al. 2013). Compared with the emerging non-S INDEL PEDV strains, S INDEL PEDV-infected piglets had lower mortality rates and less severe histopathological changes (milder villous atrophy) and less antigen in the small intestine (Table 31.1) (Chen et al. 2016a; Lin et al. 2015a). The pathogenicity of PEDV TTR-2 and TC-PC177 strains that have a large deletion in the NTD of the S protein was milder compared with that of the emerging non-S INDEL PEDV strains (Lin et al. 2016; Suzuki et al. 2016).

The infectious doses of PEDV differ for different ages of pigs: 100- to 1000-fold less PEDV was needed to infect younger pigs compared with the dose required to infect 3-week-old pigs (Thomas et al. 2015). The infectious dose of an emerging non-S INDEL PEDV strain (PC22A) was as low as 0.1 plaque-forming unit (PFU)/pig in 4-day-old Cesarean-derived colostrum-deprived (CDCD) piglets (Liu et al. 2015b). Doses of 0.1 PFU/pig and 1–10,000 PFU/pig caused diarrhea in 40 and 100% piglets, respectively. Thomas et al. (2015) compared the infectious doses for another emerging non-S INDEL PEDV strain (USA/IN19338/2013) in 5-day-old and 3-week-old pigs: 0.056 and 0.56–5600 $TCID_{50}$/pig caused diarrhea in 25 and 100% of neonatal piglets, respectively, and at least 100-fold higher doses (56–5600 $TCID_{50}$/pig) caused diarrhea in 100% of 3-week-old pigs. However, the infectious dose for older pigs, such as finisher pigs, has not been determined, but is expected to be higher than that needed to infect weaned pigs, as was observed for TGEV (Witte and Walther 1976).

During the acute phase of PEDV infection, viral RNA was detected transiently in the serum of PEDV-infected suckling and weaned pigs (Chen et al. 2016a; Jung et al. 2014, 2015a; Lohse et al. 2016; Suzuki et al. 2016). Peak RNA titers in serum were low (7–8 $\log_{10}$ GE/mL) compared with concurrent high peak RNA titers in feces (11–12 $\log_{10}$ GE/mL) (Jung et al. 2015a). Whether detection of viral RNA in serum represents infectious virus and the role of viremia in PEDV pathogenesis is unknown. In general, PEDV RNA titers are about 4–6 $\log_{10}$ higher than infectious titers (PFU or $TCID_{50}$) depending on different PEDV strains and/or the real-time RT-PCR assays (Jung et al. 2014; Song et al. 2016; Thomas et al. 2015).

Low levels of PEDV RNA were also detected in other tissues, such as the lung, liver, spleen, and muscle of pigs euthanized during acute PEDV infection (Chen et al. 2016a; Lohse et al. 2016; Park and Shin 2014). However, because the blood was not drained before collecting each tissue, the viral RNA was most likely from blood, except for the lungs, where PEDV antigens were detected by IHC (Park and Shin 2014). In the later study, the researchers found that a wild-type Korean PEDV non-S INDEL strain CNU-091222-01/2009 replicated in alveolar macrophages of infected pigs. Because no others have reported the detection of PEDV in the lungs, whether this is a unique characteristic of earlier emerging non-S INDEL strains (pre-2010) is unknown and needs to be investigated. In addition, PEDV RNA was detected from 40.8% (20/49) of sow milk samples during the emerging PEDV epidemics (Sun et al. 2012). TGEV replicated in the mammary glands of sows injected intramammarily

Table 31.1 Comparative pathogenesis of different clusters of PEDV in experimentally infected piglets (younger than 6 days of age).

PEDV strain	Inoculum/dose per pig	Pig type/age (day) at inoculation	Villous atrophy (VH:CD ratios)	Onset of clinical signs (hpi)	Vertical location of PEDV		Longitudinal distribution of PEDV		References

PID, pig infectious dose; $TCID_{50}$, 50% tissue culture infectious dose; PFU, plaque-forming unit; GE, genomic equivalent; CDCD, Cesarean-derived colostrum-deprived; SPF, specific pathogen free; VH: CD, villous height/crypt depth ratio; hpi, hours' post inoculation; D, duodenum; J, jejunum; I, ileum; cont, continuous; NR, not reported; –, +, ++, and +++ denotes none, less than 30%, 30–60%, and more than 60% of villous enterocytes that were positive for PEDV antigens, respectively.

with live TGEV during lactation (Saif and Bohl 1983). Whether PEDV replicates in the mammary glands of sows, whether the PEDV RNA represents infectious PEDV, or whether the PEDV RNA in milk is from the saliva of their infected nursing piglets is unclear. Although some PEDV strains may replicate at low levels outside of the intestine, it remains unclear whether it contributes to PEDV pathogenesis.

PEDV infection results in massive loss of enterocytes and the malfunction of infected enterocytes, leading to maldigestive and malabsorptive diarrhea (Coussement et al. 1982; Debouck et al. 1981; Jung et al. 2006). During acute PEDV infection, gut integrity was reduced, leading to loss of water into the intestinal lumen and high osmotic pressure (Annamalai et al. 2015). The following factors may contribute to the more severe clinical signs, higher mortality rates, and slower recovery in PEDV-infected neonatal piglets compared with weaned pigs:

1) Slower turnover of villous enterocytes in neonatal piglets (5–7 days) compared with 2–3 days in 3-week-old weaned pigs (Jung et al. 2015a; Moon et al. 1975).
2) Increased numbers of intestinal stem cells and proliferation of crypt cells occurred later (3 days post-PEDV) in neonatal piglets than in weaned pigs (1 day post-PEDV) (Jung et al. 2015a).
3) Deficiency in innate immunity in suckling pigs compared with weaned pigs (Annamalai et al. 2015) (see "Immunity").

Clinical signs

PED shares most clinical features with TGE including watery diarrhea, vomiting, anorexia, and depression. On breeding farms, pigs of all ages become sick. Morbidity approaches 100% in piglets, but can vary in sows. Piglets up to 1 week of age may die from dehydration, and mortality ranges from 50 to 100%. Older pigs recover after about 1 week. In sows, diarrhea is variable, and they may only show depression and anorexia. In fattening pigs, all pigs in the unit may have watery feces within a week and often show severe anorexia and depression.

The disease on a breeding farm is self-limiting and stops when the pregnant sows develop lactogenic immunity to protect their offspring. The interval between onset and cessation of the disease is generally 3–4 weeks, but may be much longer in large breeding farms with multiple separated units. After the acute outbreak has passed, diarrhea may persist on the farm in weaned pigs and become recurrent (Martelli et al. 2008). PEDV may also be involved in a multi-etiologic diarrhea syndrome in feeder pigs appearing 2–3 weeks after they enter the fattening units, particularly when the pigs originate from different sources and when new pigs are continuously added to the fattening unit (van Reeth and Pensaert 1994).

Lesions

Lesions have been described in experimentally and naturally infected suckling piglets for classical PEDV (Coussement et al. 1982; Kim and Chae 2003; Pospischil et al. 1981; Sueyoshi et al. 1995), emerging non-S INDEL (Chen et al. 2016a; Jung et al. 2015a; Madson et al. 2015; Stevenson et al. 2013), and S INDEL PEDV infections (Chen et al. 2016a; Lin et al. 2015a). Lesions are confined to the small intestine that is distended with watery, yellowish fluid. Microscopically, vacuolation, syncytia, and exfoliation of small intestinal enterocytes occur mainly on the proximal villi. The small intestinal villi are reduced in length (Figure 31.5d), and the enzymatic activity of the intestine is markedly decreased. This pathology is very similar to that observed in TGE and PDCoV (Figure 31.5). No histopathologic changes have been observed in the colon, although PEDV antigens were detected in vacuolated colonic epithelial cells (Chen et al. 2016a; Debouck et al. 1981; Jung et al. 2014).

Diagnosis

Diagnosis should be made based on both clinical signs and laboratory detection of viral RNA, viral antigens, or increased PEDV antibodies. For the detection of PEDV RNA, the most widely used laboratory diagnostic method is RT-PCR (Ishikawa et al. 1997; Kim et al. 2001; Kubota et al. 1999; Liu and Wang 2016) or real-time RT-PCR (Kim et al. 2007; Wang et al. 2014d; Zhang et al. 2016b). Loop-mediated isothermal amplification (LAMP) assays (Ren and Li 2011; Yu et al. 2015) have been developed for the detection of PEDV RNA but are used less in diagnostic laboratories. Newer technology such as the specific primer-independent metagenomic sequencing (next-generation sequencing) can be used to determine the nearly complete (lacking 5′ and 3′ ends) viral genome sequences from clinical specimens (Chen et al. 2014; Marthaler et al. 2013). *In situ* hybridization can be used to detect PEDV RNA in fixed tissues (Kim and Chae 2000; Stadler et al. 2015).

Diagnosis can be made by direct demonstration of PEDV and/or its antigens using IF or IHC tests on the small intestinal tissues of pigs euthanized acutely near the onset of diarrhea and prior to the desquamation of enterocytes (Debouck et al. 1981; Guscetti et al. 1998; Jung et al. 2014; Stevenson et al. 2013; Sueyoshi et al. 1995) (Figure 31.6b). PEDV particles can be demonstrated using direct EM or IEM of feces of pigs collected acutely after diarrhea onset. Virus particles are difficult to recognize when the virion spikes are lost or not clearly visible. Furthermore, IEM must be applied to differentiate PEDV from TGEV and PDCoV because the CoVs have identical morphology (Figure 31.2).

Isolation of field strains of PEDV from intestinal contents/homogenates or feces is done in Vero cells or in other cell types. Trypsin treatment and blind passages

may be needed before CPE appears, but early detection can be done by IF staining (Hofmann and Wyler 1988; Shibata et al. 2000). Successful isolation of PEDV in Vero cells is higher with intestinal contents/homogenates than with feces (Chen et al. 2014; Oka et al. 2014).

Antigen-capture ELISAs have been developed for detection of PEDV antigens in feces using polyclonal antibodies and MAbs (Callebaut et al. 1982; Carvajal et al. 1995), but they are not widely used.

Paired serum samples are required for serologic diagnosis of endemic PEDV. Recently, IgG and IgA antibodies to PEDV were detected in oral fluids, suggesting they may be suitable to monitor prior herd exposure to PEDV (Bjustrom-Kraft et al. 2016). PEDV antibodies have been demonstrated with indirect ELISAs using antigens consisting of cell-cultivated virus (Carvajal et al. 1995; Hofmann and Wyler 1990; Kweon et al. 1994; Thomas et al. 2015), or S and N viral proteins extracted from infected Vero cells (Knuchel et al. 1992; Oh et al. 2005), or expressed in bacteria or using mammalian expression systems (Chen et al. 2016b; Gerber et al. 2014; Gerber and Opriessnig 2015; Hou et al. 2007; Okda et al. 2015; Paudel et al. 2014; Wang et al. 2015). Blocking and competitive ELISAs have also been developed for the detection of PEDV antibodies using MAbs or polyclonal antibodies as competitive antibodies (Carvajal et al. 1995; Okda et al. 2015; van Nieuwstadt and Zetstra 1991). Serum IgG antibodies against the N proteins of PEDV can be detected by 9–14 DPI, with titers peaking around 21 DPI and then declining gradually (Okda et al. 2015). Recently, a fluorescent microsphere immunoassay (FMIA) was developed (Gimenez-Lirola et al. 2017; Okda et al. 2015), but it is not widely used due to the need for specific equipment. The VN test in Vero cells is critical to assess VN antibodies to PEDV (Oh et al. 2005; Okda et al. 2015; Paudel et al. 2014; Thomas et al. 2015). These serological assays have been widely used to monitor prior exposure to the virus and to evaluate the efficacy of vaccines.

PEDV infections must be differentiated from TGE, SeCoV, and PDCoV, which in the case of acute diarrhea in swine of all ages can only be done through laboratory testing. Since SeCoVs are recombinants between TGEV (backbone) and PEDV (mainly S protein), only assays targeting both TGEV (any genes except for S gene) and PEDV (S gene) fragments can identify those viruses. In neonatal colibacillosis or rotavirus diarrhea, adult animals are not affected, and sick pigs usually are born from gilts or young sows. Laboratory techniques must be used to differentiate PED from other causes of diarrhea in weaned or feeder pigs.

Immunity

Evidence shows that PEDV has the ability to evade host IFN responses. Of 21 PEDV-encoded proteins, at least 11 proteins have been identified as IFN antagonists, which include both ORF1ab-encoded NS proteins (nsp1, nsp3, nsp5, nsp7, nsp14, nsp15, nsp16), structural proteins (E, M, N), and the accessory protein ORF3 (Ding et al. 2014; Wang et al. 2015; Zhang et al. 2016c). Identification of the virus-encoded IFN antagonists and understanding their mechanism of action may lead to novel therapeutic targets and more effective vaccines.

PEDV-infected suckling pigs had significantly lower NK cell frequencies, undetectable NK cell activity, and lower IFN-γ-producing $CD3^{-}CD4^{-}CD8^{+}$ NK cells in blood and ileum compared with PEDV-infected weaned pigs (Annamalai et al. 2015). Deficiency in innate immune function of neonatal NK cells may contribute to the more severe PEDV infection in suckling pigs compared with weaned pigs as also reported for TGEV infections (Derbyshire et al. 1969).

Inflammatory responses play a significant role in the pathogenesis of enteric CoVs. Compared with suckling pigs, weaned pigs had a delayed proinflammatory cytokine induction that coincided with the delayed onset of infection, disease, and shedding of PEDV RNA in feces (Annamalai et al. 2015). Toll-like receptor 2 (TLR2), TLR3, and TLR9 may contribute to NF-κB activation in response to PEDV infection in small IECs *in vitro* (Cao et al. 2015). The viral proteins E and N upregulated IL-8 expression by inducing endoplasmic reticulum stress and subsequent activation of the NF-κB pathway (Xu et al. 2013a,b).

Humoral immune responses to PEDV infection are very similar to those described for TGEV [reviewed in TGEV section (Chattha et al. 2015; Saif and Sestak 2006)]. VN antibodies are detectable in the serum, but may not play an important role because protection against enteric disease is primarily dependent on the presence of sIgA antibodies in the intestinal mucosa (Chattha et al. 2015; Langel et al. 2016). Immunity may not be long lasting, but a rapid anamnestic response upon reexposure may prevent reoccurrence of disease.

Although PED occurs in pigs of all ages, piglets up to 1 week of age may experience high mortality and need to be protected by maternal antibodies, especially VN and sIgA, via colostrum and milk from immunized dams. The mechanisms of lactogenic protection described for TGEV infection apply to PED as well (reviewed in TGEV section [Chattha et al. 2015; Langel et al. 2016]). Lactogenic immunity is induced in sows by intestinal infection with PEDV, which then activates the gut–mammary–sIgA axis. Pigs lose lactogenic protection at weaning and soon become susceptible to PEDV infection. Cell-mediated immunity likely plays a role in viral clearance, but there is no experimental data on this topic. PEDV may persist on the farm in susceptible pigs as part of recurring weaning diarrhea after an acute outbreak.

Prevention and control

PEDV is highly contagious, and strict sanitation and biosecurity are required to prevent virus entrance. Do not commingle sources or groups of pigs; ensure facilities and transportation vehicles are thoroughly washed, disinfected, and dried before pigs enter; and do not share boots, clothing, or equipment between different ages of pigs.

Feedback (intentional exposure of sows to virus using feces or small intestines from acutely infected piglets) will stimulate lactogenic immunity in the sow herd, reduce clinical signs in piglets, and shorten clinical outbreaks. Feedback may also be used in the nursery, grower, or finisher pigs, but nose-to-nose contact and fecal–oral spread will quickly contaminate the entire facility. It should be recognized that other pathogens present in clinically affected animals can be transmitted via the feedback process.

In Europe, the disease has been of insufficient economic importance to develop vaccines. In China, various inactivated and/or attenuated bivalent (TGEV and PEDV) or trivalent (TGEV, PEDV, and rotavirus strain NX) vaccines based on the classical PEDV strains have been available as early as in 1999 (Ma et al. 1995; Sun et al. 2016; Wang et al. 2016a). However, classical PEDV vaccines were not efficacious in protecting pigs against the highly virulent non-S INDEL PEDV infection (Li et al. 2012; Sun et al. 2012; Wang et al. 2013) and newer vaccines (e.g. a bivalent inactivated PEDV and TGEV vaccine based on the emerging non-S INDEL PEDV strain AJ1102) have appeared in the market. In Japan, a commercial attenuated PEDV vaccine based on the classical PEDV 83P-5 strain has been in use since 1997 (Sato et al. 2011). In Korea, attenuated vaccines based on strains KPEDV-9 (Kweon et al. 1999) or DR13 (Song et al. 2007) were commercialized in 1999 and 2004, respectively. Reportedly, not all sows given the vaccines developed protective lactogenic immunity (Song et al. 2015a). Two commercial vaccines are available in the United States. The first vaccine (June 2014) was developed using a replication-deficient Venezuelan equine encephalitis virus packaging system to express the PEDV S protein (Crawford et al. 2016). The second vaccine (September 2014) is an inactivated whole virus vaccine based on an emerging non-S INDEL PEDV strain (Crawford et al. 2016).

Porcine deltacoronavirus

Relevance

In February 2014, acute outbreaks of diarrhea associated with PDCoV were observed in sows and their piglets on five Ohio farms in the United States (Wang et al. 2014a). Previously, PDCoV had been reported in the feces of domestic pigs in China in 2012 (Woo et al. 2012), but the role of the virus as an enteric pathogen was unclear at that time. PDCoV has spread nationwide in the United States (Wang et al. 2014c) and caused deaths among suckling pigs (Anon 2014). Experimental studies verified that US PDCoV isolates are enteropathogenic in nursing pigs, as evident by acute, watery diarrhea and severe intestinal lesions (Figure 31.5c and e) (Chen et al. 2015; Jung et al. 2015b). However, the clinical impact and disease severity of PDCoV is less than that of epidemic PEDV and TGEV (Anon 2014).

Since the PDCoV outbreaks in the United States, it has also been identified on swine farms in Canada, Korea, China, Thailand, Vietnam, and Laos PDR, but in Canada and Korea, PDCoV failed to spread nationwide (Lee et al. 2016b; Marthaler et al. 2014b). Differential diagnosis of PDCoV, PEDV, and TGEV is critical to control CoV diarrheas in pig farms, especially in the regions where these CoVs have emerged or reemerged.

Etiology

PDCoV belongs to the genus *Deltacoronavirus* of the family *Coronaviridae*. Morphologic and physicochemical properties of PDCoV are similar to those of other members in the family *Coronaviridae* (Figure 31.2).

All global PDCoV strains overall share high nucleotide identities (Zhang 2016) (see "Epidemiology"). However, a comprehensive genetic analysis of global strains revealed that US/Korean PDCoV strains clustered together, Chinese strains clustered separately, and Thai strains formed another cluster (Zhang 2016) (Figure 31.1). Chinese PDCoV strains had multiple mutation or deletion sites in their S, NSP, or 3′ untranslated region (UTR) genes, whereas these mutations were not found in the genomes of US PDCoV strains (Wang et al. 2016c). Several investigators reported no cross-reactivity of PDCoV with antibodies to either PEDV or TGEV (Chen et al. 2015; Ma et al. 2015). However, another study reported antigenic cross-reactivity between US PDCoV and PEDV strains, possibly sharing at least one epitope on their N proteins (Ma et al. 2016).

LLC porcine kidney (LLC-PK) and ST cells supplemented with exogenous trypsin or pancreatin support the isolation and serial propagation of PDCoV in cell culture (Hu et al. 2015). The CPE consisted of enlarged and rounded cells and then cell shrinkage and detachment.

Recent studies have demonstrated that PDCoV employs pAPN as a major receptor for cellular entry, although it remains to be elucidated whether another receptor is involved in PDCoV infection (Li et al. 2018; Wang et al. 2018; Zhu et al. 2018).

Public health

There is no evidence that PDCoV is infectious for humans or plays a role in public health.

Epidemiology

The ancestral origin of PDCoV is unclear, but considering that PDCoV emerged recently, PDCoV may be incompletely adapted to pigs. Molecular surveillance in China and Hong Kong in 2007–2011 detected DCoVs only in pigs and wild birds (Woo et al. 2012). However, DCoVs were previously isolated from rectal swabs of small mammals, including Asian leopard cats and Chinese ferret badgers, at Chinese live animal markets in 2005–2006 (Dong et al. 2007). Their helicase and S genes were closely related to those of PDCoV. The data suggest the potential interspecies transmission of DCoVs between these wild small mammals, pigs, and birds. A recent study also revealed that PDCoV-inoculated gnotobiotic (Gn) calves exhibited an acute infection without disease or intestinal lesions, but with persisting fecal viral RNA shedding and seroconversion (Jung et al. 2017). Consequently, the potential ability of PDCoV and other DCoV isolates from birds or small mammals to infect different species should be investigated.

In February 2014, PDCoV was detected in US swine. Among 42 fecal or intestinal samples collected from diarrheic sows and piglets on five Ohio farms, 39 (92.9%) were positive for PDCoV by RT-PCR (Wang et al. 2014a). The PDCoV Ohio strain HKU15-OH1987 had a 99% nucleotide identity to the two prototype strains of PDCoV, HKU15-44 and HKU15-155, reported in Chinese pigs in 2012. During a similar period, genetically similar strains, USA/IA/2014/8734 and SDCV/USA/Illinois121/2014, were identified by other US diagnostic laboratories (Li et al. 2014; Marthaler et al. 2014a). Among PDCoV-positive premises, coinfection with PEDV is common (Zhang 2016). The origin of PDCoV in US swine is unknown, although there was serologic and virologic evidence suggesting its presence in the United States prior to its detection in February 2014 (Sinha et al. 2015; Thachil et al. 2015).

PDCoV has also been reported in Canada, Korea, mainland China, Thailand, Vietnam, and Lao PDR (Dong et al. 2015; Janetanakit et al. 2016; Lee et al. 2014; Lorsirigool et al. 2016; Marthaler et al. 2014a; Saeng-Chuto et al. 2017; Song et al. 2015b). The Korean PDCoV strains (KUN14-04, SL2, and SL5) had high nucleotide identities (98.7–99.2%) to US PDCoV strains (Lee et al. 2014, 2016b). In mainland China, coinfections with PDCoV and PEDV were common (Dong et al. 2015; Song et al. 2015b). Chinese PDCoV strains had ≥98.6% nucleotide identities with each other and ≥97.1% nucleotide identities with the global PDCoV strains (Zhang 2016). The Thai PDCoV strains were highly similar to each other but formed a novel phylogenetic cluster separated from US and Chinese PDCoVs (Janetanakit et al. 2016; Saeng-Chuto et al. 2017). PDCoVs identified in Lao PDR were more closely related to Thai PDCoVs, whereas PDCoVs detected in Vietnam were more closely related to US PDCoVs (Saeng-Chuto et al. 2017).

Fecal–oral is the main PDCoV transmission route. Feces and/or vomitus and other contaminated fomites are major transmission sources of the virus. Based on experimental findings (Hu et al. 2016; Ma et al. 2015; Zhang 2016), diarrhea in infected piglets was observed for approximately 5–10 days, with persisting viral RNA shedding for up to 19–28 days in feces and for up to 42 days in oral fluids.

Pathogenesis

The pathogenesis of PDCoV has been studied in Gn or conventional piglets orally inoculated with US and/or Chinese PDCoV isolates at 5–21 days of age (Chen et al. 2015; Dong et al. 2016; Hu et al. 2016; Jung et al. 2015b; Ma et al. 2015). Clinical signs (diarrhea and/or vomiting) occurred at 1–3 DPI. Replication of PDCoV is confined to the small and large intestinal epithelia. PDCoV-infected enterocytes rapidly undergo acute necrosis (Jung et al. 2016a), leading to marked villous atrophy in the small intestine (Figure 31.5c and e), but not in the large intestine. During acute infection, PDCoV antigens are detected mainly in the villous epithelium of the atrophied mid-jejunum (Figure 31.6c) to ileum and, to a lesser extent, in duodenum, proximal jejunum, and cecum/colon. Occasionally, a few PDCoV antigens are detected in crypt epithelial cells of the jejunum and ileum (Jung et al. 2016a) and immune cells in the intestinal lamina propria, Peyer's patches, and mesenteric lymph nodes (Hu et al. 2016). Frequently, acute viremia with low PDCoV RNA titers in serum was observed (Chen et al. 2015; Hu et al. 2016; Ma et al. 2015). After pigs recovered from clinical disease, larger amounts of PDCoV antigens were detected in the gut lymphatic tissues (Hu et al. 2016). PDCoV antigens were not detected in other organs, including the respiratory tract of pigs (Jung et al. 2016b). However, by real-time RT-PCR, PDCoV RNA could be detected in low to moderate quantities in multiple organs, possibly due to viremia (Chen et al. 2015; Ma et al. 2015).

Clinical signs

Clinical signs of PDCoV infection in suckling and older pigs are similar, but milder, than those of PEDV and TGEV infections. In suckling piglets, PDCoV induces acute, watery diarrhea, frequently accompanied by vomiting, leading to dehydration, loss of body weight,

lethargy, and death. Experimentally, the onset of diarrhea coincided with, or was detected 1–2 days later than, the first detection of viral RNA in feces (Jung et al. 2015b; Ma et al. 2015).

Diarrhea is probably a consequence of malabsorption due to massive loss of absorptive enterocytes, resulting in decreased brush border membrane-bound digestive enzymes, similar to PEDV infection (Jung et al. 2006). Mild vacuolation observed in the infected colonic epithelial cells may interfere with the reabsorption of water and electrolytes (Jung et al. 2015b). Dehydration is also exacerbated by vomiting.

Seronegative pigs of all ages are susceptible to PDCoV infection. On seronegative farrowing farms, morbidity can reach up to 100% in piglets but can vary in sows. Based on field observations in US swine in 2014 (Anon 2014), PDCoV infection caused a number of deaths (up to a 40% mortality) among suckling pigs. Similarly, PDCoV diarrhea outbreaks in breeding farms in China and Thailand resulted in 64–80% mortality among suckling piglets. PDCoV infection is more severe and more likely to result in mortality in piglets as compared with older pigs. On many farms, morbidity and mortality may be affected by coinfections with other enteric viruses, such as PEDV and rotavirus (Marthaler et al. 2014b; Song et al. 2015b). The disease on breeding farms is self-limiting and stops when pregnant sows develop lactogenic immunity to protect their offspring.

PDCoV infection shares several clinical features with TGEV and PEDV infections, but the virus likely spreads more slowly among pigs, possibly due to its lower adaptation to pigs. Relative to PEDV infections, PDCoV-infected pigs shed less PDCoV RNA in the feces (Jung et al. 2015b), indicating lower replication of PDCoV in the intestine of pigs. This aspect of PDCoV infection may be a contributing factor to its lower mortality in nursing piglets, as compared with PEDV infections.

Lesions

Lesions have been described in suckling piglets experimentally and naturally infected with US, Chinese, or Thai PDCoV strains (Chen et al. 2015; Dong et al. 2016; Hu et al. 2016; Janetanakit et al. 2016; Jung et al. 2015b; Ma et al. 2015; Wang et al. 2016c). Lesions resemble those observed in TGEV and PEDV infections (Figure 31.5), but are usually less extensive.

Gross lesions are limited to the gastrointestinal tract and are characterized by thin and transparent intestinal walls (proximal jejunum to colon) with accumulation of large amounts of yellow fluid. The stomach is frequently filled with curdled milk. The transparency and fragility of affected intestines are milder, as compared with PEDV and TGEV infections. Histological lesions are characterized by acute, multifocal to diffuse, mild to severe atrophic enteritis in the proximal jejunum to ileum (Figure 31.5c and e), occasionally accompanied by mild vacuolation of the superficial epithelial cells in the cecum and colon (Jung et al. 2015b). No villous atrophy or histologic lesions were evident in the duodenum, which coincided with few PDCoV antigen-positive duodenal epithelial cells (Chen et al. 2015; Jung et al. 2015b). During acute infection, vacuolated enterocytes or massive cell exfoliation was seen on the tips or the entire villi in the jejunum and ileum. Atrophied villi were frequently fused and covered with a degenerated or regenerated flattened epithelium. Infiltration of inflammatory cells, such as macrophages, lymphocytes, and neutrophils, was evident in the lamina propria. No lesions were seen in other organs.

Diagnosis

The diagnostic approaches described earlier for TGEV and PEDV also apply to PDCoV diagnosis. Laboratory techniques should be used to differentiate PDCoV infection from PEDV, TGEV, and rotavirus diarrhea in pigs. Definitive diagnosis of PDCoV infection includes detection of PDCoV RNA or antigens in the feces or intestinal tissues from diarrheic pigs. Diagnosis can be made by RT-PCR assays that target a conserved region of PDCoV M or N genes (Marthaler et al. 2014b; Wang et al. 2014a; Zhang et al. 2016b), IF or IHC using virus-specific MAbs or polyclonal antibodies (Chen et al. 2015; Jung et al. 2015b; Ma et al. 2015), and *in situ* hybridization (Jung et al. 2015b). A real-time duplex RT-PCR assay for detection of PDCoV and/or differentiation of the virus from PEDV in intestines and feces was developed (Zhang et al. 2016b).

Direct EM can be used to demonstrate PDCoV particles in feces collected from diarrheic pigs (Figure 31.2d), but IEM using hyperimmune or convalescent sera is essential to differentiate PDCoV from PEDV or TGEV (Jung et al. 2015b). Isolation of PDCoV from feces or intestinal tissues was attempted in LLC-PK or ST cells, but the success rate was low except for a few strains (OH-FD22) (Hu et al. 2015). Serologic diagnosis of PDCoV can be conducted by IFA, VN, and ELISA assays. Isotypes of PDCoV antibodies in serum and milk can be quantitated by ELISA using antigens consisting of cell culture-grown virus (Ma et al. 2016) or S1 and N viral proteins (Okda et al. 2016; Su et al. 2016; Thachil et al. 2015).

Immunity

The immune responses of pigs to PDCoV infection are largely undefined, but they are likely similar to those described earlier for TGEV and PEDV. Hu et al. (2016) reported the development of PDCoV antibodies in serum of PDCoV-infected pigs (Hu et al. 2016). Gn pigs orally

inoculated with the original or tissue culture-grown PDCoV strain OH-FD22 had detectable serum IgG, IgA, and VN antibodies by 14 DPI that peaked at 24 DPI, when the pigs had recovered from clinical disease and fecal virus shedding. While PDCoV infection is epidemic, young piglets can be protected by transfer of maternal antibodies via colostrum and milk from immune dams, especially IgA and VN antibodies that neutralize PDCoV in the gut. Lactogenic immunity is expected to be strongly induced in sows by oral infection with PDCoV, which then activates the gut–mammary link, as described earlier for TGEV (Bohl et al. 1972; Saif et al. 1972).

Prevention and control

The prevention and control measures described earlier for TGEV and PEDV infections also apply to PDCoV infection. There are no treatments or vaccines to control PDCoV infection. Preventive or therapeutic antibiotic therapy can be implemented if there is concurrent infection with enteric bacterial pathogens. Symptomatic treatment of suckling pigs with diarrhea includes intraperitoneal administration of bicarbonate fluids and free access to water to alleviate acidosis and dehydration. If mortality is substantial among suckling piglets, feedback methods (intentional exposure of pregnant sows to virus-positive minced intestines from acutely infected piglets) will stimulate lactogenic immunity and reduce the high mortality if administered to sows at least 2 weeks pre-farrowing. During PDCoV epidemics, high-level biosecurity procedures to reduce PDCoV transmission via contaminated fomites are essential.

Hemagglutinating encephalomyelitis virus (vomiting and wasting disease)

Relevance

In 1962, Greig and coworkers isolated a viral pathogen from the brains of suckling pigs with encephalomyelitis in Canada. Designated hemagglutinating encephalomyelitis virus (HEV), the virus was later classified as a CoV (Greig et al. 1971). In 1969, an antigenically identical virus was isolated in England from suckling pigs showing anorexia, depression, vomiting, and stunting, but without signs of encephalomyelitis (Cartwright et al. 1969). The condition was called vomiting and wasting disease (VWD). Both forms of the disease were experimentally reproduced by Mengeling and Cutlip (1976) using isolates from the same farm. pHEV is widespread among swine, but the infection is generally subclinical, although some outbreaks may cause losses (Alsop 2006; Quiroga et al. 2008).

Etiology

pHEV belongs to the genus *Betacoronavirus* of the family *Coronaviridae* (Figure 31.1). The virus agglutinates erythrocytes of mice, rats, chickens, and several other animals. The natural host of pHEV is the pig. Although pHEV may show different clinical manifestations, there is only one serotype. Age-related susceptibility of the pigs, possible strain differences in virulence, and variation in pathogenesis may influence clinical signs. pHEV shows a strong tropism for neural tissues in pigs. Likewise, the virus displays neurotropism in mice and Wistar rats (Hirano et al. 2004; Yagami et al. 1993).

In vitro, only porcine cells are susceptible to pHEV. pHEV was first isolated in primary PK cells with CPE characterized by syncytia (Greig et al. 1962). pHEV was also shown by IF staining to propagate in other porcine cell cultures: adult thyroid gland, embryonic lung, and cell lines such as ST, PK-15, $IBRS_2$, SK, SK-K, and KSEK6 swine embryo kidney.

Public health

Pigs are the only species known to be susceptible to pHEV and pHEV has no public health significance.

Epidemiology

Serologic surveys (1960–1990) revealed that pHEV infection in swine occurs worldwide and is endemic in both breeding and fattening swine (Pensaert 2006). The presence of pHEV, as detected by isolation or serology, was reported in Europe, in the Western Hemisphere (United States, Canada, Argentina), in Asia (Japan, Taiwan), and in Australia.

pHEV is maintained in swine populations by infecting successive groups of pigs after replacement or weaning. The virus is excreted oronasally (Hirahara et al. 1989; Pensaert and Callebaut 1974) for 8–10 days. Transmission occurs via nasal secretions, via nose-to-nose contact, and aerogenically. Persistent virus carriers are not known to exist.

Generally, pigs will only develop disease when they become infected oronasally prior to 3–4 weeks of age and if originating from nonimmune mothers (Appel et al. 1965). Pigs with maternally derived pHEV antibodies that prevent the virus from reaching neural target tissues are clinically unaffected when exposed to pHEV (Appel et al. 1965). Pigs infected at later ages normally do not develop clinical disease. Since pHEV is endemic in most swine populations, most sows are immune and protect their offspring by maternal antibodies. Thus, clinical outbreaks are rare and usually occur in litters from nonimmune mothers, often first-parity sows. Three outbreaks are notable. In 2001, pHEV was isolated from

newborn and early weaned pigs with vomiting and posterior paralysis on a Canadian farm (Sasseville et al. 2001). Alsop (2006) described a clinically diagnosed outbreak of VWD in 2002 in a 650-sow genetic nucleus herd. Quiroga et al. (2008) described a VWD outbreak with motor disorders in Argentina in 2006. It occurred in a three-site herd with 6,000 sows where the breeder stock consisted of 55% gilts and first- or second-parity sows.

Pathogenesis

The type and severity of clinical signs vary and are related to age, possible differences in virus virulence (Mengeling and Cutlip 1976), and the course of viral pathogenesis.

The primary site of replication of pHEV in pigs is the respiratory tract (Andries and Pensaert 1980b; Hirahara et al. 1987; Mengeling et al. 1972). IF staining revealed that epithelial cells of nasal mucosa, tonsils, lungs, and some unidentified cells in the small intestine were infected. Primary replication may result in mild or subclinical signs.

Experimental studies in colostrum-deprived piglets inoculated oronasally with pHEV provided insight into pHEV pathogenesis (Andries and Pensaert 1980a). From the primary sites of replication, the virus spread via the peripheral nervous system to the CNS via different pathways. One pathway led from the nasal mucosa and tonsils to the trigeminal ganglion and the trigeminal sensory nucleus in the brain stem. A second pathway was along the vagal nerves via the vagal sensory ganglion to the vagal sensory nucleus in the brain stem. A third pathway led from the intestinal plexuses to the spinal cord, also after replication in local sensory ganglia. Viremia was of little or no importance in the pathogenesis of the disease (Andries and Pensaert 1980b).

In the CNS, the infection started in well-defined nuclei of the medulla oblongata, but progressed into the entire brain stem, the spinal cord, and sometimes also the cerebrum and cerebellum. IF staining in the brain was always restricted to the perikaryon and processes of neurons. Vomiting was induced by viral replication in the vagal sensory ganglion (ganglion distale vagi) or by impulses to the vomiting center produced by infected neurons at different sites (Andries 1982). To elucidate the pathogenesis of wasting, Andries (1982) suggested that virus-induced lesions in the intramural plexuses of the stomach may contribute to gastric stasis and delayed stomach emptying.

Clinical signs

Sneezing or coughing may be the first sign of infection because of primary pHEV replication in the upper respiratory tract. Body temperature can be elevated at disease onset, but returns to normal in 1–2 days. The incubation period for the appearance of more specific signs is 4–7 days. Two main clinical manifestations associated with pHEV neurotropism are possible in pigs below 3–4 weeks of age: (1) typical VWD with frequent vomiting leading to death or subsequent wasting and (2) acute encephalomyelitis with motor disorders. However, signs of both clinical forms may occur in the same herd during an outbreak.

For VWD, clinical signs are repeated retching and vomiting. Pigs start suckling, but withdraw from the sow and vomit the milk. The persistent vomiting and decreased food intake results in constipation and a rapid decline of condition. Neonatally infected pigs become severely dehydrated after a few days, exhibit dyspnea and cyanosis, lapse into coma, and die. Older pigs lose their appetite and become emaciated. They continue to vomit, although less frequently than in the acute stage. Wasting, often with distension of the cranial abdomen, may appear. This "wasting" state persists for several weeks and may be post weaning, requiring euthanasia. During the acute stage of VWD outbreaks, some pigs may show neurologic signs, such as abnormal gait, dullness, tremors, and nystagmus.

At the herd or farrowing unit level, morbidity varies greatly and probably depends on the proportion of nonimmune neonatal litters present at the time of infection. In litters without maternal protection, morbidity is litter dependent and may approach 100% when the infection occurs near birth. Morbidity decreases markedly with increasing age at infection. Mortality is variable, but may be 100% in neonatally infected litters.

In the Argentina outbreak (Quiroga et al. 2008), only suckling pigs were involved. Vomiting and wasting were the main signs, with slight motor disorders. Disease occurred in 27.6% of pigs <1 week old and declined to 1.6% in pigs 3 weeks of age. In this pHEV outbreak, an estimated 12.6% (3683) of the suckling pigs in the affected farrowing units died or were euthanized. After weaning, a mean of 29% (15–40%) of the pigs coming from affected farrowing units showed wasting.

Outbreaks of the motor encephalomyelitis disease in suckling pigs may start with sneezing, coughing, and vomiting 4–7 days after birth. Vomiting continues intermittently for 1–2 days, but is rarely severe. In some outbreaks, the first sign is acute depression and huddling. After 1–3 days, pigs exhibit various combinations of nervous disorders. Generalized muscle tremors and hyperesthesia are common. Pigs may have a jerky gait and walk backward, ending in a dog-sitting position. They become weak, are unable to rise, and paddle their limbs. Blindness, opisthotonus, and nystagmus may also occur. Finally, the animals become dyspneic and lie prostrate on their sides. In most cases, coma precedes death.

Morbidity and mortality in neonatal pigs is usually 100%, but older pigs show a mild transient illness in which posterior paralysis may be the most common sign. Outbreaks described in Taiwan (Chang et al. 1993) in 30- to 50-day-old pigs were characterized by fever, constipation, hyperesthesia, muscular tremor, progressive anterior paresis, posterior paresis, prostration, recumbency, and paddling movements with a morbidity of 4% and a mortality approaching 100%. The pigs died 4–5 days after the onset of clinical signs.

Lesions

The only gross lesions reported in pHEV infections are cachexia, stomach dilatation, and distension of the abdomen in some chronically affected pigs (Schlenstedt et al. 1969).

Microscopic lesions of epithelial degeneration and inflammatory cell infiltration are found in the tonsils and respiratory system of acutely diseased pigs (Cutlip and Mengeling 1972; Narita et al. 1989). A nonsuppurative encephalomyelitis was reported in 70–100% of pigs with nervous signs and in 20–60% of pigs showing VWD. The lesions are characterized by perivascular cuffing, gliosis, and neuronal degeneration (Alexander 1962; Chang et al. 1993; Richards and Savan 1960). They are most pronounced in the gray matter of the pons Varolii, medulla oblongata, and the dorsal horns of the upper spinal cord.

Microscopic changes in the stomach wall were found only in pigs showing VWD. Degeneration of the ganglia of the stomach wall and perivascular cuffing were present in 15–85% of diseased animals. The lesions were most pronounced in the pyloric gland area (Schlenstedt et al. 1969).

Diagnosis

Diagnosis can be made by virus isolation, IHC, or RT-PCR (Quiroga et al. 2008). Tonsils, brain stem, and lungs dissected aseptically from young acutely diseased piglets can be used for testing. It is difficult to isolate the virus from pigs that have been sick for more than 2–3 days. For virus isolation, suspensions are inoculated onto primary PK cells, secondary pig thyroid cells, or porcine cell lines. pHEV is detected by the presence of syncytia, by hemadsorption, or by hemagglutination. One or more blind passages may be needed since specimens often contain small amounts of infectious virus.

Antibodies to pHEV can be detected by VN or hemagglutination inhibition (HI) tests. The HI and VN tests were almost equally diagnostic in swine sera, but VN is more specific (Sasaki et al. 2003). Antibody titer results must be evaluated carefully because subclinical infections with pHEV are very common. Moreover, a significant rise in antibody titer can be detected only if acute sera are taken near the onset of clinical signs. Pigs may develop antibody titers as early as 6–7 DPI, which often coincides with early disease, making an interpretation of paired serology more difficult.

Differential diagnosis must be made between pHEV encephalomyelitis, Teschen–Talfan disease, and pseudorabies (Aujeszky's) disease. In the latter infections, clinical signs of encephalomyelitis, including motor disorders, are more severe and may appear in piglets and older pigs. Aujeszky's disease in non-vaccinated animals also induces respiratory signs in older pigs and abortions in sows. All these viruses can be grown in PK cells and pig thyroid cells, but the type of CPE differs and only pHEV causes hemadsorption and hemagglutination. They can be further differentiated by virus-specific tests.

Immunity

After infection, pigs develop detectable protective circulating antibodies (HI, VN) to pHEV in 7–9 days. The duration of antibodies has not been determined. The duration of immunity is less important in pHEV because of the resistance to disease that develops with age. Neonatal pigs born to immune mothers are fully protected by maternally derived antibodies that persist until the age of 4–18 (mean 10.5) weeks (Paul and Mengeling 1984).

Prevention and control

On most breeding farms, pHEV infection persists endemically by pig-to-pig transmission and through subclinical respiratory infections. Gilts usually contract the virus before their first farrowing and then provide protection to their offspring via colostral antibodies. When sows are not immune at farrowing, (e.g. in newly populated farms, well-isolated gilts, or small farms in which the virus is not maintained), infection of pigs within the first weeks after birth results in clinical signs. Promoting virus circulation in the farm so that gilts are immune at farrowing prevents disease in piglets.

Once clinical signs are evident, the disease will run its course; spontaneous recoveries are rare. Litters born 2–3 weeks after the onset of disease are usually protected because nonimmune gestating sows should have become infected and immune by farrowing. Piglets born to nonimmune sows early in the outbreak can be passively protected by parenteral inoculation with specific immune serum shortly after birth. Hyperimmune serum is not commercially available, but pooled serum collected from older sows (at the slaughterhouse) should be filter sterilized and tested to confirm presence of pHEV antibodies. No vaccines against pHEV are currently available.

Porcine torovirus

Relevance

Torovirus (ToV) particles were initially detected by EM in the feces of a 3-week-old piglet with diarrhea in England. Subsequent studies revealed a high seroprevalence (81–100%) in adults or young nursing piglets and high detection rates (50–75%) among subclinically infected weaned pigs (Kroneman et al. 1998; Pignatelli et al. 2010). Latter reports from Europe, North America, and South Africa suggested that ToV was endemic. In contrast, in Korea, only 6.4% (19 of 295) of diarrheic feces from 3- to 45-day-old piglets were positive for porcine ToV (Shin et al. 2010). Of these, about 74% also contained other enteric pathogens. Consequently, the link between porcine ToV and enteric disease is unclear, and there are no reports confirming porcine ToV pathogenicity or gut lesions.

Etiology

Porcine ToV represents a species within the genus *Torovirus* of the subfamily *Torovirinae* in the family *Coronaviridae*. The genomic organization, replication strategy, and properties resemble other members in the family *Coronaviridae* (de Groot et al. 2008). Like some betacoronaviruses, porcine ToVs also possess an HE protein. Notable differences from CoVs include a smaller N protein (approximately 18.7 kD) and a tubular nucleocapsid, leading to differences in ToV particle morphology (spherical, elongated, or kidney shaped) (Kroneman et al. 1998). Multiple clusters of porcine ToVs have been identified based on gene sequence analysis (de Groot et al. 2008; Pignatelli et al. 2010; Shin et al. 2010).

Epidemiology and immunity

Based on serologic and shedding data from clinically normal pigs or sows in European herds, ToVs were endemic in 14 farms tested. High seroprevalence rates (81%) were detected in sows on 10 Dutch farms by testing for cross-reactive VN antibodies to equine ToV (Kroneman et al. 1998). Similarly, 100% of sows, nursing, and older pigs in three farms in Spain were seropositive for ToV antibodies using an ELISA based on porcine ToV N protein (Pignatelli et al. 2010). Longitudinal studies revealed fecal shedding (80%) (RT-PCR or real-time RT-PCR) post weaning at 4–14 days for 1–9 days (Kroneman et al. 1998) or at 4 and 8 weeks post weaning (50–75%) (Pignatelli et al. 2010). In both studies, maternal antibody titers were initially high in piglets, declined at weaning, and then increased post infection at 11 or 15 weeks of age.

Because most pigs become infected with ToVs post weaning, maternal antibodies apparently provide at least partial protection. However, the immune correlates of protection to porcine ToV infection are not known. In one of four farms, it was postulated that ToV infection of suckling piglets in the presence of maternal antibodies delayed development of active immune responses such that these pigs, but not pigs from the other farms, shed the same ToV strain pre- and post weaning (Pignatelli et al. 2010). Genetically diverse ToV strains were detected within herds in the latter study and in Korean farms. The porcine ToVs were associated with sporadic infections among diarrheic pigs from 65 Korean farms surveyed (6.2% of farms positive) (Shin et al. 2010). Based on phylogenetic analysis of the S and N genes, the Korean ToV strains formed distinct branches with clusters corresponding to the farm of origin.

Diagnosis

Methods to propagate porcine ToVs in cell culture have not been described. For serologic studies, a cell culture-adapted equine ToV has been used to assess cross-reactive VN antibodies in swine (Kroneman et al. 1998; Pignatelli et al. 2010). Recently an indirect ELISA using recombinant purified porcine ToV N protein as antigen was developed (Pignatelli et al. 2010). In most, but not all cases, there was a good correlation between ELISA and VN tests. Discrepancies observed could reflect use of heterologous equine ToV antigen in VN, compromising detection of low titer antibodies.

Porcine ToVs have been detected in feces using IEM to identify antibody-aggregated ToV particles and differentiate them from other fecal porcine CoVs (TGEV, PEDV, and PDCoV) (Kroneman et al. 1998). For detection of ToV-specific viral RNA, RT-PCR and real-time RT-PCR targeting conserved regions of the porcine ToV N gene or the 3′ UTR of the genome have been described (Kroneman et al. 1998; Pignatelli et al. 2010; Shin et al. 2010).

Prevention and control

Based on the limited data available, the stress of transport, movement, and redistribution of pigs, even within multisite farms, could precipitate porcine ToV infection with similar or distinct co-circulating strains (Pignatelli et al. 2010). Thus, management practices applicable to control of other enteric CoV infections should be implemented for control of porcine ToVs.

Filoviruses

Hana M. Weingartl and Glenn A. Marsh

Relevance

In late 2008, outbreaks of severe disease were reported on several pig farms in the Philippines. The Philippine authorities sought help from the US Department of Agriculture (USDA) Plum Island Foreign Animal Disease Diagnostic Laboratory (FADDL) for diagnosis, and porcine reproductive and respiratory syndrome virus (PRRSV) was detected and isolated from the samples along with porcine circovirus 2 (PCV2). In addition, an unexpected cytopathic effect (CPE) was detected in Vero cell cultures, and, using a panviral microarray RNA, Reston virus (RESTV) was detected (Barrette et al. 2009). Follow-up studies of farmworkers in the Philippines detected antibodies to RESTV, suggesting human exposure. Experimental studies demonstrated that domestic swine are susceptible to infection with RESTV (Marsh et al. 2011), with the virus replicating to high titer in the absence of clinical signs.

Natural infection of pigs with Ebola virus (EBOV) has not been reported, although experimental inoculation study showed that pigs are susceptible to EBOV infection (Kobinger et al. 2011). However, the role of domestic and/or feral pigs as either reservoirs or amplifying host is still unclear.

Etiology

The family *Filoviridae* falls under the order *Mononegavirales* and is divided into three genera: *Marburgvirus*, *Ebolavirus*, and *Cuevavirus* (Afonso et al. 2016). The *Ebolavirus* genus contains five species, namely, *Reston ebolavirus*, *Bundibugyo ebolavirus*, *Sudan ebolavirus*, *Zaire ebolavirus*, and *Taï Forest ebolavirus* with respective viruses, such as Reston virus (RESTV), Bundibugyo virus (BDBV), Sudan virus (SUDV), Ebola virus (EBOV), and Taï Forest virus (TAFV) (Kuhn et al. 2010). The RESTV isolates from the Philippine outbreak (Reston-08 A, C, and E) were approximately 97% identical at the nucleotide level to the original 1989 RESTV isolate (Barrette et al. 2009) and, therefore, were not assigned a new species designation.

Filovirus virions have a characteristic filamentous shape of uniform diameter (80 nm) and variable length (800–1400 nm). This permits the use of electron microscopy for preliminary determination of the virus family (Figure 32.1). The structure of filovirus virions is the most complex in the order *Mononegavirales*. This complexity provides for highly flexible virions, presumably to allow the long particles to bend without breaking the genome (Booth et al. 2013).

Ebolaviruses are negative-strand RNA viruses with approximately 19 kb non-segmented genome, composed of seven genes (3′-NP-VP35-VP40-GP-VP30-VP24-L-5′), each coding for one protein, except for the GP gene. As a result of RNA editing and subsequent cleavage of the protein products by cellular proteases, four proteins are expressed from the GP gene: sGP, delta peptide, ssGP, and $GP_{1,2}$. The RNA genome is protected by a helical protein capsid with the major component being the nucleocapsid protein (NP), while the L (large) protein (RNA-dependent RNA polymerase) represents a minor component. The NP and virus protein 30 (VP30) (transcription factor) form an inner nucleocapsid directly associated with the outer nucleocapsid, which is composed of VP35 (polymerase cofactor) and VP24. The outer nucleocapsid is connected via putative low density projections to the matrix VP40 layer on the cytoplasmic side of the viral envelope, derived from host plasma membrane. Glycoprotein $GP_{1,2}$ trimers are either embedded in the outer layer of the lipid envelope or secreted after cleavage by the host TNF-α-converting enzyme (Booth et al. 2013; Martin et al. 2016).

Following viral attachment to one of the numerous proteins in the cell membrane that can serve as a cellular attachment factor, the filoviruses enter the cells mainly by micropinocytosis, and the $GP_{1,2}$ is proteolytically

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

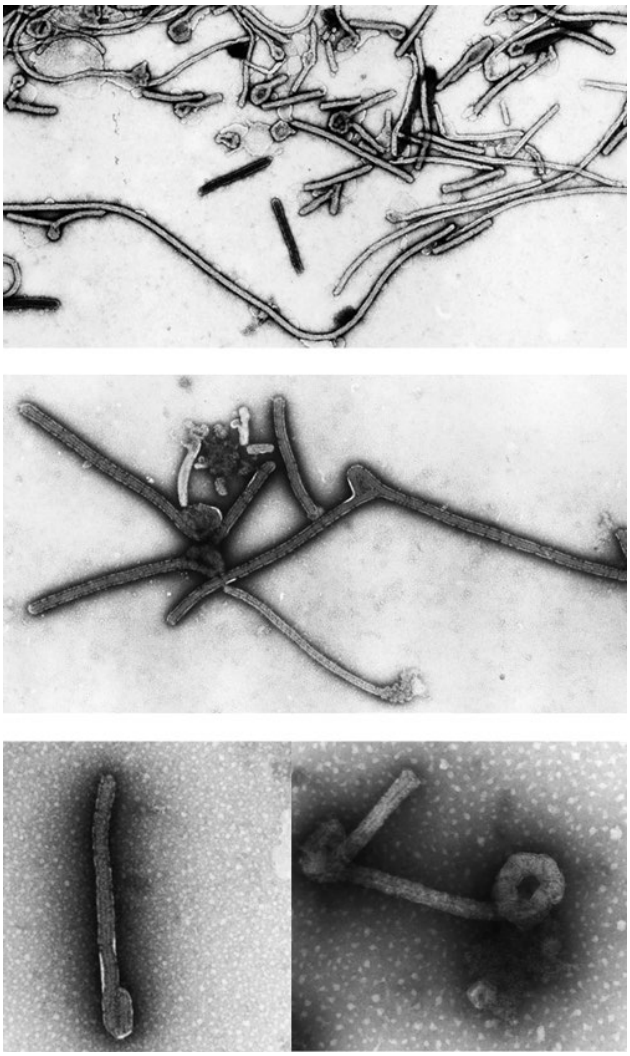

Figure 32.1 Electron micrographic images of different preparations of RESTV. Negative stain, increasing magnification from the top to the bottom. *Sources:* Two upper images from Roland et al. (2012); bottom images of individual particles courtesy of Lynn Burton.

activated in downstream endosomal vesicles. Interaction of cleaved GP_1 with NCP1 (Niemann–Pick C1 protein) anchored in the late endosomes/lysosomes triggers conformational changes in the GP_2, which leads to membrane fusion and release of the nucleocapsid into the cytoplasm. Filoviruses replicate in the cytoplasm in typical negative-stranded RNA virus fashion: primary transcription by the L protein and the VP30 transcription factor from the negative-sense genome is followed by translation, which leads to secondary transcription and production of more viral proteins. Once the viral proteins accumulate, RNA synthesis switches to genome replication. The eventual accumulation of nucleocapsid proteins results in the genome encapsidation. The $GP_{1,2}$ is glycosylated during transport through the endoplasmic reticulum and Golgi apparatus. The virion maturation is driven by the VP40 embedded in the internal layer of the plasma membrane, and the mature virions are generated by budding through the lipid bilayer of the host plasma membrane (Martin et al. 2016).

Several cell lines from different species were found to be susceptible to ebolavirus; however Vero (e.g. E6) cells have been found to be the most permissive, with the highest infectious titers in the range of 1×10^6 PFU/mL.

Public health

RESTV does not cause disease in humans and, therefore, is not a significant public health issue. However, because the mechanisms of attenuation in humans are not understood, RESTV is handled at Biosafety Level 4 (BSL-4). The concern is that outbreaks of RESTV with multiple pig-to-pig transmissions could result in virus mutations and the emergence of pathogenic strains able to cause disease in pigs and possibly humans. Identification and control of outbreaks is a key to prevent ongoing replication in pigs.

EBOV is a zoonotic virus and Ebola virus disease (EVD) outbreaks are of high public health significance. Historically, the number of outbreaks, cases, and fatalities was limited, and outbreaks were readily controlled. In December 2013, the first case of EVD occurred in Guinea. The outbreak, mainly in Guinea, Sierra Leone, and Liberia, lasted until 2016 and resulted in approximately 29,000 cases with over 11,000 fatalities. Although EVD was formerly known as Ebola hemorrhagic fever, bleeding was present in only approximately 30% of patients. In this outbreak, EVD was characterized by multiple nonspecific symptoms, such as fever and fatigue, followed by anorexia, headache, and gastrointestinal symptoms (Cherif et al. 2017).

Due to the apparent transmission of RESTV from pigs to humans in the 2008/2009 outbreak of highly pathogenic PRRSV, there is a concern that African ebolaviruses could also infect pigs (both domestic and wild) and the pigs then can serve as a source of infection for humans (Atherstone et al. 2017). In fact, increased die-outs in red river hogs (*Potamochoerus porcus*) in areas with EBOV outbreaks (Lahm et al. 2007) suggest that wild pigs could be infected with ebolavirus during outbreaks.

Reston virus

Epidemiology

Prior to the diagnosis of RESTV infection in swine in 2008, RESTV had only been associated with outbreaks of disease in nonhuman primates from the Philippines.

In addition to swine in the Philippines (Barrette et al. 2009; Sayama et al. 2012), RESTV infection of pigs in China has also been reported (Pan et al. 2014). The natural reservoir of RESTV in the Asian region has not been identified; however, several bat species in the region have been demonstrated to have antibodies that react to the virus.

Nonhuman primates are the only animals that have been demonstrated to develop fatal disease following infection with RESTV. Several humans have developed antibodies to the virus following exposure; however, disease associated with this exposure has never been recorded. This is consistent with observations in swine.

The mechanism of RESTV transmission in pigs is unknown. In experimentally infected pigs, high level of viral shedding from the nasopharynx was documented following oronasal challenge, with virus detected in nasal and tonsil swabs for up to a week after challenge (Marsh et al. 2011). This finding suggests that transmission via a droplet or aerosol route is possible; however, transmission studies have not been reported for pigs following exposure to RESTV. Virus has also been detected on rectal swabs from some animals on days 6 and 8 after exposure.

RESTV stability in the environment and susceptibility to disinfectant have not been reported, but it is expected to be similar to other filoviruses.

Pathogenesis, clinical signs, and immunity

Following exposure of 5-week-old pigs to RESTV, virus replication was observed in many different tissues. The highest levels of virus were observed in the lung and lymphoid tissues; however, virus was also detected in muscle tissue of some animals (Marsh et al. 2011). The infection profile was consistent with an acute infection, with no evidence indicating virus persistence in any tissue at necropsy on 28 days post inoculation (DPI). Clearance of virus was associated with seroconversion and occurred within 10–12 DPI. Antibodies (IgG) have been detected in pigs experimentally inoculated with RESTV within 6 DPI, and by 10 DPI all pigs had developed detectable antibody levels (Marsh et al. 2011).

In two studies of eight pigs each (Marsh et al. 2011), differences were observed in levels of viremia and virus shedding. The reason for these differences has not been determined; however, it was hypothesized that this difference may have been a consequence of season and underlying health status of animals. It is possible, although unproven, that a higher prevalence of subclinical respiratory infections in the winter may predispose animals to higher levels of virus replication. Importantly, despite the high levels of RESTV replication observed in animals following exposure, all animals remained clinically healthy, with no evidence of fever, respiratory disease, or skin lesions (Marsh et al. 2011).

Lesions

Lesions in pigs following exposure to RESTV are confined to the lymphoid and respiratory systems. Lymphadenomegaly affecting submandibular, retropharyngeal, and bronchial lymph nodes was a common finding in pigs necropsied on day 6 or 8 after exposure. Consolidation of lung lobes was also observed in some pigs, with RESTV antigen associated primarily with alveolar macrophages and also bronchoalveolar epithelial cells. Mild acute rhinitis was identified in all pigs, but antigen was only detected in submucosal lymphoid tissue and not the respiratory epithelium. Focal necrosis of tonsillar epithelium associated with neutrophil infiltrates has also been reported. By day 28 after exposure, no gross or histologic abnormalities are detected in animals (Marsh et al. 2011).

Diagnosis

Despite the fact that RESTV has not been associated with human disease, work involving infectious virus is restricted to BSL-4 laboratories in most countries. Standard culture techniques are suitable for RESTV, with Vero cells being the choice for virus isolation. Virus replication in Vero cells produces low-level CPE in 7–10 days, with immunostaining being a useful technique to confirm virus replication. Real-time RT-PCR assays targeting the L or the NP gene have been developed for the detection of RESTV in samples from pigs (Barrette et al. 2009; Marsh et al. 2011; Pan et al. 2014). Immunohistochemical staining of tissue samples can also be utilized to detect virus replication (Barrette et al. 2009; Marsh et al. 2011).

ELISA assays have been developed to detect antibodies to RESTV from swine samples, but assay performance has not been fully characterized (Marsh et al. 2011; Sayama et al. 2012). Other assays, such as virus neutralization, can be used to confirm ELISA results, although these assays require BSL-4 containment.

Prevention and control

There are no mechanisms to prevent or control RESTV (or other filovirus) infections in pigs. Given that the infection is subclinical, RESTV infections on pig farms would only be detected if routine screening for RESTV antibodies were conducted and positive results confirmed. Although the risk to humans is low, farms would probably be quarantined and depopulated. Due to the infrequency of infection in swine and the lack of disease, vaccines are unlikely to be available.

Ebola virus

Epidemiology

Human outbreaks of the four ebolaviruses – EBOV, SUDV, BDBV, and TAFV – so far occurred in a belt roughly corresponding to the tropical rain forest. Even the 2013–2016 outbreak started in a forest area of Guinea but spread through human-to-human contact throughout the West Africa, including major urban centers.

Several species of bats were determined to be disease-free ebolavirus reservoirs. Other species, such as duiker, and under laboratory conditions guinea pigs, mice, and pigs can also be infected by EBOV. Humans, great apes, and several species of nonhuman primates can be fatally infected by ebolaviruses, and there is a major concern that EBOV infections contribute to the severe decline of great ape populations, namely, gorillas, chimpanzees, and bonobos (Gonzalez et al. 2012). It has to be noted that the great apes eat pig carcasses and vice versa, which can contribute to wildlife ebolavirus transmission cycle, if the pigs are infected by EBOV in wild.

Field infections of swine with EBOV have not been reported, but pigs can be infected experimentally and transmit the virus to co-housed pigs and nonhuman primates (Weingartl et al. 2012). Shedding in pigs occurs predominantly via the respiratory tract, and infectious virus can be recovered from nasal washes and oral swabs for 3–14 DPI (Nfon et al. 2013).

Transmission of the virus to nonhuman primates housed in cages in the same room as EBOV-infected pigs is thought to occur via droplets, either by inhalation or fomites (Weingartl et al. 2012). Low amount of virus was also detected in feces, but only at 5 DPI. The virus in nasal wash (10^2–10^3 $TCID_{50}$/mL) was sufficient to infect contact piglets. A subsequent shedding in contact piglets in the range of 1×10^1–10^2 $TCID_{50}$/mL raises a question of whether virus spread in swine herds could be self-limiting (Kobinger et al. 2011).

EBOV can remain viable in liquid samples (such as blood) for many days, depending on temperature, but heating samples for 1 hour at 60 °C leads to inactivation. EBOV persisted in dried human blood for 7–10 days in the West African climate and remained viable on surfaces for days, including personal protective equipment, again depending on temperature and humidity. The virus can be inactivated with 70% ethanol or 0.5% sodium hypochlorite in minutes, and sodium hypochlorite was widely used for disinfection during the 2013–2016 outbreak. All filoviruses are also susceptible to lipid solvents and phenolic compounds. Animal facilities may be decontaminated by first removing organic material and then introducing formaldehyde vapor. A solution of 1% formaldehyde will also inactivate EBOV. On the other hand, EBOV is only moderately sensitive to ultraviolet (254 nm) irradiation (Cook et al. 2016; European Food Safety Authority 2014).

Pathogenesis, clinical signs, and lesions

EBOV pathogenesis in swine was described for experimental infections only. Four- to six-week-old pigs (Landrace) experimentally inoculated with 1×10^6 PFU/animal of EBOV-Kikwit via oronasal route developed clinical disease characterized by labored breathing, reluctance to move, and high rectal temperature (40–41.5 °C) starting at 4 DPI (Kobinger et al. 2011). In pigs, lungs appear to be the primary virus target. Virus antigen was detected in epithelial cells, endothelial cells, and alveolar macrophages, and massive infiltration of noninfected immune cells into the lungs was observed. This observation was different from the one made in the nonhuman primates co-housed with the pigs where virus antigen was also detected in lungs, primarily in macrophages; however there was no recruitment of other immune cells into the lungs (Weingartl et al. 2012).

Transient viremia (RNA detection) was observed only in some pigs at 5 or 6 DPI, and the infectious virus was detected in the lung, bladder, heart, liver, and trachea and also in draining lymph nodes of the respiratory tract, while viral RNA was present at 7 DPI in lung-associated submandibular and mesenteric lymph nodes, spleen, lung, tonsil, trachea, nasal turbinates, heart, liver, spleen, and intestine (Kobinger et al. 2011).

Age-related difference between 4- and 6-week-old piglets was observed in terms of severity of the respiratory signs: while older piglets suffered from severe acute respiratory distress, only some of the younger piglets had labored breathing. However, other age groups were not experimentally inoculated in these studies (Kobinger et al. 2011; Nfon et al. 2013; Weingartl et al. 2012).

Infection in pigs can be inapparent or with range in severity of respiratory clinical signs (rate increasing from 35 to more than 80 breaths per minute – labored with strong abdominal component) and can resemble other diseases of swine that affect the respiratory tract such as swine influenza or porcine reproductive and respiratory syndrome. Incubation period following high dose challenge is about 3 days, when the shedding starts, followed by clinical signs about a day later. Due to low number and narrow age span of the experimental animals, it is difficult to comment on morbidity and mortality rates, but it appears that both can be low in comparison with nonhuman primates, as recovery was observed early post inoculation in younger animals that were not euthanized (Weingartl et al. 2012).

Gross lesions were observed only in lungs (Figure 32.2a) and included lobe consolidation with individual lobules

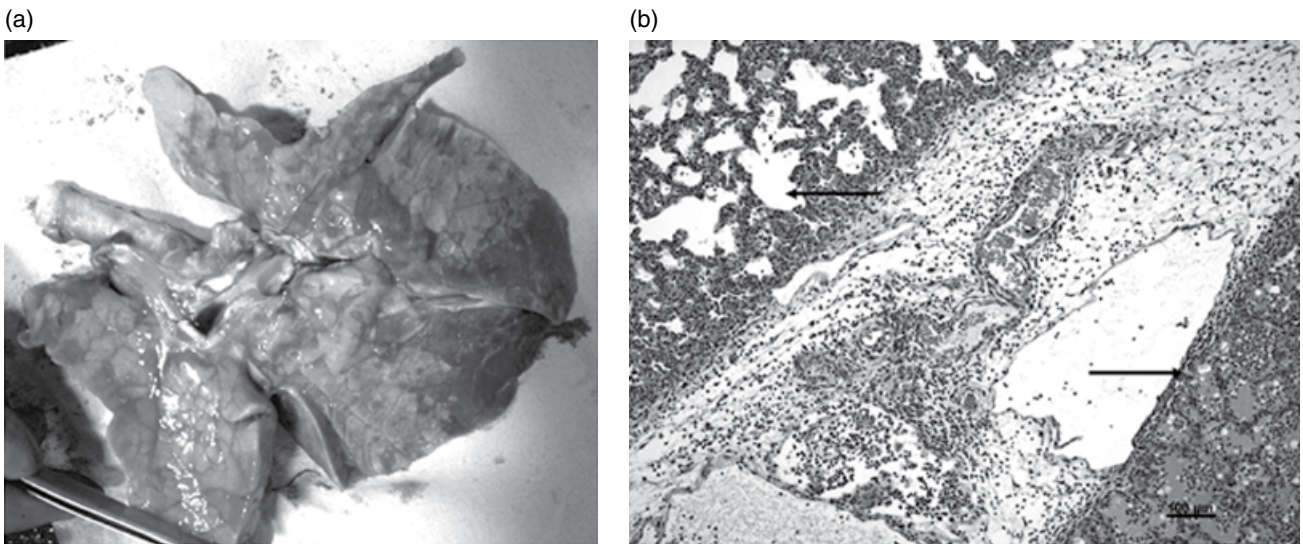

Figure 32.2 Lungs of 6-week-old piglet 5 days after inoculation with EBOV. (a) Macroscopic lesions. Lungs with consolidated lobes and dark-colored severely affected lobules. (b) Microscopic lesions. Left arrow indicates a relatively unaffected lobule; right arrow indicates a severely affected lobule with alveoli filled with fluid and inflammatory cell exudate. The interlobular septum is edematous, with vasculitis and inflammatory cell infiltrate. *Source:* Courtesy of James Neufeld.

of darker (plum) color. This pattern corresponded with bronchointerstitial pneumonia; the microscopic lesions localized to affected lobules (Figure 32.2b).

Diagnosis

Since ebolavirus infections of swine can resemble a number of respiratory diseases, diagnosis will require laboratory confirmation. Methods of virus detection include virus isolation and virus RNA and antigen detection that could be performed on inactivated samples under lower biosafety conditions.

Vero cells (E6, CV1, V76) are commonly used for virus isolation and propagation. Productive infection produces CPE in 9–10 DPI. Confirmation of virus isolation can be also performed by plaque assay combined with immunostaining, which can distinguish between the virus species (e.g. SUDV from EBOV). Diagnostic work involving live EBOV is, however, restricted to BSL-4 laboratories.

Viral RNA in samples can be detected using real-time RT-PCR, validated for swine samples (Pickering et al. 2018), and the presence of viral antigen in tissues can be confirmed by immunohistochemistry (Kobinger et al. 2011).

Methods of antibody detection available for the BSL-4 laboratories include virus neutralization, for example, microtiter plaque reduction assay (mPRNT), followed by immunohistochemical detection. Indirect IgG ELISA detecting antibodies against recombinant NP validated for swine serum samples heat inactivated at 60 °C for 1 hour is possible to perform under lower biosafety conditions. Confirmatory testing to exclude false positive samples can be done preferably by immunoblot using recombinant NP antigen, or at BSL-4 laboratory by mPRNT (Pickering et al. 2018).

Immunity

Under experimental infections with EBOV, striking differences in severity of the disease were observed between the 4-week-old and 6-week-old piglets (Kobinger et al. 2011; Nfon et al. 2013; Weingartl et al. 2012). This may be linked to the rapid development of the immune system that occurs in pigs between 3 and 6 weeks of age. It appears that dysregulation/over-activation of the pulmonary proinflammatory response causes the immunopathogenesis of ZEBOV infection in 6-week-old piglets (Nfon et al. 2013). Infiltration of neutrophils and monocytes/macrophages into the lungs, where only the macrophages are infected, was observed in all inoculated piglets, but the degree of the infiltration was far more severe in the 6-week-old animals. Genes for proinflammatory cytokines, acute-phase proteins, and chemokines were upregulated in lungs. Systemic effects included a decline in the proportion of monocyte/dendritic cells and B cells (Nfon et al. 2013).

The first IgM response was detected at 5 or 6 DPI (IgM capture ELISA using whole EBOV antigen) (Nfon et al. 2013). IgG against the recombinant NP was first detected at 7 DPI, depending on the animal. Virus neutralizing antibodies became detectable starting at 10 DPI (Pickering et al. 2018).

Flaviviruses

David T. Williams, John S. MacKenzie, and John Bingham

Overview

Flaviviruses are a diverse group of viruses that include several important pathogens, such as yellow fever virus (YFV), dengue virus (DENV), Japanese encephalitis virus (JEV), West Nile virus (WNV), Murray Valley encephalitis virus (MVEV), Saint Louis encephalitis virus (SLEV), and Zika virus (ZIKV). Taxonomically, they belong to the family *Flaviviridae*, genus *Flavivirus*, which includes 53 recognized species and 19 unclassified viruses (ICTV 2017). Flaviviruses are divided into three groups based on vector association: tick-borne, mosquito-borne, and no known vector. This chapter will focus on JEV, the most important flavivirus pathogen of swine. We will also consider two other flaviviruses, WNV and MVEV, which can infect pigs and may play a role in the transmission cycle of these viruses. Japanese encephalitis (JE) and West Nile (WN) fever are OIE-listed diseases, in recognition of their propensity to spread and zoonotic potential.

Flavivirus infections cause a range of diseases in animals. Most infections lead to subclinical infection consisting of viremia, which may be low level and of short duration. A proportion of infections lead to more serious outcomes, including neurological disease, kidney disease, reproductive failure, and, in humans, hemorrhagic syndrome. It is likely that the underlying pathogenesis is similar across the viral lineages and host species and that there is a high degree of commonality in potential disease presentation. Therefore, while it is important to consider the disease entities reported for swine, it is worthwhile also to bear in mind that disease syndromes similar to those found in other species may occur. Indeed, new flaviviral syndromes and presentations have been described in recent years (Murray et al. 2010; Ricklin et al. 2016b), leading to the belief that the flaviviruses and the diseases they cause are probably more varied than originally thought. As flaviviruses move into new geographical ranges, as they infect new species, and as they infect hosts under varied physiological and pathological profiles, further new disease outcomes are likely to emerge.

The flavivirus genome is a single-stranded positive-sense RNA molecule approximately 11 kilobases in length. A single open reading frame encodes three structural proteins (capsid, pre-membrane [prM], envelope [Env]) and seven nonstructural proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B, NS5) and is flanked by noncoding regions (Lindenbach et al. 2013). Flavivirus virions are icosahedral in shape and are approximately 50 nm in diameter. Virus particles are enveloped by a host-derived lipid membrane containing the prM/M and Env proteins and have a buoyant density of 1.19–1.23 g/cm^3 (Russell et al. 1980). The envelope surrounds the nucleocapsid, which consists of capsid proteins and genomic RNA. The prM and Env proteins are involved in virus entry and particle assembly during cellular infection. The prM protein is enzymatically cleaved during virus egress to produce the M protein and mature virions. Flavivirus NS proteins have functional roles in viral polyprotein processing, viral RNA synthesis, and evasion of innate immunity. The noncoding regions contain conserved elements and secondary structures that are involved in viral RNA replication and translation.

Flaviviruses can be inactivated with various chemicals and disinfectants, including 3 mM binary ethylenimine, 3–8% paraformaldehyde, 2% glutaraldehyde, 1% hypochlorite, ethanol, isopropanol, and 0.05% Tween 20, as well as UV light (Mayo and Beckwith 2002; Muller et al. 2016; OIE 2013; Pyke et al. 2004a). The pH of the infected matrix or medium is also important for viability; ZIKV infectivity was highest at pH 9, whereas infectivity was lost at pH ≤4 or ≥12 (Muller et al. 2016). The thermal inactivation point of flaviviruses is 40 °C (OIE 2013), and virus present in serum or media can be inactivated by heating at 56 °C for 30 minutes (Fang et al. 2009). Incubation at 28 °C reduced the infectivity of WNV by 1000-fold after 4 days, while no reduction was found in

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

virus held at 4 °C (Mayo and Beckwith 2002). An evaluation of the environmental stability of ZIKV showed that drying virus culture for 18 hours reduced infectivity by 1000-fold; however, virus remained infectious for over 3 days (Muller et al. 2016). In infected mosquitoes, WNV or JEV RNA was detectable for up to 2 weeks after mosquito death under a variety of conditions, including high temperatures and humidity, but the ability to culture virus was lost after 24–48 hours (Johansen et al. 2002; Turell et al. 2002). These studies underline the importance of surface disinfection after handling potentially infected material, as well as the need for appropriate sample handling and transport for diagnostic testing.

Japanese encephalitis virus

Relevance

Epidemics of human encephalitis suggestive of JE occurred in Japan as early as 1871, and large summer outbreaks occurred in the 1920s and 1930s (Mackenzie et al. 2007). JEV was identified as the etiological agent in 1933 in Japan (Hayashi 1934) and subsequently isolated from *Culex tritaeniorhynchus* mosquitoes (Mitamura et al. 1938). The ecology of JEV was elucidated largely by early studies in Japan that demonstrated the importance of pigs in the amplification cycle (Scherer et al. 1959b). JEV is a major cause of human viral encephalitis and childhood viral neurological infection and disability in southern, eastern, and southeastern Asia, particularly affecting rural communities (Campbell et al. 2011; Mackenzie et al. 2007). JEV can also cause fatal encephalitis in horses. In pigs, infection with JEV can result in reproductive failure and can occasionally cause neurological disease in piglets.

Etiology

JEV exists as a single serotype and two major immunotypes can be recognized by various serological methods. There are five genotypes of JEV (Schuh et al. 2013; Solomon et al. 2003). Genotype 1 comprises strains from Cambodia, China, Korea, northern Thailand, Vietnam, Japan, India, Australia, and Taiwan. Genotype 2 is composed of strains from Indonesia, Malaysia, southern Thailand, Papua New Guinea, and Australia. Genotype 3 contains isolates from the known geographic range of JEV, with the exception of the Australasian region. Genotype 4 isolates have only been found in Indonesia. Genotype 5 strains have been found in Malaysia, China (Tibet), and South Korea. Over the past two decades, viruses belonging to genotype 1 have replaced circulating genotype 2 and genotype 3 viruses in several regions.

Public health

An estimated 68,000 human cases of JE occur annually in JE-endemic areas, with a combined population of over 3 billion (Campbell et al. 2011). Of these cases, approximately 75% occur in children aged 0–14 years. The majority of human infections are asymptomatic, with 1 in 50 to 1 in 1000 infections progressing to clinical disease (Vaughn and Hoke 1992). Approximately 20–30% of clinical JE cases are fatal, 30–50% develop long-term neuropsychological sequelae, and the remaining cases fully recover. Amplification of JEV in pigs is generally thought to precede epidemic transmission. However, epidemic activity in human populations can occur in the absence of large populations or high densities of pigs (Lord et al. 2015).

Epidemiology

JEV is a zoonotic virus maintained in nature by transmission cycles involving *Culex* sp. mosquitoes and certain species of wild and domestic birds and pigs as the vertebrate hosts (Burke and Leake 1988; Endy and Nisalak 2002). Humans become infected when bitten by an infected mosquito, but they are incidental, dead-end hosts. Of particular importance in the ecology of JEV is the interplay between rice cultivation, vector densities, and pig rearing in close proximity to human habitation (Gajanana et al. 1997; Kanojia et al. 2003; Le Flohic et al. 2013).

Pigs are the principal amplification hosts of JEV, especially in epidemic areas, and the maintenance hosts in endemic areas. They develop a high and prolonged viremia following natural infection, lasting 2–4 days and capable of infecting various mosquito species. In serological surveys, pigs consistently display higher virus titers than other domestic or wild animals. They are particularly attractive to the major mosquito vectors as the source of blood meals, providing a sensitive indicator of virus transmission in endemic areas (Burke et al. 1985b). Despite the potential risk to humans if raised in open pens near human habitation, pigs have been used as sentinel animals to monitor for virus activity in a number of countries, essentially serving as an early warning system. Recent results have suggested that JEV can transmit between pigs in the absence of arthropod vectors; virus was shown to be shed in oronasal secretions, and in-contact pigs were highly susceptible to infection by this route. Furthermore, it was found that virus replicated to high levels in the tonsils, and could persist in that site for at least 25 days, even in the presence of neutralizing antibody (Ricklin et al. 2016a). These results have considerable significance for JEV epidemiology and ecology, and further studies are urgently needed to verify the reports of direct transmission.

Horses, cattle, buffaloes, and goats are dead-end hosts (Mackenzie et al. 2007), but because they attract a number of the major vector species, especially *C. tritaeniorhynchus*, they make good potential hosts for surveillance and may act as "dampers" in an outbreak situation (Johnsen et al. 1974; Peiris et al. 1993). Other animals may have relatively high seroprevalence rates, such as sheep and dogs, but viremia levels are believed to be too low to infect mosquitoes (Banerjee et al. 1979; Johnsen et al. 1974).

JEV has been isolated from a number of bats belonging to the families *Pteropodidae*, *Rhinolophidae*, *Hipposideridae*, *Miniopteridae*, and *Vespertilionidae* (Mackenzie et al. 2016; Sulkin and Allen 1974), but most experimental studies of their potential role in maintenance and transmission have been carried out in microbats, in which viremia lasts as long as 25–30 days at a level sufficiently high to infect mosquitoes.

Wild birds, particularly ardeid species, are believed to be important maintenance hosts of JEV and may act as amplifiers in epidemics (Scherer et al. 1959a; Soman et al. 1977). JEV has been isolated from a number of avian species, but the most important is undoubtedly the black-crowned night heron (*Nycticorax nycticorax*). Chickens are rarely infected and may have a limited role in transmission or surveillance. Wild birds have been implicated in the spread of JEV to new areas (Scott 1988; Solomon et al. 2003).

JEV has been isolated from many mosquito species, but not all are believed to be competent to transmit the virus. There is a consensus that *C. tritaeniorhynchus* is the major vector throughout most of Asia, but other species may be locally important, such as *C. gelidus*, *C. vishnui*, *C. fuscocephala*, *C. pseudovishnui*, *C. bitaeniorhynchus*, *C. annulirostris*, *C. quinquefasciatus*, and *Mansonia uniformis* (Burke and Leake 1988; Rosen 1986; van den Hurk et al. 2009; Vaughn and Hoke 1992). The major *Culex* vectors of JEV are rice field-breeding species that bite during the night, particularly at dusk and dawn, and prefer animals to humans for blood meals.

The means by which JEV "survives" between epidemics and overwinters in its northern range has been the subject of speculation. There are four major hypotheses: (1) the virus overwinters in mosquito eggs after vertical transmission; (2) the virus survives in hibernating mosquitoes; (3) the virus survives in hibernating animals, such as reptiles or bats; and (4) the virus is reintroduced each year by migratory birds or even by mosquitoes blown by prevailing winds from endemic areas. Possibly, each of the four methods contributes to overwintering in different situations. In support of the first hypothesis, vertical transmission occurs in several *Aedes* and *Culex* species mosquitoes in nature and under laboratory conditions (Rosen et al. 1989).

Pathogenesis

Much of our knowledge of flavivirus pathogenesis comes from model species infected with various viruses, particularly JEV, WNV, SLEV, tick-borne encephalitis virus, and MVEV. The pathogenesis of flaviviruses that have been studied to date is essentially similar. Flavivirus infections are initiated following the bite of an infected mosquito or tick, although recent evidence suggests that contact transmission between pigs may also play a significant role (Ricklin et al. 2016a). The virus is believed to initially replicate in the keratinocytes of the skin and is transferred to the lymph nodes within dendritic cells before transfer to the circulation (Johnston et al. 2000). Viremia leads to dissemination within a range of parenchymal tissues. In mammals, viral replication has been demonstrated by histological assay in neural cell bodies (brain and ganglia), in connective tissue, and in skeletal, cardiac, and smooth muscle (Bingham et al. 2014). Replication probably also occurs in lymphoid tissues, particularly tonsil, as high viral RNA loads have been detected therein (Ricklin et al. 2016b), although the precise cell type in which replication takes place has not been determined. The cell and tissue tropism range and replication amount are markedly extended in immunocompromised hosts (Armah et al. 2007; Guarner et al. 2004). The incubation period (time from exposure to first clinical signs) is 2–9 days for 75% of human cases (Rudolph et al. 2014). Viremia is detectable usually within 1–5 days postinfection (DPI) and persists for approximately 4–5 days (Huang and Wong 1963; Ricklin et al. 2016b), falling with the rise of circulating antibody. Virus can reach the central nervous system (CNS) as early as 3 DPI (Monath et al. 1983; Yamada et al. 2004). How the virus enters the brain is not known, but is believed to be either via the olfactory mucosa, where there is no blood–brain barrier (Monath et al. 1983; Yamada et al. 2009), via direct disruption of the blood–brain barrier (Chang et al. 2015), or by transneuronal spread (Samuel et al. 2007). The severity of disease is, in part, determined by immunological factors of the host, as immunoincompetence results in high levels of disseminated virus in tissues (Armah et al. 2007; Guarner et al. 2004). Neonates and young animals appear to be more likely than adults to develop severe CNS infection.

JEV infection in pigs usually results in subclinical infection with viremia (Ricklin et al. 2016a). The circumstances under which clinical disease develops in pigs are not clearly understood, but it is likely that young age, underlying incidental disease processes, and lack of prior exposure to flaviviruses are factors that increase the likelihood that infection becomes established in the CNS and other organs. JEV in pigs may infect neurons, leading to a mononuclear cell meningoencephalitis with neurological signs (Ricklin et al. 2016b; Yamada et al. 2004),

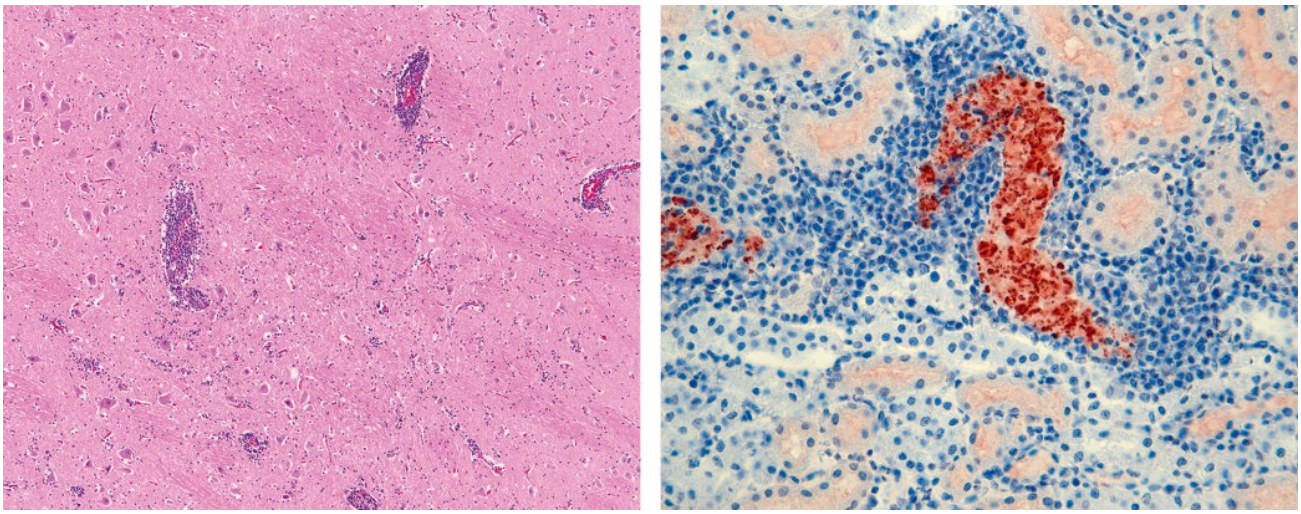

Figure 33.1 Japanese encephalitis virus infection in pigs, showing nonsuppurative inflammation in the brain (left; hematoxylin and eosin stain) and flaviviral antigen in a kidney tubule, with mononuclear cell interstitial nephritis (right; immunohistochemistry, flavivirus NS1 protein). No viral antigen was detected in affected brain. JEV was confirmed by viral sequence analysis. *Source:* Regional Animal Health Office 6, Ho Chi Minh City, Vietnam; laboratory diagnosis at Australian Animal Health Laboratory, Geelong, Australia.

or kidney tubules, resulting in interstitial nephritis (Figure 33.1; unpublished data from CSIRO, Australian Animal Health Laboratory, Australia and Regional Animal Health Office 6, Vietnam). Reproductive failure is also a recognized outcome of infection of adult pigs. JEV crosses the placenta to infect fetuses, causing abortion, stillbirths, mummification, and neonatal deaths (Burns 1950; Shimizu et al. 1954; Takashima et al. 1988). It may also infect testicular tissues in boars, causing infertility (Hashimura et al. 1954; Ogasa et al. 1977).

Clinical signs

Adult pigs do not generally show overt signs of infection. The most common disease manifestation in infected pregnant sows or gilts is reproductive failure leading to abortion and litters that contain stillborn or mummified fetuses or live, weak piglets (Burns 1950; Platt and Joo 2006; Takashima et al. 1988). Reproductive failure occurs in sows infected with JEV before 60–70 days of gestation; infections later in gestation do not appear to affect piglets. Natural infection of piglets with JEV is normally inapparent, but recent reports suggested that infection of young pigs 2–40 days of age may occasionally lead to a wasting syndrome with histological evidence of meningoencephalitis and with varying degrees of depression and hind limb tremors (Yamada et al. 2004).

JEV has also been associated with infertility in boars (Hashimura et al. 1976; Ogasa et al. 1977). Infection of boars may lead to edematous, congested testicles, resulting in lowered motile sperm counts and abnormal spermatozoa. These effects are usually temporary and complete recovery occurs in most instances.

Lesions

There are no characteristic lesions of JEV infection in sows that manifest reproductive failure. In boars, there is thickening of the tunica vaginalis and epididymis, with edema and inflammation of the epididymis, tunica vaginalis, and testis (Hashimura et al. 1976; Ogasa et al. 1977). Stillborn fetuses or live, weak piglets often present with hydrocephalus, subcutaneous (SC) edema, cerebellar hypoplasia, and spinal hypomyelinogenesis (OIE 2013). Hydrothorax, ascites, serosal petechiae, necrotic foci in the liver and spleen, and congestion in the lymph nodes, meninges, and spinal cord may also be found (Burns 1950). Infected piglets may present with diffuse nonsuppurative encephalitis, characterized by neuronal necrosis, neuronophagia, glial nodules, and perivascular cuffing in the brain and spinal cord (Yamada et al. 2004). Mononuclear cell interstitial nephritis is associated with viral replication in renal tubules (Figure 33.1).

Diagnosis

Agents causing clinical diseases characterized by abortion, fetal mummification or stillbirth, and encephalitis in pigs up to 6 months of age should be considered in the differential diagnosis. These should include pseudorabies (Aujeszky's disease) virus, classical swine fever virus, hemagglutinating encephalomyelitis virus, rubulavirus (blue eye paramyxovirus), Menangle virus, porcine brucellosis, porcine teschovirus, porcine parvovirus, porcine reproductive and respiratory syndrome virus, and salt poisoning (OIE 2013).

Laboratory diagnosis of JE normally involves virus isolation, reverse transcription polymerase chain reaction

(RT-PCR) and immunohistochemistry (IHC) for agent detection, and serological tests for antibody detection (Yang 2016). For specimen submission to the laboratory, placental tissues from fetuses, stillbirths, and neonates from cases of reproductive disease should be collected; virus may be detected in the brain, spleen, liver, or placenta. A full range of tissues should also be collected into 10% formalin for histopathology. Whole blood and serum samples should be collected for virus detection and serology. Paired serum should be collected 2–4 weeks apart. Unfixed tissues and blood/serum should be chilled and transported under refrigerated conditions. If delays in transit of ≥48 hours are anticipated, specimens should be frozen and shipped on dry ice.

Definitive diagnosis depends on the isolation or detection of JEV in clinical specimens. Since viremia lasts only a few days and virus can rarely be isolated from either blood or cerebrospinal fluid (CSF), infected brain, spleen, liver, or placental tissues may provide the best chance of virus isolation. This can be achieved by inoculating tissue homogenates (or whole blood and CSF) intracerebrally into suckling mice or onto susceptible cells. A range of cells including primary chicken embryo, the continuous *Aedes albopictus* mosquito cell line C6/36, African green monkey kidney (Vero), and baby hamster kidney (BHK) cells are permissive for JEV infection. JEV does not normally cause cytopathic effect (CPE) in C6/36 cells. Therefore, further culture in vertebrate cells and/or detection of viral antigen or RNA may be required to confirm virus isolation. Confirmatory testing of brain homogenates of mice that succumb to inoculation should be performed in a similar manner.

Of the molecular methods available for detection of JEV, RT-PCR is most commonly employed in diagnostic laboratories to identify viral genome in clinical specimens or following culture. Several assays have been reported, including both conventional and real-time tests (Pyke et al. 2004b; Tanaka 1993; Yang et al. 2004). RT-loop-mediated isothermal amplification (LAMP) assays have been reported for molecular testing of JEV infections. LAMP offers a simplified and convenient assay format for nucleic acid testing without the need for sophisticated equipment or skilled personnel (Liu et al. 2012; Parida et al. 2006). When compared with real-time RT-PCR, RT-LAMP has been shown to perform with comparable levels of sensitivity for testing swine specimens (Liu et al. 2012). Multiplex PCR assays targeting JEV and other swine pathogens may be useful in achieving a diagnosis by the process of exclusion or for surveillance activities. These include conventional assays for detecting coinfecting DNA or RNA swine viruses (Xu et al. 2012), microsphere array assays for detection of closely related flaviviruses (Foord et al. 2014), or "syndromic" real-time PCRs for diagnosis of swine viruses associated with respiratory and reproductive disease (Wu et al. 2014; Zhang et al. 2015).

JEV antigen can be detected in serum specimens using flavivirus-specific monoclonal antibodies (MAb) and in fetal tissues using IHC (Iwasaki et al. 1986; Yamada et al. 2004). Detection of antigen in infected mouse brains can be performed by hemagglutination assay using sucrose/acetone extracts, followed by a hemagglutination inhibition (HI) test using JEV reference antiserum for typing (Yang 2016).

As for other flaviviruses, serological diagnosis of JEV infections is often based on detection of serum antibodies using ELISA, HI, immunofluorescent antibody (IFA), and virus neutralization (VN) assays (Beaty et al. 1995; Burke et al. 1987; Clarke and Casals 1958; Yang 2016).

In older pigs, interpretation of serological tests needs to take a number of factors into consideration, including vaccination history and age. Maternal antibody persists in some pigs for as long as 8 months (Hale et al. 1957). IgM antibody appears 2–3 days after infection and persists for at least 2 weeks (Burke et al. 1985a) and, in some animals, several months. There is a high degree of serological cross-reactivity between flaviviruses, especially among members of the JEV group, and care must be taken in interpretation of serological results (Williams et al. 2001). In locations where related flaviviruses are known to co-circulate, these should be included in parallel testing.

Various ELISA formats have been reported or are available commercially. IgM capture (MAC-) ELISA may be used for diagnosing acute or recent infections (Pant et al. 2006). Competitive and indirect ELISAs have been developed and applied to the detection of antibody responses to JEV, including for seroprevalence studies (Kolhe et al. 2015; Pant et al. 2006; Williams et al. 2001; Yang et al. 2006). The HI test has also been used in serosurveys of pigs or wild boars (Nidaira et al. 2014; Yamanaka et al. 2010). To resolve cross-reacting antibody responses, the more specific VN test is recommended. Of the different formats described, the plaque reduction neutralization test (PRNT) is the most specific, particularly when the 90% threshold is applied. The specificity of NT antibody response can be confirmed by the demonstration of a rise in titers between paired serum samples. Results may be considered significant for the identification of JEV if titers are ≥ fourfold than a reaction against any related flavivirus. However, VN tests are technically difficult, are time consuming, and may not always yield clear results. Measurement of the magnitude of antibody response and relative differential of serum antibody titers against different flaviviruses can also be used to evaluate the significance of serological results (Pant et al. 2006). Since the viral NS1 protein is only produced by natural infection, ELISAs to detect NS1 antibodies can be used to differentiate infected from vaccinated animals (DIVA), as described for horses (Konishi et al. 2004).

Immunity

The flavivirus proteins Env, prM, and NS1 are immunogenic and the most important for inducing protective immune responses (Pierson and Diamond 2013). The Env protein is a major component of the virion surface and the main target of neutralizing antibodies. Uncleaved prM is present in immature or partially mature virus particles released from infected cells and can also elicit host immunity. NS1 is absent from the flavivirus virion, but is expressed on the surface of infected cells and is secreted in high levels, mainly as a hexamer. Antibodies to NS1 can protect against infection *in vivo* via the complement pathway or Fc-γ receptor-mediated immune complex clearance (Chung et al. 2006; Schlesinger et al. 1987).

Cross-neutralizing antibody responses to JEV have been observed in pigs following experimental infection with closely related flaviviruses. Prior exposure to MVEV prevented or suppressed the level and duration of viremia following challenge with JEV and correlated with heightened levels of existing cross-reactive virus-neutralizing antibodies to JEV (Lunt et al. 2001; Williams et al. 2001). Similar booster responses occurred if infection with WNV was followed by challenge with JEV. However, levels of JEV viremia varied, ranging from undetected or low (Ilkal et al. 1994; Williams et al. 2001) to virus titers equivalent to primary infected animals (Lunt et al. 2001). This variation may reflect differences in virus strains, breed, or age of the pigs used. In regions hyperendemic for flaviviruses, cross-reactive immunity in pigs from prior infection with related flaviviruses may be expected to inhibit subsequent infection with JEV; thus, amplification and spread of the virus may be restricted, along with a reduced risk of porcine reproductive disease.

Prevention and control

The current JEV vaccines and future directions have been extensively reviewed (Halstead and Thomas 2011; Wilder-Smith and Halstead 2010; Yun and Lee 2014). Vaccine development has largely focused on human vaccines rather than vaccines for pigs. The most commonly used JEV vaccine for human use in endemic areas of Asia is a live attenuated cell culture-derived vaccine based on the SA14-14-2 strain (genotype 3) produced in China. Elsewhere, two other vaccines have been used: a Vero cell-derived inactivated (SA-14-14-2) vaccine in use since 2009, especially for travelers, and a chimeric YFV/JEV vaccine based on the YFV 17D vaccine strain, but with the prM and E protein genes of the JEV SA14-14-2 strain. The latter virus has been licensed for use in Thailand and Australia.

Inactivated, mouse brain-derived, or live attenuated vaccines have been used to prevent virus amplification or reproductive disease in pigs in Japan (Igarashi 2002), Taiwan (Fan et al. 2013), Nepal (Pant et al. 2006), and Korea (Nah et al. 2015). The live attenuated vaccine is more efficacious than the inactivated vaccine against natural and experimental infection (Daniels et al. 2002; Ueba et al. 1978). Vaccination of swine against JEV is not widely used for two reasons: (1) immunization of large numbers of newborn animals each year is costly, and (2) the period for effective immunization using live attenuated JE vaccine is limited by the presence of maternal antibodies (Igarashi 2002). However, in areas of high JEV endemicity, pig vaccination may be efficacious in reducing the incidence of pig infections and therefore the risk of human disease (Khan et al. 2014). The emergence of genotype 1 throughout much of Asia has raised concerns about the efficacy of genotype 3-based vaccines. A study of cross-protection based on serum from humans vaccinated with genotype 3 inactivated vaccines demonstrated cross-neutralizing responses to genotypes 1–4 using a PRNT, thus implying cross-protective capacity (Erra et al. 2013). However, similar studies using horse or pig sera from genotype 3 JEV-vaccinated animals from Korea and Taiwan showed little or no cross-neutralization to a local isolate belonging to genotype 1 (Fan et al. 2013; Kang et al. 2016). This highlights the importance of further cross-protection studies to determine whether vaccination with current genotype 3 vaccine strains can prevent viremia and reproductive disease in pigs following challenge with heterologous genotype strains.

JEV infection of pigs can also be controlled by preventing their exposure to infected mosquitoes, but this is usually not practical unless pigs are maintained in a mosquito-free environment. Mosquito management and control programs implemented for public health purposes in proximity of pig farming activities may also be expected to reduce mosquito biting activity and therefore swine infections.

West Nile virus

Relevance

WNV was first isolated in Uganda in 1937 from the blood of a febrile woman (Smithburn et al. 1940). It is one of the most widely distributed flaviviruses, with a geographic range encompassing Africa, the Middle East, Europe, Asia, and Australasia (Hubalek and Halouzka 1999; Murgue et al. 2002). WNV was detected in North America in 1999 when its introduction caused an outbreak in New York City (Nash et al. 2001). Since then, it has rapidly spread throughout mainland United States, to Canada, and to Latin America and the Caribbean.

Historically, WNV infections were associated with sporadic cases or occasional outbreaks of mild disease in humans, birds, and horses; only rarely were these

associated with neurological disease. However, from the mid-1990s, large outbreaks of severe disease involving high incidences of neurological infection in humans occurred in Europe, the Mediterranean Basin, and the United States (Hayes and Gubler 2006; McLean et al. 2002; Murgue et al. 2002). These were accompanied by large numbers of equine encephalitis cases and avian mortalities (Castillo-Olivares and Wood 2004; CDC 2002). In equines, approximately 10% of infected animals develop neurological disease, with mortality ranging from 10–20% to 40–60% (Castillo-Olivares and Wood 2004; Roche et al. 2013). Large numbers of mortalities in wild birds and commercial flocks have also occurred during epidemics in the United States and Europe; however mass mortality of susceptible bird species has occurred less frequently in Europe (Komar et al. 2003; Weinberger et al. 2001). Rare cases of WNV neurological disease have also been reported in sheep, alpacas, seals, alligators, squirrels, white-tailed deer, and reindeer (Heinz-Taheny et al. 2004; Miller et al. 2003, 2005; Palmer et al. 2004; Yaeger et al. 2004). Although WNV is a significant pathogen of human, birds, and horses, it is not known to be pathogenic for pigs.

Etiology

A wide spectrum of genetic diversity exists within the WNV species, with seven distinct phylogenetic lineages recognized (Rizzoli et al. 2015). Lineages 1 and 2 were the first described (Lanciotti et al. 2002; Scherret et al. 2001). Viruses belonging to these lineages are the dominant circulating types and are responsible for human and animal disease. Lineage 1 is divided into three clades: lineage 1a comprises strains from Africa, the Middle East, Europe, the Americas, and India, lineage 1b is made up of the Australian subtype Kunjin (KUNV), and lineage 1c is composed of human and mosquito isolates from India. Lineage 2 consists of the prototype Ugandan strain and strains from Africa, Madagascar, and Europe. Additional lineages of WNV comprise isolates from Europe, Malaysia, and West Africa. These have not yet been associated with disease. Within and between lineages and clades, virulent and attenuated strains have been characterized (Perez-Ramirez et al. 2017; Prow et al. 2016).

Public Health

Approximately 20% of human infections are symptomatic, typically manifesting as a self-limited WN fever (Rizzoli et al. 2015; Sejvar 2014). Less than 1% of infections develop into disease of the CNS (meningoencephalitis, encephalomyelitis). The incidence of severe disease increases with age, with the highest risk occurring in the elderly. Case fatality rates can range between 10 and 30% during outbreaks, and neurological sequelae can persist in over half of survivors 1 year after infection.

Epidemiology

WNV exists in endemic transmission cycles involving ornithophilic mosquitoes and birds. The virus can infect a remarkable range of vectors and vertebrate hosts, thus facilitating its rapid spread throughout the world. In the United States alone, the virus has been isolated from approximately 60 species of mosquitoes, >300 species of birds, and >30 species of non-avian hosts (Gubler 2007). *Culex* species mosquitoes are the most common vector, particularly those of the *Culex pipiens* complex, but WNV has also been isolated from species of *Aedes*, *Anopheles*, *Coquillettidia*, *Culiseta*, *Mimomyia*, and *Ochlerotatus* (Hall et al. 2002; Hubalek and Halouzka 1999; Komar et al. 2003). Evidence from serological surveys and experimental infections has established birds as the primary vertebrate hosts of WNV (Komar et al. 2003). Passerine species such as the house sparrow, blue jay, and common grackle are thought to be important for epidemic transmission in urban settings, while migratory species such as storks (order *Ciconiiformes*) may be important for long-range virus transmission and spread.

The majority of non-avian species infected by WNV, including humans and horses, are incidental hosts and are thought to play only minor roles, if any, in transmission. Serological evidence of WNV infection in domestic and feral pigs has been reported in Australia, Asia, the United States, and Europe (Escribano-Romero et al. 2015; Gard et al. 1976; Geevarghese et al. 1987; Gibbs et al. 2006; Pant et al. 2006), suggesting that pigs may be useful sentinels for WNV activity. There are limited reports of WNV isolation from pigs in the field (Ilkal et al. 1994). Furthermore, experimental infections indicate that pigs are generally poor amplifying hosts of WNV (Ilkal et al. 1994; Lunt et al. 2001; Platt 2004; Teehee et al. 2005). Viremic responses can vary from undetectable to moderate and appear to depend on the age of animals and virus strain. In weanling pigs experimentally infected subcutaneously with a NY99 strain, virus titers reached sufficient levels (10^4–$10^{5.5}$ $TCID_{50}$/mL) to infect blood-feeding *C. pipiens* mosquitoes (Platt 2004). However, the duration of peak viremia was relatively short, ranging from 0.2 to 1.1 days. This contrasts with that observed in passerine birds infected with a NY99 strain, in which titers exceeded 10^8 plaque-forming units/mL for 4 days (Komar et al. 2003). Unlike JEV in pigs, transmission between infected and noninfected control pigs housed together in experimental conditions was not found (Platt 2004; Teehee et al. 2005). Adult pigs also failed to become infected by ingestion when fed WNV-infected mice (Teehee et al. 2005), in contrast to cats.

Similar to JEV transmission, WNV occurs year-round in tropical and subtropical regions, but is epidemic in temperate regions. WNV can overwinter in hibernating adult mosquitoes (Nasci et al. 2001), and evidence of vertical transmission in *Culex* species mosquitoes has also been reported (Anderson and Main 2006), indicating potential mechanisms by which the virus can survive in temperate areas. Reintroduction of WNV by viremic migratory birds or perpetuation in persistently infected birds has also been proposed (Kramer et al. 2008). In addition, ticks may play a role in WNV maintenance and overwintering (Lawrie et al. 2004; Mumcuoglu et al. 2005).

Pathogenesis, clinical signs, and lesions

There is little information available on the pathogenesis of WNV in pigs. In experimentally infected domestic pigs, no clinical signs were observed (Platt 2004; Teehee et al. 2005; unpublished observations from CSIRO, Australian Animal Health Laboratory). Platt (2004) observed moderate perivascular cuffing in the brain and spinal cord tissue of infected weanling pigs in the absence of viral antigen. In a proportion of pigs with perivascular cuffing, meningoencephalitis was also evident. In the same study, a pregnant sow was infected during the second trimester of gestation. Fetus development was unaffected by maternal infection, no abnormal histological features were observed, and no viral antigen was detected in fetal CNS tissue.

Diagnosis

Serological diagnosis is the primary means of determining WNV infections (Dauphin and Zientara 2007; Ostlund and Monaco 2013; Sambri et al. 2013). Human and veterinary specimens may be tested by ELISA, HI, and PRNT for the diagnosis of clinical cases or for serosurveillance of domestic animals and wildlife populations, including domestic and feral pigs or wild boar. IgM and IgG ELISA test kits are commercially available. In many instances, serological testing involves initial screening by ELISA or HI, followed by PRNT to confirm positive samples. As described above for JEV, serological diagnosis of WNV can be complicated by the presence of cross-reactive antibody to closely related flaviviruses, such as JEV (India), Usutu (Europe), SLEV (North America), and MVEV (Australia); therefore, these should be included in parallel testing where relevant. Serological diagnosis of horses should also take into account WNV vaccination status.

WNV can be detected in clinical specimens (e.g. CSF, blood, or tissues) or mosquitoes following isolation in cell culture using conventional or real-time RT-PCR and by immunoassay. Cell lines used for virus isolation include Vero, rabbit kidney (RK-13), pig kidney, or mosquito cells (C6/36 or AP-61). Confirmation of WNV isolation can be done by testing culture extracts by immunoassay using WNV-specific antibodies or by RT-PCR.

Antigen-capture assays can be used to detect WNV particles in field-collected avian swabs and mosquito pools and in human serum (Burkhalter et al. 2006; Hunt et al. 2002) or secreted WNV NS1 protein in serum (Saxena et al. 2013). IHC staining of fixed tissue samples from infected birds and mammals has also been used to detect WNV antigen. Caution should be exercised when testing mammalian tissues using this method because many equine WN encephalitis cases yield false-negative results (Ostlund and Monaco 2013) and nonspecific binding of primary antibody to mammalian tissues has been reported (Kauffman et al. 2003). A method for IHC staining of pig brain and spinal cord tissue has been reported (Platt 2004).

Molecular diagnostic assays have been reported for the detection of WNV RNA in infected mosquitoes and clinical specimens, including conventional (Johnson et al. 2001) or real-time RT-PCR assays (Eiden et al. 2010; Lanciotti et al. 2000; Tang et al. 2006) and RT-LAMP assays (Parida et al. 2004). Specificity for selected WNV lineages is an important regional consideration. The real-time assays cited above can detect lineage 1 and 2 viruses co-circulating in Europe. In Australia, an RT-PCR was developed for the specific detection of WNV-KUNV (lineage 1b) (Pyke et al. 2004b), found only in the Australasian region where other WNV lineages are exotic. Fall et al. (2016) described a real-time RT-PCR assay for the detection and genotyping of lineages circulating in Africa. A pan-WNV real-time RT-PCR assay has also been recently reported for the detection of viruses belonging to all of the recognized lineages (Vazquez et al. 2016).

Prevention and control

There is no specific treatment available for WNV infection. Several veterinary vaccines have been licensed (Brandler and Tangy 2013; McVey et al. 2015). In the United States and Europe, cell culture-derived inactivated whole virus vaccines have been approved for use in horses. Live canary poxvirus-vectored vaccines expressing the WNV prM and Env genes have also been approved in the United States and Europe. In the United States, a chimeric live attenuated vaccine comprising WNV prM and Env genes in a YFV 17D genome backbone was licensed for equine use, but discontinued because of a high incidence of adverse events. A DNA vaccine encoding the prM and Env genes was approved for use in horses, but also discontinued. In addition, an inactivated human cell-derived whole virus vaccine was

approved for use in geese in Israel, and a cell culture-derived inactivated whole virus vaccine was licensed for use in alligators.

Vector control activities include reducing mosquito populations through source reduction and insecticides and public education to limit exposure to mosquito bites (Kramer et al. 2008). WNV surveillance involves identifying infection in humans, horses, wildlife, and bird populations (especially corvids and sentinel chickens), by either passive or active means, as well as mosquito trapping to monitor vector abundance and virus activity (CDC 2013). The use of predictive models that include climate data (temperature, rainfall), prior disease incidence, vector density, and avian mortality can predict the relative risk of virus activity (McVey et al. 2015).

Murray Valley encephalitis

Relevance

MVEV is the most important cause of arboviral neurological disease in humans in Australia. MVEV can cause fatal encephalitis in horses (Gard et al. 1977; Gordon et al. 2012; Roche et al. 2013) and has been associated with morbidity and mortality in young farmed ducks (unpublished data from CSIRO, Australian Animal Health Laboratory). Although pigs can be infected with MVEV, no disease association has been reported (Kay et al. 1985; Lunt et al. 2001). Pigs may, however, play a role in the maintenance of virus transmission.

Etiology

Isolates of MVEV are closely related antigenically and cannot be differentiated by standard serological techniques. Four genotypes of MVEV are recognized (Williams et al. 2015). Genotype 1 is the dominant type on mainland Australia, and the most recent strains from Papua New Guinea belong to this type. There are two distinct sublineages of G1 (A and B) that recently evolved and appear to have different patterns of transmission in Australia: G1B strains have been isolated from across the mainland, whereas G1A strains have not been detected outside the northwest of the country. Genotype 2 consists only of mosquito isolates from the northwestern Australia. The remaining genotypes each comprise single isolates from Papua New Guinea made in 1956 (G3) and 1966 (G4).

Public health

Epidemics of severe encephalitis were reported between 1917 and 1925 in eastern and southeastern Australia, but no etiology could be determined. MVEV was isolated for the first time from fatal cases during a major outbreak of encephalitis in the Murray–Darling river system of southeastern Australia in 1951 (French 1952). A second major outbreak occurred in 1974, and although 58 cases (13 fatal) were reported from all mainland Australian states, the majority of cases were observed again in southeastern Australia (Marshall 1988). In 2011, following record levels of rainfall, widespread virus activity occurred across Australia, which led to 17 human cases of MVE disease and 3 deaths (Selvey et al. 2014). Sporadic cases of disease occur between outbreaks, with almost all occurring in northern and northwestern Australia, where the virus is believed to be endemic. Most human infections are asymptomatic or cause mild febrile illness, and only approximately 1:150 to 1:1000 infected individuals develop encephalitis, with fatality and morbidity rates similar to those for JE (Knox et al. 2012).

Epidemiology

Although the major epidemics of MVE occurred in southeastern Australia in the last century, MVEV is now endemic in northern Australia. The virus is also found in New Guinea and probably the eastern Indonesian archipelago.

The principal vector, *C. annulirostris*, accounts for the majority of isolates. Based on serosurveys and experimental evidence, the main vertebrate hosts are thought to be water birds belonging to the orders *Ciconiiformes*, *Pelecaniformes*, and *Anseriformes* (Marshall 1988). In particular, herons have been implicated as having a prominent role in MVEV transmission. Experimental infections of animals indicated that other vertebrates might also contribute to the transmission cycle, including gray kangaroos and rabbits (high levels of viremia), dogs, and chickens (moderate viremia) (Kay et al. 1985). MVEV has also been isolated from sentinel chickens, suggesting a potential role in the transmission cycle (Campbell and Hore 1975).

The role of pigs in the ecology of MVEV remains unclear. Serosurveys demonstrated a high prevalence of seropositive feral pigs in eastern Australia (Gard et al. 1976). However, following experimental infections, pigs were found to produce only moderate to low-grade viremia (Kay et al. 1985). Since feral pig densities are extremely high in parts of northern and eastern Australia (Choquenot et al. 1996), it has been proposed that even if only a small proportion respond to infection with viremia capable of infecting mosquito vectors, a significant contribution may be made to the maintenance or amplification of MVEV (Marshall 1988). However, a study of host-feeding preferences of *C. annulirostris* in northern Australia showed that the majority of blood meals were obtained from marsupials (>60%), suggesting

that host-seeking vectors are diverted away from feral pigs (van den Hurk et al. 2003).

It is not well understood how MVEV resurfaces in regions where occasional or rare activity is found. Virus may be reintroduced by migratory viremic water birds or windblown mosquitoes. There is also evidence that MVEV can be maintained over dry periods in desiccation-resistant eggs of *A. normensis* (Broom et al. 1989). Thus, environmental factors such as wind, rainfall, and temperature are likely to affect transmission and maintenance.

Pathogenesis and clinical signs

No disease or clinical signs following MVEV infection of pigs have been reported. There is also no available evidence that infection leads to secondary amplification in reproductive organs or fetuses. Kay et al. (1985) performed experimental infections on domestic and feral pigs aged between 6 and 20 weeks. These animals responded with low to moderate, but variable, levels of viremia lasting from 1 to 5 DPI. In some pigs, titers were considered sufficient to infect *C. annulirostris*; however this was not empirically tested. Of significance was the infection of a single pregnant sow that farrowed 14 weeks after inoculation. No mummified fetuses, stillbirths, or birth defects in the neonates were reported. Although the sow did not develop detectable viremia, an HI antibody response was observed. Surprisingly, no antibodies were detected in the offspring, and half of these developed trace viremia after challenge with MVEV, indicating little or no protection from maternal antibody. Further studies involving pregnant sows are needed to fully assess the potential for reproductive disease following MVEV infection.

Diagnosis

The majority of MVEV infections are diagnosed using serologic assays (e.g. HI, VN, IgM-IFA, and competitive ELISA) (Williams et al. 2010). HI, VN assays, and ELISA have been used for antibody detection in serological surveys of feral swine or following experimental infections of pigs (Gard et al. 1976; Lunt et al. 2001; Williams et al. 2001). IgM capture ELISA may also be used to detect antibodies following recent infection.

MVEV can be cultivated using the same range of cell lines as JEV. Isolation of MVEV from clinical specimens or mosquitoes is typically achieved using Vero cells or C6/36 cells, followed by passage in Vero cells or other vertebrate cell lines. Intracerebral (IC) inoculation of suckling mice or chorioallantoic membranes of embryonated chicken eggs has also been used. A fixed cell enzyme immunoassay with NS1-specific antibody has been used for detection of MVEV antigen following culture (Broom et al. 1998). Conventional and real-time RT-PCR assays for the detection of viral RNA in extracts of culture isolates, human clinical samples, and infected mosquitoes have been reported (Niven et al. 2017; Pyke et al. 2004b; Williams et al. 2010). A RT-LAMP assay specific for MVEV has also been described (Gong et al. 2015). In addition, MVEV has been incorporated as a target for a multiplexed microsphere array assay for detecting viral RNA (Foord et al. 2014). IHC for detecting viral antigen has been described (Barton et al. 2015).

Prevention and control

There is no vaccine to protect against, or specific antiviral drugs to treat, infections with MVEV. Prevention is largely focused on public health measures informed by arbovirus surveillance and vector management and control programs (Selvey et al. 2014). In Australia, monitoring of sentinel chickens for seroconversion to MVEV is routinely carried out in most states. Mosquito trapping in the summer and autumn months is also performed to determine vector abundance and test for the presence of virus. These programs enable early detection and warning of MVEV activity.

Other flaviviruses

There are few reports of other flaviviruses causing infections in pigs. Notably, pigs have been used in preliminary studies to develop animal models of human infections caused by DENV and ZIKV (Cassetti et al. 2010; Darbellay et al. 2017). The anatomical and physiological similarities of pigs to humans, availability of immunological reagents, and genomic, transcriptomic, and proteomic tools make pigs an attractive alternative to nonhuman primates for studying human infectious diseases (Bassols et al. 2014).

Yucatan miniature pigs infected with DENV serotype 1 (DENV1) via the SC or intravenous routes produced virus NT antibodies; however viremia was only observed following SC infection (Cassetti et al. 2010). When SC-inoculated pigs were subsequently challenged with DENV1, rash and dermal edema were observed, accompanied by DENV immune complexes in the serum, suggestive of antibody-dependent enhancement (ADE) of infection.

Neonatal pigs were inoculated with ZIKV to evaluate their susceptibility and potential to model infection (Darbellay et al. 2017). IC, intradermal (ID), or intraperitoneal routes of inoculation resulted in the development of low-level viremia, as well as IgM and NT antibody responses, in piglets. Viral RNA was also detected in the urine, brain (IC only), and spleen of infected pigs. Clinical

signs (leg weakness, ataxia, and tremor) were only observed in 2/11 IC-inoculated pigs.

The results from these studies suggest that pigs could be used to investigate the pathogenesis of DENV and ZIKV infections and test human vaccines and antivirals, but additional research is required to further develop and refine these models.

The potential for pigs to serve as amplifying or maintenance hosts for ZIKV was also investigated using 3-month-old pigs inoculated by SC and ID routes (Ragan et al. 2017). No clinical signs were observed and viremia was not detected, nor was infectious virus in tissues collected at necropsy (7 DPI). All pigs seroconverted by day 7. Therefore, although it would appear unlikely that pigs could serve as possible reservoirs for ZIKV, they might prove useful as sentinel animals.

The possibility that other flaviviruses, including many obscure ones, may emerge to cause disease in swine should not be discounted.

Hepatitis E Virus

Xiang-Jin Meng, Patrick G. Halbur, and Tanja Opriessnig

Relevance

Hepatitis E virus (HEV), the causative agent of human hepatitis E, is an important public health problem in many developing countries in Asia and Africa. Hepatitis E is also endemic in industrialized countries. As a fecal–orally transmitted disease, contaminated water or water supplies are major sources of HEV infections in humans. The mortality associated with HEV infection in humans is typically low (<1%), but can be up to 25% during pregnancy. Meng et al. (1997) isolated and characterized the first animal strain of HEV, swine hepatitis E virus (swine HEV), from piglets in the United States. Although swine HEV only causes microscopic lesions of hepatitis in pigs and no signs of clinical disease (Halbur et al. 2001), it poses a zoonotic risk to humans via direct contact with infected pigs (Meng et al. 2002; Withers et al. 2002) or through consumption of undercooked pork (Feagins et al. 2007, 2008; Yazaki et al. 2003) or pork products (Colson et al. 2010; Cossaboom et al. 2016).

Etiology

HEV is classified in the family *Hepeviridae* (Meng 2010a,b, 2016), which consists of two genera: *Orthohepevirus* (all mammalian and avian HEV isolates) and *Piscihepevirus* (cutthroat trout virus) (Smith et al. 2014). Among the four species in the genus *Orthohepevirus*, the species *Orthohepevirus A* consists of at least seven genotypes: genotype 1 and 2 HEV are restricted to humans; genotype 3 and 4 HEV infect humans, pigs, and several other species (Meng 2016); genotype 5 and 6 HEV infect wild boars; and genotype 7 HEV infects camels (Smith et al. 2014). HEV is a spherical, non-enveloped virus particle of approximately 32–34 nm in diameter. Swine HEV cannot be efficiently cultivated in cell culture.

The genome of swine HEV is a polyadenylated, single-stranded, positive-sense RNA molecule of approximately 7.2 kb (Meng et al. 1998). The genome consists of three open reading frames (ORFs), a short 5′ noncoding region (NCR), and a short 3′ NCR. ORF1 encodes nonstructural proteins, ORF2 encodes an immunogenic capsid protein, and ORF3 encodes a small multifunctional protein. ORF2 and ORF3 are translated from a single bicistronic mRNA and overlap each other, but neither overlaps ORF1 (Huang et al. 2007).

Public health

Hepatitis E is a zoonotic disease for which pigs are a reservoir (Meng 2010b, 2016). Concerns for zoonotic infections include occupational exposures, consumption of contaminated pork, and transmission of swine HEV from pig xenografts to human recipients.

Genotypes 3 and 4 strains of swine HEV infected both rhesus monkeys and a chimpanzee. Conversely, genotype 3 and 4 strains of human HEV infected pigs (Meng et al. 1998; Meng 2010a,b). Today it is recognized that genotype 3 and 4 swine HEV strains are zoonotic and infect humans (Meng 2016), although the zoonotic potential for genotype 5 and 6 strains of swine HEV from wild boars remains unknown. Pig caretakers and swine veterinarians in both developing and industrialized countries are at an increased risk of acquiring HEV infection. For example, swine veterinarians in the United States were 1.51 times more likely to be positive for anti-HEV antibodies than other blood donors (Meng et al. 2002). Withers et al. (2002) reported that swine workers in a major swine-producing state (North Carolina) in the United States had a 4.5-fold higher anti-HEV antibody prevalence rate (10.9%) than control subjects (2.4%).

Infected pigs excrete large amounts of HEV in feces, thus posing a concern for environmental safety (Yugo and Meng 2013). HEV-containing pig manure and feces

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

could contaminate irrigation or coastal water, with concomitant contamination of produce or shellfish. HEV strains of swine origin have been detected in sewage water (Pina et al. 2000).

Sporadic cases of acute hepatitis E have been linked to the consumption of contaminated raw and undercooked pig liver (Yazaki et al. 2003). Chronic hepatitis E cases in organ transplant recipients are almost exclusively linked to the zoonotic genotype 3 and 4 HEV strains of swine origin (Kamar et al. 2015). Approximately 2% of the pig liver sold in grocery stores in Japan and 11% in the United States tested positive for swine HEV RNA. Furthermore, the contaminating virus present in pig liver from the grocery stores in the United States was fully infectious (Feagins et al. 2007). HEV RNA was also detected from pork products such as sausages and chitterlings (Colson et al. 2010; Cossaboom et al. 2016). These data provide compelling evidence for zoonotic HEV transmission via direct contact with infected pigs or via consumption of contaminated pig meats (Meng 2010b).

Epidemiology

Swine HEV infection is ubiquitous in pigs worldwide, regardless of whether HEV is endemic in the respective human population. Besides domestic pigs, swine HEV also infects wild boars. Under experimental conditions, rhesus monkeys and chimpanzees were susceptible to infection by both genotype 3 and 4 swine HEV (Meng et al. 1998).

HEV seroprevalence in pigs is age dependent: one study showed that most pigs younger than 2 months of age were seronegative, whereas the majority of pigs older than 3 months of age were seropositive (Meng et al. 1997). Infection generally occurs at 2–3 months of age, shortly after maternally derived antibodies wane. Infected pigs generally have a transient viremia lasting for 1–2 weeks and shed viruses in feces for 3–7 weeks (Meng et al. 1997; Takahashi et al. 2003).

Transmission of swine HEV among pigs is presumably fecal–oral, with feces from infected pigs probably the primary source of the virus. It is believed that pigs acquire infection through direct contact with infected pigs or through ingestion of feces-contaminated feed or water. However, experimental reproduction of swine HEV infection in pigs via the oral route of inoculation proved to be difficult (Kasorndorkbua et al. 2003). Therefore, other routes of transmission cannot be ruled out.

Infectious swine HEV present in commercial pig livers is completely inactivated by adequate cooking (e.g. frying or boiling for 5 minutes). However, incubation of the contaminated pig liver homogenates at 56 °C (133 °F) for 1 hour did not abolish virus infectivity (Feagins et al. 2008). HEV is thought to resist inactivation by acidic and mild alkaline conditions in the intestinal tract.

Pathogenesis

The pathogenesis of swine HEV is largely unknown. It is assumed that HEV replicates in the gastrointestinal tract after ingestion and subsequently spreads to its target organ, the liver. Virus replication in the liver has been demonstrated (Meng et al. 1998). Extrahepatic sites of swine HEV replication have also been identified in various tissues of pigs including small intestines, colon, and hepatic and mesenteric lymph nodes (Williams et al. 2001).

Clinical signs

HEV produces subclinical infection in pigs infected under natural or experimental conditions. The incubation period, from the time of infection to virus shedding in feces, ranged from 1 to 4 weeks (Halbur et al. 2001). The percentage of HEV-infected pigs within a herd is very high (up to 80–100% in some herds); however, the morbidity and mortality attributable to swine HEV infection is not known.

Lesions

Specific-pathogen-free (SPF) pigs experimentally infected with swine HEV remained clinically normal, but mild to moderate enlargement of hepatic and mesenteric lymph nodes was observed from 7 to 55 days post inoculation (DPI) (Halbur et al. 2001). Microscopic lesions characterized by mild to moderate multifocal lymphoplasmacytic hepatitis and focal hepatocellular necrosis were also common (Figure 34.1). Hepatic inflammation and hepatocellular necrosis peaked in severity at 20 DPI (Halbur et al. 2001). Pregnant gilts infected with swine HEV had mild multifocal lymphohistiocytic hepatitis, and individual hepatocellular necrosis was observed in some gilts. No HEV-associated lesions in the reproductive tract or fetuses were observed (Kasorndorkbua et al. 2003).

Diagnosis

Swine HEV is difficult to work with because it does not grow in cell culture or cause clinical disease in pigs. Currently, the diagnosis of swine HEV infection is based on polymerase chain reaction (PCR) and ELISA. A

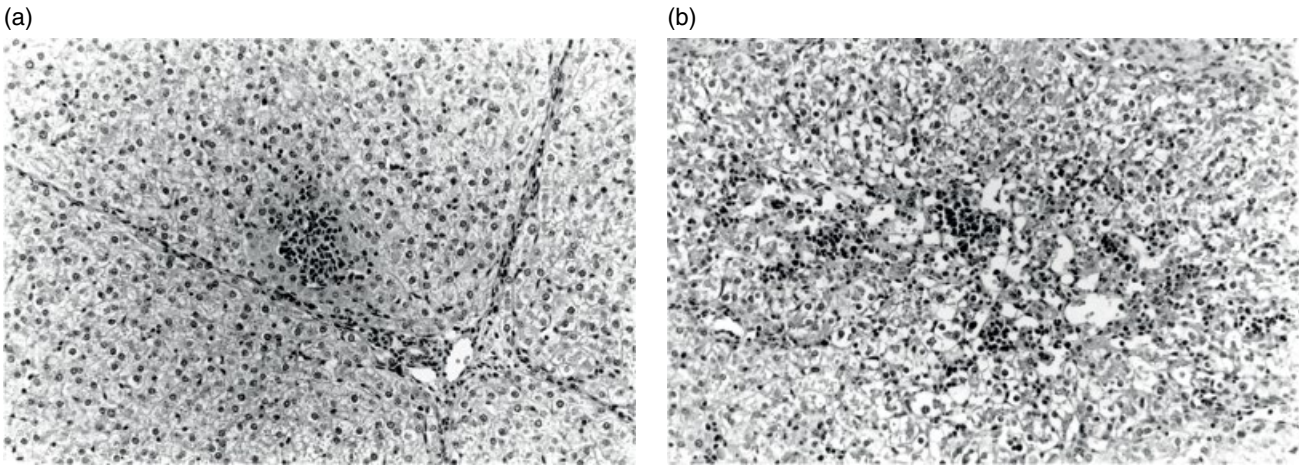

Figure 34.1 Histological liver lesions in pigs experimentally infected with swine HEV or human HEV. (a) Liver of a pig experimentally infected with the swine HEV showing mild focal infiltration of lymphocytes, plasma cells, and macrophages and mild diffuse inflammation in hepatic sinusoids at 14 days post inoculation (DPI). Hepatocytes are mildly swollen and vacuolated. (b) Liver of a pig experimentally infected with the US-2 strain of human HEV showing moderate lymphoplasmacytic and histiocytic hepatitis and severe vacuolar degeneration and swelling of hepatocytes at 14 DPI. Hematoxylin and eosin stain. *Source:* Halbur et al. (2001). Reproduced with permission of the American Society for Microbiology.

fluorescent microbead-based immunoassay has also been descried for the detection of HEV IgG antibody (Owolodun et al. 2013). The results of an ELISA based on swine HEV capsid antigen correlated well with those obtained with a genotype 1 human HEV capsid antigen (Meng et al. 2002; Zhang et al. 2011). Specific RT-PCR and real-time PCR assays have also been developed (Meng 2010a).

Immunity

The capsid protein of swine HEV is immunogenic and induces protective immunity. The capsid protein of swine HEV shares common antigenic epitopes with human and avian HEVs. Cross-challenge experiments in primates have demonstrated cross-protection following infection with different genotypes of human HEV strains (Emerson and Purcell 2003). Prior infection of pigs with a genotype 3 swine HEV protects against subsequent challenges with human genotype 3 and 4 HEV strains (Sanford et al. 2011). Piglets born to seropositive sows had maternal antibodies lasting 7–9 weeks (Meng et al. 1997). It is believed that maternal antibodies confer protective immunity to the piglets against swine HEV infection.

Prevention and control

The major concern for swine HEV is its zoonotic potential and associated pork safety concerns. A commercial vaccine against HEV ("Hecolin® HEV 239") is currently available for human use in China, but not in other countries. It may be advantageous to vaccinate pigs in order to minimize potential zoonotic transmission and eliminate pork safety concerns. Adequate personal and public hygiene can minimize HEV transmission.

Herpesviruses

Thomas C. Mettenleiter, Bernhard Ehlers, Thomas Müller, Kyoung-Jin Yoon, and Jens Peter Teifke

Overview

Herpesviruses infect a wide variety of animals from mollusks to mammals, and more than 200 distinct herpesvirus species have been recognized so far. Herpesviruses belong to the most complex and most widespread viruses. They are grouped in the order *Herpesvirales* based on the morphology of the virion and biological characteristics of their replication cycle (Davison 2010; Davison et al. 2009).

The order *Herpesvirales* includes three families: *Herpesviridae*, *Alloherpesviridae*, and *Malacoherpesviridae*. Herpesviruses infecting reptiles, birds, and mammals, which show a significant homology in their genomic sequence and gene arrangement, constitute the family *Herpesviridae*, whereas the phylogenetically more distant herpesviruses infecting amphibia and fish make up the family *Alloherpesviridae*. Herpesviruses from mollusks (ostreid herpesvirus 1 and haliotid herpesvirus 1) represent the type and only members of the *Ostreavirus* and *Aurivirus* genera of the family *Malacoherpesviridae*.

In addition to virion morphology, all herpesviruses share the capacity to establish a state of latency, resulting in lifelong association with the infected host. During latency, viral gene expression is restricted and only serves to maintain the latent state without production of infectious virus. After reactivation, infectious virus is again produced and spreads to infect other susceptible individuals. This striking biological feature is a hallmark of herpesvirus infections and explains their evolutionary success.

Within the family *Herpesviridae*, three subfamilies have been established based on distinct biology and genetic analyses: *Alphaherpesvirinae*, *Betaherpesvirinae*, and *Gammaherpesvirinae*. Herpesviruses relevant for swine are present in all three subfamilies (Table 35.1).

Members of the *Alphaherpesvirinae* have a rapid lytic replication cycle and establish latency (primarily) in neurons of sensory ganglia. They are grouped into five genera: genus *Simplexvirus*, which includes species *Human alphaherpesvirus 1* (human herpes simplex virus 1 [HSV-1]), species *Human alphaherpesvirus 2* (HSV-2), species *Bovine alphaherpesvirus 2* (bovine herpesvirus 2 [BoHV-2] [bovine mammillitis virus]), and other species; genus *Varicellovirus*, which includes species *Human alphaherpesvirus 3* (human varicella-zoster virus [VZV]), species *Bovine alphaherpesvirus 1* (BoHV-1, infectious bovine rhinotracheitis virus), species *Bovine alphaherpesvirus 5* (BoHV-5, bovine encephalitis herpesvirus), species *Equid alphaherpesvirus 1* (EHV-1), species *Equid alphaherpesvirus 3* (EHV-3), species *Equid alphaherpesvirus 4* (EHV-4), species *Suid alphaherpesvirus 1* (pseudorabies virus [PRV]), and other species; genus *Iltovirus* with infectious laryngotracheitis virus in the species *Gallid alphaherpesvirus 1*; genus *Mardivirus* with Marek's disease virus in the species *Gallid alphaherpesvirus 2*; and genus *Scutavirus* with Chelonid alphaherpesvirus 5 as type member.

Members of the *Betaherpesvirinae* generally specify larger genomes than either the alpha- or gammaherpesviruses and are characterized by extended replication cycles and strict host specificity. Genera *Cytomegalovirus* (type member human cytomegalovirus or human betaherpesvirus 5), *Muromegalovirus* (type member murid betaherpesvirus 1 or murine cytomegalovirus), *Roseolovirus* (type member human betaherpesvirus 6), and *Proboscivirus* (type member elephantid betaherpesvirus 1) have been recognized.

The *Gammaherpesvirinae* comprises herpesviruses with transforming potential and preferential association with lymphocytes grouped into genera *Lymphocryptovirus* (type member Epstein–Barr virus [EBV] or human gammaherpesvirus 4), *Rhadinovirus* (type member Kaposi's sarcoma herpesvirus [KSHV] or human gammaherpesvirus 8), *Macavirus* (type member suid gammaherpesvirus 3 [porcine lymphotropic herpesvirus 1, PLHV-1]; suid gammaherpesvirus 4 [porcine lymphotropic her-

pesvirus 2, PLHV-2]; suid gammaherpesvirus 5 [porcine lymphotropic herpesvirus 3, PLHV-3]; malignant catarrhal fever [MCF] virus, which can be alcelaphine gammaherpesvirus 1 [AlHV-1], ovine gammaherpesvirus 2 [OvHV-2], or caprine gammaherpesvirus 2 [CpHV-2], depending on species), and *Percavirus* (derived from perissodactyl and carnivore) containing equid gammaherpesvirus 2 (EHV-2), equid gammaherpesvirus 5 (EHV-5), and mustelid gammaherpesvirus 1.

Herpesvirus morphology

Herpesvirus particles consist of four structural elements: the core, which contains the linear, double-stranded DNA genome; the icosahedral nucleocapsid; a lipid envelope derived from the host cell into which viral proteins, mostly glycoproteins, are embedded; and the tegument, a proteinaceous structure linking the envelope and nucleocapsid similar to the matrix in RNA viruses (Figure 35.1). Whereas the basic morphology of the herpes virion appears identical in all members of the *Herpesvirales*, the diameter of the virus particle varies around approximately 200 nm depending on the amount of tegument. The approximately 100 nm diameter capsid shell exhibits icosahedral symmetry with a triangulation number of 16, thus consisting of 162 capsomeres with 150 hexons and 12 pentons.

Receptor-binding proteins as well as major immunogens are located in the viral envelope. Most of them are modified by the addition of carbohydrates and, thus, represent glycoproteins. Within the *Herpesviridae* glycoproteins B (gB), gH, gL, gM, and gN are conserved. Glycoprotein gB and a heterodimer of gH and gL constitute the core machinery mediating fusion between virion envelope and the host cell membrane, whereas the gM–gN heterodimeric complex functions during virion assembly.

Genomic organization and gene expression

The genomes of herpesviruses consist of linear, double-stranded DNA molecules varying in size between approximately 123,000 base pairs (simian varicellovirus) and approximately 300,000 base pairs (koi herpesvirus) encoding between 70 (VZV) and 229 (rhesus cytomegalovirus [RhCMV] [Macacine betaherpesvirus 3]) predicted proteins. Many herpesvirus genomes contain, besides singular "unique" sequences, extensive repetitive sequences that can either occur as tandem repeats at one site or in different locations in the viral genome in parallel or antiparallel orientation. Approximately 40 genes and gene products are conserved in all members of the *Herpesviridae* (Mettenleiter et al. 2008). They are mostly arranged in gene blocks and encompass proteins required for capsid structure and maturation, several tegument

and envelope proteins, the replication, cleavage, and packaging machinery for the viral genome, and proteins with enzymatic functions in nucleotide metabolism. Approximately half of the genes/proteins of each herpesvirus are not essential for viral replication in cell culture, including those relevant for transmission and spread *in vivo* and for immune modulation and evasion.

Herpesvirus replication

Herpesvirus replication is a complex process (Figure 35.2). Adsorption of free virions to target cells is mediated by virally encoded glycoproteins embedded in the virion envelope. This interaction triggers fusion between the virion envelope and the host cell membrane. Fusion primarily occurs at the cell surface, but may also be executed after endocytosis. After the release of the nucleocapsid into the cytosol, it is transported by cellular motor proteins along microtubules to the nuclear pore, where it docks with one vertex oriented toward the pore and viral genomic DNA is released into the nucleus through the nuclear pore.

In the nucleus, the linear viral genome circularizes, and viral gene expression ensues in a cascade-like fashion in the order: immediate-early (α-), early (β-), and late (γ-) gene expression. Capsid assembly occurs in the nucleus, and the resulting nucleocapsids leave the nucleus for final maturation in the cytosol by budding at the inner nuclear membrane, thereby acquiring a primary envelope that fuses with the outer nuclear membrane to release nucleocapsids into the cytosol. Viral tegument proteins then attach to the nucleocapsid prior to final (secondary) envelopment by a second budding process into vesicles of the trans-Golgi network, resulting in the formation of a complete virion within a cellular secretory vesicle. Release of mature virus particles then occurs by fusion of the vesicle with the plasma membrane. This prototypic replication cycle appears to be valid for all herpesviruses, although more or less subtle deviations may apply (Mettenleiter et al. 2009).

The spread of herpesvirus infections occurs not only via free virions but also by direct cell-to-cell spread. It is unclear whether complete virions or subviral particles (e.g. nucleocapsids) mediate this direct spread.

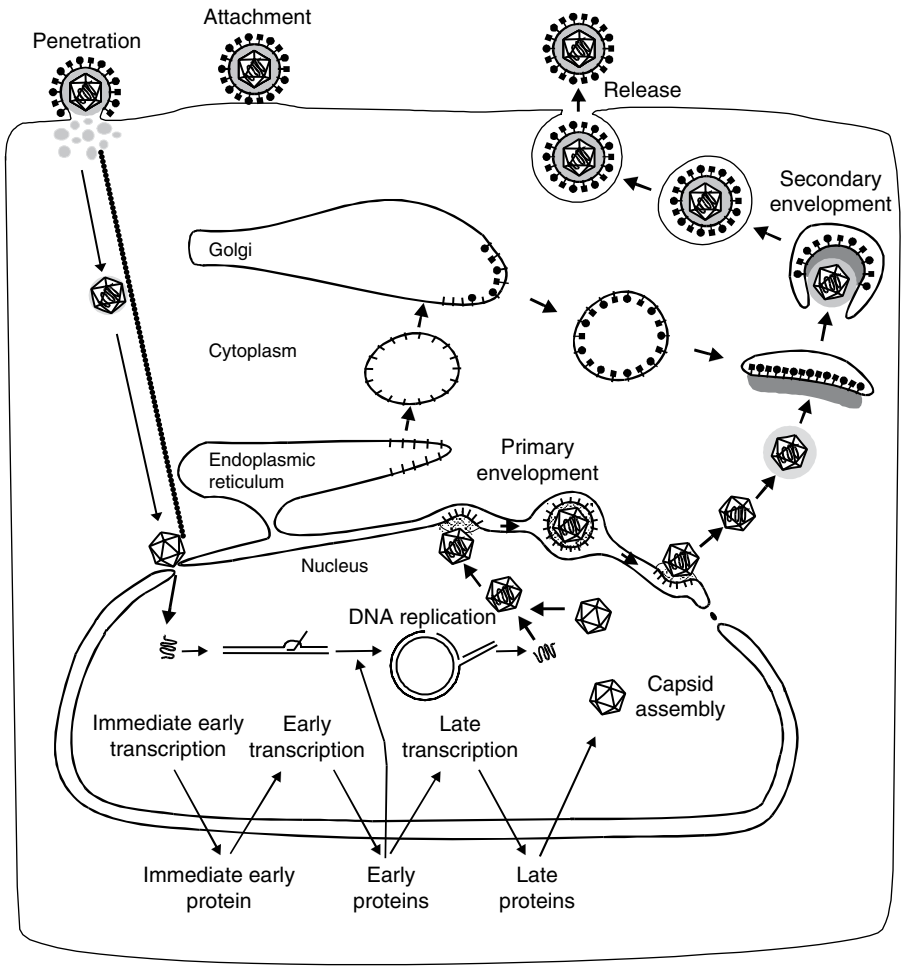

Figure 35.2 Herpesvirus replication cycle. *Source:* Mettenleiter (2004). Reproduced with permission of Elsevier.

The success of herpesviruses is mainly due to their ability to establish lifelong latency in the infected host. Thus, the viral genome persists indefinitely, even after clinical signs disappear. Spontaneous reactivation results in the formation and shedding of infectious virions able to infect susceptible animals. Alphaherpesviruses establish latency primarily in sensory neurons after replication in peripheral epithelial cells, whereas latency of betaherpesviruses is established in extraneural sites, for example, secretory glands. Latent gammaherpesviruses are mostly present in the cells of the lymphoreticular system, primarily B and T cells. Establishment and maintenance of the latent state are achieved by different mechanisms in the different herpesvirus subfamilies. However, they have in common a restricted expression of specific latency-related genes with a concomitant absence of lytic viral gene expression.

Suid alphaherpesvirus 1 (Aujeszky's disease virus; pseudorabies virus)

Relevance

Although the taxonomic species name *Suid alphaherpesvirus 1* indicates that the natural host of PRV is pigs, clinical PRV was first described in 1813 in cattle. This was because PRV infection in swine, particularly in older animals, may produce only innocuous respiratory signs or may be clinically inapparent, whereas productive infection in other susceptible species is invariably fatal and characterized by severe central nervous signs. Thus, the rabies-like clinical picture in cattle prompted the use of the term "pseudorabies" in Switzerland in 1849. Likewise, "mad itch" was used to describe the disease in cattle in the United States in the first half of the nineteenth century because PRV causes excessive pruritus.

In 1902, the Hungarian veterinary pathologist Aladár Aujeszky reported the isolation of the infectious agent from a diseased ox, a dog, and a cat and differentiated it from rabies (Aujeszky 1902). It could be passaged in rabbits reproducing the typical clinical signs. Guinea pigs and mice were also found to be susceptible, whereas chicken and doves were resistant. Thus, the disease became widely known as Aujeszky's disease (AD). It was not until 1931 that Richard Shope established that the agent of "mad itch" was also present in domestic pig holdings in the United States. Erich Traub in Germany was the first to cultivate PRV *in vitro* in organ explants in 1933. One year later, Sabin and Wright reported a serological relationship between PRV and herpes simplex virus, resulting in the inclusion of PRV into the herpesvirus group.

Role in swine health

Whereas PRV exhibits a wide host range capable of infecting basically all mammals except higher primates, only pigs are able to survive a productive infection and are thus considered the natural host. PRV infections in swine soared after the Second World War, particularly in Europe, when intensive pig breeding and farrowing were established. In the 1970s, PRV became a major scourge of pigs worldwide, distributed primarily by global movement of animals and animal products.

Although field isolates and strains differ in virulence, they can cause devastating losses by fatal infection of piglets and abortions in pregnant animals. Pigs exhibit a pronounced age resistance against PRV, with younger animals more susceptible to fatal infections characterized by neuronal signs, such as ataxia, convulsions, and sudden death. In contrast, older animals (>1 year) primarily present with respiratory distress or even subclinical infection. In pregnant animals, infection of fetuses results in resorption, mummification, or abortion.

Early eradication programs focused on elimination (culling) of infected herds met with some success, for example, in Great Britain or Scandinavian countries. However, advances in molecular biology produced the first so-called marker vaccines that allowed serological differentiation between vaccinated and infected animals. These vaccines provided the basis for cost-effective control and, eventually, PRV eradication (van Oirschot 1999).

Etiology

PRV belongs to the genus *Varicellovirus* in the subfamily *Alphaherpesvirinae* of the family *Herpesviridae* (Davison 2010). Only a single serotype is known. Isolates were initially differentiated by the restriction pattern of viral genomes after cleavage with sequence-specific endonucleases, such as Bam HI or Kpn I (Herrmann et al. 1984).

In 2004, the complete genome sequence of PRV assembled from various strains was described (Klupp et al. 2004) and recently supplemented by complete isogenic genome sequences (Szpara et al. 2011). The PRV genome encompasses approximately 140–143 kbp and contains at least 72 open reading frames (ORFs) encoding 70 different proteins (Figure 35.3). The viral genome consists of two unique portions, the long (U_L) and short (U_S) unique regions, and two large inverted repeats (terminal repeat [TR] and internal repeat [IR]), which bracket the U_S. This results in inversion of the U_S relative to the U_L and the existence of two isomeric forms of the viral genome, that is, a class D herpesvirus genome.

Laboratory cultivation

Due to its broad host range, many cell lines and primary cell cultures from different species are permissive for PRV. Cell lines generally used for PRV replication and

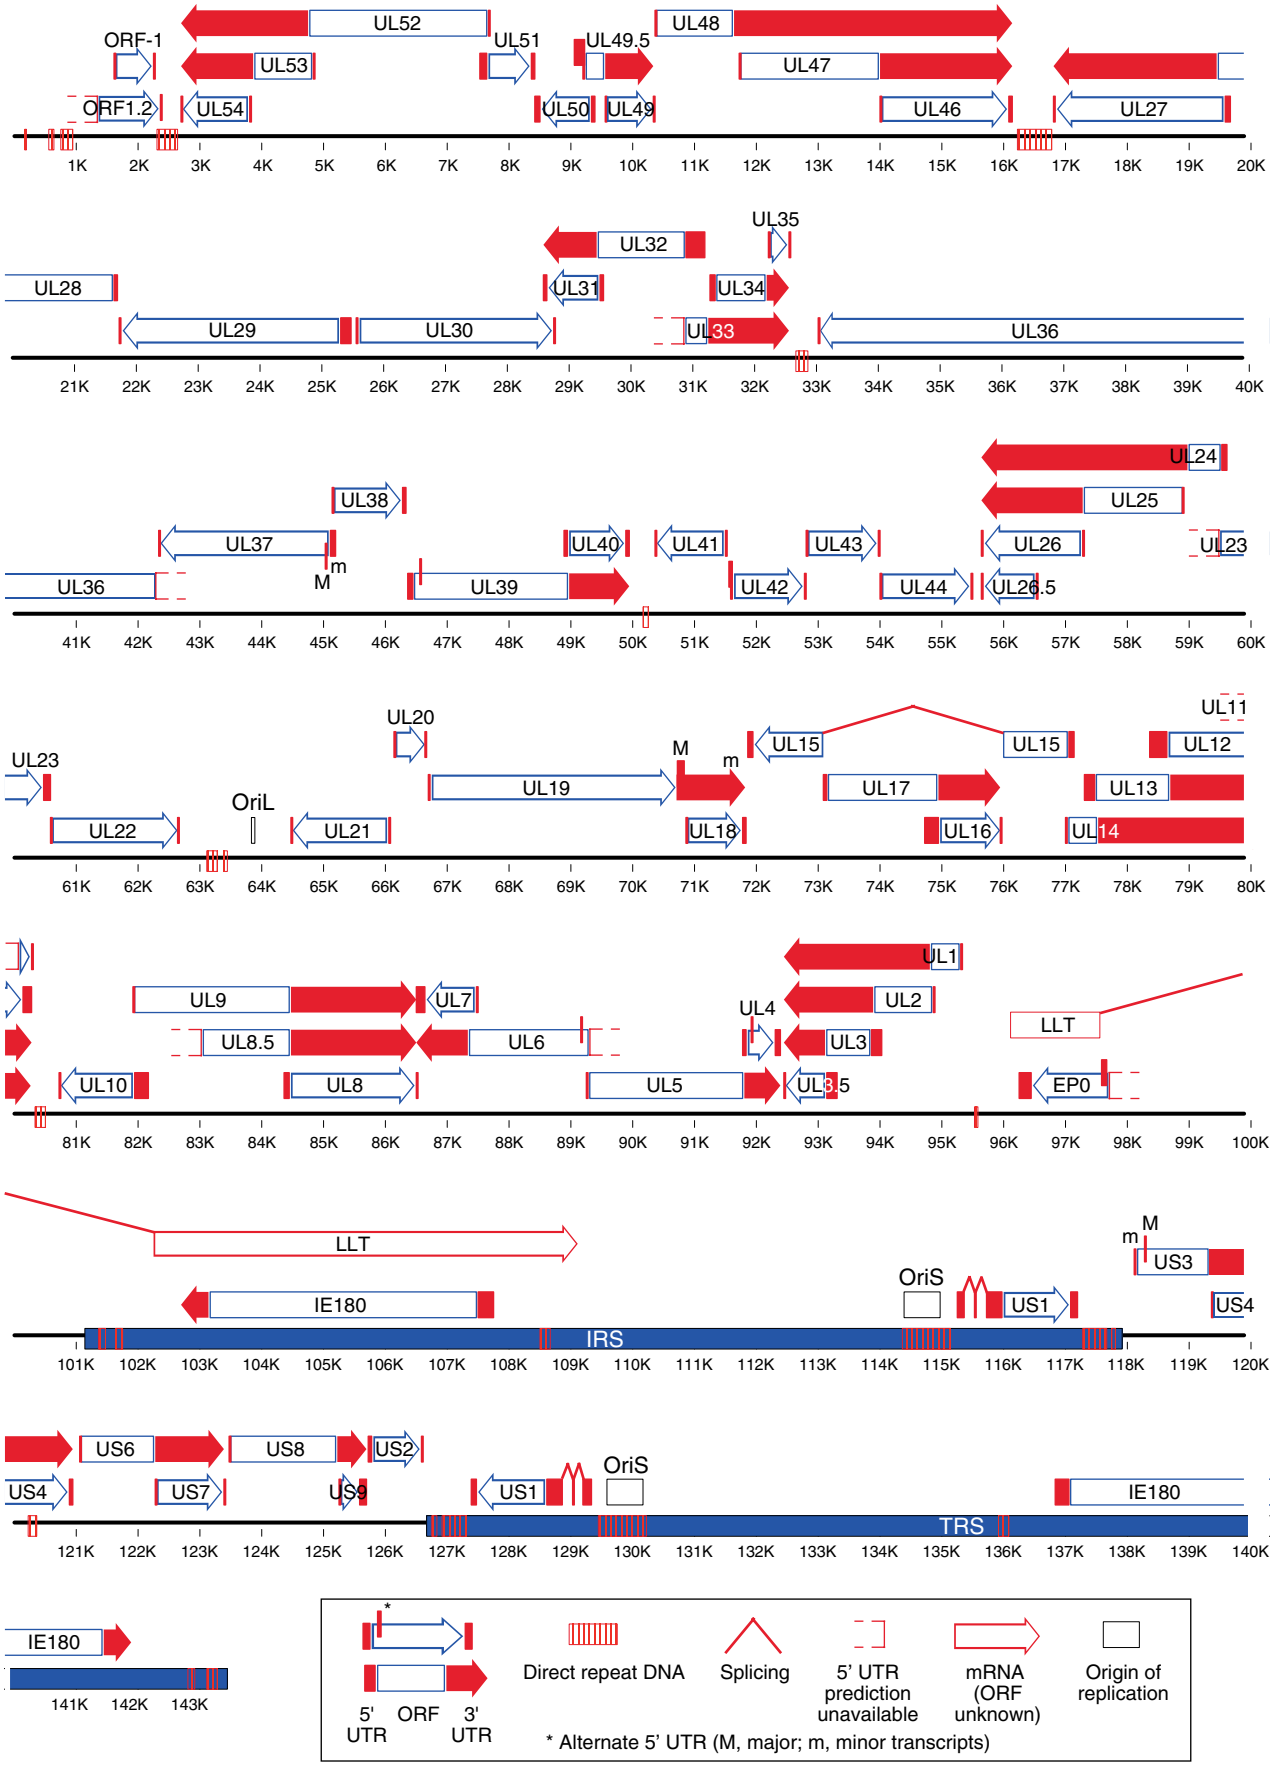

Figure 35.3 Predicted PRV transcript and gene organization. The linear form of the PRV genome is shown with U_L being followed by IR, U_S, and TR. The predicted locations of open reading frames, 5′ and 3′ untranslated regions, DNA repeats, splice sites, and origins of replication (Ori) are depicted. *Source:* Klupp et al. (2004). LLT, large latency transcript; UTR, untranslated region.

experimental analysis include rabbit kidney (RK-13), porcine kidney (PK-15), Madin–Darby bovine kidney (MDBK), or primate Vero cells. PRV undergoes lytic replication, resulting in cytopathic effect (CPE) manifested either by immediate cell destruction (plaque formation) or by formation of syncytia due to the fusion activity of viral glycoproteins exposed at the cell surface. The appearance of CPE depends on the infectious dose but is routinely seen in 6–24 hours. Infected cells can be unambiguously identified by immunostaining using PRV-specific antibodies. Genetically engineered viral variants expressing reporter proteins such as β-galactosidase or fluorescent proteins can be used to track virus infection in cell culture and in experimental animal infections. These viruses are also used for neuronal circuit tracing based on the capacity of PRV to spread transsynaptically in neuronal networks (Curanovic and Enquist 2009).

Public health

Although isolated reports describe putative infections of humans with PRV, they are not conclusive, and it is generally accepted, and has been demonstrated even by self-inoculation, that humans are resistant against natural PRV infection (Jentzsch and Apostoloff 1970).

Epidemiology

AD has an almost worldwide distribution, except for Norway, Australia, and most of the Southeast Asian islands. It occurs particularly in regions with dense pig populations. The disease had not existed widely outside Eastern Europe before the 1960s, but had spread nearly globally by the end of the 1980s assisted by the emergence of more virulent PRV strains and changes in swine management, notably total confinement of large numbers of pigs and continuous farrowing. As a result, PRV became one of the most important infectious diseases of domestic pigs.

Due to increased control efforts and the strict implementation of national eradication programs, AD virtually disappeared from domestic pigs in several parts of the world in recent decades. In Europe, PRV has been eliminated from domestic pig populations in Austria, Cyprus, the Czech Republic, Denmark, Finland, France, Germany, Hungary, Luxembourg, the Netherlands, Sweden, Switzerland, Slovakia, and Great Britain (England, Scotland, and Wales). Canada, New Zealand, and the United States are also free of AD in domestic pigs (Hahn et al. 2010; MacDiarmid 2000; Müller et al. 2003). In PRV-free countries, vaccination is prohibited. AD is still endemic in eastern and southeastern Europe, Latin America, Africa, and Asia. Nonetheless, more countries are implementing national eradication programs to eliminate PRV. However, it is noteworthy that emergence of novel PRV variants could occur and bring additional challenges to eradicate PRV. For example, since late 2011, PRV variants have emerged in a large number of swine herds in many regions of China, and the traditional Bartha-K61 vaccines did not appear to be very effective against the PRV variants (Sun et al. 2016; Yu et al. 2014).

Despite successful elimination of PRV from domestic pigs, the disease is widespread in populations of nondomestic swine, including feral pigs, wild boar, and hybrids, around the world (Müller et al. 2000, 2011). Although PRV in wild boar generally has not impacted the AD-free status of domestic pigs, infected wild boars represent a constant danger for reintroduction of PRV into free herds and regions.

In Europe, PRV is present in wild boar in many countries, for example, France, Germany, Spain, Italy, Slovenia, Croatia, the Czech Republic, Poland, Austria, and Serbia. Seroprevalence in these populations ranges from 4 to 66% at the national level (Lipowski et al. 2002; Milicevic et al. 2016; Müller et al. 2010, 2011; Steinrigl et al. 2012). PRV is also endemic in feral swine populations in the United States (Hahn et al. 2010). Although the prevalence of PRV infection in wild boar in other parts of the world is not known, isolation of PRV from wild boar (and hunting dogs) has been reported across Europe, as well as from feral pigs in the United States (Hahn et al. 2010; Müller et al. 2010).

Molecular characterization of a large number of PRV isolates using Bam HI restriction fragment length polymorphism revealed four major genome types. Type I is found predominantly in the United States and central Europe, whereas types II and III circulate in central Europe and northern Europe, respectively. Type IV is restricted to Asia. Within the major genome types, several subtypes can be distinguished (Christensen 1995; Herrmann et al. 1984) aided by phylogenetic analyses of PRV field strains using partial sequence analysis of the gC gene (Fonseca et al. 2010; Hahn et al. 2010; Müller et al. 2010; Sozzi et al. 2014). In addition, full genome sequences from strains isolated in different countries are becoming available (Mathijs et al. 2016; Yu et al. 2016).

Susceptible species

Pigs are the only natural host for PRV, but the virus can naturally infect cattle, sheep, cats, dogs, mice, and rats, causing fatal disease (Pensaert and Kluge 1989). Dogs seem to be highly susceptible, and there are numerous reports of PRV infection of dogs, particularly hunting dogs, either due to consuming raw meat or by direct contact with PRV-infected swine (Müller et al. 2011; Steinrigl et al. 2012; Moreno et al. 2015). Infections have also been reported in brown bear, black bear, Florida panther, raccoon, coyote, deer, and farm fur animal species (mink and foxes) (Banks et al. 1999; Bitsch and Munch 1971;

Glass et al. 1994). Only swine (*Suidae*) are able to survive a productive PRV infection (Enquist et al. 1998). The susceptibility of other members of the artiodactyl suborder *Suina*, for example, *Tayassuidae* (peccaries) and possibly hippopotamuses, has not been established. Therefore, reports of low PRV seroprevalence (<1%) in free-ranging peccaries in the southwestern United States should be interpreted with caution (Corn et al. 1987). Of the laboratory species, the rabbit is the most susceptible and develops intense local pruritus at the inoculation site. Guinea pigs are less susceptible and may resist subcutaneous inoculation, but succumb to intracerebral or intraperitoneal inoculation (Ashworth et al. 1980).

Transmission

In general, rather high quantities of virus, for example, $>1 \times 10^4$–10^5 median tissue culture infectious dose ($TCID_{50}$), are necessary to infect animals, except piglets (1×10^2 $TCID_{50}$). Thus, PRV is not very contagious (Wittmann 1991). Larger quantities of virus are necessary for oral than for intranasal infection (Jakubik 1977).

The virus is spread primarily by direct contact between swine or by contact with PRV-contaminated fomites, for example, contaminated bedding and water, meat products, and carcasses of rats, raccoons, swine, and other infected animals. The mucosae of the nasal and oral cavities are the main entry points (Donaldson 1983). Conjunctival infection may also lead to rapid onset of disease. Transmission among pigs can also occur during breeding from exposure to contaminated vaginal mucosa or semen (Beran 1991). Within feral swine and wild boar populations, PRV appears to be preferentially transmitted by the venereal route. This mode of transmission differs from that seen in natural transmission in domestic swine, where contaminated secretions, excretions, and aerosols are responsible (Romero et al. 2001). During gestation, PRV can be vertically transmitted transplacentally, mainly in the last third of gestation. The virus can also spread via colostrum to suckling piglets (Beran 1991).

Under favorable circumstances (high virus load in the air, ventilation), PRV is disseminated by the movement of air within buildings and for short distances outside, depending on the climatic conditions (Schoenbaum et al. 1990; Vannier 1988). Long-distance airborne transmission of PRV (Christensen et al. 1990) is still disputed. Although dogs, cats, and wild animals, for example, raccoons, skunks, and rats, are considered potential carriers within an endemic area (Kirkpatrick et al. 1980), their role in virus transmission may be limited due to excretion of only very low amounts of virus and rapid death (Wittmann 1991).

PRV-infected nondomestic swine pose a limited risk to domestic animals, unless they come into direct contact, for example, during breeding or feeding. Movement (trade and transport) of infected pigs during the incubation or latent phase of infection poses the greatest risk of spreading the disease, as pigs that shed virus may immediately infect new units (Blaha 1989; Wittmann 1991). After recovery, pigs remain carriers of latent virus to be reactivated, for example, by transport stress. For this reason, the World Organization for Animal Health (OIE) set international standards and recommendations for movement of pigs between areas with differing disease status (free, provisionally free, endemic; OIE 2009).

Duration and routes of shedding

Infected swine shed PRV in high concentrations in almost all body secretions, excretions, and aerosols. Virus titers in nasal and pharyngeal secretions may reach maximum values of 1×10^6–10^8 $TCID_{50}$. Virus can be isolated from oropharyngeal swabs for 18–25 days with virus titers of up to 1×10^6 $TCID_{50}$. At the peak of virus excretion, one pig may excrete $1 \times 10^{5.3}$ $TCID_{50}$ into the air during a 24 hour period (Müller et al. 2001; Wittmann 1991). Virus shedding starts 1–2 days after infection, prior to the onset of viremia and clinical signs, reaching a peak at 2–5 days and lasting up to 17 days. Transplacental transmission leads to considerable virus shedding during abortion and birth (Beran 1991; Blaha 1989). Virus can also be found in vaginal and preputial secretions, in ejaculate for up to 12 days, and in milk for 2–3 days. It is occasionally shed in urine and has been detected in rectal swabs, but not in feces, for up to 10 days (Wittmann 1991).

Persistence in the environment

Infectious PRV is rather resistant to environmental conditions, depending on pH, humidity, and temperature (Pejsak and Truszczynski 2006; Wittmann 1991). On average, about 50% infectivity is destroyed within 24 hours (Schoenbaum et al. 1990). Ultraviolet light and dry or arid conditions inactivate the virus. However, it is stable at pH 4–12, and even at extreme pH values of 2.0 and 13.5, complete inactivation can take 2–4 hours (Benndorf and Hantschel 1963). Although strain-dependent thermal sensitivity of PRV has been described (Bartha et al. 1969; Golais and Sabo 1975; Platt et al. 1980), in general, it is relatively heat resistant and stable at normal or low temperatures, remaining infectious at 25 °C (77 °F), 15 °C (59 °F), and 4 °C (39 °F) for about 6, 9, and 20 weeks, respectively. At certain subzero temperatures, for example, −18 to −25 °C (0 to −13 °F) and at −40 °C (−40 °F), PRV remains stable for years. At higher temperatures, it is inactivated rapidly between 60 and 1 minutes at 60 °C (140 °F) and 100 °C (212 °F), respectively.

Infectivity of PRV in an aerosol decreases by 50% in less than 1 hour (Schoenbaum et al. 1990). In slurry, PRV remains infectious for 1–2 months, depending on the

season (Kretzschmar 1970). At high virus doses ($10^{6.5}$ $TCID_{50}$/mL), however, infectious virus could still be detected after 27 weeks at 4 °C (39 °F) and 15 weeks at 23 °C (73 °F). Under anaerobic conditions in slurry, PRV was inactivated at 5 and 20 °C after 15 and 2 weeks and at 35 and 55 °C after 5 hours and 10 minutes, respectively (Botner 1991). In aerated slurry at pH 9.6 and 44 °C (111 °F), infectivity disappeared in 8–21 days. Infectious PRV persisted in soil for 5–6 weeks, in well water for 7 days, on hay and straw for 15 and 40 days, and on sacks and wood for 10 and 15 days in summer and in winter, respectively (Schoenbaum et al. 1991; Wittmann 1991). PRV remained infectious in swine urine and waste pit effluent for 2 weeks and less than 1 day, respectively (Schoenbaum et al. 1991).

On straw, concrete, and pelleted feed, PRV infectivity drops below detectable levels within 4 days (Schoenbaum et al. 1991). In waste food fermented by *Lactobacillus acidophilus*, the virus was inactivated at 20 °C (68 °F) and 30 °C (86 °F) within 24 hours, but remained infectious at 10 °C (50 °F) for 48 hours and at 5 °C (41 °F) for 96 hours. Heating of waste food to 70 °C (158 °F) or 80 °C (176 °F) destroyed the virus within 10 or 5 minutes, respectively. Maturation of pig meat at 4 °C (39 °F) does not inactivate the virus. However, in meat, the virus is believed to be inactivated at −18 °C (0 °F) within 40 days and after heat treatment of meat and meat products at 80 °C (176 °F) (Donaldson 1983).

Susceptibility to disinfectants

Orthophenolphenate compounds, peracetic acid, formalin, 2% sodium hydroxide, trisodium phosphate iodide disinfectants, 1–2% quaternary ammonium compounds, hypochlorites, and chlorine (chlorhexidine) solutions are suitable disinfectants (Beran 1991), with a slightly reduced effectiveness in the presence of organic matter. For large-scale disinfection, calcium chloride preparations dissolved in water, crude chloramines, and preparations containing at least 1% active formaldehyde may be used. Lime (20 kg Ca $[OH]_2/m^3$) is recommended for disinfecting slurry. PRV is relatively resistant to changes in pH between 4 and 12 (Benndorf and Hantschel 1963); hence, pure acid and lye preparations can only be used as disinfectants to a limited extent. The same applies to phenol- and alcohol-based disinfectants (Blaha 1989).

Pathogenesis

After oronasal infection of the natural host and primary replication in epithelial cells of the upper respiratory tract, the virus reaches the tonsil and local lymph nodes by way of lymph vessels. Then the virus gains access to neurons innervating the facial and oropharyngeal area, in particular the olfactory, trigeminal, and glossopharyngeal nerves. By fast axonal retrograde transport, it spreads centripetally and reaches the cell bodies of infected neurons, where either lytic or latent infection ensues. PRV is also able to cross synapses to infect neurons of higher order (Pomeranz et al. 2006). Viremia disseminates it to many organs, where the virus replicates in epithelia, vascular endothelium, lymphocytes, and macrophages (Kritas et al. 1999; Mettenleiter 2000). Recent transcriptomic analysis of PRV infection demonstrated early induction of the host innate immune response, including upregulation of interferon responsive genes, inflammatory response genes, and cytokine–cytokine receptor interactions. The expression of proinflammatory cytokines, chemokines, adhesion molecules, and inflammatory enzymes and their receptors and adaptive immune response coincide with fever and pneumonia observed during the first week postinfection. At 6 days postinfection (DPI), a significant shift toward downregulation of these transcripts including oxidative phosphorylation and RIG-I-like and Toll-like receptor pathways is noted. At 14 DPI there is a significant alteration of genes most likely involved in cell death signaling, while cell regrowth and renewal are upregulated with cell cycle mitotic signaling gene sets (Miller et al. 2016).

Replication of PRV in the central nervous system (CNS) is characterized by nonsuppurative meningoencephalitis causing severe central nervous disorders (Enquist 1994; Pensaert and Kluge 1989). Trigeminal ganglia, sacral ganglia, and tonsils are considered prime sites of latency in pigs. The demonstration of the sacral ganglia as the most common sites of PRV latency in feral swine supported the hypothesis that these viruses are primarily transmitted venereally and not by the respiratory route, as is common in domestic swine and in which the trigeminal ganglia are the predominant sites of virus latency (Romero et al. 2001). In non-porcine species, PRV is rather strictly neuroinvasive (Mettenleiter 2000).

Virulence factors

PRV strains differ widely in virulence; hence the isolate involved affects the severity of disease in pigs and the quantity and duration of virus shedding (Maes et al. 1983). Virulence also affects the tissue tropism of infecting PRV strains. Whereas highly virulent PRV strains are predominantly neuroinvasive, strains of moderate or low virulence exhibit weak neuroinvasiveness, but distinct pneumotropism. Highly adapted or attenuated PRV strains have acquired a tropism for the reproductive system (Romero et al. 2001).

PRV virulence is controlled by multiple genes (Lomniczi and Kaplan 1987; Lomniczi et al. 1984). Proteins determining virulence are found among viral membrane glycoproteins, virus-encoded enzymes, and nonessential capsid-associated proteins (Mettenleiter 2000). According to their role in viral replication in cell culture, glycoproteins (g) are either nonessential (gC,

gE, gG, gI, gM, gN) or essential (gB, gD, gH, gK, gL). In terms of virulence, glycoproteins that mediate attachment of PRV to target cells, gC and gD, are of special interest because they may directly determine viral tropism. Virus-encoded enzymes involved in nucleic acid metabolism, for example, thymidine kinase or dUTPase, are major determinants of virulence, and their inactivation leads to strong attenuation of the virus. Neuroinvasiveness and virulence are also determined by viral envelope glycoproteins (Card et al. 1992; Karger and Mettenleiter 1993). Glycoprotein gE is one of the key proteins in neuroinvasion, in both trigeminal and olfactory pathways. Deletion of the gene encoding gE significantly decreases virulence and results in restricted neuronal infection (Enquist et al. 1998). Glycoprotein gC, a major viral membrane protein required for efficient adsorption of virus in cell culture, has no obvious role in determining the pattern of neuronal infectivity, but appears to function with gE to influence neurovirulence. Besides gE and thymidine kinase, inactivation of several other PRV genes has been shown to result in the attenuation of the virus. In fact, inactivation of many genes, whose products are nonessential for viral replication in cell culture, decreases PRV virulence to a variable extent (Mettenleiter 2000).

Latency

A hallmark of herpesviruses is their capacity to persist in a latent state for the lifetime of the host (Wittmann and Rziha 1989). In PRV infection, latency is established primarily in the neurons of the trigeminal and sacral ganglia but also in the tonsils (Romero et al. 2003). No infectious virus is produced during latency, but viral genomic DNA persists extrachromosomally (Brown et al. 1995; Cheung 1995; Gutekunst 1979; Rziha et al. 1986). Under control of a latency-active promoter (LAP) (Jin et al. 2000), only a small portion of the viral genome is transcribed from part of the IR and adjoining U_L region (Cheung 1989; Priola et al. 1990) into an 8.4 kb latency-associated transcript (LAT), which overlaps in antiparallel orientation the mRNA coding for the major immediate-early protein, IE180. Thus, it has been hypothesized that hybrid formation of the two transcripts may modulate the establishment and/or maintenance of latency and reactivation (Mettenleiter et al. 2008). Within the LAT locus, a cluster of nine microRNAs has been identified that may affect the host response of porcine trigeminal ganglia during latency (Mahjoub et al. 2015). However, the exact molecular mechanism of the establishment of and reactivation from latency remains unclear.

Because of the potential to reactivate and shed infectious PRV, latently infected animals are a major threat to disease control. Reactivation can occur under stress (transport, handling, temperature) or hormonal (gestation, farrowing) stimulation. Latent virus can be detected by demonstration of viral DNA or LAT using polymerase chain reaction (PCR) or nucleic acid hybridization techniques. Since no latent antigen is produced in PRV, specific serological detection is not possible. Reactivation can be induced experimentally, for example, administration of high doses of corticosteroids produces virus shedding and transmission (Mengeling et al. 1992). Interestingly, precolonization of sites of latency appears to interfere with subsequent colonization after challenge (Schang et al. 1994). Although live attenuated vaccine strains are limited in their replication in the animal, they may also induce latency, but with reduced efficiency.

Clinical signs

The incubation period in pigs is affected by the infectious dose, the route of infection, and the host species. The incubation period normally ranges from 1 to 8 days, but may take up to 3 weeks. In other susceptible animal species, the course of disease is peracute with incubation periods of 2–3 days.

Infection of pigs with PRV produces a high fever, followed by anorexia, listlessness, dyspnea, excessive salivation, vomiting, trembling, and, eventually, marked incoordination, especially of the hind legs. Involvement of the respiratory tract with coughing, sneezing, dyspnea, and aspiration pneumonia may occur. In adult swine, high morbidity is predominantly due to respiratory involvement.

The presence and severity of clinical signs, as well as morbidity and mortality, depend on the age and immunological status of the pig (Nauwynck 1997). Furthermore, the route of infection and the virulence of the PRV strain are important factors (Schmidt et al. 2001).

In general, PRV infections in fully susceptible swine result in high morbidity and mortality, especially in juvenile animals in which meningoencephalitis and viremia-associated signs predominate. In neonatal pigs less than 7 days of age, the disease may be characterized by sudden death with few, if any, clinical signs. In 2- to 3-week-old piglets, severe signs of CNS involvement, for example, trembling, incoordination, convulsion, tremor, ataxia, and paralysis, are seen (Figure 35.4) with mortality up to 100%. Older animals (3–6 weeks of age) may show neurological signs, but usually develop age-dependent resistance. Mortality may decrease to 50% by the fourth week of age, to less than 5% in 5-month-old pigs, and even lower as the age of the infected pigs increases.

Clinical signs can be present for 6–10 days. Animals may recover within a few days, but lose weight over the course of the disease. In finishing and fattening pigs, because of the population density, clinical signs can amplify, and animals often die from secondary bacterial pneumonia. Signs in gilts and sows depend on the phase of gestation and include embryonic death,

Figure 35.4 PRV infection in piglets. Central nervous signs observed after intranasal infection of 4- to 6-week-old piglets with virulent PRV include ataxia and convulsions.

resorption of fetuses, mummified fetuses, abortion, or stillbirth, in addition to respiratory signs and fever. Pigs surviving a PRV infection become latently infected (Nauwynck 1997).

In the case of coinfections with other swine viruses, for example, porcine reproductive and respiratory syndrome virus (PRRSV), porcine circovirus type 2 (PCV2), and swine influenza virus, a severe and often fatal proliferative and necrotizing pneumonia (PNP) may develop in weaning and post weaning pigs (Morandi et al. 2010).

Natural resistance to PRV in particular pig breeds associated with specific quantitative trait loci has been described (Reiner et al. 2002), but the mechanism is unclear.

In PRV-infected nondomestic swine, clinical signs are rare, indicating that circulating PRV variants are highly adapted to the host population (Müller et al. 2001). In Spain and Germany, rare cases of clinical AD in juvenile wild boar have been reported, indicating that these field viruses can induce disease in wild pigs that is clinically and pathologically identical to AD in domestic pigs (Gortazar et al. 2002; Schulze et al. 2010).

For other susceptible animal species, a peracute fatal course of infection is characteristic. Often, extreme pruritus resulting in severe self-mutilation is the only clinical sign observed. Dead mice, rats, dogs, or cats on farms are telltale signs for the presence of PRV prior to the onset of clinical signs in infected pigs. This also applies to hunting dogs.

Lesions

Gross lesions

There are no pathognomonic gross lesions in pigs and changes are often absent or minimal. Gross lesions may occur in non-neural tissues, including lymphoid organs, and respiratory, digestive, and reproductive tracts. Particularly in young suckling pigs lacking passive immunity,

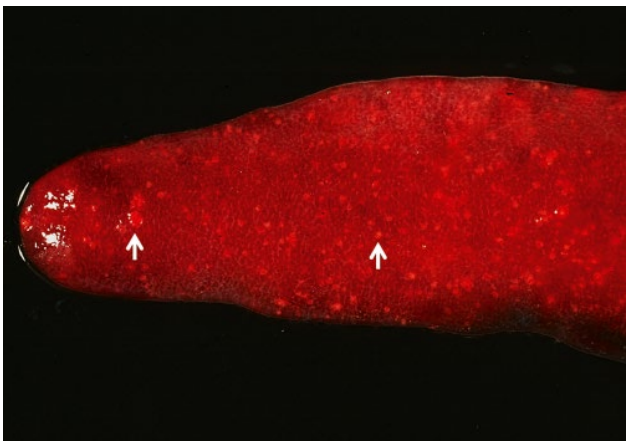

Figure 35.5 Multifocal acute coagulative necroses (two of them marked by arrows) of the spleen parenchyma after infection with PRV. *Source:* courtesy of Dr. W. Thiel, Detmold Germany.

multiple small foci (1–3 mm in diameter) of acute hemorrhagic necrosis characteristic of alphaherpesviral infections may be seen in the liver, spleen (Figure 35.5), lung, intestines, and adrenals. Typically, exudative keratoconjunctivitis, serous to fibrinonecrotic rhinitis, laryngitis, tracheitis, and necrotizing tonsillitis may be present. The CNS is free of gross lesions except for leptomeningeal hyperemia.

Gross lesions in the upper respiratory tract are most common, including rhinitis with patchy epithelial necrosis and necrotizing laryngotracheitis, often in conjunction with multifocal tonsillar necrosis. Lesions in the lower respiratory tract may include pulmonary edema and scattered small foci of necrosis, hemorrhage, or bronchointerstitial pneumonia (Becker 1964). However, the pulmonary lesions are less consistent and are composed of areas of reddening and consolidation scattered throughout the lungs, especially in the cranioventral lung lobes.

In sows, necrotizing placentitis and endometritis with thickened, edematous wall of the uterus are observed after abortion (Kluge and Maré 1978). Aborted fetuses may be macerated, or occasionally, mummified (stillbirth, mummified fetuses, embryonic death, infertility [SMEDI]). In fetuses or neonatal pigs, necrotic foci in the liver, spleen, lungs, and tonsils are common (Kluge and Maré 1976). PRV infection may also cause edema of the scrotal region.

Microscopic lesions

Microscopic lesions in pigs reflect the neuroinvasive and epitheliotropic properties of PRV. CNS lesions are characterized by a nonsuppurative meningoencephalomyelitis in the gray and white matter and ganglioneuritis of the trigeminal and paravertebral ganglia (Figure 35.6; Baskerville et al. 1973). Death may occur before neuronal degeneration or nonsuppurative inflammatory reactions in the brain become visible. If animals survive long enough, CNS injury can be marked, leading to focal neuronal degeneration and necrosis, with neuronophagia, satellitosis, and gliosis. In particular, young piglets tend to develop panencephalitis with the most severe lesions in the cerebral cortex, brain stem, spinal ganglia, and basal ganglia of the brain.

Perivascular cuffing consists predominantly of pyknotic and karyorrhectic mononuclear cells. Similar lesions exist in the spinal cord, especially in the cervical and thoracic segments. Meninges covering affected areas of the brain and cord may be thickened because of mononuclear cell infiltration.

Intranuclear eosinophilic inclusion bodies are not commonly detected in pigs, but can be present in the neurons, astrocytes, oligodendroglia, and endothelial cells. Lymphoplasmacytic inflammation with neuronal degeneration and necrosis of the myenteric plexus of the gastrointestinal tract is also described (Ezura et al. 1995).

Epithelial lesions consist of multifocal areas of coagulative or lytic, partially hemorrhagic, necrosis in the liver, tonsils, lungs, spleen, placenta, and adrenals with the presence of the amphophilic intranuclear inclusions. Viral intranuclear inclusion bodies are much more common in lesions outside the nervous system (Kluge et al. 1999). They are present in tonsil crypt epithelial cells adjacent to necrotic foci and are frequently found in the airway epithelium, within the connective tissue, and in cells sloughed into alveolar spaces. However, the specificity of the lesions must be confirmed by immunostaining.

Mucosal epithelial necrosis and submucosal infiltrations of mononuclear cells occur in the upper respiratory tract (Baskerville 1971; Baskerville et al. 1973). In the lungs, necrosis of the bronchi, bronchioli, and pneumocytes is found. Also, peribronchial mucous gland epithelium may be involved in the inflammatory process. Alveolar edema and cellular infiltration may be multifocal or diffuse. Lymphocytes, macrophages, and, less frequent, plasma cells and neutrophils are the characteristic inflammatory cells.

In the uterus, multifocal to diffuse lymphohistiocytic endometritis and vaginitis and necrotic placentitis with coagulative necrosis of chorionic fossae develop (Bolin et al. 1985; Kluge et al. 1999). Intranuclear inclusion bodies are present in degenerate trophoblasts associated with necrotic lesions (Kluge et al. 1999; Kluge and Maré 1978).

In the male reproductive tract, degeneration of seminiferous tubules and necrotic foci in the tunica albuginea

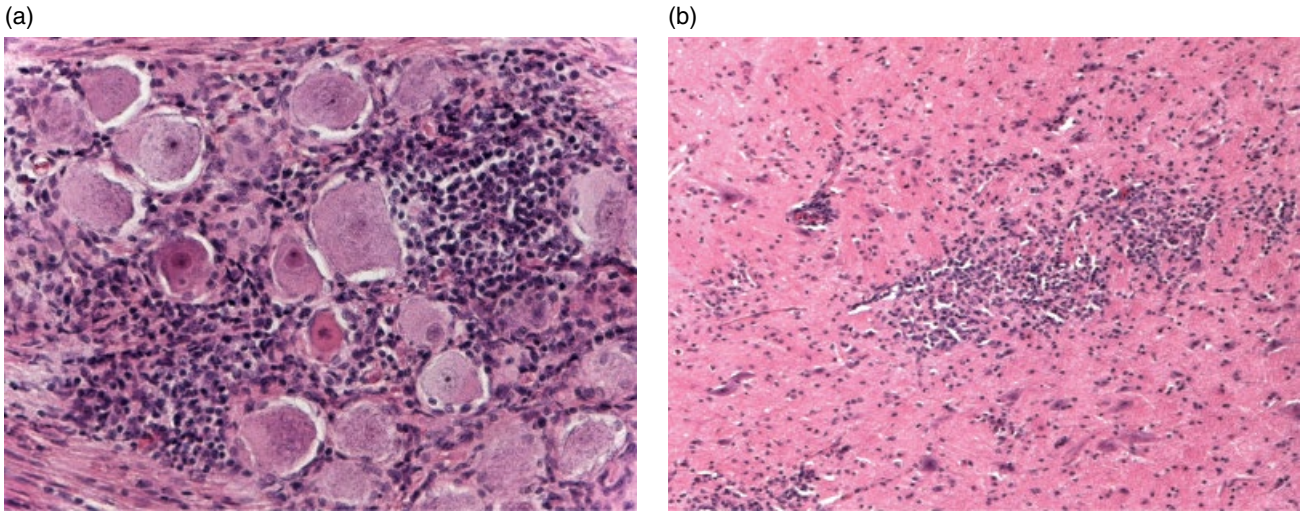

Figure 35.6 (a) Diffuse lymphoplasmacytic ganglioneuritis in the trigeminal ganglion with degeneration and necrosis of perikarya and (b) multifocal-to-coalescing nonsuppurative encephalitis in the medulla with neuronal degeneration and perivascular cuffing 8 days after PRV infection under experimental conditions.

of the testicles may be observed (Hall et al. 1984). Boars with exudative periorchitis have necrotic and inflammatory lesions in the serosa covering the genital organs. Spermatozoal abnormalities occur.

Aborted or stillborn piglets usually exhibit no evidence of encephalitis, but foci of necrosis may be found in the liver and other parenchymatous organs, together with focal bronchiolar necrosis and interstitial pneumonia. Focal necrosis of the mucosal epithelium involving the muscularis mucosa and tunica muscularis develops in the intestines (Narita et al. 1984b). Intranuclear inclusion bodies may be present in degenerative crypt epithelial cells.

The occurrence of hemorrhage and fibrin exudation results from the involvement of connective tissue and endothelium. Necrotizing vasculitis of the arterioles, venules, and lymphatic vessels around the tonsils and submaxillary lymph nodes is observed in piglets (Narita et al. 1984a). Endothelial nuclei are pyknotic and karyorrhectic, and the vessel walls are infiltrated by neutrophils. Intranuclear inclusion bodies are often present in affected endothelial cells (Kluge et al. 1999).

Diagnosis

Differential diagnosis

Several infectious and noninfectious diseases may produce clinical signs in pigs similar to pseudorabies, including rabies, porcine polioencephalomyelitis (teschovirus and sapelovirus infection), porcine astrovirus type 3 infection, classical and African swine fever, Nipah virus infection, Japanese encephalitis, hemagglutinating encephalomyelitis, encephalomyocarditis (EMC), porcine circovirus (PCV2), highly virulent strains of PRRSV, bacterial meningoencephalitis such as *Streptococcus suis* infection, swine influenza, salt poisoning, hypoglycemia, organic arsenic or mercury poisoning, congenital tremors, and other diseases causing abortion.

In species other than the pig, PRV is rather strictly neuroinvasive (Mettenleiter 2000), and diseases of the CNS, such as rabies, scrapie (sheep), and bovine spongiform encephalopathy (BSE), and diseases or conditions causing persistent itching need to be excluded.

Pathological examination

In pigs, the trigeminal ganglia, olfactory ganglia, and tonsils are the preferred tissues for isolation or detection of PRV. The virus can also be recovered from other organs, for example, lungs, spleen, liver, kidneys, lymph nodes, and pharyngeal mucosa. In latently infected pigs, virus isolation is most successful from the trigeminal ganglion in domestic pigs and the sacral ganglia in feral pigs.

PRV antigen can be detected either in cryosections by immunofluorescence or in formalin-fixed paraffin-embedded tissues by immunohistochemistry. PRV DNA can be visualized by *in situ* hybridization. In non-porcine species, the segment of the spinal cord that innervates the pruritic area of the skin should be collected. The affected area of the skin, together with the subcutaneous tissues, should also be submitted.

Samples for virus isolation should be sent to the laboratory under cold conditions. Postmortem serum can also be collected for serology. Serological tests can also be performed on muscle exudate ("meat juice") samples.

Laboratory confirmation

Rapid detection of viral infection is essential for the effective control of PRV. Clinical observations are only sufficient to lead to a suspicion of AD because the infection produces no pathognomonic clinical signs or gross postmortem lesions in swine. Therefore, laboratory confirmation is required.

Virus detection

Viral antigen can be detected using immunoperoxidase and/or immunofluorescence staining with polyclonal or monoclonal antibodies (mAbs) on impression smears and cryosections of tissues, for example, brain, lungs, and tonsils (Allan et al. 1984; Onno et al. 1988). Diagnosis is confirmed by virus isolation in conventional cell cultures requiring approximately 2–5 days, depending on the time of development of virus-specific CPE.

A variety of cells can be used for the recovery of PRV, including rabbit lung (ZP), rabbit kidney (RK-13), hamster kidney (BHK-21), porcine kidney (PK-15, SK6), African green monkey kidney (VERO), mink lung (ML), ferret kidney (FK), ovine fetal lung (OFL), bovine turbinate (BT), and turkey embryo kidney (TEK) cells (Onyekaba et al. 1987). In general, a porcine kidney cell line is employed under routine laboratory conditions.

PRV can be isolated from secretions, excretions, and tissues, for example, brain, tonsils, lungs, and spleen, of infected animals. In latently infected pigs, the trigeminal ganglia and tonsils are the most consistent sites for virus isolation. As there is no CPE characteristic of PRV and CPE may vary with the prevailing PRV strain and cell line used, virus identity is confirmed by immunofluorescence, immunoperoxidase, or neutralization assays using specific antisera or mAbs. In the absence of any obvious CPE, blind passages should be performed. Rapid detection of PRV by shell vial technique has been described (Tahir and Goyal 1995).

Detection of PRV DNA in secretions or organ samples using PCR (Jestin et al. 1990) is the method of choice. In general, primers should target regions of the genome conserved among PRV strains. Several conventional PCRs targeting genes encoding gB, gC, gD, or gE have been established (Müller et al. 2010; Schang and Osorio 1993), but there is no established international standard.

PRV-specific nested and real-time quantitative PCR assays have been described (Tombácz et al. 2009; van Rijn et al. 2004) with the capacity to differentiate between wild-type and gene-deleted vaccine viruses (Fonseca et al. 2010; Ma et al. 2008; Wernike et al. 2014).

Antibody detection

At one time, the virus neutralization (VN) test was considered the reference standard serum antibody assay (Bitsch and Ekildsen 1982), but it has been widely replaced by ELISAs. Robust and sensitive indirect or competitive ELISAs detect antibodies against the complete PRV or against distinct viral antigens (Toma 1982). The latex agglutination test (LAT) (Rodgers et al. 1996) and immunoblotting (Todd et al. 1987) are alternatives. VN and LAT are highly reliable but cannot differentiate between antibodies resulting from natural infection or vaccination. The development of ELISAs able to detect serum antibodies against gE (or gC or gG) (van Oirschot et al. 1986) allowed for the differentiation of infection from vaccination and led to the "marker" or differentiating infected from vaccinated animal (DIVA) concept. These ELISAs became a key part of PRV eradication programs.

Immunity

The major immunogens of PRV that elicit antibody-dependent and cell-mediated immunity have been identified (Mettenleiter 1996). Most are envelope glycoproteins, although the major immediate-early protein also induces an antibody response. The attachment glycoprotein gC is a major target of complement-independent neutralizing antibodies (Hampl et al. 1984; Lukacs et al. 1985) and T-cell-mediated immune responses (Ober et al. 2000; Zuckermann et al. 1990). Complement-independent neutralizing antibodies directed against gB and gD have also been identified (Hampl et al. 1984; Lukacs et al. 1985). These antibodies function by inhibiting attachment (anti-gC, anti-gD) or penetration (anti-gB) of virions. Correlated with these findings, subunit vaccines containing gB, gC, or gD, as well as DNA vaccines expressing these proteins, were able to confer at least some level of immunity against challenge virus infection (Gerdts et al. 1997; Mettenleiter 1996).

Like other herpesviruses, PRV also tries to avoid cellular immune responses by immune evasion. Binding of antibodies to viral glycoproteins exposed at the surface of infected cells results in their internalization, which may hide them from the immune system (van de Walle et al. 2003). This effect is mediated by endocytosis motifs in the C-terminal intracellular domains of gD and gB (Ficinska et al. 2005). The gE–gI complex exhibits Fc receptor activity (Favoreel et al. 1997), which may also contribute to immune evasion, as does binding of complement factor 3 by PRV gC (Huemer et al. 1992). Immune evasion is also effected by blocking major histocompatibility complex (MHC) class I-dependent antigen presentation by gN-mediated inhibition of transport of peptides from the cytosol to the endoplasmic reticulum by TAP (Koppers-Lalic et al. 2005).

Despite these immune evasion mechanisms, solid immunity against PRV infection can be induced by vaccination with inactivated viruses, modified live viruses, protein antigens, or DNA. In particular, modified live viruses attenuated either by passaging *in vitro* in cell culture or in embryonated poultry eggs have proven highly effective in decreasing clinical signs of AD (Bartha 1961), although they do not prevent infection by, and subsequent latency of, field virus. However, precolonization of ganglia by latent vaccine virus reduces latency of superinfecting wild-type PRV (Schang et al. 1994).

Immune responses

Onset of the immune response to PRV in infected and vaccinated pigs is rapid. However, slight variations in the development of the immune response may depend on the PRV strain, the route of infection, and individual pig immune competency.

PRV-specific serum antibodies are already present when the animals show clinical signs of disease (Kretzschmar 1970). Using highly sensitive serological assays (e.g. ELISAs and immunoblotting), antibodies can be detected as early as 5–7 days post inoculation, but not until 12 days post inoculation by VN. In infected animals, antibodies are almost exclusively immunoglobulin M (IgM) up to 7 days post inoculation, which persist until day 18, while in vaccinated animals, they have almost disappeared by this time (Müller et al. 2001; Rodák et al. 1987). IgG antibodies appear sooner in infected (day 7 post inoculation) than in vaccinated (day 10 post inoculation) pigs, reaching higher mean titers. In contrast, IgA antibodies seem to be present only in infected pigs from day 10 post inoculation.

Similar antibody dynamics and distribution can be detected in oropharyngeal swabs, except that IgG and IgM titers are considerably lower than in the serum, whereas IgA titers in oropharyngeal swabs are higher than in the serum (Rodák et al. 1987). About 3 weeks post inoculation, IgG antibodies reach maximum levels and, in general, persist for the life of the pig. Only in exceptional cases, virusneutralizing antibodies were reported to have disappeared after 2–3 months (Blaha 1989).

Protective immunity

Immunity after infection is durable, very stable, and protective against viremia and clinical disease. Even massive intracerebral inoculation can be resisted.

However, sterilizing immunity is not achieved. Although a significantly higher infectious dose is required to provoke exogenous infection, those virus doses are easily shed within an infected herd (Blaha 1989). In latently infected pigs, reactivation of latent PRV due to immunosuppression or new exposure to virulent virus may result in increasing virus-neutralizing antibody titers. However, there is no evidence that reactivation of latent virus is associated with any unique immunological response (Mengeling 1991).

Maternal immunity

In both domestic and nondomestic pigs, immune sows transfer PRV-specific antibodies to their offspring even years after infection. In general, maternally derived virus-neutralizing antibodies, mostly IgG, can be detected up to 14–15 weeks postpartum. Their duration is dependent on the original concentration (Iglesias and Trujano 1989; Müller et al. 2005). With 11 and 21 days in domestic pigs and wild boar, respectively, the half-life of maternal antibodies is considerably longer than known for other infections. However, anti-PRV antibodies can be detected by ELISA as long as 27 weeks postpartum, that is, twice as long as in VN assays (Müller et al. 2005; Tenhagen et al. 1995).

Maternally derived immunity prevents the transmission of PRV in newborn piglets and is able to protect against clinical disease after infection by limiting virus replication in the CNS. However, the correlation between the level of maternal immunity and protection against neuroinvasion in maternally immune neonatal pigs is dependent on the PRV strain. High virus-neutralizing antibody titers protect neonatal pigs almost completely against neural invasion, whereas low titers do not (Kritas et al. 1999). Maternally derived antibodies inhibit the ability of piglets to respond to vaccination (Tielen et al. 1981; Weigel et al. 1995), but recombinant vaccinia virus vaccines expressing PRV glycoproteins are able to circumvent maternally derived antibodies and stimulate active immunity (Brockmeier et al. 1997).

Prevention and control

Due to the rapid increase in AD in the 1970s, test and slaughter programs were initiated in several countries, including England, Switzerland, and Denmark in the early 1980s (Watson 1986). Although costly, they succeeded in eliminating AD from national pig herds, although new outbreaks did occur due to introduction of virus by trade or air. In other countries, control of disease, but not infection, was achieved by blanket vaccination with inactivated (particularly in breeding animals) and modified live virus vaccines (in finishers). In East Germany, for example, AD control was based on a combination of large-scale vaccination of breeding herds with attenuated live vaccines and rigorous stamping-out policy, especially in the final phase of eradication until successful termination of the AD eradication program in 1985 (Müller et al. 2003). Whereas inactivated and attenuated vaccines were efficacious in reducing disease, they did not lead to the elimination of virus, since none of them prevented latent infection and subsequent reactivation and shedding of virulent field virus.

Beginning in the 1980s, novel strategies in animal disease control were pioneered by the first use of genetically engineered live PRV vaccines lacking virulence-determining genes (Freuling et al. 2017). The first major improvement occurred in 1986 when the first recombinant DNA-derived modified live virus vaccine was licensed in the United States (Kit and Kit 1991). It carried a genetically engineered deletion of the thymidine kinase gene, a gene that is relevant for virulence. At about the same time, it was discovered that several classical AD vaccine strains, for example, the Bartha strain (Bartha 1961), carried deletions of the gene encoding immunogenic glycoprotein gE (Mettenleiter et al. 1985) that did not impair their potency as vaccines. After the development of an ELISA to measure anti-gE antibodies in the animal (van Oirschot et al. 1986), the combination of marker vaccine and differential ELISA made it possible to discriminate between vaccinated, PRV-uninfected animals (PRV-positive, but gE-negative) and wild-type PRV-infected (gE-positive) animals. Subsequently, additional nonessential glycoproteins, for example, gC or gG, were also deleted by genetic engineering and used as markers with appropriate serological assay systems. Since then, AD has been the prime example of using companion diagnostic ELISA tests to differentiate infected from vaccinated animals (DIVA) (Freuling et al. 2017). Thus, marker vaccines against AD were the first genetically modified live vaccines used on a wide scale (Quint et al. 1987). Detailed reviews on the development of PRV vaccines have been published elsewhere (Dong et al. 2014; Freuling et al. 2017; Mengeling et al. 1997). The combination of highly efficacious DIVA vaccines and accurate differential ELISAs has made eradication of AD from large areas of the world practical and feasible.

Porcine cytomegalovirus

Relevance

Porcine cytomegalovirus (PCMV) infection was originally designated "inclusion body rhinitis" (sometimes abbreviated as "IBR," but not to be confused with "infectious bovine rhinotracheitis") based on the histopathological observation of basophilic intranuclear inclusion bodies in cytomegalic cells of the nasal mucosa of pigs with rhinitis (Done 1955). Ultrastructural investi-

gations demonstrated herpes virions in epithelial cells of the turbinate mucous glands, lachrymal and salivary glands, and the renal tubuli. The virus grew slowly in cell culture and produced cytomegaly with large intranuclear inclusions (Yoon and Edington 2006).

Infections with PCMV are ubiquitous. PCMV exists in nearly all pig populations, but clinical disease is rare with the exception of young piglets, in which a fatal systemic disease develops. In immunologically susceptible herds, the virus causes fetal and piglet mortality, runting, rhinitis, pneumonia, and sometimes neurological signs (Yoon and Edington 2006).

Etiology

PCMV (SuHV-2) belongs to the subfamily *Betaherpesvirinae* in the family *Herpesviridae*, but is not assigned to any genus (Table 35.1; Davison 2010). Comparative genetic studies indicate that PCMV is genetically closer to human herpesviruses 6 and 7 than to cytomegaloviruses (Rupasinghe et al. 2001; Widen et al. 2001).

PCMV particles exhibit typical herpes virion morphology (Duncan et al. 1965; Valicek and Smid 1979). No distinct PCMV serotypes or genotypes have been identified, although some genetic variation was noted in polymerase and gB genes among PCMV isolates from different geographical origins (Widen et al. 2001). Possible antigenic variability has also been reported (Tajima and Kawamura 1998). The virus is sensitive to chloroform and ether. Virus infectivity is preserved at subzero temperatures (Booth et al. 1967).

PCMV can be isolated in porcine pulmonary macrophages and propagated up to maximum titers of 1×10^5–10^6 $TICD_{50}$/mL *in vitro*, for example, in primary pig lung (PL) cells, primary swine testicle (ST), PK-15 cell line, and porcine turbinate (PT) (Yoon and Edington 2006).

Basophilic intranuclear and, occasionally, small acidophilic intracytoplasmic inclusions (Figure 35.7) are present in infected cytomegalic cells (Watt et al. 1973). Since CPEs are lacking in cell culture, confirmatory immunostaining is necessary (Figure 35.8).

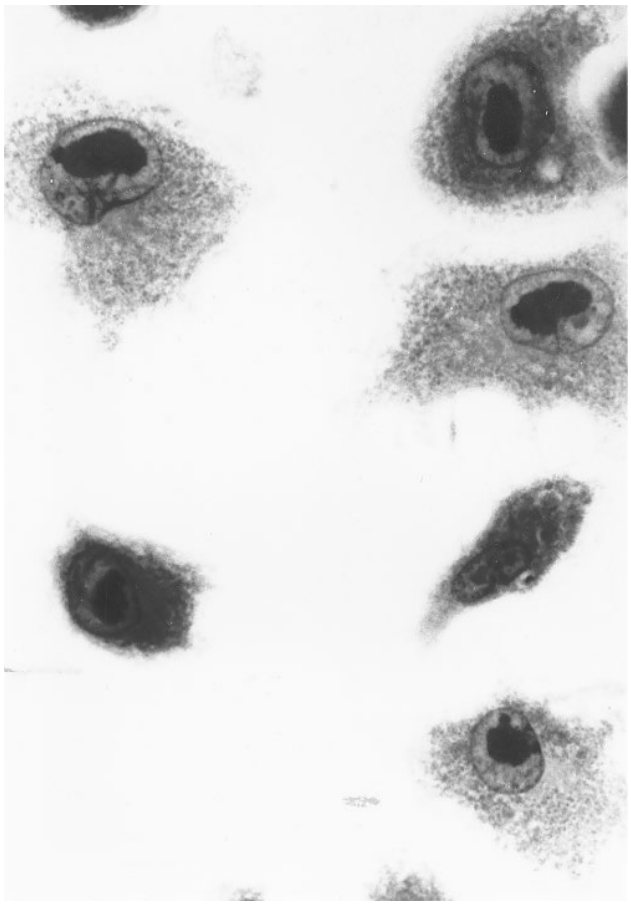

Figure 35.7 Cultured pig macrophages 11 days after inoculation with PCMV. Note the basophilic intranuclear inclusions in the enlarged cells (May–Grünwald–Giemsa; ×720). *Source:* courtesy of R.G. Watt.

Public health

PCMV is ubiquitous in pig populations and induces latent infections in pigs (Garkavenko et al. 2004; Tucker et al. 1999). Although no human infections have been reported, the potential use of live porcine cells, tissues, and organs for xenotransplantation has led to concerns regarding exposure of immunocompromised humans to infectious PCMV. Cross-species transmission of PCMV was reported in pig-to-primate xenotransplantation (Mueller et al. 2002), but a pig-to-primate islet xenotransplantation study found no evidence of the transmission of PCMV or other viruses into primate recipients (Garkavenko et al. 2008; Morozov et al. 2016a; Plotzki et al. 2015; Wynyard et al. 2014). More recent data suggested that PCMV could infect human fibroblasts *in vitro* (Whitteker et al. 2008). PCMV has also been detected in the tissues of recipient nonhuman primates, although no disease was reported (Ekser et al. 2009; Morozov et al. 2016b). PCMV plays no role in the more traditional or routine areas of concern to public health.

Epidemiology

PCMV is highly prevalent throughout the world with herd prevalence greater than 90% and more than 98% of animals positive in Europe, North America, and Japan (Collett and Roberts 2002; Deim et al. 2006; Yoon and Edington 2006).

Inclusion body rhinitis is an acute-to-subacute disease of about 4-week-old suckling piglets. Non-porcine reservoirs and arthropod vectors have not been reported.

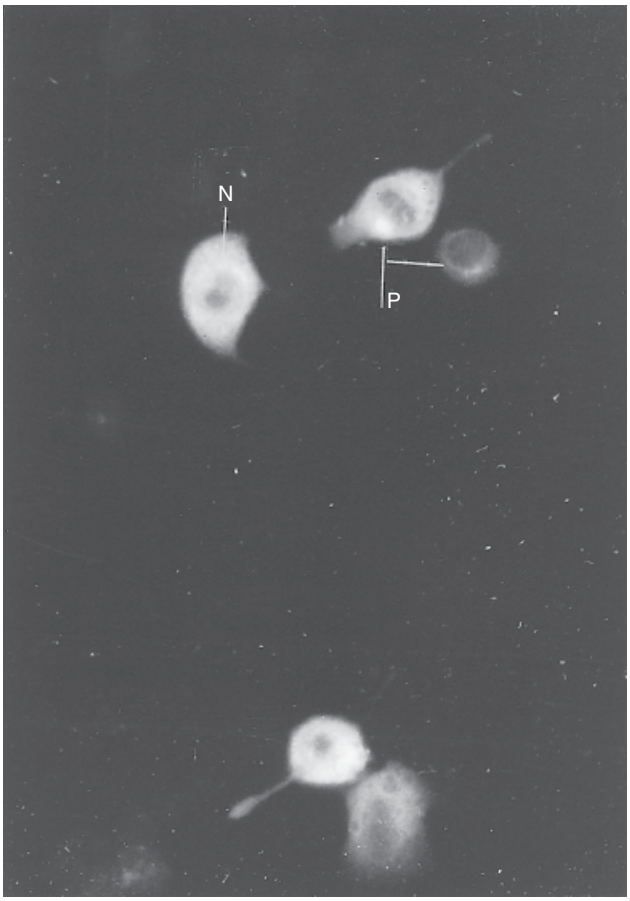

Figure 35.8 Lung macrophage cultures showing fluorescence after indirect immunofluorescence (IIF) using specific PCMV antiserum. The nuclear staining (N) is most intense at the membrane. Cytoplasmic and discrete paranuclear fluorescence (P) can also be seen (×480).

Natural infection with PCMV is limited to pigs. The virus does not replicate in mice, rabbits, dogs, cattle, or chicken embryos. However, virus replication was detected in tissues of baboons that received xenografts of porcine origin (Morozov et al. 2016a; Mueller et al. 2002).

PCMV is transmitted horizontally via the oronasal route, but congenital transmission is also well documented (Yoon and Edington 2006). Infection most commonly occurs perinatally in commercial pig holdings (Watt 1978).

PCMV can be recovered from nasal and ocular discharge, urine, and cervical fluid (Yoon and Edington 2006). The majority of pigs shed PCMV in nasal secretions between 3 and 8 weeks of age (Plowright et al. 1976). This suggests that infection is usually acquired by contact within the infected cohort. Virus recrudescence from latent infections is possible (Edington et al. 1976c; Narita et al. 1985).

The stability of PCMV in the environment is unknown. No specific disinfectants are recommended.

Pathogenesis

The primary replication site of PCMV is the nasal mucosa and/or the lachrymal or Harderian glands. Cell-associated viremia follows primary replication 14–21 DPI in animals older than 3 weeks (Edington et al. 1976c, 1977). Shedding in nasal secretions lasts from 10 to over 30 days. Congenitally infected pigs excrete virus until death (Edington et al. 1977). Excretion in cervical fluids from pregnant sows is found concomitant with fetal deaths.

The site of secondary viral replication varies with age. In nursery or growing pigs, PCMV spreads to the nasal mucosal glands, Harderian and lachrymal glands, kidney tubules, and, more rarely, the epididymis and mucous glands of the esophagus. Hepatocytes and duodenal epithelium are rarely infected. It remains unclear how PCMV spreads systemically. Apparently, PCMV is able to infect cells of the monocyte–macrophage system and endothelial cells, causing renal petechiation, particularly in the subcapsular spaces (Sekiguchi et al. 2012).

In the fetus or neonate, there is predominantly infection of capillary endothelium and sinusoids of lymphoid tissues, thus resulting in systemic spread of PCMV and generalized lesions (Edington et al. 1977, 1988). This observation is important in terms of PCMV eradication from pigs bred for xenotransplantation. That is, spleens from donor animals should be examined as part of quality control procedures (Clark et al. 2003). Using microarray techniques, differential expression of genes associated with inflammation, immunosuppression, cellular and metabolic processes, networks of cytokine–cytokine receptor interactions, the TGF-β signaling pathway, the lymphocyte receptor signaling pathway, and the TNF-α signaling pathway was shown (Liu et al. 2014).

Clinical signs

Incubation period for PCMV may be 10–20 days (Edington et al. 1977). During viremia, animals become depressed and anorexic. Neonates may die without any clinical signs, whereas others exhibit shivering, sneezing, respiratory distress, poor weight gain, and rhinitis. A black discoloration may occasionally be observed around the eyes due to conjunctival discharge. The disease is generally self-limiting. In pigs older than 3 weeks, the course of disease is usually subclinical to mild, but can lead to death of the fetus or newborn pig. Affected pigs show respiratory signs, for example, sneezing, catarrhal nasal exudate and discharge, and coughing with dyspnea, and develop rhinitis or neurological disease (Yoon and Edington 2006). There is no link between PCMV infection and atrophic rhinitis (Edington et al. 1976b). Embryonic death and infertility may occur (Edington et al. 1977, 1988; L'Ecuyer et al. 1972; Yoon et al. 1996).

PCMV has been associated with the porcine respiratory disease complex (PRDC) in pigs of different ages (Orr et al. 1988). A significant correlation between PCMV and PCV2 infection was found, and it is speculated that the presence of PCMV causes exacerbation of PRDC (Hansen et al. 2010).

Although infection is usually subclinical in older pigs if uncomplicated, morbidity after congenital or neonatal infection is 100%. The mortality in a naive herd can be 10%, but it may increase to 50% in the presence of secondary bacterial or viral infections (Yoon and Edington 2006).

Lesions

Whereas epithelia are the target tissue in older pigs, generalized infection affects reticuloendothelial tissues in the fetus or neonate (Edington et al. 1976a).

Macroscopic changes are usually only seen in piglets less than 3 weeks of age with systemic PCMV infection, in which case catarrhal rhinitis, hydrothorax and hydropericardium, pulmonary and subcutaneous edema, and renal petechiation can be present. In fetal infections, stillbirths, mummification, embryonic death, and infertility are seen.

Microscopically, 8–12 µm basophilic intranuclear inclusion bodies, cytomegaly, and karyomegaly are seen in the nasal mucous glands (Figure 35.9), acinar and duct epithelium of Harderian and lachrymal glands, and renal tubular epithelium. The major sites of replication develop focal lymphoid hyperplasia (Figure 35.10).

Interstitial nephritis and random focal gliosis in the CNS with inclusion bodies can be additional findings, with a predilection for the choroid plexus, cerebellum, and olfactory lobes (Yoon and Edington 2006). In the acute fatal syndrome, most basophilic inclusions are seen in the capillary endothelium and sinusoidal cells of the lymphoid tissues. Multifocal edema or hemorrhage results from vascular damage. Mononuclear cells and macrophages with inclusions are found in the blood vessels, alveoli, and spleen. Focal hepatocellular necrosis and inclusions in glomerular capillary endothelium are further lesions.

Diagnosis

PCMV-associated diseases must be differentiated from infection with classical swine fever virus, enterovirus, parvovirus, PRRSV, PCV2, and PRV. Virus isolation or PCR-based assays for detection of viral DNA can be used for positive identification (Fryer et al. 2001; Hamel et al. 1999; Morozov et al. 2016c; Widen et al. 1999). Antemortem samples of choice are swabs with nasal secretion or scrapings and whole blood (Edington et al. 1976a; Watt et al. 1973).

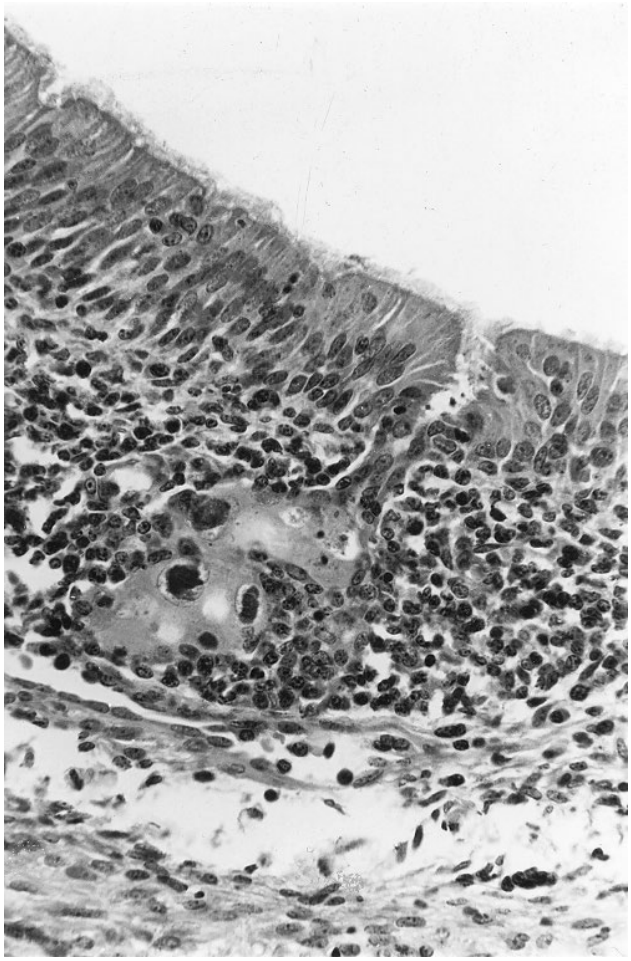

Figure 35.9 The basophilic intranuclear inclusion, translucent halo, and defined nuclear membrane are prominent in the enlarged superficial mucous gland epithelium of an animal 18 days after experimental intranasal inoculation (hematoxylin and eosin [H&E]; ×480).

Preferred postmortem samples are turbinate mucosa, lungs, pulmonary macrophages obtained by lung lavage, and kidneys. In cases of early reproductive failure, PCMV can occasionally be demonstrated in the brain, liver, and bone marrow of fetuses (Yoon and Edington 2006).

Virus isolation is possible on primary or immortalized cells. Viral antigen can be detected by immunostaining on frozen tissue sections. The combination of inclusion bodies, cytomegaly, and karyomegaly is pathognomonic (Yoon and Edington 2006). PCMV infection in a herd is confirmed by serology using serum samples from grower–finishers. ELISAs have been described and adapted to differentiate IgG and IgM responses (Tajima et al. 1994). It should be noted that no PCMV antibodies are induced by *in utero* infection. Therefore, antibody is not expected in colostrum-deprived neonatal sera.

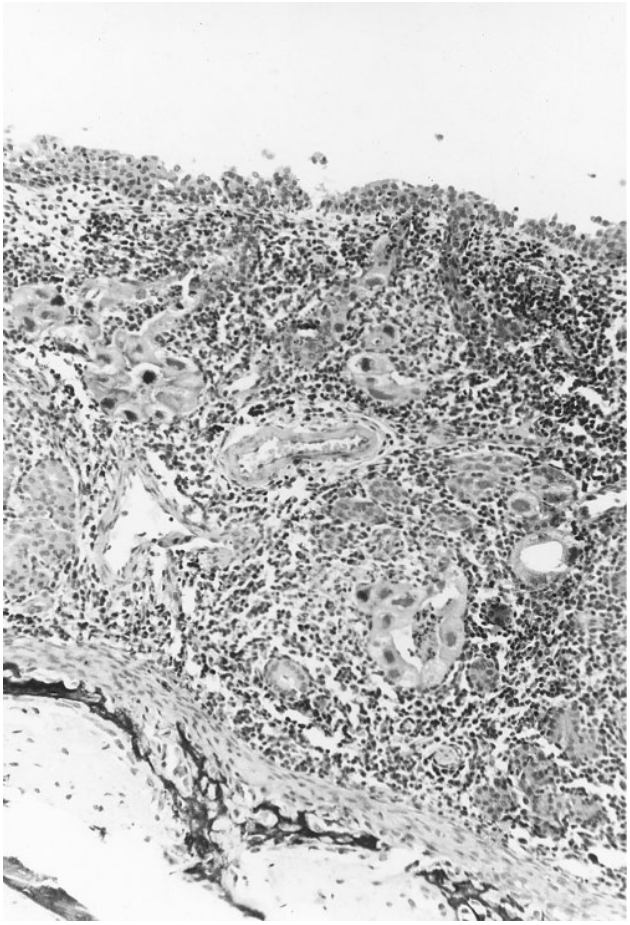

Figure 35.10 The lamina propria is heavily infiltrated with lymphocytes and plasma cells 24 days after inoculation with PCMV. Many of the acini of the mucous glands still show cytomegaly and prominent inclusion bodies (hematoxylin and eosin [H&E]; ×120).

Immunity

After experimental infection, antibodies are detected by indirect immunofluorescent antibody (IFA) tests 2–3 weeks after inoculation. IFA-detectable antibodies peak at approximately 6 weeks and remain at high levels for at least 10–11 weeks (Edington et al. 1976c, 1977). Development of serum antibody levels detectable by IFA coincides with the disappearance of viremia, but nasal excretion of virus continues for another 2–3 weeks. Piglets with congenital and neonatal infections do not seroconvert but excrete virus and develop fatal systemic infections (Edington et al. 1977). Piglets acquire maternal antibodies and these provide some protection, but virus is shed even in the presence of circulating maternal antibody in PCMV-endemic farms (Plowright et al. 1976). Maternal antibodies persist for approximately 2 months (Tajima et al. 1994).

Prevention and control

No vaccine or specific treatment for PCMV is available. Introduction of new stock into herds poses a significant risk due to reactivation of latent infections or primary infection of susceptible herds.

Porcine lymphotropic herpesviruses

Relevance

The detection by PCR of the genetic material of two porcine herpesviruses in leukocytes and lymphoid organs of healthy pigs (*Sus scrofa*) led to the discovery of PLHV-1 and PLHV-2. Sequence analysis revealed that they were the first porcine herpesviruses belonging to the subfamily *Gammaherpesvirinae* (Ehlers et al. 1999a). In 2003, a third porcine gammaherpesvirus, PLHV-3, was identified (Chmielewicz et al. 2003a).

Little is known about the pathogenic potential of the PLHVs. However, the presence of these viruses in apparently healthy pigs (Chmielewicz et al. 2003a; Ehlers et al. 1999a; Ulrich et al. 1999) raised concerns about the safety of pig-to-human xenotransplantation. These concerns were reinforced by the high worldwide prevalence of the PLHVs, the difficulties in eliminating them from pigs bred for use as tissue and organ donors (Tucker et al. 2003), and the association of PLHV-1 with a porcine lymphoproliferative disease of high mortality (Goltz et al. 2002; Huang et al. 2001).

Etiology

Approaches to characterize the PLHV genomes were hampered by the fact that propagation of these viruses in cell culture was not successful. Therefore, the genomes were amplified directly from PLHV-positive pig samples by a PCR-based genome walking technique. About 101 kb, 68 kb, and 98 kb of PLHV-1, PLHV-2, and PLHV-3, respectively, were characterized and found to harbor more than 60 genes with counterparts in other herpesviruses (Chmielewicz et al. 2003a; Goltz et al. 2002; Lindner et al. 2007). Upon comparison of genes conserved among the *Herpesviridae*, the PLHVs were then classified by the International Committee on Taxonomy of Viruses (ICTV) as members of the subfamily *Gammaherpesvirinae* and named suid gammaherpesvirus 3 (PLHV-1), suid gammaherpesvirus 4 (PLHV-2), and suid gammaherpesvirus 5 (PLHV-3) (Table 35.1; Davison et al. 2009). Close relatives of the PLHVs were also found in other suid species, that is, *Phacochoerus africanus* and *Sus barbatus* (Ehlers and Lowden 2004).

Phylogenetic analysis revealed that the PLHVs are most closely related to a group of ruminant gammaherpesviruses (Figure 35.11). Members of this group cause

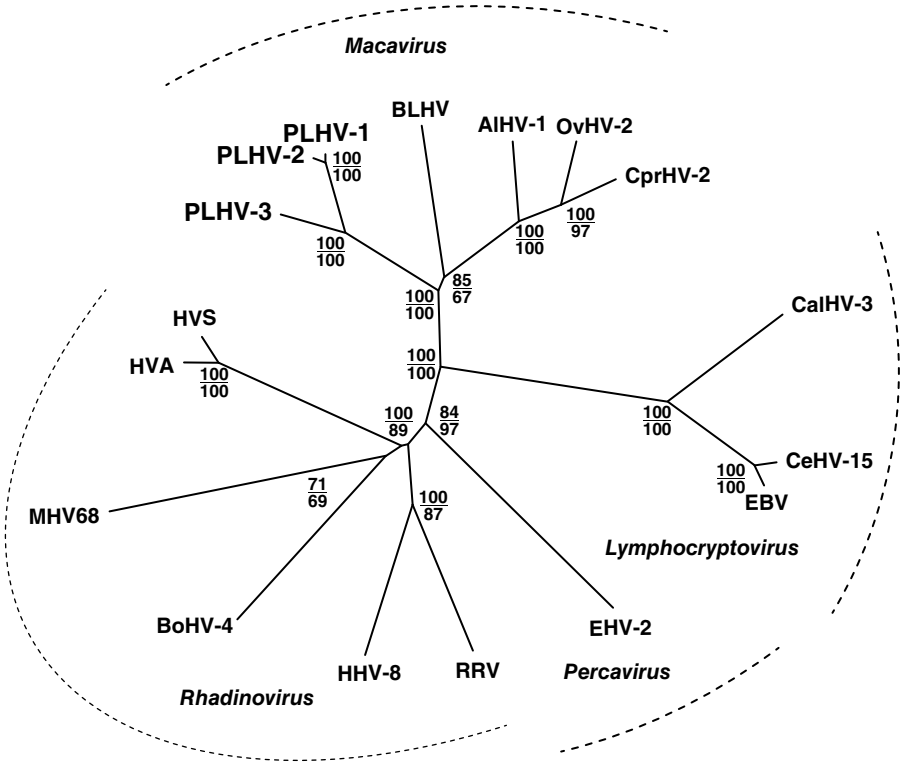

Figure 35.11 Phylogenetic tree showing the positions of the PLHVs within the herpesvirus subfamily *Gammaherpesvirinae*, genus *Macavirus*. Members of the genera *Macavirus*, *Rhadinovirus*, *Percavirus*, and *Lymphocryptovirus* were included. The tree was constructed using a multiple amino acid sequence alignment of concatenated glycoprotein B and DNA polymerase sequences. The bootstrap values derived from 100 repetitions are indicated at the branching points of the tree. The upper values were obtained with neighbor-joining analysis, and the lower values were obtained with parsimony analysis. *Source:* Adapted from Chmielewicz et al. (2003a), and reprinted by permission of the publisher.. PLHV, porcine lymphotropic herpesvirus; BLHV, bovine lymphotropic herpesvirus; AlHV-1, Alcelaphine gammaherpesvirus 1; OvHV-2, Ovine gammaherpesvirus 2; CprHV-2, Caprine gammaherpesvirus 2; CalHV-3, Callitrichine gammaherpesvirus 3; CeHV-15, Cercopithecine gammaherpesvirus 15; EBV, Epstein–Barr virus; EHV-2, Equid gammaherpesvirus 2; RRV, rhesus monkey rhadinovirus; HHV-8, Human gammaherpesvirus 8; BoHV-4, Bovine gammaherpesvirus 4; MHV68, Murine gammaherpesvirus 68; HVA, Herpesvirus ateles or Ateline gammaherpesvirus 3; HVS, *Herpesvirus saimiri* or Saimiriine gammaherpesvirus 2.

MCF in foreign hosts (AlHV-1, ovine herpesvirus 2, caprine herpesvirus 2) (Li et al. 2003; Russell et al. 2009). These viruses were all classified as members of the newly established genus *Macavirus* (Table 35.1; Davison et al. 2009).

The approximately 100 kb determined for PLHV-1 and PLHV-3 encompass the ORFs ORF03 to ORF69 (ORF nomenclature according to *Herpesvirus saimiri* [HVS]). In addition, five ORFs were identified that have counterparts only in the gammaherpesviruses AlHV-1, equine herpesvirus 2 (EHV-2), and/or EBV, but not in HVS or KSHV. These encode a viral BCL-2 protein (ORFE4/BALF1), a G-protein-coupled receptor (ORFA5/BILF1), an immediate-early transactivator (ORFA6/BZLF1), a cell fusion protein (ORFA7/BZLF2), and a cell attachment protein (ORFA8/BLLF1) (Chmielewicz et al. 2003a; Goltz et al. 2002; Lindner et al. 2007).

Due to long intragenomic repeat regions, an entire PLHV genome could not be amplified by genome walking. However, Gardella gel electrophoresis and blotting revealed the total length as slightly shorter than the genome of EBV (approximately 170 kb) (Chmielewicz et al. 2003a).

More than 20 porcine cell lines were tested by PCR for the presence of PLHV sequences. One of them, the B-cell line L23, was found to carry PLHV-3 genomes (Chmielewicz et al. 2003a). However, attempts to induce efficient lytic replication failed (B. Ehlers, unpublished data). Attempts to isolate PLHV from primary samples were not reported. Therefore, a lytic cell culture system is not available.

Public health

The PLHVs have the potential to cause a lymphoproliferative disease of high mortality in experimentally immunosuppressed pigs that resembles the posttransplantation lymphoproliferative disease (PTLD) in humans. The PLHVs are closely related to AlHV-1 and OvHV-2, which are innocuous in their natural hosts, but

cause MCF in other animals. Porcine cells, tissues, and organs offer a potential solution to the shortage of organs available for human-to-human allotransplantation (Yang and Sykes 2007), but the pathogenic potential and worldwide prevalence of the PLHVs in pigs have raised concerns regarding the consequences of pig-to-human xenotransplants in immunosuppressed humans (Ehlers et al. 1999a; Mueller and Fishman 2004).

Epidemiology

Knowledge on the epidemiology of the PLHVs is limited, but there is growing evidence that they are present in pigs and their relatives in the family *Suidae* worldwide. PLHVs were detected in domestic pigs (*S. scrofa domestica*) from Germany, Italy, France, Belgium, Denmark, Ireland, the United Kingdom, the United States, Australia, and Vietnam and in wild boar (*S. scrofa*) from Germany, the United States, and Australia (Chmielewicz et al. 2003a,b; Ehlers et al. 1999a; Garkavenko et al. 2004; Goltz et al. 2002; McMahon et al. 2006; Tucker et al. 2003; Ulrich et al. 1999; B. Ehlers, unpublished data). PLHV-1 sequences were also amplified from *S. barbatus oi*, *S. barbatus*, *S. celebensis*, and *P. africanus*. PLHV-3 sequences were identified in *Babyrousa babyrussa* and a sequence with 98% identity to the PLHV-3 DPOL gene in *S. barbatus* (Ehlers and Lowden 2004).

The prevalence of the PLHVs was determined with real-time PCR in German domestic pigs. Depending on the sample type (blood, spleen, and lungs), prevalences of 48–62% (PLHV-1), 16–41% (PLHV-2), and 54–78% (PLHV-3) were estimated. In German wild boar, PLHV-1 was detected in 1 of 19 and PLHV-2 in 18 of 19 bone marrow samples (Ulrich et al. 1999). Spleens of domestic pigs from Ireland were 74, 21, and 45% positive for PLHV-1, PLHV-2, or PLHV-3, respectively (McMahon et al. 2006). In New Zealand, 95% of domestic piglets (20 weeks) and pigs (>6 months) were PCR positive for PLHV-2. PLHV-1 was not detected and PLHV-3 was not tested (Garkavenko et al. 2004). In the United Kingdom, PLHV sequences were amplified in 80 and 67% of adult Large White pigs and adult miniature swine, respectively (Tucker et al. 2003). These data indicated a high PLHV prevalence in commercial and experimental pig herds. They further revealed a remarkably low level of intraspecies sequence variation (well below 1%) in coding regions. This indicated that the PLHVs are genetically stable and well adapted to their natural host.

Very few data allow conclusions about the mode of PLHV transmission. Cesarean-derived pigs were found to be far less frequently infected with PLHVs than conventionally reared pigs. This reduced rate may indicate that PLHVs are rarely transmitted *in utero*, but frequently postpartum (Tucker et al. 2003). Further evidence for horizontal transmission as the major route emerged by repeated analysis of piglets after birth using ELISA and PCR. These data indicated *de novo* PLHV infection by contact to the infected dam and subsequent seroconversion (Brema et al. 2008).

Pathogenesis, clinical signs, and lesions

A clinical disease associated with PLHV infection under field conditions is not known. The closely related gammaherpesviruses naturally infecting wildebeest (AlHV-1) and sheep (OvHV-2) can be horizontally transmitted to cattle or pigs and cause MCF, a lymphoproliferative disease of high mortality (Russell et al. 2009). Therefore, the PLHVs might have a similar pathogenic potential, either in foreign hosts or in their natural host. The latter may be difficult to observe since most commercial pigs are slaughtered at approximately 6 months of age.

Evidence for the pathogenicity of the PLHVs under experimental conditions came from immunosuppressed miniature swine subjected to allogeneic hematopoietic stem cell transplantation. A high incidence of PTLD was observed, B-cell proliferation occurred, and the majority of the animals died (Huang et al. 2001). In the PTLD-affected individuals, high PLHV-1 genome copy numbers were detected. In addition, transcripts of several PLHV-1 genes were demonstrated in PTLD pigs, but not in healthy pigs, strongly suggesting a causative role of PLHV-1 in PTLD (Goltz et al. 2002; Huang et al. 2001). Similar findings were reported after allogeneic spleen transplantation in miniature swine (Dor et al. 2004).

The clinical signs of experimental porcine PTLD resemble those of human PTLD associated with EBV, a human gammaherpesvirus. Lethargy, fever, anorexia, enlarged lymph nodes, and elevated numbers of leukocytes were observed. Pigs suffering from PTLD showed enlarged lymphoreticular organs, airway obstruction, and respiratory failure. Microscopically, a mixture of immunoblasts, plasmacytoid cells, and plasma cells was typical of porcine PTLD (Huang et al. 2001).

Pigs have the potential to be used as cell, tissue, and organ donors in pig-to-human xenotransplantation. The theoretical concern is that PLHVs might recombine with human herpesviruses in the human xenotransplant recipients, giving rise to recombinants with novel pathogenic properties. In addition, activation of human herpesviruses through PLHVs might occur in xenotransplant patients, leading to lytic infection and rejection of the transplanted organ (Santoni et al. 2006).

Diagnosis

Nucleic acid-based and antibody-based diagnostic assays are available for PLHV diagnosis. Three independent real-time PCR assays have been developed to quantify PLHV-1, PLHV-2, or PLHV-3 genome copy numbers in

porcine samples (Chmielewicz et al. 2003a). Single-round conventional PCR assays for the specific detection of a certain PLHV or the simultaneous detection of PLHV-1 and PLHV-2 have also been published (Chmielewicz et al. 2003a; Ehlers et al. 1999a). The very low level of PLHV intraspecies variation (<1% in coding regions) ensures the conservation of the primer binding sites used in the PCR and real-time PCR assays.

In addition, a panherpes consensus PCR has been designed for the universal detection of all mammalian and avian herpesviruses with degenerate primers (Ehlers et al. 1999b). This assay readily amplifies PLHV DNA polymerase sequences (Chmielewicz et al. 2003a; Ehlers et al. 1999a). However, many porcine specimens are infected with more than one PLHV. Due to the degenerate nature and universal binding properties of the consensus primers, sequences of only one virus are preferentially amplified from a mixture. Therefore, the simultaneous diagnosis of multiple PLHV infections in a single specimen is usually not successful using the panherpes consensus PCR.

With the PCR assays described above, the PLHVs were frequently detected in blood leukocytes, in lymphoreticular organs (spleen, lymph nodes, tonsils, bone marrow), and in the lungs (Chmielewicz et al. 2003a; Ehlers et al. 1999a; Ulrich et al. 1999). Since organ samples are not readily available from live pigs, routine PLHV diagnosis relies on testing white blood cells. This has to be taken with caution since PLHVs are more frequently detected in the spleen and lungs than in the blood (Chmielewicz et al. 2003a).

Two ELISA-based serological assays have been published, using recombinant gB of PLHV-1 as antigen, for the detection of anti-PLHV antibodies (Brema et al. 2008; Plotzki et al. 2016). The assay (Brema et al. 2008) was used for the analysis of sera from groups of pigs, differing by age and origin. Seropositivity ranged from 38% (piglets) to 90% (gilts) and 100% (breeding sows, miniature pigs, and pigs for slaughter). Compared with the percentages of PCR-positive samples in the same groups of sera (20, 80, and 0–75%, respectively), this ELISA is suitable for PLHV diagnosis (Brema et al. 2008).

Immunity

The type and efficacy of immune responses against the PLHVs are largely unknown. Test systems relying on viral cell culture are not available, and infection studies with cultured viruses are not possible at present. A group of 12 piglets was tested repeatedly after birth until the age of 156 days for the presence of anti-PLHV antibodies (Brema et al. 2008). At birth, antibodies of probable maternal origin were detected, which declined to background levels during the first 3 weeks of life. Thereafter, seroconversion due to *de novo* PLHV infection by contact with the infected dam (or already infected piglets) was observed (Figure 35.12).

In the blood, the PLHVs infect predominantly B cells. This was assessed with real-time PCR analysis of microbead-sorted B cells, T cells, and macrophages (Chmielewicz et al. 2003b). In immunosuppressed miniature swine developing PTLD, a rise of PLHV-1 genome copies and a concomitant expansion of the B cells were observed (Huang et al. 2001). In addition, transcripts of an ORF were found in the PTLD-affected pigs, which encode a protein for B-cell entry (Goltz et al. 2002).

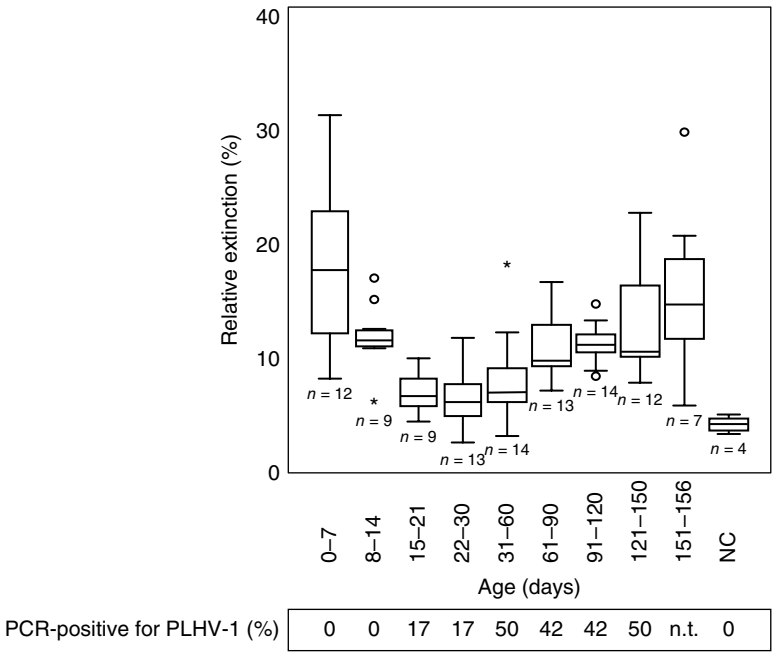

Figure 35.12 Analysis of PLHV antibody titers in piglets of different ages. Sera were obtained from newborn pigs up to 5 months of age and split into nine age groups (days 0–7, 8–14, 15–21, 22–30, 31–60, 61–90, 91–120, 121–150, and 151–156). All sera were examined for anti-PLHV antibodies by ELISA. The number of samples (*n*) in each group is shown below each box plot. Outliers (circles) and extreme values (stars) are also shown. ELISA was performed using 1.25 µg antigen (N-terminal part of PLHV-1 glycoprotein B) per well and 1 : 50 diluted swine sera. In addition, peripheral blood leukocyte samples were analyzed for PLHV-1 DNA by PCR. The percentages of PCR-positive samples are listed in the box at the bottom of the figure. *Source:* Brema et al. (2008). Reproduced with permission of John Wiley and Sons.

Prevention and control

Concerns regarding the safety of pig-to-human xenotransplantation make PLHV-free donor pigs a desirable goal. Early weaning of piglets failed to exclude PLHV (Mueller et al. 2005), but a markedly reduced prevalence of PLHVs was achieved using Cesarean-derived, barrier-reared breeding conditions (Tucker et al. 2003; Morozov et al. 2016d). These results indicated that the derivation of PLHV-free animals is a realistic objective.

Ovine herpesvirus 2 causing porcine malignant catarrhal fever

Relevance

MCF is a sporadic, systemic gammaherpesvirus infection of ungulates. It was first described as a fatal disease, primarily of cattle, characterized by high fever, copious nasal discharge, corneal opacity, generalized lymphadenopathy with lymphopenia, inflammation, necrosis of mucosal surfaces, and vasculitis. In Europe, an association with sheep was recognized as a prerequisite (Götze and Liess 1930), whereas in Africa, the source of infection was wildebeests (*Connochaetes taurinus*), which are inapparent carriers (Plowright et al. 1960). Later, the sheep-associated (SA) form was reported worldwide in a wide variety of species belonging to the subfamily *Bovinae* and the family *Cervidae* (Hüssy et al. 2000; Müller-Doblies 1998; Plowright 1990).

A naturally occurring disease similar to MCF has been described in pigs, particularly in Scandinavian countries (Løken et al. 1998). However, the first cases of MCF in pigs were reported from Italy and Germany, where single sows developed clinical signs resembling the disease in cattle (Kurtze 1950; Morselli 1901). For decades, overt disease in swine seemed to be limited to Norway, but has since occurred in Finland, Sweden, and North America (Alcaraz et al. 2009; Bratberg 1980; Gauger et al. 2010; Grytting 1974; Holmgren et al. 1983; Løken et al. 2009; Okkenhaug and Kjelvik 1995; Syrjälä et al. 2006). Other cases of porcine MCF were also reported from Switzerland (Pohlenz et al. 1974). Although the etiology had not been clarified, in most reports, contact with sheep was mentioned before the disease was noted (Albini et al. 2003a).

Porcine MCF is a very rare, poorly documented disease of swine (Alcaraz et al. 2009). The small number of reported cases of MCF is mainly based on the fact that the clinical signs can be subtle and nonspecific and diagnostic tools are not generally available (Albini et al. 2003a). Compared with other herpesviral diseases of pigs, porcine MCF does not pose a significant threat to the porcine population, even if underdiagnosed in the field.

Etiology

There are two etiologically distinct forms of MCF: (1) a wildebeest-associated form (WA-MCF), caused by AlHV-1, and (2) a sheep-associated form (SA-MCF), occurring worldwide and caused by OvHV-2 (Baxter et al. 1993; Meier-Trummer et al. 2010). Together with caprine herpesvirus 2 (CpHV-2) and the malignant catarrhal fever virus of white-tailed deer (WTD-MCFV) and based on their molecular biology, these viruses belong to the genus *Macavirus* within the subfamily *Gammaherpesvirinae* and are closely related to PLHV-1–PLHV-3 (Figure 35.11). In contrast to AlHV-1, there is no permissive cell culture system for OvHV-2.

Public health

OvHV-2 infection in humans has not been reported.

Epidemiology

Knowledge about porcine MCF caused by OvHV-2 is sparse, although a few cases with proven etiology were reported from European countries and North America (Albini et al. 2003a,b; Alcaraz et al. 2009). This may reflect the limited availability of molecular diagnostic assays and the possibility that a considerable number of cases may not be recognized due to abortive forms with full clinical recovery. However, it cannot be excluded that the low frequency of MCF cases in pigs is due to the low susceptibility of pigs.

In general, gammaherpesviruses have a narrow host range (Ackermann 2005, 2006; Meier-Trummer et al. 2010). However, OvHV-2 affects a broader range of natural hosts such as sheep, goats, cattle, bison, swine, mule deer, and, at least experimentally, rabbits and hamsters (Ackermann 2006; Albini et al. 2003b; Jacobsen et al. 2007; Li et al. 2003; Løken et al. 1998; O'Toole et al. 2007). Sheep and goats remain healthy upon infection, whereas the other susceptible hosts develop MCF (Meier-Trummer et al. 2010).

The exact mode of transmission of OvHV-2 is uncertain, but there is convincing evidence that the predominant mode is via nasal secretions (Li et al. 2004; Løken et al. 2009) by contact or aerosol, mainly from lambs under 1 year old (Russell et al. 2009). However, descriptions of outbreaks of SA-MCF in cattle on farms with no contact with sheep have also been documented (Kersting 1985). Pigs and sheep usually do not share close environments, which might also explain the infrequent presentation of MCF in pigs (Alcaraz et al. 2009). However, a case of MCF in a Vietnamese potbellied pig in a zoological garden, kept in proximity with sheep and goats, has been described recently (Lapp et al. 2015).

MCF-susceptible species are thought to be dead-end hosts that do not transmit virus, thus limiting the spread of disease during outbreaks (Russell et al. 2009). OvHV-2 transmission by the respiratory route of sheep had strongly been postulated on the basis of the detection of infectivity in nasal secretions (Taus et al. 2005).

Pathogenesis

OvHV-2 DNA can be detected in tissues of pigs with MCF, but not in healthy pigs. Simultaneous infections with OvHV-2 and other porcine gammaherpesviruses have never been observed (Albini et al. 2003a,b).

MCF in ruminants has an autoimmune-like pathology, mainly caused by the cytotoxic action of noninfected lymphocytes under the regulatory influence of a small number of infected cells. Cerebral vasculitis and perivasculitis in MCF-affected cattle and bison contain $CD8^+$ OvHV-2-infected lymphocytes in large numbers, as shown by *in situ* PCR. Therefore, the pathogenesis of MCF may be due to the direct action of virus-infected, dysregulated cytotoxic T cells at sites of lesions (Russell et al. 2009). Whether this model also applies for pigs is not yet known.

Clinical signs

The clinical signs and lesions in pigs are similar to those described for MCF in cattle. Usually, pigs of any age over 3 months can be affected (Løken et al. 1998).

No reliable data are available concerning the incubation period in pigs. Cattle can show clinical signs as soon as 9 days after exposure to sheep, but some cases occur 70 days or longer after contact. In bison exposed to sheep, the incubation period is often a month or more.

Clinically, porcine MCF is associated with a high and persistent fever (40.5–42 °C; 105–107.6 °F), anorexia, depression, weight loss, recumbency, a high pulse rate, and expiration dyspnea with loud snoring stenotic sounds. Foul-smelling nasal discharge and partially dried crusts in and around the nostrils, obstructing the upper airways, cause strained respiration. Ocular discharge, nystagmus, bilateral corneal edema, and keratoconjunctivitis often develop. Signs of CNS disease may appear, mostly as ataxia (central vestibular), hyperesthesia, tremors, and balance loss with convulsions or paralysis of hind limbs (Alcaraz et al. 2009; Lapp et al. 2015). In the cases reported from Norway, diarrhea has been occasionally seen, but all four Swiss cases had diarrhea (Løken et al. 1998). Multiple to coalescent small, slightly elevated red foci are seen in the skin. Pregnant sows may abort before death occurs (Albini et al. 2003b).

Hematological changes can include lymphopenia and a moderate neutrophilia. There can be biochemical abnormalities such as increases in urea, total bilirubin, and creatinine (Løken et al. 1998).

Incubation period and severity of clinical signs vary with the virus, the host, and other factors that are not completely understood. Evidence suggests that subclinical or clinical courses are possible, depending on whether the animals were stressed by handling. The clinical course of the disease is usually short, with death generally occurring after 2–4 days (Løken et al. 1998).

Lesions

Macroscopic lesions can be scant and not typical. Usually, pigs with MCF are in good body condition. They have cyanotic areas or petechiation in their skin. Fine crusts can cover the hyperemic skin. The lymph nodes are moderately enlarged, hyperemic, and moist on cut surfaces. The mucosa of the respiratory tract is characterized by hyperemia and covered by mucopurulent exudate. The lungs are congested and edematous; catarrhal or suppurative bronchitis and bronchopneumonia may develop. The spleen and liver can be engorged. No consistent gross lesions are reported for the alimentary tract. Kidneys are occasionally swollen and pale, and multiple cortical grayish-red foci up to 5 mm in diameter can be present. The CNS appears normal upon gross examination, although hyperemic meninges may be seen. Corneal opacity, conjunctivitis, and acral cyanosis are observed at necropsy (Albini et al. 2003b; Løken et al. 1998).

The most consistent histological finding, and the hallmark of MCF in pigs, is acute vasculitis in the CNS and other organs. This is characterized by the presence of numerous adventitial and transmural mononuclear cells and focal and segmental fibrinoid necrosis of the vessel walls in many of the tissues, including myocardium, spleen, leptomeninges and neuroparenchyma of the brain and spinal cord, skin, and kidneys. The lymphoproliferative vasculitis and associated degeneration and necrosis are most prominent in the media and adventitia of medium-sized and small arteries (panarteritis).

In the skin, perivascular and intravascular accumulations of mononuclear inflammatory cells occur in the dermis associated with subepithelial edema and focal epidermal necrosis. Lymph nodes show hyperplasia of lymphoid cells within the paracortex with scattered areas of necrosis. The alveolar septa of the lungs are thickened with increased numbers of lymphocytes and plasma cells. Perilobular and periportal accumulations of lymphoid cells are found in the liver. Multifocal lymphoplasmacytic interstitial nephritis, with necrotizing arteritis and periarteritis involving blastic lymphoid infiltrates, occurs in the kidney (Figure 35.13).

Cerebrum, cerebellum, and meninges show mild to moderate perivascular cuffs and transmural infiltrations of mononuclear cells, including some histiocytes and

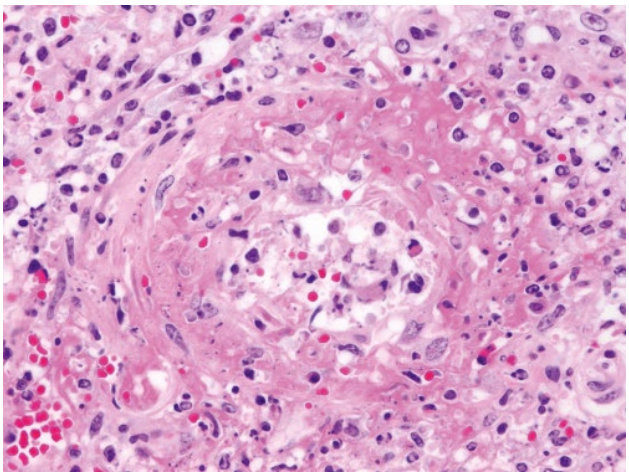

Figure 35.13 Mesentery; Vietnamese potbellied pig; medium-sized artery with lymphoplasmacytic vasculitis and transmural fibrinoid necrosis (hematoxylin and eosin [H&E]; *Source:* Courtesy Dr. Peter Wohlsein, University of Veterinary Medicine Hannover).

very few neutrophils with minimal karyorrhectic debris and plasma exudation into Virchow–Robin spaces. Ocular lesions consist of corneal edema and lymphoplasmacytic conjunctivitis. The uvea and retina are heavily infiltrated by lymphocytes, especially prominent around the blood vessels and in vessel walls (Løken et al. 1998). Lymphocytic optic neuritis can also be present. Similar moderate blastic lymphoid infiltrates might be present in the zona glomerulosa of the adrenal cortex and the intestinal submucosa (Alcaraz et al. 2009). Rarely, intranuclear inclusion bodies can be found.

Diagnosis

Differential diagnoses include Aujeszky's disease in particular, but also classical swine fever, African swine fever, porcine teschovirus infection, PCV2 infection, and rabies. Since lesions found at necropsy are not sufficiently specific for an etiological diagnosis, histopathology including molecular tests is necessary to confirm MCF. As in cattle, panarteritis is the most significant histological lesion. Consistent changes are seen in the brain. It is beneficial to microscopically investigate the epidural carotid rete mirabile around the pituitary gland for characteristic vasculitis, as in cattle. A combination of arteritis, lymphoid hyperplasia, and multifocal intraepithelial lymphocytic infiltrates is very characteristic for MCF and is essentially consistent with the classical head-and-eye form of MCF seen in ruminants (Løken et al. 1998).

Diagnosis of MCF depends on a combination of clinical signs, histopathology, and detection of virus-specific antibodies in blood or DNA in peripheral blood leukocytes or lymphoid tissue samples (Baxter et al. 1993). The OIE recognizes histopathology as the definitive diagnostic test for cattle, but laboratories have adopted other approaches, such as PCR assays that detect OvHV-2 DNA sequences. Using a mAb (15A) specific for a conserved antigen, a competitive inhibition ELISA test has been developed and refined (Li et al. 1994, 2001). A direct ELISA has been developed recently that offers a simple and inexpensive alternative. Conventional and real-time PCR assays allow sensitive confirmation of the presence of OvHV-2 in infected pigs and may also be useful for phylogenetic and epidemiological studies in natural and MCF-susceptible hosts (Albini et al. 2003a; Baxter et al. 1993; Hüssy et al. 2001; Russell et al. 2009).

Immunity

Prophylactic immunization is not available.

Prevention and control

Despite the low rate of porcine MCF in Europe and North America, it is important to discourage contact between pigs and sheep to minimize any infections.

Influenza Viruses

Kristien Van Reeth and Amy L. Vincent

Relevance

The first reports of influenza-like disease in pigs occurred concurrently in the United States and Europe in conjunction with the 1918 human influenza pandemic. Contemporary genetic analyses confirmed that the early H1N1 swine viruses, progenitors of the "classical" H1N1 lineage of swine influenza viruses, and the human viruses of 1918 were closely related, with both derived from a wholly avian ancestral virus (Taubenberger and Palese 2006). One anecdotal report suggested that the ecobiological association between human and swine influenza began long before 1918 (Morens and Taubenberger 2014; Worobey et al. 2014).

Influenza viruses of genus (type) A, B, C, and D have been identified. Influenza A virus (IAV) is infectious for a wide range of host species, including birds, mammals, and bats. Influenza B virus mainly causes respiratory disease in humans, although it can also infect seals and pigs (Ran et al. 2015). Influenza C virus is infectious for humans and pigs (Guo et al. 1983). Influenza D virus (initially called influenza C-like virus) was first isolated from a diseased pig in 2011 (Hause et al. 2013), but this virus primarily affects cattle and is not known to infect or cause illness in humans. Among the four genera of influenza viruses, only IAVs are of routine clinical significance in swine. Therefore, the remainder of this chapter is focused on IAVs.

IAV is a major cause of acute respiratory disease outbreaks in pigs (Loeffen et al. 1999; Terebuh et al. 2010), but infections are frequently subclinical. The epidemiology of influenza A virus in swine (IAV-S) encompasses a complex interplay of viruses of human, avian, and swine evolutionary origins. Conversely, pigs are postulated to play important roles as intermediate hosts in the reassortment and/or adaptation events leading to development of influenza viruses of pandemic potential for people (Subbarao et al. 2006; Webster et al. 1992). On the other hand, it is now clear that human-to-swine transmission of influenza virus is far more frequent than swine-to-human and is central in globally seeding swine populations with new viral diversity (Nelson and Vincent 2015).

Genetic reassortment of human, avian, and/or swine IAVs is extremely common in pigs, and the resulting viruses have fundamentally altered the epidemiology of influenza in pigs in many parts of the world. Most recently, the 2009 pandemic H1N1 (H1N1pdm09) virus arose as the result of reassortment between North American and Eurasian lineages of IAV-S (Garten et al. 2009; Smith et al. 2009). H1N1pdm09 then infected swine populations worldwide via humans. Not only was this virus antigenically distinct from previously known viruses circulating in swine, but it has now reassorted extensively with almost all of the regionally established swine IAVs, leading to a further expansion of novel IAV-S genotypes and an increasingly complex epidemiological picture.

Etiology

Influenza viruses are members of the family *Orthomyxoviridae* that includes seven genera: *Influenzavirus A*, *Influenzavirus B*, *Influenzavirus C*, *Influenzavirus D*, *Isavirus*, *Quaranjavirus*, and *Thogotovirus*. Influenza viruses are polymorphic, enveloped viruses approximately 80–120 nm in diameter (Figure 36.1). The lipid envelope renders the virus highly susceptible to detergents and most commonly used antiviral disinfectants.

Influenza viruses possess 7–8 separate segments of negative-sense RNA (8 segments for influenza A and influenza B viruses; 7 segments for influenza C and influenza D viruses) (Hause et al. 2014; Shaw and Palese 2013). A schematic diagram of IAV particle is shown in Figure 36.1. Eight segments of IAV encode 10–12 viral proteins (the PB1, M, and NS segments can encode more

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

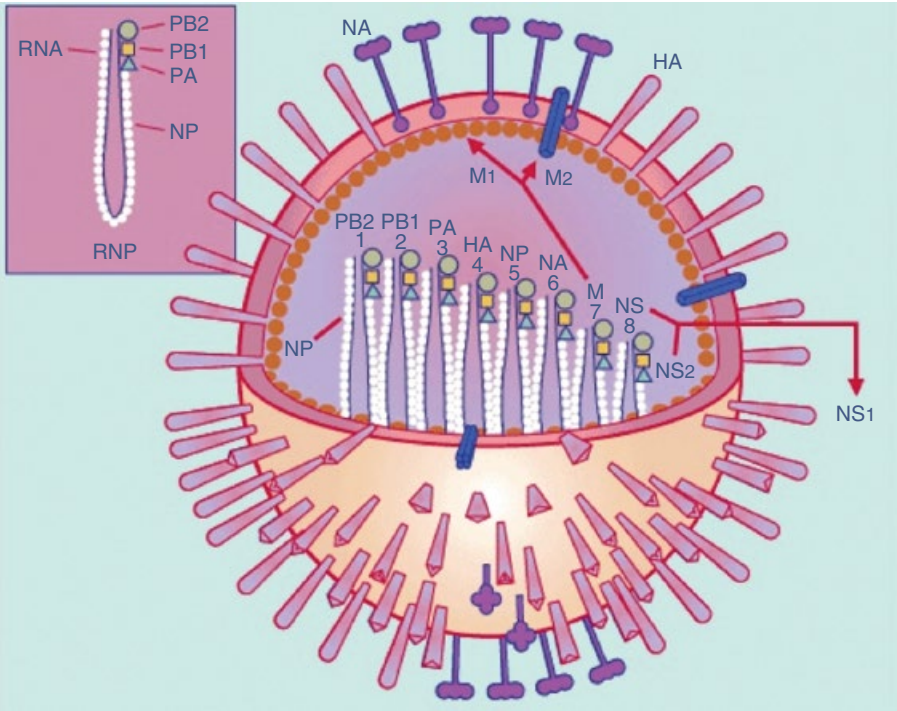

Figure 36.1 Structure of an influenza A virus. The hemagglutinin (HA), neuraminidase (NA), and part of the matrix2 (M2) protein are on the outer surface of the virion and protrude through the envelope. The viral RNA segments are coated with nucleoprotein (NP) and bound by a complex of three polymerases (PB2, PB1, PA). The eight segments are arranged according to their length, which puts the HA gene at place 4 and the NA gene at place 6. NS1 is the single nonstructural protein and is not part of the viral particle. *Source:* Wright and Webster (2001).

than one protein). The segmented nature of the influenza genome allows two viruses (within the same genera) that coinfect a single host to exchange RNA segments during viral replication, a process known as genetic "reassortment." Reassortment between members of different genera has not been reported (Shaw and Palese 2013).

IAVs are named using the following convention: A/species of origin/location of isolation/isolate number/year of isolation (subtype) (e.g. A/Swine/Wisconsin/125/97[H1N1]). If no species is designated, it is, by default, a human isolate. A detailed review of influenza virus structure and genetics can be found elsewhere (Shaw and Palese 2013).

IAV subtypes are defined by the hemagglutinin (HA or H) and neuraminidase (NA or N) spike-like glycoproteins that project from the surface of the viral envelope. There are 16 HAs and 9 NAs that are conventionally distinguished antigenically and genetically, but 2 additional HAs (H17–H18) and NAs (N10–N11) have recently been identified in bats (Tong et al. 2013; Wu et al. 2014). The combination of HA and NA in a virus defines its subtype (e.g. H1N1, H1N2, H3N2). The HA viral glycoprotein mediates attachment to sialic acid-containing receptors on the host cell and is the principal target for the induction of neutralizing antibodies. At the molecular level, sialic acids are attached to galactose residues by alpha2,3 or alpha2,6 linkages. In binding tests, human influenza viruses prefer to bind to 2,6-linked ("human-type") receptors, whereas avian viruses prefer 2,3-linked ("avian-type") receptors. Sialic acid binding is also responsible for the agglutination of red blood cells, and this property is used in diagnostic applications (hemagglutination (HA) and hemagglutination inhibition (HI) assays – see below). The NA viral glycoprotein enables virus release from the infected cell by breaking the bonds between sialic acids and adjacent sugar residues.

Depending on the strain of virus and species of bird, IAVs in waterfowl can infect and be shed from the respiratory and/or the enteric tract (Webster et al. 1978). Enteric infection leads to virus excretion in feces, which can play a role in avian influenza virus outbreaks (Rohani et al. 2009) and possibly in avian-to-swine transmission (Karasin et al. 2000b, 2004; Ma et al. 2007). Although interspecies IAV transmission occurs, there is a strong species barrier (Landolt and Olsen 2007; Neumann and Kawaoka 2006; Van Reeth 2013), particularly between birds and mammals. Thus, only a very restricted number of HA subtypes have become endemic in mammals (e.g. H1, H2, and H3 in humans; H1 and H3 in pigs; H3 and H8 in horses). In contrast, 16 HA and 9 NA subtypes have been found in IAVs in wild waterfowl, the global reservoir of influenza viruses (Hinshaw et al. 1980; Webby and Webster 2001; Webster et al. 1992).

Both subtype and genotype are important in understanding the epidemiology and evolution of IAVs. Genotyping is done by sequencing each viral RNA segment and then conducting a phylogenetic analysis to generate an 8-gene "constellation." These analyses define the evolutionary lineages (host species and geographic region) from which each viral gene originated. A phylogenetic lineage refers to a group of viruses that share a common genetic origin for a particular gene. It is possible for a virus to possess genes from distinct lineages, a reflection of the different origins of individual genes. Genotyping has been an important tool in recent years for understanding the origins and continued evolution of influenza in pigs.

Public health

Human infections with swine IAVs of various subtypes, lineages, and genotypes have been reported (Freidl et al. 2014; Myers et al. 2007; Shinde et al. 2009; Van Reeth 2007), particularly with H3N2, H1N2, and H1N1 viruses of the North American triple-reassortant lineages (Bowman et al. 2014; Choi et al. 2015; Jhung et al. 2013). The number of documented infections is small compared with the number of people in contact with pigs worldwide. However, limited studies of IAV-S antibodies in humans suggest that IAV-S infections may be widespread and undiagnosed (Gray et al. 2007; Myers et al. 2006, 2007; Olsen et al. 2002; Terebuh et al. 2010). Granted, the interpretation of such studies is compromised by the technical limitations of differentiating antibodies against swine versus human influenza viruses by serology (Sikkema et al. 2016). This is especially true at the current time with the circulation of the H1N1pdm09 virus in people and repeated human-to-swine transmission of this virus (Nelson et al. 2015c). In addition, most H1 and H3 swine IAVs are derived from viruses that once circulated in the human population (Nelson et al. 2015a,b). With the exception of the swine influenza outbreak at Fort Dix, New Jersey, in 1976 (Top and Russell 1977), evidence for person-to-person spread of swine-lineage viruses is scarce (Jhung et al. 2013; Myers et al. 2007), although the pandemic of 2009 differs in this regard.

Pandemic strains of IAV must possess at least three properties: able to infect humans, able to spread person to person, and able to evade immunity in the human population. Such viruses may develop through *in toto* transmission from an animal host (e.g. emergence of a wholly avian virus to create the 1918 pandemic strain [Taubenberger and Palese 2006]) or through genetic reassortment between a virus with an immunologically unique HA and another virus(es), ideally one already adapted to human infection. The "Asian flu" virus of the 1957 pandemic and the "Hong Kong" virus of the 1968 pandemic both arose via the latter mechanism, with reassortment between a novel avian virus (providing new HA, PB1 [and NA in 1957] genes) and the previously circulating seasonal human IAV (Kawaoka et al. 1989; Webby and Webster 2001; Webster et al. 1992). The H1N1pdm09 virus likely arose through a combination of these two scenarios from a unique "intercontinental" reassortment between swine IAVs of North American and Eurasian lineages (Figure 36.2) (Mena et al. 2016; Smith et al. 2009), followed by *in toto* transmission from pigs to humans, human-to-human transmission, and global spread by humans (Chowell et al. 2011; Dawood et al. 2009; Garten et al. 2009; Mena et al. 2016). Evidence that this reassortment event occurred in pigs and the reassorted precursor virus circulated in pigs in Mexico during the years prior to its reemergence as a human pandemic strain has been reported (Mena et al. 2016).

All eight influenza genomic segments contribute to host range (i.e. "multigenic" species specificity) (Landolt and Olsen 2007; Neumann and Kawaoka 2006; Van Reeth 2013), but the HA is particularly important because of its role in receptor binding and the presumed differences in viral receptors between different hosts (Ito 2000; Landolt and Olsen 2007; Matrosovich et al. 2000; Nicholls et al. 2008).

The human-type receptor is found throughout the upper and lower respiratory tract of humans, as well as pigs, whereas the avian-type receptor is almost exclusively found in the lungs of both species (Nelli et al. 2010; Nicholls et al. 2007; Shinya et al. 2006; Van Poucke et al. 2010). The scarcity of avian-type receptors in the nose and trachea of humans is believed to hamper transmission of avian viruses to and between humans; the same may also apply to pigs.

However, receptor recognition is complicated, and the implications for host range are not fully appreciated (Bateman et al. 2008, 2010; Byrd-Leotis et al. 2014; Gambaryan et al. 2005; Nicholls et al. 2008; Sorrell et al. 2011; van Riel et al. 2010). For instance, virus binding to a given sialic acid may not lead to productive infection of cells (Bateman et al. 2008, 2010), and additional receptors were recently discovered in pigs (Byrd-Leotis et al. 2014). In addition, both types of sialic acids are also expressed in humans and some land-based poultry species (Gambaryan et al. 2002; Landolt and Olsen 2007; Pillai et al. 2010; Wan and Perez 2006; Webby and Webster 2001), so they are not unique to pigs. Nonetheless, pigs remain the focus, in particular because of the genetic origins of the H1N1pdm09 virus.

Epidemiology

Susceptible species

In addition to domestic pigs and humans, IAV-S can infect wild boar (Saliki et al. 1998), domestic turkeys (Choi et al. 2004; Hinshaw et al. 1983; Ludwig et al. 1994;

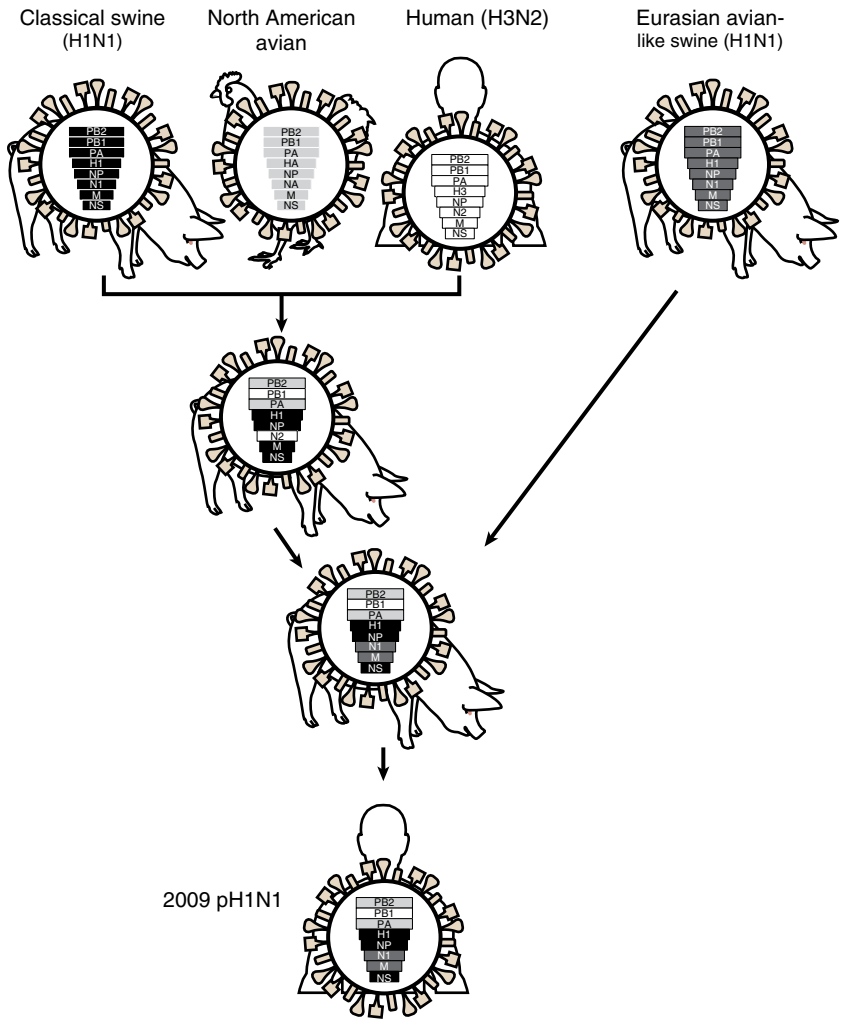

Figure 36.2 Supposed origin of the 2009 pH1N1 influenza virus. The genes encoding the NA and M proteins seem to be derived from Eurasian avian-like swine H1N1 IAVs. The remaining six genes are most closely related to those of trH1N2 swine IAVs with a mix of human, swine, and avian virus genes, which are widespread in swine in the United States. These two viruses likely reassorted in a pig or another animal species some 10 years ago. *Source:* Adapted from Neumann et al. (2009). Reproduced with permission of Springer Nature.

Olsen et al. 2006; Suarez et al. 2002; Tang et al. 2005; Wood et al. 1997; Wright et al. 1992), and, rarely, free-ranging waterfowl (Olsen et al. 2003).

Although naturally acquired infections of pigs with avian influenza viruses have been documented in many parts of the world, only the European avian-like swine H1N1 virus became swine adapted (Brown et al. 1997; Donatelli et al. 1991; Kyriakis et al. 2011; Scholtissek et al. 1983; Van Reeth et al. 2008). Other avian influenza virus subtypes have been sporadically detected in pigs in North America or Asia, including avian H1N1, H2N3, H3N2, H3N3, H4N6, H4N8, H5N1, H5N2, and especially H9N2 viruses (Brown 2000; Choi et al. 2005; Cong et al. 2008; Guan et al. 1996; Karasin et al. 2000b, 2004; Kida et al. 1988; Lee et al. 2009; Ma et al. 2007; Peiris et al. 2001; Shi et al. 2008; Su et al. 2012; Takano et al. 2009; Yu et al. 2008a). In some instances, these viruses spread between pigs on a limited scale, but they have not formed a stable lineage in swine (Choi et al. 2005; Jung et al. 2007; Nidom et al. 2010; Santhia et al. 2009). This is consistent with experimental studies showing that avian influenza viruses are restricted in their replication in pigs and transmission between pigs (Balzli et al. 2016; Choi et al. 2005; De Vleeschauwer et al. 2009a,b; Lee et al. 2009; Lipatov et al. 2008; Manzoor et al. 2009).

There is evidence that avian influenza viruses must mutate or reassort with swine-adapted viruses to replicate efficiently in pigs (Abente et al. 2016; Mancera Gracia et al. 2017; Qiao et al. 2012), but no natural reassortant viruses have been able to maintain themselves in swine (Bi et al. 2010; Cong et al. 2007, 2010; Lee et al. 2009; Shi et al. 2008).

Sequencing has shown that many swine lineages contain gene segment contributions from human seasonal viruses (Nelson et al. 2015c). Numerous reports demonstrated that human viruses were transmitted to swine and remained undetected for decades in under-sampled swine populations. Introductions of seasonal H3N2 and H1N1 from humans to pigs at different points in time, in different geographic regions, and with reassortment and evolution within swine added marked heterogeneity to the genetic lineages of IAV-S currently circulating

globally. H1N1, H1N2, and H3N2 viruses maintained in swine populations worldwide are primarily reassortants with a mix of human- and swine-adapted genes, with distinct genetic properties of the HA based on the year of introduction from human to swine (or avian to swine in the case of the Eurasian avian H1N1 lineage). This allows for discrimination of IAV-S isolates from different regions, as well as discrimination of swine-adapted viruses from contemporary human seasonal influenza strains. A global nomenclature system along with an automated Web-based tool was generated to facilitate the identification and classification of swine H1 lineages (Anderson et al. 2016).

Once established in swine, antigenic drift in a given HA lineage is slower in swine than in humans. That is, swine viruses retained more antigenic cross-reactivity to precursor human viruses compared with contemporary human seasonal viruses (de Jong et al. 1999, 2007; Kyriakis et al. 2011). However, antigenic analyses of various IAV-S lineages and comparisons to human-lineage precursors revealed a tremendous amount of antigenic diversity in IAV-S overall due to the regular human-to-swine transmission events that seeded multiple endemic lineages, as well as the geographic separation of swine populations (Lewis et al. 2016). Thus, swine can act as reservoirs for older human HAs. Several studies have shown a lack of protective serum antibody titers against endemic swine IAVs in people born after the circulation of the respective human precursor viruses (Bangaru et al. 2016; Bravo-Vasquez et al. 2017; Hoschler et al. 2013; Qiu et al. 2015b). Swine IAVs, therefore, pose a threat for reintroduction into the human population, once immunity has waned sufficiently to allow widespread transmission.

Transmission

IAV-S can be detected throughout the year (Hinshaw et al. 1978; Kaplan et al. 2015; Kyriakis et al. 2011; Olsen et al. 2000; Van Reeth and Pensaert 1994), with seasonal disease peaks. Influenza viruses are most likely to be introduced into herds with the movement of animals. The primary route of virus transmission is direct contact with infectious oronasal secretions, with virus titers of up to 1×10^7 infectious particles/mL at the peak of shedding in nasal secretions (De Vleeschauwer et al. 2009a,b; Landolt et al. 2003; Larsen et al. 2000; Van Reeth et al. 2003a). Additionally, aerosol detection of IAV-S during naturally occurring outbreaks in swine barns demonstrated significant amounts of virus in the air. Thus, aerosolized virus is also a source of infection, an exposure risk to humans during outbreaks (Neira et al. 2016), and may contribute to IAV-S infections on farms with high biosecurity. In some cases, viruses will disappear from finishing herds, especially with all-in/all-out management, only to be reintroduced later. In breeding herds, virus was more frequently detected in replacement gilts and suckling piglets compared with sows (Diaz et al. 2015). On farrow-to-finish farms, the virus may persist in the growing pig populations due to the continuous introduction of susceptible young pigs with declining levels of maternal immunity (Loeffen et al. 2009).

Geographic distribution

2009 Pandemic H1N1 (H1N1pdm09) virus in pigs

The distribution of subtypes and genotypes of endemic IAV-S varies widely among geographic regions. The exception is H1N1pdm09, which is widely distributed – largely through repeated reintroduction from humans to swine (Forgie et al. 2011; Hofshagen et al. 2009; Howden et al. 2009; Pareda et al. 2010; Vijaykrishna et al. 2010; Welsh et al. 2010). Although the H1N1pdm09 virus was coined "swine flu," there is no evidence to suggest that infection in pigs contributed to widespread human transmission or maintenance as a human seasonal strain. Although H1N1pdm09 has only been maintained in pigs in its entirety on a limited basis, reassortment with regional endemic subtypes and lineages has been widespread, with various genes incorporated (Charoenvisal et al. 2013; Kanehira et al. 2014; Kim et al. 2014; Kitikoon et al. 2013b; Lange et al. 2013; Liang et al. 2014; Nelson et al. 2012a, b, c; Pascua et al. 2013a, b; Poonsuk et al. 2013; Vijaykrishna et al. 2011; Watson et al. 2015). The impact of H1N1pdm09 introductions to pigs on the evolution of endemic swine lineages in various regions is discussed below.

IAV-S in North America

The United States, Canada, and Mexico share North American lineages, albeit with regional differences in the relative predominance and genetic variation within clades. Reports are limited, but it appears that pigs in Mexico have viruses with an ancestral origin that overlaps with some of the North American swine lineages (Anderson et al. 2016; Lopez-Robles et al. 2014; Mena et al. 2016), as well as a potentially unique human seasonal lineage H3N2 (Nelson et al. 2015a).

Classical H1N1 lineage viruses were the dominant cause of influenza among pigs in North America from 1930 through the 1990s (Chambers et al. 1991; Hinshaw et al. 1978; Olsen et al. 2000). In 1998, triple-reassortant (tr) H3N2 viruses were identified with HA, NA, and PB1 genes of human influenza virus lineage; M, NP, and NS genes of classical swine H1N1 virus lineage; and PA and PB2 genes of North American avian virus lineage (Karasin et al. 2000c; Zhou et al. 1999). The PB2, PB1, PA, NP, M, and NS genes were referred to as the triple-reassortant internal gene (TRIG) cassette (Vincent et al. 2008b). TRIG-containing H3N2 IAV-S strains spread

widely throughout the North American swine population and evolved into the contemporary phylogenetic clade IV (Olsen et al. 2006; Richt et al. 2003; Webby et al. 2000, 2004). These viruses also reached parts of Asia. The trH3N2 and the existing classical swine H1N1 viruses reassorted to produce trH1N2 (Choi et al. 2002a,b; Karasin et al. 2000a, 2002) and trH1N1 (Subbarao et al. 2006).

Two additional genotypes of trH1 virus emerged in the early 2000s containing the TRIG cassette, but the H1 and N1 or N2 genes derived from two seasonal human influenza virus introductions, resulting in delta1 and delta2 clades (Vincent et al. 2009b). For clarity, the H1 HA genes among US swine viruses were designated to 5 phylogenetic clades before 2009: alpha, beta, and gamma of classical H1 origin and delta1 and delta2 of human seasonal H1 origin (Vincent et al. 2009b,c).

H1N1pdm09 further expanded the diversity of IAV-S strains by contributing the internal genes to preexisting endemic subtypes in multiple combinations via reassortment (Ducatez et al. 2011; Kitikoon et al. 2013b; Liu et al. 2012), with the matrix gene found in a majority of endemic IAV-S strains in 2012 (Anderson et al. 2013; Rajao et al. 2016). The resulting reassortant viruses are currently undergoing rapid genetic evolution, most notably in surface glycoprotein HA genes (Kitikoon et al. 2013a; Rajao et al. 2016).

It remains to be seen if all of the expanded HA genetic clades will sustain transmission and evolution, but the biological consequences of the genetic diversity are recognized by antigenic drift (Feng et al. 2013; Lewis et al. 2014). In 2012, a virus with newly introduced human seasonal H3 and N2 genes in combination with H1N1pdm09 internal genes was first isolated in the United States, followed by infrequent detections of reassorted humanlike H3N1 and H3N2 isolates with a mix of TRIG and pdm09 internal genes (Rajao et al. 2015). Since 2014, detections of the humanlike H3N2 continued to rise, and it now appears to be an established clade in the United States (Rajao et al. 2016).

IAV-S in South America

Very few publically accessible IAV-S sequences from swine isolates are available from South America. Argentina reported distinct human-lineage viruses of H1N1, H1N2, and H3N2 subtypes (Cappuccio et al. 2011; Pereda et al. 2011), along with a reassorted human H3N2 with internal genes from the H1N1pdm09 virus (Dibarbora et al. 2013). In Brazil, an H1N2 with H1 and N2 genes of human seasonal origin and internal genes (M, NP, PB1, PB2, and PA) from H1N1pdm09 were detected (Biondo et al. 2014), followed by an additional lineage of humanlike H1N2 and H3N2 reassortants with the H1N1pdm09 internal genes (Nelson et al. 2015b). Chile has also reported two human seasonal lineage H1 paired with N1 or N2 and one H3N2 that are each distinct from those found in other South American countries (Nelson et al. 2015a).

IAV-S in Europe

Three IAV-S subtypes have been circulating in European swine for decades. Avian-like H1N1 viruses (H1avN1) were introduced from wild ducks to pigs in 1979 (Pensaert et al. 1981; Scholtissek et al. 1983) and have remained one of the major lineages on the European mainland. The European swine H3N2 viruses were derived from descendants of the 1968 "Hong Kong" pandemic human virus, but they have acquired the internal gene cassette from the H1avN1 virus through reassortment (Campitelli et al. 1997; Castrucci et al. 1993; de Jong et al. 1999; Haesebrouck et al. 1985). In the mid-1990s, H1N2 viruses became established in European pigs. The dominant H1N2 viruses (H1huN2) retained the genotype of these reassortant H3N2 viruses, but they acquired the H1 gene from a human seasonal H1N1 virus from the mid-1980s (Brown et al. 1998; Marozin et al. 2002; Schrader and Suss 2003; Van Reeth et al. 2004). Thus, these three subtypes share common internal genes, but they have clearly distinguishable HAs.

As occurred elsewhere, the introduction of H1N1pdm09 in European swine led to an increase in second-generation reassortants between the pandemic virus and the established endemic lineages (Watson et al. 2015). Among the most frequently reported genotypes were H1huN2 and H1pdmN2, with internal genes from H1N1pdm09. Between 2009 and 2013 the European Surveillance Network for Influenza in Pigs identified 23 different genotypes in 14 different countries (Watson et al. 2015). Regardless, the six genotypes mentioned above were the most frequent and accounted for 77% of the detections (Simon et al. 2014; Watson et al. 2015).

However, large differences were found between countries, and the emergence of H1N1pdm09 appears to have changed the ratios between various lineages in several countries as compared to the pre-2009 situation (Kyriakis et al. 2011). Most remarkable was the contrast between mainland Europe, where H1avN1-based genotypes were prevailing, and the United Kingdom, with a predominance of H1N1pdm09-based genotypes (Simon et al. 2014; Watson et al. 2015). While H1avN1 was still reported at a high prevalence in all European mainland countries, H3N2 and H1huN2 had an inverse relationship with each other. During recent years H3N2 was virtually absent in France, Poland, the United Kingdom, and Denmark. A reassortant H1avN2 virus accounted for 70% of the swine IAVs in Denmark, but was found at much lower frequencies in only a few other countries (Simon et al. 2014).

IAV-S in Asia

The epidemiology of IAV-S in Asia differs among countries, with reporting generally limited to China, South Korea, Japan, Thailand, Taiwan, and Vietnam. Since the 1970s, H3N2 viruses were repeatedly transmitted from people to pigs, and variants of the Hong Kong/68 pandemic virus co-circulate in pigs with several contemporary humanlike H3N2 viruses (Choi et al. 2013; Kida et al. 1988; Nerome et al. 1995; Peiris et al. 2001; Sun et al. 2009; Yu et al. 2007, 2008b). Human seasonal H1-related viruses are less widespread in Asian swine and had not been reported beyond China (Lu et al. 2010; Sun et al. 2009; Yu et al. 2007, 2009b) until recent reports in Vietnam (Takemae et al. 2016).

Prior to 2009, co-circulating viruses in China included H1N2 viruses carrying a classical H1 and an NA of contemporary human origin, multiple lineages of human-origin H3N2, Eurasian avian-like H1N1 viruses (Guan et al. 1996; Shortridge et al. 1977), and North American TRIG viruses (Vijaykrishna et al. 2011). South Korea also imported North American TRIG-containing H1 and H3 viruses (Lee et al. 2008), and reassortant viruses with Eurasian avian-like H1 (Pascua et al. 2013a) have been reported. Various H3N2 reassortant viruses were also reported throughout Asia, and some have a common ancestor with European or North American virus lineages (Takemae et al. 2008; Yu et al. 2008b). Thai swine H1N1 viruses clustered as either classical H1 or Eurasian H1 swine lineages with specific genotype reassortment patterns (Takemae et al. 2008). H3N2 viruses with human-lineage HA and NA genes of either European swine descent or a more recent human seasonal lineage were detected, with a mixture of the internal genes derived from Eurasian and classical swine lineages. H1N2 viruses containing combinations of genes from the endemic H1N1 viruses and humanlike H3N2 are also present (Takemae et al. 2008).

The H1N1pdm09 was also introduced to swine in Asia and reassorted with the endemic subtypes in China (Vijaykrishna et al. 2010), Japan (Matsuu et al. 2012), and Thailand (Kitikoon et al. 2011). Similar to other regions, the contemporary Thai H1N1, H1N2, and H3N2 viruses incorporated various internal gene segments from H1N1pdm09 (Charoenvisal et al. 2013; Poonsuk et al. 2013) as in other Asian countries (Lu et al. 2010; Vijaykrishna et al. 2010; Xu et al. 2011; Yu et al. 2008b, 2009a), resulting in multiple, very complex reassortant viruses.

Pathogenesis

The pathogenesis of influenza in pigs is well studied and very similar to that in humans (De Vleeschauwer et al. 2009a; Khatri et al. 2010; Van Reeth et al. 1998). Influenza is an acute infection of the respiratory tract. Virus replication is limited to epithelial cells of the upper and lower respiratory tract of pigs – the nasal mucosa, ethmoid, trachea, and lungs – and virus excretion and transmission occur exclusively via the respiratory route. Infectious virus can thus be isolated from the tissues mentioned, as well as from tonsils and lymph nodes in the respiratory tract, bronchoalveolar lavage (BAL) fluid, and nasal, tonsillar, or oropharyngeal swabs (Brown et al. 1993; De Vleeschauwer et al. 2009a,b; Heinen et al. 2001b; Khatri et al. 2010; Landolt et al. 2003; Richt et al. 2003; Vincent et al. 2009a). In most experimental studies, virus can be isolated from 1 day post inoculation onward and becomes undetectable after approximately 7 days. IAV-S has a preference for the lower over the upper respiratory tract (De Vleeschauwer et al. 2009a; Khatri et al. 2010). This is shown by virus titration and by immunohistochemical studies that reveal massive numbers of viral antigen-positive cells in bronchial, bronchiolar, and alveolar epithelia, compared with fewer positive cells in the nasal mucosa (Figure 36.3). Viral nucleic acid or antigen has also been found in alveolar macrophages, but there is no proof for a productive infection of these cells (Brookes et al. 2010; Jung et al. 2002; Weingartl et al. 2010). IAV-S is unlikely to spread beyond the respiratory tract. The brain stem is the single extra-respiratory tissue from which low amounts of virus are occasionally isolated (De Vleeschauwer et al. 2009a). Only one study describes a low titered and transient viremia (Brown et al. 1993). In a few studies, feces, intestines, or spleen occasionally tested positive by PCR, but virus-positive cells have

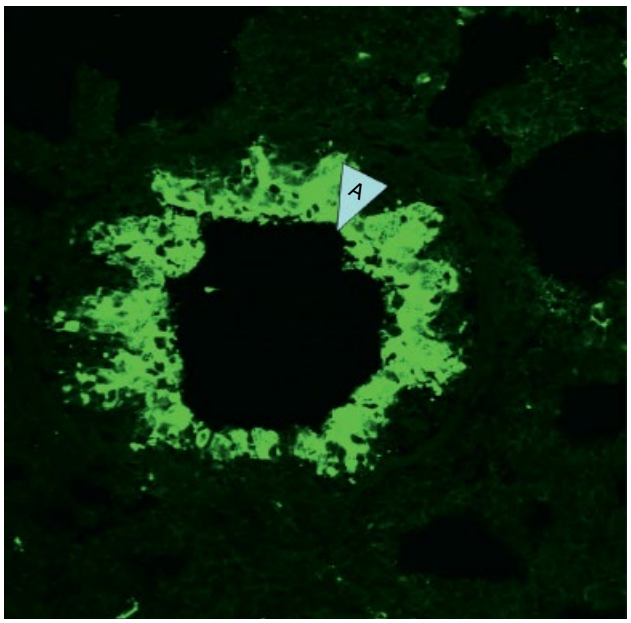

Figure 36.3 Immunofluorescence staining of influenza A virus antigen-positive cells in the lungs of a pig. In smaller bronchioli (A), up to 100% of the epithelial lining may be infected.

never been demonstrated outside the respiratory tract (Brookes et al. 2010; De Vleeschauwer et al. 2009a). Pig infection studies with the H1N1pdm09 virus confirmed the absence of virus in pork and muscle tissue, so IAV in swine is not a food safety or pork trade concern (Brookes et al. 2010; Vincent et al. 2009a).

Infection with IAV-S is easily reproduced by experimental inoculation of influenza-naïve pigs via intranasal (IN), aerosol, or intratracheal (IT) routes, but the kinetics of virus replication in the respiratory tract and the severity of lung inflammation and disease are markedly dependent upon the strain, inoculation route, and dose (Hemmink et al. 2016; Pomorska-Mol et al. 2014a). IT inoculation produces the characteristic infiltration of the lungs with neutrophils and the typical lower respiratory tract disease. Virus titers in lung may exceed 1×10^8 infectious particles/g of tissue. Infection also produces high fever (≥40.5 °C) and lethargy (De Vleeschauwer et al. 2009a; Van Reeth et al. 1998, 2002). Less invasive methods – IN inoculation or IT inoculation of a lower virus dose – result in slower kinetics of viral replication in the lungs, milder lung inflammation, and less specific clinical signs, mainly nasal discharge, sneezing, and low to moderate fevers, or subclinical infection (Brown et al. 1993; Larsen et al. 2000; Richt et al. 2003). Cytokines that are produced by the host during the acute stage of infection appear to be associated with the difference between subclinical infection and disease. Titers of interferon-alpha and interferon-gamma, tumor necrosis factor-alpha, and the interleukins 1, 6, and 12 in BAL fluids are considerably higher after IT inoculation than after IN inoculation. Experimental studies support the notion that a heavy viral load in the lungs is required to induce high levels of these cytokines, which in turn induce acute-phase proteins, and the typical lung inflammation and disease (Barbé et al. 2011; Kim et al. 2009; Pomorska-Mol et al. 2014b; Van Reeth et al. 1998, 2002). Factors that reduce the extent of virus replication in pigs in the field – partial active or passive immunity and sanitary measures to reduce infection pressure – are likely to reduce the severity of illness. Many cytokines, however, also have antiviral and immunostimulating effects and thus may contribute to clearance of influenza viruses.

Experimental infection studies have not yielded convincing evidence for distinct differences in the pathogenesis or virulence between IAV-S lineages or strains, rather a spectrum of similar clinical signs. The H1N1pdm09 virus has a similar pathogenic course in pigs as the previously established swine IAVs (Brookes et al. 2010; Hemmink et al. 2016; Lange et al. 2009; Vincent et al. 2009a; Weingartl et al. 2010). Although some studies describe more extensive lung lesions, one must consider the impact of factors that may vary between studies such as the inoculation dose and route of inoculation, as well as differences in replication competency between viruses and biological variation between pigs. In most comparative studies, lesion differences are not dramatic (Henningson et al. 2015; Janke 2014; Landolt et al. 2003; Richt et al. 2003; Sreta et al. 2009; Vincent et al. 2006, 2009b). On the other hand, researchers have demonstrated differing lung lesions, virus shedding patterns, and innate and adaptive immune responses following aerosol, IN, and contact infection with a single H1N1pdm09 isolate (Hemmink et al. 2016). One study has reported differences in transmission efficiency between North American H3N2 reassortant genotypes with H1N1pdm09 internal genes (Ma et al. 2015). In comparison to swine-adapted strains, infection studies with avian or human influenza viruses typically result in a mild or subclinical infection, consistent with low to moderate virus titers in the respiratory tract (Choi et al. 2005; De Vleeschauwer et al. 2009a; Landolt et al. 2003; Lipatov et al. 2008).

Clinical signs

Infections with any of the endemic swine IAVs are clinically similar, and all can produce acute respiratory episodes (Karasin et al. 2000a–c, 2002; Loeffen et al. 1999; Zhou et al. 1999). Experimental studies have failed to demonstrate differences in clinical signs or lesions among IAV-S strains (see above).

Typical swine flu outbreaks are characterized by high fever (40.5–41.5 °C), anorexia, inactivity, huddling, reluctance to rise, tachypnea, and, after a few days, coughing. Labored abdominal breathing and dyspnea are most typical. The onset of the disease is sudden, after an incubation period of 1–3 days. Morbidity is high (up to 100%), but mortality is low (usually less than 1%) in uncomplicated infections. Generally, rapid recovery begins 5–7 days after onset. Acute outbreaks of clinically typical IAV-S are generally limited to fully susceptible, seronegative pigs, either unprotected nursery pigs or older pigs (Loeffen et al. 1999).

In addition to immune status, other factors also affect the clinical outcome of IAV-S infection, including age, infection pressure, climatic conditions, housing, and concurrent infections. Secondary bacterial infections with *Actinobacillus pleuropneumoniae*, *Pasteurella multocida*, *Mycoplasma hyopneumoniae*, *Haemophilus parasuis*, or *Streptococcus suis* type 2 may enhance the severity of clinical disease. Other respiratory viruses, such as porcine respiratory coronavirus (PRCV) and porcine reproductive and respiratory syndrome virus (PRRSV), frequently infect pigs around the same age as IAV-S (Van Reeth and Pensaert 1994). Of these pathogens, PRRSV, *M. hyopneumoniae*, and IAV-S are most frequently detected in 10- to 22-week-old pigs in association with the "porcine respiratory disease complex

(PRDC)" (Thacker et al. 2001). Dual-infection studies combining IAV-S infection with *M. hyopneumoniae*, *Bordetella bronchiseptica*, PRCV, or PRRSV showed more severe disease in dual infections as compared with IAV-S alone (Brockmeier et al. 2002; Deblanc et al. 2012, 2013; Kowalczyk et al. 2014). However, consistently reproducing clinical signs caused by combinations of infectious agents is challenging, and some studies failed to show enhancement of disease. Thus, the role of IAV-S in PRDC remains elusive.

Subsequent to an influenza outbreak in a herd, producers and veterinarians sometimes report reduced reproductive performance – increased infertility, abortion, small weak litters, and stillbirths. However, little data exist to suggest that influenza viruses infect the reproductive tract of pigs or directly induce reproductive disease (Kwit et al. 2014, 2015).

Lesions

Like clinical signs, lung lesions can be mild or unremarkable. When present, the gross lesions found in uncomplicated influenza are mainly those of a viral pneumonia and limited to the apical and cardiac lobes of the lung. The percent of lung tissue with grossly visible consolidation varies greatly within and between experimental infection studies, but >50% of the lung may be affected by 4–5 days post inoculation (Janke 2014; Khatri et al. 2010; Landolt et al. 2003; Richt et al. 2003). Generally, there is a sharp line of demarcation between the affected and normal lung tissues, and the involved areas will be purple and firm. Some interlobular edema may be evident, airways may be filled with blood-tinged fibrinous exudates, and the associated bronchial and mediastinal lymph nodes are usually enlarged. In naturally occurring influenza, these lesions may be complicated or masked by concurrent, especially bacterial, infections.

Microscopically, the hallmarks of IAV include necrosis of lung epithelia, desquamation/denudation of the bronchial epithelial cell layer, and airways obstructed with necrotic epithelial and inflammatory cells, mainly neutrophils (Haesebrouck et al. 1985; Haesebrouck and Pensaert 1986; Janke 2014) (Figure 36.4). Neutrophils may account for up to 50% of the cell population in BAL fluids collected 24 hours after IT inoculation, while macrophages are the dominant cells in uninfected healthy pigs (Barbé et al. 2011; Khatri et al. 2010; Van Reeth et al. 1998). The neutrophils not only cause obstruction of the airways but also contribute to lung damage by release of their enzymes. After a few days, there is peribronchial and perivascular infiltration of lymphocytes (Landolt et al. 2003; Richt et al. 2003). Similar pathologic lesions have been observed in clinically typical IAV-S outbreaks in the field (Loeffen et al. 1999).

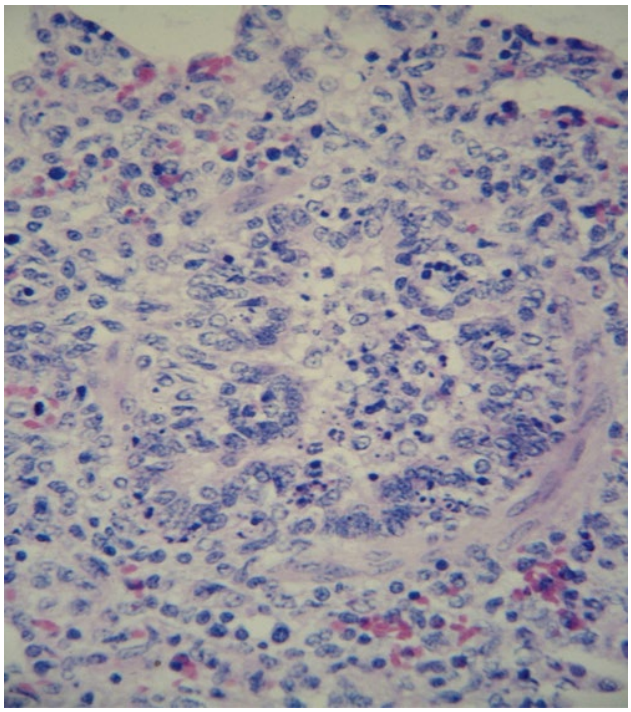

Figure 36.4 Small bronchiole with desquamation of epithelial cells after experimental infection of a pig with swine influenza A virus. The lumen is completely obstructed by desquamated epithelial cells and neutrophils.

"Vaccine-associated enhanced respiratory disease" (VAERD) has been described in pigs vaccinated with experimental whole virus inactivated vaccine and challenged with heterologous strains of the same IAV-S subtype (Vincent et al. 2008a, 2012). VAERD is characterized by more gross and microscopic pathology in vaccinated pigs versus unvaccinated controls following challenge. It appears to be restricted to pairs of viruses of the same HA subtype, which have drifted sufficiently so as to no longer stimulate cross-reacting HI or virus neutralization (VN) antibodies (Khurana et al. 2013).

Diagnosis

There are no pathognomonic signs, and swine influenza must be differentiated from a variety of respiratory diseases of swine with similar clinical and pathologic presentation. A diagnosis is only possible through isolation of virus, through detection of viral proteins or nucleic acid, or by demonstration of virus-specific antibodies. Diagnostic techniques for IAV-S have been described in detail (Swenson et al. 2015). The sensitivity of these approaches will be dependent on the specialized reagents used in the assay(s) and their "degree of match" to circulating field strains.

Figure 36.5 Collection of nasal swabs for the detection of influenza virus. Restrain the pig with the head upward and then insert the swab into the nasal cavity in a dorsal-medial direction. Use a circular motion to gently collect as much nasal secretion as possible.

IAV for detection by isolation or RT-PCR is most likely to be found in nasal and pharyngeal secretions during the febrile period of illness. Samples should be collected on polyester (e.g. Dacron®), not cotton, swabs (Figure 36.5). Swabs should be suspended in a suitable transport medium, such as cell culture medium or phosphate-buffered saline at neutral pH, and kept cold. If the samples for virus isolation can be tested within 48 hours after collection, they should be maintained at refrigerator temperature (4 °C). If samples are held longer, storage at −70 °C is recommended because IAV-S is not stable at −20 °C. Virus may also be isolated/detected from the trachea or lung tissues of pigs that die or are euthanized during the acute stage of the disease. The tissue should be held under the same conditions as swab material until ready for culture. Oral fluids are increasingly used for screening populations for IAV-S and other swine pathogens (Detmer et al. 2011; Goodell et al. 2013; Panyasing et al. 2014). Although isolation and sequencing rates are lower for oral fluids than for other specimens, RT-PCRs work reasonably well. Madin–Darby canine kidney (MDCK) is the most commonly used cell line for IAV-S virus isolation, although embryonated chicken eggs and other primary cells or continuous cell lines can be used (Zhang and Gauger 2014).

Historically, IAV HA and NA subtypes were determined by HI and neuraminidase inhibition (NI) tests using HA and NA subtype-specific antibodies. Currently, molecular methods based on detecting gene signatures unique to different subtypes (e.g. RT-PCR, gene sequencing, microarrays, whole genome sequencing) are generally used to detect and characterize IAVs (Ducatez et al. 2011; Heil et al. 2010).

RT-PCR assays (traditional and real-time technologies) provide highly analytically sensitive and specific detection of viral nucleic acid extracted from clinical sample preparations. Well-validated methods are at least equivalent to virus isolation (Landolt et al. 2005), with greater speed, reduced cost, and scalability as inherent advantages. However, due to increased analytical sensitivity in these assays, "weak" positive samples may contain degraded, rather than infectious, virus and not yield a virus isolate.

RT-PCR assays can be classified into two broad types. The first allow generic detection of any IAV and are applicable to all swine IAVs, but do not provide information on the virus subtype. These assays usually offer high levels of analytical sensitivity and specificity and are most suitable for initial screening of clinical samples (Spackman et al. 2002). The second are subtype-specific assays designed to detect specific HA subtypes and possibly to discriminate strains within the same HA subtype (e.g. classical, avian-like swine, or H1N1pdm09 viruses). These are usually of slightly lower analytical sensitivity and less useful for primary screening of samples from clinical cases than the pan-influenza A assays. The occurrence of H1N1pdm09 virus in pigs has required that any method be applicable to both endemic IAV-S and this virus (Hiromoto et al. 2010; Lorusso et al. 2010; Slomka et al. 2010).

Other methods for detecting virus or viral antigen can be applied to fresh, non-autolyzed tissues of the respiratory tract, including the lung and trachea. These include direct or indirect immunofluorescence techniques (Onno et al. 1990) and immunohistochemical detection in fixed tissue (Swenson et al. 2001; Vincent et al. 1997). In addition, commercial enzyme immunoassay membrane tests to rapidly detect influenza antigens in nasal swabs can be used without laboratory facilities (Nava et al. 2013). Although easy to perform, these tests generally lack sufficient analytical sensitivity to reliably detect virus shed from the nasal cavity and do not differentiate between virus subtypes.

Serological tests are used to demonstrate the presence of influenza-specific antibodies. Diagnosis of acute IAV-S infection by serology requires the use of paired acute and convalescent (3–4-week interval) serum samples. Serology is most useful to determine the immune status of a herd, levels of maternally derived antibody in the young piglets and their kinetics, post vaccination antibody titers and for pre-movement testing of pigs.

The HI test remains the most common test for specific anti-IAV-S antibody detection. A number of ELISA assays for IAV-S are commercially available. Broadly, these can be separated into two groups. The first group of assays detect antibody to a highly conserved core antigen of influenza A, such as the nucleoprotein. These tests generally have good diagnostic sensitivity (Ciacci-Zanella et al. 2010) and are useful as a screening assay to determine herd status, but they do not differentiate between virus subtypes. The second group of ELISAs detect subtype-specific antibodies. These ELISA assays generally offer lower diagnostic sensitivity than the HI

test (Barbé et al. 2009; Leuwerke et al. 2008) but may have application in studies where status to a specific virus subtype/strain is required. VN assays show similar performance characteristics to the HI test (Leuwerke et al. 2008; Van Reeth et al. 2006), but they are more appropriate for use in specialized laboratories.

Interpretation of serologic data is complicated by the concurrent circulation of different virus subtypes and gene lineages. This is especially problematical with co-circulation of strains within the same subtype. For example, H1 viruses possess variable cross-reactivity in tests that detect antibodies to the HA, such as HI and VN, as well as subtype-specific ELISAs (Barbé et al. 2009; Leuwerke et al. 2008). The emergence of the H1N1pdm09 virus in pigs has further complicated interpretation through a broad spectrum and sometimes unpredictable range of cross-reacting antibody responses with endemic strains in HI and VN tests (Dürrwald et al. 2010; Kyriakis et al. 2010b; Vincent et al. 2010b). Therefore, where H1N1 is endemic, infection with the H1N1pdm09 virus may not be diagnosed by serological tests alone (Kyriakis et al. 2010b).

Immunity

The adaptive immune response to IAV-S infection includes both humoral and cell-mediated immunity (CMI). Antibody responses mainly develop to the HA, NA, M, and NP proteins (Shaw and Palese 2013). Only antibodies to the globular head region of the HA can block attachment of the virus to host cell receptors and neutralize viral infectivity. These antibodies can be measured in VN or HI assays. Antibodies against the NA primarily act after infection has been initiated by limiting virus release from infected cells. Antibodies to other proteins also cannot prevent the initiation of infection, but they can mediate killing of infected cells by antibody-dependent mechanisms.

T cells are more broadly directed against epitopes on all internal and surface proteins. CD4+ or helper T cells facilitate the antibody and CMI responses, whereas CD8+ T cells differentiate into cytotoxic T lymphocytes (CTLs) and kill virus-infected cells directly, thereby helping in clearing virus from the lungs. Thus, the CTLs are the key players of the CMI response, but studies in pigs have mainly measured T helper cell activity because it is technically difficult to quantify CTLs in outbred animal species. Similarly, most studies have focused on the antibody response in serum, while mucosal antibodies in the respiratory tract are most important for protection.

The immune response to IAV-S infection is rapid and efficient with complete elimination of the virus from the respiratory tract within 7 days post inoculation. T-cell responses have been detected from 7 days post inoculation onward (Heinen et al. 2001a, b; Khatri et al. 2010; Larsen et al. 2000). HI antibodies in serum can be detected by 7–10 days post inoculation and peak by 2–3 weeks post inoculation (Heinen et al. 2000; Larsen et al. 2000). Antibody titers remain high for several weeks before beginning to decline by 8–10 weeks post inoculation (Van Reeth et al. 2004, 2006).

As would be expected, IgM and later IgG are the dominant isotypes in serum, whereas IgA is the main isotype in nasal washes (Heinen et al. 2000; Larsen et al. 2000). Larsen et al. (2000) demonstrated antibody-secreting cells in nasal mucosal tissue, which proved that antibodies are locally produced in the respiratory tract of pigs. Antibodies at the lung level are, at least in part, transudated from serum, as suggested by the dominance of virus-specific IgG in BAL samples of pigs (Heinen et al. 2000). However, substantial IgA levels have also been found in lung lavage fluids of IAV-infected pigs (Kitikoon et al. 2006; Larsen et al. 2000), and local antibody production in the lung parenchyma cannot be excluded.

After a primary IAV-S infection, there is solid protection against reinfection with the same or a similar virus strain (De Vleeschauwer et al. 2011; Larsen et al. 2000; Van Reeth et al. 2003a). Based on findings in humans, it is assumed that this immunity may last for several years, but its exact duration has not been studied in the pig. HA-specific VN antibodies are likely the primary mediators of this "homologous" immunity. Protection studies to prove the role of other immune mechanisms in the pig are still lacking.

Because of the concurrent circulation of different subtypes and lineages of influenza viruses, pigs are typically exposed to antigenically different IAV-S strains during their lifetime. There is no serologic cross-reaction between H1 and H3 subtype IAV-S strains in the HI test, nor in some cases between viruses within H1 and H3 lineages. Still, several experimental infection studies have shown cross-protection between influenza viruses in the absence of cross-reactive serum HI antibodies. There is evidence for complete or partial cross-protection between the three European H1 IAV-S lineages, between North American alpha- and gamma-cluster H1 IAVs, and between European and North American H1N1 as well as H3N2 IAV-S lineages (Busquets et al. 2010; De Vleeschauwer et al. 2011; Qiu et al. 2014, 2015a; Van Reeth et al. 2003a; Vincent et al. 2008a). The immune mediators of this "broad" protection need further study but may include a combination of mucosal IgA antibodies, CMI responses, and cross-reactive VN and/or NI antibodies. Cross-protection between H1 and H3 IAV-S lineages, in contrast, is minimal (Kappes et al. 2012; Qiu et al. 2015a).

The immune response after intramuscular administration of killed IAV-S vaccine is fundamentally different from live virus infection. Vaccination immunity relies largely on inducing high titers of serum HI and VN antibodies to the HA of the vaccine strain(s). In contrast, mucosal antibodies or CD8+ T cells are not efficiently induced by inactivated virus vaccines.

Maternally derived serum IgG antibodies to IAV-S can protect young pigs against antigenically related viruses, but they will also interfere with the development of an active antibody response to vaccination or infection. Maternal IAV-S antibody levels in newborn pigs reflect the dam's immune status. Thereafter, passive IAV-S antibody declines in the pig over a period of 4–14 weeks (Loeffen et al. 2003). Research showed that pigs with maternal antibodies were not completely protected from nasal virus shedding upon challenge, but some pigs showed protection against clinical disease (Loeffen et al. 2003; Renshaw 1975).

Prevention and control

Vaccination is the primary means of preventing influenza in pigs. Most commercial IAV-S vaccines are inactivated whole virus vaccines with an adjuvant. Primary vaccination consists of two intramuscular injections 2–4 weeks apart, with twice-yearly booster vaccinations recommended for sows. Routine pre-farrow booster vaccination of sows results in higher and longer-lasting maternal IAV-S antibody levels – which may protect pigs against clinical disease through the nursery phase. Vaccination of feeder pigs is less commonly performed and may be difficult to combine with vaccination of sows because prolonged passive immunity may interfere with effective vaccination of piglets. However, this strategy may be beneficial in herds where influenza is a problem in growers/finishers.

Inactivated whole virus vaccines are intended to induce serum antibodies to the viral HA. NI antibodies have also been detected in the serum of vaccinated pigs, and they may play a secondary role in protection (Duerrwald et al. 2013; Sandbulte et al. 2016). Experimental vaccination-challenge studies have shown a strong inverse correlation between virus titers in the lungs post challenge and pre-challenge serum HI or VN antibody titers to the challenge virus. Depending on the virus-specific antibody titer, virus replication will either be completely blocked or reduced, perhaps sufficiently so as to prevent disease (Van Reeth et al. 2017b). Inactivated vaccines are thus designed to protect individual pigs against the clinical effects of IAV-S by reducing lung virus titers. Although beneficial effects on nasal virus excretion or IAV-S transmission have been found in some studies, the reduction of virus titers in the lungs is almost invariably greater than that in the upper airways (Van Reeth et al. 2017b). This is consistent with the lack of mucosal IgA antibodies after vaccination with inactivated vaccines and with a more efficient transudation of serum antibodies in the lungs than in the nose.

Because HA antibodies are subtype and strain specific, traditional inactivated IAV-S vaccine strains should match the circulating strains. In keeping with the different virus lineages in Europe versus the United States, the vaccines for each region are produced locally and contain entirely different strains. Unlike for human influenza vaccines, there is no formal system for recommending IAV-S vaccine strains. Even within a continent, there is no standardization of vaccine strains, and the antigenic mass and adjuvants can also differ between different commercial products. In Europe, a trivalent vaccine containing H1N1, H3N2, and H1N2 strains and a Carbomer adjuvant is currently the major vaccine on the market. Bivalent vaccines containing H1N1 and H3N2 strains from the 1970s and 1980s combined with oil- or aluminum hydroxide-based adjuvants are also used in Spain and Italy. In North America, two of the four commercial vaccines contain swine IAV strains from multiple H1 and/or H3 clades. A monovalent vaccine for the H1N1pdm09 influenza virus is only available in North America and not in Europe. Custom-made, inactivated autogenous vaccines are also used in the United States (reviewed by Sandbulte et al. (2015)). IAV-S vaccines are not available in many countries, including China. In general, the commercial products available in North America are also available in South America, whereas locally produced vaccines based on local strains are often used in Japan and South Korea (Van Reeth et al. 2017b).

The efficacy of inactivated IAV-S vaccines is confounded by the current diversity in IAV-S strains. It is highly unlikely that one strain per subtype would be efficacious globally. In addition, a single H1 or H3 vaccine strain will frequently fail to cross-protect against all of the co-circulating virus lineages within a given region, and multiple within-subtype strains seem to be required. For example, European bivalent H1N1/H3N2 vaccines failed to induce cross-reactive HI antibodies or protection against the European H1N2 virus lineage (Van Reeth et al. 2003b). In the United States, polyvalent commercial vaccines containing cluster IV H3N2 offered better protection against a drifted contemporary cluster IV strain than an older commercial vaccine containing only cluster I H3N2 (Loving et al. 2013). In 2009–2010, the existing European and North American vaccines were shown to induce partial serological cross-reaction and cross-protection against the novel H1N1pdm09 virus, but superior protection was obtained with specific monovalent vaccines (Dürrwald et al. 2010; Kyriakis et al. 2010b; Vincent et al. 2010a). The genetic and antigenic proximity between vaccine and field strains is often used to infer vaccine efficacy, but sequence analyses or antigenic data are unreliable predictors. Factors like the immunogenicity of vaccine strains, the antigenic mass, and the adjuvant are also determinants of vaccine potency and cross-reactivity. In particular, the oil-based adjuvants used in many IAV-S vaccines likely account for the much broader protection afforded by these vaccines compared with that observed with unadjuvanted influenza vaccines for humans. These

additional factors could explain why some commercial vaccines in Europe have shown the ability to provide protection against mismatched H1N1 and H3N2 swine IAVs isolated over the course of many years (De Vleeschauwer et al. 2015; Heinen et al. 2001b; Kyriakis et al. 2010a; Van Reeth et al. 2001). The HA of the challenge strains used in these studies showed only 78–93% and 84–92% amino acid homology with that of H1 and H3 vaccine strains, respectively. Similarly, Canadian researchers have shown significant cross-cluster protection against a 2008 alpha-cluster H1N1 IAV-S with a trivalent commercial vaccine containing gamma- and delta2-cluster H1N1 strains only. Despite a common ancestral HA, the alpha- and gamma-cluster viruses shared only 87.2% nucleic acid sequence homology. Though cross-protection challenge data remain the ultimate test, one of the most relevant ways to evaluate the suitability of vaccine strains is to test vaccine-induced antisera for reactivity against field isolates in HI or VN assays.

IN administration of live attenuated influenza virus (LAIV) vaccines is the preferred method for inducing respiratory mucosal antibodies for preventing or reducing IAV-S transmission in the population. Stably attenuated vaccines have been developed by reverse genetics technology (Van Reeth et al. 2017b), and the first of its kind for swine became available in 2018 in the United States. The fully licensed commercial bivalent H3N2 and H1N1 LAIV is based on prior work with an H3N2 containing a truncated NS-1 protein, shown to be attenuated in pigs (Solórzano et al. 2005). In vaccination-challenge studies, LAIV vaccines protect against antigenic variants of the vaccine strain, but multivalent formulations will be required to protect against a variety of swine H1 and H3 IAVs. In contrast to most label recommendations for inactivated vaccines for swine, the label for the newly licensed LAIV is for healthy pigs 1 day of age or older, and marketed to protect growing pigs. Maternal antibody interference was demonstrated to be less pronounced with LAIV, thus it may be used in suckling pigs prior to weaning. Although the impact may be less dramatic than is the case for killed vaccines, the presence of matching maternal antibodies reduces the efficacy and therefore the effects of preexisting active immunity, and establishing other correlates of protection rather than serum HI titers for LAIV vaccines requires further study.

Most IAV-S vaccine is used in gilts and sows that were previously infected with one or more swine IAVs. In one study, pigs primed by IN inoculation with live contemporary European swine IAV(s) were injected with a single dose of commercial inactivated vaccine based on older H1N1 and H3N2 strains. Unlike infection or vaccination alone, the prime-boost approach resulted in a dramatic increase in HI antibody titers to all virus strains used for immunization and broader anti-H1 antibody responses (Van Reeth et al. 2006). This may mean that a close antigenic match between killed vaccine and circulating strains is less important in pigs primed by infection with field strains.

These data are in line with studies in humans in which it was shown that vaccination or infection with a given influenza virus strain stimulates an antibody response against that particular strain but also against all strains of that subtype to which the individual has previously been exposed (Fonville et al. 2014).

In further support of this concept, a recent study using inactivated H3N2 IAV-S vaccines showed that priming with one strain and then boosting pigs with an antigenically diverse strain elicited antibodies and protection against both strains, unlike the traditional approach of using identical strains for primary and booster vaccinations (Van Reeth et al. 2017a). The heterologous prime-boost strategy also induced antibodies to H3 clades that were not included in the vaccine. This approach could increase vaccine efficacy in the current era of increasing IAV-S diversity.

Recombinant protein vaccines, viral vector vaccines, and DNA vaccines have been tested experimentally, with largely disappointing results. One new generation IAV-S vaccine is currently licensed. In the United States, an RNA "replicon" particle vaccine expressing the HA of a North American cluster IV H3N2 IAV-S and farm strain-specific replicon particle vaccines are available (see Van Reeth and Ma 2013; Van Reeth et al. 2017b).

Acknowledgments

The authors have adapted their chapter from that written for the 10th edition and would like to thank Christopher Olsen and Ian Brown for their contribution to the previous edition.

Paramyxoviruses

Peter D. Kirkland, Alberto Stephano, and Hana M. Weingartl

Overview

The family *Paramyxoviridae* contains viral pathogens of international significance in most animal species and humans. Prior to the Menangle and Nipah virus outbreaks, there were no major paramyxovirus pathogens of pigs, the single possible exception being the porcine rubulavirus that causes blue eye (BE) disease (blue eye paramyxovirus [BEP]). However, BEP is confined to Mexico. During a 3-year period commencing in 1997, several new paramyxoviruses were identified, and two (Menangle and Nipah viruses) were found to be serious pathogens in both pigs and humans.

The family *Paramyxoviridae* encompasses a group of large (150–400 nm in diameter) pleomorphic viruses. The genome consists of a long single strand of RNA within a herringbone-like nucleocapsid. A lipid envelope that usually contains an outer fringe of surface projections or "spikes" surrounds the nucleocapsid.

Previously the family *Paramyxoviridae* included two subfamilies: *Paramyxovirinae* and *Pneumovirinae*. However, these two subfamilies were removed in the International Committee on Taxonomy of Viruses report released in 2016 (https://talk.ictvonline.org/taxonomy), and two families, *Paramyxoviridae* and *Pneumoviridae*, were proposed. There are seven genera in the family *Paramyxoviridae*: *Aquaparamyxovirus*, *Avulavirus*, *Ferlavirus*, *Henipavirus*, *Morbillivirus*, *Respirovirus*, and *Rubulavirus*. Also there are major pathogens of animals and humans in each of these genera: Newcastle disease virus of poultry in the genus *Avulavirus*, canine distemper and human measles viruses in the genus *Morbillivirus*, several parainfluenza viruses of animals and humans in the genus *Respirovirus*, and human mumps virus, BEP, and Menangle virus in the genus *Rubulavirus*. The genus *Henipavirus* was created for two of the most recently recognized and closely related paramyxoviruses, Hendra and Nipah, reflecting their morphological and genetic differences from other paramyxoviruses.

Because of their tissue tropisms, there are broad similarities in the diseases caused by paramyxoviruses. Typically, pathogenic paramyxoviruses are associated with diseases of the central nervous system (CNS) (canine distemper and Newcastle disease) and respiratory system (parainfluenza infections, Hendra, Nipah, and Newcastle disease). Some, especially Menangle virus and BEP, are also important reproductive pathogens.

The paramyxoviruses that cause significant disease in pigs are BEP, Menangle virus, and Nipah virus. There have been occasional reports of other paramyxoviruses associated with respiratory and CNS disease in pigs in Japan (Sasahara et al. 1954), Canada (Greig et al. 1971), Israel (Lipkind et al. 1986), and the United States (Janke et al. 2001; Qiao et al. 2010), but none has proven to be of significance. Recently porcine parainfluenza virus 1 (PPIV-1) has been identified in pigs in Hong Kong, China, and the United States and appears to be widespread (Lau et al. 2013; Palinski et al. 2016). Hendra virus is not known to have infected pigs naturally, but experimental infections caused clinical signs in pigs similar to Nipah virus (Li et al. 2010; Pickering et al. 2016). This chapter will provide an overview of BEP, Menangle, and Nipah viruses and the diseases they cause in pigs. The recently identified PPIV-1 will be briefly discussed.

Porcine rubulavirus (blue eye disease)

Relevance

BE is a disease of swine caused by infection with BEP (Stephano et al. 1988b) or porcine rubulavirus, also known as La Piedad-Michoacan virus (LPMV). BE was first reported in 1980 in central Mexico, with numerous outbreaks of encephalitis and corneal opacity in piglets (Stephano et al. 1982). A hemagglutinating

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

virus was isolated, characterized, and identified as a serologically distinct member of the family *Paramyxoviridae* (Stephano and Gay 1983, 1984, 1985a; Stephano et al. 1986b).

The first reported outbreak of BE was on a commercial farm with 2500 sows in La Piedad, Michoacán, Mexico (Stephano et al. 1982). Thereafter, BE was recognized as an important pathogen in central Mexico, with serological evidence of BEP in at least 16 Mexican states (Stephano et al. 1988b). The disease is still seen only in central Mexico and has never been reported outside of Mexico.

Etiology

Extensive molecular characterization of BEP (Berg et al. 1991, 1992; Sundqvist et al. 1990, 1992), combined with its morphology and biological properties, support its placement in the genus *Rubulavirus*.

BEP particles are similar to other paramyxoviruses, measuring 135–148 nm by 257–360 nm (Figure 37.1). The virion is pleomorphic, but usually more or less spherical. No filamentous forms have been observed. Nucleocapsids from disrupted virus particles have a diameter of 20 nm and a length of 1000–1630 nm (Figure 37.2) or more (Stephano and Gay 1985a).

In the laboratory, BEP replicates and produces cytopathology in a wide range of cell cultures from many different animal species, including both continuous cell lines and primary cell cultures. Changes consist of individual rounded cells, cytoplasmic vacuoles, and syncytium formation. Some cells also contain viral inclusion bodies (Moreno-Lopez et al. 1986; Stephano and Gay 1985a; Stephano et al. 1986a). The chick embryo also supports BEP replication.

BEP agglutinates erythrocytes from a wide range of animal species, as well as humans. Spontaneous elution occurs at 37 °C after 30–60 minutes. Hemadsorption of chicken erythrocytes has also been described (Stephano and Gay 1985a; Stephano et al. 1986b).

BEP is not known to share any antigens with other paramyxoviruses (Stephano et al. 1986b), but comparison of genome organization indicates that BEP is closely related to Mapuera virus from bats (Wang et al. 2007). Antigenic differences have been observed between different isolates of BEP (Sánchez-Betancourt et al. 2012).

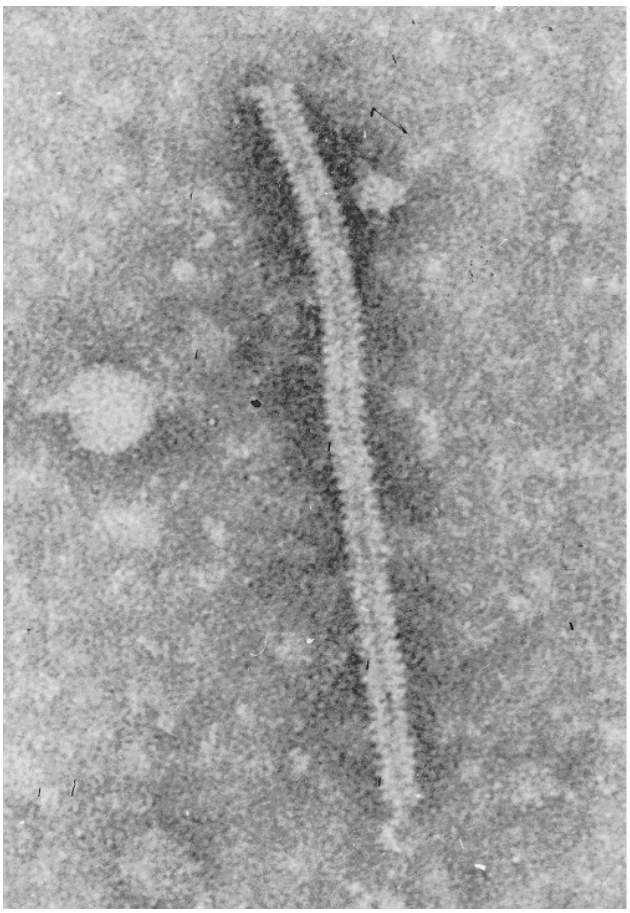

Figure 37.2 Fraction of a nucleocapsid from a disrupted BEP (negative stain electron microscopy; ×203,000).

Public health

Unlike some of the other paramyxoviruses, BEP does not have any public health significance and is not infectious for humans.

Epidemiology

Pigs are the only species known to be clinically affected by BEP following natural exposure. Experimentally, BEP affects mice, rats, and chick embryos. Rabbits, dogs, cats, and peccaries do not show clinical signs; rabbits, cats, and peccaries produce antibodies (Stephano and Gay 1985a; Stephano et al. 1988a).

Subclinically infected pigs from affected farms are the primary source of BEP. The virus is apparently transmitted by nose-to-nose contact between infected and susceptible pigs. Thus, BE was reproduced in susceptible pigs placed in contact with experimentally infected pigs as long as 19 days after inoculation.

The virus is mainly disseminated in nasal secretions and urine. Transmission through semen is possible, and virus can be recovered from semen, testis, epididymis, prostate, seminal vesicles, and bulbourethral glands 10–45 days after inoculation (Solís et al. 2007). The virus may also be disseminated by fomites (e.g. people and vehicles) and possibly by bats (Wang et al. 2007), birds, and wind. Other sources of infection have not been demonstrated.

The disease is self-limiting in closed herds. Sentinel pigs introduced into a farm 6–12 months after an outbreak did not seroconvert. Further, positive animals moved to seronegative herds did not spread the virus (Stephano and Gay 1986b; Stephano et al. 1986a). However, the disease can recur if a susceptible group of pigs is introduced into a farm and large farms with a continuous system of production may have cases periodically. Although there was evidence of persistence of BEP RNA in the brain, lung, lymph nodes, pancreas, and epididymis up to 57 and 277 days in experimentally infected pigs, neither infectious virus nor viral antigen was detected, even after immunosuppression (Cuevas et al. 2009; Wiman et al. 1998).

Seemingly, genetically and antigenically distinct strains of BEP can circulate simultaneously in swine populations. Three genetic variants of BEP were identified in central Mexico, and a new generation of viruses has apparently begun to emerge (Cuevas-Romero et al. 2016). Cross-neutralization studies suggested that the hemagglutinin–neuraminidase (HN) protein was not the only antigenic determinant participating in the antigenic changes detected among BEP strains (Sánchez-Betancourt et al. 2012).

Pathogenesis

It is believed that BEP infection is acquired by inhalation. Experimentally, intratracheal or intranasal exposures are effective routes of infection. The initial site of BEP replication is the nasal mucosa and tonsils. Thereafter, BEP spreads quickly to the brain through the olfactory and trigeminal nerves and subsequently to other organs by viremia. Dissemination by viremia is indicated by the appearance of interstitial pneumonia and isolation of BEP from blood and various organs in either naturally or experimentally infected pigs (e.g. brain, lung, tonsil, liver, turbinate, spleen, kidney, mesenteric lymph node, heart, pancreas, ovary, etc.) (Allan et al. 1996; Stephano and Gay 1983; Stephano et al. 1988b). Variation in the viral neuraminidase is associated with differences in virulence among BEP isolates (Sánchez-Betancourt et al. 2008).

CNS manifestations occur early in the disease. Nervous signs have been induced in 1-day-old piglets 20–66 hours after inoculation, weaned pigs (21–50 days old) developed a nervous syndrome at 11 days post inoculation (DPI), and pregnant sows or gilts developed reproductive failure when inoculated during pregnancy after the virus crossed the placenta and reached the fetuses.

Corneal opacity may occasionally be observed in these cases. The cause of the corneal opacity is unknown, but anterior uveitis is commonly observed microscopically in the cornea (Stephano and Gay 1986b). The opacity usually occurs late in the course of the disease and is thought to be due to an immunological reaction similar to that observed in dogs after adenovirus-induced hepatitis.

Infection of pregnant sows and gilts results in reproductive failure due to embryonic mortality. BEP virus can cross the placenta. In the first one-third of gestation, affected sows usually return to estrus. When infection occurs later in gestation, the result is stillbirths and fetal mummification. Abortion can also occur (Hernández-Jáuregui et al. 2004; Stephano and Gay 1984).

Intranasal inoculation of young boars results in inflammation and edema of the testis and epididymis within 15 days of exposure. By 30 days, there is necrosis of the seminiferous tubules and rupture of the epithelial wall of the epididymis with leakage of spermatozoa from the lumen, leading to abscess formation. Boars sacrificed 80 days after infection showed fibrosis and granuloma formation in the epididymis, as well as testicular atrophy (Ramirez et al. 1995).

Clinical signs

An outbreak of BE may start in any area of a pig farm, but is usually first observed in the farrowing house, with CNS signs and high piglet mortality. At about the same time, corneal opacity may be observed in some weaned or fattening pigs (Stephano and Gay 1985a, 1986a; Stephano et al. 1988a). Mortality increases rapidly and then declines within a short time. Once the initial outbreak

is over, no new clinical cases appear, unless susceptible pigs are introduced into the population. Clinical signs are variable and depend primarily on the age of the pig. However, corneal opacity, the sign that gives the disease its name, frequently occurs in pigs of all ages without other signs and resolves spontaneously.

During an outbreak, about 20% of the litters farrowed are affected. In these litters, piglet morbidity is 20–50%, and mortality in affected piglets is about 90%. In the first cases observed, piglets usually died within 48 hours of the appearance of clinical signs, but in later cases, death occurred after 4–6 days. During an initial outbreak, deaths occur for 2–9 weeks, depending on the management system. Most of the sows suckling affected litters are clinically normal. Some show moderate anorexia 1 or 2 days before the appearance of clinical signs in piglets. Corneal opacity has also been observed in the farrowing house during outbreaks.

Piglets 2–15 days old are the most susceptible and the onset of clinical signs is sudden. Healthy piglets may suddenly become prostrate, generally in lateral recumbency, or show nervous signs. However, the disease usually runs a course that starts with fever, rough hair coat, and an arched back, sometimes accompanied by constipation or diarrhea. These signs are followed by progressive nervous signs, including ataxia, weakness, rigidity (mainly of the hind legs), muscle tremor, and abnormal posture, such as a sitting position. Anorexia does not occur as long as piglets can still walk. Some piglets are hyperexcitable and may squeal and show paddling movements when handled. Other signs include lethargy, with some involuntary movements, dilated pupils, apparent blindness, and, occasionally, nystagmus. Some piglets suffer from conjunctivitis, with swollen eyelids and lacrimation. Often the eyelids are closed and adherent with exudate. In up to 10% of affected piglets, either unilateral or bilateral corneal opacity is present.

Pigs older than 30 days show moderate and transient clinical signs such as anorexia, fever, sneezing, and coughing. Nervous signs are less common and less obvious but, when present, consist of listlessness, ataxia, circling, and, rarely, swaying of the head. Unilateral or bilateral corneal opacity and conjunctivitis continue to appear on the farm for another month without other signs. Fewer than 2% of pigs older than 30 days are affected, and the mortality is generally low. Outbreaks with 20% mortality and severe CNS manifestations have been observed in 15–45 kg pigs. Corneal opacity was present in up to 30% of these pigs (Stephano and Gay 1985b).

In pregnant sows, reproductive failure lasting 2–11 months (usually 4 months) is observed. Reproductive signs during outbreaks include an increase in the number of animals returning to estrus, a reduction in farrowing rate, and an increase in the weaning-to-service interval and nonproductive sow days. The rate of stillbirths and mummified fetuses also increases, and, consequently, there is a reduction in the number of pigs born alive. Later, there is also a reduction in the total number of pigs born. Abortion is not a cardinal feature, but has sometimes been observed during an acute outbreak. Gilts and other adult pigs occasionally develop corneal opacity.

Boars, like other adult animals, generally do not show clinical signs, but mild anorexia and corneal opacity have been reported. Semen evaluation demonstrated that about 30% of boars in herds infected with BEP showed temporary or permanent infertility, with a decrease in concentration, an increase in abnormalities, and a decrease in motility and viability of spermatozoa. In some boars there is azoospermia, and the ejaculate becomes clear and resembles coconut water. Some boars develop swollen testicles. The testis and epididymis become turgid with marked edema. Later, some develop a granular texture and most atrophy (generally unilateral) or become soft and flabby with, or without, granular epididymitis. Boars with severe lesions lose libido (Campos and Carbajal 1989; Stephano et al. 1990).

Differences in clinical signs became evident a few years after the virus was discovered. In 1980, piglets were primarily affected. Mortality and CNS disorders in pigs older than 30 days were uncommon. In 1983, severe outbreaks of encephalitis with high mortality in pigs weighing 15–45 kg were observed on badly managed farms, always with concomitant viral and bacterial diseases (Stephano and Gay 1985b, 1986a). Also in 1983, reproductive failure in sows and transient infertility in boars were identified (Stephano and Gay 1984, 1985a). In 1988, severe orchitis, epididymitis, and testicular atrophy in boars became evident (Campos and Carbajal 1989; Stephano et al. 1990).

Lesions

There are no specific gross changes in cases of BE. In piglets, a mild pneumonia is frequently observed at the ventral tips of the cranial lung lobes. There is mild distension of the stomach with milk, distension of the urinary bladder, and a slight accumulation of peritoneal fluid with fibrin. The brain is often congested and there is an increase in the quantity of cerebrospinal fluid. Conjunctivitis, chemosis, and varying degrees of corneal opacity (Figure 37.3), usually unilateral, are observed. Vesicle formation, ulcers, and keratoconus have been observed in the cornea, as well as exudate in the anterior chamber. Pericardial and renal hemorrhages are occasionally observed (Stephano and Gay 1985a, 1986b).

Boars develop swollen testicles and epididymes. These changes are frequently unilateral. Orchitis, epididymitis, and,

Figure 37.3 Corneal opacity in a 7-day-old piglet.

later, atrophy of the testicle, with or without granulomatous formation, in the epididymis are observed. Hemorrhages are occasionally observed in the tunica albuginea, epididymis, or testis (Campos and Carbajal 1989; Ramirez et al. 1995; Stephano et al. 1990).

The main histological changes are seen in the brain and spinal cord. These reflect a nonsuppurative encephalomyelitis affecting mainly the gray matter of the thalamus, midbrain, and cerebral cortex and include a multifocal and diffuse gliosis, perivascular cuffing with lymphocytes, plasma cells, and reticular cells, neuronal necrosis, neuronophagia, meningitis, and choroiditis (Ramirez and Stephano 1982). Intracytoplasmic inclusion bodies are found in neurons (Stephano and Gay 1986b; Stephano et al. 1988a).

The lungs have localized areas of interstitial pneumonia characterized by thickened septa with mononuclear cell infiltration.

Changes in the eye are mainly corneal opacity, characterized by corneal edema and anterior uveitis. Neutrophils, macrophages, or mononuclear cells infiltrate the iridocorneal endothelium, corneoscleral angle, and cornea (Stephano and Gay 1986b; Stephano et al. 1988a).

In boars, the affected testes show degeneration and necrosis of the germinal epithelium. The interstitial tissue shows Leydig cell hyperplasia, mononuclear cell infiltration, hyalinization of the vascular wall, and fibrosis. The epididymis shows vesicle formation, loss of epithelial cilia, rupture of the epithelial wall, presence of spermatozoa in the intertubular space, and severe infiltration of inflammatory mononuclear cells with macrophage phagocytosis of fragmented sperm. Fibrosis and spermatic granuloma are organized.

Diagnosis

Clinical signs such as encephalitis, corneal opacity, and reproductive failure in the sow and orchitis and epididymitis in the boar are consistent with a diagnosis of BE. Histological lesions, such as nonsuppurative encephalitis, anterior uveitis, keratitis, orchitis, and epididymitis, provide additional diagnostic evidence. The presence of intracytoplasmic inclusions in neurons and corneal epithelium in conjunction with these clinical signs and histological findings provides strong support for a diagnosis of BE.

Other causes of encephalitis and reproductive disease must also be considered, e.g. pseudorabies (Aujeszky's disease) virus and porcine reproductive and respiratory syndrome virus (PRRSV). Only BEP produces corneal opacity along with orchitis and epididymitis in boars (Campos and Carbajal 1989; Stephano and Gay 1985b; Stephano et al. 1988a, 1990).

Paired serum samples (15 days apart) are recommended for serological confirmation by hemagglutination inhibition (HI), virus neutralization (VN), or ELISA. HI is the most frequently used test, but false-positive titers up to 1/16 have been detected when chicken erythrocytes were used or when the antigen was grown in chicken embryos (Ramirez et al. 1996). Therefore, bovine erythrocytes are recommended. Naturally infected pigs develop antibodies that usually persist for life.

The brain is the best tissue for virus isolation and antigen detection, but the lung and tonsil are also suitable (Stephano et al. 1988a). PK-15 cells or primary pig kidney cells are preferred for virus isolation. Virus replication induces syncytium formation. Direct immunofluorescence and polymerase chain reaction (PCR) have been used to detect virus in tissue sections and monolayers (Cuevas et al. 2009; Stephano and Gay 1985a; Stephano et al. 1988a). Quantitative real-time polymerase chain reaction (qRT-PCR) assays are more sensitive and detect either the phosphoprotein gene or the nucleoprotein gene across all strains of BEP (Rivera-Benitez et al. 2013).

Prevention and control

As with most viral diseases of swine, there is no specific treatment. Pigs with corneal opacity frequently recover spontaneously, whereas pigs with central nervous signs generally die. Antimicrobial therapy is commonly used to treat and prevent secondary infections. At present, there are two commercial inactivated virus vaccines approved for use in pregnant sows, gilts, boars, and piglets. However, some data indicate that a monovalent vaccine will not completely protect against the different antigenic subtypes (Escobar-Lopez et al. 2012).

Herd health programs are the most reliable method of preventing the introduction of BEP into a farm. Replacements should be selected from a healthy herd and quarantined prior to introduction. Standard biosecurity measures provide insurance against infection (e.g. perimeter fencing, separate load-out areas, changing rooms and showers, wildlife control [birds, rats, and mice], prompt waste removal and disposal of dead pigs, control of the movement of personnel, visitors, and vehicles). Serological screening of replacement animals is recommended.

Elimination of BEP from infected herds has been accomplished by management practices (e.g. herd closure, cleaning, and disinfecting, all-in/all-out production, elimination of clinically affected animals, and disposal of dead pigs). Serological testing of the population and sentinel animals (BEP seronegative pigs) should be used to confirm the elimination of BEP (Stephano et al. 1986b).

Menangle virus

Relevance

Menangle virus was first identified during a disease outbreak in New South Wales, Australia, in 1997 and was subsequently eradicated from the affected farms. The virus causes reproductive disease and congenital defects in pigs, occasionally causes moderately severe disease in humans, and has fruit bats (*Pteropus* sp., flying foxes) as a reservoir host. Although there are no records of the occurrence of disease in any other country, bats in Papua New Guinea are known to carry the virus (Breed et al. 2010).

Etiology

Like BEP, Menangle virus is a member of the genus *Rubulavirus* within the family *Paramyxoviridae* (Bowden et al. 2001). Other well-known viruses in this genus are human rubulavirus 2 (formerly human parainfluenza virus type 2), human rubulavirus 4 (formerly human parainfluenza virus type 4), and human mumps virus.

Menangle virus has typical paramyxovirus morphology. Virions are pleomorphic with both spherical and elongated forms that range in size from 100 to 350 nm. Virions possess a single layer of surface spikes approximately 17 nm in length. Ruptured particles reveal long herringbone-shaped nucleocapsids of approximately 19 nm in diameter (Philbey et al. 1998).

Menangle virus induces pronounced cytopathology in cell culture, including prominent vacuolation of cells and the development of large syncytia. The virus replicates and produces cytopathology in a wide range of cell types from many animal species, including birds and fish. There is no evidence of hemadsorption or hemagglutinating activity (Philbey et al. 1998). Menangle virus is not related antigenically to any other paramyxovirus.

Public health

In contrast to Nipah virus, Menangle virus does not appear to be highly infectious for humans. However, care should be taken when working with potentially infected pigs or suspect reproductive specimens. While only 2 out of more than 30 humans directly exposed to infected pigs were infected with the virus, both experienced a severe febrile illness associated with a macular rash, followed by prolonged debility (Chant et al. 1998). There was no evidence of infection in a large number of other people, including veterinarians, abattoir workers, and laboratory workers, who had less direct and less protracted contact with potentially infective material. Transmission to humans may require the contamination of cuts and abrasions with infectious body fluids or tissues or possibly splashing of material onto the conjunctivae (Chant et al. 1998).

Epidemiology

Studies of archival and newly collected sera suggested that Menangle virus was not highly contagious among the pigs on the affected farm (Kirkland et al. 2001). This was deduced by the relatively slow spread of infection in a building that contained pens of sows (i.e. it took several weeks for all of the sows to become infected). Nevertheless, the virus was widely dispersed through the pig population on the affected farm. About 6 months after the estimated time of entry of the virus to the farm, a high proportion (>90%) of sera collected from pigs of all ages contained high levels of virus-neutralizing (VN) antibody. Positive VN antibody titers ranged from 1/16 to 1/4096 and remained high for at least 2 years after infection. In contrast, all samples collected prior to the estimated time of entry of the virus into the pig population were negative. All serum samples collected at the two grower–fattening farms were positive (Kirkland et al. 2001). Testing of 1114 swine sera from other pig farms throughout Australia indicated that infection was confined to the affected pig farm and the two associated grow-out facilities.

Following the initial spread of the infection through the herd, the virus was maintained by infection of young pigs at about 10–12 weeks of age (i.e. as they lost the protection provided by maternally derived antibodies). In a large pig population, the constant availability of susceptible animals was sufficient to ensure persistence of the virus. In smaller pig herds, such persistence would be much less likely. Almost all selected replacement breeding

pigs on the farm had been exposed to the virus and were seropositive before mating at around 28–30 weeks of age, preventing further reproductive failure.

It appeared that close contact between pigs was required for spread of infection and that the virus did not survive in the environment for long. Susceptible sentinel pigs moved into an uncleaned area occupied 3 days previously by infected pigs did not become infected.

It is believed that flying foxes are a reservoir of Menangle virus (Kirkland et al. 2001; Philbey et al. 1998). During the summer–autumn period, when the virus was thought to have entered the pig farm, there was a large breeding colony of gray-headed fruit bats (*Pteropus poliocephalus*), as well as little red fruit bats (*P. scapulatus*), roosting within 200 m of the affected pig farm. Sera collected from gray-headed fruit bats in this colony had VN antibodies to Menangle virus. A more extensive study of sera collected from several species of fruit bats in various locations in Australia found that approximately one-third were seropositive, with VN titers ranging from 1/16 to 1/256. Positive samples were found in gray-headed fruit bats, black fruit bats (*P. alecto*), and spectacled fruit bats (*P. conspicillatus*), but not in little red fruit bats. These results indicated that Menangle virus was endemic in the fruit bat population and preceded the infection in pigs. Subsequently, seropositive fruit bats have been detected in Papua New Guinea (Breed et al. 2010), and Menangle virus has been isolated from the urine of fruit bats (Barr et al. 2012).

Except for spread to humans, there is no evidence that this virus has spread naturally to other animal species. Samples collected from rodents, birds, cattle, sheep, cats, and a dog in the vicinity of the affected pig farm were all seronegative.

Pathogenesis

The route of transmission of Menangle virus and the mechanism of spread are not known, although fecal–oral or urinary–oral transmission is suspected (Love et al. 2001). Experimental transmission studies in weaned pigs have shown that virus is shed in both feces and urine (Bowden et al. 2012). Virus was detected longer in urine than in any other source. Infection in pigs appears to be of short duration (10–14 days) (Bowden et al. 2012) and results in strong immunity. Virus was not detected in surviving piglets born during the outbreak, suggesting that persistent infection is unlikely. There is also strong circumstantial evidence that adult pigs do not become persistently infected.

The principal cause of reproductive loss associated with Menangle virus appears to be *in utero* infection, often resulting in fetal death. In many sows, there was early death of the whole litter, resulting in a delayed return to estrus or sometimes a state of pseudopregnancy.

Figure 37.4 Litter of piglets affected by Menangle virus.

At parturition, affected litters sometimes contained piglets of varying size and with a range of abnormalities. Some piglets were mummified and were of different gestational ages, some piglets were stillborn and had congenital malformations, and there were a few normal piglets (Figure 37.4). These findings indicated that as with parvovirus, transplacental infection of a few fetuses can occur early in gestation followed by progressive spread of the virus from fetus to fetus within the uterus. The teratogenic defects observed are the direct result of virus replication and cell destruction in rapidly developing fetal tissues.

Clinical signs

To date, there has only been one known disease outbreak due to Menangle virus in pigs (Love et al. 2001; Philbey et al. 1998). In 1997, over a 5-month period (mid-April to early September), sows in a 3000-sow, intensive farrow-to-finish pig farm near Sydney, New South Wales, Australia, experienced severe reproductive failure (Love et al. 2001). There was a marked increase in the incidence of mummified fetuses and stillborn piglets. After

a period, some of the stillborn piglets were born with severe malformations. Sows in all four breeding units on the farm were affected. There were some weeks when the farrowing rate decreased from an expected 82% to as low as 38%. Many sows showed delayed returns to estrus at approximately 28 days after mating, while others remained in a state of pseudopregnancy until more than 60 days post mating. The disease occurred sequentially in all four breeding units at the pig farm, affecting the progeny of sows of all parities. In the weeks of low farrowing rates, up to 45% of sows farrowed litters with reduced numbers of live piglets and an increase in the proportion of mummified and stillborn piglets, some of which had congenital deformities.

Individual litters contained mummified fetuses of varying size, ranging upward in gestational age from 30 days, together with stillborn piglets (some with malformations) and a few normal piglets (Figure 37.4). Teratogenic defects including arthrogryposis, brachygnathia, and kyphosis were frequently seen in stillborn piglets, and there were occasional cases of artiodactyla (Love et al. 2001). The cranium of some piglets was slightly domed.

Although the virus was also detected on two associated growing farms, there were no breeding animals held on these farms, and no clinical disease was recognized. Virus had apparently spread to these farms (separated from the main farm and each other by several hundred kilometers) when young growing pigs were moved. There were no clinical signs evident in growing pigs of any age, and the only clinical signs in sows on the main farm were those associated with reproductive failure. No clinical signs were observed in weaner aged pigs after experimental infection (Bowden et al. 2012). It is not known whether Menangle virus can be spread in the semen of acutely infected boars.

Following the isolation of Menangle virus, two seropositive workers were identified (Chant et al. 1998). During subsequent medical investigations, it was found that both had experienced a severe febrile illness with headache. Extensive testing failed to identify any other possible cause of the illness, and it was concluded that the disease was due to Menangle virus infection (Chant et al. 1998). Both workers recovered fully after a prolonged period of convalescence.

Lesions

Affected litters usually consist of a mixture of mummified fetuses, autolyzed and fresh stillborn piglets, and a few normal live piglets (Love et al. 2001; Philbey et al. 1998). Congenital defects, including arthrogryposis, brachygnathia, kyphosis, and, occasionally, artiodactyla, are only seen in dead piglets. Affected stillborn piglets frequently have slight to severe degeneration of the brain and spinal cord (Figure 37.5). Gross defects ranging from

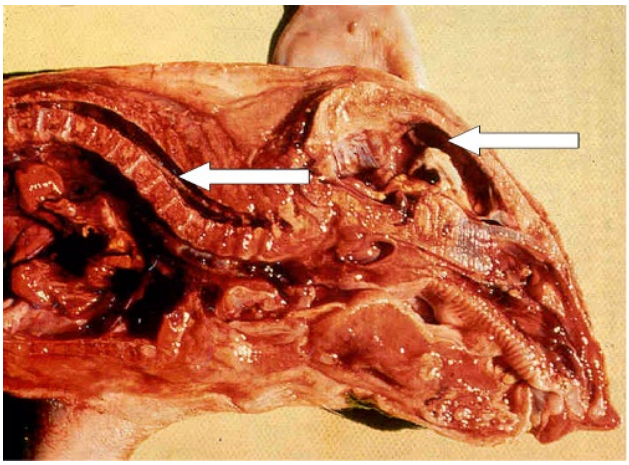

Figure 37.5 CNS abnormalities due to *in utero* Menangle virus infection.

porencephaly to hydranencephaly are most common in the cerebrum. Occasionally, there may be fibrinous body cavity effusions and pulmonary hypoplasia.

Histological changes are most marked in the CNS (Love et al. 2001; Philbey et al. 1998). There is extensive degeneration and necrosis of gray and white matter of the brain and spinal cord associated with infiltrations of macrophages and other inflammatory cells. Intranuclear and intracytoplasmic inclusion bodies may be observed in neurons of the cerebrum and spinal cord. These bodies are eosinophilic to amphophilic and consist of aggregates of nucleocapsids. Nonsuppurative multifocal meningitis, myocarditis, and, occasionally, hepatitis may be present in some cases.

Diagnosis

Menangle virus has only been detected in the 1997 outbreak; thus most pig populations should be fully susceptible. A marked reduction in normal live piglets at farrowing and a number of stillborn piglets with teratogenic defects is suggestive of Menangle virus infection. The most rapid method of excluding Menangle virus infection is to test affected sows for the presence of specific antibody to the virus or to test tissues from affected piglets in a qRT-PCR assay.

At farrowing, litters with mummified fetuses of varying sizes together with stillborn piglets are indicative of *in utero* viral infection. By far the most common cause of similar losses is porcine parvovirus, but a variety of other viral infections, including encephalomyocarditis virus, pestiviruses (e.g. classical swine fever virus and Bungowannah virus), pseudorabies (Aujeszky's disease) virus, Japanese encephalitis virus, porcine reproductive and respiratory syndrome (PRRS) virus, and porcine rubulavirus (BEP), may cause significant fetal death. A feature that distinguishes Menangle virus infection from all but Japanese encephalitis virus infection is the presence of

congenital malformations in piglets. However, it should be noted that these are only evident in approximately one-third of affected litters. In addition, many of these other viral infections cause disease in both piglets and adults. BEP is the only other paramyxovirus to cause significant fetal loss as a presenting sign but differs from Menangle virus in that neurological and other signs are usually observed in young piglets and the virus can be readily distinguished by its ability to agglutinate erythrocytes from mammals and birds (Moreno-Lopez et al. 1986). Reproductive disease is not a major feature of infection with Nipah virus.

For laboratory diagnosis, fetal specimens should be collected for virus detection by either PCR or virus isolation in cell culture, serology, and pathology. Virus can be isolated from a number of organs from stillborn piglets, especially the brain, lung, and myocardium. A wide range of cell cultures supports replication of Menangle virus, but baby hamster kidney cells (BHK-21) have been used for the isolation of the virus from field specimens. Three to five passages may be necessary before suggestive cytopathology is observed. As the virus does not hemagglutinate, identification will depend on electron microscopy, neutralization of an isolate with specific antiserum, or testing by a Menangle virus specific qRT-PCR assay (Bowden et al. 2012). This qRT-PCR assay has also been used for the direct detection of Menangle virus in tissues, swabs of mucosal surfaces, and various excretions. Specific antibodies may be detected in body cavity fluids of some stillborn piglets.

Prevention and control

There is no specific treatment for Menangle virus. By the time clinical signs are observed, the virus is likely to be widely disseminated in the affected population, negating measures to limit spread.

Fruit bats (Megachiroptera) are the primary source of infection for pig populations. Megachiroptera are not found in North America, but are present in Africa, the Middle East, southern Asia, Australia, and many Pacific Islands. It is not known whether small bats (Microchiroptera) are susceptible to Menangle virus, but it is important to restrict direct and indirect contact between pigs and bats to prevent introduction of this virus to pigs. Fruit bats do not normally enter pig farm buildings, but they defecate and urinate during flight over and around buildings and occasionally inadvertently drop their young in flight. Cover all outside areas (e.g. outside walkways) to prevent contamination of the facilities and infection of the herd. Flowering trees and fruiting trees should not be grown in the immediate vicinity of pig farm buildings, as these may attract fruit bat activity.

In an outbreak of reproductive disease, the infection will probably have already spread through the entire population of a pig farm by the time the first affected litters are farrowed. In small piggeries, there would be insufficient numbers of susceptible animals available to maintain a cycle of infection, as there is no carrier state and, unlike parvovirus, environmental survival of this virus is poor. In large piggeries, infection may become endemic, with the infection being maintained in groups of pigs as they lose their maternally derived protection. In such a situation, it is important to maximize the opportunity for infection of all selected replacement breeding stock prior to mating.

The eradication of Menangle virus from an endemically infected pig population can be achieved by moving all the age groups in which infection is active (e.g. pigs between 10 and 16 weeks of age) to another site (Love et al. 2001). If affected facilities are cleaned, vacated for a few weeks, and then restocked with unexposed pigs or pigs known to be immune to the virus, the cycle of endemic infection in the herd should be broken and the virus eliminated naturally.

Nipah virus

Relevance

Nipah virus is a zoonotic virus that first caused a major epidemic in pigs in 1998–1999 in a relatively small geographic area in Southeast Asia, but has since been detected in other countries in Asia. In this instance, it is believed that the virus jumped from a wildlife reservoir to domestic pigs and then spread to humans and to other domestic animals including cats, dogs, and horses. The virus was not contagious in cats or dogs, but was associated with a high case fatality rate. Nipah virus poses a continuing threat in countries where pteropid bats are present.

Etiology

Nipah virus and the related Hendra virus are negative-stranded RNA viruses in the family *Paramyxoviridae*, genus *Henipavirus* (Chua et al. 2000). Two genotypes of Nipah virus have been identified to date: genotype Malaysia and genotype Bangladesh (Lo et al. 2012). Nipah is a large pleomorphic virus similar to most paramyxoviruses. Virus particles vary in size, but their average diameter is 500 nm. Surface spikes on the envelope are approximately 10 nm in length. The typical long "herringbone- shaped" nucleocapsids have a diameter of approximately 21 nm and an average length of 1.67 µm.

Nipah virus replicates readily in several continuous cell lines, especially Vero and BHK-21, and produces

cytopathic effects (CPE) in 3–4 days. In Vero cells, virus replication induces large syncytia in which the cell nuclei are arranged around the periphery of the multinucleated cell (Daniels et al. 2002). Antigenically, Nipah virus is closely related to Hendra virus, and diagnostic reagents for Hendra virus have been utilized to assist Nipah virus investigations.

Public health

Nipah virus presents a serious threat to public health. Although the first recognized outbreak of Nipah virus was confined to a relatively small geographical area, it resulted in numerous human infections and deaths in pig farmers and other people who had close contact with pigs, including abattoir workers in a neighboring country. Later, human disease outbreaks without the known involvement of pigs occurred in India and Bangladesh and in 2014 in the Philippines, where horses were identified as the source of human infection (Ching et al. 2015; Luby and Gurley 2012). If there is a risk of an outbreak, it is essential to prevent the movement of all animals and minimize human contact with potentially infected animals.

Epidemiology

There is strong evidence that fruit bats mainly from the genus *Pteropus* are a reservoir of Nipah virus (Luby and Gurley 2012). The disease outbreak observed in Malaysia is assumed to be the result of the virus "jumping" from bats into farmed domestic pigs (Chua et al. 2000). Observations made during the outbreak in 1998–1999 in Malaysia indicated that Nipah virus was highly contagious among swine (Mohd Nor et al. 2000). Direct, and possibly airborne, exposure to secretions from infected animals was the presumed mode of transmission of Nipah virus among pigs. This was supported by detection of the virus in the epithelium of the upper and lower respiratory tract, as well as airways and oral/nasal swabs. The pattern of human infection suggested spread via sputum or large droplets rather than by fine aerosol. Coughing, a frequent clinical sign in infected pigs, or loud squealing would facilitate such a mode of transmission. Contact with infected animals and subcutaneous, oral, and nasal routes of inoculation may result in infection (Hooper et al. 2001; Middleton et al. 2002; Weingartl et al. 2006).

During the outbreak in Malaysia, Nipah virus infected other domestic animals. Large numbers of dogs died on infected farms, and clinically affected dogs were identified during investigations of outbreaks on swine farms (Chua et al. 2000; Daniels et al. 2000). Nipah virus was isolated from the kidney of a clinically affected dog (Chua et al. 2000), which suggests that urinary excretion by domestic carnivores may be a mode of spread, but there was no evidence of lateral transmission between dogs (Asiah et al. 2001). Cats were also reported by farmers to have been affected. Under experimental conditions, cats were susceptible to infection and excreted Nipah virus in urine (Muniandy 2001).

In Malaysia, the movement of infected pigs was the primary means by which Nipah virus spread between farms, between states, and internationally to Singapore, where abattoir workers processing Malaysian pigs became infected (Mohd Nor et al. 2000; Paton et al. 1999). The outbreak probably originated from a point source (Lye et al. 2001), implying that the virus moved from its wildlife reservoir on only one occasion.

Human infection was associated with close contact with infected pigs (Parashar et al. 2000). Feeding or handling pigs, assisting with farrowing, treatment, and removal of sick or dead pigs were most likely to result in infection. Living on an infected pig farm was not a significant risk factor.

Later outbreaks in Bangladesh and India had higher case fatality rates than the first outbreak in Malaysia and Singapore, and human-to-human transmission of the virus was reported. Significantly, drinking date palm sap, apparently contaminated by flying foxes, was associated with some of the index cases, while contact with pigs was not reported (Luby and Gurley 2012).

The more recent outbreak of Nipah virus in the Philippines was presumed to be a result of Nipah virus transmission from bats to horses and from sick horses to humans. Horse slaughter and consumption of horse meat were considered to be the main mode of transmission to humans, and human-to-human transmission occurred in 30% of cases. Furthermore, cats that were fed meat from affected horses were also fatally infected (Ching et al. 2015).

Pathogenesis

Pathogenesis studies with Nipah virus in swine have been limited to pigs 4–10 weeks of age due to the constraints of working under Biosafety Level 4 (BSL-4) conditions. Nipah virus primarily targets three systems: vascular, nervous, and lymphoreticular. Upon oronasal inoculation, Nipah virus infects a number of cell types present in the oronasal mucosa: epithelial cells, cells of the immune system, and, presumably, extracellular peripheral nerve endings of the cranial nerves, leading to direct invasion of the brain in some animals (Weingartl et al. 2005). Endothelial cells of small blood and lymph vessels are an early characteristic target for Nipah virus. Infection of endothelial cells and cells of the immune system leads to viremia and subsequent spread of Nipah virus, as the virus appears to prefer endothelial cells of specific organs and tissues (Meisner et al. 2009). Infection

of endothelial cells results in vasculitis and recruitment of immune cells that can be also infected (Berhane et al. 2008). The virus productively infects monocytes, NK cells, and CD8+ T lymphocytes (Stachowiak and Weingartl 2012), and viral antigen was detected in macrophages and dendritic cells. In addition, lymphocyte necrosis and depletion were observed, especially in lymph nodes. Reduction of specific populations of immune cells may be a contributing factor in secondary infections (Berhane et al. 2008). In addition, infiltration of infected immune cells into parenchyma, as well as direct infection of cells adjacent to the endothelial cells, further increases the virus load in tissues. Thus, Nipah virus can alternatively infect the CNS by crossing the blood–brain barrier (Weingartl et al. 2005).

Infection of the lower respiratory tract most likely occurs by viremia and the associated vascular damage and infiltration of infected mononuclear cells. However direct infection of epithelial cells due to inhalation of the virus, or spread of the virus along the respiratory epithelium from the upper respiratory tract, or a combination of all routes cannot be excluded.

Clinical signs

Nipah virus differs from most paramyxoviruses in that it causes a severe, often fatal disease in a number of species. Disease and death in people may be the first indication of an outbreak. Nipah virus infection of humans presents as an encephalitis and/or severe respiratory disease. A full clinical description of Nipah virus-induced disease in humans has been provided elsewhere (Chua et al. 1999; Goh et al. 2000; Hossain et al. 2008).

Nipah virus infection in pigs may be subclinical or result in acute febrile disease with respiratory and/or CNS signs, for which reason it was initially termed "porcine respiratory and encephalitis syndrome." Clinical signs of Nipah virus infection in pigs vary by age (Mohd Nor et al. 2000) and vary in severity from self-limiting to occasionally fatal. There are no pathognomonic clinical signs of Nipah virus infection in pigs, although a "barking" cough is considered characteristic.

In field outbreaks, an acute febrile illness was described in weaner and grower pigs, with temperatures of ≥40 °C (104 °F). Respiratory signs ranging from increased or forced respiration to a harsh, paroxysmal nonproductive cough (a loud barking cough) or open-mouth breathing were prominent, especially if animals were forced to move. Neurological signs such as muscle fasciculation, rear leg weakness, and varying degrees of spastic paresis and uncoordinated gait when driven and hurried were observed. Clinical signs may progress to lateral recumbency accompanied by thrashing of the limbs or tetanic spasms. Mortality in this age group is low (<5%). Animals that die may show blood-tinged discharge from the nose. However, infection is frequently subclinical.

Acute death was occasionally observed in sows and boars, either with no prior clinical signs or within 24 hours of onset of clinical disease. However, sudden death in sows and boars is considered an unusual outcome of Nipah virus infection. A bloody nasal discharge was frequently apparent after death. Neurological signs were frequently observed, and included head pressing, agitation displayed as biting the bars of the pen, tetanic spasms or seizures, and an apparent pharyngeal muscle paralysis resulting in the inability to swallow, frothy salivation, and drooping of the tongue. Abortions were also reported.

Suckling pigs showed open-mouth breathing, leg weakness with muscle tremors, and neurological twitches. Mortality was high in this age group, but whether from primary disease or because of disease in the sow was not clearly established.

Under experimental conditions, the majority of infected piglets did not develop apparent disease, although they showed a transient increase in rectal temperatures between 3 and 6 DPI. Some developed mild respiratory signs, and about 20% of piglets that were inoculated nasally or subcutaneously developed CNS signs requiring euthanasia (Berhane et al. 2008; Middleton et al. 2002; Pickering et al. 2016; Weingartl et al. 2005, 2006). However, clinical signs observed after the first week post inoculation were suspected to be partially due to secondary infection, and bacteria, including *Enterococcus faecalis*, *Streptococcus suis*, and *Staphylococcus hyicus*, were isolated from piglets with different signs (Berhane et al. 2008; Middleton et al. 2002).

Lesions

The most common clinical sign in pigs is respiratory disease characterized by severe coughing. However, there is no pathognomonic gross pathology, and concurrent pulmonary disease from other causes may be present. Macroscopic lesions were consistently observed in the lungs and meninges of pigs infected with Nipah virus, both naturally and experimentally. Mild to severe pulmonary consolidation was also observed in subclinical cases, as well as distended interlobular septa on cut surfaces. Occasionally, dark depressed lobules were notable, mostly in the diaphragmatic lobes. In the Malaysian outbreak, bronchi and trachea of pigs were frequently filled with exudate or frothy fluid sometimes tinged with blood. Enlarged lymph nodes, most frequently bronchial, submandibular, and mesenteric, were also observed. In cases with neurological disease, the meninges were congested and edematous. In experimentally infected animals, Nipah virus-related gross pathological lesions resolved by approximately 3 weeks post inoculation

(Berhane et al. 2008; Hooper et al. 2001; Middleton et al. 2002; Weingartl et al. 2005).

Microscopically, the presence of multinucleated alveolar macrophages and syncytial cells in respiratory epithelium may indicate Nipah virus infection. Infrequently, syncytia may be found in the endothelium of small blood and lymphoid vessels (Figure 37.6), mainly in the lung, spleen, and lymph nodes. In the absence of fresh tissue, this suspicion could be confirmed by immunohistochemistry (IHC). Syncytia in the endothelium stain especially strongly for Nipah virus antigen.

Other microscopic lesions in the lungs include interstitial pneumonia with peribronchiolar, peribronchial, and perivascular infiltration of mononuclear cells and vasculitis often with fibrinoid necrosis. In some instances, alveolitis with infected macrophages, cellular debris (also in bronchioles), and proteinaceous fluid has been observed. Viral antigen has been detected in the endothelial cells, in the smooth muscle cells of the tunica media, and in macrophages and bronchiolar and, less frequently, alveolar epithelial cells (Berhane et al. 2008; Hooper et al. 2001; Middleton et al. 2002; Tanimura et al. 2004; Weingartl et al. 2005).

In cases with neurological disease, a nonsuppurative meningitis or meningoencephalitis was observed more frequently than encephalitis. Prominent perivascular cuffing was observed in the meninges and sometimes also in the brain. Virus antigen was detected in neurons and glial cells, endothelial and smooth muscle cells of the tunica media of blood vessels, infiltrating mononuclear cells, ependyma, choroid plexus, and the meninges (Hooper et al. 2001; Middleton et al. 2002; Weingartl et al. 2005).

Important pathological changes occur in the lymphoid organs and tissues. Besides the presence of syncytia in endothelial cells of blood and lymphoid vessels and vasculitis, necrosis of lymphocytes and their depletion from the lymph nodes are another important feature of Nipah virus infection in swine. Nipah virus antigen is detected mainly in endothelial cells, multinucleated giant cells, and dendritic cells (Berhane et al. 2008; Hooper et al. 2001; Middleton et al. 2002; Weingartl et al. 2005, 2006) (Figure 37.7). Other organs, such as the kidney (Middleton et al. 2002; Tanimura et al. 2004), can also be affected, most likely due to vascular damage, but the extent and frequency of lesions are much less significant than those described for the lung, brain, lymph nodes, and spleen.

Diagnosis

Nipah virus may be suspected if a clinical picture consistent with Nipah virus disease occurs on a pig farm in an area where there is opportunity for contact with pteropid bats. The list of differential diagnoses should include those that cause sudden death in boars and/or sows; reproductive failure characterized by abortion; respiratory disease in any age group characterized by severe coughing; and neurological disease characterized by tremors, muscle fasciculation, and agonal thrashing of the limbs or tetanic spasms in lateral recumbency.

Nipah virus does not produce pathognomonic clinical signs, and clinical signs vary by the age and reproductive status of the animals affected. Thus, the differential diagnosis may vary with the age and class of pigs affected.

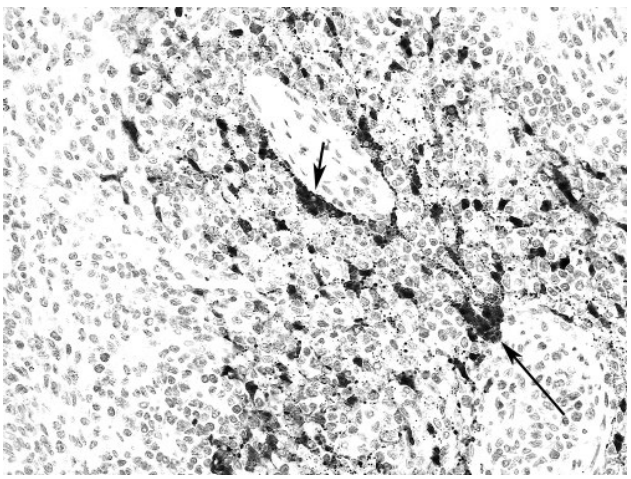

Figure 37.7 Immunohistochemical staining of submandibular lymph nodes revealed abundant Nipah virus antigen (black) within lymphocytes, reticulodendritic cells, and multinucleated syncytial cells (arrows). *Source:* Photo courtesy of Dr. Carissa Emburry-Hyatt.

In addition, secondary infections with other microorganisms can contribute to a wide range of nonspecific clinical signs. Animals coinfected with other pathogens, such as classical swine fever virus and opportunistic bacteria, are likely to display clinical signs most compatible with the coinfectants (Berhane et al. 2008). This may partially explain how it was possible for Nipah virus to be present, but unidentified, in pigs in Malaysia since 1996, as indicated in retrospective studies of archival specimens (Chua et al. 2000).

Nipah virus is a high-risk (BSL-4) zoonotic agent, and extreme care must be taken during sample collection in cases suspected to involve Nipah virus. Antemortem and post mortem sampling has to be conducted while wearing personal protective equipment, including respiratory protection, in a manner that will exclude human contact with body fluids from affected animals. Nasal and oral specimens are most effective for virus detection from live animals and serum for antibody detection. Nipah virus is detectable in oral and nasal swabs at 2 DPI, prior to the onset of clinical signs, and shedding can last up to 3 weeks post infection. Antibody against Nipah virus becomes detectable in all animals 10 DPI. From post mortem samples, trigeminal ganglion, olfactory bulb, cerebrospinal fluid, lung-associated lymph nodes, lungs, and spleen may be the most useful for virus detection by RT-PCR or virus isolation (Berhane et al. 2008; Daniels 2001; Middleton et al. 2002; Weingartl et al. 2005).

Nipah virus is a high-risk zoonotic agent, and diagnostic procedures that do not amplify the virus and minimize the handling of infectious material are preferred. Detection of viral RNA by reverse transcription polymerase chain reaction (RT-PCR) is rapid, usually more sensitive than virus isolation, and offers greater biosafety for the operator. Real-time RT-PCR (qRT-PCR) assays specific for Hendra virus or Nipah virus have been described (Guillaume et al. 2004; Li et al. 2010; Pickering et al. 2016) and allow the reliable detection of viral RNA in a wide range of tissues and serum.

Demonstration of viral antigens in formalin-fixed post mortem samples is also a rapid and safe option for confirmation of a diagnosis, albeit less sensitive than real-time RT-PCR. Nipah virus antigens have been demonstrated in formalin-fixed tissues, especially the lung and upper airways, meninges, spleen, olfactory bulb, trigeminal ganglion, lymph nodes, and kidney (Daniels 2001; Middleton et al. 2002; Weingartl et al. 2005). It is likely that a retrospective confirmation could be achieved with formalin-fixed tissues (Chua et al. 1999; Hooper and Williamson 2000).

When virus isolates are required, either for confirmation of a diagnosis or for additional research, procedures should be conducted in a BSL-4 laboratory. Vero cells are preferred for virus isolation. Cytopathology characterized by the formation of large syncytia may be observed in 2–3 days, but several passages of at least 5 days are usually conducted before declaring an isolation attempt unsuccessful.

ELISA is the preferred method for antibody detection because of the availability of recombinant reagents (e.g. NiV N or GP protein) and high throughput capacity of ELISAs (Pickering et al. 2016). Prior to testing, serum samples should be heated at 60 °C for 1 hour to eliminate the possibility that samples might contain infectious virus. Any ELISA reactors should be confirmed by VN, either by CPE reduction or by microtiter plaque reduction neutralization assay (Daniels 2001; Weingartl et al. 2006), again under BSL-4 conditions.

Specimen collection and diagnostic assays available for Nipah and Hendra viruses are also reviewed elsewhere (Daniels and Narasiman 2008).

Immunity

Neutralizing antibodies provide protection against Nipah virus disease in pigs (Weingartl et al. 2006) and appear 7–10 DPI, reaching maximum titers (approximately 1/1280) by 14–16 DPI (Berhane et al. 2008; Middleton et al. 2002). Full protection against Nipah virus challenge, however, requires both the development of neutralizing antibodies and cell-mediated immune response (Pickering et al. 2016). There is currently no evidence that persistent infections occur, although the possibility cannot be excluded.

Prevention and control

Nipah virus is a dangerous zoonotic agent and treatment of affected animals should not be considered. In countries where pteropid bats may be a reservoir of Nipah virus, pig farms should be managed to ensure that infection cannot reach the population (Choo 2001; Daniels 2001). That is, farms should be devoid of fruit trees and other vegetation that might attract the bats to the proximity of the animal housing. Strict biosecurity should be in place to preclude the importation of infected animals. Herd replacements should be isolated and quarantined prior to introduction.

Control measures in cases of confirmed Nipah virus infection will reflect its extreme hazard as a zoonotic agent. It is essential to prevent spread of infection among domestic animals and to preclude the possibility of infection of humans. Rapid eradication is the recommended response. This was achieved in Malaysia by quarantine of infected premises and the culling of all susceptible animals on those premises. It is essential that quarantine and associated movement controls be enforced during this period of culling (Mangat 2001).

Porcine parainfluenza virus 1

Relevance

PPIV-1 was identified in pigs in 2013 in Hong Kong, China, with sequences most closely related to human parainfluenza virus 1 and Sendai virus (Lau et al. 2013). PPIV-1 is widespread in the United States and likely elsewhere (Palinski et al. 2016). Field and experimental studies have demonstrated PPIV-1 replication and shedding in pigs, but clinical signs and pathological changes produced by PPIV-1 infection appear to be minimal (Palinski et al. 2016; Gauger et al. 2016; Sun et al. 2013; Welch et al. 2018).

Etiology

PPIV-1 (species name *Porcine respirovirus 1*) is a member of the genus *Respirovirus* in the family *Paramyxoviridae*. PPIV-1 has a single-stranded, negative-sense linear RNA genome approximately 15 kb in length, and the viral genome consists of six genes (3′-N-P-M-F-HN-L-5′), which encode the nucleocapsid (N), phosphoprotein (P), matrix (M), fusion (F), hemagglutinin–neuraminidase (HN), and large (L) proteins, respectively (Lau et al. 2013; Palinski et al. 2016; Park et al. 2017a).

PPIV-1 can be propagated in a rhesus monkey kidney epithelial cell line (LLC-MK2) in the presence of trypsin and produces CPE, including syncytia formation (Park et al. 2017b).

Public health

There are no reports of PPIV-1 infections in humans. However, PPIV-1 is genetically similar to human parainfluenza 1, and the possibility of human infection should be a consideration until human susceptibility or resistance to PPIV-1 is clearly established.

Epidemiology

PPIV-1 was first detected by PCR in 12 of 386 nasopharyngeal swabs (3.1%) and 2 of 303 rectal swabs (0.7%) collected from slaughtered pigs in Hong Kong between September 2008 and June 2012 (Lau et al. 2013). Subsequently, Sun et al. (2013) detected a virus with over 92.5% nucleotide identity to the Hong Kong PPIV-1 in piglets exhibiting influenza-like respiratory signs on farms in Iowa, Illinois, Oklahoma, and North Carolina in the United States. Subsequently, Palinski et al. (2016) detected PPIV-1 not only in piglets with moderate cough, sneezing, and serous nasal discharge on commercial farms in Oklahoma and Illinois but also in pigs with no clinical signs on a farm in Nebraska. PPIV-1 PCR testing of 279 lung, oral fluid, and nasal swab samples produced 17 (6.1%) positive samples (Palinski et al. 2016).

Gauger et al. (2016) reported that PPIV-1 PCR testing of 1,589 diagnostic submission samples collected in the spring to fall of 2016 from 27 US states produced 542 (34.1%) positive samples. PPIV-1 was detected most often in nursery pigs, followed by grow–finish pigs, and was uncommon in suckling and adult pigs (Gauger et al. 2016). The US PPIV-1 strains had 97–98% nucleotide identity to each other and 90–96% nucleotide identity to the Chinese PPIV-1 at the whole genome level (Palinski et al. 2016; Park et al. 2017a). Cumulatively, the data suggest that PPIV-1 is widespread.

PPIV-1 is assumed to be transmitted mainly via aerosols. Under experimental conditions, naïve pigs placed 0.6 m (2 ft) from PPIV-1-inoculated pigs became infected (Welch et al. 2018).

Pathogenesis, clinical signs, lesions, and immunity

There are few reports on PPIV-1 pathogenesis, clinical signs, lesions, or immunity. Influenza-like signs such as moderate cough, minor sneezing, and serous nasal discharge were noted in the initial cases in which PPIV-1 was detected by PCR (Palinski et al. 2016; Sun et al. 2013). However, the contribution of PPIV-1 to the observed clinical signs is uncertain because other viruses including porcine astrovirus 4, PCV2, porcine kobuvirus, and/or porcine hemagglutinating encephalomyelitis virus were detected concomitantly with PPIV-1 in some cases (Palinski et al. 2016).

Palinski et al. (2016) randomly selected 11 weaned pigs (18–19 days of age) from a farm naturally infected with PPIV-1 and placed them in an animal research unit for follow-up investigation. At day 0, 6 of 11 pigs (55%) were PPIV-1 positive by PCR, and 3 additional pigs became PPIV-1 PCR positive during the 2-week observation period. Virus was detected in nasal secretions for 2–10 days by PCR, but no clinical signs were observed. Histopathological examination revealed only atelectasis in the lung tissues in 4 of 8 pigs. *In situ* hybridization (ISH) revealed PPIV-1 in turbinate respiratory epithelial cells and the trachea of only 1 pig.

Welch et al. (2018) conducted experimental inoculation studies using a PPIV-1 cell culture isolate in PPIV-1 seronegative conventional pigs (3 weeks of age) and Cesarean-derived colostrum-deprived (CDCD) pigs. In 30 conventional pigs inoculated intranasally and intratracheally, PPIV-1 was detected in nasal swabs from 29/30 pigs by PCR at 1 DPI, and all pigs were PPIV-1 PCR positive from DPI 2 to 9. Viral shedding significantly decreased by 14 DPI but was detectable in some pigs through 21 DPI. Naïve conventional pigs placed 0.6 m

(2 ft) from PPIV-1-inoculated pigs on DPI 2 were PPIV-1 PCR positive 1 day later. The same pattern of viral shedding was seen in 10 CDCD pigs receiving the same dose of virus by the same inoculation routes as the conventional pigs.

Although PPIV-1 shedding was demonstrated under experimental conditions, no clinical signs were observed in either conventional or CDCD pigs, with the exception of sporadic mild coughing after 9 DPI in the conventional pigs.

Macroscopic lung lesions were minimal in PPIV-1-inoculated pigs, and histopathology lung lesion scores were not significantly different between the PPIV-1-inoculated pigs and control pigs. PPIV-1 antigen was detected in abundance by IHC in the epithelium of pulmonary bronchi and bronchioles, tracheal epithelium, and the turbinate epithelium when examined at 5 DPI. Preliminary data showed that pigs seroconverted at 21 DPI by serum VN test and indirect fluorescent antibody assay.

Diagnosis

PPIV-1 infection must be differentiated from agents that produce respiratory signs, such as influenza virus, PRRSV, PCV2, and others. A PPIV-1-specific real-time RT-PCR has been developed (Lau et al. 2013; Palinski et al. 2016), and nucleotide sequencing and comparative analyses can be used for further characterization.

PPIV-1 can be isolated on LLC-MK2 cells (Park et al. 2017b). Appropriate specimens for PPIV-1 PCR and virus isolation include lung, nasal swab, and oral fluid samples. Experimental ISH, IHC, and serological assays have been developed for PPIV-1; however, the diagnostic performance of these assays is not well established.

Prevention and control

The clinical significance of PPIV-1 infection is not fully understood, and no specific prevention and control measures have been developed for PPIV-1.

Parvoviruses

Uwe Truyen and André Felipe Streck

Relevance

Porcine parvovirus (PPV) was first detected in 1965 by Anton Mayr and coworkers in Munich, Germany, as a contaminant of a porcine primary cell line used for the propagation of classical swine fever virus (Mahnel 1965; Mayr et al. 1968). To differentiate this historical virus from newly identified PPVs, it is designated "PPV1" in the remainder of this chapter. Infection with PPV1 causes reproductive losses in swine characterized by stillbirths, mummification, embryonic death, and infertility (SMEDI). The affected sow does not typically show clinical signs, and virus transmission to the fetuses only occurs if she is seronegative. PPV1 is probably the most important cause of reproductive failure in pigs worldwide, but it took several years to link PPV1 to endemic reproductive disorders and to show that it was globally distributed (Cartwright and Huck 1967; Joo et al. 1976a; Mengeling and Cutlip 1976).

More recently, PPVs 2, 3, 4, 5, 6, and 7 were identified in swine in various countries (Cheung et al. 2010; Cságola et al. 2012; Cui et al. 2017; Hijikata et al. 2001; Lau et al. 2008; Palinski et al. 2016; Streck et al. 2013; Xiao et al. 2013b). PPVs 2–7 may be detected even in the absence of PPV1 (Cui et al. 2017). Current work shows the highest prevalence in growing–finishing pigs and the lowest in pigs <9 weeks of age, with PPV2 the most frequently detected (Cui et al. 2017; Opriessnig et al. 2014). The role of these viruses in swine health has not been defined, that is, no association with clinical signs has been established. Further, the prevalence of these viruses in clinically healthy animals raises the possibility that they are commensals (Streck et al. 2015a).

Etiology

The family *Parvoviridae* consists of two subfamilies: *Parvovirinae* and *Densovirinae*. Viruses in the subfamily *Parvovirinae* mainly infect vertebrate hosts, whereas viruses in the subfamily *Densovirinae* mainly infect arthropods. PPVs 1–7 and porcine bocaviruses belong to the subfamily *Parvovirinae* (Table 38.1). Porcine bocaviruses have not been shown to be pathogenic in pigs and are not discussed in this chapter.

Like the closely related parvoviruses of carnivores, canine parvovirus and feline panleukopenia virus, the PPV virion is about 28 nm in diameter and consists of 60 copies of the structural protein VP1/VP2, about 90% of which are VP2 and 10% VP1 molecules. The capsid structure is characterized by a simple T = 1 icosahedral symmetry (Simpson et al. 2002).

The PPV genome is a single-stranded DNA molecule of about 5000 bases. Like all parvoviruses, complex palindromic hairpin structures located at each terminus are required for DNA replication. The genome encodes four proteins transcribed from two promoters. "Alternative splicing" extends the coding capacity of the small genome. Two nonstructural (NS) proteins, NS1 and NS2, operate in the replication of the virus, particularly for DNA replication. Two structural proteins (VP1 and VP2) are transcribed and translated from the parvovirus genome. The smaller protein (VP2) is produced by splicing from the same RNA template as the larger protein (VP1). Thus, the entire VP2 sequence is present in the VP1 sequence, but the latter has a unique amino terminus of about 120 amino acids (see Cotmore and Tattersall [2006] for a review of parvovirus genome organization and gene expression). Some VP molecules are posttranslationally trimmed by proteases to create the minor protein VP3.

Sequence analyses of recent isolates suggested active evolution of PPV1. Specifically, sequence alignments and phylogenetic studies of the capsid protein gene (VP1) revealed a new cluster of viruses characterized by specific nucleotide and amino acid changes (represented by the predominant strain 27a) (Zimmermann et al. 2006) (Figure 38.1). Preliminary data indicated that these "new" viruses (here called *27a-like* viruses) were spreading through European pig populations and perhaps worldwide. The appearance of the 27a-like viruses could be important because changes in the capsid protein influence the

antigenic properties of the virus. There is only one serotype for PPV1, and all PPV1 isolates show a high degree of cross-reactivity in various serological tests, for example, virus neutralization or hemagglutination inhibition (HI) assays. However, differences in cross-neutralization of some 27a-like viruses have been demonstrated using sera raised against "classic" PPV1 strains (Zeeuw et al. 2007).

Based on genomic sequences, the phylogeny of PPV1 isolates suggests a rather geographic clustering and a broad distribution of the 27a-like viruses (Cadar et al. 2012; Streck et al. 2011). These viruses are characterized by specific sequences in the capsid protein gene, resulting in specific amino acid changes at positions 414, 419, and 436, predominantly located in the protein loops (Streck et al. 2015). Because PPV1 protein loops are generally located on the capsid surface, these amino acid substitutions may influence receptor binding and/or antigenicity. Based on studies done using animal models and on observations in vaccinated herds, it appears that the 27a-like viruses do not cause the outbreaks in PPV-vaccinated sows that would be expected if there were true immune escape. To understand the importance of these mutations, a series of mutants containing amino acid substitutions of the 27a-like viruses were constructed. The mutants (containing 27a mutations) had relatively higher replication efficiency when compared to the classical NADL-2 or Kresse strains. This has possibly contributed to the predominance of the 27a-like viruses.

Public health

There is no evidence that PPVs are infectious for humans or play any role in public health.

Epidemiology

PPV1 is endemic in pigs in most of the world. Although antibody responses must be interpreted cautiously because of the extensive use of inactivated vaccines, serological surveys in various parts of the world showed that PPV1 antibodies were present in 70–100% of the herds (Foni and Gualandi 1989; Nash 1990; Oravainen et al. 2005; Robinson et al. 1985). PPV1 HI antibody titers ≥512 (a typical field infection titer) were found in approximately 40% of animals in vaccinated herds (Oravainen et al. 2005).

PPV2 was first detected in Myanmar (Hijikata et al. 2001) and then reported in multiple countries such as China, Hungary, the United States, Germany, Thailand, Japan, South Korea, and Poland (Cságola et al. 2012; Cui et al. 2017; Lee et al. 2017; Saekhow and Ikeda 2015; Saekhow et al. 2014; Streck et al. 2013; Wang et al. 2010; Xiao et al. 2013). PPV3, also known as porcine hokovirus or PARV4-like virus, has been identified in many places, including Hong Kong, Romania, Germany, the United States, China, and Poland (Adlhoch et al. 2010; Cadar et al. 2011; Cheung et al. 2010; Cui et al. 2017; Lau et al. 2008; Zhong et al. 2016). PPV4 was initially detected from pigs in the United States (Cheung et al. 2010) and then detected in China, Hungary, Romania, Poland, and elsewhere (Cadar et al. 2013; Cui et al. 2017; Cságola et al. 2012; Huang et al. 2010). PPV5 was first identified in pigs in the United States (Xiao et al. 2013) and subsequently in China and Poland (Cui et al. 2017; Wu et al. 2014). PPV6 was first reported in pigs in China in 2014 and then detected in the United States and Poland (Cui et al. 2017; Ni et al. 2014; Schirtzinger et al. 2015). PPV7 has been reported in the United States and China (Palinski et al. 2016; Xing et al. 2018).

Although PPVs 2–7 are commonly detected in pigs, their clinical significance and basic epidemiology, including transmission routes, pathogenesis, clinical signs, and lesions, have not been established. Therefore, the remainder of this discussion reflects information based on studies of PPV1.

PPV1 readily replicates in susceptible pigs, although clinical signs (reproductive losses) only occur in pregnant females. The virus is shed in feces and other secretions from acutely infected pigs, and the epidemiology of PPV1 is shaped by the capacity of the virus to resist inactivation in the environment. That is, PPV1 can remain infectious for months in the environment and contaminated tools and may therefore be a constant source of new infections.

PPV1 can be transported between herds via fomites, for example, the clothes, boots, and equipment. Likewise, rodents functioning as mechanical vectors have reportedly introduced the virus into herds. The virus can also be introduced into populations by infected boars. Whether PPV1 is shed in the semen of infected boars or whether PPV1 in semen represents environmental contamination is unresolved. Regardless, there are numerous reports on PPV1 in the semen of naturally infected boars (Cartwright and Huck 1967; Ruckerbauer et al. 1978).

PPV1 is resistant to inactivation by ethanol (70%) and quaternary ammonium (0.05%), as well as low concentrations of sodium hypochlorite (2,500 ppm) and peracetic acid (0.2%), but is readily inactivated by aldehyde-based disinfectants and higher concentrations of sodium hypochlorite (25,000 ppm) and hydrogen peroxide (7.5%). The virus is relatively heat stable and may resist dry (but not moist) heat at 90 °C (194 °F) (Eterpi et al. 2009). For efficient disinfection an efficacy-tested disinfectant based on peracetic acid, aldehydes, or sodium hypochlorite (the latter only at concentrations above 2500 ppm) should be used.

The introduction of PPV1 into a herd does not cause immediate problems if a sufficient proportion of the

sows are immune through vaccination or natural exposure. However, the virus is able to replicate even in vaccinated pigs (Foerster et al. 2016; Jóźwik et al. 2009). This was demonstrated by a sharp rise in antibody titers in vaccinated sows of the same magnitude as in unvaccinated controls and by active shedding of the challenge virus from vaccinated sows. Thus, virus circulation within a population cannot be completely prevented by vaccination.

Pathogenesis

The pathogenesis of PPV1 reflects the ability of the virus to infect the fetus (Mengeling et al. 2000). However, it is not clear how PPV1 actually crosses the porcine transplacental barrier. As in other viruses, PPV1 could reach the fetus in one of three ways: in body fluids, such as blood or lymph; by progressive replication through continuous placental cell layers; or in cells, such as macrophages or lymphocytes (Mengeling et al. 2000).

After primary replication in lymphoid tissues, PPV1 is distributed systemically via cell-free viremia (Brown et al. 1980; Paul et al. 1980). However, the swine epitheliochorial placenta is composed of six tissue layers that completely separate maternal from fetal blood circulation, and placental cells are so closely connected that they do not allow the passage of even small molecules, for example, antibodies. Placental cells are not susceptible to PPV1 infection, and PPV1 has not been demonstrated in placental tissues, so it is not likely that the virus can cross the barrier through progressive replication (Mengeling et al. 1978). Therefore, it is most probable that the virus reaches the fetus via virus-infected immune cells. Studies have reported both the presence of the virus in lymphoid tissues from pigs (Lucas et al. 1974; Mengeling et al. 2000) and fetal lymphocytes in the circulatory system of pregnant sows (Rudek and Kwiatkowska 1983). Virus replication in macrophages has not been observed, but phagocytized PPV1 remains infectious for an extended period of time (Paul et al. 1979).

Once in the fetus, PPV1 encounters an environment conducive to virus replication because of the high mitotic index of most tissues of the developing fetus. The virus can be detected in many tissues and organs, suggesting that there is no specific tissue tropism (Wilhelm et al. 2005).

PPV1 enters cells through a series of interactions that culminate in the release of viral genetic material into a cell compartment in which replication can occur (Harbison et al. 2008). The entry mechanisms of PPV are unclear, but include clathrin-mediated endocytosis, or macropinocytosis, followed by transportation through the endosomal pathway (Boisvert et al. 2010). Endosomal trafficking and acidification are essential for PPV to enter in the nucleus (Boisvert et al. 2010), resulting in reversible modifications of the capsid that allow the virus to escape from the endosome (Farr et al. 2005; Vihinen-Ranta et al. 2002). In this process, the phospholipase A2 motif (PLA2) must be externalized from the capsid. This motif activity is essential for breaking the vesicular membranes, resulting in the formation of pores (Girod et al. 2002). After the virus arrives in the nucleus, PPV replicates using the cells own replication mechanism. The virus replicates in cells in replication phase (S) using the cellular DNA polymerase for DNA replication. This explains the requirement for cells with a higher replication index (Rhode 1973). The PPV1 replication decreased mitochondrial membrane potential. The subsequent oxidative damage also leads to the release of cellular toxic proteins such as cytochrome c from the mitochondria to the cytosol (Zhao et al. 2016), subsequently triggering apoptosis and causing cell death and tissue damage in viral diseases.

Factors affecting the severity of disease

Several PPV1 biotypes with marked differences in pathogenicity are recognized (Choi et al. 1987; Kresse et al. 1985; Mengeling and Cutlip 1975; Mengeling et al. 1984). Some PPV1s are completely nonpathogenic and do not cause disease even if experimentally inoculated into a fetus; others can cause disease even in immunocompetent fetuses, that is, after day 70 of gestation (see Table 38.2).

The genetic basis of pathogenicity has not been resolved, but the structural protein VP1/VP2 appears to play a major role. Presumably, pathogenicity or virulence

Table 38.2 Viremia, transplacental transmission, and death caused by distinct porcine parvovirus 1 (PPV1) strains.

Virus isolate	Viremia after oral inoculation	Fetal death after intrauterine inoculation	Transplacental transmission after oral inoculation	Death of immunocompetent fetuses
NADL-2	–	+	–	–
NADL-8	+	+	+	–
Kresse	+	+	+	+
KBSH	–	–	–	–

is determined (at least in part) by tissue tropism (Bergeron et al. 1996). *In vitro* studies using recombinant viruses derived from pathogenic (Kresse strain) and nonpathogenic (NADL-2 strain) PPV1s identified "allotropic determinants" and showed that single amino acids in the capsid protein affected an isolate's capacity to replicate in certain cell lines. Comparisons between Kresse and NADL-2 genomes showed that the noncoding regions were nearly identical. All differences found in the NS region were silent, while six of the eight differences identified in the structural genes (VP1/VP2) altered the coding sequence. Among the VP2 amino acids, five changes were consistent with comparisons in field isolates (I-215-T, D-378-G, H-383-Q, S-436-P, and R-565-K) and three of these (D-378-G, H-383-Q, and S-436-P) were considered responsible for differences in tissue tropism (Bergeron et al. 1996). Vasudevacharya and Compans (1992) showed that just two changes were sufficient to extend the host range of a PPV1 variant to canine cells *in vitro*. One of the mutations occurred in the NS gene and the other in the capsid gene (Vasudevacharya and Compans 1992).

In addition to tissue tropism, the absence of duplication of a 127 nucleotide sequence directly downstream of the VP1 gene was associated with virulence. That is, all but one of the virulent field isolates examined lacked this repeat (Bergeron et al. 1996; Soares et al. 2003; Zimmermann et al. 2006).

The pathogenicity of PPV1 is also influenced by the presence of other viruses. In particular, the recognition of low-level PPV1 contamination in the inoculum used in experiments that reproduced post weaning multisystemic wasting syndrome (PMWS) in gnotobiotic pigs (Ellis et al. 1999) led to the recognition that PPV1 in combination with porcine circovirus type 2 (PCV2) can increase the severity of the PMWS lesions (Kennedy et al. 2000). However, PPV1 coinfection is not a necessary requirement for the development of PMWS (Ellis et al. 2004).

Clinical signs

PPV1 is widespread among swine, but the frequency of reproductive losses is difficult to estimate because evidence of infection may appear weeks after infection, that is, an increase in the return-to-estrus index or the observation of affected litters. Likewise, diagnostic tests on fetal tissues often produce false-negative results, possibly due to the autolyzed state of fetal tissues and the high antibody titers in the sows.

Maternal reproductive failure is the major and only well-established clinical sign of PPV1 infection. Reproductive losses are typically low in vaccinated herds, but PPV1 can cause devastating abortion storms in unvaccinated herds or in situations in which the vaccine was administered incorrectly. Diarrhea and skin lesions, with PPV1 and PPV-like structures in diarrheic feces and isolation of PPV1 from "vesicle-like" skin lesions, have been described (Brown et al. 1980; Dea et al. 1985; Duhamel et al. 1991). These reports represent rare findings in which the etiological role of the virus remains to be fully established.

Even under experimental conditions, gilts and boars infected with PPV1 remain clinically healthy, except for reproductive losses in seronegative gilts or sows (Mengeling and Cutlip 1976; Mengeling and Paul 1981; Thacker et al. 1987; Zeeuw et al. 2007). A moderate and transient lymphopenia may be observed 5–10 days post inoculation, regardless of gender or age (Joo et al. 1976a; Mengeling and Cutlip 1976; Zeeuw et al. 2007).

The early phases of PPV1 infection and the incubation period are not well defined. Apparently, the virus first replicates in the tonsils and oral/nasal cavities. After 1–3 days, the virus reaches the lymphatic system and causes a cell-free viremia. Transplacental transmission and subsequent embryo/fetal infection occur around 15 days after inoculation of susceptible gestating females with PPV1 (Brown et al. 1980; Mengeling et al. 1978; Paul et al. 1980).

Reproductive clinical signs correlate to the stage of gestation at which infection occurs (Figure 38.2). At the beginning of gestation, the conceptus is protected by the zona pellucida and is not susceptible to infection. Thereafter and until approximately day 35 of gestation, PPV1 infection results in embryonic death and maternal resorption of fetal tissues. About gestation day 35, fetal organogenesis is essentially complete, and ossification of the fetal skeleton begins. PPV1 infection after this time typically results in fetal death followed by mummification. At or about day 70 of gestation, the fetus is able to mount an effective immune response and eliminate the virus. After day 70, fetal infection is subclinical, and the piglet is born with anti-PPV antibodies (Bachmann et al. 1975; Joo et al. 1977; Lenghaus et al. 1978; Mengeling et al. 2000).

Lesions

Experimental PPV1 inoculation in boars, gilts, and sows does not produce gross lesions (Bachmann et al. 1975; Lenghaus et al. 1978; Mengeling and Cutlip 1976; Thacker et al. 1987). Embryonic death followed by resorption of fluids and soft tissues is the most common sequel to PPV1 infection. Gross lesions in fetuses include a variable degree of stunting before other external changes are evident. Occasionally, blood vessels on the body surface become prominent due to congestion and leakage of blood into connective tissues. Congestion,

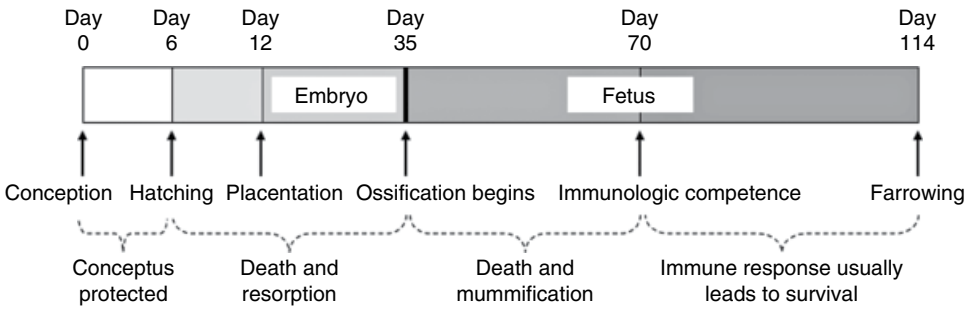

Figure 38.2 Consequence of PPV1 infection by day of gestation. *Source:* Adapted from Mengeling et al. (2000). Reproduced with permission of Elsevier.

edema, hemorrhage with accumulation of serosanguinous fluids in body cavities, and hemorrhagic discoloration, which becomes progressively darker after death and dehydration (mummification), are typical signs of PPV infection (Figure 38.3). The placenta can be dehydrated and brown to gray in color and the extra-fetal fluid volume reduced (Joo et al. 1977; Lenghaus et al. 1978). After fetuses become immunocompetent, no macroscopic changes are observed post infection (Bachmann et al. 1975).

PPV1 has also been associated with cutaneous lesions in piglets. Kresse et al. (1985) associated PPV1 with an epidemic disease in piglets characterized by slit-like erosions and vesicle-like lesions involving the oral cavity and snout. Whitaker et al. (1990) associated PPV1 with a necrotic and exudative dermatitis in piglets. However, experimental cutaneous inoculation of this virus into piglets produced no lesions, which led to the conclusion that PPV1 may only predispose piglets to secondary skin disease (Lager and Mengeling 1994).

Microscopic lesions have been observed in tissues of gilts necropsied after their fetuses were infected by transuterine inoculation of the virus. Seronegative gilts infected at 70 days of gestation and necropsied at 12 and 21 days post inoculation had focal accumulation of mononuclear cells adjacent to the endometrium and in deeper layers of the lamina propria. There was also marked perivascular cuffing of plasma cells and lymphocytes in the brains, spinal cord, and choroid of the eye (Hogg et al. 1977). When fetuses were inoculated at time points earlier in gestation (35, 50, and 60 days) and the dams necropsied 7 and 11 days later, the lesions were similar. However, at that time uterine lesions were more severe and included extensive cuffing of mononuclear cells around myometrial and endometrial vessels (Lenghaus et al. 1978). Only focal accumulations of lymphocytes were detected in the uteri of gilts that were seropositive when their fetuses were inoculated (Cutlip and Mengeling 1975).

Histopathological changes in the fetus tend to be widespread, and the major microscopic lesions represent necrosis of cells in developing organ systems (Joo et al. 1977; Lenghaus et al. 1978). Hemorrhages are present in subcutaneous tissues and muscle masses. Necrosis and

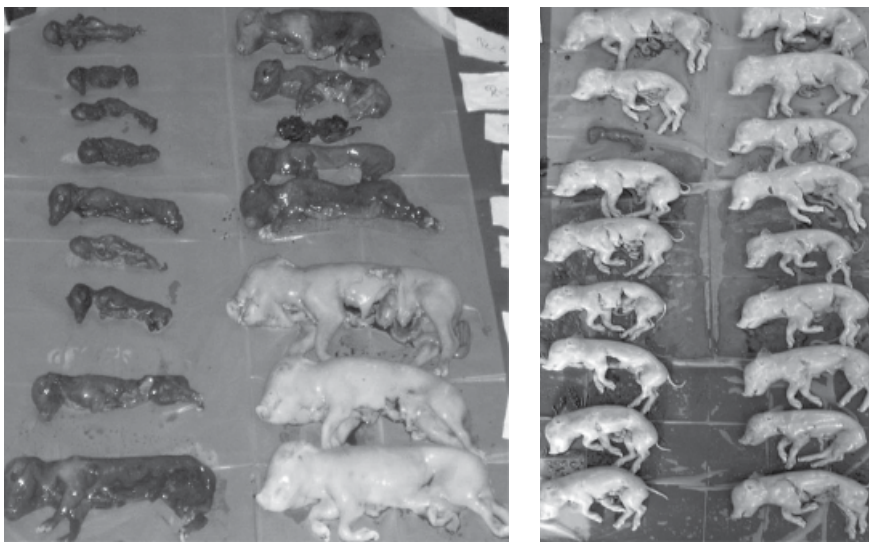

Figure 38.3 Litters of inoculated pregnant sows on day 90 of gestation displaying distinct levels of lesions. The sows were exposed to different PPV1 isolates (27a and NADL-2) on day 40 of gestation. mineralization are common in the lungs, kidneys, and skeletal muscle, particularly extensive in the liver and heart (Lenghaus et al. 1978) (Figure 38.4). After the fetuses become immunocompetent, microscopic lesions are primarily endometrial hypertrophy and mononuclear cell infiltration (Hogg et al. 1977; Joo et al. 1977). Meningoencephalitis characterized by perivascular cuffing with proliferating adventitial cells, histiocytes, and a few plasma cells in the gray and white matter of the cerebrum and leptomeninges were also seen in PPV1-infected live fetuses delivered late in gestation or in stillborn piglets (Hogg et al. 1977; Joo et al. 1977; Narita et al. 1975).

PPV1 has also been associated with a nonsuppurative myocarditis in piglets characterized by single foci of mild to moderate infiltration of mononuclear cells and hemorrhages between the cardiac myocytes (Bolt et al. 1997).

In boars, experimental intratesticular inoculation with PPV1 generated acute degeneration of the seminiferous epithelium, with formation and sloughing of multinucleated cells. Microscopic lesions were not observed after intramuscular inoculation (Thacker et al. 1987).

Diagnosis

Consider PPV1 when reproductive consequences compatible with PPV1 infection are observed, for example, an increase in the return-to-estrus index or delays in parturition with increased numbers of mummified fetuses and smaller litters, especially in first- or second-parity females. A mix of normal pigs and mummified fetuses that died at different development stages in the same litter is a strong indication of PPV1 infection. PPV1 infection does not normally cause abortions and does not cause clinical signs in adults (Mengeling 1978; Mengeling and Cutlip 1975). Given this clinical picture, the differential diagnosis should also include pseudorabies (Aujeszky's disease), brucellosis, leptospirosis, porcine reproductive and respiratory syndrome (PRRS), toxoplasmosis, nonspecific bacterial uterine infection, and others.

Laboratory submissions for the confirmation of PPV1 infection should include mummified fetuses and fetal remains. Detection of viral antigen in fetal tissues by immunofluorescence (IF) is a reliable procedure for the diagnosis of PPV1 (Mengeling 1978; Mengeling and Cutlip 1975). Alternatively, paired serum samples from gilts and sows can be used to document PPV1 infection. However, serum should be collected at the time of reproductive failure and a second sample 2–4 weeks later. Serum or fluids from fetuses, stillborn piglets, or umbilical cord serum before ingestion of colostrum ingestion can also be tested for PPV-specific antibodies.

PPV1 agglutinates erythrocytes of a variety of animal species, including rat, monkey, chicken, guinea pig, and human (blood group 0) (Siegl 1976). The virus grows readily in renal or testicular cells. Primary cell cultures present a higher risk of contamination with adventitious agents and are composed of cells with a lower index of division. Therefore, continuous cell lines (ESK, PK-15, SK6, ST, STE, and SPEV) are typically used for virus

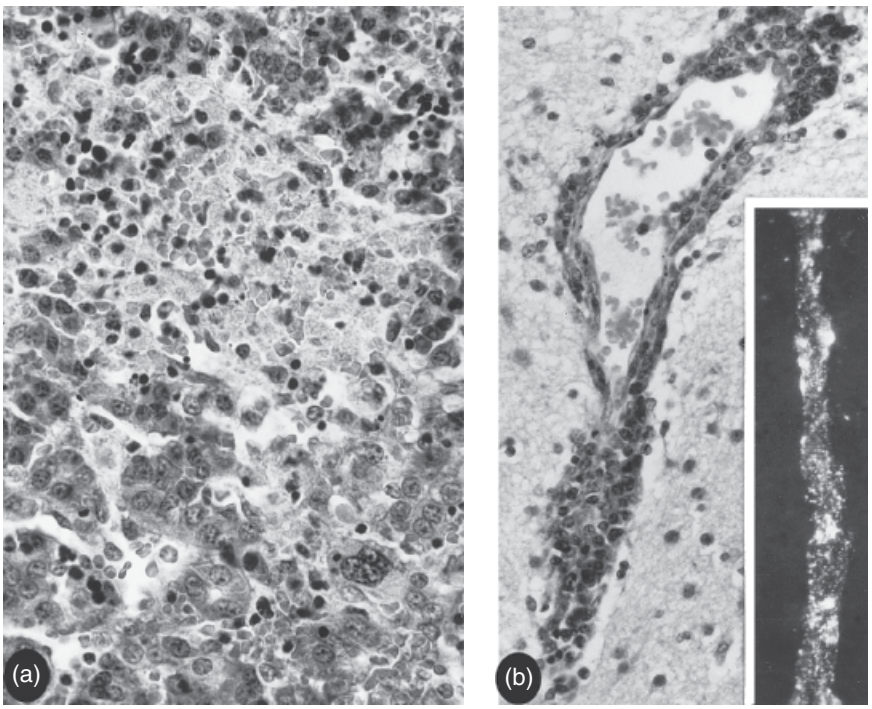

Figure 38.4 Tissues of PPV1-infected fetuses of gilts experimentally infected oronasally. (a) Necrotic focus in the liver of a live fetus of a gilt infected on day 40 of gestation and killed 42 days later; the fetus had numerous macroscopic lesions (hematoxylin and eosin [H&E]; ×400). (b) Perivascular cuffing with mononuclear cells in the cerebrum of a live fetus, littermate of (a); the fetus had no macroscopic lesions (H&E; ×320). propagation and titration (Mengeling 1972; Zimmermann et al. 2006). Cytopathic effects of PPV1 in cell cultures include intranuclear inclusions, pyknotic nucleus, granulations, irregular shape, slow replication, and subsequent cell death (Cartwright et al. 1969; Mengeling 1972). IF microscopy may be used to confirm PPV1 infection of cell cultures and to titrate virus (Johnson 1973; Mengeling 1978) (Figure 38.5). Alternatively, since PPV1 produces a viral hemagglutinin, the virus may also be titrated based on the hemagglutinating activity of PPV1 for erythrocytes of certain species (Joo et al. 1976b; Siegl 1976). Infectious PPV1 is slowly, but progressively, lost after fetal death (Mengeling and Cutlip 1975). Therefore, the likelihood of successful recovery of virus will depend on the condition of fetal tissues at the time of collection, but attempted virus isolation from autolyzed tissues is unproductive.

For routine diagnostics, polymerase chain reaction (PCR) is the most useful technique for the detection of PPV1 in fetal tissues, semen, and other samples. Numerous PCR protocols (and PCR-based, as qPCR and RPA) have been described (Chen et al. 2009; Gradil et al. 1994; Miao et al. 2009; Molitor et al. 1991; Prikhod'ko et al. 2003; Soares et al. 1999; Streck et al. 2015; Wilhelm et al. 2006; Yang et al. 2016), including multiplex PCRs (Cao et al. 2005; Huang et al. 2004; Kim and Chae 2003) mostly for the concurrent detection of PPV1 and PCV2.

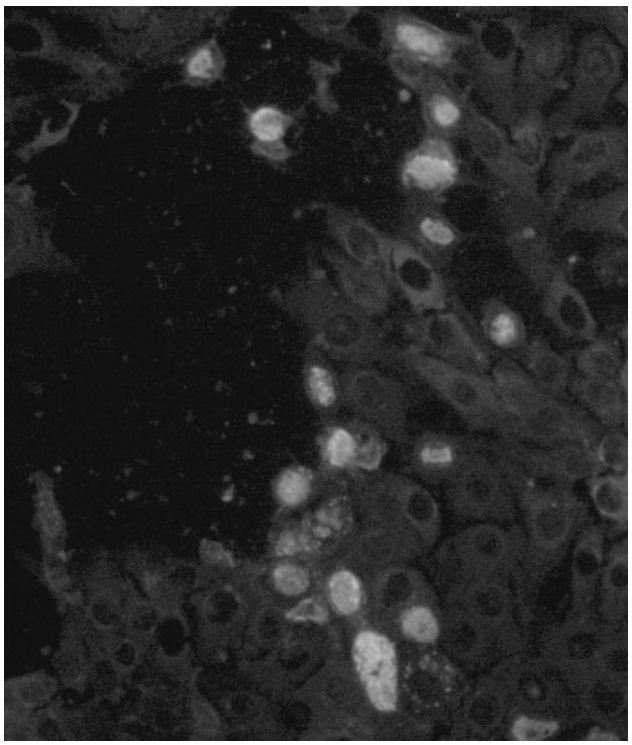

Figure 38.5 Indirect immunofluorescence of PK-15 cells infected with PPV1. Positive nuclear fluorescence is seen 5 days post infection (×400).

These methods are considered to possess higher diagnostic sensitivity and specificity than hemagglutination and are better suited for the detection of PPV1 in autolyzed tissues.

Serology may be useful for the diagnosis of PPV1 when fetal tissues are not available; however, the normally high prevalence of PPV1 in populations and the time lag between infection and the observation of reproductive losses often present challenges to the interpretation of results. For these reasons, paired serum samples should be evaluated in the context of changes in antibody titers between the two samples. Since the virus cannot cross the placental barrier, antibody-positive fluids or sera from fetuses, and pigs prior to consumption of colostrum, are indicative of an intrauterine infection.

The HI assay is commonly used for detection and quantification of PPV1-specific serum antibodies. Importantly, HI results may be affected by incubation temperature and the source of erythrocytes. Serum to be assayed in the HI test is usually pretreated by heat inactivation (56 °C [133 °F] for 30 minutes) followed by adsorption with erythrocytes (to remove nonspecific hemagglutinins) and kaolin (to remove or reduce nonspecific inhibitors of hemagglutination) (Mengeling 1972; Morimoto et al. 1972).

The enzyme-linked immunosorbent assay (ELISA) format is a preferable alternative to HI because it can be standardized and automated for high-throughput testing. Furthermore, it does not require pretreatment of serum before testing (Hohdatsu et al. 1988; Westenbrink et al. 1989). Differential ELISAs can distinguish vaccinated animals from animals infected with PPV1 (Madsen et al. 1997; Qing et al. 2006). Inactivated vaccines only elicit antibodies against the structural proteins (VP1/VP2), whereas differential ELISAs detect antibodies produced against the NS proteins that are expressed during virus replication in infected pigs.

Detection of PPVs 2–7 relies on molecular assays, such as PCR. Virus isolation of PPVs 2–7 in cell culture is difficult, and virus-specific reagents, such as monoclonal antibodies, are not widely available. Likewise assays for the detection of antibodies against PPVs 2–7 are not available, although some assay development has been conducted (Cságola et al. 2016).

Immunity

Piglets from seropositive dams are protected by colostral antibodies consumed in the first day of life. Antibodies against PPV1 are 10 times more concentrated in the colostrum relative to serum. Piglet starts to produce its own antibody in the second week of life. In most pigs, maternal antibody levels decrease steadily and reach non-detectable titers after around 20 weeks of age. In

some cases however, they may persist for up to 9 months and may interfere with the ability of young gilts to respond to vaccination.

Active immunity after field infection or vaccination with PPV1 develops within a few days. Antibodies are detected by HI or virus neutralization tests as early as 6 days post infection. There is a marked difference between antibody titers induced by commercial inactivated vaccines and infection with field virus. By HI, vaccine antibody titers are typically ≤500 or lower, whereas the infection titers regularly exceed 1 : 2000. The persistence of antibodies has been described for 4 months to 4 years for PPV1 (Johnson et al. 1976; Joo and Johnson 1977). Antibodies may prevent clinical disease, but infection and subsequent shedding of field virus occurs (Foerster et al. 2016; Jóźwik et al. 2009). Cellular immunity has also been described, and the proliferation of virus-specific $CD4^+$ and $CD8^+$ T cells proliferating after PPV antigen contact has been demonstrated (Ladekjaer-Mikkelsen and Nielsen 2002). Comparisons of immunity and/or immune responses of pigs to PPV1 versus PPVs 2–7 are not available.

Prevention and control

PPV1 is prevalent in the pig population and highly stable in the environment. These factors make it difficult to establish and maintain breeding populations free of the virus. A more practical goal in commercial herds is to maintain herd immunity against PPV1. Historically, swine producers used various approaches to infect gilts with PPV1 before the first breeding, for example, intentional infection of gilts to PPV1 by exposure to virus-contaminated tissues from affected litters. Approaches of this type are both unreliable and dangerous because they can result in the dissemination of other pathogens in the population, for example, classical swine fever virus. More preferable and reliable is regular vaccination of breeding females against PPV1 (no commercial vaccines against PPVs 2–7 are available at present).

Most commercial PPV1 vaccines are based on chemical-inactivated (formalin, beta-propiolactone, or binary ethyleneimine) tissue culture-derived virus adjuvanted with mineral oil or aluminum hydroxide. These vaccines induce antibody titers sufficient to prevent disease, but not infection (Jóźwik et al. 2009; Foerster et al. 2016). In controlled studies, antibody titers stimulated by inactivated vaccines were detected for 4–13 months after vaccination (Joo and Johnson 1977; Vannier et al. 1986). Therefore, regular revaccination of breeding sows at 4–6-month intervals may be necessary to maintain protective immunity in sows.

Modified live virus (MLV) vaccines for PPV1 have also been developed. Vaccination with MLVs induces a long-lasting immune response, with viremia and shedding of the vaccine virus occurring for a short time post-vaccination. There are few reports on MLVs, and most are based on NADL-2 virus as the vaccine virus (Paul and Mengeling 1980, 1984). Parenteral transmission was more effective than oral administration, and the quantity of virus administered was related to subsequent virus shedding and antibody titers.

In all cases (for inactivated or MLV), transplacental transmission of PPV1 was prevented. Limited experimental infections of pregnant sows with the PPV1 reference strain Impfstoffwerke Dessau-Tornau (IDT), strain Stendal, strain NADL-2, and the field isolates 27a and 143 revealed that vaccination prevented reproductive disorders and a very strong humoral immune response (Jóźwik et al. 2009; Foerster et al. 2016; Zeeuw et al. 2007).

Several subunit vaccines have been described for PPV1, with most based on expression of the viral VP2 protein in a baculovirus system. They provided protection comparable with inactivated full-virus vaccines (Antonis et al. 2006).

Review of the current vaccination strategy against PPV1 infection is warranted. The use of inactivated full-virus vaccines for protection against the closely related canine and feline parvoviruses is no longer common, and inactivated whole virus vaccines have largely been replaced by MLVs. The few remaining licensed inactivated vaccines are used for special purposes, for example, vaccination of exotic zoo felids. MLVs in carnivores induce a long-lasting immune response that provides protection for several years. In swine, the appearance of "new" genotypes or antigenic types of PPV1 needs to be closely watched. New PPV1 vaccines that induce longer-lasting immunity and protect against all of the prevalent virus strains circulating in pig populations are needed.

Pestiviruses

Peter D. Kirkland, Marie-Frédérique Le Potier, and Deborah Finlaison

Overview

The pestiviruses are small (approximately 40–60 nm), enveloped, roughly spherical, positive-sense, single-stranded RNA viruses in the genus *Pestivirus* of the family *Flaviviridae* (Becher et al. 1999). Currently the genus *Pestivirus* includes four formally recognized species: classical swine fever virus (CSFV), bovine viral diarrhea viruses 1 and 2 (BVDV-1 and BVDV-2), and border disease virus (BDV).

Molecular characterization suggests that there are other species in the genus *Pestivirus*. These include the "pestivirus of giraffe" (Becher et al. 2003; Harasawa et al. 2000), the "HoBi" and related viruses isolated from fetal bovine serum and cattle (Schirrmeier et al. 2004), a virus isolated from pronghorn antelope in the United States (Vilcek et al. 2005), Bungowannah virus identified in an outbreak of disease in pigs in Australia (Kirkland et al. 2007), and, most recently, an "atypical porcine pestivirus" (APPV) identified in multiple countries (Beer et al. 2017; de Groof et al. 2016; Hause et al. 2015; Mosena et al. 2018; Munoz-Gonzalez et al. 2017; Postel et al. 2016a; Zhang et al. 2017). Another novel pestivirus, provisionally called "Linda" (lateral shaking inducing neurodegenerative agent) virus, was identified in Austria in 2015 from piglets with congenital tremor (Lamp et al. 2017). Interspecies transmission of the pestiviruses is well known, and the possibility that pigs could be infected with any of the other pestiviruses cannot be excluded.

The new taxonomic species names have been proposed for the genus *Pestivirus* (Smith et al. 2017). The four current species are proposed to be renamed as *Pestivirus A* (formerly *Bovine viral diarrhea virus 1*), *Pestivirus B* (*Bovine viral diarrhea virus 2*), *Pestivirus C* (*Classical swine fever virus*), and *Pestivirus D* (*Border disease virus*). In addition, seven new species (and example isolates) are proposed: *Pestivirus* E (pronghorn pestivirus), *Pestivirus F* (Bungowannah virus), *Pestivirus G* (giraffe pestivirus), *Pestivirus H* (Hobi-like pestivirus), *Pestivirus I* (Aydin-like pestivirus), *Pestivirus J* (rat pestivirus), and *Pestivirus K* (APPV).

The most important pestivirus of pigs is CSFV. Infection of pigs with BVDV or BDV can result in disease, especially reproductive loss, but without major clinical impact. Bungowannah virus is a significant pathogen, but the known geographical distribution of Bungowannah virus is extremely limited, having only been found in two herds in Australia. Although APPV has only been identified recently, it is probably widespread in the global pig population.

The majority of pestiviruses are non-cytopathogenic in cell culture, but some CSFV strains and some BVDV isolates from cases of mucosal disease are cytopathogenic *in vitro* (Gallei et al. 2008).

The pestivirus genome is 12.5–16.5 kb in size and encodes a single polyprotein (Meyers et al. 1989) encompassing all of the structural proteins (C, E^{rns}, E1, and E2) and the nonstructural proteins (N^{pro}, p7, NS2/3, NS4A, NS4B, NS5A, and NS5B) as follows: NH_2-(N^{pro}-C-E^{rns}-E1-E2-p7-NS2/3-NS4A-NS4B-NS5A-NS5B)-COOH. The single polyprotein is co- and posttranslationally converted to mature proteins by a combination of virus and host cell proteases. The structure and function of some envelope proteins have been studied in detail. Even if the nonstructural proteins are better characterized, studies are still needed to understand their role in RNA replication and virion morphogenesis (Ji et al. 2015; Tautz et al. 2015). Little is known about mechanisms of viral RNA replication, packaging, or assembly of viral particles. Virions are released from the host cell by exocytosis, usually without morphological cell damage, the exception being the cytopathogenic strains that are relatively uncommon in nature and arise from mutations of the predominant non-cytopathogenic population.

As enveloped viruses, the pestiviruses are very susceptible to treatment with detergents and lipid solvents. Although they are relatively susceptible to the effects of high or low pH and/or temperature above 60 °C (140 °F),

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

inactivation can be variable among viruses and markedly influenced by their environment. A protein-rich medium usually enhances the stability of pestiviruses (Edwards 2000).

Public health

There is no evidence of human infection with pestivirus, and they are not of any significance for public health or food safety.

Classical swine fever

Relevance

Classical swine fever (CSF), formerly known as "hog cholera," is a highly contagious viral disease of worldwide importance and one of the World Organization for Animal Health (OIE)-listed diseases. Clinical outbreaks suggestive of CSF were reported in the early nineteenth century (Fuchs 1968; Kernkamp 1961; USDA 1889), and CSF was recognized as viral in nature in 1903 (Wise 1981). Wild and domestic pigs are the only natural reservoirs of CSFV. CSFV is endemic in parts of Eastern Europe, Southeast Asia, Central America, and South America. Although eradicated from domestic pigs and wild boars in Western Europe, CSFV remains endemic in some populations of wild boar in Eastern Europe, and farms in these areas are at risk of reinfection.

Etiology

CSFV is antigenically and genetically diverse but relatively stable for an RNA virus. This has been demonstrated experimentally by serial passages in both cell culture and pigs (Vanderhallen et al. 1999) and, in the field, by a study of the isolates collected over 4 years following an outbreak in wild boars (Goller et al. 2016; Simon et al. 2013). Recombination between strains may be possible (He et al. 2007). Antigenic variability among CSFV isolates has been characterized using monoclonal antibodies with 21 antigenic virus types defined on the basis of two panels of monoclonal antibodies directed against E2 and E^{rns} glycoproteins (Kosmidou et al. 1995).

Genetic characterization of new CSFV isolates has become standardized in terms of the genomic fragment sequenced, the algorithms used in constructing phylogenetic trees, and the classification of the genetic groups. Three regions of the viral genome are usually evaluated: the 3′ end of the polymerase gene (NS5B), 150 nucleotides of the 5′ nontranslated region (NTR), and 190 nucleotides of the gene encoding E2. Genetic typing is most commonly based on the E2 glycoprotein because abundant sequence data are available.

CSFV is divided into three major genetic groups (Lowings et al. 1996), each with three or four subgroups (1.1, 1.2, 1.3; 2.1, 2.2, 2.3; 3.1, 3.2, 3.3, 3.4) (Paton et al. 2000). Phylogenetic analyses have demonstrated a link between genotype and geographic origin (Greiser-Wilke et al. 2000). Group 1 isolates are present in South America (Pereda et al. 2005) and Russia (Vlasova et al. 2003). Most viruses belonging to group 2 were isolated from outbreaks in Western, Central, or Eastern Europe (Blome et al. 2010) and some Asian countries (Blacksell et al. 2004; Kamakawa et al. 2006; Pan et al. 2005). More recently, group 2 was reported in Colombia, South America (Garrido Haro et al. 2018). Group 3 viruses are apparently confined to Asia (Parchariyanon et al. 2000). An overview of the global distribution of genotypes is depicted in Beer et al. 2015. The EU Community Reference Laboratory for CSF in Hanover, Germany, has developed a Web-accessible database of sequences from isolates throughout the world. This database is a useful tool for identifying possible viral sources for outbreaks occurring in previously uninfected areas (Postel et al. 2016b).

Epidemiology

Domestic pig populations in Australia, New Zealand, North America, and Western Europe are free of CSF (Beer et al. 2015). In South America, Chile and Uruguay have been declared CSF-free. Argentina, free of outbreaks since 1999, stopped vaccination in April 2004 (Vargas Terán et al. 2004). Extensive areas of Central and South America continue to control the disease by vaccination (Morilla and Carvajal 2002). CSF remains endemic in Asia (Luo et al. 2014; Roychoudhury et al. 2014), and although the situation in Africa is not well defined, the disease has been identified in Madagascar and South Africa (Sandvik et al. 2005).

The reemergence of CSF is always a risk and several areas previously free of CSF have had incursions in recent years. For example, CSF reemerged in Cuba in 1993 after an absence of more than 20 years. In spite of a campaign of total depopulation carried out in the Caribbean, new infections have occurred, leading the authorities to turn to vaccination as the method of control (Frias-Lepoureau 2002; Pereda et al. 2005).

Under natural circumstances, the primary routes of transmission are oronasal by direct or indirect contact with infected wild or domestic pigs or oral by ingestion of contaminated foodstuffs (Edwards 2000; Fritzemeier et al. 2000; Weesendorp et al. 2011). In finishing units and in areas with small pig farms, transport and introduction of infected pigs accounts for the majority of outbreaks and for the spread of the disease (Ribbens et al. 2004).

Airborne spread of CSFV has been demonstrated under experimental conditions (Weesendorp et al. 2009)

and could play an important role under field conditions facilitating the rapid spread of the virus, at least within a compartment (Weesendorp et al. 2014).

The possibility of CSFV transmission by semen was considered during the epidemic in the Netherlands (Hennecken et al. 2000). Infected boars can shed CSFV in semen, and it is assumed that the virus might be transmitted by artificial insemination (de Smit et al. 1999; Floegel et al. 2000).

Transmission of CSFV by rodents, dogs, and cats has been shown experimentally to be unlikely, even as mechanical vectors (Dewulf et al. 2001a). Thus, euthanasia of pets during an outbreak cannot be justified, as long as they do not leave the infected farm.

Indirect transmission via people can occur when biosecurity is deficient, for example, visitors entering the premises without changing into clothing and boots supplied by the farm (Elbers et al. 2001). However, it may be assumed that if basic hygiene measures are taken, the risk of transmitting the virus in this fashion is very low. Vehicles (trucks, trailers, cars) can carry virus-contaminated feces and urine over long distances. Depending on the temperature and duration of the transport, CSFV could survive for some hours or days in urine or feces, therefore presenting a risk of indirect contamination (Weesendorp et al. 2008).

A quantitative approach to understanding CSFV spread among animals and herds is an area of active interest. One objective is to identify the biological and population factors that affect the rate of transmission (Klinkenberg et al. 2002). Experimentally, it was shown that the virulence of the strain could influence the dynamics of virus spread (Durand et al. 2009). Pigs infected with highly virulent strains shed significantly more virus in all their secretions and excretions over the entire infectious period than pigs infected with moderately or lowly virulent strains. Exceptions were the pigs that developed the chronic form of infection after inoculation with a moderately virulent strain. During the entire infectious period, they excreted the largest amounts of virus, because they excreted virus continuously and for a long duration. This study highlighted the crucial role chronically infected pigs may play in the transmission of CSFV. Furthermore, it demonstrated the importance of discriminating between strains and the clinical appearance of infection when using excretion data for modeling (Weesendorp et al. 2011).

Mathematical models that predict the course of an epidemic could provide guidance for decision-making to control an outbreak. Such models have been created and tested with data from the epidemic in the Netherlands (Horst et al. 1999) and in Belgium (Mintiens et al. 2003). More recently, the results of the assessment of traditional control measures, such as preemptive culling and movement restrictions, have shown that movement restrictions have more impact than preemptive culling on the success of control (Thulke et al. 2011).

The survival and inactivation of CSFV has been reviewed (Edwards 2000). Typical of enveloped viruses, CSFV is inactivated by organic solvents (ether or chloroform) and by detergents. Sodium hydroxide (2%) is still considered the most suitable for disinfection of contaminated premises.

In spite of the fact that CSFV is an enveloped virus, CSFV survives for prolonged periods under certain conditions (i.e. cool, moist, protein-rich conditions, such as those found in meat), but in liquid manure CSFV can survive for 2 weeks at 20 °C (68 °F) and more than 6 weeks at 4 °C (39 °F). CSFV is relatively stable over pH ranging from 5 to 10. The rate of inactivation under pH 5 is dependent on the temperature. Thermal and pH stability may vary by strain, but inactivation of the virus is primarily dependent on the medium. For example, CSFV in cell culture loses its infectivity after 10 minutes at 60 °C (140 °F) but survives for up to 30 minutes at 68 °C (154 °F) in defibrinated blood. The inactivation of CSFV in feces and urine from pigs intranasally inoculated with a highly or moderately virulent CSFV strain was inversely related to the storage temperature. Average half-life values were 2–4 days at 5 °C (41 °F) and 1–3 hours at 30 °C (86 °F). Significant differences were observed in survival between virus strains in feces, but not in urine (Weesendorp et al. 2008). For these reasons, it is difficult to give guidelines for the survival of CSFV in the environment.

Pathogenesis

Transmission of CSFV is most commonly oronasal, with primary virus replication in the tonsils. From the tonsils, it spreads to the regional lymph nodes and then via the peripheral blood to bone marrow, visceral lymph nodes, and lymphoid structures associated with the small intestine and spleen. The spread of the virus within the pig is usually complete in less than 6 days.

Within the pig, CSFV replicates in monocyte–macrophage cells and vascular endothelial cells. CSFV is immunosuppressive and neutralizing antibodies may not appear until 2–3 weeks after infection. Leukopenia, in particular lymphopenia, is a classic early event (Susa et al. 1992). CSF leukopenia affects leukocyte subpopulations unequally, with B lymphocytes, helper T cells, and cytotoxic T cells the most affected. Depletion of lymphocyte subpopulations occurs shortly before virus can be detected in serum by reverse transcription polymerase chain reaction (RT-PCR).

The severity of the changes in bone marrow and circulating leukocytes suggest that effects of the virus on uninfected cells are induced indirectly (e.g. by a soluble

factor or by cell-to-cell contact) and are not a direct effect of the virus or viral protein(s). Research has shown that the glycoprotein E^{rns} at high concentration induces apoptosis in lymphocytes *in vitro* (Bruschke et al. 1997). However, exposure to supernatant from infected cells did not induce apoptosis in target cells. Although the process is still not fully understood, such a mechanism could also account for the delay in cellular and humoral immune responses (Summerfield et al. 2001).

In cell culture, most CSFV strains grow without producing cytopathic effect and without inducing interferon-alpha (IFN-alpha) secretion by infected cells. Indeed, CSFV infection causes cells to acquire a greater capacity to resist apoptosis (Ruggli et al. 2003). These observations provide evidence that CSFV interferes with cellular antiviral activity and suggests the possibility that the lesions seen in pigs have an immunopathological basis.

Interactions between CSFV and the monocyte–macrophage system result in the release of mediator molecules that promote the progression of the disease. Changes in hemostatic balance are thought to be caused by proinflammatory and antiviral factors that mediate the thrombocytopenia and hemorrhage characteristics of CSFV infection (Knoetig et al. 1999). The production of inflammatory cytokines by infected endothelial cells could play a role in immunosuppression and facilitate virus dissemination by attracting monocytic cells (Bensaude et al. 2004). A study further argued the role of cytokines in CSFV pathogeny. Levels of the antiviral cytokine IFN-alpha and the cytokine IL-12 coordinating innate and adaptive immune responses were enhanced when the anti-inflammatory cytokine TGF-β1 was reduced after CSFV infection (Renson et al. 2014). It has been recognized that CSFV can replicate in dendritic cells, and it is possible that these highly mobile cells disseminate CSFV to various sites in the body, especially lymphoid tissues (Jamin et al. 2008). Of themselves, interactions between CSFV-infected dendritic cells and lymphocytes are not sufficient to induce lymphocyte depletion without other interactions within the environment of the lymphoid follicles (Carrasco et al. 2004; Jamin et al. 2008).

The expression of differences in virulence between strains is a result of the CSFV–host interactions. The evasion of the host's innate immune responses delays the onset of acquired immunity and produces the resultant pathogenic effects. Results from a comparative microarray analysis strongly suggest that CSFV subverts the interferon response, leading to bystanding killing of lymphocytes and lymphopenia, the severity of which might be due to the host's loss of control of interferon production (Renson et al. 2010).

Clinical signs

In the acute form of CSF, the initial clinical signs include anorexia, lethargy, conjunctivitis, respiratory signs, and constipation followed by diarrhea (Cariolet et al. 2008; Floegel-Niesmann et al. 2009). In the chronic form, the same clinical signs are observed, but the pigs survive for 2–3 months before dying. Nonspecific signs (e.g. intermittent hyperthermia, chronic enteritis, and wasting) may also be seen.

Historically, peracute, acute, chronic, or prenatal forms of CSF were attributed to distinct levels of virus virulence. However, virus strain virulence is difficult to define because clinical signs also depend on pig age, breed, health status, and immune status (Depner et al. 1997; Floegel-Niesmann et al. 2009; Moennig et al. 2003).

Since the early 1980s, diagnosis of CSF based on clinical signs has been problematic and resulted in the belated recognition of CSF outbreaks, thereby giving time for the virus to spread (Durand et al. 2009). CSF is one of several diseases characterized by cutaneous hyperemia or cyanosis and nonspecific clinical signs. Particularly when CSFV strains of lower virulence are involved, it may be difficult to differentiate CSF from African swine fever (ASF), porcine reproductive and respiratory syndrome (PRRS), post weaning dermatitis and nephropathy syndrome (PDNS), salmonella, or cumarin poisoning. The one constant sign in CSF is hyperthermia usually >40 °C (>140 °F), with piglets often piled in a corner. Clinical signs are more marked in piglets than adults, in which hyperthermia may be lower (39.5 °C, 103 °F).

CSFV is able to cross the placenta and infect fetuses at any stage of pregnancy. Depending on the strain and the time of gestation, infection can cause abortion and stillbirths. However, infection at 50–70 days of gestation can lead to the birth of persistently viremic piglets. Such piglets initially appear clinically normal but subsequently begin to waste or develop congenital tremors (Vannier et al. 1981). This course of infection has been described as "late-onset CSF" (Van Oirschot and Terpstra 1977). Similar to BVDV in ruminants, these animals shed high levels of virus for several months and are important reservoirs of CSFV.

Depending on the virulence of the strain of virus and the host response, infected pigs can show clinical signs within 3–6 days of exposure to the virus and die rapidly, recover, or develop chronic disease, which is invariably fatal. Animals may start to shed virus within a few days of infection and before the onset of clinical signs. With less virulent strains, the time to the onset of disease can be as long as 13–19 days (Durand et al. 2009). However, due to the nonspecific nature of clinical signs, especially with strains of moderate or low virulence, the virus may remain undetected in a herd for 4–8 weeks, which increases the risk of further dissemination.

Lesions

CSF lesions vary in severity and distribution, depending on the course of the disease. In acute forms, the pathological picture is often hemorrhagic. Leukopenia, thrombocytopenia, petechiae, and ecchymoses in the skin, lymph nodes, larynx, bladder, kidney (Figure 39.1), and ileocecal junction are often described. Multifocal infarction of the margin of the spleen is characteristic of CSF, but is not always present (Figure 39.2). Swollen or hemorrhagic lymph nodes or tonsils are common (Figure 39.3). In chronic forms, button ulcers in the cecum or large intestine may be present (Figure 39.4), as well as a generalized depletion of lymphoid tissues. Hemorrhagic and inflammatory lesions are less common, or even absent, despite the degeneration of endothelial cells. Congenital CSF can result in abortion, fetal mummification, stillbirths, and congenital malformations, such as central dysmyelinogenesis, cerebellar hypoplasia, microencephaly, and pulmonary hypoplasia (van der Molen and van Oirschot 1981).

Floegel-Niesmann et al. (2009) compared the clinical signs and lesions produced by six field strains isolated during the last decade from domestic pigs or wild boars in Europe to a reference strain (Alfort 187). Comparing lesions in skin, subcutis and serosae, tonsil, spleen, kidney, lymph nodes, ileum and rectum, brain, and respiratory system, they found that lymph nodes were the tissues most severely affected by all isolates, followed by necrotic lesions in the ileum and hyperemia of the blood vessels of the brain. Thus, these tissues were the most reliable for diagnosis of CSF. Infarction of the spleen and necrotic lesions of the tonsil, although commonly described in the earlier literature, were infrequent. Likewise, respiratory signs were absent or mild.

Diagnosis

Response to CSF epidemics in Europe has shown that early recognition of CSF and prompt elimination of CSFV-infected animals is the key to control. The longer CSF remains undetected, the greater the opportunity for the virus to spread. It should be recognized that farmers and veterinarians detected 75% of the recent CSFV epidemics based on clinical observations. The need to establish a standardized protocol for evaluating herds for CSF has been recognized (Elbers et al. 2002; Floegel-Niesmann et al. 2009; Mittelholzer et al. 2000). However, the list of clinical criteria cannot be overly complex if it is to be used in the field. Average daily gain and feed consumption are two quantifiable measures that may be of use (Cariolet et al. 2008). Body temperature may also be useful, since hyperthermia is consistently associated with CSF and appears before, or concurrently, with the first clinical signs.

Because CSF has no pathognomonic clinical signs, laboratory diagnosis is always required. Since CSFV, BVDV, and BDV share common antigens, it is of the utmost importance to discriminate among these. A variety of methods for the detection of CSFV, components of the virion (antigens or nucleic acid), or specific antibodies against viral antigens are available. While pan-pestivirus diagnostic assays are useful for screening specimens, positive results must be confirmed with CSFV-specific assays. Real-time reverse transcription polymerase chain reaction (rRT-PCR) assays are now widely used to detect nucleic acid from pestiviruses, and both pan-reactive and CSFV-specific assays are available. Monoclonal antibodies that distinguish between pestiviruses are used in a variety of techniques to specifically identify the virus (e.g. virus isolation [VI], fluorescent antibody test [FAT], or enzyme-linked immunosorbent assay [ELISA] tests).

It is not feasible to perform all available diagnostic assays during an outbreak. Therefore, it is important to perform the assay(s) most appropriate to the situation and intended purpose. Since the key to controlling an outbreak is prevention of virus spread among farms, the assay of choice in terms of diagnostic sensitivity, diagnostic specificity, and speed is rRT-PCR. However, since the period of viremia is short, antibody detection assays are also useful, especially in herds where clinical signs have been present for more than 2 weeks (Greiser-Wilke et al. 2007).

Detection of CSFV

Depending on the virulence of the strain, the tests, and the specimens, virus can be detected within 24 hours after infection (Liu et al. 2011a). Virus may be isolated from whole blood collected in heparin or EDTA or serum, plasma, and buffy coat. The tissues most likely to contain virus are tonsils, spleen, jejunum, ileum, ileocecal, mesenteric, and retropharyngeal lymph nodes.

Although VI is the reference method to confirm the infection, it is labor intensive, time consuming, and incompatible with the rapid response required to prevent further spread of virus in CSFV eradication programs. The purpose of VI, at least in reference laboratories, is to isolate viruses for detailed characterization and for use in vaccination studies. CSFV can be isolated on porcine kidney cell lines (PK-15 or SK6). It is critical that all cells, media, and reagents have been previously determined to be free of pestiviruses or antibodies against pestiviruses.

rRT-PCR assays are currently the preferred method for the detection of viral RNA. These assays have both high sensitivity (diagnostic and analytical) and specificity, particularly probe-based assays (Hoffmann et al. 2005, 2011; Le Potier et al. 2006). Several CSFV-specific rRT-PCR kits are commercially available (Le Dimna et al. 2008). Protocols have been specifically designed for the detection of genome of the C strain of live vaccine (Liu et al. 2011b), while others were designed to allow a simultaneous detection of CSFV and ASF virus genome (Haines et al. 2013).

A wide variety of samples are suitable for testing by rRT-PCR, but mainly whole blood samples, swabs, and tissue samples are used for the diagnosis of CSF. Besides whole blood, serum, plasma, or leukocytes can be used. Preferred tissue samples for VI are the tonsil, spleen, ileum, and lymph nodes. Kidney samples may be less suitable.

Good quality, fresh specimens are preferred, but viral RNA can still be detected in specimens in which virus is inactivated or VI is no longer possible due to bacterial contamination or autolysis (e.g. wild boar samples) (Petrov et al. 2014). rRT-PCR is not affected by the presence of antibodies, so specimens from animals of any age can be tested. Viral RNA can also be detected for a long time in certain tissues (e.g. viral RNA was detectable in tonsils of pigs that had recovered from CSFV infection for at least 9 weeks) (Blome et al. 2006).

Depending on the genomic region that is targeted for amplification, rRT-PCR can be designed to differentiate between virus species (CSFV, BVDV, and BDV) and even strains of CSFV (Zhang et al. 2012). Depending on the vaccine and the sample to be tested, rRT-PCR can be used as a genetic DIVA test. Newly developed C-strain-specific rRT-PCRs (Leifer et al. 2009) can be used to test vaccinated animals for the presence of modified live virus (MLV) vaccines, but infection with wild-type virus cannot be ruled out in the case of a positive result. Combining different PCR assays that are specific for vaccine or wild-type virus (Liu et al. 2009; Zhao et al. 2008) and partial sequencing can be used to detect or rule out wild-type virus infections (Blome et al. 2011).

The high sensitivity of rRT-PCR will support the testing of pooled samples (Depner et al. 2007; Le Dimna et al. 2008), which can significantly increase throughput. There are, however, other considerations including the time to prepare sample pools and the need to retest all individual samples in a positive pool. To avoid a loss of sensitivity, detailed knowledge of the performance characteristics of the assay and the levels of RNA likely to be detected (e.g. clinical cases vs. screening in vaccinated populations) needs to be established prior to pooling.

In general, it can be concluded with a high degree of confidence that a negative RT-PCR result indicates that the tested animal or tissue sample is not infectious to other pigs. In contrast, a positive RT-PCR result does not necessarily imply that the animal is infectious (Haegeman et al. 2006).

Antigen-capture ELISAs may be used for early diagnosis of CSFV in live pigs. Double-antibody sandwich ELISAs are based on monoclonal and/or polyclonal antibodies directed against a variety of viral proteins. Serum, buffy coat fraction, whole blood in heparin or EDTA, or tissue homogenates can be tested in these assays. The technique is relatively simple to perform, does not require tissue culture facilities, is suitable for automation, and provides results within 36 hours (Depner et al. 1995). However, it is important to recognize the diagnostic limitations of antigen-capture ELISAs. All currently available commercial assays are less sensitive than VI on cell culture (Blome et al. 2006). In addition, their diagnostic sensitivity is significantly better on blood samples from piglets compared with samples from adult pigs or samples from mild or subclinical cases (Anonymous 2002). To compensate for the lack of diagnostic sensitivity, all pigs showing pyrexia in suspect herds should be tested. These tests also have lower diagnostic specificity and false-positive reactions may occur. For these reasons, the use of antigen-capture ELISAs is only recommended on samples from animals with clinical signs or pathological lesions compatible with CSF and for screening herds suspected to have been recently infected.

Although the direct FAT on frozen sections was the method of choice for detecting viral antigen, given the high sensitivity, throughput, and rapid turnaround provided by rRT-PCR, it is unlikely that this would be the assay of choice in a future outbreak.

Detection of anti-CSFV antibodies

The virus neutralization (VN) test has been considered the reference assay for the detection of CSFV-specific antibodies. CSFV neutralizing antibody levels are determined by endpoint titration of serum. However, the VN test requires good quality serum samples and the use of a cell culture system. As the VN test is relatively time consuming and takes 3–5 days to obtain results, it is not the assay of choice for routine large-scale testing.

Because of antibody cross-reactions among pestiviruses, VN tests can be used to identify the virus with which an animal has been infected. Samples are tested in dual or multiple VN tests, and the CSFV neutralizing antibody titers are compared with neutralizing antibody titers against BVDV or BDV reference strains. A difference of fourfold or more between the endpoints of the two titrations is considered conclusive for infection by the virus species yielding the highest neutralizing antibody titer (Anonymous 2002). This method is frequently used to screen neighboring herds around an outbreak prior to lifting control measures.

ELISAs for the detection of anti-CSFV antibodies are useful for conducting epidemiological surveys and for monitoring CSFV-free areas. Competitive ELISAs are based on competition between anti-CSFV serum antibodies and a CSFV-specific monoclonal antibody directed against the viral glycoprotein E2 (gp55). Cross-reactions with antibodies against other pestiviruses are reduced in the competitive ELISA format. A baculovirus recombinant E2 protein is often used as the antigen in the system. ELISA-detectable antibodies appear 10–15 days post infection, similar to the period described for the appearance of neutralizing antibodies.

The E^{rns}-ELISAs were developed as differential companion tests for use in E2-subunit-vaccinated populations (Van Rijn et al. 1999). More recently, other E^{rns}-ELISAs have been developed to be potentially used as companion ELISAs (Aebischer et al. 2013). However there is still scope for improvement of commercial ELISAs before recommending them as a companion test for the differential diagnosis with the new marker chimeric vaccine CP7_E2Alf (Schroeder et al. 2012).

Prototype pen-side antibody detection tests have been reported and could be useful in the assessment of serological prevalence for a vaccine program (Li et al. 2012).

Immunity

Even though CSFV can induce immunosuppression, pigs that recover develop neutralizing antibodies to the virus. Neutralizing antibodies are induced by the envelope glycoprotein E2, while the envelope protein E^{rns} and the nonstructural protein NS3 induce non-neutralizing antibodies. Therefore, clearance of the virus is possible after the onset of production of neutralizing antibodies at 10–20 days after infection.

Both CSFV-specific neutralizing activity and specific killer cell activity are important for an effective immune response (Renson et al. 2014). The dual combination of cellular immunity and neutralizing antibody is optimal for providing fast and complete protection that results in sterilizing immunity. However, each component in itself has the potential to protect pigs from a lethal CSFV infection. E2-subunit vaccines protect pigs by inducing

high titers of neutralizing antibodies (Bouma et al. 1999), but experimental infection with related pestiviruses or chimeric constructs were also protective, even though they did not induce detectable neutralizing activity (Reimann et al. 2004; Voigt et al. 2007).

Pigs that have been either vaccinated or infected are resistant to subsequent virus challenge. CSFV is antigenically quite stable for an RNA virus and cross-protection exists between different genogroups and even between BVDV and CSFV (Leforban et al. 1992). Maternal antibodies can confer protective immunity to piglets for 8–12 weeks, depending on the level of neutralizing antibodies in the colostrum (Kaden and Lange 2004). However, these antibodies can also interfere with the response to vaccination (Vandeputte et al. 2001).

Prevention and control

CSF is endemic in many parts of the world and remains a disease of worldwide importance. Although some regions are free of CSFV, it is still present at the borders between free and endemic areas and in some wild boar populations (Laddomada 2000). The risk of reintroducing CSFV into free areas is still high. Producers and veterinarians are in the best position to detect CSF outbreaks in free areas, but early detection will require both vigilance and training in the recognition of clinical signs.

For purposes of international trade, free areas maintain a "no vaccination" policy against CSF. Thus, control is based on early detection and stamping out infected or suspected herds, with the implementation of concomitant quarantine measures (Anonymous 2001). However, the eradication of CSF outbreaks in Europe by stamping out has raised concerns regarding the "no vaccine" policy. This is especially true in pig-dense areas, where a variety of factors increase the risk of disease spread (Koenen et al. 1996; Mintiens et al. 2003). In certain situations, like the 1997 outbreak in the Netherlands, movement restrictions that prevented the movement of pigs to slaughter resulted in the unnecessary euthanasia of large numbers of animals. While the use of vaccine has economic consequences (i.e. vaccinated areas are banned from international trade for at least 1 year), emergency vaccination in the face of an outbreak is more likely to be considered in the future.

Various CSFV vaccines are available, including the well-known live "Chinese" C strain, the Thiverval strain, and newer marker vaccines that allow differentiation of field virus-infected from vaccinated animals (Blome et al. 2017). The traditional live vaccines based on MLV induce fast protection (Graham et al. 2012), even by the oral route (Renson et al. 2013), with a high level of protection against clinical disease, and neutralizing antibodies are detectable at 2 weeks post challenge (Dahle and Liess 1995). Duration of immunity is 6–10 months, regardless of the route of administration (intramuscular or oronasal) (Kaden and Lange 2001; Kaden et al. 2008). The primary drawback of MLV is that it is impossible to differentiate vaccine antibodies from field virus-induced antibodies.

An E2 recombinant protein subunit vaccine is commercially available and provides the means to differentiate infected from vaccinated animals (DIVA). The efficacy of the baculovirus-expressed E2 protein marker vaccines has been evaluated in vaccination-challenge and transmission trials, but with variable results. A single dose of vaccine prevented clinical signs and mortality due to a CSFV challenge 3 weeks after vaccination (Bouma et al. 1999), but at least 14 days were needed to obtain clinical protection (Bouma et al. 2000; Uttenthal et al. 2001). If challenged earlier, no protection against clinical disease and no reduction of virus shedding were observed (Uttenthal et al. 2001).

Evaluation of the E2 marker vaccines showed that transplacental transmission of CSFV occurred even when two doses of vaccine were administered and challenge occurred 14 days after the second dose. The two-dose vaccination protocol protected pregnant gilts from clinical disease, but did not prevent horizontal or vertical spread of the CSFV (Dewulf et al. 2001b). Thus, transplacental infection would not be prevented in most vaccinated animals under the conditions of emergency vaccination. Vaccination could not prevent the "carrier sow syndrome" and, subsequently, the late-onset form of CSF (Depner et al. 2001).

Recently, the development of CSF vaccine has focused on five strategies, mainly based on genetically engineered constructs: immunogenic CSFV peptides, DNA vaccines, viral vectors expressing CSFV proteins, chimeric pestiviruses, and trans-complemented deleted CSFV genomes (replicons) (Blome et al. 2017). The chimeric pestivirus CP7-E2Alf has been licensed after being widely assessed for its safety and potency (Gabriel et al. 2012). It has been shown to induce a high level of immunity and protection, whatever the route of inoculation (oral or intramuscular); to prevent further virus spread; and to be safe in growing pigs and pregnant sows. Maternal-derived antibodies (Eblé et al. 2014) or preexisting BVDV-1 antibodies (Drager et al. 2016) do not seem to dramatically interfere with the efficacy of the vaccine. This vaccine could be used in an emergency vaccination program to control CSF spreading either in domestic pigs or wild boar populations. If a fully validated companion kit were available, its DIVA properties could make it a very valuable tool to control an outbreak while allowing for serological surveillance.

Classical swine fever in wild boars

Wild boars are potential reservoirs of CSF, as most outbreaks in domestic pigs have been ascribed to

transmission from wild boars (52% according to Fritzemeier et al. 2000). As a consequence, oral mass vaccination of wild boar has been implemented with success since the 1990s in the European Communities for limiting virus spread and persistence within natural populations (Rossi et al. 2015). CSFV infection is seemingly harmless for wild boars, as little mortality has been reported in past outbreaks. In the presence of natural or man-made barriers, CSFV in wild boar populations can be confined to a defined area until it is eliminated (Pol et al. 2008).

Classic measures for CSFV control in wild boars involved reduced hunting to allow the virus to spread within the susceptible population and induce mortality or immunity, followed by targeted hunting of the most susceptible animals (i.e. juveniles and the young sows). In some areas where it has been difficult to eradicate CSFV using standard methods, oral vaccination using live C strain distributed in oral bait has been attempted (Kaden et al. 2000). The safety of this vaccine has been demonstrated for other wild animal species (Chenut et al. 1999).

In pigs, the oral vaccine can induce strong protective immunity in 10 days (Kaden and Lange 2001). However, recent analysis of the data from oral vaccination field campaigns has shown that three doses were required to induce immunity in the field. Due to poor access to baits, young boars did not acquire sufficient protective immunity in most field studies (Kaden et al. 2002). Vaccination seems more effective if it is used on a preventive basis and delivered at least 1 year before the virus enters the area, giving time for a high level of population immunity to be achieved. Routine vaccination around an outbreak has been proposed to prevent the spread of disease (Rossi et al. 2010).

When vaccine is used, the only method to differentiate infected from vaccinated boars is detection of the virus by DIVA rRT-PCR (Leifer et al. 2009). Therefore, it is rather difficult to decide when to stop vaccination. Antibodies to CSFV can persist for many years and interfere with surveillance after the completion of oral mass vaccination. It is therefore recommended to increase active surveillance in order to detect dead wild boar. However, as it is rare to find carcasses in nature, serological surveillance on young animals is also recommended in combination with data modeling to identify seroprevalence hot spots exceeding 5% in young animals. In these areas, targeted serological and virological surveillance should be implemented (Saubusse et al. 2016). In the future, the use of an oral DIVA vaccine that would permit serological monitoring of a vaccinated population for the spread of wild-type virus would be valuable. The chimeric pestivirus CP7_E2alf is currently the most promising live vaccine candidate for oral application.

Bungowannah virus

Relevance

In June 2003, a severe disease outbreak characterized by an increase in stillbirths, preweaning mortality, and mummified fetuses occurred on two properties in southern New South Wales, Australia. Because the cause was unknown at the time of the outbreak, the term "porcine myocarditis syndrome" (PMC) was used to describe the disease (McOrist et al. 2004). Subsequently, a previously unidentified pestivirus, named Bungowannah virus, was identified as the cause of PMC (Finlaison et al. 2009, 2010; Kirkland et al. 2007).

Bungowannah virus has only been recognized on two farms in Australia, and its origin remains obscure. It is highly pathogenic for the porcine fetus, a feature consistent with its distant genetic relatedness to CSFV. Clinically, fetal infection with Bungowannah virus could be confused with a low virulence strain of CSFV. It is of concern that this virus is not detected by diagnostic assays that were considered to react with all members of the pestivirus genus. The global significance of this pestivirus remains unclear. Bungowannah virus has not been detected outside of Australia, but only very limited surveys have been conducted (Abrahante et al. 2014).

Etiology

Bungowannah virus is genetically distinct from CSFV, but molecular characterization supports its inclusion in genus *Pestivirus*. Phylogenetic analysis and limited antigenic cross-reactivity indicate that this pestivirus is genetically quite divergent from the recognized species of pestiviruses and also distinct from the more recently recognized APPV (Hause et al. 2015; Kirkland et al. 2007, 2015a). Bungowannah virus is non-cytopathic in cell culture and replicates to the highest titers in continuous porcine kidney cell lines; it also has a capacity to replicate efficiently in a surprisingly wide range of cells from other species, including bats (Kirkland et al. 2007; Richter et al. 2014).

Epidemiology

Bungowannah virus has only been identified in two related piggeries in New South Wales, Australia. The source of the virus is not known. The virus was eradicated from one site, and while efforts were made to eradicate the virus at the second larger multiunit site in 2010, they were ultimately unsuccessful, and the virus remains endemic. Reintroduction was thought to have occurred via aerosols generated during decontamination of an infected module 0.5–1.5 km away from the Bungowannah virus-free unit (Kirkland et al. 2015b). Other piggeries

connected to the affected farms were free of infection, and there is no evidence of infection on other farms in Australia. Serological surveillance in Germany has not identified antibodies to this virus, and a survey of undiagnosed cases of abortion and respiratory disease in the upper Midwestern United States also failed to detect evidence of the virus (Abrahante et al. 2014). While PMC is readily detected in a fully susceptible population, it is possible that it could remain unrecognized in countries where CSFV is present or pigs are affected with similar clinical entities.

Under field conditions, disease caused by Bungowannah virus has only been reported in pigs (McOrist et al. 2004). Experimentally, nonpregnant sheep and cattle have also been infected, but without evidence of disease (Kirkland et al. 2015b). The significance of fetal infection in the calf before development of immunocompetence is not clear as neutralizing antibodies could be detected in precolostral sera of the animals that became infected (Kirkland et al. 2015b).

Due to the large amount of virus shed into the environment by persistently infected pigs, postnatal transmission presumably occurs following oronasal exposure (D Finlaison, personal communication). Intranasal exposure of pigs under experimental conditions readily established infection. The risk of transmission by embryos or semen has not been fully evaluated. Strategic testing of young boars for high neutralizing antibody and negative PCR results on semen prior to movement to a quarantine facility has not been associated with introduction of Bungowannah virus to uninfected sites. Bungowannah virus RNA has been detected in the semen of approximately 20% of boars at the time of initial screening, despite high serum neutralizing antibody titers. It has not been determined whether this semen would be infective for female pigs via artificial insemination. VI studies on semen have been limited, although the RNA load in some samples is sufficiently high that transmission could be expected (Kirkland et al. 2015b).

If an animal is first infected during pregnancy, there is a high risk of transplacental transmission and fetal infection. During experimental studies fetal infection occurred in the litters of 87% of sows that became infected (Kirkland et al. 2015b).

Following the experimental infection of 5- to 6-week-old pigs by the intranasal route, viral shedding was detected by rRT-PCR for 3–10 days post challenge in oropharyngeal and nasal secretions. The duration of shedding and amount of virus shed in feces and conjunctival secretions was markedly lower (Finlaison et al. 2012). Limited experimental studies suggested that transmission is poor from transiently infected animals.

Experimental inoculation of pregnant pigs (Kirkland et al. 2015b) suggested that the epidemiology of Bungowannah virus was similar to *in utero* infections with BVDV, BDV, and low virulence CSFV. High quantities of Bungowannah virus RNA were detected in placenta and fluids (fetal and/or vaginal) at farrowing, irrespective of the stage of gestation at which infection occurred. Thus, fetal fluids and placenta are an important source of environmental contamination.

All infected piglets shed high quantities of Bungowannah virus RNA at birth, regardless of whether the dam was challenged before or after the approximate age of immunocompetence in the fetal pig (70 days). The duration of postnatal virus shedding was inversely related to the stage of gestation at which infection occurred. Thus, fetuses infected in late gestation had the shortest period of shedding (1–2 weeks of age). Most pigs from sows infected at 55 or 75 days gestation had Bungowannah virus-specific antibody at birth.

Animals persistently infected with Bungowannah virus have not been identified in the field, but they were observed during experimental studies. These pigs shed high quantities of Bungowannah virus in oropharyngeal secretions, urine, and feces, and the infection was readily transmitted to naïve pigs.

Specific studies on the persistence of Bungowannah virus in the environment and its susceptibility to disinfectants have not been carried out, but its characteristics are probably similar to those of CSFV and BVDV. Successful eradication from the affected farm described above was carried out with a combination of measures including depopulation, disinfection (detergent/Virkon/sodium hypochlorite), and site biosecurity measures.

Pathogenesis

The primary route of viral entry is presumed to be oronasal, with primary replication in the tonsils, like CSFV. Although this site of replication is yet to be confirmed, virus has been detected in oropharyngeal secretions at the earliest sampling time of 3 days post inoculation and in high quantities in tonsil tissue.

Unlike CSFV, there appears to be no appreciable clinical effects following postnatal infection with Bungowannah virus, regardless of the dose of virus (Finlaison et al. 2012). Thus, disease appears to be wholly the result of *in utero* infection of the fetus with the clinical outcome and lesions dependent on the stage of gestation at which infection occurs. Direct intrauterine transmission appears likely, and during experimental studies, most litters were completely infected by 20 days post infection (Finlaison et al. 2010).

Litters were most severely affected when sows were infected at approximately 35 days of gestation, with approximately 40% of fetuses either stillborn or mummified and 70% of the piglets born alive dying before 3 weeks of age. Of the small group of animals that survived to weaning, over 80% were persistently infected (Kirkland et al. 2015b).

Infection of the sow at ~55, ~75, or ~90 days gestation resulted in 10–15% stillbirths, with the number of mummified piglets close to normal production targets. Preweaning losses were also elevated (29%) in piglets from sows infected at 90 days of pregnancy. Persistently infected animals were immunotolerant, and most failed to mount a humoral immune response (Kirkland et al. 2015b). The pig fetus appears to be first able to mount a humoral immune response to Bungowannah virus at 57–73 days of gestation (Finlaison et al. 2010).

Clinical signs

To date, there has only been one known Bungowannah virus outbreak in pigs (McOrist et al. 2004). The most significant effects of Bungowannah virus infection were the consequence of *in utero* infection. Sudden death in healthy 2- to 3-week-old pigs triggered the initial disease investigation, but the nature of the losses altered within 2–3 weeks of the commencement of the outbreak. Sudden death became less common, and increased numbers of stillborn pigs and preweaning mortalities in the early postnatal period were noted. Piglets born alive from affected litters showed greatly reduced viability. Evidence from the field outbreak suggested that litter size remained relatively unaffected. At the peak of the outbreak, preweaning mortality reached 50%, 40% of fetuses were stillborn, and 13% were mummified in some production units. In a herd consisting of approximately 30,000 sows, it is estimated that 50,000 pigs were lost from production due to PMC over a 15-month period (Finlaison et al. 2009).

Pigs persistently infected with Bungowannah virus were not identified during the outbreak of PMC, but have subsequently been produced following experimental infection of pregnant sows up to 56 days gestation (Kirkland et al. 2015b). Those resulting from sow challenge at around 35 days of gestation experienced poor viability and high mortality in the early postnatal period. The few piglets that appeared clinically normal soon after birth developed a syndrome similar to "late-onset CSF" in the weeks following weaning, becoming severely stunted with high morbidity and mortality compared with unaffected cohorts of the same age. A small proportion of pigs born following infection of the sow at approximately 55 days appeared to be persistently infected and exhibited stunting compared with age-matched cohorts but had better long-term survival. Some of these animals seroconverted and appeared to clear the infection, cease viral shedding, and grow better after this occurred. The term "chronically infected" may therefore be more appropriate for these than "persistently infected" pigs as the latter exhibit lifelong virus excretion.

Postnatal infection with Bungowannah virus is associated with few clinical effects. An incubation period of 3–5 days prior to the detection of viremia has been observed following experimental intranasal infection of weaner aged pigs. While mild transient temperature rises were recorded, no other evidence of disease was noted (Finlaison et al. 2012). Likewise, on the piggeries affected by PMC, dams of the affected piglets were clinically normal with normal feed intake and body temperature (McOrist et al. 2004). Once the virus becomes endemic in a population, if animals are infected prior to first breeding, clinical disease may not be recognized despite ongoing transmission.

Lesions

Field cases of PMC were associated with increased stillbirths (both recent and long-standing with autolysis), fetal mummification, and preweaning mortalities (McOrist et al. 2004). A range of gross lesions were observed, including subcutaneous edema spread particularly over the head and thorax of some stillborn piglets; a dilated heart; irregular areas of myocardial pallor; increased pericardial, thoracic, and abdominal fluid; and occasional fibrin tags on the thoracic and abdominal viscera. The placentas appeared normal. Up to 50% of stillborn pigs may have elevated IgG levels. During experimental studies, some piglets born to sows infected with Bungowannah virus at 35 days of pregnancy exhibited purpura that appeared to resolve over approximately 7 days, an absence of facial whiskers, and white focal lesions in the cerebrum. Gross lesions were not observed in weaner pigs at necropsy 6 weeks post inoculation following experimental infection.

Histopathological findings in affected piglets consistently included acute-to-subacute multifocal, nonsuppurative myocarditis, with myonecrosis occasionally observed. Inflammation was frequently mild and localized and myofiber destruction was minimal. A minority of cases in older neonatal piglets had early myocardial fibrosis. Occasional affected piglets had nonsuppurative interstitial pneumonia, encephalitis, hepatitis, and lymphadenitis (McOrist et al. 2004). During experimental studies acute myocarditis was observed following infection of the dam in late gestation (day 90) (Kirkland et al. 2015b).

Diagnosis

While Bungowannah virus has to date only been identified in Australia, its origin remains unknown, and it should be included within the differential diagnoses of viral pathogens causing reproductive disease in the pig. In addition, the clinical presentation has similarities to *in utero* infection with CSFV, BVDV, and BDV and with "late-onset" CSF. For laboratory diagnosis, samples should be collected for rRT-PCR, histopathology, and serology.

Rapid identification of infected fetuses is best achieved with detection of Bungowannah viral RNA by rRT-PCR (Finlaison et al. 2009). Viral RNA can be readily detected in fetal fluids, pharyngeal swabs, and tissues of infected fetuses. Virus can be isolated from a number of tissues, including lung and lymphoid tissues, although it is not routinely used for diagnostic purposes because rRT-PCR has higher sensitivity. Additionally, the virus is not cytopathic in cell culture, so immunoperoxidase staining is required to detect virus replication in cell cultures (Kirkland et al. 2007).

Serology by peroxidase-linked immunoassay (PLA) or virus neutralization (VN) test is best utilized for surveillance and monitoring purposes. For diagnostic applications, PLA may be performed on poor quality samples that may not be suitable for testing by VN. This is of particular use for fetal specimens. Approximately 50% of stillborn piglets can have elevated IgG levels, and specific antibodies can be detected in the serum and fluids from body cavities of stillborn piglets. Pericardial and thoracic fluids are usually of better quality than peritoneal fluid.

Immunity

To date, only humoral immune responses to Bungowannah virus have been studied. During experimental studies, antibody was detected from 12 days post inoculation in weaner pigs challenged intranasally (Finlaison et al. 2012) and from 17 days in fetuses infected by direct inoculation (Finlaison et al. 2010). Postnatally, the production of specific antibody is associated with clearing of the viremia and cessation of viral shedding. In contrast, although the pig fetus is immunocompetent and able to produce detectable antibodies to Bungowannah virus from around 70 days of gestation (Finlaison et al. 2010), the humoral immune response of the fetal piglet was not sufficient to clear the infection prior to birth (Kirkland et al. 2015b). Following suckling, these animals developed high antibody titers that were maintained for at least 2–3 months. It is not known how long this naturally acquired antibody persists postnatally. Maternally derived antibody waned by approximately 2 months of age in persistently infected piglets and uninfected piglets from infected dams.

Prevention and control

There is no specific treatment for PMC or vaccine against Bungowannah virus. As the origin of the virus remains unknown, only general biosecurity measures can be adopted to prevent introduction of the virus into a population. If the virus is detected early in an outbreak, measures can be taken to attempt to reduce the impact of the disease. Evidence of poor postnatal transmission suggests that the most significant spread will occur following the farrowing of affected litters or by persistently infected piglets. In the face of an outbreak, it will be important to maximize exposure of breeding animals prior to mating to reduce the duration of the outbreak and to prevent possible exposure of pregnant animals.

Bungowannah virus eradication from an endemically infected piggery has been achieved through a combination of measures including depopulation, cleaning, disinfection, site biosecurity, and repopulation with previously unexposed animals.

Bovine viral diarrhea and border disease viruses

Relevance

Pigs are susceptible to pestiviruses other than CSFV and Bungowannah virus. Cross-species transmission among artiodactyls has been reported for strains of both BVDV and BDV (Carbrey et al. 1976; Terpstra and Wensvoort 1988).

Infection with either BVDV or BDV can complicate CSFV control or eradication programs. Cross-neutralization tests and tests using monoclonal antibodies (Leforban et al. 1990a; Wensvoort 1989) suggest that BVDV may have been isolated from pigs in the past and misidentified as CSFV by tests based on polyclonal antibodies. Likewise, serum antibodies against BVDV or BDV have the potential to cross-react in assays for the detection of CSFV antibodies. Because of cross-reactions among pestiviruses, it is essential to identify the specific etiologic agent when pestivirus antibodies are detected in CSF eradication programs.

Natural infection of swine with BVDV was first reported in Australia in 1964, but BVDV was not isolated from a naturally infected pig until 1973 (Fernelius et al. 1973). The teratogenic properties of pestiviruses are well established (Terpstra and Wensvoort 1988; Vannier et al. 1988; Wensvoort and Terpstra 1988), and infection of pregnant sows with BVDV or BDV may induce a pathology resembling congenital CSF.

Although natural infection of pigs with BVDV or BDV is relatively uncommon, interspecies transmission may occur in countries where pigs are raised in close contact with ruminants. Disease is most likely to occur when pregnant sows are infected, but may only affect a small number of litters until piglets are born and further transmission occurs. If the source of virus is a contaminated vaccine, the initial impact is likely to be much greater.

Etiology

BVDV and BDV are typical pestivirus species and cannot be differentiated morphologically or structurally from

CSFV (Laude 1979). However, they can be readily differentiated using monoclonal antibodies and molecular assays targeting the viral genome.

Epidemiology

The prevalence of BVDV antibodies in the pig populations of CSFV-free countries (Australia, Ireland, Great Britain, Denmark) has been estimated at 1.6–43.5%, depending on the age of the animals and possibly on the degree of contact with cattle (Jensen 1985). In countries where CSFV is present, the situation with regard to BVDV antibodies seems to be about the same.

Cattle are the most common source of BVDV infection in pigs. In units with dairy farming, one potential source of infection is BVDV-contaminated whey or milk fed to sows (Terpstra and Wensvoort 1988). In some cases, pigs have had contact with cattle recently vaccinated with BVDV (Stewart et al. 1971). In other reports, pigs and cattle were kept in separate lots and buildings, but personnel and equipment moved freely between the different farm units (Carbrey et al. 1976).

The prolonged presence of a persistently infected litter of pigs is the most likely source of BVDV or BDV to susceptible pregnant sows (Terpstra and Wensvoort 1988; Vannier et al. 1988). Persistent BDV infection of piglets occurs when sows are infected during early pregnancy (i.e. fetuses are transplacentally infected) and piglets become immunotolerant and persistently infected (Vannier et al. 1988). The course of the infection is quite similar to that described for BVD infection in pregnant cows (Baker 1987). When a pregnant sow is infected under experimental conditions, the litter may consist of a mixture of virus-positive and antibody-positive piglets. This suggests variability in the time at which individual fetuses became infected (Edwards et al. 1995). Congenitally BDV-infected piglets appear to excrete large amounts of virus, since susceptible young animals kept in contact rapidly seroconvert and produce high antibody titers. Conversely, when piglets are infected after birth, spread of infection to in-contact animals does not occur, suggesting low or perhaps no excretion of virus (Vannier et al. 1988).

Pigs may also become infected through the use of MLV vaccines (CSF or Aujeszky's disease) or other biologicals contaminated with virus (Vannier et al. 1988; Wensvoort and Terpstra 1988). While contaminants could be of either bovine or ovine origin, bovine are far more likely to be involved as most pestiviruses found in bovine serum products are strains of BVDV.

Pathogenesis

BVDV and BDV are pathogenic for fetal pigs, but relatively nonpathogenic for pigs after birth, apart from a slight increase in body temperature and a slight leukopenia and/or thrombocytopenia in some pigs (Makoschey et al. 2002). The ability of BVDV and BDV to establish intrauterine infections in swine is well established (Stewart et al. 1980; Vannier et al. 1988; Wrathall et al. 1978). The degree of clinical disease depends upon the stage of gestation at which the infection occurred. Clinical signs are more severe if sows are infected during the first trimester of pregnancy. The most severe clinical signs and lesions in fetuses or piglets are observed when sows are infected 25–41 days post breeding (Leforban et al. 1990b; Mengeling 1988). Under experimental conditions, piglets infected *in utero* with BVDV or BDV became persistently infected and were immunotolerant. After the disappearance of maternal antibodies, no active humoral response was detected in the majority of piglets. Furthermore, the virus was isolated from piglets and was shed by some, as evidenced by infection in young animals placed in contact.

In some experimental infections of pregnant sows with BDV, the onset of the clinical signs in the piglets was delayed until 13–14 days after birth. The reason for the delayed response is unknown, but colostral antibodies ingested by piglets would presumably block the replication of the virus and/or delay disease in transplacentally infected piglets (Leforban et al. 1990b; Mengeling 1988; Vannier et al. 1988).

The pathogenicity of BVDV or BDV seems to depend on the strain used in the experiment. BDV seems to be more consistently pathogenic for fetuses, whereas variable results are obtained with BVDV viral strains. The Singer strain, adapted to replicate in porcine cells, and BVDV strain 87/6 can infect and cause mortality in porcine fetuses, whereas the NADL strain does not induce clinical disease in piglets (Edwards et al. 1995; Leforban et al. 1990b; Mengeling 1988). Dahle et al. (1993) intranasally inoculated weaned pigs with BVDV strain Osloss/2482, then 4 weeks later challenged with decreasing doses of CSFV. After CSFV challenge, the only clinical sign observed was fever in one animal, although most animals became viremic.

Clinical signs

In the field, infection of pigs with BVDV usually occurs without clinical signs. In some cases, however, natural infection of pig herds with pestiviruses other than CSF has been associated with breeding problems (e.g. poor conception rates, small litters, and a few abortions). Hyperthermia and colic spasms have also been described (Carbrey et al. 1976). In the Netherlands and France, signs compatible with congenital CSF infection were described in piglets born to sows vaccinated 4 months earlier with CSF or Aujeszky's disease (pseudorabies) vaccines contaminated with a ruminant pestivirus

(Vannier et al. 1988; Wensvoort and Terpstra 1988). Clinical signs in piglets included anemia, rough hair coats, growth retardation, wasting, congenital tremors, conjunctivitis, diarrhea, polyarthritis, petechiae in the skin, and blue ear tips (Terpstra and Wensvoort 1988).

Natural infection of sows with BDV has been reported to result in reproductive signs (e.g. repeat breeding and mummified and stillborn pigs at farrowing) (Vannier et al. 1988). A high proportion of piglets from infected sows showed eyelid edema, locomotor disorders, and, occasionally, diarrhea and arthritis. The mortality rate in affected litters at 2 days of age ranged from 30 to 70%.

Experimental inoculation of pregnant sows with BDV field strains at 30–32 days of gestation produced transplacental infection of fetuses and newborn piglets with low body weights and short body lengths (Wrathall et al. 1978). Leforban et al. (1990b) reported an increase in perinatal mortality and eyelid edema, hyperthermia, and anemia in survivors during the second week of life. Slow growth rates, respiratory signs, and diarrhea developed in pigs, some of which died by 2 months of age. Pigs without respiratory and enteric signs survived and had normal growth despite marked snout deformations, including prognathism in one individual. BDV was isolated from blood and organs of all dead piglets, but not from survivors. When 40-day-old specific-pathogen-free (SPF) pigs were placed in contact with BDV transplacentally infected piglets, they did not show clinical signs, but developed high levels of antibody to BDV that was able to completely protect them against challenge with a virulent strain of CSFV.

Lesions

When infected postnatally with BVDV or BDV, no or very mild lesions are observed in pigs. Hyperemia of the small intestine was seen in one pig 11 days after being placed in contact with calves infected with the NADL strain of BVDV (Stewart et al. 1971). A transient leukopenia was detected during the first week following experimental infection of pigs with a pig isolate of BVDV (Carbrey et al. 1976). *In utero* infection of fetuses by transplacental transmission is followed by consistent pathological disorders in fetuses or piglets. In 13 naturally occurring BVDV outbreaks in the Netherlands, chronic gastroenteritis and septicemia with hemorrhages in lymph nodes, epicardium, and kidneys were the most consistent lesions reported. Inflammation of the digestive tract was frequently characterized by catarrh, hypertrophy, or ulceration of the mucosa. Necrotic tonsillitis, icterus, polyserositis, polyarthritis, and atrophy of the thymus were also noted (Terpstra 1987). A porcine BVDV isolate administered to gilts at 42–46 days of gestation produced significant microscopic lesions in the leptomeninges and the choroid plexus of the fetus characterized by collections of lymphocytes, histiocytes, and cellular accumulation in the vascular adventitia and perivascular spaces (Stewart et al. 1980).

In the case of BDV, experimental inoculation of sows on day 34 of gestation produced cerebellar hypoplasia in 9 of 19 live-born piglets, with a small meningocele in one of the 9 (Wrathall et al. 1978). The French BDV isolate Aveyron (Chappuis et al. 1984) inoculated into sows at day 30 of gestation produced lesions in lymphoid tissues in some piglets. Marked hemorrhages in lymph nodes and other lymphoid tissues were found in stillborn fetuses or in piglets that died shortly after birth. Histological examination of lymph nodes, spleen, and tonsil revealed marked subacute inflammatory lesions characterized by accumulations of lymphocytes, plasmacytes, and eosinophilic polymorphonuclear leukocytes, numerous secondary follicles, increased populations of reticulocytes, and lymphoid hypoplasia with pyknosis and karyorrhexis. Thymus, liver, and nervous tissues were normal (Leforban et al. 1990b).

Diagnosis

BVDV or BDV may be isolated using the same methods described for CFSV and from the same tissues submitted for CSFV diagnosis (i.e. tonsils, spleen, kidney, and whole blood collected in heparin or EDTA). However, if BVDV or BDV is isolated from pigs, these viruses grow better and to a higher titer in cells of ruminant origin, and of the homologous species, rather than in porcine cells (Wensvoort et al. 1989). In CSF-free countries, BVDV and BDV must be considered in the differential diagnosis of CSFV, and all CSF suspect cases should be tested for BVDV and BDV.

Pestiviruses have some shared antigens, and serological tests for the detection of antibodies against CSFV may cross-react with antibodies to ruminant pestiviruses. The practical importance of this is that the presence of ruminant pestivirus antibodies in pig sera often causes false-positive reactions in serological surveys for CSFV. This presents problems in CSFV eradication campaigns and in epidemiological surveys for CSFV (Jensen 1985).

Immunity

There is little practical interest in establishing protection by vaccination in pigs against BVDV or BDV. Consequently, there has been little done to study the immune response of pigs to these viruses. Nevertheless, the characteristics of the immune response are considered similar to that induced in pigs by CSFV.

Prevention and control

To prevent BVDV or BDV infection in pigs, it is necessary to avoid direct or indirect contact with cattle or sheep. Natural infection with BVDV often occurs when pigs are fed with cow's milk or bovine offal, and these practices should be avoided.

Inadvertent transmission of these viruses is a risk when live virus vaccines are used because of contamination of media and/or cells used in production of the vaccine. Cells used for multiplication of master seed virus used to prepare vaccine can be contaminated by BVDV or BDV. Indeed, some batches of CSF and Aujeszky's disease vaccines were contaminated by a pestivirus (probably BDV) because secondary lamb kidney cells were used to propagate the vaccine strain virus (Vannier et al. 1988; Wensvoort and Terpstra 1988). Both bovine and non-bovine cell lines can be contaminated with pestiviruses, and all cell cultures need to be monitored carefully for their presence. The primary source of contamination of cells is usually bovine serum added to the nutrient medium. Fetal infection with BVDV is extremely common. As commercial batches of fetal bovine serum usually involve pooling of serum from many calves or fetuses, the likelihood of BVDV contamination is high (Rossi et al. 1980). Hobi virus, one of the novel pestiviruses, has also been detected in some batches of fetal bovine serum (Ståhl et al. 2007) and may also present a possible risk, although nothing is known about its capacity to infect the pig. Therefore, to avoid interspecies transfer of these viruses, the systematic testing and treatment of bovine serum and of biological products used for the preparation of vaccines is strongly recommended.

Atypical porcine pestivirus (APPV)

Relevance

In 2015 a previously unrecognized pestivirus was detected in the United States (Hause et al. 2015). Later studies showed that this virus is also present in Europe (Beer et al. 2017; de Groof et al. 2016; Munoz-Gonzalez et al. 2017; Postel et al. 2016a; Schwarz et al. 2017), China (Zhang et al. 2017), and Brazil (Mosena et al. 2018), appearing to have a global distribution. Field observations and experimental studies suggest that APPV is associated with congenital tremors (Arruda et al. 2016; Schwarz et al. 2017). Its clinical relevance remains to be defined, although present evidence suggests it to be a cause of sporadic disease.

Etiology

APPV has been shown to be genetically most closely related to pestiviruses found in bats and rats (Hause et al. 2015) and to be very distinct from other pestiviruses, including CSFV and the other genetically distant pestivirus Bungowannah virus.

Epidemiology

So far APPV genomic RNA has been detected by PCR in pig samples from multiple countries, including the United States (Hause et al. 2015), Germany (Beer et al. 2017; Postel et al. 2016a), the Netherlands (de Groof et al. 2016), Austria (Schwarz et al. 2017), Spain (Munoz-Gonzalez et al. 2017), China (Zhang et al. 2017), and Brazil (Mosena et al. 2018). Investigations of 1,460 serum samples of healthy pigs from different parts of Europe and Asia demonstrated a geographically wide distribution of APPV (Postel et al. 2017). Considerable genetic variability was detected between strains in the United States, Europe, and Asia (de Groof et al. 2016; Postel et al. 2017).

Transmission of APPV remains unclear. Experimental study suggests that *in utero* infection and transplacental transmission to fetuses can occur (Arruda et al. 2016). Interestingly, APPV has also been detected in preputial swabs and semen of boars (de Groof et al. 2016; Gatto et al. 2017; Schwarz et al. 2017) although the role of semen in the transmission of APPV is unclear.

Little is known about the persistence of APPV in the environment and its susceptibility to disinfectants, but it could be expected to share the features of most other pestiviruses.

Pathogenesis

Presently available information suggests that APPV is only a pathogen of the fetus as a result of transplacental infection. Experimental infection of sows has resulted in the birth of piglets with a neurological disease frequently described as "congenital tremors" (Arruda et al. 2016).

Clinical signs

The only clinical entity with which APPV has been associated is the congenital tremor syndrome observed in newborn piglets. No disease has been observed in weaner aged piglets or sows. Depending on severity, signs consist of intermittent head shaking ranging to continuous trembling of the whole body as a result of myoclonic contractions.

Lesions

No gross changes have been detected in affected piglets. Histologically, lesions are restricted to the central nervous system (CNS) where hypomyelination of the white matter of the spinal cord and brain stem is observed (Schwarz et al. 2017). Virus as detected by rRT-PCR is

widely distributed in most tissues, with higher concentrations in the brain stem, spinal cord, tonsils, mesenteric lymph nodes, and serum (Arruda et al. 2016; de Groof et al. 2016; Schwarz et al. 2017).

Diagnosis

APPV was first detected using "next-generation" nucleic acid sequencing technology. This provided an insight into the virus genome and supported the development of rRT-PCR assays specific for APPV. APPV-related disease can be confirmed by testing of CNS tissue, tonsils, lymph nodes, and serum by rRT-PCR assay (Arruda et al. 2016; de Groof et al. 2016; Schwarz et al. 2017). A strain of APPV has also been isolated (Beer et al. 2017), which should provide for the development of VN test. Both an indirect (Hause et al. 2015) and blocking ELISAs (Schwarz et al. 2017) have been developed using recombinant antigens and may be useful for serological screening of populations.

Immunity

Although little is currently known about the duration of immunity following postnatal infection with APPV, it is expected that natural infection will lead to long-lived, perhaps lifetime immunity in pigs. This hypothesis is supported by the apparent lack of disease and infrequent occurrence of the congenital tremor syndrome, despite the apparent widespread distribution of the virus.

Prevention and control

Until there is knowledge of the epidemiology of APPV and also its clinical significance, the need for prevention or control measures and their nature cannot be determined.

Picornaviruses

Soren Alexandersen, Nick J. Knowles, Graham J. Belsham, Aldo Dekker, Charles Nfon, Zhidong Zhang, and Frank Koenen

Overview

The family *Picornaviridae* is one of five families in the order *Picornavirales*, the others being *Dicistroviridae* and *Iflaviridae* (both infecting invertebrates), *Marnaviridae* (infecting algae), and *Secoviridae* (infecting plants) (Le Gall et al. 2008). There are currently 35 genera in the *Picornaviridae*, eight of which contain viruses that infect pigs: *Aphthovirus*, *Cardiovirus*, *Enterovirus*, *Kobuvirus*, *Pasivirus*, *Sapelovirus*, *Senecavirus*, and *Teschovirus* (Table 40.1; Figure 40.1) (Knowles et al. 2012).

Picornaviruses for which genome sequence data have become available, but which have not yet been assigned to specific taxa, include porcine picornavirus Japan (PPVJ) (Naoi et al. 2016) as well as other picornaviruses of bats, cats, cattle, chickens, dogs, ducks, lemurs, seals, rabbits, rodents, wild birds, and reptiles.

Picornaviruses infect vertebrate hosts and enter host cells using receptor-mediated endocytosis or possibly, for the enteroviruses, by direct entry of RNA across the plasma membrane following changes induced in the virus particle by receptor binding. They replicate in the cytoplasm of infected cells.

Molecular biology

Picornaviruses are small, roughly spherical viruses with a protein shell (capsid) approximately 30 nm in diameter (Ehrenfeld et al. 2010). The capsid contains a single copy of positive-sense RNA approximately 7–10 kb in length with a small virus-encoded polypeptide (VPg) covalently linked to the 5′ terminus (Figure 40.2).

The picornavirus genome includes two untranslated regions (UTRs), one preceding and one following the single open reading frame (ORF) (apart from dicipiviruses that have two ORFs, one encoding the capsid polypeptides and the other the nonstructural polypeptides, which are separated by an intergenic region containing a second internal ribosome entry site (IRES) [see below]).

Various RNA elements in the long (500–1300 nucleotide) 5′ untranslated region (5′ UTR) are involved in controlling virus replication and the initiation of viral protein synthesis and include an IRES. There are five different IRES types (I–V) (Belsham 2009; Sweeney et al. 2012). These differ in their secondary structure and mechanism of action, for example, requirement for cellular factors. IRES type IV is also found in some members of the virus family *Flaviviridae*, such as hepatitis C virus and classical swine fever virus. The 3′ untranslated region (3′ UTR) is usually much shorter (approximately 35–750 nucleotides) and also contains structures involved in virus replication. It is followed by a poly(A) tail.

The ORF is translated into a polyprotein that is usually processed by one or two virus-encoded proteinases. Between two and five primary cleavages take place during translation, while others occur later to produce the various mature proteins.

The leader polypeptide (L) is not present in all genera. For example, there is no leader protein in the enteroviruses, and it is quite diverse among the other picornavirus species. In some, including aphthoviruses and erboviruses, it is a papain-like cysteine proteinase.

The P1 (or P1-2A) capsid precursor includes the three structural proteins (VP0, VP3, and VP1) that form the basic capsid subunit (protomer). Five of these subunits come together to form a pentameric unit and 12 of these can "self-assemble" to form the complete capsid. In about half of the genera, when the RNA is packaged, there is maturation cleavage within VP0 that produces VP4 (located on the inside of the capsid) and VP2.

The P2 region consists of 2A (except when 2A is part of the P1-2A precursor), 2B, and 2C. 2A is highly variable between picornavirus species, not only in primary sequence but also in number and function. In enteroviruses, 2A is a chymotrypsin-like cysteine proteinase

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

[a] SVDV-1 is a genetic sublineage of human coxsackievirus B5.
[b] SVDV-2 is a genetic sublineage of human coxsackievirus B4.
[c] Enteroviruses G5 and G7 have only been isolated from sheep.
[d] Formerly *Porcine enterovirus A*.

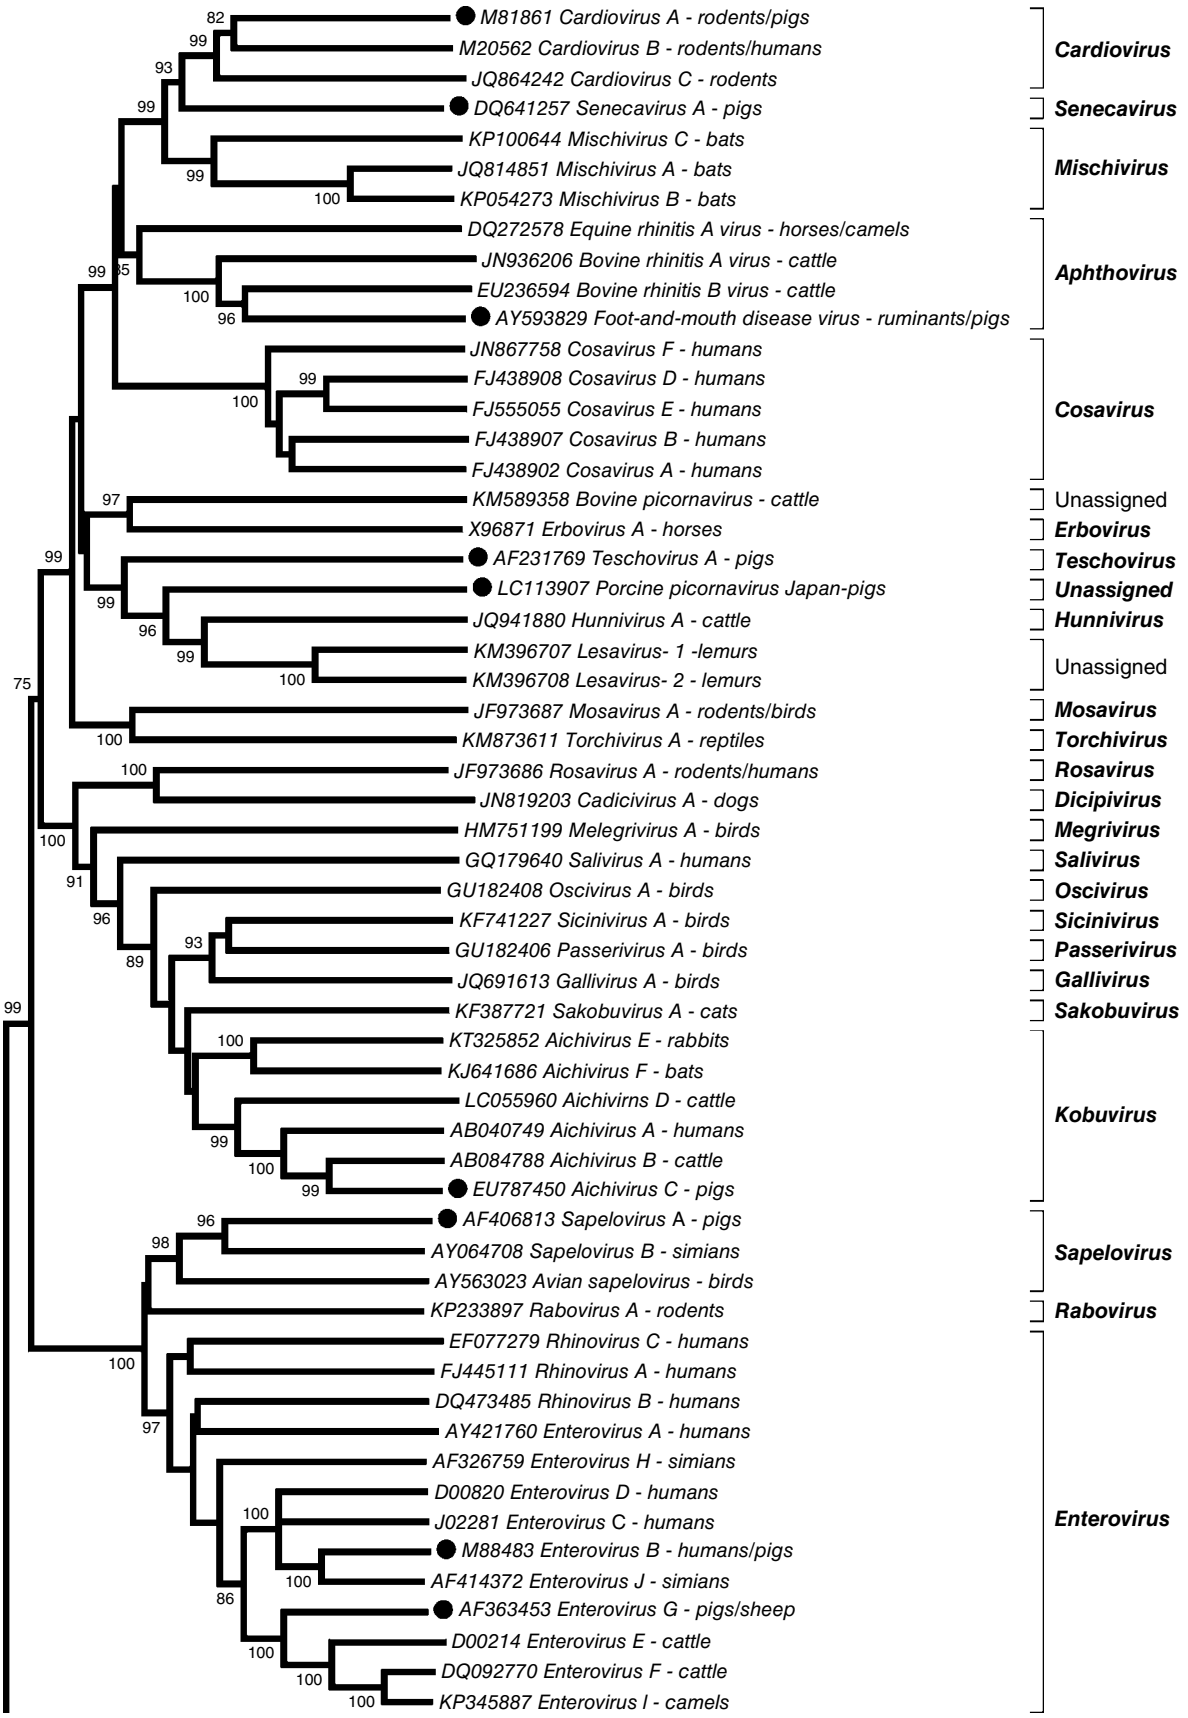

Figure 40.1 Midpoint-rooted neighbor-joining tree showing the relationships between the polymerase sequences of 86 picornaviruses. The tree was constructed with MEGA 7 (Kumar et al. 2016) using a percentage amino acid matrix. Species, rather than virus, names were used to identify each sequence, and each genus is bracketed. Picornaviruses that infect pigs are indicated by black circles.

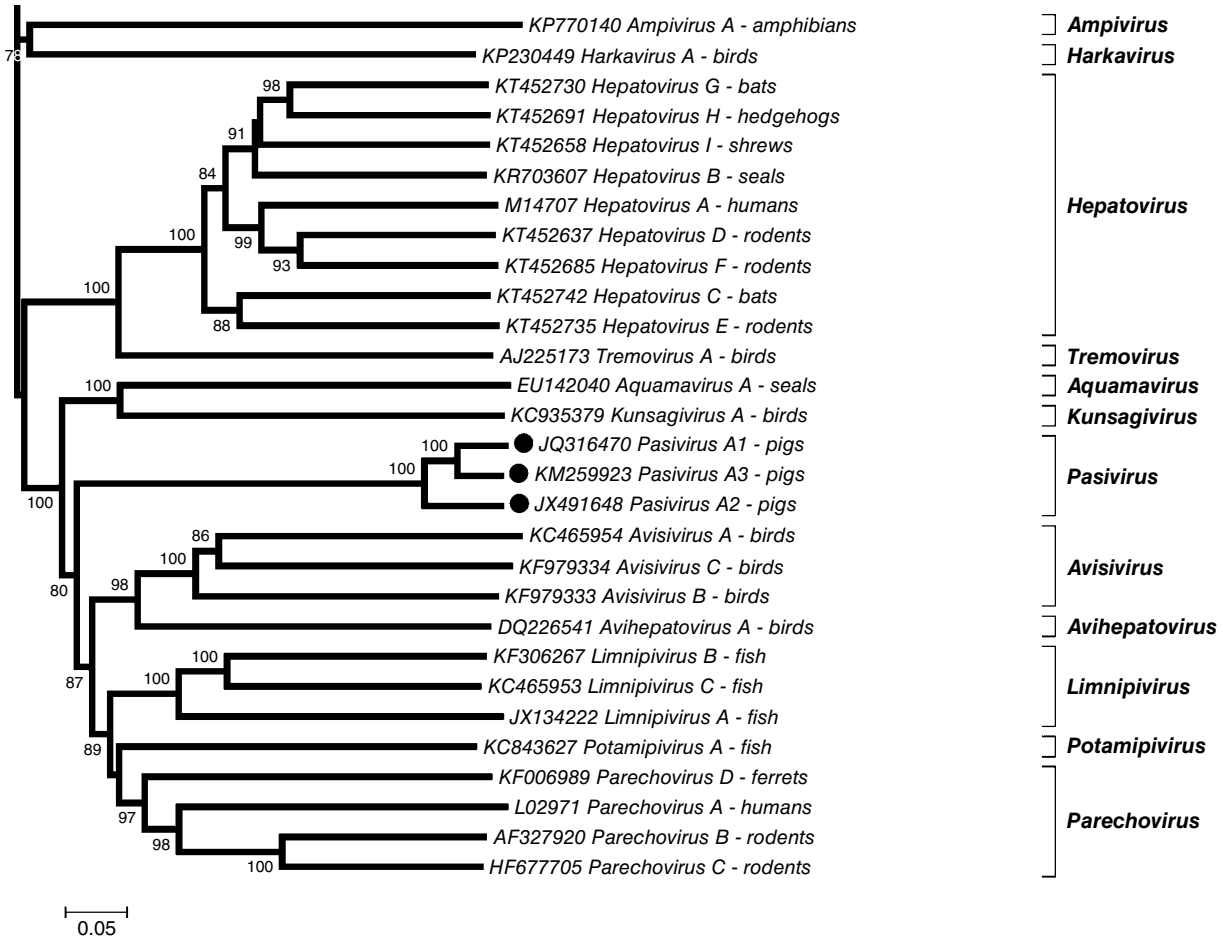

Figure 40.1 (Cont'd)

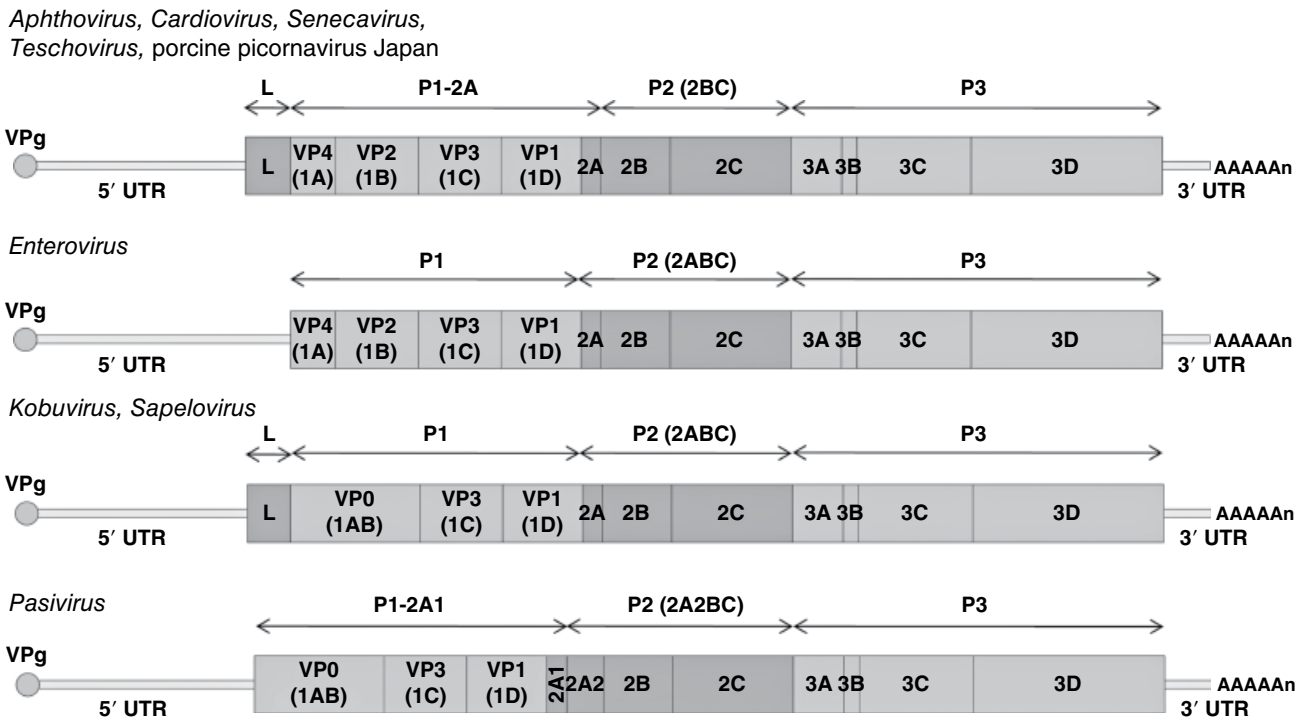

Figure 40.2 Alternative picornavirus genome organizations showing the untranslated regions, polyprotein coding region, and the location of the mature polypeptides. The presence and form of the L and 2A proteins are quite variable between genera. Foot-and-mouth disease virus differs from other aphthoviruses in having three, in tandem, 3B regions.

involved in host cell translation shutoff. In aphthoviruses, erboviruses, cardioviruses, pasiviruses, senecaviruses, and teschoviruses, it includes a short polypeptide sequence believed to mediate protein translation interruption of 2A and 2B at a specific NPG↓P motif. Therefore, in these viruses, the capsid precursor is P1-2A. In pasiviruses a second 2A of unknown function appears to be present. In kobuviruses, parechoviruses, and tremoviruses, the 2A protein belongs to the H-rev107 family of proteins. In hepatoviruses, 2A is involved in capsid assembly. In cardioviruses, the 2A protein also disrupts nucleocytoplasmic trafficking by nonproteolytic mechanisms that may contribute to the host cell translation shutoff. In addition, in some picornaviruses, multiple 2A motifs (cardioviruses, Ljungan virus) or proteins (aquamaviruses, avihepatoviruses, avisiviruses, kunsagiviruses, limnipiviruses, megriviruses and potamipiviruses) may be present. 2B, in multimeric form, can act as a viroporin. 2C belongs to the SF3 helicase family of AAA+ ATPases and has some role in RNA replication but may also contribute to the process of capsid assembly (at least for enteroviruses; see Wang et al. 2012). The FMDV 2B and 2C proteins together (or as 2BC) can also inhibit transport of proteins within the cell to the cell surface (Moffat et al. 2007); this may block the recognition of virus-infected cells by the host immune system.

The P3 region is the precursor for 3A, 3B, 3C, and 3D. 3A is a membrane-bound protein involved in viral RNA replication. 3B is a small genome-linked protein (VPg) that acts as a primer for RNA synthesis (between one and three copies are present in different picornaviruses). 3C is a chymotrypsin-like cysteine proteinase that performs the majority of the cleavages between the viral proteins. 3D is the RNA-dependent RNA polymerase. Since picornaviruses produce only 11–15 mature proteins, most are probably multifunctional. In addition, some of the processing intermediates, for example, 3CD, also have distinct functional roles.

Within species *Enterovirus G*, examples of EV-G1, EV-G2, and EV-G17 have been found that contain a porcine torovirus-like papain-like cysteine protease (PLCP) coding region inserted between 2C and 3A (Conceição-Neto et al. 2017; Knutson et al. 2017; Shang et al. 2017; Tsuchiaka et al. 2018). The inserted region maintains 3C-like cleavage sites, which would result in the production of 2C, 3A, and the PLCP polypeptides. This is unique among picornaviruses, and the PLCP protein presumably fulfills an important function. Interestingly, the PLCP regions EV-G1 and EV-G17 only share 87% nucleotide and 86% amino acid (aa) identities.

Diseases of picornaviruses

The variety of diseases caused by picornaviruses ranges from acute and sometimes fatal paralysis (e.g. poliomyelitis in humans) to mild respiratory disease (e.g. rhinoviruses in humans and equine rhinitis viruses in horses) and to inapparent infections in many hosts. The principal picornaviral diseases of pigs are acute vesicular disease caused by foot-and-mouth disease virus (FMDV), swine vesicular disease virus (SVDV), and Seneca Valley virus (SVV) (by some incorrectly referred to as Senecavirus A although this is the name of the species and not the virus); acute fatal myocarditis caused by encephalomyocarditis virus (EMCV) and FMDV; reproductive failure caused by EMCV; and teschovirus encephalomyelitis caused by porcine teschovirus (PTV).

It has been recognized in the last few years that some recently characterized picornaviruses are infectious for swine, including SVV and porcine kobuvirus (PKV). Nucleotide sequence analyses (Krumbholz et al. 2002; Zell et al. 2001) showed that the viruses initially described as "porcine enteroviruses" (PEVs) actually included a variety of different types of picornaviruses, many of which are teschoviruses (PEV-1–7 and 11–13). The group also includes 20 true enteroviruses (EV-G1 to EV-G20) belonging to the species *Enterovirus G*; 17 of them infect pigs (Table 40.1). PEV-8, formerly classified in the species *Porcine enterovirus A*, now belongs to genus *Sapelovirus* (species *Sapelovirus A*) and is known as porcine sapelovirus (PSV). SVDV-1 and SVDV-2 are also true enteroviruses, but are not included among the PEVs because they are closely related to the human coxsackievirus B5 and coxsackievirus B4, respectively.

Diagnostic reverse transcription polymerase chain reaction (RT-PCR) assays that distinguish between the different types of enteric porcine picornaviruses have been described (Krumbholz et al. 2003; Palmquist et al. 2002). An unexpected cross-reaction of specific primers designed to recognize the 5′ UTR of the teschoviruses with PSV was observed by Palmquist et al. (2002), but the products detected were of a different size. It has been shown that the teschoviruses and PSV all have a shared type of IRES structure within the 5′ UTR (Chard et al. 2006) and have some highly conserved motifs that are presumably responsible for the cross-recognition.

The clinical importance of PSV, PKV, pasivirus, PEV, and PPVJ is not well characterized, but there is some evidence that they are pathogenic for pigs, as discussed later in the chapter.

Foot-and-mouth disease virus

Relevance

Foot-and-mouth disease (FMD) is a severe, clinically acute vesicular disease of cloven-hoofed animals, including domesticated and wild swine and ruminants (Alexandersen and Mowat 2005; Thomson 1994). Because of its potential for rapid and extensive spread

within and between countries and its severe economic consequences, including its effect on trade (Leforban and Gerbier 2002), FMD is on the World Organization for Animal Health (OIE) list of diseases.

FMD has been known in Europe for many centuries and was probably one of the diseases described by the Italian physician Hieronymi Fracastorii in his work *De Contagione et Contagiosis Morbis et Eorum Curatione* in 1546 (English translation in Wright 1930). FMD spread from Europe to the Americas in the 1860s, initially to Argentina, with subsequent spread from there (Olascoaga 1984). FMDV remains endemic to many areas of the world, exceptions including North, Central, and most of South America, Australia, New Zealand, and Europe.

The scientific study of the disease and of the virus began at the end of the nineteenth century when Loeffler and Frosch demonstrated that a filterable agent could cause FMD (Brown 2003). The existence of FMDV serotypes was discovered in the 1920s (serotypes O, A, and C), followed by the recognition of Southern African territories (SAT) 1, 2, and 3 serotypes in the 1940s and serotype Asia 1 in the 1950s.

In 1947, Frenkel showed that large amounts of FMDV could be produced in cattle tongue epithelium harvested at slaughter. This discovery formed the basis of the vaccination programs initiated in Europe in the 1950s. These programs intensified in the 1960s and 1970s when continuous cell cultures made it possible to produce the large amounts of FMDV needed to produce many million doses of vaccine per year (Brown 2003; Sutmoller et al. 2003). Vaccination programs primarily focused on cattle, except when particularly aggressive strains of serotype C, and to a lesser extent serotype O, made it necessary to vaccinate swine, as occurred in the 1960s (Sutmoller et al. 2003).

Thousands of outbreaks of FMD occurred in Europe in the twentieth century, with larger epidemics every 5–10 years (Leforban and Gerbier 2002). This situation continued until 1970–1973, after which the situation improved significantly due to the availability of high-quality vaccines. FMD was eradicated from the EU, and, in 1991, prophylactic vaccination was stopped.

In North America, FMD was last reported in 1929 in the United States, in 1952 in Canada, and in 1954 in Mexico. Stamping out was used to eradicate the infection in the United States and Canada, while a combination of vaccination and stamping out was used in Mexico (Sutmoller et al. 2003). Due to significant vaccination efforts, especially under the Hemispheric Program for the Eradication of FMD (PHEFA), FMD has been controlled and/or eradicated in most countries in South America (Clavijo et al. 2017; Sutmoller et al. 2003).

Etiology

FMDV, a member of genus *Aphthovirus* in the family *Picornaviridae* (Belsham 1993), is a non-enveloped, icosahedral virus, 26–30 nm in diameter, containing a single positive-sense RNA approximately 8,300 nucleotides in length that includes the 5′ UTR, a large polyprotein coding region, and the 3′ UTR. The complete viral capsid consists of 60 copies of each of the four structural proteins (VP1–4), with many critical determinants for infection and immunity inherent in the VP1 protein. The structural proteins VP1–3 are exposed on the surface of the virus, while VP4 is located internally. FMDV comprises seven different serotypes: A, O, C, SAT1, SAT2, SAT3, and Asia 1. Notably, no FMDV serotype C has been reported since it was last detected in Kenya and Brazil in 2004 (Sangula et al. 2011).

FMDV can be propagated in continuous cell cultures, such as baby hamster kidney (BHK) cells (Mowat and Chapman 1962), a continuous porcine kidney cell line constitutively expressing bovine αVβ6 integrin (LFBKαVβ6) (LaRocco et al. 2013, 2015), fetal goat tongue cells ZZ-R127 (Brehm et al. 2009), and IB-RS-2 pig kidney cells, as well as porcine, bovine, ovine, and caprine primary cells. Kidney cells or primary bovine thyroid (BTY) cells are particularly susceptible to FMDV infection (Alexandersen et al. 2003c; Snowdon 1966). Field samples are most successfully cultured in porcine or ruminant cells, depending on the species from which the sample is derived. Thus, the usual diagnostic procedure for swine samples is to inoculate both swine and ruminant cell cultures, while samples from ruminants may either follow the same procedure or only be inoculated onto ruminant cells. FMDV can also be grown in unweaned mice (Skinner 1951).

Public health

Although historical sources report the occurrence of FMD in humans, the evidence indicates that FMDV is not zoonotic and is not a public health concern. In the vast majority of human cases, the appearance of blisters or vesicular lesions was due to other agents, including viruses such as the human enteroviruses in the *Picornaviridae* family that cause "hand, foot, and mouth disease" in humans. There have also been reports of mild clinical signs in humans after the ingestion of untreated milk or after close contact with acutely infected animals.

Proof of causality requires the isolation and identification of the agent, its successful transmission to a known susceptible species, and subsequently serological evidence in the infected individual. Most of the reports of FMD in people lack this evidence and probably did not involve FMDV. The one case in which FMDV was confirmed (Armstrong et al. 1967) involved a man that lived

on an FMD-affected farm in the United Kingdom in 1966 and consumed milk from a cow that later showed signs of FMD. Vesicular lesions developed in his mouth, on his hands, and between his toes, and FMDV serotype O was isolated. His serum, collected 30 days after infection, had high serotype O antibody titers. Thus, there was evidence that this man had been infected with FMDV. In contrast, in the UK 2001 FMD epidemic, in which 2030 outbreaks occurred among livestock, none of the 15 human suspect cases were positive for FMDV by RT-PCR (Turbitt 2001). Thus, the infection of humans with FMDV cannot be totally excluded, but it is extremely rare and in the one documented case it had only mild and transient consequences (Bauer 1997; Donaldson and Knowles 2001; Wright et al. 2010).

It follows that human infection does not have any significant role in the epidemiology of FMDV. However, people may play a significant role in passive transport of the virus from infected animals or contaminated surfaces to susceptible animals. Humans may even passively carry the virus in their respiratory tract for a day or more (Sellers et al. 1970; Sellers et al. 1971). Thus, the role of people in FMDV transmission is an important consideration in control programs.

Epidemiology

Geographic distribution

FMDV infection is endemic in large areas of Africa (mainly the SAT serotypes, but also serotypes O and A), Asia, and the Middle East (serotypes O, A, and Asia 1). Serotypes O and A were endemic in South America. However, with the exception of Venezuela and Colombia, no FMD outbreaks have been reported in the region since 2012. The last reported outbreaks in Venezuela and Colombia were in 2013 and 2017, respectively, and were caused by serotype O. Serotype C seems to have disappeared. FMD control/eradication in South America has been the result of the considerable effort expended on vaccination programs in the continent, leading to countries or regions that have achieved the official OIE status "Free of FMD" with or without vaccination.

The virus has shown an extraordinary ability to cross international boundaries and cause epidemics in previously free areas, as illustrated by the 2001 epidemic in the United Kingdom and continental Europe, as well as the outbreaks in the year 2000 in South Africa, Japan, and South Korea (Knowles et al. 2001). It has been estimated that the direct cost of the UK epidemic in 2001 was approximately $5 billion US dollars (USD) and the indirect costs from the combined losses of agricultural exports and tourist trade an additional $10 billion USD (Alexandersen et al. 2003c).

Introductions into FMDV-free countries after 2001 included Japan, with a high number of outbreaks of serotype O in 2010, and South Korea, which was able to control the 2000 and 2002 outbreaks, but experienced outbreaks of FMD in 2010 and 2014–2016. More significantly, both serotype A and serotype O appeared in South Korea within a period of a few months. Taiwan experienced an incursion of a porcinophilic strain of serotype O in 1997. Despite a massive vaccination effort and hopes of stopping vaccination in 2009, Taiwan is still not free of FMDV. Two outbreaks due to serotypes Asia 1 and O occurred in previously FMD-free Russia in 2016. These examples show that unless global eradication is achieved, FMDV will continue to spread and countries will need to be prepared.

Susceptible species

With minor exceptions, FMDV affects members of the order Artiodactyla (cloven-hoofed animals), including domestic and wild ruminants and pigs (Thomson 1994). When considering the hosts of FMDV, it is important to distinguish between species that play a significant role in the epidemiology of the disease and those that do not. The latter category would include species that only play a role under certain conditions or are only susceptible to FMDV under experimental conditions. Because they are susceptible to FMDV, these species cannot be excluded as epidemiological risks, but under field conditions, they appear to be of little or no importance (Alexandersen and Mowat 2005).

The species of greatest significance in the field include cattle, pigs, small ruminants (sheep and goats), and the water buffalo, particularly in Asia and South America. The African buffalo (*Syncerus caffer*) plays an important role as the natural maintenance host of the SAT serotypes in Africa, but other wildlife such as impala, kudu, antelopes, mountain gazelle, wild boar, and so on may also be involved in the natural epidemiology of FMDV (Thomson et al. 2003).

Species that may present some level of risk or may contribute to the transmission of virus under certain conditions include the North American bison, elk, deer, llamas, alpacas, and Bactrian camels, but not dromedary camels (Alexandersen and Mowat 2005; Alexandersen et al. 2008; Larska et al. 2008; Rhyan et al. 2008), as well as other animals of the order Artiodactyla. Interestingly, the Indian elephant, but not the African elephant, is in this category (Bengis et al. 1984; Hedger 1972; Hedger and Brooksby 1976; Howell et al. 1973; Piragino 1970). Although these species do not appear to play an important role in the wild, they may present a risk if they come into close contact with livestock, for example, when kept in zoos or under crowded conditions, such as deer farms.

A variety of other species may be infected with FMDV, but not routinely involved in the epidemiology of FMDV. However, all animals, even highly resistant animals, such

as horses and carnivores, can serve as mechanical vectors if they become contaminated with the virus and subsequently come in close contact with susceptible livestock.

The susceptibility of small mammals to infection has been extensively researched (reviewed in Alexandersen and Mowat (2005)). In brief, the coypu, water vole, mole, and the brown rat are susceptible to experimental FMDV infection, but, like other small rodents, for example, mice, are unlikely to play a role in the epidemiology of FMD because FMDV infection is usually rapidly fatal in these species. Conversely, rats appear to survive experimental infection and could migrate considerable distances. For this reason, rodent control is considered an important component of efficient FMDV outbreak control. All the same, there is nothing to suggest that rodents could maintain the disease or cause recurrence of FMDV after it is eradicated from domestic livestock.

FMDV infection in wild Australian species was mild, and clinical signs were rare, although viremia was detected and some of the animals developed antibodies. In contrast, the tree kangaroo developed tongue lesions (Snowdon 1968), and lesions were also observed in a kangaroo in a zoo in India (Bhattacharya et al. 2003). However, what role Australian wildlife species might play if FMDV were introduced into the region cannot be determined experimentally because many species that are susceptible under experimental conditions play little or no epidemiological role under field conditions.

Other species shown to be susceptible to FMDV under experimental conditions include mice, guinea pigs, rabbits, cats, dogs, mink, monkeys, snakes, birds, chickens, and embryonated eggs (Cottral and Bachrach 1968; Hyslop 1970; Skinner 1954). Interpretation of these studies must be done in the context of the experimental design. For example, in mice, susceptibility was highly dependent on age (only very young mice being highly susceptible) and the genotype of the strain of mice (Skinner 1951, 1953). Moreover, the virus had to be directly injected into the animal. Inoculation of mice did not produce vesicles, but produced infection and inflammation of the skeletal muscles (Platt 1956) or, in older mice, the pancreas (Platt 1959). Infection of the other species listed above (Henderson 1949) required multiple passage of the virus to adapt the virus to the host. Consequently, infection of these species is possible, but they are not likely to play a role in the field because infection required forced passage of high FMDV doses, leading to virus adaptation to the new vertebrate species. Often, the virus was then less fit for the original host.

Hedgehogs have long been given a special status in regard to FMDV. This is because the hedgehog is highly susceptible to experimental infection, can easily transmit the infection to other hedgehogs or livestock, and appears to excrete the virus in respiratory exhalations when infected. Although there is a report describing lesions and isolation of FMDV from hedgehogs under field conditions (McLauchlan and Henderson 1947), hedgehogs actually appear to play no role in the epidemiology of FMD. Nevertheless, during an epidemic it may be wise to exclude the access of hedgehogs to susceptible livestock.

Transmission

Under field conditions, pigs usually become infected with FMDV by direct or indirect contact with infected animals, through contaminated fomites, and, occasionally, via consumption of FMDV-contaminated products, for example, waste food. When animals are in close proximity, the movement of FMDV in aerosols and secretions from infected animals to the respiratory tract of recipient animals is probably the most common form of transmission. Intact skin provides good protection against FMDV, but abrasions or cuts in the skin permit transmission by physical contact with excretions or secretions containing infectious virus. Such skin lesions are not uncommon in swine kept on concrete floors or as a result of aggressive interactions between animals.

Transmission of virus may occur indirectly via contact with FMDV-contaminated personnel, vehicles, products, and so forth. Husbandry or disease control activities (e.g. physical handling of animals, tail or tooth clipping, vaccination, clinical examination, or collecting blood samples) increase the risk of indirect spread of the virus. Transmission has resulted from the use of contaminated instruments, medications, and FMD vaccines containing live virus before optimal inactivants were used (Beck and Strohmaier 1987).

Our understanding of the process of FMDV transmission comes primarily from experimental studies attempting to simulate natural exposure by direct or indirect contact, contaminated products or fomites, and virus aerosols. The infective dose for different routes can be calculated in such studies, but the estimates are invariably bounded by the constraints and practical considerations of performing FMDV studies under appropriate biosecurity measures (Alexandersen et al. 2003c).

Intradermal or subdermal injection of virus into the tongue, coronary bands, and heel bulbs, or application of a suspension of virus to damaged (scarified) skin, targets the highly susceptible epithelial regions (Alexandersen et al. 2003c) and simulates natural infection through damaged skin. The infectious dose by this route may be $\leq 1 \times 10^2$ tissue culture 50% infective doses ($TCID_{50}$). By comparison, a single infected animal may excrete 1×10^{10} $TCID_{50}$ or more per day at the peak of excretion, most of it in vesicular fluid, saliva, nasal fluid, and other excretions (Alexandersen et al. 2003c). Direct entry of the virus into the circulatory system by intravenous inoculation also results in infection but appears to be less

efficient and more variable than the routes targeting epithelia. Intramuscular inoculation is relatively inefficient and requires a dose of $\geq 1 \times 10^4$ $TCID_{50}$ (Burrows et al. 1981; Donaldson et al. 1984).

Several somewhat recent outbreaks of FMD have been linked to virus in contaminated human food waste subsequently fed to animals. For example, the South Africa 2000 and UK 2001 epidemics probably involved feeding unheated food waste to pigs (Alexandersen et al. 2003a; Knowles et al. 2001). The estimated infectious dose by oral exposure for pigs and ruminants is 1×10^4–10^5 and 1×10^5–10^6 $TCID_{50}$, respectively (Sellers 1971). It is conceivable that abrasions or damage to the epithelium of the buccal cavity by bone or other objects commonly present in waste food could reduce the dose required to achieve infection by the oral route.

Transmission via aerosols

Airborne transmission of FMDV is a dynamic, complex process affected by the species of animals (usually swine as the source and cattle or sheep as the recipient species), the number of animals, topography of the area, and the meteorological conditions. Airborne transmission of FMDV over significant distances becomes a significant risk when large numbers of pigs are infected because they respire large quantities of virus. Pigs aerosolize up to 1×10^6 $TCID_{50}$ per pig per day for most strains of FMDV, although up to $1 \times 10^{8.6}$ $TCID_{50}$ per pig per day has been recorded. In contrast, ruminants aerosolize less virus in their respirations (1×10^4–10^5 $TCID_{50}$ per day), but are highly susceptible to infection by inhalation. Ruminants can be infected experimentally by airborne exposure to low concentrations of FMDV (1×10^1 $TCID_{50}$), whereas pigs require airborne exposures of more than 1×10^3 $TCID_{50}$, and infection only occurs if the virus is delivered at a high concentration (Alexandersen and Donaldson 2002; Alexandersen et al. 2003b,c; Donaldson 1986; Donaldson et al. 1987, 1970). Therefore, in situations where airborne spread of FMDV occurs, it is most often from infected pigs to cattle and sheep located downwind.

Long-distance airborne spread requires atmospheric conditions that maintain the infectivity of the virus and keep the aerosol plume ("virus cloud") intact. For example, FMDV infectivity is dependent on relative humidity above 55%. Sunlight has little or no direct effect on infectivity. Stable atmospheric conditions with continuous steady or slight wind, cloud cover, and a level topography, for example, large tracts of water, tend to preserve the virus plume and increase the likelihood of airborne transmission (Alexandersen et al. 2003c; Donaldson et al. 2001; Gloster and Alexandersen 2004; Gloster et al. 2005). In contrast, air turbulence from wind, topography, trees, or buildings disperses the virus and reduces the probability of transmission.

Models to predict airborne spread of FMDV were used successfully in the United Kingdom in 1981 and 2001 and in Italy in 1993 (Alexandersen et al. 2003a; Donaldson et al. 1982; Gloster et al. 2003; Maragon et al. 1994). Current models suggest that most isolates of FMDV are unlikely to spread more than 20 km via aerosol, even under a "worst-case" scenario, that is, meteorological conditions optimal for maintaining the virus plume, the virus originating from a large population of infected pigs, and cattle located downwind of the pigs. However, specific factors can significantly affect the potential distance of airborne transmission. For example, (1) some strains of FMDV, in particular C Noville, which appears to be excreted at very high levels, may have the potential for longer spread under some conditions. (2) If the source farm contains large numbers of infected cattle or sheep excreting maximal levels of FMDV rather than pigs, the predicted distance of airborne spread would be less than 2 km (Donaldson et al. 2001). (3) Because pigs are more resistant to airborne FMDV, spread to pigs is only likely to occur at distances of 200 m or less (Alexandersen et al. 2003b,c; Donaldson et al. 2001). Thus, distances for aerosol transmission should be considered estimates, not absolutes, as some of the important parameters in the transmission model are variable or not well understood.

Aerosols are also created by splashes from infected milk and urine, by the use of high-pressure hoses to clean FMDV-contaminated animal housing and equipment, and by the process of applying infected slurry on pastures. However, the infectivity of such aerosols is probably much lower than that of aerosols exhaled by infected animals.

Duration and routes of shedding

All secretions and excretions from infected animals contain infectious virus, and some contain significant titers before the development of clinical signs. Thus, saliva, nasal and lachrymal fluid, milk, and respiratory exhalations may contain virus during the prodromal period. Urine and feces also contain virus, but to a lesser extent. It appears that feces contain only small amounts of virus (Parker 1971), but are likely to be contaminated further by desquamated lesion material, vesicular fluid, and saliva. Since preputial lesions are sometimes present, it is possible that these are the source of infectious FMDV in urine. In sheep, virus could be detected in respiratory exhalations 1–2 days before the appearance of clinical signs (Alexandersen et al. 2002b; Sellers and Parker 1969). In contrast, the peak of airborne viral excretion in cattle and pigs occurred after early generalized lesions had developed (Alexandersen et al. 2003b,c). Virus is also excreted in milk and semen (Burrows 1968; McVicar et al. 1977) from shortly before clinical signs appear and through the clinical phase, in a pattern that largely mirrors the profile of viremia. Large amounts of virus are excreted

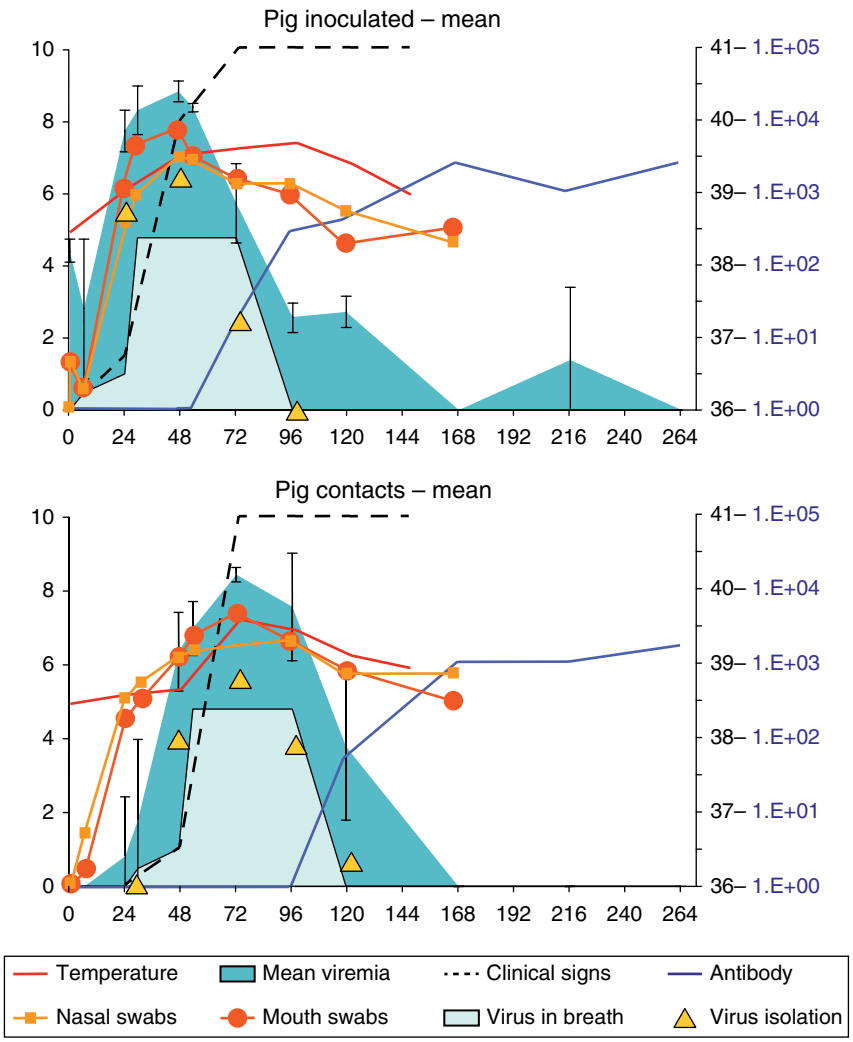

Figure 40.3 Graphs showing the time course of infection in pigs inoculated with FMDV O UKG 2001 virus (top) or kept in contact with such pigs (bottom). Time on the x-axes is given in hours. The mean levels of FMDV RNA (log_{10} genomes per milliliter) in serum samples (indicated as mean viremia) and in mouth and nasal swabs are shown together with the development of clinical signs (score of 0–6 scaled to fit on the 0–10 axis) on the left y-axes and the log_{10} ELISA antibody titer and the body temperature (°C) on the right. Virus in breath is given in log_{10} $TCID_{50}$/h, and the slopes are predicted, as only levels above approximately 2 log_{10} $TCID_{50}$/h can be measured with the methods used. Selected data on the concentration of infectious virus in serum samples, determined by virus titration in cell culture, are shown in addition. *Source:* Alexandersen et al. (2003b). Reproduced with permission from Elsevier.

in vesicular fluid, in desquamated vesicular epithelium, and in saliva (Hyslop 1965; Scott et al. 1966).

The overall pattern of viral excretion for pigs is illustrated in Figure 40.3. Airborne viral excretion coincided with the appearance of vesicular lesions and occurred within the viremic phase. Viral RNA was recovered in nasal swabs from inoculated animals soon after they developed viremia and probably reflected early production and excretion of virus. The detection of infectivity and viral RNA (Alexandersen et al. 2003b) in nasal swabs from contact animals up to 3 days before they showed signs of infection, as well as in animals after the viremic phase, probably represented background environmental virus that had been inhaled and trapped in the respiratory tract. The pattern of excretion by pigs is similar to that in cattle, but the amounts of virus and viral RNA recovered in the blood and breath are higher in pigs (Alexandersen et al. 2001, 2003b).

A sharp decline in viral excretion and load occurs around days 4–5 of clinical disease, when a significant antibody titer can be detected. However, although all secretions and excretions (other than oropharyngeal fluid in ruminants) are free of detectable infectivity at 10–14 days post infection, infectious virus already excreted during the preclinical and acute clinical phases is stable in the environment for weeks. Although tissues are also usually free from infectious virus by this time after infection, low levels of viral RNA may be found in lymph nodes and tonsils up to 4 weeks after infection (Stenfeldt et al. 2016; Zhang and Bashiruddin 2009).

Persistence in the animal

Some ruminant species exposed to FMDV become carriers (Sutmoller and Gaggero 1965; Van Bekkum et al. 1959), irrespective of whether they are fully susceptible or immune as a result of vaccination or recovery from previous infection. The percentage of ruminants that become carriers under experimental conditions is variable, but averages around 50%. The virus titer in oropharyngeal samples from carriers is usually low and declines over time. The maximum reported duration of the carrier state in ruminants is species dependent:

cattle, 3.5 years; sheep, 9 months; goats, 4 months; African buffalo, 5 years; and water buffalo, 2 months.

In contrast, pigs do not become carriers of FMDV and do not harbor the infectious virus for more than 28 days. FMDV has been found in relatively high concentrations in soft palate, tonsil, and pharynx in early infection in pigs infected by contact exposure (Alexandersen et al. 2001; Oleksiewicz et al. 2001), but there was no detectable virus and only a low residual level of viral RNA in lymph nodes and tonsils by 3–4 weeks after infection (Stenfeldt et al. 2016; Zhang and Bashiruddin 2009). Why FMDV persists in the pharyngeal region of ruminants, but not of pigs, is unknown.

Persistence in the environment

Quantitative data on the persistence of FMDV in the environment is sparse (Cottral 1969; Donaldson 1997; Sanson 1994), and results are not amenable to direct comparison because of differences in experimental design, procedures, and analyses. Typically, the kinetic curve for the decay of FMDV infectivity is biphasic: an initial steep decay curve followed by a prolonged, shallow tail. Residual virus may be remarkably resistant, especially in the presence of high concentrations of organic material.

FMDV can remain infectious in the environment for weeks, and, for any point in time, the relevant question is whether there is sufficient residual infectivity in the material or environment to initiate infection in an exposed animal. The duration of virus infectivity in the environment will depend on the matrix, the initial concentration of the virus, and the ambient conditions, for example, relative humidity, temperature, pH, and so on.

There are isolated reports of the persistence of infectious FMDV for long periods, for example, on hay and straw for at least 20 weeks and in fecal slurry for 6 months in winter (Hyslop 1970; Kindyakov 1938). More typical are reports of infectious FMDV for up to 4 weeks on cow's hair at 18–20 °C (64–68 °F), up to 14 days in dry feces, up to 39 days in urine, 3 days on soil in summer, and up to 28 days in autumn.

Most FMDV strains are only stable at lower temperatures and at pH 7–8, becoming increasingly labile at pH values outside that range (Bachrach et al. 1957; Bachrach 1968). The acidity produced in carcass meat during rigor mortis in cattle will inactivate the virus, but such acidity is variable in pig meat. Furthermore, the pH in the bone marrow, lymph nodes, certain organs, and offal does not decline during rigor mortis. Therefore, virus can be found in such material (especially if refrigerated or frozen) for a long time and may cause new outbreaks if fed to livestock as unheated waste food (Donaldson 1987).

Inactivation of virus by sunlight is indirect and occurs mainly through the effects of drying and temperature (Donaldson 1987; Donaldson and Alexandersen 2003). Drying will inactivate most, but not all, virus; hence aerosolized virus is stable at relative humidity above 55–60%. The drying of fluids or organic material containing the virus will also inactivate a large proportion of the virus, but remaining infectious virus may be more stable after drying, thereby creating a "tail" of infectivity.

Thus, the time that infectious virus will remain in the environment is difficult to predict, and restocking after an outbreak has to be done with care and only after thorough disinfection of the premises. Additional information on the stability of infectious FMDV is available elsewhere (Bachrach 1968; Bøtner and Belsham 2012; Cottral 1969; Donaldson 1987; McColl et al. 1995).

Susceptibility to disinfectants

FMDV is resistant to detergents and organic solvents, such as ether and chloroform, but can be inactivated by appropriate disinfectants and heat (Brown et al. 1963; Cunliffe et al. 1979; Dekker 1998; Fellowes 1960; Hole et al. 2017; Sellers 1968). Disinfectants that are either acidic or alkaline are highly effective, in particular alkaline disinfectants such as sodium hydroxide and sodium carbonate that also disperse organic material. The dispersing effect can be further improved by adding a small amount of detergent (not in itself an effective disinfectant of FMDV) to further increase penetration of the disinfectant and the solubilization of organic material present. Oxidizing disinfectants such as Accelerated Hydrogen Peroxide® (AHP®), sodium hypochlorite (bleach), Virkon™ S, and aldehydes, such as formaldehyde and glutaraldehyde, can be effective when applied at the correct dose and given sufficient time to work.

Pathogenesis

The pharyngeal area is the primary site of infection, except when the virus directly enters via the cornified epithelia or the circulation by damage to the intact integument. In contact- or aerosol-exposed animals, virus may be detected in the pharynx 1–3 days before viremia or clinical disease (Alexandersen et al. 2003b,c). The dorsal surface of the soft palate, the adjacent nasopharynx, and perhaps the tonsil are sites of particular significance for initial virus entry and replication. Most of the oral cavity is covered by cornified/keratinized stratified squamous epithelia, that is, a superficial layer of dead cells. In contrast, the dorsal soft palate, the roof of the pharynx, and part of the tonsil is covered by special noncornified epithelia, and therefore, live cells are on the surface of the tissue. Easily accessible to FMDV in this anatomical location, these cells provide efficient virus entry if the appropriate receptors are present.

FMDV entry into cells *in vivo* is believed to involve attachment of the viral capsid to host integrins, for example, alphaV-beta6, on the surface of target cells

(Berryman et al. 2005; Duque and Baxt 2003; Jackson et al. 2000; Monaghan et al. 2005). Little is known about the role of FMDV receptors in the context of host range, target cells, or virus persistence.

After initial replication in the pharynx, or in the skin if the virus has entered directly through damaged integument, the virus spreads to the regional lymph nodes (Henderson 1948) and into the circulation (Alexandersen et al. 2003c). Viremia usually lasts 4–5 days. Viral seeding of secondary sites is followed by multiple cycles of viral replication and spread, with the main sites of viral amplification in the cornified epithelia of the skin, tongue, and mouth. Although vesicular epithelia contain the highest concentration of virus, apparently normal skin, both hairy and hairless, also contains significant amounts (Alexandersen et al. 2001). Experimental studies suggest that lymph nodes, as well as lymphocytes and macrophages, play little or no part in FMDV replication and that any virus present in lymphoid organs is produced elsewhere, that is, the epithelia of the pharynx, mouth, and skin (Alexandersen et al. 2003c; Burrows et al. 1981; Cottral et al. 1963; Murphy et al. 2010).

Factors affecting the severity of disease

The severity of disease is affected by the virulence of the strain of FMDV involved, the inoculating dose (higher doses produce more severe clinical disease), and the physical activity of the animals (Alexandersen et al. 2003b; Murphy et al. 2010; Platt 1961; Quan et al. 2004, 2009). Little is known regarding host genetic factors associated with disease or resistance to disease, although indigenous cattle breeds in FMDV-endemic countries, for example, zebu breeds (*Bos indicus*), often exhibit less severe or no clinical signs compared to European breeds (*Bos taurus*). A difference among breeds has not been reported for pigs.

Activity associated with crowding, fighting, and damage to the skin and mucosa are more likely to lead to severe lesions. Trauma or intense physical stress increases the lateral or local spread of the virus to additional cells (Platt 1961), leading to larger foci of infected cells that, together with a physical separation of damaged tissue, appear as vesicles. The high vascularity of the coronary band, in combination with the severe local inflammatory response, may lead to cutaneous tension or stress and increased vascular permeability, both of which are likely to contribute to the development of visible vesicular lesions (Platt 1961).

While the temporal pattern of FMDV replication and the development of specific lesions are well described, relatively little is known about the pathogenesis of general acute clinical signs, for example, fever, depression/dullness, and reduced feed intake. The severity of clinical signs is not necessarily correlated with the severity of the vesicular lesions. Although FMDV, SVDV, and SVV cause very similar vesicular lesions in pigs, FMDV causes much more severe general clinical disease than SVDV or SVV. Possibly, FMDV causes a more severe proinflammatory host reaction, which is manifested as fever, general depression/dullness, reduced feed intake, occasional inability to maintain body temperature, and even mortality. These aspects of FMD, although not well understood, are probably the result of virus–host interactions extending beyond the observed acute cytopathology in virus-infected cells. Factors responsible may include cell death (releasing so-called danger signals), virus–antibody immune complex formation, complement activation, and the release of cytokines, prostaglandins, and acute-phase proteins.

Interferons alpha and beta may have a role in the host response to FMDV infection, and various FMDV isolates may differ in their ability to induce an interferon response (Chinsangaram et al. 1999; Cottral et al. 1966; Kothmann et al. 1973; McVicar et al. 1973; Seibold et al. 1964; Sellers 1963; Stenfeldt et al. 2011). For example, a large FMDV plaque size in porcine cells was associated with high virulence in pigs (Borgen and Schwobel 1964; Sellers et al. 1959). Studies on haptoglobin (Hofner et al. 1994; Stenfeldt et al. 2011) indicated that this acute-phase protein is elevated in FMDV-infected cattle when viremia and clinical signs become evident, suggesting that the inflammatory response is activated.

Clinical signs

Incubation period

The incubation period for FMDV is highly variable and depends on the virus strain, exposure dose, the route of exposure, the animal species, and the husbandry conditions (Alexandersen et al. 2002b, 2003a,b,c; Quan et al. 2004, 2009). Under experimental conditions, the mean incubation period was 3.5 days for continuous, direct cattle-to-cattle contact and 2 days for intensive sheep-to-sheep contact. Pigs were readily infected by direct and intensive pig-to-pig contact exposure and had a mean incubation period of 1–3 days, but up to 9 days, depending on the intensity of contact (Alexandersen et al. 2002b, 2003b; Quan et al. 2004, 2009). These differences confirm the close relationship between exposure dose and length of incubation: the higher the dose or the intensity of contact, the shorter the incubation period. Under field conditions, the dose of FMDV will depend on several factors, including stocking density, that is, intensive or extensive management, and how the animals are housed and handled.

The incubation period for farm-to-farm airborne spread ranges from 4 to 14 days (Sellers and Forman 1973), which is also the normal range for farm-to-farm spread by indirect contact. The incubation period for

Figure 40.4 (a and b) FMD generalized lesions in pigs 3–5 days after exposure to pigs inoculated with FMDV O_1 Lausanne. Unruptured vesicles are evident along the coronary bands. (c) Lesion on the snout of a pig inoculated with FMDV O UK 2001. *Source:* Alexandersen and Mowat (2005). Reproduced with permission from Springer Nature.

farm-to-farm spread resulting from direct contact may range from 2 to 14 days (Garland and Donaldson 1990). The period for within-farm spread is generally 2–14 days, but may be as short as 24 hours, especially in pigs and under very high challenge conditions. When spread is occurring within a herd or flock, the typical incubation period is 2–6 days, although under certain conditions it may be as short as 1 day or as long as 14 days.

Clinical signs

FMD is characterized by an acute febrile reaction and the formation of vesicles in and around the mouth and on the feet (Figure 40.4). On handling, heat and local pain may be detected in the feet 1–2 days before vesicular lesions appear. Lameness or lesions may not be a consistent finding in all animals. Animals kept on soft bedding are less likely to develop severe foot lesions or show lameness.

Clinical disease is usually severe in pigs. The pain from foot lesions causes lameness, manifested by foot "flicking," a tucked-up stance, reluctance to stand or walk, and inappetence. Early signs include acute lameness, reluctance to stand, adoption of a dog-sitting posture, depression, loss of appetite, and fever. Severely affected pigs become lethargic, huddle together, and have reduced or no feed intake (Kitching and Alexandersen 2002). Fever is often variable in degree and duration; it may be as high as 42 °C (107.6 °F), but is often brief and in the 39–40 °C (102–104 °F) range, and thus close to/within the normal range for pigs. Body temperature in severely affected pigs may be below normal (Kitching and Alexandersen 2002). Consequently, body temperature in pigs can be used to support other clinical findings, but should not be used to exclude the possibility of FMDV infection.

Morbidity and mortality

Mortality in adult animals is generally low, but may be high in young animals, especially piglets, due to acute myocarditis. Although mortality is usually not significant in animals with vesicular lesions, secondary bacterial infections in vesicular lesions may lead to chronic lameness, wasting, or mortality.

FMD may cause abortion in pregnant animals, but the pathogenesis has not been established. It is possible that the fever associated with FMDV infection may be a factor, but it is also possible that the virus crosses the placenta and infects the fetus (Ryan et al. 2008a, 2007).

Stocking density may affect the expression of clinical signs at the population level. Thus, animals housed in confinement often show obvious clinical disease, while, for example, infected sheep kept under extensive conditions may show no overt signs of infection (Alexandersen et al. 2003c). Similarly, vaccines will not prevent infection but may prevent development of severe clinical disease, hence allowing the infection to continue unrecognized for some time.

Lesions

Gross lesions

Lesions often appear initially as blanched areas that subsequently develop into vesicles. They are found most consistently in and around the mouth, and on the feet, but may also be seen on the snout, teats, mammary gland, prepuce, vulva, and other sites. Lesions of the feet of swine may include the shedding of claws ("thimbling"). The accessory digits may be affected, as well as pressure points on the knees, hocks, and elbows, particularly if kept on concrete. Lactating sows may develop vesicles on the udder (Kitching and Alexandersen 2002). The expression of gross lesions may differ by virus isolate and species-specific virulence. For example, the O Taiwan 1997 strain caused severe lesions in pigs, but no cases were seen in ruminants (Dunn and Donaldson 1997).

If oral lesions are present in pigs, they are most often on the tongue, either far back on the dorsum or as tiny lesions at the tip. Vesicles on the feet of pigs are most often seen in the interdigital space, at the bulb of the heel, and along the coronary band. As in sheep and goats, oral lesions in pigs may heal without much exudate or subsequent scarring. However, soon after rupture, the base of vesiculated areas often becomes covered within a few days by a serofibrinous exudate. The regeneration of epithelia is usually well advanced within 2 weeks, although usually with a variable degree of scarring, in particular after the occurrence of severe lesions. The rupture of vesicles, especially on the feet or teats, may predispose the affected areas to secondary bacterial infections, which may complicate and prolong the healing processes.

The age of lesions can be assessed using the following criteria: development of vesicles on days 0–2, rupture of vesicles on days 1–3 (initially with fragments of epithelia attached), sharply marginated erosion (days 2–3), with the sharpness lost around day 3, serofibrinous exudation on days 4–6, and beginning of repair with a marked fibrous tissue margin at day 7 or more (Anonymous 1986). Severe lesions of the coronary bands, as seen especially in pigs, may often lead to a separation of the horn during the acute inflammatory stage. If the horn is not shed, a ring will be formed in the horn that becomes visible below the coronary band approximately 1 week after the first appearance of clinical disease. This ring progresses down the hoof as the horn grows. Growth rate is approximately 1–2 mm per week, with faster horn growth in younger animals.

In young animals (pigs less than 8 weeks of age) that die from acute myocarditis, visual examination often reveals the heart to be soft and flaccid, with white or grayish stripes (the so-called tiger heart) or spots, seen mainly in the left ventricle and interventricular septum. In young animals dying from hyperacute disease, there may be no significant visible lesions in the heart and an absence of vesicular lesions, but the virus can usually be isolated from the myocardium or from blood, and lesions can be detected by histopathological examination (Donaldson et al. 1984). Occasionally, the skeletal muscles may also be affected. Furthermore, in ewes, FMDV can cross the placenta leading to infection and death in fetal lambs with no visible specific gross abnormalities in the infected fetuses (Ryan et al. 2007).

The significance of FMD acute myocarditis for the spread of the disease is not well understood. Possibly, there is little virus excretion, since death usually occurs early before the development of vesicular lesions. However, although in such cases FMDV mainly replicates in the heart, a significant viremia may occur (Donaldson et al. 1984), and virus may be present in respirations, saliva, nasal fluid, and so forth (Ryan et al. 2008b).

Microscopic lesions

The first histopathological changes in the cornified stratified squamous epithelium are ballooning degeneration and increased cytoplasmic eosinophilic staining of the cells in the stratum spinosum and the onset of intercellular edema within the dermis. These early lesions are detectable only by microscopic examination (Gailiunas 1968; Yilma 1980). This early stage may be followed by necrosis and subsequent mononuclear cell and granulocyte infiltration. The lesions, now macroscopically visible, develop further into vesicles by separation of the epithelium from the underlying tissue and filling of the cavity with vesicular fluid. In some cases, the vesicular fluid production may be high, and the

resulting vesicles large. In other cases, the amount of fluid may be limited, and the epithelium may undergo necrosis or be torn off by physical trauma without the formation of an obvious vesicle. The variability seen is most likely due to combinations of viral strain virulence, thickness of the affected skin, and husbandry conditions, especially as they affect physical stress on different regions of the skin. In young animals dying from acute disease, there is lymphohistiocytic myocarditis with hyaline degeneration, necrosis of myocytes, and infiltration with mononuclear cells.

In pigs, it is puzzling that no lesions develop on the soft palate or the dorsal part of the pharynx, despite the presence of significant amounts of virus. Possibly, the infection causes no acute cytopathology in the transitional epithelial cells found in these areas. Alternatively, the viral cytopathology is restricted to a few cells and is, therefore, not easily detected. Or perhaps, since the epithelia of this region are noncornified, the development of distinguishable lesions is somehow prevented. Regardless, the underlying mechanisms behind this apparent lack of cytopathology are unknown.

In infected sheep fetuses, no pathology was observed in the epithelium because FMDV RNA was located mainly in the subepithelial muscle of the tongue and in the myocardium. The replication of FMDV in the myocardium did not lead to classical "tiger heart" striations, as reported in piglets and calves (Ryan et al. 2007).

Diagnosis

Differential diagnosis

The clinical diagnosis of FMD is sometimes difficult, for example, in sheep and goats, in which clinical signs are often mild (Alexandersen et al. 2002b; Donaldson and Sellers 2000; Hughes et al. 2002). Moreover, certain strains of the virus may be of low virulence for some species (Donaldson 1998). In pigs, several other viral vesicular diseases, including swine vesicular disease (SVD), vesicular stomatitis, and SVV and vesivirus infection, cannot be distinguished from FMD on the basis of clinical findings. PEV infections have also been implicated in vesicular diseases in swine (so-called idiopathic vesicular disease). If the disease is not noted early, any vesicles present will have ruptured and will be indistinguishable from erosive lesions, such as those induced by trauma, caustic substances, and photosensitivity. Thus, a definitive diagnosis requires urgent laboratory investigation.

Pathological evaluation

The first step in the diagnostic evaluation is to determine whether vesicles are present. If no vesicles are present, it should be established whether there are lesions that could be consistent with older stages of vesicles, that is, after rupture and loss of the overlying lesion epithelia and thus resembling erosions. Although detailed gross examination of lesions may help in the evaluation, only laboratory testing can confirm or refute the presence of FMDV.

Virus detection

Definitive diagnosis of FMD must be carried out at specialized laboratories. Enzyme-linked immunosorbent assays (ELISAs) have supplanted the earlier use of the complement fixation test due to their sensitivity, specificity, and ability to test large numbers of samples (throughput), and in recent years initial virus detection is often done by real-time RT-PCR.

Laboratory diagnosis is traditionally made by ELISA detection of specific FMDV antigens in epithelial tissue suspensions, often with concurrent attempts at cell culture isolation and the application of ELISA to any samples showing cytopathic effect (Ferris and Dawson 1988; Hamblin et al. 1984; Roeder and Le Blanc Smith 1987). These tests are used to confirm the diagnosis and identify the FMDV serotype.

Given a sample with sufficient quantities of virus, a positive result for FMDV (including serotyping) can be obtained in 3–4 hours by antigen ELISA (Ferris and Dawson 1988; Hamblin et al. 1984; Have et al. 1984; Roeder and Le Blanc Smith 1987). However, samples with low quantities of virus may yield weak, inconclusive, or negative results. Thus, the antigen ELISA is highly specific and very suitable for confirming positive cases, but a negative result requires further examination in highly susceptible cell cultures or by real-time RT-PCR before FMD can be ruled out.

Most often, field samples are routinely inoculated onto primary BTY cells (Snowdon 1966) or bovine or lamb kidney cells, as well as on an established line of porcine kidney cells (IB-RS-2 cells) (De Castro 1964). Recently, two cell lines, ZZ-R 1272 and LFBK-αvβ6, have been reported to have high sensitivity to various FMDV strains (LaRocco et al. 2013, 2015). Cultures showing a cytopathic effect are confirmed by antigen ELISA or RT-PCR and sequencing using cell culture supernatant. For most FMDV strains, the BTY cell system is about 10 times more sensitive than other cultures (Burrows et al. 1981; Snowdon 1966). However, certain pig-adapted strains, for example, the O Taiwan 1997 strain (Dunn and Donaldson 1997), grow better in IB-RS-2 cells. Virus isolation in BTY and IB-RS-2 cell cultures essentially detects all positive samples with more than 1–5 infectious units per milliliter or per 0.1 g. Depending upon the amount of virus present, two 48 h passages may be required before a final result can be determined. However, if the specimens are of low quality or if the transport conditions were less than optimal, a small proportion of samples may give negative results for infectivity, but positive results by ELISA or RT-PCR.

RT-PCR assays have been developed for the detection of FMDV, but initially none seemed to be of sufficient sensitivity, specificity, and robustness for routine diagnostics (House and Meyer 1993; Moss and Haas 1999; Reid et al. 1998, 1999). RT-PCR assays for serotyping FMDV have been described, but the initial procedures were labor intensive (Callens and De Clercq 1997; Reid et al. 1998, 1999; Vangrysperre and De Clercq 1996). Alexandersen et al. (2000) developed an RT-PCR ELISA of increased sensitivity and included a simple and aqueous-phase (SNAP) hybridization step for optimal specificity, speed, and ease of use. Both conventional polymerase chain reaction (PCR) techniques and the SNAP method can provide serotype-specific results, but they are not of sufficiently high throughput for use in an epidemic.

Fluorogenic "real-time" RT-PCR methods combine the total RNA extraction and reverse transcription (RT) procedures of conventional RT-PCR with fluorogenic probe PCR amplification in real-time PCR equipment. This approach is able to achieve high sensitivity and specificity for the detection of FMDV genomes of all seven serotypes (Alexandersen et al. 2003b,c; Callahan et al. 2002; Hearps et al. 2002; Moniwa et al. 2007; Moonen et al. 2003; Rasmussen et al. 2003; Reid et al. 2002). The assay can be used for the detection of FMDV in tissue samples, serum samples, swab samples, and tissue culture supernatants and can include automated procedures for nucleic acid extraction, RT, and PCR amplification stages to increase sample throughput (Reid et al. 2003). In addition, some of these assays may be used on portable platforms (Ambagala et al. 2017; Callahan et al. 2002; Hearps et al. 2002; King et al. 2008).

Real-time RT-PCR methods are now as diagnostically effective as the combined ELISA/virus isolation system. These assays provide good agreement with virus isolation with same-day turnaround. With experimental samples, the sensitivity of RT-PCR is often higher than virus isolation. The timeliness of investigating suspect cases could be further improved by conducting the testing on or near the farm, but this type of testing, especially in a portable format, will require further evaluation. Serotyping RT-PCR methods and RT-LAMP assays have also been described and may have diagnostic potential (Bachanek-Bankowska et al. 2016; Dukes et al. 2006; Jamal and Belsham 2015; Reid et al. 2014; Waters et al. 2014).

In addition to the methods described above, "pen-side" antigen detection methods have been developed based essentially on the same principle as the antigen ELISA, but with a pan-serotype monoclonal antibody in a format adapted for field use (Ferris et al. 2009; Reid et al. 2001; Ryan et al. 2008a). Laboratory trials indicated that the sensitivity of this approach is equal to, or probably greater than, the traditional antigen ELISA. Field validation of such tests is a high priority. It has also been shown that intact viral RNA can be recovered from such pen-side devices and this can be used for further characterization (e.g. using RT-PCR and sequencing) of the virus (Fowler et al. 2014).

Antibody detection

The liquid-phase blocking ELISA was formerly in routine use at many laboratories for FMDV antibody detection (Hamblin et al. 1986). The diagnostic sensitivity of the assay is close to 100%, but the specificity is only approximately 95%. Since specimens with inconclusive ELISA results require testing by virus neutralization (VN) (Golding et al. 1976), the liquid-phase blocking ELISA is not the optimal test for large-scale screening because numerous VNs are likely to be required because of the relatively low specificity of the assay.

The OIE considers the VN the definitive "reference standard" for the final assessment of inconclusive ELISA results. At the World Reference Laboratory, the specificity of the VN for serotype O antibodies at a dilution of 1 : 45 was 100% (Paiba et al. 2004). However, it is likely that some of the newer tests may completely replace the VN when sufficient validation data become available.

Solid-phase competitive or blocking ELISAs (SP-C or SP-B ELISAs) possess both high sensitivity and specificity (Chénard et al. 2003; Have and Holm-Jensen 1983; Li et al. 2012; Mackay et al. 2001; Sorensen et al. 1992). Such assays may detect all experimentally infected animals at 5–8 days after infection and for many months thereafter (Paiba et al. 2004).

Research on vaccines from which FMDV nonstructural proteins (nsp) have been removed offers the future promise of a DIVA (differentiate infected from vaccinated animals) vaccine even in animals vaccinated more than once. Tests to detect antibodies against the conserved nsp of FMDV have already been reported (Berger et al. 1990; Bergmann et al. 1993; Lubroth and Brown 1995; Mackay 1998; Neitzert et al. 1991; Shen et al. 1999; Sorensen et al. 1998). In vaccinated populations, such tests could be used to differentiate vaccinates from infected animals on a herd basis. Unvaccinated populations can be screened by tests that detect antibodies to structural antigens, and a negative result will exclude FMDV in a statistically robust manner.

Immunity

The host immune response, including antibody production detected as early as 3–4 days after the first clinical signs, usually results in the clearance of FMDV, except in those infected ruminants that develop a persistent infection of the pharyngeal region. Clearance of virus from "peripheral" or "external" sites, for example, nasal

and oral surfaces, is less efficient. The virus may remain in the vesicular epithelium of foot lesions for 10–14 days, that is, longer than in oral lesions (Oliver et al. 1988).

Humoral response

ELISA can detect circulating antibodies 3–5 days after the appearance of clinical signs. Detection of antibodies by VN is usually 1–2 days later than ELISA. Coincident with the first detection of antibody, there is a progressive, rapid clearance of virus from the circulation and a significant reduction of virus in most organs, excretions, and secretions. The antibody response normally remains high for many months after infection and may still be detectable after several years. However, in fast-growing young pigs, antibodies may have a half-life as short as 1 week and may remain detectable for only a few months.

Immunity to FMDV is primarily mediated by circulating antibodies, and protection after infection or immunization (active or passive) is closely correlated with the antibody titer. Circulating antibodies capable of binding to the surface of virions will facilitate opsonization and uptake by phagocytes located in the liver, spleen, and elsewhere and thus rapidly reduce or prevent viremia (McCullough et al. 1992). As viremia is an important phase in the early infection process, its reduction or prevention will have a corresponding effect on acute generalized disease. However, since circulating antibodies will not prevent primary local infection (e.g. at the sites of intradermal entry or in the pharynx), it would seem that they prevent disease, but not infection (McVicar and Sutmoller 1976).

Infection with FMDV induces a strong mucosal immunoglobulin A (IgA) response that may protect against reinfection with the same virus, but traditional inactivated vaccines induce a very weak or no secretory IgA response. It is possible that vaccines with a high antigenic mass may induce some secretory IgA production in swine and that this response, if sufficiently high, may protect against infection (Eble et al. 2007; Pacheco et al. 2010).

Cell-mediated and innate responses

Although it is possible to protect pigs with passively acquired antibodies and although immunity to FMDV appears to be primarily mediated by circulating antibodies, immunity after vaccination or infection must necessarily involve more than just humoral immunity. However, little is known about the cell-mediated immune response to FMDV infection.

In swine, FMDV infection results in a significant lymphopenia. T-cell activity is significantly reduced during acute infection, possibly the result of increased interleukin (IL)-10 production by dendritic cells (Diaz-San Segundo et al. 2009; Golde et al. 2008; Grubman et al. 2008).

Both a CD4 and a CD8 T-cell response can be demonstrated in infected or vaccinated animals. However, the development of neutralizing antibodies and of class switching appears to be independent of a CD4 T-cell response, and the CD8 T-cell response may be of limited effect during acute infection, because acute FMDV infection rapidly results in reduced major histocompatibility complex (MHC) class I surface expression on infected cells. Moreover, the acute infection itself rapidly kills infected cells (Childerstone et al. 1999; Gerner et al. 2009; Guzman et al. 2008; Juleff et al. 2009; Sanz-Parra et al. 1998).

Likewise, the innate immune response is poorly described, and some studies suggest that the innate response plays a minor or no role in protection (Alves et al. 2009; Summerfield et al. 2009). Swine can be protected by interferons, as shown using replication-defective adenovirus expressing type I or type I and II interferons, a promising tool for potential new emergency vaccines or, rather, antivirals (Diaz-San Segundo et al. 2010). Furthermore, FMDV induces a rapid transient type I interferon response in pigs, which peaks 2–3 days post infection and may contribute to the rapid clearance of viremia (Nfon et al. 2010). Although FMDV is highly sensitive to interferons, the virus has efficient mechanisms to block interferon production in infected cells by blocking cellular protein synthesis via the FMDV leader protein (Belsham 2005). Other innate immune responses may work through natural killer cells (NK cells), but FMDV also appears able to counteract this mechanism by significantly reducing NK cell function during acute infection (Toka et al. 2009). Overall, it appears that FMDV has evolved efficient mechanisms for immune evasion during the acute stages of infection (Golde et al. 2008; Grubman et al. 2008). Nevertheless, emergency vaccines may provide early protection by induction of a combination of innate and adaptive immune responses.

Maternal immunity

Maternal immunity against FMDV is transferred to the offspring via colostral immunoglobulins from previously infected or vaccinated dams. Provided the levels are sufficiently high and directed toward the relevant challenge strain, this may protect piglets up to 8–12 weeks of age. Piglets respond poorly to FMD vaccination and are best protected by maternal immunity. They should not be vaccinated before 8–12 weeks of age, by which time maternal immunity is waning and they are able to respond to FMD vaccination (Francis and Black 1986; Kitching and Alexandersen 2002; Kitching and Salt 1995; Morgan and McKercher 1977).

Prevention and control

The most common methods of spreading FMDV are (1) movement of infected animals, (2) feeding of contaminated

animal products to susceptible livestock, and (3) movement of virus on fomites or mechanical vectors (humans and animals). Transmission by these routes can be prevented by application of strict disease control measures, that is, movement restrictions and biosecurity procedures. It should be borne in mind that virtually any surface or product could be contaminated with the virus, if the infection is present in the region or country. Airborne transmission of FMDV is essentially uncontrollable and not uncommon over short distances, but rarely occurs over long distances. However, when long-distance transmission occurs, the consequences can be dramatic (Anonymous 1969; Donaldson et al. 1982; Gloster et al. 1981, 1982).

FMDV has a wide host range, a low infectious dose, a rapid rate of replication, a high level of viral excretion, and multiple modes of transmission. Therefore, it is essential to identify suspect cases, conduct the diagnostic evaluation, and implement the appropriate response as quickly as possible. Extreme measures are required to eradicate FMDV, and, if they are not rapidly and effectively applied, there is a high probability that an outbreak will reach epidemic proportions.

There is currently no way of treating FMDV-infected pigs, and once the virus has been introduced into a swine farm, it is unlikely to disappear unless all the animals, both infected and uninfected, are euthanized, the carcasses removed (buried, rendered, or incinerated), and the premises disinfected (Alexandersen et al. 2003c; Kitching and Alexandersen 2002). Therefore, the response to the positive identification of FMDV is euthanasia of all susceptible animal species on infected farms, while vaccination may be used in noninfected farms. Depending on local regulations, animals suspected of having been exposed to FMDV could be transported to an abattoir for slaughter, if it is possible to avoid the risk of transmitting FMDV to other susceptible animals. Products from such animals must be heat treated and canned.

Control of FMDV is complicated by the existence of carrier ruminants (Alexandersen et al. 2002a; Sutmoller and Gaggero 1965; Van Bekkum et al. 1959). It is noteworthy that pigs do not become carriers (Alexandersen et al. 2003b; Stenfeldt et al. 2016). Recognition of the carrier state and the possible disease risk presented by carrier animals had a major impact on the design of control and eradication strategies for FMD. Experience has shown that total stamping out, whereby all susceptible species on infected premises are euthanized, both affected and apparently normal, is necessary to ensure the elimination of persistently infected carriers (Alexandersen et al. 2002a; Hedger and Stubbins 1971). These strategies have been shown to be effective under varying conditions in many countries. The risk posed by ruminant carriers has also had a marked influence on the safeguards taken to manage the risk of FMD associated with international livestock movements. These measures, mainly directed at animals originating from countries where the disease is either endemic or sporadic, range from complete embargo to quarantine and testing.

During the UK 2001 epidemic, mathematical models played a major part in influencing disease control strategy. However, they had not been used previously under operational conditions (Ferguson et al. 2001) and the assumptions behind them, as well as the justification for the use of such average-based, mathematically-derived, centrally controlled procedures and their actual impact on efficient disease management are still highly contentious.

Vaccines and vaccination

There are seven serotypes of FMDV, and infection or vaccination with one serotype does not protect against infection or disease with any of the other serotypes. Moreover, a wide range of strains may exist within a serotype, some of which may be sufficiently divergent to reduce the efficacy of a given vaccine (Kitching 1998; Kitching et al. 1989). As a general rule, protection against heterologous strains will be lower than against the homologous strain (Goris et al. 2008). Therefore, FMDV vaccine antigens need to be tailored to strains circulating in the region or strains with the potential to be introduced. Preparedness for emergency vaccination requires accurate intelligence with respect to the strains most likely to be introduced. An alternate strategy is to be broadly prepared against a large number of FMDV antigens.

The degree of cross-protection that one vaccine strain provides a vaccinated animal when challenged with another strain of the same serotype can only be assessed in animal trials, but most trials offer only limited insight because the low number of animals typically used offers low statistical power.

The antigenic relatedness of FMDV strains can be assessed in the laboratory using ELISA and VN methods. These results help select vaccine strain(s) most appropriate for use against a given field strain. Notably, these indirect methods are highly dependent on the individual laboratory doing the tests, the actual composition and potency of the vaccines, and other factors (Jamal et al. 2008; Maradei et al. 2008; Mattion et al. 2009; Paton et al. 2005).

Thus, although vaccines are available to control FMD, the existence of multiple serotypes of FMDV, each with multiple continuously evolving strains, should be considered when considering a control program that includes vaccination. Further, it should be recognized that vaccine-induced population protection usually only lasts 4–6 months and that susceptible animals are continuously introduced into swine populations through reproduction and animal movement. Consequently, vaccination programs often require two or more doses per year (Domenech et al. 2010). It should also be noted that

once established in the swine population, FMD is difficult to control by vaccination (Orsel and Bouma 2009; Orsel et al. 2007) and even more difficult to eradicate, as shown by the efforts in Taiwan, which, after nearly 15 years of vaccination following the 1997 introduction, has not eradicated FMD. Nevertheless, the successful eradication of FMD from the EU has clearly shown that eradication can be achieved using prophylactic vaccination with good quality vaccines, but it should be realized that this required a coordinated and efficient control effort, including stamping out of infected farms, over many years (Leforban and Gerbier 2002).

Swine vesicular disease virus

Relevance

In 1966 a new disease emerged in pigs in Italy. The disease was clinically recognized as FMD but was caused by an enterovirus (Nardelli et al. 1968). This disease was later called swine vesicular disease. The virus (SVDV) was subsequently isolated in Hong Kong in 1971 (Mowat et al. 1972). In 1972, SVD was diagnosed in the United Kingdom, Austria, Italy, Poland, and subsequently elsewhere (see Table 40.2). Recently, only Portugal and Italy have reported outbreaks of SVD (Table 40.2). The virus may still be present in some Asian countries although the last reported outbreak was in Taiwan in year 2000. North and South America are considered free of SVD. Most of the recent outbreaks in Italy were not discovered by clinical inspection, but by serological screening of subclinical infections. In the absence of serological screening, the disease would probably be underreported in Italy. Therefore, it is likely that the virus is present in more countries than those that have reported the disease.

Table 40.2 Year of first and last reports of swine vesicular disease outbreaks in the world. The data are based on the FAO Animal Health Yearbook (1971–1996) and information obtained from the European reference laboratory for vesicular diseases in Pirbright (United Kingdom).

Europe	Year of first report	Year of last report
Italy	1966	2015[a]
Portugal	1995	2007
Netherlands	1975	1994
Belgium	1979	1993
Spain	1993	1993
Romania	1973	1987
Germany	1973	1985
France	1973	1983
United Kingdom	1972	1982
Austria	1972	1979
Greece	1979	1979
Malta	1975	1975
Russia[b]	1975	1975
Switzerland	1974	1975
Ukraine	1972	1972
Poland	1972	1972
Bulgaria	1971	1971
Asia		
Taiwan	1997	2000
Hong Kong	1970	1991
Japan	1973	1975

[a] No outbreaks were recorded in 2016, and the latest reports in Italy were mostly triggered by detection of antibodies to the virus and not due to detection of clinical disease.
[b] These outbreaks were caused by SVDV-2, a variant of human coxsackievirus B4.

Significance to swine health and/or public health

Until 2015, SVD was listed by the OIE, because SVD lesions resemble FMD lesions. The disease was removed from the list as the production losses due to SVD are very limited and modern diagnostic techniques make it easy to differentiate between SVD and FMD infections; even "on-farm" diagnosis is possible (Ferris et al. 2009). In the FMD outbreak in 1997 in Taiwan, the presence of SVD in the country probably delayed the reporting of FMD cases, which may have led to more FMDV-infected farms. To avoid missing an FMD outbreak, SVD is still under official control in many OIE member states.

Shortly after SVDV was identified, it was shown that the structural proteins of SVDV are closely related to the structural proteins of coxsackievirus B5. Therefore, it was suggested that infection of humans by SVDV could be possible (Brown et al. 1976). There is one report where infection with SVDV might have been the cause of hospitalization of one person. Since the virus is closely related (see below) to the human coxsackievirus B5 (within the coding sequence for the structural proteins) and echovirus 9 (within the sequences encoding the nsp) (Zhang et al. 1999), infection of human cells is not unexpected. However, severe illness in humans has not been reported recently, not even from laboratories working with large amounts of live virus during large-scale screening. Thus, it remains uncertain whether the illness leading to the single hospitalization was caused by SVDV infection. Furthermore, recent studies suggest that the virus has further adapted to swine and that SVD viruses isolated after 1993 have lost the ability to infect human cells and have completely lost any original zoonotic potential. Consequently, currently circulating strains

and isolates obtained after 1993 should not be considered zoonotic (Jimenez-Clavero et al. 2005). SVDV is not the only human enterovirus that entered the swine population, but also a coxsackievirus B4-like strain (termed SVDV-2) causing vesicular lesions in pigs was detected in 1975 in Russia (Lomakina et al. 2016).

Etiology

SVDV is classified as an enterovirus within the family *Picornaviridae* and belongs to the species *Enterovirus B*. Like other picornaviruses, SVDV is non-enveloped. It has a single-stranded positive-sense RNA genome, and the virus particles are approximately 30–32 nm in diameter (Nardelli et al. 1968). Antigenic studies have revealed only small antigenic differences; therefore SVDV is considered a single serotype. Isolates, however, can be divided into four distinct phylogenetic groups by comparing monoclonal antibody reaction patterns or nucleotide sequences of the 1D (VP1) coding sequence (Borrego et al. 2002a,b; Brocchi et al. 1997).

The SVDV genome consists of approximately 7,400 nucleotides and encodes a single polyprotein of 2815 aa (Inoue et al. 1989). This polyprotein is posttranslationally cleaved into 11 mature proteins (plus various precursors). Four of these proteins – 1A, 1B, 1C, and 1D – form the virus capsid (Fry et al. 2003; Jimenez-Clavero et al. 2003), and one of these proteins, 3B (VPg), is linked directly to RNA and is, therefore, a component of the virion (but only 1 copy per particle; cf. 60 copies of each of the capsid proteins). The nsp are involved in virus replication and interruption of host cell functions (e.g. cellular protein synthesis).

The virus can be grown on primary or secondary porcine kidney cells and a wide range of pig kidney-derived cell lines and sometimes even on secondary lamb kidney cells (Aldo Dekker, unpublished observations). The virus is lethal to newborn mice (Nardelli et al. 1968). This links it to its ancestor virus coxsackievirus B5 because, in the enterovirus group, only coxsackieviruses can infect mice (Graves 1995). Sequence data show that SVDV has approximately 75–85% nucleotide identity with coxsackievirus B5 (Knowles and McCauley 1997) within the coding sequence for the structural proteins. There is also high sequence identity to echovirus 9 in the coding sequence for the nsp (Zhang et al. 1999). Phylogenetic analyses indicate that SVDV and recent coxsackie B5 isolates probably shared a common ancestor in the period 1945–1965, most likely close to 1961 (Bruhn et al. 2015; Zhang et al. 1999).

Epidemiology

Geographic distribution

SVDV has only been isolated in Asia and in Europe and outbreaks have been reported in a limited number of countries (Table 40.2). The only country that has reported SVDV detection recently is Italy, but it is possible that SVDV is present in other countries since only a few countries test for antibodies against SVDV.

Susceptible species

Not only Euro-Asian pigs but also American one-toed pigs are susceptible to the virus (Wilder et al. 1974). Relatively high titers of SVDV have been detected in the pharynx of sheep kept in close contact with SVDV-infected pigs (Burrows et al. 1974), and neutralizing antibodies were detected in some of these contact sheep, while similar experiments with cattle showed no signs of infection (Burrows et al. 1974). Thus, these studies might indicate that after close contact with infected swine, the virus may have replicated in the sheep; however, there is no indication that sheep or other ruminants play any role in the epidemiology of SVD.

Transmission

An epidemiological field study in the United Kingdom for the period 1972–1981 revealed that the main source of infection was movement of pigs (48%), either because infected pigs were transported (16%) or contaminated transport vehicles were used (21%) or through contacts at markets (11%). A second significant source of infection (15%) was feeding virus-contaminated waste food (Hedger and Mann 1989). The routes of transmission were very similar in the first phase of the Italian 2006 SVD outbreak: 12 of 36 outbreaks (33%) were caused by movement of infected pigs, 11 of 36 (31%) were caused by use of a contaminated transport vehicle, 11 of 36 (31%) were caused by infection via other indirect routes, while the route of introduction to 2 of 36 farms (5%) was unknown. In Italy, there was no indication that swill feeding played a role. Seventeen outbreaks occurred after more stringent control measures were implemented in the second phase: in 1 of 17, a person had previously visited an infected premises; in 5 of 17 cases the infection was transmitted between different locations owned by the same farmer (Bellini et al. 2010a); and the source of virus could not be determined for the remainder. The difference in transmission characteristics between the first and second phase of the Italian 2006 outbreak was further confirmed by spatial analysis of the outbreak farms. That is, in the first phase a higher probability for relative long-distance transmission was observed compared with the second phase (Nassuato et al. 2013).

The exceptional stability of the virus outside the host is the reason why indirect contact (e.g. through contaminated transport vehicles and swill feeding) plays an important role in the epidemiology of SVD. Transmission can occur not only by direct contact between infected and susceptible pigs but also via contact with a contaminated environment. The latter can lead to viremia within

1 day and clinical signs within 2 days – similar to infection by direct inoculation or direct contact (Dekker et al. 1995a). Studies on SVDV transmission within an outbreak farm showed that spread between pens most likely occurred when there was a shared open drainage system or frequent movement of pigs between pens. SVD, therefore, is considered a "pen disease" rather than a farm disease (Hedger and Mann 1989; Dekker et al. 2002).

Since clinically affected herds are culled immediately, it is not easy to study the transmission of SVD in field conditions. However, IgM and IgG ELISAs have been developed to study the time the virus was introduced (Brocchi et al. 1995; Dekker et al. 2002). These ELISAs allow for the estimation of the time of introduction; however, the isotype profiles of most infected animals are similar after approximately 50 days. Therefore, an estimation of the time of introduction beyond 50 days is not possible (Dekker et al. 2002).

The role of wildlife is most likely negligible, although there are not many studies in regions with SVD outbreaks. No SVDV antibodies have been detected in wild boar in countries not reporting the disease, for example, the Netherlands (Dekkers and Elbers 2000) and Croatia (Roic et al. 2012). Also, no SVDV antibodies were detected in wild boar sampled in 2005–2006 in Italy in the Campania region, although SVD was detected in domestic pigs in the same period (Montagnaro et al. 2010).

Duration and routes of shedding

The duration of SVDV shedding from vesicles is at least 7 days (Dekker et al. 1995a), but longer in feces. One report described recovery of virus up to 126 days after infection (Lin 1998), but it has been difficult to reproduce these findings (Lin et al. 2001). In a recent study, viral genome was detected 7–14 days after infection in oral fluids; interestingly these fluids could also be used to detect antibodies to the virus (mostly after day 7), making these fluids an interesting sample for early diagnosis (Senthilkumaran et al. 2017).

Persistence in the environment (inactivation by heat, UV, desiccation, etc.)

The virus remains infectious for months in carcasses and processed meat (e.g. salami or pepperoni sausages), which explains the role of swill feeding in the epidemiology of SVD (Hedger and Mann 1989; Mebus et al. 1997). SVDV remains infectious in slurry for a long time (Karpinski and Tereszczuk 1977), and inactivation of SVDV in slurry is more difficult than other significant pathogens (e.g. African swine fever virus) (Turner and Williams 1999).

Susceptibility to disinfectants

SVDV is stable over a wide range of pH, and consequently, acidic or alkaline disinfectants that work well for other pathogens (e.g. FMDV) are not effective for SVDV. As with many of the other picornaviruses, SVDV is also resistant to detergents and organic solvents, such as ether and chloroform. A 4-$\log_{10}$ reduction in infectivity in 5–6 minutes was not found with many commonly used disinfectants; only sodium hydroxide (1%) was able to inactivate SVDV adequately. If prolonged contact times between virus and disinfectant are an option, then inactivation is often possible to achieve, for example, formaldehyde (2%) was effective after 18 minutes (Terpstra 1992).

Pathogenesis

Virus entry, site of primary replication, spread within the body and sites of secondary virus replication

It has been suggested that SVDV enters the pig through the skin or the mucous membrane of the digestive tract (Chu et al. 1979; Lai et al. 1979; Mann and Hutchings 1980). Experimental SVDV infection can lead to clinical signs within 2 days, and SVDV has been isolated from a wide range of tissues (Burrows et al. 1974; Chu et al. 1979; Dekker et al. 1995a; Lai et al. 1979). After contact of pigs with a SVDV-contaminated environment, viremia can develop within 1 day, similar to the time frame observed when pigs are directly inoculated (Dekker et al. 1995a).

SVDV lesions are mainly observed in epithelial tissues and infection via the skin is very effective (Burrows et al. 1974). Virus titers in the myocardium and the brain can significantly exceed those in plasma. Epithelial tissues and sometimes the myocardium and brain are probably the sites of virus replication (Chu et al. 1979; Lai et al. 1979). Lymph nodes also may contain high titers of SVDV after experimental infection. It is not known, however, whether these tissues are positive because of the drainage of virus or because of virus replication (Dekker et al. 1995a). More research is necessary to identify the cells in lymph nodes (or other tissues) that support SVDV replication.

Factors affecting the severity of disease

SVD may run a subclinical, mild, or severe course. The latter was only seen when pigs were housed on a concrete floor in humid conditions (Hedger and Mann 1989; Kanno et al. 1996; Kodama et al. 1980). This suggests that the environment can be a factor in the observed virulence of the disease.

Experiments to show differences in virulence between strains showed that lesions were often difficult to observe without careful examination, so reports of differences in virulence in the field are probably biased by differences in the methods by which observations were collected. In the most recent SVDV detections in Italy, the cases were

never reported based on clinical disease, but always by the detection of SVDV-specific antibodies in the monitoring program. This suggests that the current strains mostly cause subclinical infections.

Host genetic factors associated with disease

Host genetic factors are not known to be associated with SVD.

Clinical signs

Incubation period

Experimental infection by intradermal injection in the heel bulb can lead to clinical signs in 1–2 days. In experiments in which pigs were exposed to a contaminated environment, lesions were first observed 2 days after exposure (Dekker et al. 1995a). This showed that the time to onset of clinical signs could also be very short in natural exposure. The 2006 outbreaks in Italy were detected in the beginning of October, but epidemiological studies indicated that the virus must have been present in August (Bellini et al. 2010a). This long period between introduction and detection was probably due to subclinical infection, as well as poor detection and reporting.

Morbidity and mortality rates

Mortality is not a reported feature of SVDV infection. Morbidity can be high, but depends on many factors, including virulence of the strain, type of farm, and, most importantly, time between infection and detection. The seroprevalence at the time of detection ranged from approximately 7% on a farm in which the disease was clinically detected to almost 90% in a collection center that was traced after receiving presumably infected pigs (Dekker et al. 2002).

Lesions

Gross lesions

In pigs infected with SVDV, vesicles appear around the coronary bands (Figures 40.5 and 40.6), on the skin of the metacarpus and metatarsus, and to a lesser extent on the snout, tongue, and lips. Lesions are indistinguishable from those induced by an FMDV infection. The clinical signs caused by SVDV are, however, much milder than those caused by FMDV. In experimental studies (Dekker et al. 1995a), fever was rare and lameness was almost never observed. Sudden death due to heart degeneration, often observed in young piglets infected with FMDV, is not seen with SVDV.

In typical cases of SVD, lesions are first noticed at the junction of the heel and the coronary band (Figures 40.5 and 40.6). The whole of the coronary band may eventually be involved, and the lesions may spread to the metatarsal and metacarpal regions. The hoof wall and sole may be damaged so extensively that the claw(s) sloughs off. In lactating sows, lesions on the udder and teats can be seen (Figure 40.7). Occasionally, the skin of the thorax and abdomen is involved. Lesions in the mouth and on the lips and snout occur in up to 10% of the cases. Those on the snout are mostly on the dorsal face of the rostrum and may be hemorrhagic in appearance. Tongue lesions are transient and heal rapidly (Hedger and Mann 1989).

Figure 40.5 Vesicular lesion in the interdigital space of a pig infected with SVDV. A vesicle on the coronary band extending to the heel bulb.

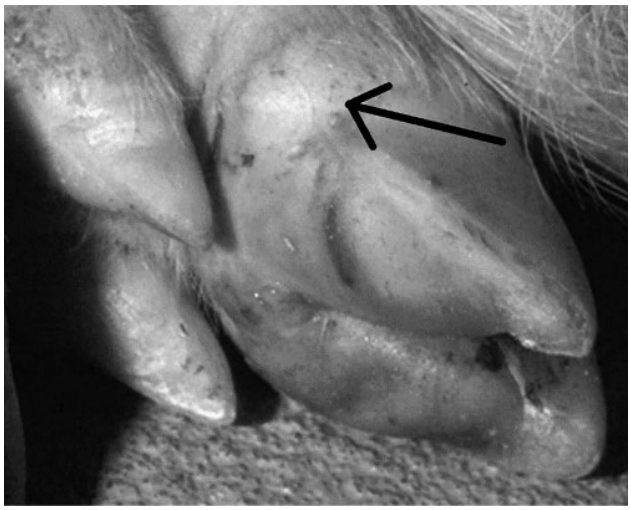

Figure 40.6 Vesicular lesion on the coronary band of a pig infected with SVDV.

Microscopic lesions

Early experimental infection by SVDV has been studied in skin sections showing replication in the epidermal layer of the skin with indication of rapid spread to the

Figure 40.7 Teat lesions in a lactating sow infected with SVDV (outbreak NET/1/1992).

dermis (Mulder et al. 1997). Histological studies on the morphogenesis of vesicles in SVD have not been done, but it is considered to follow the same pattern as observed in FMD, starting with ballooning of epithelial cells and microvesicles in the stratum spinosum (Mohan et al. 2008). In experimentally infected animals, nonsuppurative meningoencephalitis may occur, but this does not result in signs of impaired central nervous system (CNS) function (Chu et al. 1979).

Diagnosis

Differential diagnosis

A farm with signs of a vesicular disease in pigs should be considered infected with FMDV until proven otherwise. Specific vesicular lesions are also seen in some other virus infections, for example, in vesicular stomatitis, SVV infection, and vesicular exanthema. FMDV can be found in many parts of the world and is the most relevant differential diagnosis. Vesicular stomatitis is endemic in and restricted to the Western Hemisphere; it has rarely been diagnosed elsewhere. Since 2008, SVV has been frequently associated with vesicular disease, not only in North and South America but also in China (Hause et al. 2016; Qian et al. 2016). Vesicular exanthema is caused by a calicivirus and was last observed in the United States in 1956.

Pathological evaluation

Lesions in pigs initially start with blanching of the coronary band, and since it is often the posterior part of the interdigital space that is affected, this is most easily observed in a recumbent pig. The areas develop into large fluid-filled vesicles that rupture in 1–2 days, after which erosion-like lesions are observed. True vesicular lesions are only caused by a limited number of diseases (see above), but erosions seen after vesicular lesions have ruptured are not specific for SVD and can be due to various causes. Foot lesions not caused by SVDV infection are often observed in sows, with more than 60% of sows with lesions at the sole–heel junction (Anil et al. 2007; Geudeke 1992). Therefore, it is unlikely that hoof lesions in sows will result in a clinical report; it is more likely that nose or udder lesions (Figure 40.7) will result in notification by the farmer or his veterinarian.

Laboratory confirmation

Methods of virus detection

Virus isolation on IB-RS-2 cells (De Castro 1964) is considered one of the most sensitive methods for laboratory diagnosis. SK6, PK-15, and primary or secondary porcine kidney cells are also susceptible to SVDV (Callens 1999; Nardelli et al. 1968). Several RT-PCR techniques have been developed to detect SVDV (Lin et al. 1997; McMenamy et al. 2011; Niedbalski 2009; Reid et al. 2004). Recent RT-PCR techniques are often multiplex real-time RT-PCRs designed to differentiate between various vesicular diseases (Fernandez et al. 2008; Peng et al. 2015; Wang et al. 2015). RT-PCR is the first choice for detection of SVDV in feces or organs. Virus isolation takes more time and has a similar sensitivity. In vesicular material, however, the amount of virus is very high, and an ELISA can therefore easily be used for antigen detection and identification (Roeder and Le Blanc Smith 1987).

Methods of antibody detection

SVD is considered one single serotype, and, after an outbreak, surveys based on the detection of SVDV-specific antibody are essential to prove that no infected farms have been missed. After an SVDV infection, high titers of neutralizing antibodies are found (Nardelli et al. 1968). Virus neutralization (VN) tests, however, are laborious, and ELISA tests have been developed (Armstrong and Barnett 1989; Brocchi et al. 1995; Chénard et al. 1998; Dekker et al. 1995b; Hamblin and Crowther 1982). An ELISA is easier to perform than a VN test but produces more false-positive results. The specificity of the ELISA can be increased by using monoclonal antibodies (Brocchi et al. 1995; Chénard et al. 1998) and is therefore adopted as the standard test by the OIE.

Immunity

Immune responses

The immune response to infection is rapid. IgM is detectable in 50% of the pigs 4 days post inoculation (DPI), followed by an IgG response detectable in 50% of the pigs after approximately 12 DPI (Brocchi et al. 1995; Dekker et al. 2002). Based on several experimental infection studies with various SVDV strains, approximately 50% of the pigs will be positive in the SVD ELISA by 7 DPI and by day 8 in the VN test (Chénard et al. 1998).

Protective immunity

Experimental SVDV vaccines have been developed (Delagneau et al. 1974; Gourreau et al. 1975; McKercher and Graves 1976; Mowat et al. 1974). In addition to monovalent SVD vaccines, combinations with FMD (McKercher and Graves 1976; Mitev et al. 1978) and more recently a SVD subunit vaccine have also been described. No SVD vaccine is commercially available, and, to date, vaccination of pigs has not been undertaken in the field.

Maternal immunity

Piglets born to SVDV-infected sows receive antibodies against SVDV in colostrum. The half-life of these antibodies in piglets is longer (30–50 days) (Bellini et al. 2010b) than the half-life of anti-FMDV antibodies (7–21 days) found in piglets following FMD vaccination (Francis and Black 1984). This means that maternally derived antibodies can be found in piglets up to almost 6 months of age. This should be taken into account when interpreting results of serological tests on outbreak farms.

Prevention and control

Methods to treat pigs or control outbreaks

SVD is no longer listed by the OIE, but SVD is still considered a notifiable disease in many countries, particularly countries that export pigs and/or pork. In the face of trade embargos resulting from SVD outbreaks, stamping out infected herd(s) is the quickest method to control the outbreak and regain an SVD-free status.

Methods to prevent introduction of agent or avoid outbreaks

Although SVDV is resistant to environmental factors and many commonly used disinfectants (Terpstra 1992), pigs transported within cleaned and properly disinfected vehicles do not often get infected. Even on farms where infection is present in one compartment, the infection does not spread easily to other compartments if strict hygienic measures are applied. In the past, swill feeding has contributed significantly to transmission of SVD. Even if swill feeding is not allowed, pigs should not be allowed to come into contact with foodstuffs left by visitors or farm personnel.

Methods to eliminate agent from herds

Stamping out whole farms followed by thorough disinfection and cleaning is practiced to rapidly eliminate SVDV. Indirect evidence suggests that elimination of SVDV by partial depopulation is probably possible. Specifically, in the Netherlands (1995), antibodies against SVD were detected in fattening pigs, indicating that they had been exposed to SVDV. A test and removal procedure was followed, with the removal of seropositive animals followed by disinfection and thorough cleaning of the areas in which the positive pigs had been housed. After 3–4 rounds of testing and removal, the serological prevalence was reduced to zero. The success of this case can be explained by studies that have shown that transmission of SVDV is limited in subclinically infected pigs (Burrows et al. 1974). In contrast, transmission occurs very quickly in cases of clinical infection. Therefore, it is unlikely that partial depopulation will be successful if pigs are clinically ill.

Encephalomyocarditis virus

Relevance

EMCV is a rodent-borne virus first described in 1940 (Jungeblut and Sanders 1940). Later, EMCV was isolated from a chimpanzee with myocarditis in Florida (Helwig and Schmidt 1945), and anti-EMCV antibodies or EMCV were subsequently detected in a variety of animal species (Tesh and Wallace 1978).

Infection of swine with EMCV is not uncommon, but clinical disease is infrequent. During an outbreak of acute disease in Panama in 1958, Murnane et al. (1960) isolated EMCV from the lung and spleen of a pig that suddenly collapsed and died within a few minutes. This was the first time that EMCV had been recognized as a swine pathogen. In pigs, disease due to EMCV may take one of two main forms: an acute myocarditis, usually causing sudden death in young pigs, and/or reproductive failure in sows.

EMCV outbreaks with high mortality in pigs have been reported in Australia, South Africa, New Zealand, Cuba, and Canada (Acland and Littlejohns 1975; Dea et al. 1991; Seaman et al. 1986). In Europe, clinical disease caused by EMCV was first observed among domestic pigs in 1986 and has since increased in frequency. Outbreaks of acute myocarditis have been reported in Italy, Greece, Belgium, and Cyprus (Koenen et al. 1999; Vansteenkiste et al. 2016). EMCV outbreaks are often clustered in so-called endemic areas (Maurice et al. 2007). In Belgium, EMCV was also frequently isolated in cases of reproductive failure (Koenen et al. 1999). In the endemic area of Italy, a seroprevalence of between 5 and 15%, exceptionally more than 60%, was found in farms with clinical EMC in a high density breeding area (Salogni et al. 2016). In 50% of the farms without clinical EMC, a similar seroprevalence level was detected (Maurice et al. 2005). In the United Kingdom, antibodies against EMCV were detected in 28% of clinically normal slaughterhouse pigs (Sangar et al. 1977); however no attempt was made to isolate virus. In Asia, outbreaks associated with reproductive failure have been reported in China (Feng et al. 2015), as well as the seroprevalence of 7.7% in wild boar in South Korea (Jeoung et al. 2015).

Etiology

EMCV (species *Cardiovirus A*) belongs to the genus *Cardiovirus* of the family *Picornaviridae*. Several antigenically similar viruses, including Columbia-SK and Mengo, were isolated during the 1940s and are considered to be in the same serotype as EMCV (i.e. EMCV-1). A second serotype, EMCV-2, has been isolated from a wood mouse in Germany (Philips et al. 2012). Many properties of EMCV are common to other picornaviruses. It is ether resistant and stable over a wide range of pH. It is inactivated after 30 minutes at 60 °C (140 °F), but some strains have shown a marked thermal stability (Joo 1999).

Although EMCV is antigenically stable, the 1D (VP1 capsid protein) coding region of EMCV displays considerable genetic variability. A single mutation in the nucleotide sequence can be involved in attenuation or confer diabetogenicity to a particular EMCV strain (Nelsen-Salz et al. 1996). In particular, the Greek isolates appear to differ genetically from those isolated in Belgium, Italy, and Cyprus (Knowles et al. 1998).

EMCV replicates well in cell cultures originating from several animal species, including rodents, swine, and primates. BHK-21 and Vero cells are used most commonly. The virus also replicates in mice and chicken embryos and is pathogenic in many laboratory animals. Acute fatal disease is produced in mice and hamsters after inoculation by various routes. Neurological disease due to encephalitis has been reported, but myocarditis is more frequently seen at necropsy. Pathogenicity in rats, guinea pigs, rabbits, and monkeys appears to vary depending on the age of the animals and the virus strains used.

The virus has hemagglutinating activity with guinea pig, rat, horse, and sheep erythrocytes, but differences in this activity among EMCV strains have been reported (Kim et al. 1991). Serial passage of EMCV in cell culture can alter *in vitro* growth characteristics, reduce virulence, and affect hemagglutinating activity (Zimmerman 1994).

Public health

The impact of EMCV on public health is believed to be minimal. Despite the frequency of infection in swine, Zimmerman (1994) found no association between infection and transmission of disease to humans even in persons at greatest risk (veterinarians, animal caretakers, and laboratory staff). A serological survey indicated a seroprevalence of >17% in cities located within the tropical rain forest in Peru (Czechowicz et al. 2011). In 2011, in Mexico, seroconversion in 47% of blood samples taken from 85 swine-specialist veterinarians sampled during a congress was detected (Rivera-Benitez et al. 2014). In 2009, EMCV was isolated from people with febrile illness in Peru (Oberste et al. 2009). Interestingly these viruses were most closely related to EMCVs isolated from pigs in Europe.

In the light of the ubiquitous presence of EMCV around the world in several animal species, including primates after a rodent plague (Canelli et al. 2010), secondary infections in immunocompromised persons can be expected to occur. In addition, the risk related to EMCV infection may become more important if pigs are used as donors for human xenografts. The experimental infection of a mouse through the transplantation of pig organs infected with EMCV validated this concern. A 2012 study shows that a myocardial (B279/95) and a rat strain (1086C) productively infect primary human cardiomyocytes and induce complete cytolysis (Brewer et al. 2003; Hammoumi et al. 2012).

Epidemiology

At one time considered a disease of subtropical or tropical areas, EMCVs are now noteworthy for their widespread geographical distribution and large number of susceptible hosts. EMCV infection has now been identified by virus isolation or the presence of antibodies throughout the world. In certain countries, a seasonal pattern of the outbreaks, with peaks in autumn, was noticed (Maurice et al. 2007).

EMCV is generally regarded as a rodent virus, although EMCVs have been isolated from over 30 species of mammals and birds. In mammals, the host range includes monkeys, chimpanzees, elephants, lions, squirrels, mongoose, raccoons, and swine (both domestic and wild boar). An episode of lion deaths at a zoo was found to be due to feeding carcasses of African elephants that had died of EMCV infection (Simpson et al. 1977). Among all outbreaks in wildlife, those in elephants are best documented (Grobler et al. 1995; Hunter et al. 1998; Reddacliff et al. 1997). In rodents, the virus usually persists without causing disease (Acland 1989; Zimmerman 1994). Infected rodents show high levels of the virus in the heart, spleen, lung, pancreas, Peyer's patches, and thymus and excrete the virus in their feces and urine (Spyrou et al. 2004).

Since infected pigs can excrete the virus, at least for a short period, direct pig-to-pig contact and contact with infected dead pigs are potential routes of virus spread at the farm level (Billinis et al. 1999; Maurice et al. 2002). Transplacental transmission may also occur (Christianson et al. 1992; Koenen and Vanderhallen 1997; Links et al. 1986). Although rigorous risk studies are scarce, a factor related to the introduction and/or spread of EMCV into pig farms includes the presence of rodents, which may play a role as a virus reservoir and contribute to spread either in their feces or as infected carcasses (Acland 1989; Spyrou et al. 2004). Feed and water contaminated with EMCV by rodents or infected rodent carcasses are considered important sources of swine infection. These findings are confirmed by a

matched case–control study (Maurice et al. 2007) in an area in Belgium where clinical EMCV outbreaks were regularly reported. The data indicated clusters of factors: (1) rodents, (2) general farm setup, and (3) general hygiene are associated with clinical EMCV. However, the conclusion was that the presence of mice was the most significant risk factor for clinical EMCV infection. A simulation suggested that in a compartmentalized pig housing unit, one single EMCV introduction is unlikely to cause a major outbreak by direct pig-to-pig transmission alone. Other mechanisms such as multiple introductions from a rodent reservoir may be required for large outbreaks to occur (Maurice et al. 2016).

Pathogenesis

Natural infection of swine is most likely to occur by the oral route. The course of the infection in swine appears to be influenced by virus strain, exposure dose, passage history, and susceptibility of the individual animal. For example, some strains cause either reproductive failure or myocardial death, while others can give rise to both (Koenen and Vanderhallen 1997). Australian strains were shown to be more virulent than New Zealand strains (Horner and Hunter 1979; Littlejohns and Acland 1975), and certain isolates in Florida were found to cause only myocarditis without death (Gainer et al. 1968). Other critical factors, such as the route of infection and age of the pigs, were found to be important factors in the spread of the virus under experimental conditions (Billinis et al. 2004; Littlejohns and Acland 1975).

After experimental oral infections in young pigs, virus was demonstrated as early as 6 hours post inoculation in the intestinal tract. In the heart and tonsils, focal positive reactions were found only in the cytoplasm of isolated macrophages and myocardial cells during the first 30 hours post inoculation. After 30 hours, some animals died with typical postmortem lesions, and clear positive immunohistochemical reactions were observed in the tonsils and heart. Three days post infection, the virus was also isolated from blood. The highest virus titers were recovered from heart muscle, in both experimental and natural infections. Myocardial lesions were predominant at necropsy. Gelmetti et al. (2006) concluded that virus replication in the heart, the target organ, is followed by myocarditis, with severe myocarditis resulting in sudden death in susceptible pigs. Proinflammatory cytokines such as IL-1β, tumor necrosis factor-α (TNF-α), and IL-6 have been implicated in the pathogenesis of myocarditis caused by EMCV infections (Robinson et al. 2009).

The consequences of transplacental EMCV infection are not well understood. Following intramuscular infection of pregnant sows with EMCV, a transplacental infection resulting in fetal death was observed 2 weeks post inoculation. Early farrowing, abortion, and mummification were observed in sows infected in mid- or late gestation, while evidence for fetal infection in sows during early pregnancy was not conclusive (Koenen and Vanderhallen 1997; Love and Grewal 1986). Antibodies and virus were recovered from fetuses, but the lesions varied from none to large diffuse patches in the heart, depending on the experiment (Kim et al. 1989a; Koenen and Vanderhallen 1997). Infection of swine fetuses *in utero* with laboratory-passaged strains produced little pathology.

In rats experimentally infected with a myocardial EMCV strain, no clinical or macroscopic lesions were observed in any organs. Virus was isolated from several tissues from 3 DPI until the end of the observation at day 62. EMCV was most frequently isolated from Peyer's patches and thymus, even in rats killed at 60 DPI. This finding indicated that this tissue represented a site of persistence after oral infection (Spyrou et al. 2004). The virus has seldom been pathogenic for rabbits and rhesus monkeys, causing inapparent infections despite high levels of viremia. In mice, certain strains cause predominantly fatal encephalitis, widespread myocardial damage, or even specific destruction of pancreatic beta cells (Cerutis et al. 1989).

Clinical signs

Many EMCV infections in a wide range of species are nonlethal and probably subclinical. Younger pigs are generally more susceptible to developing clinical disease, especially in the first weeks of life. In young pigs, the infection is most commonly characterized by acute disease with sudden death due to myocardial failure. Other clinical signs such as anorexia, listlessness, trembling, staggering, paralysis, or dyspnea have also been observed. Experimentally infected swine (Craighead et al. 1963; Littlejohns and Acland 1975) have shown temperatures up to 41 °C (106 °F) and death at 2–11 DPI (usually 3–5 days), or occasionally recovery with chronic myocarditis. Extremely high mortality, approaching 100%, can occur in pigs of preweaning age (Joo 1999). Infections in pigs from post weaning age to adulthood are usually subclinical, although mortality may occasionally be observed, even in adult pigs. In experimental infections, Billinis et al. (2004) found a high fatality rate in 20- and 40-day-old pigs, but none of the challenged 105-day-old pigs died.

In breeding females, clinical signs may vary from inapparent infection to various forms of reproductive failure, including abortion and increased numbers of mummified and stillborn fetuses (Dea et al. 1991; Koenen and Vanderhallen 1997).

Lesions

Pigs dying from the acute phase of cardiac failure may show only epicardial hemorrhage and no gross lesions.

Hydropericardium, hydrothorax, and pulmonary edema are frequently observed at necropsy. The heart is usually enlarged, soft, and pale. The most striking lesions are found in the myocardium where multiple foci of various sizes are found, especially in the right ventricle, which may extend to varying depths within the myocardium. They are often ill defined, circular, and linear and grayish/white in color (Figures 40.8 and 40.9). These lesions are observed more frequently in fattening pigs than in suckling piglets (Littlejohns and Acland 1975).

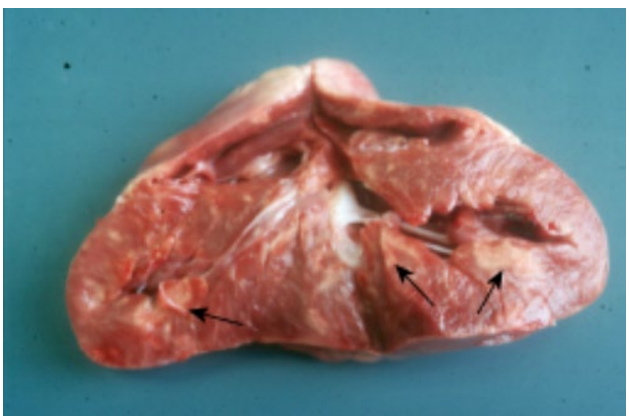

Figure 40.9 Sagittal section of the heart of pig with EMCV infection showing multiple foci of various sizes especially in the right ventricle, extending to varying depths. *Source:* Regional Animal Health Centre, Flanders, Torhout, Belgium. Reproduced with permission of John Wiley and Sons.

Infected fetuses are usually apparently normal, but can be hemorrhagic and edematous. With some virus strains, the fetuses can become mummified in various states of development, depending on the stage of infection. Macroscopic myocardial lesions are exceptional.

Histopathologically, the most significant findings in young pigs are seen in the heart. A positive immunohistochemical reaction is chiefly localized to the cytoplasm of myocardial cells. Its intensity and distribution is in accordance with the severity of the lesions. Sometimes, the positive reaction is detected in the Purkinje fibers and in the endothelial cells next to these. Mineralization of necrotic heart muscle is common (Figure 40.10) but not always present. In the tonsils, a positive immunohistochemical reaction is located in necrotic debris filling the crypts and in the cytoplasm of monocyte–macrophage lineage cells. This last finding was also noticed in lymph nodes (Gelmetti et al. 2006; Papaioannou et al. 2003; Psychas et al. 2001). Congestion with meningitis, perivascular infiltration with mononuclear cells, and some neural degeneration may be observed in the brain (Acland and Littlejohns 1975). Nonsuppurative encephalitis and myocarditis have also been described in swine fetuses with natural EMCV infection (Kim et al. 1989b).

Diagnosis

In newborn and suckling piglets, the disease is often characterized by sudden death between 3 days and 5 weeks of age. In most cases the piglets are found dead without any clinical signs. In finishing pigs, sudden death is also the most characteristic sign. All age categories can be affected, but mostly pigs of 60–70 kg (130–155 lbs.) are involved. The disease is often restricted to one barn, and deaths often occur in the late afternoon when the pigs are most active. In some pigs, squealing can be heard just before dying. In others dyspnea can be noticed.

A clinical history of reproductive failure and preweaning mortality is a useful indication of EMCV infection (Joo 1999). EMCV-induced reproductive problems should be differentiated from other pathogens causing reproductive problems in sows. EMCV causes reproductive failure in sows of all parities, while porcine parvovirus infection is manifested by an increase in mummification, mainly in gilt litters, without neonatal mortality. Other infections such as FMD, porcine reproductive and respiratory syndrome (PRRS), pseudorabies, porcine circovirus, and leptospirosis should also be considered.

Histopathological lesions may play an important role in making a diagnosis. A variable degree of nonsuppurative interstitial myocarditis or encephalitis (infiltration of lymphocytes, histiocytes, and plasma cells) is indicative of EMCV infection.

A conclusive diagnosis of EMCV should be demonstrated by virus isolation in mice or cell culture. BHK-21 cells are the most sensitive, but HeLa or Vero cell lines are also commonly used. Infected cell monolayers show a rapid and complete cytopathic effect (CPE). Virus identification can then be made by cross-serum neutralization with a reference antiserum or by staining with an anti-EMCV fluorescent antibody conjugate. Molecular methods, such as nucleic acid probes or RT-PCR for the detection of EMCV, have been reported (Kassimi et al. 2002; Vanderhallen and Koenen 1997; Yuan et al. 2014). Molecular methods are more sensitive and specific for diagnosis, especially when followed by sequencing.

Serological tests for the detection of serum antibodies against EMCV include hemagglutination inhibition (HI), ELISA, latex agglutination, immunofluorescent antibody (IFA) assay, agar-gel immunodiffusion (AGID), and VN. The VN and ELISA are the most commonly used methods and have been shown to be specific. For VN, antibody titers of ≥1 : 16 appear to be significant (Joo 1999).

Immunity

Neutralizing antibodies can be detected as early as 5–7 days after inoculation and may persist for an extended period (from 6 months to 1 year). Maternal antibodies remain for at least 2 months.

Proinflammatory cytokines such as IL-1β, TNF-α, and IL-6 have been implicated in the pathogenesis of myocarditis caused by EMCV infections (Robinson et al. 2009).

EMCV exists as two serotypes (although only a single isolation of EMCV-2 has been described; Philipps et al. 2012). Within EMCV-1 there is little antigenic variation; therefore cross-protection between all EMCV strains is likely to occur. No cross-neutralization was found between EMCV-1 and 62 human enterovirus serotypes or 11 porcine "enterovirus" serotypes (Zimmerman 1994). As discussed elsewhere in this chapter, most of these "enteroviruses" are now classified as teschoviruses.

Prevention and control

There is no treatment for the disease, but, in the acute phase, mortality may be minimized by avoiding stress or excitement of the pigs at risk. Rodents are often thought to play a role in the introduction and subsequent spread of EMCV on farms. Therefore, pig producers, especially in endemic areas, are advised to maintain rodent control to prevent clinical outbreaks of EMCV.

Pigs exposed to manure through slatted floors or to movement of manure between manure pits were found to be significantly protected against EMCV (Maurice et al. 2007), perhaps due to low-level exposure leading to subclinical infections.

The virus can be inactivated in water containing 0.5 ppm residual chlorine. For disinfectants, iodine-based preparations or mercuric chloride can be used.

An inactivated EMCV-1 vaccine is commercially available in the United States. The vaccine produced a strong humoral immune response in vaccinated pigs, and vaccinates were protected from clinical disease when challenged with virulent EMCV that killed 60% of unvaccinated controls. Also, protection against transplacental infection was demonstrated under experimental conditions. An EMCV vaccine candidate composed of noninfectious viruslike particles (VLPs) has been described (Jeoung et al. 2012).

Porcine teschovirus

Relevance

The first evidence of PTV infection was the occurrence of Teschen disease, a pig polioencephalomyelitis with high mortality, in Czechoslovakia over 75 years ago (Kouba 2009). PTVs are ubiquitous, and no conventional herd of pigs has been shown to be free of infection. While the majority of infections are subclinical, PTVs have been associated with a variety of clinical conditions, including polioencephalomyelitis, reproductive disease, enteric disease, and pneumonia. Strains that have not been shown to be pathogenic were previously referred to as enteric cytopathic swine orphan (ECSO) or enteric cytopathic porcine orphan (ECPO) viruses, but these terms are no longer in general use.

Etiology

PTVs were originally classified as PEVs. More recently, the genomic sequences of the prototype strains of all the PEV/PTV serotypes have been determined, as well as

partial genomic data on a number of additional isolates (Doherty et al. 1999; Kaku et al. 1999, 2001; Zell et al. 2001). Comparative analyses of these data showed that the PEVs fell into three genetic groups: (1) PEV types 1–7 and 11–13, (2) PEV type 8, and (3) PEV types 9 and 10. Prior to reclassification, PEVs were divided into three subgroups based on physicochemical properties, type of CPE produced in PK cells, and different cell culture host ranges (Knowles et al. 1979). The new classification scheme corresponds with the CPE groups defined earlier. The CPE group I viruses also possessed a leader polypeptide and a 2A/2B cleavage mechanism similar to the aphthoviruses, cardioviruses, and erboviruses.

Thus, the 10 former PEV serotypes 1–7 and 11–13 were renamed PTV-1 to PTV-10 and reclassified as a single species, *Teschovirus A* (former species name *Porcine teschovirus*), in a new genus, *Teschovirus*. Three additional types, PTV-11 to PTV-13, were also designated based on serological and/or molecular sequence data (Boros et al. 2012b; Cano-Gómez et al. 2011a; Zell et al. 2001). The remaining three PEV serotypes 8–10 are now classified in two species, *Sapelovirus A* (PEV-8, renamed PSV-1) and *Enterovirus G* (PEV-9 and PEV-10, renamed EV-G1 and -G2), in the genera *Sapelovirus* and *Enterovirus*, respectively.

As with all picornaviruses, the virions of PTVs are spherical and non-enveloped, with a diameter of 25–30 nm. A single-stranded RNA genome is surrounded by an icosahedral capsid consisting of 60 copies of four polypeptides. A small basic virus-encoded protein (VPg) is linked to the 5′ end of the genome. No three-dimensional structure data are yet available.

The serotypic classification of PTVs is based upon the VN tests (Dunne et al. 1971; Knowles et al. 1979). In the 1960s and 1970s, there were numerous attempts to achieve a uniform classification of PEVs, and these studies culminated in a classification of eight serotypes (Dunne et al. 1971). This was later extended to 13 serotypes (Auerbach et al. 1994; Knowles et al. 1979) (Table 40.1). A complement fixation test, suitable for rapid screening and typing of PTVs/PEVs, has also been described (Knowles and Buckley 1980). Subsequent findings (Knowles 1983) suggested that additional serotypes may exist. Honda et al. (1990b) compared the prototype strains found in Japan with 11 internationally recognized PTV serotypes by VN and suggested a further four candidate serotypes. Some limited cross-reactivity among the existing serotypes was evident, and Hazlett and Derbyshire (1978) showed that gastrointestinal antibodies were more broadly specific than serum antibodies.

PTVs are stable when treated with lipid solvents and relatively stable to heat. However, heating in the presence of halide ions tends to destabilize the virus. PTVs are stable at pH 2–9. Hemagglutination has not been demonstrated.

PTVs are readily cultivated in the laboratory in cell cultures of porcine origin. They are normally grown in primary or secondary PK cell cultures or in established cell lines such as IB-RS-2, but they may also be cultivated in other cells of porcine origin, such as the SST cell line, or in primary swine testes cells (Knowles et al. 1979).

Public health

PTVs are not known to be infectious for humans.

Epidemiology

Teschen disease has continued to occur sporadically, mainly in Central Europe but also in Africa. Milder forms of polioencephalomyelitis (Talfan disease, benign enzootic paresis), caused by serologically related but less virulent strains of PTV, have been reported in the last 50 years in Western Europe, North America, and Australia.

The only known natural host for PTVs is the pig. The virulent PTV-1 strains associated with classical Teschen disease appear to be restricted to those areas in which the disease occurs and they have not been isolated in North America. Less virulent PTV-1 strains and representatives of the other PTV serotypes appear to be ubiquitous.

Transmission of PTV infection is most frequently by the fecal–oral route, and indirect transmission by fomites is likely to occur since the viruses are relatively stable.

Endemic infection with several PTV serotypes can usually be demonstrated in conventional herds and is probably maintained in groups of weaned piglets. Singh and Bohl (1972) demonstrated waves of infection with six different serotypes over a period of 26 months in a long-term study of infection in a single herd. Piglets normally acquire infection shortly after weaning, when maternally derived antibodies are withdrawn and pigs from several litters are mixed, and it persists for at least several weeks. Adults rarely excrete virus but have high antibody levels. Pigs of any age are, however, fully susceptible to infection with a virus belonging to a serotype to which they have not previously been exposed.

PTVs are highly resistant to inactivation in the environment and may survive for long periods in liquid manure. Likewise, PTVs are relatively resistant to many disinfectants. Of 10 commonly used disinfectants tested by Derbyshire and Arkell (1971) against the Talfan virus, only sodium hypochlorite was effective.

Pathogenesis

Natural infection occurs by ingestion of the virus. It is well established (Long 1985) that initial replication occurs in the tonsil and intestinal tract. The large intestine and ileum are infected more frequently than the upper small intestine, and the former tissues contain

higher titers of virus. It has not been clearly established which cells in the intestine support viral replication, but by analogy with experiments on poliovirus (Kanamitsu et al. 1967), it is probable that the reticuloendothelial tissue of the lamina propria is involved. Epithelial cell destruction is not a feature of these infections. Viremia follows regularly in infections with the virulent PTV-1 strains, but less regularly with the less virulent strains, and leads to infection of the CNS (Holman et al. 1966).

It may be assumed that the pregnant uterus is also infected by viremic spread of the virus, since embryonic or fetal infections were demonstrated in gilts following nasal or oral inoculation of PTV (Huang et al. 1980). Intranasal inoculation of the virus may lead experimentally to lung infection (Meyer et al. 1966), but the significance of the natural inhalation of viral aerosols is not known. It has also been clearly demonstrated that when piglets are inoculated parenterally with PTVs, the virus rapidly infects the intestine. Extraintestinal infections are relatively transient, whereas the virus persists in the large intestine for several weeks.

Clinical signs

Although PTV infections are most frequently subclinical, various clinical syndromes have been associated with certain serotypes (Table 40.3) as outlined below.

Polioencephalomyelitis

The most severe form of polioencephalomyelitis is produced by the highly virulent PTV-1 strains that cause Teschen disease. This is a disease of high morbidity and high mortality, affecting all ages of swine and associated with major economic losses. The early signs of Teschen disease include fever, anorexia, and listlessness, rapidly followed by locomotor ataxia. In severe cases, there may be nystagmus, convulsions, opisthotonus, and coma. Paralysis ensues and the animal may assume a dog-sitting posture or remain in lateral recumbency. Stimulation by sound or touch may elicit uncoordinated limb movements or opisthotonus. Death is commonly within 3–4 days of the onset of clinical signs. Since the appetite returns after the acute phase, some animals may be kept alive by careful nursing, but these cases show muscle wasting and residual paralysis.

The less virulent PTV-1 strains (Talfan disease, benign enzootic paresis) and strains belonging to other serotypes associated with polioencephalomyelitis produce a milder disease with relatively low morbidity and mortality. Mainly young pigs are affected, and the disease rarely progresses to complete paralysis. Encephalomyelitis due to teschovirus infection has been reported in pigs in both the United States (Pogranichniy et al. 2003) and Japan (Yamada et al. 2004). Cesarean-derived colostrum-deprived pigs intravenously inoculated with PTV-2 and PTV-11, isolated from US swine, developed neurological signs consistent with teschovirus encephalomyelitis with more severe neurological signs observed in PTV-11-inoculated pigs (Matias Ferreyra et al. 2017).

Reproductive disorders

The term SMEDI was introduced initially (Dunne et al. 1965) to designate a group of viruses, subsequently shown to be PTVs, that had been isolated in association with stillbirth (S), mummified fetuses (M), embryonic death (ED), and infertility (I). Subsequent studies by the same group of workers and by others (Pensaert et al. 1973; Pensaert and De Meurichy 1973) indicated that the SMEDI could be reproduced experimentally. However, it is now well established that parvovirus infection may also lead to ED and fetal mummification and parvoviruses may be more frequently associated with these disorders of early and mid-gestation. Other findings (Cropper et al. 1976) substantiate a role for both PTV and parvoviruses in these disorders. Experimental (Bielaaski and Raeside 1977) and field (Kirkbride and McAdaragh 1978) data confirm an association between teschovirus infection and abortion in swine. These reproductive disorders are not usually accompanied by clinical signs in the sow or gilt. PTVs have also been isolated from the male genital tract (Phillips et al. 1972).

Table 40.3 Natural or experimental clinical syndromes associated with porcine enteric picornavirus infection.

Syndrome	PTV serotypes	Other picornaviruses
Polioencephalomyelitis	PTV-1, PTV-2, PTV-3, PTV-5, PTV-11	—
Reproductive disorders	PTV-1, PTV-3, PTV-6	PSV
Diarrhea	PTV-1, PTV-2, PTV-3, PTV-5	PSV
Pneumonia	PTV-1, PTV-2, PTV-3	PSV
Pericarditis and myocarditis	PTV-2, PTV-3	—
Cutaneous lesions	—	PEV-9, PEV-10

Diarrhea

The role of PTVs as enteric pathogens is uncertain. They have frequently been isolated from the feces of piglets with diarrhea, but since they can be readily isolated from normal piglets, particularly post weaning, and since diarrhea can be caused by a variety of other viral and bacterial agents, their presence may be coincidental. However, diarrhea has been produced experimentally by PTVs in piglets believed to be free of other pathogens. The diarrhea is mild and relatively transient, and it seems clear that PTVs are considerably less important enteric pathogens than rotaviruses or coronaviruses. When piglets were infected with PTVs together with rotaviruses, the disease was less severe than in piglets infected only with the rotavirus (Janke et al. 1988).

Pneumonia, pericarditis, and myocarditis

The role of PTVs as respiratory pathogens is also uncertain. It is probable that alone they rarely cause clinical signs of respiratory disease. Experimentally, two serotypes of PTV have been shown capable of producing pericarditis, and in one experiment myocardial involvement occurred (Long et al. 1969). These findings might lead to a suspicion of teschovirus infection in the case of sudden death in piglets, although EMCV would be higher on the list of differentials.

Possible association with cutaneous lesions

During the course of investigations of SVD outbreaks in the United Kingdom, many adventitious agents were isolated from samples of epithelium and feces. Most of these isolates were identified as teschoviruses or enteroviruses (Knowles 1983).

Lesions

No specific changes have been associated with intestinal PTV infections. They do not appear to cause the villous atrophy characteristic of primary intestinal pathogens, such as coronaviruses and rotaviruses. Other than muscle atrophy in chronic cases, no gross lesions are found in polioencephalomyelitis. The histological lesions associated with the latter are widely distributed in the CNS but are especially numerous in the ventral columns of the spinal cord, the cerebellar cortex, and the brain stem. The changes are more marked and extensive in Teschen disease than in milder encephalomyelitides, such as Talfan disease. The neurons show progressive diffuse chromatolysis (Koestner et al. 1966) and focal areas of gliosis and perivascular lymphocytes, particularly over the cerebellum, that may also occur.

The SMEDI syndrome is remarkable for the lack of specific lesions in stillborn or neonatal piglets, although mild focal gliosis and perivascular cuffing in the brain stem have been found occasionally. Placental changes are restricted to nonspecific degeneration.

Pneumonic lesions have been produced by several investigators. Smith et al. (1973) described areas of grayish-red consolidation in the ventral anterior lobes of lungs infected with a PTV-2 strain. Exudates were observed in the alveoli and bronchi, as well as slight perivascular and peribronchiolar cuffing and some hyperplasia of the bronchiolar epithelium.

A PTV-3 strain consistently produced serofibrinous pericarditis experimentally, and the more severely affected piglets showed focal myocardial necrosis (Long et al. 1969).

Diagnosis

Teschen disease (also known as teschovirus encephalomyelitis) is designated as a notifiable disease by the OIE and details of internationally accepted diagnostic methods are described (OIE 2008).

The occurrence of clinical signs associated with polioencephalomyelitis is suggestive of viral infection, but the differentiation of teschoviral infection from other neurotropic viruses requires isolation of the virus from the CNS, the demonstration of viral antigen by specific immunofluorescence, or the detection of viral RNA by RT-PCR. Similarly, with reproductive disorders, diarrhea, pneumonia, pericarditis, and myocarditis, there are no diagnostic clinical signs that would suggest PTV involvement, and laboratory diagnosis is required.

Virus detection

Virus isolation from the CNS requires the collection of tissues from a piglet showing early nervous signs. Animals that have been paralyzed for several days may no longer contain infectious virus in the CNS (Lynch et al. 1984). The virus may be isolated in PK cell cultures from suspensions of the spinal cord, brain stem, or cerebellum. The virus may subsequently be identified on the basis of its physicochemical characteristics or by immunostaining (Watanabe et al. 1971). Serological identification of the isolate is desirable. Isolation of a PTV from the gastrointestinal tract of a piglet with nervous signs does not establish the etiology of the disease, since the enteric infection may be coincidental.

In the SMEDI syndrome, mummified fetuses carried to term rarely contain live virus but may contain viral antigen detectable by immunofluorescence. Virus isolation in PK cell culture may be attempted from tissues of aborted or stillborn fetuses. Lung tissue appears to be the most reliable source for the isolation of PTVs from fetuses (Huang et al. 1980). VN test on the body fluids of such fetuses can be carried out against the SMEDI-associated PTV serotypes.

In the investigation of pneumonia or diarrhea, virus isolation from the respiratory or intestinal tract may be attempted, but the virological findings should be interpreted cautiously, especially in relation to diarrhea, since enteric infections with PTVs are common in healthy piglets. In one study PTVs and PEVs were isolated from 57% of porcine fecal samples submitted for SVD diagnosis over a 7-year period (Knowles 1983).

Isolated viruses may be identified by VN (Knowles et al. 1979), complement fixation (Knowles and Buckley 1980), or immunofluorescence (Auerbach et al. 1994; Dauber 1999) tests if suitable reference reagents are available. Monoclonal antibodies capable of detecting PTVs have been described (Dauber 1999).

Genomic sequence data are available for all the PTVs, and it is possible to use RT-PCR to detect viral RNA in clinical samples or to identify viruses isolated in cell culture. Palmquist et al. (2002) described an RT-PCR using a single set of primers for the simultaneous detection and differentiation (based on amplicon size) of PTVs and PSV. Nested RT-PCR assays to specifically detect PTV-1 and to differentiate PTV, PSV, and PEVs from each other using virus-specific primer sets have also been described (Zell et al. 2000). Improvements to these assays resulted in the development of a one-step real-time PCR (Cano-Gómez et al. 2011b; Chiu et al. 2014; Krumbholz et al. 2003; Zhang et al. 2013).

Antibody detection

Serology is of little value for diagnosis, unless paired sera are available and the serotype known, in which case VN would be suitable. An ELISA suitable for mass screening has been described for the detection of antibodies against Teschen disease virus (Hubschle et al. 1983). However, as these viruses are ubiquitous, serological surveys may not be very helpful.

Immunity

Infected pigs mount a classical humoral protective immune response (IgM and IgG). Mucosal immunity (IgA) may be produced and have a protective effect in the gastrointestinal tract. In an experimental study of PTV infection in piglets, it was shown that cell-mediated responses were weak, localized, and not associated with significant antiviral activity (Brundage et al. 1980).

Humoral antibody is thought to be important for protection. Immunosuppression of pigs infected with a PTV by cyclophosphamide treatment led to the lack of a serological response and a persistent infection of the intestinal tract (Derbyshire 1983). This resulted in severe diarrhea and, in one case, signs of encephalomyelitis. Presence of high levels of virus-neutralizing IgA antibody in the gastrointestinal tract may protect against oral challenge (Hazlett and Derbyshire 1977).

Since antibody is probably the most important factor in protection, at least for teschoviruses, the relatively large number of serotypes would suggest that cross-protection might not occur.

It has been reported for PTV-1 that maternal antibody has no effect on embryonic or fetal infections after the virus has reached the uterus (Huang et al. 1980). However, preinfection antibody in sows would probably limit infection and prevent the virus from reaching the uterus. Colostral antibody would be expected to protect piglets from infection.

Prevention and control

As with most viral infections, control measures for PTV depend on prevention rather than treatment. Potential antiviral chemotherapeutics for porcine enteric picornaviruses have received little attention. Piglets with mild polioencephalomyelitis may recover if nursing care is provided during the period of transient paresis.

Vaccination has been practiced in the field only for the control of Teschen disease. The earlier Teschen disease vaccines, containing inactivated virus of pig tissue origin, have been superseded by attenuated or inactivated cell culture vaccines. Mayr (1959) attenuated Teschen disease virus by cell culture passage and showed that live or formalin-inactivated vaccines prepared from this virus induced similar levels of protection in piglets. Success has been claimed for a Teschen disease eradication program involving ring vaccination and slaughter (Schaupp 1968). Restrictions on the import of swine and pork products from areas in which Teschen disease is endemic seem to be effective in limiting the spread of virulent PTV-1 strains.

Vaccination has not been practiced against the milder forms of polioencephalomyelitis or against the other clinical manifestations of PTV infection in swine. Only the SMEDI syndrome is of sufficient economic importance to justify specific control measures in the field, but the multiplicity of serotypes that may be involved complicates the development of an effective vaccine.

Currently, the best approach for the prevention of reproductive disorders associated with PTVs is the application of management practices that ensure that gilts are exposed to the infection with endemic viruses at least 1 month before breeding. This can be achieved naturally if the animals remain in a single building from birth to breeding, with thorough mixing of piglets from different litters at weaning. If breeding stock is segregated at an early age, they should be exposed to fecal material from recently weaned piglets. This can be readily accomplished by "feedback," that is, adding fresh feces to the feed of gilts or by dosing gilts with capsules of feces derived from a pooled sample collected from weaned piglets in several pens. The objective is to ensure exposure to the widest possible range of the viruses present in

the herd. The operation of a closed herd system reduces the risk of introducing extraneous viruses, but it is not possible to eliminate this risk, since the relatively resistant enteric picornaviruses can be transmitted by a variety of fomites. If the introduction of fresh stock is essential for breeding purposes, before the gilts or sows are bred, they should be exposed by feedback to any virus that may be present or introduced.

Exclusion of PTVs by repopulation of herds with specific-pathogen-free (SPF) stock seems to be difficult or impossible to achieve over a prolonged period. At least, these viruses have been isolated from commercial SPF herds, and the accidental introduction of Talfan virus into SPF gilts maintained under strict isolation has been described (Parker et al. 1981). Since transplacental infection of fetuses may occur, even gnotobiotic pigs may be infected.

Seneca Valley virus

Relevance

Between 1988 and 2001, 11 antigenically related picorna-like viruses were isolated from samples taken from pigs in various states in the United States. In 2002, a picorna-like virus (named Seneca Valley virus) was isolated at Genetic Therapy Inc. (Gaithersburg, MD, USA) while cultivating adenovirus 5-based vectors in PER.C6 cells (Hales et al. 2008). Comparison of the nucleotide sequences of these viruses led to the recognition that these were all the same virus, and the name Seneca Valley virus was adopted (Hales et al. 2008; Knowles et al. 2006).

Since 1997, an increasing association of SVV with idiopathic vesicular disease led to the recognition of the role of the virus in vesicular disease outbreaks in pigs (Knowles et al. 2006; Pasma et al. 2008; Singh et al. 2012). Coinfection with other porcine viruses seemed necessary for induction of vesicular lesions in pigs, and earlier efforts to reproduce the disease in pigs experimentally inoculated with SVV were futile (Yang et al. 2012). However, in recent outbreaks in Brazil and the United States in 2014 and 2015, SVV seemed to be the sole virus isolated from sick pigs, implicating SVV as a direct cause of vesicular disease in pigs (Leme et al. 2016a). Subsequently, vesicular lesions were induced in pigs following experimental inoculation with 2015 US isolates of SVV (Joshi et al. 2016b, Montiel et al. 2016).

Etiology

SVV is a picornavirus in the species *Senecavirus A* (formerly called *Seneca Valley virus*) in the genus *Senecavirus* (Knowles et al. 2012). All known SVV isolates belong to a single serotype, SVV-1. They also form a single genetic lineage, leading to the conclusion that they have a recent common origin (Knowles et al. 2016). Although referred to as Senecavirus A or Seneca A virus in recent publications, the virus common name is Seneca Valley virus.

The genome of SVV consists of approximately 7,310 nucleotides and encodes a single polyprotein of 2181 aa (Hales et al. 2008). This polyprotein is posttranslationally cleaved into 12 mature proteins (including a leader polypeptide with unknown function). Four of these proteins – 1A (VP4), 1B (VP2), 1C (VP3), and 1D (VP1) – form the virus capsid (Venkataraman et al. 2008), and one of these proteins, 3B (VPg), is linked directly to RNA. The nsp are involved in virus replication and interruption of host cell functions.

SVV can be grown in a number of different cells including PK-15, IB-RS-2, lamb kidney, Vero, LLC-MK2, and RK-13 (NJ Knowles, unpublished data), LFBKαVβ6, swine testis (ST), swine kidney (SK-RST), and human lung cancer cells (NCI-H1299) (Goolia et al. 2017; Yang et al. 2012). Identification may be achieved by standard serological assays (e.g. VN or ELISA) using suitable antisera such as monoclonal antibodies (Yang et al. 2012). Competitive ELISA, conventional RT-PCR, and real-time SYBR Green and Taqman® RT-PCR assays (rRT-PCR) have been developed (Bracht et al. 2016; Fowler et al. 2017; Leme et al. 2015; Yang et al. 2012).

Public health

SVV has no known public health significance. In fact one isolate, SVV-001, has been developed as a cancer therapy due to its ability to kill cancerous, but not normal, human cells (Burke 2016; Reddy et al. 2007).

Epidemiology

SVV was first found in 1988 in pigs in the United States. Since then SVV has been isolated from pigs in at least 10 states (California, Illinois, Iowa, Kansas, Louisiana, Minnesota, New Jersey, North Carolina, Ohio, and South Dakota). More recently there has been an increase of vesicular disease in the United States along with the isolation of SVV (Baker et al. 2017; Canning et al. 2016; Gimenez-Lirola et al. 2016; Guo et al. 2016; Hause et al. 2016; Wang et al. 2016). In 2007, SVV was isolated from imported pigs in Minnesota that were traced to pig farms in Manitoba, Canada, where the virus was also detected (Pasma et al. 2008). Later, SVV was also found in the brain of a pig in Canada in 2011 and 2016 (L.G. Koster and M.L. Killian, unpublished data). Since late 2014, SVV has also been found in pigs in the Goias, Minas Gerais, Paraná, and Santa Catarina states of Brazil (Laguardia-Nascimento et al. 2016; Leme et al.

2015, 2016b; Vannucci et al. 2015); in the Guangdong and Hubei provinces of the People's Republic of China (Qian et al. 2016; Wu et al. 2016, 2017); in Lamphun Province in the northern region of Thailand (Saeng-chuto et al. 2018); and in central western Colombia (Sun et al. 2017).

Only pigs are known to be infected by the virus, although there have not been comprehensible serological surveys of other domesticated or wild animals. Vesicular disease (indistinguishable from FMD, SVD, VS, and VES) has been reproduced experimentally in pigs (Joshi et al. 2016b; Montiel et al. 2016).

It is not understood how SVV is transmitted, but it is likely to be by the fecal–oral route or via cuts and abrasions. Vertical transmission has been suggested, but not proven (Leme et al. 2016b).

SVV RNA has been detected in the tonsils of experimentally infected pigs for up to 38 DPI by rRT-PCR and *in situ* hybridization (Joshi et al. 2016b). It has been postulated that virus shedding may occur via the feces or in urine (Leme et al. 2016b). Ruptured vesicles are also a source of virus.

Little is currently known about the persistence of the virus in the environment; however, SVV has been isolated from mice and houseflies on a farm where SVV-induced vesicular disease was present (Joshi et al. 2016a). Nucleotide sequence studies showed that the viruses present in pigs, mice, and flies were essentially identical (Joshi et al. 2016a).

Accelerated hydrogen peroxide® and Virkon® have been found to be effective disinfectants against SVV for use in the laboratory (Hole et al. 2017). Other commonly used disinfectants that are used for SVD (e.g. iodophors) may be suitable for use with SVV, but have not been tested.

Pathogenesis

Little is known about virus entry. Virus or virus RNA has been detected in epithelial tissues, tongue, gingiva, myocardium, lung, renal pelvis, liver, urinary bladder, brain, and small intestine (Leme et al. 2016b). There are no known virulence factors, but stress, especially during transportation, is postulated to be a predisposing factor for SVV-associated vesicular disease (Baker et al. 2017, Joshi et al. 2016b).

Clinical signs

The virus has a relatively short incubation period since in experimentally infected animals viremia was detected at 3 DPI and lesions observed at 4 DPI (Joshi et al. 2016b; Montiel et al. 2016). Clinical signs observed in the field included lameness in up to 80–90% of pigs, as well as vesicles and erosions on the coronary bands and snouts. Fever and loss of condition are negligible in adult pigs, and no adverse effects on farrowing were observed in pregnant sows (Baker et al. 2017; Pasma et al. 2008; Vannucci et al. 2015). Experimentally, clinical signs are characterized by lethargy and lameness at 4 DPI that persisted for 2–10 days (Joshi et al. 2016b). Vesicular lesions were first observed at 4 DPI on the snout and/or feet, affecting the coronary bands, dewclaws, interdigital space, and heel/sole of SVV-infected animals (Joshi et al. 2016b). A short viremia was observed between 3 and 10 DPI, whereas virus shedding was detected between 1 and 28 DPI in oral and nasal secretions and feces (Joshi et al. 2016b).

Although neonatal piglets do not typically show vesicular lesions like sows, other clinical signs of SVV infection have been observed in this age group. During outbreaks in Brazil in 2014–2015, one-week-old or younger piglets developed diarrhea accompanied by muscle weakness, reduced activity, increased salivation, and some neurologic signs. Redness of the skin and sudden deaths were also observed in this age group. Because SVV had been detected in sows from the same farms, it was suspected to be the cause of the clinical signs in neonates. Furthermore, SVV was detected in tissues from piglets that died suddenly. Piglets that survived usually recovered in 3–10 days (Leme et al. 2016a; Vannucci et al. 2015).

Morbidity and mortality

Some increase in mortality has been associated with SVV infection (Baker et al. 2017; Segalés et al. 2017). In Brazil, 20–30% mortality in neonatal piglets was recorded in farms where sows had developed SVV-associated vesicular lesions a week prior. Earlier reports in 2014 suggested even higher mortality (30–70%) in piglets ≤4 days of age. Pigs with sudden death were examined at necropsy, and SVV detected in multiple tissues, suggesting that SVV infection might have been responsible for the neonatal mortality (Leme et al. 2016a; Vannucci et al. 2015). Mortality is rare in adult pigs.

Lesions

In one study the principal gross findings included faint rib impressions on the pleural surface of the lungs, diphtheritic glossitis, and ulcerative lesions at the coronary band (Leme et al. 2016b). Histopathology revealed interstitial pneumonia, myocarditis, diphtheritic glossitis, encephalitis, and atrophy of intestinal villi with vacuolation of the superficial epithelial cells (Leme et al. 2016b). Immunohistochemistry with SVV-specific monoclonal antibodies demonstrated immunoreactivity of the choroid plexus of the cerebrum, degenerate epithelium of ulcerative lesions of the tongue, the urothelium of the kidney and urinary bladder, and the superficial cells of

the intestine (Leme et al. 2016b). Experimentally, within 4 DPI, 50% of pigs had intact or ruptured vesicular lesions on the coronary bands or the interdigital spaces (Montiel et al. 2016). Minimal to mild lameness occurred in some animals. After 5 DPI, almost 100% of pigs had vesicular lesions. Lesion severity ranged from blanched coronary bands to ulcerations and erosions from ruptured vesicles. Focal necrosis and crusting of either the interdigital space, the coronary band, or both developed in some animals. Severe lesions in a subset of the cohort progressed to multifocal deep ulcers. In general, vesicular lesions were 0.2–2 cm in diameter (Montiel et al. 2016).

Diagnosis

The vesicular lesions caused by SVV are indistinguishable from those produced by FMD, SVD, VS, and VES. Therefore, laboratory testing is mandatory. Inoculation of susceptible cell cultures, particular of porcine origin, will result in a rapid CPE. Virus identification can be achieved using VN, ELISA, or rRT-PCR. A conventional RT-PCR targeting the VP3/VP1 region (Leme et al. 2015), a SYBR Green-based rRT-PCR assay targeting the VP1 region (Bracht et al. 2016), and a Taqman® rRT-PCR targeting the 3D region (Dall-Agnol et al. 2017; Fowler et al. 2017) have all been described. The detection of SVV antibodies using competitive ELISA, VN, and immunofluorescent antibody test (IFAT) has been described (Goolia et al. 2017; Yang et al. 2012).

Immunity

Serological responses to SVV have been characterized by detection of neutralizing antibody 5 DPI, which coincided with decreased levels of viremia, virus shedding, and viral load in tissues (Joshi et al. 2016b).

Prevention and control

There have been few attempts to control outbreaks of SVV, and in the absence of clinical disease, the virus probably spreads easily in the pig population. No vaccines have been developed, but an experimental vaccine using inactivated cell culture-derived SVV has been successfully tested in pigs (Yang et al. 2018).

Porcine kobuvirus

The genus *Kobuvirus* initially consisted of the human Aichi virus (species *Aichivirus A*) and the bovine kobuvirus (species *Aichivirus B*). However, Reuter et al. (2009) reported the sequence of a PKV (species *Aichivirus C*) about 60% identical at the nucleotide sequence level to the Aichi virus and bovine kobuvirus. PKV was initially detected in an RT-PCR analysis for the presence of porcine sapovirus, a calicivirus, in fecal samples from healthy pigs in Hungary. A nonspecific PCR product was sequenced and found to be related to the known kobuviruses. Following the characterization of this virus, some 60% of the pigs at the farm were found to be carrying the virus, including about 90% of the animals under 3 weeks of age. Subsequently, an extremely high (99%) incidence of PKV was found in piglets with diarrhea in Thailand (Khamrin et al. 2009), and in a study from China (Yu et al. 2009), about 30% of fecal samples from healthy pigs were positive by RT-PCR using specific primers for this virus. However, no experimental studies demonstrating a causal role in disease have yet been published.

Porcine sapelovirus

Formerly called both PEV-8 and CPE type II group PEVs, PSV is a member (species *Sapelovirus A*) of genus *Sapelovirus*, along with some simian and avian picornaviruses. PSVs are antigenically diverse (Dunne et al. 1971) and have been associated with the SMEDI syndrome (Dunne et al. 1965) and diarrhea (Honda et al. 1990a). Experimentally, pregnant pigs infected with PSV developed fetal infections (Huang et al. 1980). In addition to cells of porcine origin, PSV can be cultivated in monkey kidney (e.g. Vero) and BHK-21 cells (Knowles et al. 1979). PSV was found in the spinal cords of pigs showing ataxia and paraparesis, and viral antigen co-localized in the spinal cord lesions of affected animals by an antibody known to react with PSV (Schock et al. 2014). PSV has also been detected in central nervous tissues of pigs with polioencephalomyelitis in the United States by PSV-specific RT-PCR and *in situ* hybridization (Arruda et al. 2017). A Korean PSV strain has been shown to induce diarrhea and intestinal pathology in experimentally infected piglets (Kim et al. 2016). The virus also displayed extraintestinal tropisms such as mild, nonsuppurative myelitis, encephalitis, and pneumonia in piglets. An RT-LAMP assay for the detection of PSV has been reported (Wang et al. 2014). A minor groove binder assay for real-time PCR detection of PSV has also been described (Chen et al. 2014).

Porcine enteroviruses

There is little evidence for the association of true PEVs with disease. During the course of investigations of SVD outbreaks in the United Kingdom, many adventitious agents were isolated from samples of epithelium and

feces. Most of these isolates were identified as enteric picornaviruses (Knowles 1983). PTVs and PSV were evenly distributed in feces samples (41 and 44%, respectively) and in epithelial samples (21% in each case); however, PEV-9 and PEV-10 were rarely found in feces (15%) and more commonly found in epithelial samples (58%) (Knowles 1988). Examination of another virus collection again revealed an approximately even distribution of PTV and PSV (57 and 43%, respectively), while PEV-9 and PEV-10 were not detected (Knowles 1988). It was assumed that most of the PTV and PSV isolates identified in epithelial samples were incidental contaminants, but the low frequency of PEV-9 and PEV-10 in feces could not explain the much higher isolation rate from epithelial tissue collected from atypical skin lesions. PEVs can be cultivated in pig, hamster (BHK-21), monkey (e.g. Vero), and some human (HeLa) cell cultures (Knowles et al. 1979).

Recently, the species *Porcine enterovirus B* (to which PEV-9 and PEV-10 belonged) has been renamed *Enterovirus G*, and the two types have been renamed EV-G1 (PEV-9) and EV-G2 (PEV-10). An additional 18 new types have been designated EV-G3 to EV-G20 (Boros et al. 2011, 2012a,c; Bunke et al. 2018; Moon et al. 2012; Shang et al. 2017; Van Dung et al. 2014, 2016; Wang et al. 2017). Among these 20 types, EV-G5 and EV-G7 have only been isolated from sheep, while EV-G20 has only been found in goats; the remaining 17 types have been detected in either domestic pigs or wild boar (Table 40.1). EV-G was reported for the first time in the United States in 2014 (Anbalagan et al. 2014).

Swine pasiviruses

Sauvage et al. (2012) recently described the molecular detection of a new picornavirus in healthy pigs in France. It was named swine pasivirus: "Pasivirus" for "Parecho sister-clade virus," with swine pasivirus 1 (PaV-1) proposed as the type species. A second swine pasivirus was identified in pig feces in China (Yu et al. 2013a,b) and a third in Hungary (Boros et al. 2015). The three viruses share 72–75% nucleotide identity and 74–77% aa identity in their VP1 regions, suggesting they belong to three distinct (geno)types: PaV-A1, PaV-A2, and PaV-A3. Swine pasiviruses have also been detected in pigs in the United States (Guo et al. 2018) and in Romania (L. Buburuzan, M. Eloit, M. Zaulet and V. Petrovan, unpublished data). They have not yet been cultivated in cell cultures. The role of pasiviruses in swine disease is not known; however, antibodies to PaV-1 have been detected in humans (Arnold et al. 2015; Yu et al. 2013b).

Porcine picornavirus Japan

PPVJ was found in the feces of healthy pigs in Japan in 2015 (Naoi et al. 2016). It is most closely related to members of the genera *Teschovirus* and *Hunnivirus* and the candidate genus *Lesavirus*. It has been suggested that it may represent a new species in a novel picornavirus genus (Naoi et al. 2016). The authors were not able to isolate the virus using a porcine kidney cell line (CPK) or Vero cells. However, using a conventional RT-PCR, targeted against the 3D coding region, the virus was detected in pigs on seven out of 12 farms examined. Nothing is known about the potential for PPVJ to cause disease in pigs.

Other picornaviruses detected in pigs

In a recent study of picornaviruses in humans and pigs in Bolivia, human parechovirus (type 4), human cosavirus (untyped), and a *Cardiovirus B* (untyped) were detected in pig feces (Nix et al. 2013). The significance of these findings is unclear as similar viruses were also detected in human fecal samples collected at the same time.

Porcine Reproductive and Respiratory Syndrome Viruses (Porcine Arteriviruses)

Jeffrey J. Zimmerman, Scott A. Dee, Derald J. Holtkamp, Michael P. Murtaugh, Tomasz Stadejek, Gregory W. Stevenson, Montserrat Torremorell, Hanchun Yang, and Jianqiang Zhang

Relevance

In the late 1980s, severe outbreaks characterized by severe reproductive losses, respiratory disease, reduction in growth rate, and increased mortality were reported in the United States (Hill 1990; Keffaber 1989). Initial efforts to identify the etiology were unsuccessful. Clinically similar outbreaks were reported in Germany in November 1990, but no common link was found between the outbreaks in Germany and the United States (Anon 1991). The etiology of the disease was established in 1991 when Koch's postulates were fulfilled with a previously unrecognized RNA virus (Terpstra et al. 1991a; Wensvoort et al. 1991). European researchers introduced the term "porcine reproductive and respiratory syndrome" (PRRS) in 1991 (Terpstra et al. 1991b). The origin of porcine reproductive and respiratory syndrome virus (PRRSV) remains unknown. In the years following the initial reports, outbreaks were widely documented, and the virus is now endemic in most swine-producing regions of the world. Control of PRRSV remains problematic, and economic studies have uniformly shown that PRRSV inflicts major losses on swine health and productivity (Holtkamp et al. 2013; Nathues et al. 2017; Neumann et al. 2005; Nieuwenhuis et al. 2012; Zhang and Kono, 2012). In Europe and North America, the cost of PRRSV to the industry has been estimated at $6.25–$15.25 USD per pig marketed (Holtkamp et al. 2013; Nathues et al. 2017). For this reason, elimination of PRRSV from herds, regions, and countries is considered the optimal solution.

Etiology

Taxonomy and classification

PRRSV type 1 (PRRSV-1) and PRRSV type 2 (PRRSV-2) are currently regarded as two species classified with 15 other species of primate, rodent, and equine viruses in the family *Arteriviridae*. The two prototype genomes (PRRSV-1 strain Lelystad and PRRSV-2 strain VR-2332) were both discovered around 1991 in Europe (PRRSV-1) and North America (PRRSV-2), but vary by approximately 44% in nucleotide sequence. Today, both species share worldwide distribution, with PRRSV-1 being predominant in Europe and PRRSV-2 predominant in the Americas and Asia.

Phylogenetic analyses, based largely on open reading frame (ORF) 5, which encodes the major envelope glycoprotein (GP5), show that both PRRSV species are remarkably diverse. Intra-type pairwise nucleotide sequence variation up to 30% is present in PRRSV-1 viruses, and it exceeds 21% in PRRSV-2 viruses. Although the origin of PRRSV is not known, the extensive differences between PRRSV-1 and PRRSV-2 suggest that their ancestor(s) evolved independently in ecologically or geographically distinct environments for an extended period of time in an as yet unidentified host. (Note: The possibility of recombination between PRRSV-1 and PRRSV-2 isolates cannot be completely excluded, but is considered highly unlikely [van Vugt et al. 2001].)

Four genetic subtypes are described in PRRSV-1. The subtypes 2, 3, and 4 present in Russia, Belarus, Ukraine, Lithuania, and Latvia have significantly larger diversity and likely earlier divergence times than globally spread subtype 1. These data suggest that PRRSV-1 was established in countries in the former Soviet Union long before the first reported epidemic outbreak in Western Europe, suggesting that this region was the primordial reservoir in which PRRSV-1 evolved (Stadejek et al. 2006). The apparent segregation of independent genetic viral subtypes between Western and Eastern Europe is consistent with biologically independent swine populations until political changes in Europe in the 1990s facilitated increased movement of animals across borders.

In the phylogeny of ORF5 of subtype 1 strains, 12 diverse clades have been defined (Shi et al. 2010b). Nine

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

diverse lineages have been defined in the phylogeny of PRRSV-2 ORF5, corresponding to groups in subtype 1 of PRRSV-1 (Shi et al. 2010a,b). Seven lineages are primarily in North America and two are exclusively found in East Asia. Phylogenetic analysis indicated that PRRSV-2 lineages, like PRRSV-1 subtypes, may have diverged prior to the discovery of PRRSV-2 in North America. Thus, transmission and evolution of PRRSV-2 was likely extensive prior to the recognition of PRRS as a new swine disease. The presence of PRRSV-2 in Asia appears to be due primarily to introductions of North American lineages, followed by local diversification, leading to new disease outbreaks and increased virulence (An et al. 2007, 2010; Hu et al. 2009; Shi et al. 2010a; Zhao et al. 2015).

The taxonomic emphasis on ORF5 may obscure important genetic variation in other regions of the PRRSV genome, since strains within either PRRSV species can recombine. Thus, a fuller picture of PRRSV genetic relationships and evolutionary origins may be facilitated by whole genome analyses and comparisons of multiple protein coding regions, including the polymerase gene, which is widely used in RNA viral evolutionary analyses.

Other methods of describing PRRSV isolates

Restriction fragment length polymorphism (RFLP) typing is based on identifying restriction endonuclease cleavage patterns of three restriction enzymes (MluI, HincII, and SacII) in PRRSV ORF5 (Wesley et al. 1998). Restriction endonucleases cleave a nucleic acid chain at a predetermined sequence of nucleotides; thus viruses with the same RFLP pattern contain the same restriction cleavage sites. However, RFLP typing has several major weaknesses: (1) RFLP types do not correlate with genetic relationships of field isolates; (2) the RFLP pattern is not a stable characteristic, even changing as a virus is passed in pigs; (3) it is not broadly adopted outside of North America; and (4) the RFLP identification terminology is too complex. In 2018, five MluI digestion patterns, 163 HincII digestion patterns, and 18 SacII digestion patterns were recognized in PRRSV-2 (Stephanie Rossow, personal communication).

Serotyping has been explored as a method of grouping PRRSV isolates, but it has been difficult to identify distinct serologic relationships. This problem is exacerbated by differences in the strength of the antibody response among individual pigs to PRRSV infection (Johnson et al. 2007). Serotyping based on virus neutralization (VN) is beset by variable and inconsistent appearance of neutralizing antibodies in immune pigs (Nelson et al. 1994; Robinson et al. 2015). Also, VN has not been shown to reproducibly identify related clusters of viruses, and cross-neutralization has not been related to efficacious cross-protection against challenge with virulent PRRSV. On the contrary, immune cross-protection appears to be broad between viruses in which there is no evidence of serological cross-neutralization (Opriessnig et al. 2005).

Other methods include glycotyping (i.e. clustering of PRRSV isolates by predicted N-linked glycosylation patterns in GP5) and typing by a specific amino acid sequence in GP5 (Kim 2008). For both methods, there is an absence of published data supporting their value.

The issue of quasispecies confounds attempts at grouping PRRSVs within a species. RNA viruses with high mutation rates are proposed to exist in an infected host as a cloud of mutationally distinct genomes. Theoretically, genetic diversity increases reproductive fitness and may be necessary for evolutionary success. Quasispecies might help explain the exceptional genetic diversity of PRRSV and facilitate emergence of mutants resistant to existing immunity. However, sequential pig-to-pig passages of PRRSV did not increase the genetic variation within individual pigs, and no evidence for immunological selection of escape mutants has been described in experimental or field settings (Chang et al. 2002; Goldberg et al. 2003). Thus, the role or significance of quasispecies in PRRSV etiology is unclear.

Physicochemical and biological properties

PRRSV is a small, enveloped, positive-sense single-stranded RNA virus. The virion includes an infectious RNA genome of approximately 15 kb in a proteinaceous nucleocapsid, surrounded by a lipid-containing envelope with five or six structural proteins. Virions are small, pleomorphic spheroids approximately 50–70 nm in diameter, with inapparent surface projections that cover the virion surface (Benfield et al. 1992; Spilman et al. 2009). The buoyant density of infectious viral particles is approximately 1.18–1.22 g/cm^3 in cesium chloride (Benfield et al. 1992). PRRSV is stable in media, serum, and tissue homogenates at −70 °C (−94 °F), but its half-life decreases with increasing temperature. Jacobs et al. (2010) observed no difference in inactivation rate among 4 PRRSV-2 isolates and estimated the virus half-life at 4 °C (39 °F), 155 hours; 10 °C (50 °F), 84.5 hours; 20 °C (68 °F), 27.4 hours; and 30 °C (86 °F), 1.6 hours. The virus is stable at neutral pH but is inactivated below pH 6 or above pH 7.5 (Benfield et al. 1992; Bloemraad et al. 1994). It is inactivated by lipid solvents and is highly unstable in solutions containing low concentrations of ionic or non-ionic detergents due to loss of infectivity through disruption of the viral envelope.

Genomic organization and gene expression

The genomic organization of PRRSV is similar to that of other arteriviruses, consisting of approximately 15,000 nucleotides organized into about 11 ORFs (1a, 1b, 2a, 2b,

3, 4, 5a, 5, 6, 7 and a short transframe ORF) that are expressed from genomic and subgenomic (sg) mRNAs (sgmRNAs). ORFs 1a and 1b comprise 80% of the genome and encode the protein cleavage, homologous recombination, and RNA replicase machinery for viral transcription, replication, and immunomodulation. ORF1a and ORF1b are translated as large polypeptides, which are then proteolytically processed into approximately 12 nonstructural proteins (nsp).

Eight ORFs (2a, 2b, 3–7, and 5a) located downstream of ORF1b at the 3′ end of the genome encode the viral structural proteins. Expression is accomplished by formation of sgmRNAs containing the viral 5′ leader sequence ligated at a conserved leader–body junction site upstream of each ORF. Protein expression occurs by translation of the first ORF downstream of the leader sequence in each sgmRNA, except in sgmRNA2 and sgmRNA5, each of which encodes two proteins in different reading frames (Wu et al. 2005; Johnson et al. 2011). Subgenomic mRNA7 expression is most abundant, followed by sgmRNA6 and sgmRNA5 and then by sgmRNA2, sgmRNA3, and sgmRNA4. The noncoding untranslated 5′ leader sequence and 3′ untranslated sequence downstream of ORF7 are conserved within PRRSV-1 and PRRSV-2 strains. These sequences are presumed to be essential for viral replication.

A third RNA species, heteroclite RNA, consists of genomic RNA ligated at noncanonical junction sites downstream of the 5′ leader and within structural protein coding ORFs in the 3′ end (Yuan et al. 2000). Heteroclite RNAs are produced under all conditions of viral growth and vary in size, but all lack nsp9 encoding the polymerase. They appear to be incorporated into virions and can be translated, but their significance is not known (Yuan et al. 2004).

Nonstructural proteins

PRRSV nsps are encoded in one of two large polyproteins translated from the full-length genomic RNA molecule. ORF1a is translated into a large polyprotein (pp) 1a of approximately 260 to 277 kDa that is proteolytically cleaved into smaller active proteins including four proteases (nsp1-alpha, nsp1-beta, nsp2, and nsp4) that carry out the cleavage events in ORF1a- and ORF1b-encoded proteins. PRRSV has a 'slippery' sequence and an unusual RNA loop structure at the ORF1a/1b overlapping region that direct a -1 programmed ribosomal frameshifting during translation of ORF1b, resulting in an pp1ab polyprotein containing an additional approximately 160–170 kDa of protein. The proteases in ORF1a cleave the additional polyprotein (the ORF1b-encoded portion of pp1ab) into approximately six proteins that contain the replicase activity, including an RNA-dependent RNA polymerase, a helicase, and an endoribonuclease. The replication complex is in cytoplasmic compartments that are continuous with endoplasmic reticulum (van der Hoeven et al. 2016).

In addition to endoproteolytic activity, nsp1-alpha and nsp1-beta may contribute to viral pathogenicity by blocking type 1 interferon synthesis directly or via inhibition of signaling pathways (Beura et al. 2010; Chen et al. 2010). Nsp2 shows extensive size polymorphisms due to variable in-frame deletions that are frequently observed in highly virulent strains. However, the nsp2 region does not appear to determine virulence (Zhou et al. 2009b).

Structural proteins

The most abundant structural protein is N, a small (15 kDa), highly basic, genetically diverse polypeptide that interacts with the viral RNA in the assembly of infectious particles (Stadejek et al. 2013). It is expressed at high levels in infected cells and represents 20–40% of the total protein content of the virion. It is active in nuclear shuttling and localization to the nucleolus and may influence nuclear processes during replication, possibly through ribosomal RNA precursor processing and ribosome biogenesis (Yoo et al. 2003). Its abundant expression and antigenicity make it a good target for immunodiagnostic assays, but a role in immune protection has not been demonstrated.

The two major envelope proteins are a non-glycosylated matrix (M) envelope protein, which lacks a signal sequence and accumulates in the endoplasmic reticulum, and GP5, with which M forms disulfide-linked heterodimers that are incorporated into the virion envelope. GP5, after cleavage of the signal peptide, contains an ectodomain of about 30 amino acids in length and is predicted to contain 2–5 N-linked glycans. The GP5/M heterodimer is essential for virion formation, but GP5/M alone is not sufficient for viral infectivity (Das et al. 2010; Wissink et al. 2005).

The 29–30 kDa GP2, 45–50 kDa GP3, and 31–35 kDa GP4 glycoproteins are present in low amounts and form a trimeric envelope protein complex. The presence of all three proteins is required for their assembly and incorporation into the virion and for viral infectivity (Wissink et al. 2005). The trimeric structure mediates infection alone or through an interaction with GP5 (Das et al. 2010; Wissink et al. 2005). These observations explain why replacement of EAV GP5 with PRRSV GP5 in EAV did not change the tropism of EAV to porcine macrophages (Dobbe et al. 2001). The minor envelope glycoprotein complex mediates infection of permissive porcine cells through an interaction with CD163 (Calvert et al. 2007; Das et al. 2010; Tian et al. 2012).

Laboratory cultivation

PRRSV-1 and PRRSV-2 grow primarily in porcine macrophages of the lung and lymphoid tissues and in dendritic cells. In the laboratory, PRRSV is cultivated on

alveolar macrophages isolated from young pigs and on simian cells, especially the African green monkey MA-104 cell line and its derivative, MARC-145. PRRSV-1 isolates grow readily on porcine macrophages but are difficult to adapt to simian cell culture. PRRSV-2 field isolates grow preferentially on macrophages but are frequently adaptable to simian cell culture with several blind passages, whereas cell culture-adapted vaccine strains are preferentially isolated on MARC-145 cells (de Abin et al. 2009). Variation in the ability of both PRRSV species to grow *in vitro* suggests that both porcine macrophages and simian cells should be used for virus isolation (VI) whenever possible.

Characterization of host cell surface molecules involved in PRRSV infection, especially CD163, has resulted in the development of transgenic PK-15 and CHO cell lines that permit infection by vaccine strains and field isolates (Delrue et al. 2010; Van Gorp et al. 2008). Established cell lines that are readily permissive to PRRSV-1 and PRRSV-2 field isolates will facilitate VI, especially for PRRSV-1 isolates.

Public health

PRRSV is not infectious for humans or cells of human origin and has no public health significance.

Epidemiology

Geographic distribution

As diagnostic assays became available during the 1990s, PRRSV was found to have spread nearly everywhere domestic pigs are raised. Retrospective serologic studies found that PRRSV was present in Canada by 1979 (Carman et al. 1995), the United States by 1985 (Zimmerman et al. 1997a), and the former German Democratic Republic by 1987 (Ohlinger et al. 2000). In Asia, anti-PRRSV antibodies were retrospectively documented in serum from pigs imported into the Republic of Korea (South Korea) in 1985 (Shin et al. 1993), in serum samples collected in 1987 in Taiwan (Chiou 2003), and in samples collected in 1988 in Japan (Hirose et al. 1995). In all cases, the serologic evidence of PRRSV preceded the recognition of clinical PRRS.

Some countries are believed to be free of PRRSV, including Argentina (Perfumo and Sanguinetti 2003), Australia (Garner et al. 1997), Brazil (Ciacci-Zanella et al. 2004), Cuba (Alfonso and Frías-Lepoureau 2003), Finland (Bøtner 2003), New Zealand (Motha et al. 1997), Norway (OIE 1997), Sweden (Carlsson et al. 2009), and Switzerland (Nathues et al. 2016). Experience has shown that remaining free of PRRSV requires vigilance (Carlsson et al. 2009; Nathues et al. 2016; Ramos et al. 2018).

Susceptible species

Pigs (*Sus scrofa*) and the collared peccary (*Pecari tajacu*) are susceptible to PRRSV (Molina-Barrios et al. 2018). The prevalence of PRRSV in free-ranging feral swine is low, and their contribution to PRRSV ecology is undefined (Albina et al. 2000; Pedersen et al. 2018; Stankevicius et al. 2014; Wyckoff et al. 2009). The susceptibility of other species within superfamily *Suoidea* (i.e. families *Suidae* and *Tayassuidae*) has not been established. Zimmerman et al. (1997b) reported PRRSV infection in mallard ducks (*Anas platyrhynchos*), but subsequent workers have not replicated these results. Species considered insusceptible to PRRSV include cats, dogs, guinea pigs, house sparrows and starlings, mice, opossums, raccoons, rats, and skunks (Hooper et al. 1994; Rosenfeld et al. 2009; Wills et al. 2000a).

Routes of shedding

Infected animals shed virus in oral and nasal secretions (Christianson et al. 1993; Rossow et al. 1994; Wills et al. 1997a), urine (Wills et al. 1997a), semen (Swenson et al. 1994a), and occasionally feces (Christianson et al. 1993). PRRSV-naïve females inoculated in late gestation shed virus in mammary secretions (Wagstrom et al. 2001). Virus isolates can vary significantly in the level and duration of shedding by pigs (Cho et al. 2006a,b).

Shedding of PRRSV in semen is of particular concern because of the potential for long-distance virus transmission through artificial insemination (Nathues et al. 2014, 2016). The duration of semen shedding varies widely among boars (Christopher-Hennings et al. 1996). Swenson et al. (1994a) found infectious virus in the semen of experimentally infected boars for up to 43 days following exposure. By PCR, Christopher-Hennings et al. (1995a) detected viral RNA in the semen of experimentally infected boars for up to 92 days post inoculation (DPI) and isolated PRRSV from the bulbourethral gland of a boar euthanized 101 DPI. Semen shedding of modified live virus (MLV) vaccine virus occurred for up to 39 days in one study, but prior vaccination eliminated or reduced shedding upon challenge (Christopher-Hennings et al. 1997).

Persistent infection

Persistence is the most significant epidemiological feature of PRRSV infection. Persistence reflects the inability of the immune system to clear the primary infection, with virus continuing to replicate in specific cells over time. PRRSV produces a "chronic persistent" infection – a type of persistent infection in which the virus is eventually cleared. None of the diagnostic tests currently available can differentiate carriers from animals that have successfully cleared the virus.

Persistent PRRSV infection has been documented through transmission experiments and by detection of virus in animals. A number of studies have reported detection of infectious virus for 100–165 DPI, particularly from tonsil or lymphoid tissues (Allende et al. 2000; Benfield et al. 2000b; Fangman et al. 2007; Horter et al. 2002; Wills et al. 1997b). Persistent infection is not a function of pig age at the time of infection. Persistence occurs regardless of whether the pig is exposed *in utero* (Benfield et al. 1997, 2000b; Rowland et al. 1999), as a young animal, or as an adult (Bierk et al. 2001; Christopher-Hennings et al. 1995a; Fairbanks et al. 2002; Zimmerman et al. 1992). The mechanism(s) by which the virus is able to persevere in the face of an active immune response has not been identified, but apparently does not involve evasion of immunity through continual *in vivo* viral mutation. Chang et al. (2002, 2009) found relatively low rates of mutation in persistently infected animals.

Transmission

Swine are susceptible to PRRSV by intranasal, intramuscular, oral, intrauterine, and vaginal routes of exposure, but the probability that a given dose will result in infection differs by route. Hermann et al. (2005) estimated the "infectious dose 50" (ID_{50}), i.e. the dose required to infect one-half of the exposed animals, for oral and intranasal routes of exposure to be $1 \times 10^{5.3}$ $TCID_{50}$ and $1 \times 10^{4.0}$ $TCID_{50}$, respectively. Based on data from Benfield et al. (2000a), the ID_{50} for exposure via artificial insemination is approximately $1 \times 10^{4.5}$ $TCID_{50}$. Pigs are particularly susceptible to infection via parenteral exposure (breaks in the skin barrier). Thus, Yoon et al. (1999) found that intramuscular inoculation with ≤20 PRRSV particles resulted in infection. In the field, potential parenteral exposures include standard husbandry practices such as ear notching, tail docking, teeth clipping, tattooing, and inoculations with medications and biologics. Likewise, because PRRSV is present in oropharyngeal fluids for weeks following infection, parenteral exposure may occur via bites, cuts, scrapes, and/or abrasions that occur during aggressive interactions among infected and susceptible pigs. Bierk et al. (2001) associated transmission with aggressive behavior between carrier sows and susceptible contacts.

Indirect transmission involves transmission by inanimate objects (e.g. equipment, instruments, clothing) or substances (e.g. water, food), aerosols, and possibly arthropod vectors. Aerosol transmission is dependent on the viral variant and environmental factors. Dee et al. (2010) found that the meteorological conditions supportive of airborne transport and transmission included low temperatures, moderate levels of relative humidity, a rising barometric pressure, and slow directional winds in combination with low sunlight levels representative of cloudy days or early morning periods prior to sunrise.

Vertical transmission

PRRSV is transmitted from viremic dams transplacentally to fetuses, resulting in fetal death or the birth of infected pigs that are weak or may appear normal (Bøtner et al. 1994; Christianson et al. 1992; Harding et al. 2017; Terpstra et al. 1991a). Some pigs in affected litters may escape infection. PRRSV can replicate in fetuses 14 days of gestational age or older, but infection of fetuses during the first two-thirds of gestation is uncommon because most PRRSVs cross the placenta efficiently only in the last trimester of pregnancy (Christianson et al. 1993; Lager and Mengeling 1995; Mengeling et al. 1994; Prieto et al. 1996a,b). Transit is independent of the reproductive virulence of the virus isolate. Park et al. (1996) showed that PRRSV isolates of low and high virulence for fetuses crossed the placenta with equal efficiency when sows were inoculated at 90 days of gestation.

Transmission within herds

Once infected, PRRSV tends to circulate within a herd indefinitely. Endemicity is driven by persistent PRRSV infections (carrier animals) and the continual availability of susceptible animals introduced through birth or purchase. The virus is perpetuated by a cycle of transmission from dams to pigs either *in utero* or postpartum or by commingling susceptible animals with infected animals. Under conditions in which susceptible and infectious pigs are mixed, e.g. at weaning, a large proportion of the population may quickly become infected. Dee and Joo (1994a) reported 80–100% of pigs in three swine herds were infected by 8–9 weeks of age, and Maes (1997) found 96% of market hogs sampled from 50 herds to be positive. However, marked differences in infection rates between groups, pens, or rooms of animals may be observed in endemically infected herds. Houben et al. (1995) even found transmission to vary within litters. Some littermates seroconverted as early as 6–8 weeks of age, but other individuals reached 12 weeks of age, the end of the monitoring period, still free of PRRSV infection.

Transmission between herds

The role of infected pigs, virus-contaminated semen, and aerosols in herd-to-herd transmission is firmly established (Dee et al. 2010; Mousing et al. 1997; Otake et al. 2010; Weigel et al. 2000). Goldberg et al. (2000) evaluated the ORF5 gene sequences from 55 field isolates and concluded that PRRSV was most commonly

introduced into herds through animals or semen. Mortensen et al. (2002) found that PRRSV entered negative herds through the introduction of animals and semen and through area spread from neighboring farms, which they attributed to aerosol transmission. Torremorell et al. (2004) attributed over 80% of new infections in commercial systems to area spread from neighboring units, the movement of pigs in PRRSV-infected transports, the lack of compliance of the biosecurity protocols, or possibly introduction via insects. Le Potier et al. (1997) found that 45% of herds suspected to have become infected through area spread were located within 500 m (0.3 miles) of the postulated source herd and only 2% were 1 km from the initial outbreak. Herd density and proximity to infected herds are definitive risk factors, but recent studies have also underlined the extensive connectivity of contemporary production systems and the potential to move PRRSV through the movement of animals, personnel, equipment, transport, and other links (Amirpour Haredasht et al. 2017; Arruda et al. 2016, 2017, 2018; Lee et al. 2017; Lowe et al. 2017).

Stability in the environment

Shedding of virus in oropharyngeal fluids, in urine, and to a much lesser extent in feces results in environmental contamination. PRRSV is stable at pH 6.5–7.5, with infectivity rapidly lost at pH outside this range (Benfield et al. 1992; Bloemraad et al. 1994). The virus is stable for months to years at temperatures of –70 °C and – 20 °C, but quickly inactivated by heat and drying. At 25–27 °C, infectious virus was not detected on dry materials (e.g. plastic, stainless steel, rubber, alfalfa, wood shavings, straw, corn, swine starter feed, or denim cloth) beyond day zero (Pirtle and Beran 1996).

In the presence of moisture, the stability of infectious PRRSV is dependent on specific conditions of temperature, the matrix, and pH. Jacobs et al. (2010) observed no difference in inactivation rate among 4 type 2 isolates in solution and estimated the virus half-life at 4 °C (39 °F), 155 hours; 10 °C (50 °F), 84.5 hours; 20 °C (68 °F), 27.4 hours; and 30 °C (86 °F), 1.6 hours. As reviewed by Linhares et al. (2012a), half-life estimates are relatively consistent among reports. As noted by Linhares et al. (2012a), PRRSV half-life in manure was slightly shorter than virus in solution for any given temperature.

The thermal stability of PRRSV in serum and tissues is similar to that described for virus stored in media. PRRSV was isolated from 47, 14, and 7% of porcine serum samples stored at 25 °C for 24, 48, and 72 hours, respectively. When serum was stored at 4 °C or – 20 °C, PRRSV was isolated from 85% of the samples after 72 hours (Van Alstine et al. 1993).

Disinfection

PRRSV is inactivated by lipid solvents, e.g. chloroform and ether (Benfield et al. 1992). PRRSV is highly unstable in solutions containing low concentrations of detergents, which disrupt the envelope with concomitant release of the noninfectious core particles and loss of infectivity (Snijder and Meulenberg 2001). At "room temperature," Shirai et al. (2000) reported complete inactivation of PRRSV with chlorine (0.03%) in 10 minutes, iodine (0.0075%) in 1 minute, and a quaternary ammonium compound (0.0063%) in 1 minute. Decontamination protocols involving drying, thermo-assisted drying, and foaming disinfectants containing glutaraldehyde and quaternary ammonium chloride compounds are effective at inactivating PRRSV in farrowing rooms and transport vehicles in cold and warm climates (Dee et al. 2004, 2005a; Schneider et al. 2015).

Pathogenesis

PRRSV replicates in a subset of monocyte-derived cells that display CD163, the only required cell receptor for PRRSV binding, internalization, and replication (Calvert et al. 2007; Prather et al. 2013; Van Gorp et al. 2008). Although not required, co-expression of cell surface sialoadhesin (Sn, CD169) may augment viral internalization (Van Breedam et al. 2013). In an *in vitro* study, non-permissive PK-15 cells co-expressing CD163 and Sn produced 10–100× more virus compared with cells expressing only CD163 (Van Gorp et al. 2008). The predominant cells known to support PRRSV replication *in vivo* include pulmonary alveolar macrophages (PAM) and pulmonary intravascular macrophages (PIM) in the lung (Thanawongnuwech et al. 1997b, 2000b; Wensvoort et al. 1991) and monocyte-derived macrophages (MDM) in lymphoid tissues (Duan et al. 1997). PRRSV replicates to a lesser extent in dendritic cells (Loving et al. 2007) and in MDM that reside in most organs in perivascular locations.

The frequent recombination and mutation of the PRRSV genome has led to periodic emergence of strains with atypically high virulence, including PRRSV-2 strains in North America (Mengeling et al. 1998; Wang et al. 2015c), PRRSV-1 strains in Europe (Karniychuk et al. 2010), and PRRSV-2 strains in China (Li et al. 2007, Tian et al. 2007) and elsewhere in Southeast Asia, where they are known as high pathogenicity (HP-PRRS).

Postnatal PRRS

PRRSV viral infection can be divided into three distinct stages: acute infection, persistence, and extinction (Lunney et al. 2016). Acute infection follows exposure

and is characterized by rapid spread to primary sites of replication in lung and lymphoid tissues. Viremia can usually be detected 6–48 hours post exposure. Viral loads peak by 4–14 DPI, with typical levels of 1×10^2–10^5 $TCID_{50}$ per ml of serum or gram of lung tissue, but may be $\geq 10^8$ $TCID_{50}$ in HP-PRRS (Guo et al. 2013a; Hu et al. 2013). Increased replication in high virulence strains may be due to a broader cell tropism. Studies comparing an atypical PRRSV-1 strain with lower virulence PRRSV-1 strains revealed that the atypically virulent strain replicated in macrophages with a CD163+Sn- phenotype, in addition to the CD163+Sn+ phenotype in which the lower virulence strains replicated (Frydas et al. 2013, 2015; Frydas and Nauwynck 2016). Lesser amounts of virus can be detected in a variety of other tissues. Certain strains of PRRSV may exhibit atypical tissue tropisms, such as so-called neurotropic strains of PRRSV that replicate in MDM in the brain (Rossow et al. 1999; Thanawongnuwech et al. 1997a). Some HP-PRRSV strains also exhibit increased tropism for the brain (Brockmeier et al. 2017; Lunney et al. 2016). Clinical disease is observed at the times of highest viral titers, i.e. in the early acute infection. After peaking, virus titers in serum decrease rapidly. Most pigs are no longer viremic by 21–28 DPI. Pig age at the time of PRRSV exposure affects disease; younger pigs replicate virus to higher titers and have longer duration of viremia and shedding when compared with older pigs (Cho et al. 2006b; Klinge et al. 2009; van der Linden et al. 2003).

The persistence stage begins when viremia ends and is characterized by absence of clinical disease, progressively diminishing PRRSV replication in lymph nodes and tonsil, and progressively diminishing viral shedding (Allende et al. 2000; Rowland and Yoo 2003; Wills et al. 1997b).

The extinction phase begins when viral shedding ends and is complete when virus is cleared, the duration varies between pigs, but can be as long as 250 days post exposure (Wills et al. 2003). No diagnostic test is able to reveal the initiation of the extinction phase.

Disease is produced by a variety of mechanisms. Cell death in PRRSV-infected macrophages is by necrosis, as well as apoptosis, involving activation of caspases and a mitochondria-mediated pathway (Costers et al. 2008; Lee and Kleiboeker 2007). However a majority of apoptotic cells in PRRSV-infected tissues are not infected with virus (Duan et al. 1997; Mengeling et al. 1995), but are killed indirectly by bystander apoptosis. In the lung, cells killed by bystander apoptosis are mostly macrophages with fewer lymphocytes and alveolar pneumocytes; in lymph nodes and thymus, cells are mostly lymphocytes, with fewer macrophages (Feng et al. 2002; Labarque et al. 2003; Sirinarumitr et al. 1998; Sur et al. 1998; Wang et al. 2014). A feature of HP-PRRS strains is induction of higher levels of bystander apoptosis in a variety of tissues. For example, bystander apoptosis in thymic CD3+ thymocytes is 5–40× that of lower pathogenicity PRRSV-2 strains (He et al. 2012; Li et al. 2014; Wang et al. 2015a).

PRRSV markedly alters innate immunity and inflammatory and immunoregulatory cytokines in a strain-specific manner (see reviews by Butler et al. 2014; Lunney et al. 2016). Secretion of proinflammatory cytokines from PRRSV-infected macrophages, including TNF-alpha, IL-1, and IL-6 (Choi et al. 2001; Suradhat and Thanawongnuwech 2003; Thanawongnuwech et al. 2004; van Gucht et al. 2003), is known to promote influx and activation of leukocytes, increased microvascular permeability (pulmonary edema), and induction of systemic effects such as pyrexia, anorexia, and lethargy. Alteration of levels of these and others in HP-PRRS is exacerbated and suggested as a potential cause of death similar to "macrophage activation syndrome" or "cytokine storms" in humans (Behrens et al. 2011; Guo et al. 2013a). Among other mechanisms, PRRSV-induced alterations of immunoregulatory cytokines, as well as alteration in numbers of various lymphocyte subsets, result in a delay of effective adaptive immunity, including delayed production of neutralizing antibodies and delay of a sterilizing cell-mediated immune (CMI) response. Delay in neutralizing antibody response is credited for the extended duration of viremia and delay in CMI for the extended persistence in lymphoid tissues.

PRRSV infection predisposes to *S. suis* and possibly other septicemias and opportunistic bacterial pneumonia in a strain-dependent manner (Brockmeier et al. 2000; Feng et al. 2001; Galina et al. 1994; Thanawongnuwech et al. 2000a; Wills et al. 2000b). This is believed to be due to PRRSV-induced reduction in bacterial phagocytic and killing capacity by PIM and PAM (Thanawongnuwech et al. 1998a,b, 2000b) and likely other MDM. Outbreaks of HP-PRRS in Southeast Asia, known as "porcine high fever disease" (PHFD), were associated with concurrent septicemia and/or bacterial bronchopneumonia (Li et al. 2007; Metwally et al. 2010; Xu et al. 2010). In a study by Brockmeier et al. (2017), both atypical US and HP-PRRS strains of PRRSV induced more severe secondary bacterial bronchopneumonia when compared with lower virulence US and Chinese PRRSV strains in a dual bacteria + PRRSV inoculation model.

Gram-negative bacterial coinfections may enhance PRRS through the action of bacterial lipopolysaccharide (LPS). Bacterial LPS (endotoxin) is a major component of gram-negative bacterial cell walls that acts systemically in sepsis and locally in the respiratory tract when inhaled in high levels in dust in poorly ventilated swine buildings (Zejda et al. 1994). Intratracheal administration of LPS in PRRSV-inoculated pigs resulted in more severe respiratory disease associated with 10–100× elevations in inflammatory cytokines IL-1, IL-6, and

TNF-alpha compared with pigs given only PRRSV or LPS (Labarque et al. 2002; van Gucht et al. 2003). *In vitro* studies in PAM cultures suggest that PRRSV infection causes elevated secretion of inflammatory cytokines through upregulation of CD14, the LPS receptor, on PAM cell membranes (Qiao et al. 2011).

In addition to bacterial diseases, PRRSV also significantly enhances replication of porcine circovirus type 2 (PCV2), resulting in more severe PRRS viral pneumonia, as well as lesions of PCV2-associated porcine multisystemic wasting syndrome (Allan et al. 2000; Harms et al. 2001).

The severity of PRRS can also be influenced by host susceptibility. The first indication of natural genetic resistance to PRRSV was provided by Halbur et al. (1998) who demonstrated that Meishan pigs had lower viral titers and less severe lesions than Duroc pigs when inoculated with PRRSV. Since then, a region on *Sus scrofa* chromosome 4 (SSC4) surrounding the single nucleotide polymorphism (SNP) marker WUR10000125 (WUR) has been identified that is strongly associated with improved weight gain and lower viral loads in PRRSV-inoculated pigs that are homozygous or heterozygous for the dominant allele (Boddicker et al. 2012, 2014a,b; Rowland et al. 2012; Schroyen et al. 2016). However, this trait varies in efficacy based on PRRSV strain (Hess et al. 2016).

Reproductive PRRS

Acute PRRS in boars and sows can lead to reproductive failure in a strain-dependent manner (Mengeling et al. 1996, 1998; Park et al. 1996). During acute PRRS, viral shedding in semen can result in venereal transmission to sows (Swenson et al. 1994b; Yaeger et al. 1993). Venereal transmission infects sows by direct transit through the endometrium, since preimplantation embryos are refractory to PRRSV infection (Lager et al. 1999; Mateusen et al. 2007; Prieto et al. 1996b). This is likely due to their lack of Sn+ macrophages (Mateusen et al. 2007). Postimplantation fetuses of all ages are susceptible to PRRSV infection (Christianson et al. 1993; Lager and Mengeling 1995; Lager et al. 1996; Mateusen et al. 2007; Prieto et al. 1996b). However, PRRSV crosses the maternal–fetal interface (MFI) in pregnant females to infect fetuses with high efficiency only in the third trimester (Christianson et al. 1992; Kranker et al. 1998. Lager et al. 1997a,b; Mengeling et al. 1994, 1998; Terpstra et al. 1991a; Wang et al. 2015a). But a minority of strains, including some HP-PRRS strains, are able to cross the placenta mid-gestation with moderate efficiency and kill fetuses (Han et al. 2017; Wang et al. 2015b).

Resistance to PRRSV transit at the MFI seems to be two way. Intra-fetal or intra-amniotic inoculation of fetuses with PRRSV 45–50 days of gestation did not result in passage of PRRSV from fetus to dam (Christianson et al. 1993). The reason for resistance to PRRSV transit at the MFI during early and mid-gestation and for efficient transit during late gestation may be due, in part, to numbers of PRRSV-permissive cells in the fetal placenta and other fetal tissues. Karniychuk et al. (2009) demonstrated that during early and mid-gestation, the predominant macrophage phenotype is the less permissive CD163+Sn–, whereas in late gestation it is the highly permissive CD163+Sn+.

Fetuses are infected by transit of PRRSV from the dam via the MFI to fetal placenta or by transmission from adjacent intrauterine PRRSV-infected fetuses (Ladinig et al. 2014, 2015a). PRRSV replicates to its highest titers in fetal thymus, tonsils, and lymph nodes (Karniychuk et al. 2011; Kranker et al. 1998; Mengeling et al. 1994; Rowland 2010), contributing to fetal death or, if pregnancy continues to term, birth of PRRSV-infected piglets (Kranker et al. 1998; Mengeling et al. 1994). Lesions are observed in a minority of PRRSV-infected fetuses (Christianson et al. 1992; Lager et al. 1996; Novakovic et al. 2016; Rossow et al. 1996), leading some to question whether viral replication in fetuses is the sole or significant cause of fetal death (Karniychuk et al. 2011; Karniychuk and Nauwynck 2013; Novakovic et al. 2017).

Several studies have provided evidence that events at the MFI may determine transit of PRRSV from dam to fetus and/or contribute to fetal outcome. A study of the MFI in gilts inoculated with PRRSV at 90 days of gestation confirmed direct apoptosis in CD163+Sn+ cells with spatially and numerically correlated bystander apoptosis in both the maternal endometrium and interfacing fetal placenta (Karniychuk et al. 2011). A much larger study confirmed in PRRSV-infected dams that, at the MFI for a particular fetus, the amount of direct and bystander apoptosis is directly proportional to the number of PRRSV-infected macrophages in the maternal endometrium, the PRRSV load in the respective fetal thymus, and the risk for fetal death (Ladinig et al. 2015b; Novakovic et al. 2017). Furthermore, bystander apoptosis at the MFI included endometrial epithelial cells and placental trophoblasts that were associated with micro or rarely larger separations of the placenta from the endometrium. These findings suggested that PRRSV replication in macrophages in the maternal endometrium, by causing indirect killing of maternal and fetal cells at the MFI, could provide the means of PRRSV transit to the fetus and/or contribute, along with PRRSV replication in fetal tissues, to fetal death.

Clinical signs

Descriptions of the clinical signs of PRRS in swine herds are generally similar in North America (Bilodeau et al. 1991; Keffaber 1989; Loula 1991; Moore 1990; Sanford 1992), South America (Dewey 2000), Europe

(Anon 1992; Busse et al. 1992; de Jong et al. 1991; Gordon 1992; Hopper et al. 1992; Leyk 1991; Wensvoort et al. 1991; White 1992a,b), and Asia (Chiou 2003; Thanawongnuwech and Thacker 2003; Tong and Qiu 2003; Yang et al. 2003).

Clinical presentation of PRRS varies among herds, ranging from subclinical to devastating. Clinical signs of PRRSV are influenced by virulence of virus strain, host immune status, host susceptibility, exposure to LPS, concurrent infections, and other management factors (White 1992a).

Clinical epidemics occur in immunologically naive populations, and all ages are affected, whereas endemic PRRS occurs in herds that have some degree of immunity to the infecting PRRSV. In endemic PRRS, clinical disease is observed in susceptible subpopulations, usually in nursery–grower pigs when maternal immunity decays, and/or in replacement gilts or sows that have previously escaped infection, as well as their congenitally infected progeny.

Antigenic variation is great enough among variants of PRRSV that entry or emergence of a new, relatively unrelated virus can cause epidemics in endemically PRRSV-infected herds or regions (Li et al. 2007; Tian et al. 2007; Wang et al. 2015c; Zhou et al. 2008).

"Atypical" highly virulent strains periodically emerge that extend the severity or range of clinical signs (Karniychuk et al. 2010; Mengeling et al. 1998; Wang et al. 2015c). Notable among these are HP-PRRSV strains that emerged in China in 2006 (Li et al. 2007; Tian et al. 2007) and elsewhere in Southeast Asia (Feng et al. 2008; Metwally et al. 2010; Ni et al. 2012). These viruses are genetically homologous, contain a discontinuous 30-amino-acid deletion in the nsp2 gene (Zhou et al. 2009a), and are typically fatal for pigs inoculated under experimental conditions (Li et al. 2007; Tian et al. 2007; Zhou et al. 2008; Zhou et al. 2009b). In "high fever disease" outbreaks, HP-PRRSV is often found concurrently with other pathogens, e.g. classical swine fever virus, Aujeszky's disease virus, streptococci, *H. parasuis*, and others.

Epidemic infection

The first phase of acute illness in a PRRS epidemic lasts two or more weeks and affects animals of all ages. It begins in one or more stages of production and quickly spreads in 3–7 or more days, depending on size and composition of the site, to all stages of production. The spread of the disease through a segregated group of pigs usually requires 7–10 or more days, although individuals may escape infection for weeks or months, depending on virus strain, herd size, and type of housing.

The second phase of reproductive failure may begin before the first phase of acute illness is completed and continues for 1–4 months. This phase is characterized by reproductive failure, primarily in sows that were viremic in their third trimester, and by high preweaning mortality in their live-born progeny. When reproductive performance and preweaning mortality return to near pre-outbreak levels, endemic infection of most herds continues.

Sows and boars

During the phase of acute illness, 1–3% of litters may be lost in sows that are at 21–109 days of gestation. This presents as overt abortions or, later, as irregular returns to estrus or nonpregnant sows (Hopper et al. 1992; Keffaber 1989; Loula 1991; White 1992a). Also observed inconsistently in acutely ill sows are agalactia (Hopper et al. 1992), incoordination (de Jong et al. 1991), and/or a dramatic exacerbation of endemic diseases, such as sarcoptic mange, atrophic rhinitis, or cystitis/pyelonephritis (White 1992a).

Mortality in sows is typically 1–4% during acute illness and is sometimes associated with pulmonary edema and/or cystitis/nephritis (Hopper et al. 1992; Loula 1991). A few cases of severe acute PRRS in sows have been described with 10–50% abortions, up to 10% mortality, and nervous signs such as ataxia, circling, and paresis (Epperson and Holler 1997; Halbur and Bush 1997). Abortion rates of 40–100% and sow mortality of ≥10% are reported in Southeast Asia for acute HP-PRRS (Han et al. 2017).

Not all affected sows are clinically ill during acute PRRS. Typically, 5–80% of sows farrow on day 100–118 of gestation and have litters composed of any combination of normal pigs, weak variably sized pigs, and dead pigs that are fresh stillborn (intrapartum death), autolytic (brown), partially mummified, or completely mummified fetuses. Typically, pigs born dead comprise 0–100% of each affected litter and 7–35% of the total pigs born in a farrowing group. In time, there is a shift from predominantly stillborn pigs and large partially mummified pigs to smaller more completely mummified pigs, to small weak-born pigs, and to pigs of normal size and vigor (Keffaber 1989; Loula 1991; White 1992a). In some herds, the majority of abnormal pigs are born alive, premature, weak, and small, but few are born dead (Gordon 1992). Periparturient mortality in sows may be 1–2% (de Jong et al. 1991; Keffaber 1989). Surviving sows on the subsequent breeding often have delayed return to estrus and low conception rates.

Boars acutely infected by PRRSV, in addition to anorexia, lethargy, and respiratory clinical signs, may lack libido and have variable reduction in semen quality (de Jong et al. 1991; Feitsma et al. 1992; Prieto et al. 1994). Changes in sperm occur 2–10 weeks after infection with virus and include reduced motility and acrosomal defects, but it is unclear whether conception rates are affected (Lager et al. 1996; Prieto et al. 1996a,b; Swenson et al. 1994b; Yaeger et al. 1993).

Suckling pigs

During the 1- to 4-month phase of late-term reproductive failure, there is high preweaning mortality (up to 60%) in pigs born prematurely and at term associated most consistently with listlessness, emaciation/starvation, splayleg posture, hyperpnea, dyspnea ("thumping"), and chemosis. Seen less commonly are somnolence, tremors or paddling (Keffaber 1989; Loula 1991; Rossow et al. 1999), anemia and thrombocytopenia with consequent hemorrhage from navels and elsewhere, and an increase in bacterial polyarthritis and meningitis (Hopper et al. 1992; White 1992a). Watery diarrhea was commonly reported in the United Kingdom (Gordon 1992; Hopper et al. 1992; White 1992a) and less commonly elsewhere (Keffaber 1989; Leyk 1991). Mortality reported for HP-PRRS in suckling pigs is often as high as 100% (Han et al. 2017).

Weanling and grower pigs

Acute PRRSV infection in nursery or grower–finisher pigs is characterized most consistently by anorexia, lethargy, cutaneous hyperemia, hyperpnea and/or dyspnea, variable coughing, rough hair coats, variable reduction in average daily gain, and elevated mortality of 12–20% (Moore 1990; White 1992b). Uncommonly, nervous signs including tremors, ataxia, and convulsions are reported (Thanawongnuwech et al. 1997a). Additionally with HP-PRRS strains, a prolonged high fever of 40–42 °C (104–108 °F), rapid weight loss, and high mortality are consistently observed, and inconsistently observed are cyanosis, vomiting, diarrhea, constipation, tremors, and conjunctivitis (Brockmeier et al. 2017; Guo et al. 2013a,b; Hu et al. 2013; Li et al. 2007; Tian et al. 2007; Zhou et al. 2008). Concurrent with acute PRRS, a higher than usual incidence of endemic diseases is often reported (Brockmeier et al. 2017; Han et al. 2017; Keffaber et al. 1992; Loula 1991; Moore 1990; Stevenson et al. 1993; White 1992a). Diseases most commonly reported include streptococcal meningitis, Glässer's disease, exudative dermatitis, sarcoptic mange, and bacterial bronchopneumonia.

Endemic infection of herds

Once introduced into a herd, PRRSV becomes endemic in nearly all cases. In endemically infected herds, PRRS is most often seen as regular or occasional outbreaks of typical acute PRRS in susceptible nursery or grower–finisher pigs (Keffaber et al. 1992; Stevenson et al. 1993). Clinical signs are also observed in groups of susceptible gilts or replacement boars exposed to PRRSV after introduction into the herd (Dee et al. 1996; Dee and Joo 1994b; Grosse-Beilage and Grosse-Beilage 1992) but may also be seen in susceptible sows. Acute clinical disease in gilts or boars is as described for epidemics. The reproductive consequences depend on the number of gilts/sows infected and the stage of their reproductive cycle when infected, both of which may vary widely (Torrison et al. 1994). If few gilts are infected on an ongoing basis, then there may be scattered abortions, irregular returns to estrus, nonpregnant gilts, and late-term reproductive failure with abnormal litters typical of PRRS. These may only be recognized if records are evaluated on a parity-specific basis (White 1992b). Alternatively, gilts may escape exposure to PRRSV until there is a significant subpopulation of susceptible gilts in various stages of gestation. In this situation, endemic PRRS in the breeding herd manifests as periodic mini-outbreaks of PRRS in gilts and, less commonly, sows that are identical to those in an epidemic (Dee and Joo 1994b).

Lesions

Postnatal lesions

Similar lesions are described in all ages of pigs with PRRSV infection. The severity and distribution of lesions varies with the virulence of the infecting virus (Brockmeier et al. 2017; Done and Paton 1995; Guo et al. 2013b; Halbur et al. 1996b; Karniychuk et al. 2010; Morgan et al. 2014; Pol et al. 1991). Most inoculation studies in which lesions have been described were in suckling or weaned pigs 1–105 days of age (Collins et al. 1992; Dea et al. 1992; Guo et al. 2013b; Halbur et al. 1995b, 1996a,b; Li et al. 2007; Karniychuk et al. 2010; Morgan et al. 2014; Pol et al. 1991; Rossow et al. 1994, 1995; Zhou et al. 2008).

Consistent gross and microscopic lesions are observed in the lungs and lymph nodes 4 to ≥28 DPI. There is interstitial pneumonia that varies in severity. Distribution may be cranialventral to diffuse, consistency varies from slightly firm and resilient to moderately firm and rubbery, color varies from tan to dark redpurple, and pulmonary edema varies from mild to severe with separation of lobules. In HP-PRRS, the lungs may be hemorrhagic. Many lymph nodes in most pigs are enlarged 2–10× normal. Early post exposure, enlarged nodes are edematous, tan, and moderately firm and in HP-PRRS may be hemorrhagic. Later, nodes are firm and white or light tan in a nodular or diffuse pattern. Uncommonly, there are multiple fluid-filled 2–5 mm diameter cortical cysts. Gross lesions unique to pigs infected at ≤13 days of age include periocular edema 6–23 DPI, scrotal edema 11–14 DPI, and subcutaneous edema 2–7 DPI (Rossow et al. 1994, 1995). Additional gross lesions frequently observed with HP-PRRS include multifocal cutaneous, epicardial, and renal cortical hemorrhages, chemosis, conjunctivitis, and thymic atrophy (Guo et al. 2013b; Han et al. 2017; Li et al. 2007; Zhou et al. 2008).

The most consistent microscopic lesions are observed in the lungs and lymphoid tissues. Alveolar septa are

expanded by macrophages, lymphocytes, and plasma cells and may be lined by hyperplastic type II pneumocytes. Alveoli may contain necrotic macrophages, cell debris, and serous fluid. Lymphocytes and plasma cells form cuffs around airways and blood vessels. Edema may expand interlobular connective tissues and with HP-PRRS there may be multifocal hemorrhage. Germinal centers in lymph nodes early in the course of infection are necrotic and depleted. Later germinal centers are large and composed of blast-type lymphocytes. There may be lymphoid necrosis and depletion in the thymus, from mild to moderate and multifocal to diffuse and severe, resulting in nearly complete cortical atrophy as described for some HP-PRRS strains (Brockmeier et al. 2017; He et al. 2012; Wang et al. 2011). Lymphoid depletion followed later by hyperplasia may also be observed in periarteriolar lymphoid sheaths of the spleen and in lymphoid follicles in tonsil and Peyer's patches (Halbur et al. 1995b; Pol et al. 1991).

Other microscopic lesions include segmental lymphohistiocytic perivascular cuffing in the epicardium and myocardium with occasional cuffing of Purkinje fibers (Halbur et al. 1995a, 1996b; Rossow et al. 1994, 1995). Kidneys may have mild periglomerular and peritubular lymphohistiocytic aggregates and mild to severe segmental lymphohistiocytic necrotizing vasculitis that is most severe in the renal pelvis and medulla (Cooper et al. 1997; Rossow et al. 1995). Mild lymphohistiocytic encephalitis characterized by multifocal gliosis and segmental lymphohistiocytic perivascular cuffs may also be observed (Brockmeier et al. 2017; Collins et al. 1992; Halbur et al. 1996b; Han et al. 2017; Rossow et al. 1995, 1999; Thanawongnuwech et al. 1997a). More severe encephalitis may uncommonly be observed that also includes lymphohistiocytic necrotizing vasculitis (Thanawongnuwech et al. 1997a).

Pregnant sows frequently have microscopic lesions in the uterus (Christianson et al. 1992; Lager and Halbur 1996; Novakovic et al. 2016, 2017; Stockhofe-Zurwieden et al. 1993). The myometrium and/or endometrium are edematous with lymphohistiocytic perivascular cuffs. Less commonly, there are segmental lymphohistiocytic vasculitis in small vessels and microseparations at the MFI between endometrial epithelium and placental trophoblasts that contain eosinophilic proteinaceous fluid and cell debris.

Atrophy of seminiferous tubules may be observed in 5- to 6-month-old boars 7–25 DPI (Sur et al. 1997). Atrophic tubules have PRRSV antigen and nucleic acid in germinal epithelial cells, giant cells with 2–15 nuclei, and apoptosis and depletion of germ cells.

Fetal lesions

Gestational age at expulsion and composition of litters is typically more suggestive of PRRS than gross or microscopic lesions in fetuses. In most cases of PRRS reproductive failure, litters are delivered in late gestation, but before term, and are composed of variable proportions of clinically normal pigs, small- or normal-sized weak pigs, dead variably autolyzed pigs, and mummies. Dead pigs may be coated with a thick brown mixture of meconium and amniotic fluid, a nonspecific finding that suggests fetal stress and/or hypoxia (Lager and Halbur 1996; Stockhofe-Zurwieden et al. 1993). Lesions in fetuses and stillborn pigs are uncommon and rarely contribute to a definitive diagnosis of PRRS.

PRRSV-specific gross lesions are best observed in fetuses with little or no *in utero* autolysis (Bøtner et al. 1994; Collins et al. 1992; Done and Paton 1995), but are more commonly seen in live-born PRRSV-infected littermates that die or are sacrificed within a few days after birth. Gross lesions may include perirenal edema, edema of the splenic ligament, mesenteric edema, ascites, hydrothorax, hydroperitoneum, and segmental enlargement of the umbilical cord by hemorrhage (Dea et al. 1992; Lager and Halbur 1996; Plana Duran et al. 1992).

Microscopic lesions are mild and may include lymphoid depletion and follicular atrophy in mesenteric lymph nodes; lymphohistiocytic segmental arteritis and periarteritis in umbilical cord, lung, heart, and kidney; multifocal interstitial pneumonia with occasional hyperplasia of type II pneumocytes; mild periportal hepatitis; myocarditis with loss of myocardial fibers; multifocal leukoencephalitis; and thymic atrophy (Lager and Halbur 1996; Novakovic et al. 2016; Plana Duran et al. 1992; Rossow et al. 1996; Sur et al. 1996).

Diagnosis

The possible involvement of PRRSV is suggested in any herd with reproductive disease in breeding swine and/or respiratory disease in pigs of any age. Infection with some PRRSV strains has been associated with neurological signs (e.g. shivering, lameness, and opisthotonos) (Cao et al. 2012; Tian et al. 2007). Analysis of production records in herds with clinically active PRRSV may show increased abortions, early farrowings, stillbirths, preweaning mortality, and nonproductive sow days. However, the absence of clinical signs does not mean that a population is free of PRRSV: this is established by testing. Notably absent is a test capable of differentiating inapparently infected (non-viremic) carrier animals from animals that have cleared the virus (Molina et al. 2008).

Pathological evaluation

PRRSV infection does not produce pathognomonic gross or microscopic lesions, and aborted fetuses and stillborn pigs rarely have lesions of diagnostic value. Gross lesions of interstitial pneumonia and enlarged

lymph nodes may be observed in infected pigs of all ages (Lager and Halbur 1996; Stevenson et al. 1993). Microscopically, interstitial pneumonia is the primary lesion. Typically, concurrent viral and/or bacterial infections complicate the clinical picture and diagnosis.

Depending on the region, the differential diagnosis of PRRSV infection may include classical swine fever virus, cytomegalovirus, hemagglutinating encephalomyelitis virus, leptospirosis, parvovirus, PCV2, pseudorabies (Aujeszky's disease) virus, swine influenza virus, and teschovirus (Halbur 2003). Therefore, a definitive diagnosis requires laboratory confirmation of the presence of virus, viral products, and/or antibodies.

Diagnostic specimens

Specimens typically collected for laboratory testing include serum or blood, tissues (e.g. lung, tonsil, and lymph nodes), bronchoalveolar lavage (BAL), semen, and oral fluid specimens from individual or groups of pigs (Decorte et al. 2015; Fablet et al. 2017; Kittawornrat et al. 2010; Olsen et al. 2013a,b; Prickett and Zimmerman 2010). "Processing fluid," a composite sample composed of the exudate from tissues collected at the time of piglet castration and tail docking, has also been shown to be useful for the detection of PRRSV RNA and antibody (Lopez et al. 2018). In reproductive failure, PRRSV detection is recommended on three sample sources: fetal/stillborn thymus and lung pools, serum pools from dams, and processing fluids from neonatal live-born littermates or cohorts.

Virus isolation

The success rate for VI varies among specimens, with serum the preferred antemortem sample because of the prolonged period of PRRSV viremia, but lung and lymphoid tissue samples collected at necropsy may also be used. Specimens for VI should be refrigerated (4°C) immediately after collection and shipped for testing within 24–48 hours. The virus is heat labile and has a narrow range of pH stability (Benfield et al. 1992; Bloemraad et al. 1994; Jacobs et al. 2010; Van Alstine et al. 1993).

PRRSV can be isolated on porcine alveolar macrophages or sublines (CL-2621, MARC-145) of the African monkey kidney cell line MA-104 (Benfield et al. 1992; Kim et al. 1993). PRRSVs vary in their ability to replicate in PAMs and MA-104 cells (Bautista et al. 1993), and, ideally, VI should be attempted on both cell types for optimum recovery of virus. PAMs are reportedly more sensitive than MARC-145 cells for VI (de Abin et al. 2009; Yoon et al. 2003). However, PAMs are primary cells and cannot be continuously passed, but need to be prepared periodically, and batches of PAMs vary in their susceptibility to the virus. Recently, an immortalized cell line (ZMAC-1, ATCC® PTA-8764) derived from PAMs became available for VI (Calzada-Nova et al. 2012). Preliminary data showed that the rate of PRRSV-2 and PRRSV-1 VI from PRRSV RNA-positive serum and lung samples was significantly higher in ZMAC-1 cells than in MARC-145 cells (Yim-Im et al. 2017). Isolation of PRRSV on cell culture may be confirmed by reverse transcription PCR (RT-PCR) or by visualizing viral antigens in the cytoplasm of infected cells by fluorescent antibody (FA) or immunohistochemistry (IHC) using PRRSV-specific monoclonal antibodies. Negative stain electron microscopy (EM) can also be used to visualize virus particles in cell culture fluids.

Detection of viral antigens

Methods for the routine detection of PRRSV antigens include IHC and FA staining. Tissues (lung, tonsil, lymph nodes, heart, brain, thymus, spleen, and kidney) can be fixed in 10% neutral buffered formalin for microscopic evaluation and IHC staining using PRRSV-specific monoclonal antibody against the highly conserved nucleocapsid (N) protein (Halbur et al. 1994; Van Alstine et al. 2002; Yaeger 2002). The combination of histopathology and IHC allows visualization of viral antigens in the cytoplasm of cells within, or contiguous to, microscopic lesions (Halbur et al. 1994). Tissues should be processed within 48 hours of fixation to avoid degradation of PRRSV antigens and loss of IHC-positive cells (Van Alstine et al. 2002). Lesions and viral antigens are best observed during acute infection (4–14 DPI). Viral antigen can also be detected in frozen tissue sections by FA (Benfield et al. 1992; Halbur et al. 1996a; Rossow et al. 1995). The FA test is faster and less expensive than IHC but requires unfixed tissues. Detection of viral antigen by IHC or FA is significantly less analytically and diagnostically sensitive than methods for detection of viral nucleic acids.

Detection and characterization of viral nucleic acids

Nucleic acid-based PRRSV detection methods include RT-PCR, sequencing, *in situ* hybridization (ISH), and loop-mediated isothermal amplification (LAMP). The specimen types used for PRRSV VI can also be used for PRRSV RNA detection.

RT-PCR

The PRRSV RT-PCR was initially developed to detect PRRSV RNA in semen and serum of boars (Christopher-Hennings et al. 1995b, 1996, 2001). Various PRRSV PCR formats have since been described. Real-time RT-PCR (rRT-PCR) is widely used because it is analytically sensitive, analytically specific, and compatible with high-throughput testing. PRRSV rRT-PCR can also

quantify PRRSV genomic copies. Notably, current assays cannot differentiate RNA from infectious virus vs. noninfectious (inactivated) PRRSV. Commercial rRT-PCR assays are available for the detection of PRRSV-1 and/or PRRSV-2, but variation in diagnostic performance has been reported (Gerber et al. 2013; Harmon et al. 2012).

PRRSV RT-PCR can be conducted on all specimens typically collected for laboratory testing. During acute infection, serum and tissues are the preferred specimens. The duration of RT-PCR-detectable viremia differs among PRRSV strains, but conservatively is from 2 to 21 DPI. Under experimental conditions, approximately 50% and 10% of pigs were PCR positive at approximately 50 DPI and 100 DPI in serum, respectively (Horter et al. 2002; Molina et al. 2008). Virus persists longer in the tonsil and lymph nodes than in serum, lung, and other specimens. For example, virus was detected in tonsil and oropharyngeal scrapings at 130 and 157 DPI, respectively, under experimental conditions (Rowland and Yoo 2003; Wills et al. 2003).

Pooling (i.e. combining ≥2 individual samples into one sample) can not only improve testing efficiency and reduce costs but can also lead to false-negative test results. Gerber et al. (2013) reported that pooling five serum or blood swab samples did not reduce PRRSV rRT-PCR detection rates if the pool contained at least one positive sample with a relatively high concentration of viral RNA. Pooling of population-based samples (e.g. oral fluid and processing fluid samples) for PRRSV RT-PCR testing is not recommended.

Sequencing

Prior to the ready availability of sequencing, PRRSV isolates were identified and differentiated by ORF5 RFLP (Umthun and Mengeling 1999; Wesley et al. 1998). RFLP patterns do not characterize genetic relatedness among viruses or predict viral virulence (van Geelen et al. 2018). Although sequencing renders the use of RFLP highly questionable, RFLP will continue to be used until an equally convenient system for describing PRRSV isolates is established.

Sequencing and phylogenetic analyses provide precise and accurate genetic characterizations of PRRSV isolates and the means for comparing them. Sequence identity matrices and dendrograms (phylogenetic trees) are used to compare PRRSV isolates at the genetic level. ORF5 (major envelope protein) is the most common target for PRRSV sequencing. ORF5 sequences are highly variable, and there is an extensive databank of sequences available for comparison. However, ORF5 is only approximately 4% of the entire PRRSV genome, or 12% of the structural genes, and thus may be insufficient to provide the breadth of evidence needed for differentiating PRRSV strains.

Whole genome sequencing, an approach that provides more comprehensive information for genetic comparisons, has become more commonplace with the development of next-generation sequencing (NGS) technology. NGS can determine whole genome sequences faster and at lower cost than previous technologies. High-throughput whole genome sequencing of PRRSV from cell culture materials and clinical specimens using NGS has been described (Zhang et al. 2017).

In situ hybridization (ISH)

An ISH test using a PRRSV-specific nucleic acid probe has been described for the detection of PRRSV in cell culture and formalin-fixed tissues (Larochelle et al. 1996), but is not widely used in diagnostic laboratories.

Reverse transcription loop-mediated isothermal amplification

LAMP assay is similar to RT-PCR in that a specific fragment of the DNA is amplified, but LAMP can be done at a constant temperature in a water bath or heat block with no need of a thermal cycler. A number of RT-LAMP assays have been described for the detection of PRRSV (Li et al. 2009; Park et al. 2016; Rovira et al. 2009). While RT-LAMP tests have lower diagnostic sensitivity than RT-PCR, there is potential for this technique to be adapted in laboratories where RT-PCR instrumentation is too expensive or technical to be implemented (Rovira et al. 2009).

Detection of antibody

PRRSV antibodies can be routinely detected in serum and oral fluid specimens (Benfield et al. 1992; Gerber et al. 2014; Kittawornrat et al. 2012a,b; Langenhorst et al. 2012; Ouyang et al. 2013; Rotolo et al. 2018; Sattler et al. 2015). Single serum samples are of limited value due to the high prevalence of PRRSV in herds. For that reason, a single positive antibody result does not prove a causal role for PRRSV in a clinical diagnosis. In addition, detection of antibodies in weaned pigs may represent circulating maternal (IgG) PRRSV antibodies (Rotolo et al. 2018). Therefore, seroconversion (negative to positive) and/or rising levels of PRRSV-specific antibody in serum or oral fluid samples collected over time are used to diagnose or track PRRSV infections. Notably, DIVA vaccines have not been developed, and current antibody assays cannot differentiate antibodies produced by infection from those produced by MLV vaccines.

The tests most commonly used to detect antibodies to PRRSV are immunoperoxidase monolayer assay (IPMA), indirect fluorescent antibody (IFA), ELISA, and VN. The fluorescent microsphere immunoassay (FMIA) has been used to detect PRRSV antibodies in serum and oral fluid samples (Gerber et al. 2014; Langenhorst et al. 2012), but

has not been widely implemented in diagnostic laboratories.

IPMA and IFA may be performed using either PAM or MA-104 cells (Pejsak and Podgórska 2015). In particular, IFA performance (diagnostic sensitivity, diagnostic specificity, and reproducibility) can be affected by the technical skill of laboratory personnel and antigenic differences between the PRRSV isolate used in the IFA and the field virus that induced antibodies in the pig. To a large extent, these tests have been replaced by antibody ELISAs.

Commercial antibody ELISAs are widely available for the detection of IgG antibodies against PRRSV nucleocapsid antigens in serum and oral fluid samples, albeit commercial PRRSV ELISAs vary in diagnostic performance (Sattler et al. 2014). ELISAs based on nsp 1, 2, 7, and 9 (Brown et al. 2009; Cong et al. 2013; Janková and Celer 2012; Molina et al. 2008) have been used in research, but have not been commercialized.

The ELISA format is considered diagnostically sensitive, diagnostically specific, and compatible with high-throughput testing. Most commercial ELISAs are designed to detect antibodies to both PRRSV-1 and PRRSV-2, but some are genotype specific. Antibody can be detected by ELISA in serum or oral fluid samples as early as 9 DPI, but the response varies among individual pigs and among virus isolates (Horter et al. 2002; Johnson et al. 2004). Johnson et al. (2004) found that virulent PRRSV isolates induced a faster and stronger humoral immune response. There is no detectable difference in antibody response between persistently infected animals and those that have cleared the virus, i.e. ELISA results cannot be used to predict carrier status (Fangman et al. 2007; Horter et al. 2002; Molina et al. 2008).

Commercial ELISAs typically target IgG antibodies because of the higher concentration of IgG compared with IgM and IgA in the samples. The presence of maternal IgG antibody in young pigs can make it difficult to determine whether a positive ELISA result is due to infection, vaccination, or maternal antibody. However, Rotolo et al. (2018) reported that a combined IgM–IgA oral fluid ELISA was able to detect PRRSV-specific IgM and IgA antibody produced by pigs in response to PRRSV infection, despite the presence of maternal IgG.

The VN test detects antibodies capable of neutralizing a constant amount of PRRSV in cell culture. Neutralizing antibody appears approximately 4 weeks after infection and persists for at least 210 days (Meier et al. 2003; Molina et al. 2008; Wills et al. 1997b). Neutralizing antibodies can completely inactivate homologous virus but may only partially neutralize heterologous virus isolates (Lopez and Osorio, 2004; Robinson et al. 2015). Therefore, like IFA, the magnitude of the VN response will depend, in part, on the homology between the PRRSV isolate used in the test and the field virus that induced antibodies in the pig. The VN test has not been standardized between laboratories and is not generally used as a routine diagnostic.

Immunity

Infection with PRRSV induces immunity that eventually controls the initial infection, eliminates the virus, and establishes memory that is variably protective against future infection. Live virus is necessary for induction of immune protection. Killed virus, subunit proteins, and other experimental vaccines that do not contain live PRRSV do not induce effective protection against PRRSV. The properties that confer protection have not been identified despite extensive examination of major and minor envelope proteins and testing of recombinant viruses containing nonstructural and structural coding regions implicated in virulence or protection.

Resistance to infection increases with age, i.e. sows are more resistant to viral replication and disease than weaned pigs (Klinge et al. 2009). Immune induction may be independent of age, but findings related to infection and immunity in young pigs should be interpreted cautiously when applied to older swine. Immunity to PRRSV appears to be the same for PRRSV-1 and PRRSV-2, but the majority of the research has been conducted on PRRSV-2 isolates and strains.

Humoral immune response

Humoral IgM antibodies appear within 1 week of infection against many PRRSV structural and nonstructural proteins (Brown et al. 2009; de Lima et al. 2006; Johnson et al. 2007; Molina et al. 2008; Mulupuri et al. 2008). The strength and kinetics of antibody responses is variable among individual proteins in any given pig and among individual pigs in a group.

It appears that humoral immunity to PRRSV, once acquired, is highly durable. However, anti-N antibodies may decay more rapidly even though virus is present in lymphoid tissues. Since many serodiagnostics are based on nucleocapsid antigen, it is possible to misdiagnose immune animals as nonimmune several months after exposure (Batista et al. 2004).

Anatomically, actively secreting and memory PRRSV-specific B cells reside in diverse lymphoid tissues, especially lymph nodes draining the lungs and genital areas, spleen, and tonsil (Mulupuri et al. 2008).

Neutralizing antibodies are key to the control of many viral infections, but their role in controlling PRRSV infection is controversial. The appearance of neutralizing antibodies in primary infection mainly occurs after viremia is already resolved, but neutralizing antibody titer is the best predictor of level and duration of viremia (Molina et al. 2008). Passive transfer of homologous

neutralizing antibodies was shown to prevent reproductive disease and viral transmission to offspring (Osorio et al. 2002). High titers of broadly neutralizing activity in naturally infected pigs can provide cross-protection against heterologous PRRSV (Robinson et al. 2015, 2018). The viral neutralization target appears to be one or more epitopes in the minor envelope glycoproteins (GP2, GP3, GP4) that form a trimeric complex that mediates cellular infection (Das et al. 2010). GP5 is not required for macrophage infection and anti-GP5 antibodies do not neutralize infection (Dobbe et al. 2001; Li and Murtaugh 2012). It seems likely that additional factors, including genetic variation in neutralizing epitopes, variation in immunodominance, epitope masking by glycosylation, and variation in host response, may contribute to individual variation in viral neutralizing capability. Since broadly neutralizing immune serum can control viremia, there may be a role for antibody-based strategies as an immunotherapeutic.

Cell-mediated immune response

T-cell immunity is poorly understood in swine due to an inability to expand antigen-specific T-cell populations *in vitro* and a lack of tools and reagents to examine antigen-specific responses *in vitro* or *in vivo*. In the case of PRRSV, except for one study, it has been difficult to demonstrate protein-specific T-cell proliferation or cytotoxicity in classical cell culture systems (Bautista et al. 1999). New approaches may address this problem (Jeong et al. 2010). Interferon-γ ELISPOT using live PRRSV in leukocyte cultures has shown a consistent T-cell response to PRRSV infection, but its significance is uncertain (Xiao et al. 2004). The source of interferon-γ is difficult to determine since it is produced by Th1 helper T cells, activated cytotoxic T cells, and natural killer cells. IFN-γ-secreting cells often increase with pig age, but there is no correlation with resolution of PRRSV infection (Klinge et al. 2009).

Cytokine expression that might indicate T-cell responses indicative of Th1 or Th2 regulation may not be informative in pigs (Klinge et al. 2009; Murtaugh et al. 2009). Regulatory T cells (Tregs) and the Th3 cytokine IL-10 are induced by PRRSV or PRRSV-infected dendritic cells (Gomez-Laguna et al. 2009; Silva-Campa et al. 2009; Wongyanin et al. 2010). Tregs may be important in PRRSV since the delayed induction of immunity and prolonged infection indicate the potential for a T-cell response that is suppressive rather than ameliorative.

Protective immunity

At the individual pig level, exposure to PRRSV elicits protection against subsequent challenge. Immunological protection is premised on the induction of memory B and T cells that persist in the body after all evidence of primary infection is gone. Memory B cells against structural and nonstructural viral proteins are present before viremia is extinguished (Mulupuri et al. 2008). Even though memory B cells appear to be quite abundant, there is no anamnestic response to viral challenge (Foss et al. 2002). Pigs consistently show substantial resistance to infection, but show no significant change in antibody levels, which is a hallmark of memory. These observations are relevant to vaccine development since they raise the possibility that the mechanism of immunological protection may not be entirely dependent on memory lymphocytes. In the related arterivirus of mice (lactate dehydrogenase-elevating virus (LDV)), resistance to infection is attributed to the depletion of permissive macrophages (Cafruny et al. 2003). No data shows that a similar mechanism exists against PRRSV in swine.

In the time before sterilizing immunity is established, it is possible that resistance to challenge could be due to ongoing immunity to the first exposure. One flaw in the understanding of protection is that almost all challenge experiments are performed before the first infection has been resolved. In these cases, it is not certain that memory is required. In commercial pig production, the duration of PRRSV infection (persistent infection) often exceeds the life span of market pigs (Molina et al. 2008).

Cross-protection

Vaccines based on specific PRRSV strains are dependent on induction of cross-protective immunity for efficacy. Cross-protection studies in the growing pig consistently show significant improvement in clinical indicators of health, lung pathology and histopathology, and growth performance (Johnson et al. 2004; Mengeling et al. 2003; Opriessnig et al. 2005; Wei et al. 2013). Studies in pregnant sows are less common but also show significant improvement in reproductive performance (Lager et al. 1999; Mengeling et al. 1999).

In the field, the degree of cross-protection is a major concern, particularly for reproductive PRRS, since outbreaks are known to occur in herds with solid immunity induced by regular vaccination or inoculation programs. Incomplete protection can give rise to viremic piglets that cause outbreaks in downstream nurseries. In contrast, vaccine intervention in a finisher outbreak that results in partial reduction in disease severity and reduces economic losses at market may be judged a success.

High levels of cross-protective antibodies are present in immune pigs (Robinson et al. 2015, 2018). However, the uneven translation to cross-protection in the field indicates that biological factors, in addition to viral genetic variation, affect its efficacy. These factors may include physiological variation in pig susceptibility to

infection (Klinge et al. 2009) and genetic variation in host tolerance to PRRSV infection (Halbur et al. 1998; Lewis et al. 2009; Petry et al. 2007).

Maternal immunity

The appearance of PRRSV in weaned pigs has been associated with the loss of maternal antibody, and the duration of maternal protection was correlated with neutralizing antibody titer (Chung et al. 1997). However, piglets nursing on nonimmune sows showed less severe disease and shorter duration of viremia after challenge than piglets nursing on immune sows (Shibata et al. 1998). The finding may indicate that infection occurred *in utero* or from virus shed in milk (Wagstrom et al. 2001). In PRRSV-1-vaccinated sows, maternally derived antibodies impaired humoral and cellular immune responses, though the impact on protection and viral transmission was not examined (Fablet et al. 2016).

Genetic resistance

The challenge of achieving effective immunological control of PRRSV has so far proven insurmountable. The discovery that CD163, a macrophage scavenger receptor, is the PRRSV receptor on permissive cells, combined with new technologies for germ-line modification of animals, has provided proof that pigs lacking CD163 alone are completely resistant to both PRRSV-1 and PRRSV-2 (Calvert et al. 2007; Prather et al. 2013; Wells et al. 2017; Whitworth et al. 2016). Deletion of CD163 compromises pig health so that gene-knockout pigs are not suitable for commercial production. A more subtle partial deletion of CD163 confers resistance to PRRSV-1 but not PRRSV-2 (Wells et al. 2017), although its potential side effects are not yet known. Given the power of these new technologies, developments in the search for pigs that are commercially viable yet genetically resistant to PRRSV and other pathogens will continue apace.

Prevention and control

Prevention

Prevention is the implementation of actions strategically designed to reduce the probability of introducing PRRSV into negative herds or new PRRSV variants into positive herds. Every swine premises is different, so the first step is to identify site-specific hazards. Examples of routine events with the potential to carry virus into a herd are listed in Table 41.1. The second step in biosecurity is to recognize that a series of failures must occur for PRRSV to be introduced into a population (Figure 41.1). These are the critical control points at which specific actions can be taken to prevent the introduction of the virus. Examples of such actions include the use of quarantine facilities and testing protocols for incoming breeding stock, sanitation and drying protocols for transport vehicles and incoming supplies, personnel entry protocols such as shower-in facilities or Danish entry systems, and insect control programs, i.e. screens, habitat management, and insecticides. For herds in swine-dense regions, PRRSV prevention may include the use of air filtration or air treatment systems. Filtration has been shown to effectively reduce the risk of the introduction of PRRSV and other airborne agents, such as *Mycoplasma hyopneumoniae*, under both laboratory and field conditions (Dee et al. 2010; Pitkin et al. 2009; Spronk et al. 2010).

Table 41.1 Examples of routine events with the potential to carry PRRSV into a swine herd.

Swine movement	People movement
Semen delivery	Entry of on-farm employees
Gilt delivery	Repair inside/outside barns
Cull removal	Other visitors (vets, vendors, etc.)
Weaned pig removal	
Vehicles/deliveries	Other hazards
Mortality removal	Pork/food product entry
Feed delivery	Manure removal
Propane/fuel delivery	Entry of other animals
Garbage removal	Entry of air/water
Tools/supplies delivery	

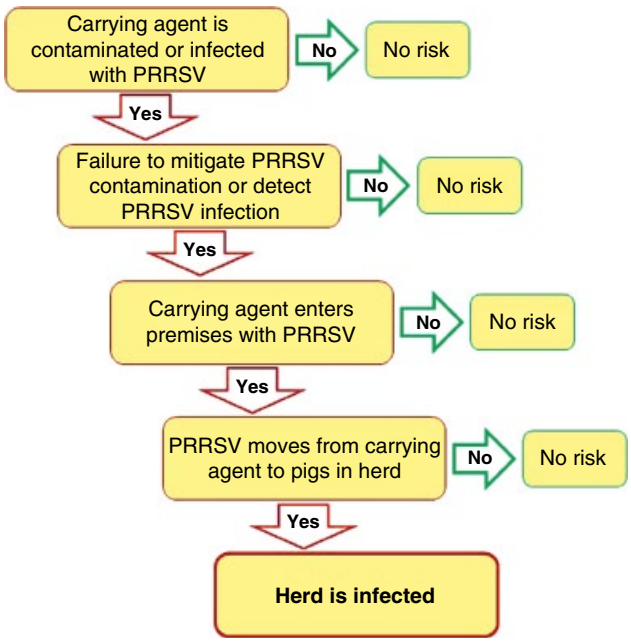

Figure 41.1 Chronological series of events required for PRRSV to be introduced into a swine herd.

Control

Specific treatments or methods to reduce the clinical effects of PRRSV are limited. Therefore, the objective of control is to ameliorate the adverse effects of the virus in the various stages of production. During an acute outbreak, it is common to administer anti-inflammatories to control fever along with antibiotics to manage secondary bacterial infections. As hematogenous spread of PRRSV via contaminated needles is well documented (Otake et al. 2002), changing needles between animals and/or the use of needle-free technologies may assist in controlling spread.

Chronically infected herds are best managed through pig flow strategies, such as McREBEL management in the farrowing house and all-in/all-out animal flow or partial depopulation, to prevent endemic viral circulation post weaning (Dee et al. 1994; McCaw 2000). The use of modified live vaccines has been demonstrated to reduce production and economic losses and the shedding of wild-type virus (Linhares et al. 2012b). Proper sanitation and disinfection of facilities is critical for reduction of viral load and subsequent challenge to incoming groups of healthy pigs.

Gilt acclimatization

A key aspect to any control program is management of the gilt pool (Dee et al. 1994). The introduction of naïve replacement gilts into an infected breeding population results in recurrent episodes of reproductive failure and both horizontal and vertical transmission of virus from dam to offspring. To properly acclimatize incoming replacement gilts, many production systems use designated facilities for gilt development units (GDUs) (Dee et al. 1997). Replacement gilts enter these facilities at a young age, i.e. at weaning or 25 kg. This allows adequate time (4–6 months) for the development of protective immunity through the use of modified live vaccines and/or exposure to farm-specific wild-type virus via live virus inoculation (LVI).

LVI typically involves the administration of a standardized dose of a farm-specific PRRSV strain using serum from an infected animal. This method has inherent risks and requires a thoughtful approach and high-quality control standards. That is, while the safety and efficacy of commercial vaccines is well established, the same cannot be said for LVI. Therefore, to improve the safety of this approach, it is important to properly characterize the virus in the inoculum through nucleic acid sequencing, quantify the dose, and screen the material for the presence of adventitious agents.

Along with the use of a GDU to manage the immunity of replacement gilts, it is also important to develop a controlled approach of managing immunity in the breeding herd. Similar protocols (whole herd vaccination and/or LVI) have been applied to eliminate subpopulations of naïve animals within the chronically infected herd (Dee et al. 1996). Once again, proper preparation of the live virus inoculum as well as discussion of the potential side effects of whole herd administration of PRRSV-positive serum with farm personnel and ownership groups is important to properly manage expectations. Application of a comprehensive herd immunization approach has been shown to be successful in decreasing the time to PRRSV-negative weaned pig production and the improved biological and financial performance of the infected farm. More specifically the use of whole herd vaccination using a modified live vaccine in the face of outbreaks resulted in the recovery of production losses more rapidly and the reduction of total piglet loss than herds where immunization was performed by LVI. However, the production of negative groups of pigs (i.e. farm PRRSV stability) was achieved sooner when an LVI protocol was implemented (Linhares et al. 2014).

Eradication

Elimination of PRRSV from a population is justified by clear improvements in pig health and productivity. Spontaneous elimination of PRRSV from a herd has been described (Freese and Joo 1994), but is a near impossibility in contemporary production systems.

Several methods have been used to eliminate PRRSV (Corzo et al. 2010). These include total depopulation/repopulation, partial depopulation, test and removal, and herd closure. Among these, herd closure is the most common method to eliminate PRRSV from breeding herds.

Herd closure consists of the temporal interruption of introduction of replacement animals into an infected herd, while herd immunity builds after an outbreak or the intentional exposure of resident animals to PRRSV or after vaccination with a modified live vaccine (Corzo et al. 2010; Linhares et al. 2014; Molina et al. 2008; Torremorell et al. 2003). Herd closure is based on the premise that, although PRRSV produces a chronic persistent infection, the immune system is eventually able to clear the virus from all tissues.

Herd closure periods vary between herds based on different factors such as exposure method, the presence of prior immunity, type of virus, or management factors. The period for herd closure may range between 12 and 42 weeks, and a median of 26.6 weeks has been documented for a group of herds (Linhares et al. 2014). After that period, introduction of negative replacement animals follows the attrition or scheduled culling of the previously infected animals. The herd closure method is also referred as "load–close–expose" when groups of gilts are introduced prior to closure and exposure.

Total herd depopulation and repopulation is also a successful technique, but it is costly and may only be

justifiable if the elimination of other concurrent diseases is desired.

Partial depopulation is indicated for the elimination of the virus from growing pigs when shedding from the breeding population has completely stopped. This strategy is commonly used in combination with herd closure or mass vaccination and unidirectional pig flow protocols (Dee et al. 1993, 1997; Dee and Molitor 1998).

Elimination by test and removal has also been documented and consists of testing all individuals in the entire breeding herd to identify PRRSV-infected animals using antibody and nucleic acid tests and then removing any positive animals from the farm (Dee and Phillips 1998; Dee et al. 2004, 2005b). This method is more costly and labor intensive than herd closure, but it is an option for herds where the presence of persistently infected animals is considered a potential risk for failure of the program or where there is a desire to expedite the removal of serologically positive animals.

Surveillance

Prevention, control, and/or eradication efforts need ongoing population data to set baselines, track changes, and measure success (or failure). PRRSV infection is often silent, i.e. does not produce clinical signs. Therefore, assessments of population status vis-à-vis PRRSV must be based on testing. Serum is the traditional surveillance specimen, although other individual animal specimens may be used, e.g. semen and blood swabs. "Pooling" samples prior to testing, i.e. combining two or more discrete samples into one prior to testing, is one strategy for reducing test costs. However, more recent work has shown that oral fluid specimens and/or neonatal processing fluids provide more sensitive surveillance and with less effort expended on sample collection and at a lower testing cost (Kittawornrat et al. 2014; Lopez et al. 2018; Olsen et al. 2013a,b; Rotolo et al. 2017, 2018). Regardless of the approach selected, surveillance should be performed on a routine basis.

Swinepox Virus

Tânia Rosária Pereira Freitas

Revelance

Swinepox occurs sporadically in pigs worldwide and is generally associated with poor sanitation. This is a skin disease and typically produces pustular (pox) skin lesions in localized areas, with more severe forms in young pigs (<3–4 months). The causative agent is swinepox virus (SwPV) and swine are the only susceptible species. It is noteworthy that pustular skin disease caused by vaccinia virus (VACV) was observed in pigs during the successful campaign to eradicate smallpox from humans using VACV-based vaccines (Delhon 2017). However, the recent emergence of VACV in bovine and buffalo (Medaglia et al. 2009; Singh et al. 2007) suggests the need to determine whether these VACV can spread to pigs.

Etiology

Poxviruses belong to the family *Poxviridae*, which includes two subfamilies: *Chordopoxvirinae* (members infecting vertebrates) and *Entomopoxvirinae* (members infecting insects) (Damon 2013). SwPV is the sole member of the genus *Suipoxvirus* in the subfamily *Chordopoxvirinae*. Genus *Orthopoxvirus* in this subfamily includes important poxviruses, such as variola virus, VACV, cowpox virus, monkeypox virus, and others.

The structure and the composition of the SwPV virion resemble those of the VACV, and large brick-shaped membrane-bound virus particles measuring approximately 240 × 310 nm may be observed by electron microscopy (Figure 42.1) (Condit et al. 2006; Conroy and Meyer 1971; Moussatche and Condit 2015).

Poxviruses contain a DNA genome and are the only known family of DNA viruses replicating and assembling in the cytoplasm of the host cell. The SwPV genome is a linear double-stranded DNA molecule of 146 kb containing a conserved central coding region with inverted terminal repeat sequences at both ends. The virus genome is predicted to contain 150 genes, of which 146 conserved genes encode proteins involved in basic replicative functions, viral virulence, host range, and immune evasion similar with other poxviruses (Afonso et al. 2002). Poxvirus-infected cells produce two forms of progeny virions: mature virions (MVs) and extracellular enveloped virions (EEVs) (Traktman 1996). As shown in Figure 42.2, viral genome DNA and nucleoprotein are organized as a nucleosome within the central biconcave core, and the core membrane has regular subunit structure. The virion core and lateral bodies are enclosed within the outer membrane (lipoprotein) to form the MV, which may acquire an additional envelope composed of host cellular membrane and virus-specific proteins to form the EEV (Figure 42.2). In infected cells, the majority of progeny virions are MVs that are released by budding or after cell lysis, whereas some virions (EEVs) exit the cell by exocytosis (Delhon 2017). MVs are very stable, whereas EEVs are relatively fragile (Delhon 2017).

SwPV appears to be antigenically distinct from other poxviruses. SwPV antibodies do not cross-react with vaccinia, cowpox, or fowlpox viruses in precipitation tests and do not cross-neutralize other poxviruses (de Boer 1975; Meyer and Conroy 1972; Ouchi et al. 1992). SwPV strains from various geographic regions have shown high nucleotide identity (96–100%) when compared to the genomic sequences of a SwPV prototype strain (SwPV-Nebraska) (Afonso et al. 2002; Borst et al. 1990; Medaglia et al. 2011; Riyesh et al. 2016), suggesting that there is little genetic variability among SwPV strains.

Successful SwPV virus isolation has been reported in primary cultures of pig kidney cells (de Boer 1975; Kasza et al. 1960; Paton et al. 1990) and/or continuous porcine kidney cell lines such as PK-15 (Garg and Meyer 1972; Paton et al. 1990; Riyesh et al. 2016). Cytopathic effects, characterized by intranuclear vacuoles, cytoplasmic inclusion bodies, and destruction of most of the cells, are observed starting from the second to fourth blind passages and in subsequent passages usually within 3–5 days

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

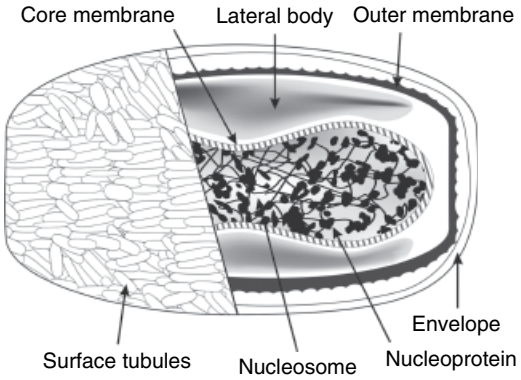

Figure 42.2 Schematic structure of a poxvirus virion.

post inoculation (de Boer 1975; Kasza et al. 1960; Riyesh et al. 2016). Attempts to isolate or grow SwPV in non-swine cell cultures or on chicken chorioallantoic membranes have been unsuccessful (Garg and Meyer 1972; Kasza et al. 1960; Meyer and Conroy 1972; Paton et al. 1990).

The restricted host range of SwPV and its ability to induce solid immune responses have stimulated interests in using SwPV as a vaccine vector (Foley et al. 1991; Tripathy 1999). SwPV has been used for expressing proteins of some swine pathogens, such as pseudorabies virus (van der Leek et al. 1994), classical swine fever virus (Hahn et al. 2001), swine influenza virus (Xu et al. 2013), *Streptococcus suis* (Huang et al. 2012), porcine circovirus 2 (Lin et al. 2012), porcine reproductive and respiratory syndrome virus (Lin et al. 2017), transmissible gastroenteritis virus, and porcine epidemic diarrhea virus (Yuan et al. 2015, 2017), as well as for expressing antigens of some non-swine pathogens (Winslow et al. 2003, 2005).

Public health

SwPV is not zoonotic and there is no evidence that SwPV is a threat in public health.

Epidemiology

Swinepox was first reported in North America in 1929 (McNutt et al. 1929) and thereafter in many regions of the world (Neufeld 1981; Shope 1940), including Europe (Borst et al. 1990; de Boer 1975; Moorkamp et al. 2008; Paton et al. 1990), Brazil (Medaglia et al. 2011), India (Manickam and Mohan 1987), and elsewhere.

The pig is the only natural host of SwPV. SwPV can infect pigs of all ages, but swinepox disease only occurs sporadically, and clinical disease is most commonly seen in young pigs. Under experimental conditions, SwPV failed to cause lesions in the scarified skin of rabbits and guinea pigs nor infected kidney cells from cattle and rabbits (Kasza et al. 1960).

SwPV is transmitted most commonly between swine by the bite of the pig louse, *Haematopinus suis*, whose prevalence in pig populations is variable and geographically dependent, for example, 96.1–100% in Kenya and 2.5% in Germany (Damriyasa et al. 2004; Kagira et al. 2013). Poor sanitation can increase susceptibility to lice infestation (Damriyasa et al. 2004). Flies (*Stomoxys calcitrans*) and mosquitoes may also be mechanical vectors for SwPV transmission (Fenner 1996). SwPV may also be horizontally transmitted between pigs by direct contact of nasal and oral secretions and by desquamated scabs coming into contact with skin abrasions. Vertical (transplacental) SwPV transmission is possible, as evidenced by sporadic cases of congenital infections (Borst et al. 1990; Neufeld 1981; Paton et al. 1990).

Smallpox eradication in humans using VACV-based vaccines was associated with the spread of VACV to pigs and the appearance of pustular skin lesions (Delhon 2017). Subsequent to successful smallpox eradication, swinepox is only associated with SwPV. However, since 1999 VACV has reappeared in some regions and is endemic in cattle (Medaglia et al. 2009) and in Asian buffalo herds (Singh et al. 2007). Differentiation of SwPV from VACV becomes relevant for evaluating whether VACV infection can spread to pigs.

Pathogenesis

SwPV enters the host through a break in the skin and then replicates in the cytoplasm of keratinocytes of the stratum spinosum, causing hydropic degeneration (Cheville 1966a; Meyer and Conroy 1972). Lymphadenitis of regional lymph nodes may occur, but virus has not

been isolated from lymph nodes (Kasza and Griesemer 1962). Infectious virus can be isolated from the skin lesion materials as early as 3 days post intradermal inoculation (Kasza and Griesemer 1962). It remains unclear how virus spreads from the primary site of replication to secondary sites; viremia has been proposed to account for this process, but substantiating evidence is needed. It has been suggested that congenital infections may result from viremic sows, but virus has not been isolated from blood samples from infected animals (Borst et al. 1990; Kasza and Griesemer 1962; Paton et al. 1990; Shope 1940).

Clinical signs

The clinical signs of SwPV infection are age dependent. Pigs of all ages are susceptible to SwPV, but the disease is most severe in piglets and young pigs <3–4 months of age. In contrast, SwPV infection in adults is usually mild and self-limiting. In young pigs that are affected, morbidity may be high, but the mortality is usually very low. In congenital infections, the affected piglets may be stillborn or die within a few days after birth, although the sows may appear clinically normal.

SwPV-induced cutaneous lesions are commonly found on the flanks, ventral abdomen, legs, inguinal areas, and ears and less frequently on the face near the eyes (Figure 42.3) (Delhon et al. 2012). These areas often coincide with insect vectors' preferred feeding areas. Lesions can also be found on the teats of sows and on skin surface, bulbs of the heels, coronets, face, lips, tongue, and oral mucosa of suckling piglets (Olufemi et al. 1981). In congenital SwPV infections, lesions may be observed over the entire body of the newborn piglets (Borst et al. 1990; Neufeld 1981; Paton et al. 1990).

The incubation period of SwPV infection may be 4–14 days under field conditions (de Boer 1975; McNutt et al. 1929) and 3–6 days in experimental inoculations (Kasza and Griesemer 1962; Paton et al. 1990). Lesions evolve from maculae, papulae, and vesicles to umbilicated lesions with pustular content, followed by crusting. At the macular stage, lesions are pale, flat, round spots 1–5 mm in diameter. In about 48 hours, these progress to

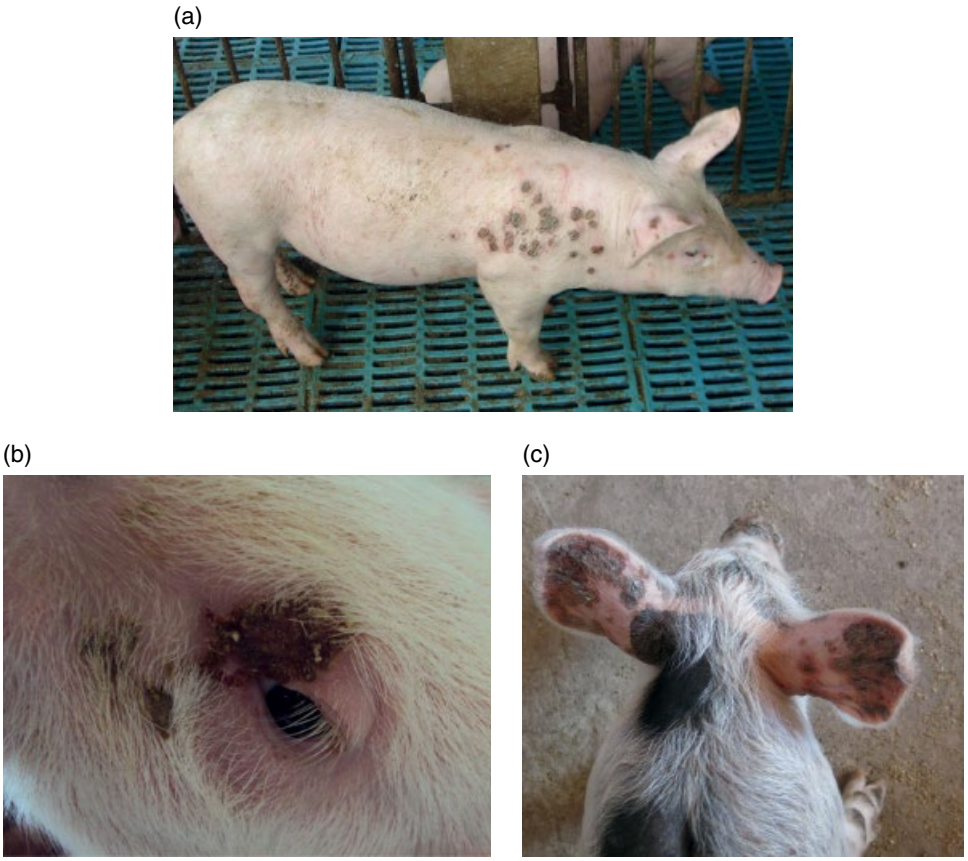

Figure 42.3 Swinepox lesions on skin. The pustular lesions in the dorsal and the lateral flank of young pig (a). The crust formation near the palpebrae (b) and the ears (c). *Source:* Images (a) and (b): Courtesy of Pereira, Adriana Cassia (Centro de Pesquisa e Patologia Animal, Paulinia, Sao Paulo, Brazil.); image (c): Courtesy of Robério G. Olinda (Centro de Saúde e Tecnologia Rural, Universidade Federal de Campina Grande, Campus de Patos, Patos, Paraíba, Brasil).

papulae 1–2 mm in height and 1–2 cm in diameter. In young animals, the appearance of papulae may be accompanied by slight elevation of body temperature and loss of appetite (Kasza and Griesemer 1962; Kasza et al. 1960). A true vesicular stage may be absent or inapparent (Borst et al. 1990; Kasza and Griesemer 1962). The lesions usually become umbilicated and then are replaced by crusts in about 1 week. Eventually crusts fall off, leaving spots on the skin. The recovery of swinepox could be delayed if secondary bacterial and/or parasitic infections occur (Fenner 1996).

Lesions

The classic histological alteration of SwPV infection is the hydropic degeneration of the stratum spinosum keratinocytes of the epidermis, occurring in the papular stage of lesions (Figure 42.4a). As a result, thickening of the epidermis due to the fluid accumulation within the cells can be observed. The epidermal hyperplasia caused by SwPV may be less marked when compared with other poxvirus infections (McNutt et al. 1929; Schwarte and Biester 1941). Another typical histopathological observation is inclusion bodies in the enlarged cytoplasm of infected cells (Figure 42.4b) (Cheville 1966a,b). Hydropic degeneration and inclusion bodies can also be observed in the outer root sheaths of the hair follicles (Kasza and Griesemer 1962; Meyer and Conroy 1972). Concomitantly, margination of chromatin and a large central vacuole (central nuclear clearing) can be seen in the nucleus (Cheville 1966a; Kasza and Griesemer 1962; Meyer and Conroy 1972).

The rupture and coalescence of epidermal cells may form a few small vesicles. Subsequently, infiltration of inflammatory cells (lymphocytes, neutrophils, eosinophils, and histiocytes) into the underlying dermis converts vesicles to pustules. The basal layer undergoes extensive necrosis with infiltration of leukocytes during the pustular stage. Prior to initiating regeneration of the epidermis, the necrosis of apical keratinocytes and crust formation are predominant. At this stage, the regional lymph nodes become edematous, hyperemic, and hyperplastic, but virus antigens may be detected in some cells (Cheville 1966b). In the crusting stage, the lesions mature and heal; the crusts desquamate and leave regenerated epithelium and a little keratinization as a white macula.

Diagnosis

A presumptive diagnosis of swinepox is based on the observation of typical pox lesions on the skin of affected animals, especially under poor sanitary conditions and with lice and/or fly infestations (Cheville 1966b). The differential diagnosis includes vesicular diseases (foot-and-mouth disease, vesicular exanthema of swine, vesicular stomatitis, swine vesicular disease, Seneca Valley virus), skin lesions associated with classical swine fever virus, erysipelas, pityriasis rosea, streptococcal dermatitis, vegetative dermatitis, parasitic skin disease, allergic skin lesion, nutritional disorders, and sunburn.

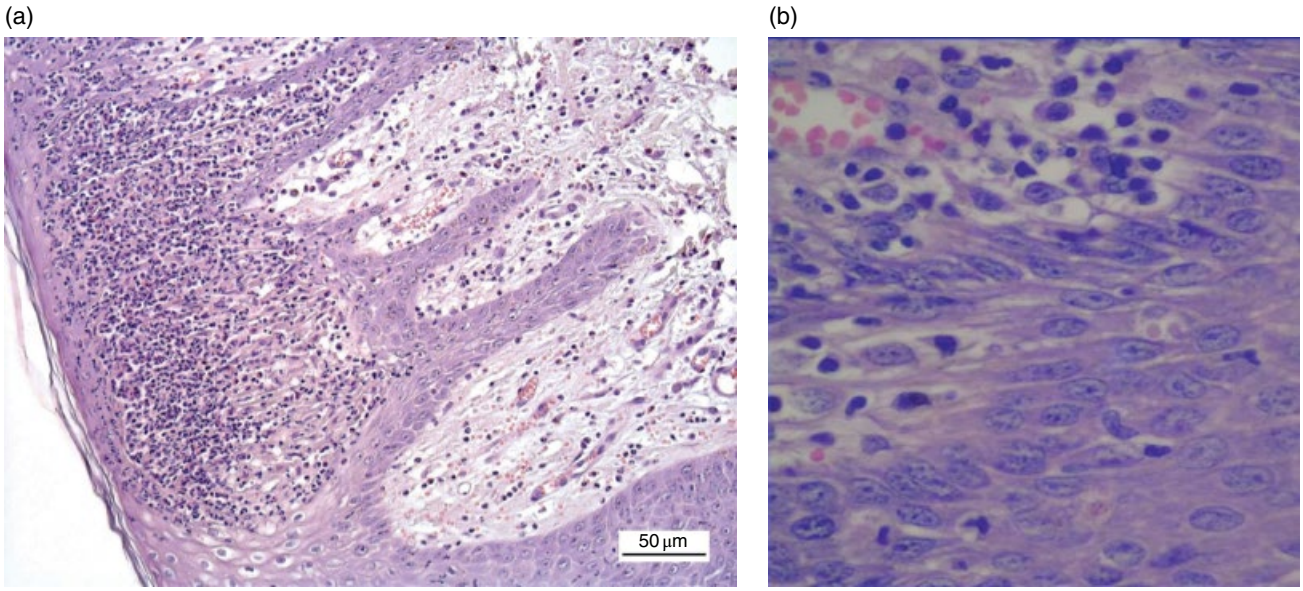

Figure 42.4 Histopathological changes caused by swinepox virus. (a) The severe hydropic degeneration on stratum spinosum of the epidermis. (b) Eosinophilic inclusion body in the cytoplasm of keratinocytes of the epidermis. Hematoxylin and eosin. *Source:* Courtesy of Robério G. Olinda (Centro de Saúde e Tecnologia Rural, Universidade Federal de Campina Grande, Campus de Patos, Patos, Paraíba, Brasil).

Examinations by electron microscopy and histopathology may confirm involvement of SwPV. SwPV infection has some pathognomonic histopathological changes in the epidermis: ballooned stratum spinosum keratinocytes containing cytoplasmic eosinophilic inclusion bodies and a "vacuolated" nucleus. Virus isolation in primary swine kidney cells or PK-15 cell line followed by immunofluorescence staining or virus neutralization using SwPV-specific antibodies is definite confirmation (Borst et al. 1990). Immunocytochemistry on skin samples or infected cell cultures can be a confirmatory method as well. Papular/pustular exudates or crusted materials are appropriate clinical samples for virus isolation. Multiple blind passages should be attempted before considering the sample negative by virus isolation test.

Serological assays to detect SwPV antibody include precipitation antibody tests, immunoelectroosmophoresis (IEOP), serum virus neutralization, and ELISA (Deng et al. 2013). Swine do not develop high levels of neutralizing antibody (Kasza et al. 1960; Shope 1940); therefore, negative neutralizing antibody results should be interpreted with caution.

SwPV-specific polymerase chain reaction (PCR) assays provide a rapid and sensitive method to reliably detect SwPV DNA in samples. This also allows for differentiation from VACV, when needed. In several countries, VACV is endemic in cattle or buffaloes, and there is a risk of VACV spreading to pigs. Differentiation of SwPV from VACV can be achieved using multiplex PCRs (Medaglia et al. 2011, 2015; Singh et al. 2007).

Immunity

Like other viruses, SwPV infection of pigs may elicit innate, humoral, and cell-mediated immune responses. However, SwPV can also potentially modulate the host immune responses (Afonso et al. 2002; Shchelkunov 2012). Limited information concerning the SwPV immune response is available. Convalescent swine are resistant to SwPV challenge, indicating that SwPV infection induces protective immunity (de Boer 1975; Garg and Meyer 1972; Kasza et al. 1960; Schwarte and Biester 1941; Shope 1940). SwPV neutralizing antibody may be detected in swine sera as early as 7 days post inoculation, but antibody titers are low and may become undetected at 50 days post inoculation (Kasza et al. 1960; Meyer and Conroy 1972; Shope 1940; Williams et al. 1989). Maternal antibody may protect suckling piglets (Nelson 1932), but high neonatal mortality and piglets born with skin lesions have also been reported (Borst et al. 1990; Neufeld 1981; Olufemi et al. 1981), indicating that passive protection may not be adequate.

Prevention and control

There is no specific treatment for swinepox. Antibiotic treatment is recommended if it is necessary to control secondary bacterial infections. Swinepox is of relatively low economic impact, and no vaccine has been developed. The best prevention and control is good animal husbandry, including ectoparasite control.

Reoviruses (Rotaviruses and Reoviruses)

Frances K. Shepherd, Matthew J. Freeman, Marie R. Culhane, and Douglas G. Marthaler

Overview

Viruses in the family *Reoviridae* are non-enveloped, icosahedral viruses with a capsid approximately 75 nm in diameter composed of a triple protein layer. The family *Reoviridae* includes two subfamilies, *Sedoreovirinae* and *Spinareovirinae*, of six and nine genera, respectively. Individual viruses within the family infect a variety of hosts, including mammals, birds, reptiles, amphibians, fish, mollusks, crustaceans, insects, plants, and fungi (Mertens et al. 2005). Viruses in this family infecting pigs are rotaviruses (RVs) in the genus *Rotavirus* in the subfamily *Sedoreovirinae* and reoviruses in the genus *Orthoreovirus* in the subfamily *Spinareovirinae*. The RV and reovirus genomes are composed of 11 and 10 segments of double-stranded (ds) RNA (dsRNA), respectively. Reassortment is common within reoviruses and each RV species due to their segmented genome.

RVs and reoviruses are ubiquitous. RVs are a major cause of diarrhea in neonatal and young pigs. However, the association of reoviruses with pig disease is unclear since reoviruses have been found in both healthy pigs and those with respiratory, enteric, and reproductive disease.

Porcine rotavirus

Relevance

RVs are a major cause of diarrhea in humans and animals, including pigs. RV infections can be found in both clinical and subclinical pigs (Amimo et al. 2015; Theuns et al. 2016b). RV infections can also occur in combination with enteric bacteria, leading to increased disease severity, including dehydration, diarrhea, and death (Theuns et al. 2014). Among the 10 RV groups (rotavirus A [RVA] to rotavirus J [RVJ]), RVA, rotavirus B (RVB), rotavirus C (RVC), rotavirus E (RVE), and rotavirus H (RVH) have been reported in pigs (Vlasova et al. 2017).

Porcine RVA was discovered in 1975 (Rodger et al. 1975). Atypical swine RV (non-RVA) strains were discovered in the 1980s and classified into groups B, C, and E (RVB, RVC, RVE) (Bridger 1980; Chasey and Davies 1984; Chasey et al. 1986; Pedley et al. 1986). In 2011, RVH was identified in pigs from Japan and then found in Brazil, the United States, and South Africa (Molinari et al. 2015; Nyaga et al. 2016; Wakuda et al. 2011). Historically, RVA was considered the most prevalent and pathogenic in pigs, but RVC has been identified as a significant cause of enteritis in neonatal pigs (Marthaler et al. 2013; Theuns et al. 2016b), and RVB has been associated with infections in older animals. Whether RVE and RVH are significant pathogens has not been established.

Etiology

The RV genome consists of 11 segments of dsRNA encoding viral proteins (VP) 1–4, 6, and 7 and nonstructural proteins (nsp) 1–5. Each gene segment encodes for a single protein, except for segment 11, which encodes for nsp5 and nsp6 proteins in some RV species. RVs are unique in the sense that the nsp4 produces an enterotoxin that contributes to viral pathogenesis (Estes and Greenberg 2013). The VP1, VP2, and VP3 proteins form the inner capsid of the virion. The middle capsid layer is made up of the VP6 protein while the outer capsid is composed of the VP7 and VP4 proteins. The VP4 is proteolytically cleaved into VP5 and VP8 proteins forming the spike that is used for host attachment and infectivity (Estes and Greenberg 2013; Prasad et al. 1988). The complete three-layered RV particles (inner, middle, and outer capsid layers) resemble a wheel with a smooth surface when visualized by electron microscopy (Figure 43.1a). The outer capsid layer of VP7 and VP4 can be removed by various chemical and enzymatic treatments, and the remaining double-layered particles without the outer capsid have rough outlines (Figure 43.1b).

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

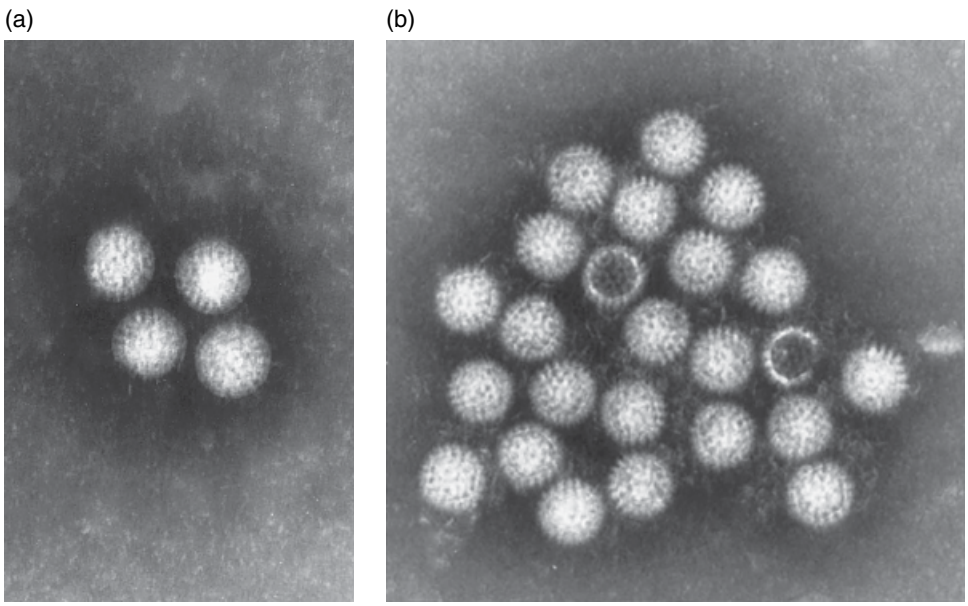

Figure 43.1 Rotavirus particles in feces viewed by negative-staining EM (×130,000). (a) Triple-layered virus particles with intact outer capsids have characteristic smooth outlines. (b) Double-layered particles lack outer capsids and have spiked outlines. *Source:* Chang et al. (2012). Reproduced with permission of John Wiley and Sons.

Historically, RVs were grouped based on banding patterns of the dsRNA in an electropherogram and cross-neutralization capabilities in plaque reduction assays (Estes and Greenberg 2013). Today, RV species are classified based on sequencing of the VP6 using a 53% nucleotide identity cutoff value (Matthijnssens et al. 2008b, 2012), resulting in 10 RV species *Rotavirus A* to *Rotavirus J* (corresponding to viruses RVA-RVJ) (Bányai et al. 2016; Vlasova et al. 2017). A genotype constellation scheme for the 11 RVA gene segments has been developed using nucleotide percent identity cutoffs (Matthijnssens et al. 2008b). Similar genotype schemes have been developed for some genes of the other RV species as well. A binary classification system is used to describe RV strains based on VP7 or G genotype (for the glycoprotein VP7) and VP4 or P genotype (for the protease-sensitive VP4). A standardized naming system for RV strains reported in GenBank® has been established by the Rotavirus Classification Working Group, which includes information on each RV species, host species and wild type or cell culture adapted, country of origin, strain name, year of identification, and G and P genotypes (Matthijnssens et al. 2011).

RVs grow in culture with varying success. Trypsin or pancreatin aids in the growth of RV in cell culture, facilitating cleavage of the outer capsid protein VP4. *In vitro*, visualization of cytopathic effects, such as a rounding phenotype of the cells, is indicative of RV growth.

Rotavirus A

RVA has been propagated in cultures of rhesus monkey kidney (MA104) cells (Saif et al. 1988a). HepG2 liver cells, pancreatic islet cells, colon adenocarcinoma, or other kidney cell lines are also permissive for RVA growth (Arnold et al. 2009; Coulson et al. 2002; Ramig and Galle 1990). The development of polarized small intestinal cell lines is a promising model system for representing *in vivo* growth and replication (Porta et al. 2016). While most RVA strains tend to grow well in culture, some RVA strains remain difficult to propagate.

Through the use of neutralization assays, 27 G serotypes have been assigned to RVA strains (Estes and Greenberg 2013). Given the ease of sequencing, neutralization assays are rarely performed. Genotypic analysis of RVA VP7 uses an 80% nucleotide identity cutoff value to designate different G genotypes (Matthijnssens et al. 2008b). To date, all known G genotypes and serotypes are identical. There have been 18 RVA P serotypes identified (Estes and Greenberg 2013). Unlike G serotype and genotype classifications, P serotypes and genotypes do not necessarily correspond; thus the P genotype is reported in brackets ([X]), while the serotype is not. It is difficult to obtain the necessary reagents to determine the P serotype by neutralization assays. Therefore, only the P genotype is known for many RVA strains. The RVA P genotypes are also defined by an 80% VP4 gene nucleotide identity cutoff value (Matthijnssens et al. 2008a). The genotypes for VP6, VP1, VP2, VP3, nsp1, nsp2, nsp3, nsp4, and nsp5, designated I, R, C, M, A, N, T, E, and H,

Table 43.1 Rotavirus A (RVA) gene segments, number of genotypes, and nucleotide identity cutoff values.

Gene segment number	Gene segment	Name of genotypes (abbreviation)	Nucleotide identity cutoff values (%) for RVA	RVA genotypes found in pigs
9	VP7	Glycosylated (G)	80	G1–G6, G8–G12, and G26
4	VP4	Protease sensitive (P)	80	P[1], P[5]–P[8], P[11], P[13], P[14], P[19], P[23], P[26], P[27], P[32], and P[34]
6	VP6	Inner capsid (I)	85	I1, I2, and I5
1	VP1	RNA-dependent RNA polymerase (R)	83	R1
2	VP2	Core protein (C)	84	C1 and C2
3	VP3	Methyltransferase (M)	81	M1
5	nsp1	Interferon antagonist (A)	79	A1 and A8
8	nsp2	NTPase (N)	85	N1
7	nsp3	Translation enhancer (T)	85	T1
10	nsp4	Enterotoxin (E)	85	E1 and E9
11	nsp5	Phosphoprotein (H)	91	H1

are classified using an 85, 83, 84, 81, 79, 85, 85, 85, and 91% nucleotide identity cutoff value, respectively (Table 43.1).

Rotavirus B

Reports of successful RVB propagation are rare. Porcine kidney cells were used to culture a single strain of RVB (SKA-1) in 1996 using pancreatin, but the strain was later determined by sequencing to belong to a RVH strain (Sanekata et al. 1996). Due to the challenges with growing RVB, serotyping is uncommon, and information regarding circulating serotypes is unknown. Instead, RVB strains are classified using an 80% nucleotide identity cutoff value for VP7, resulting in 21 G genotypes (Lahon et al. 2014; Marthaler et al. 2012).

Rotavirus C

A limited number of RVC strains have been cultured in MA104 and primary porcine kidney cells, with high pancreatin or trypsin concentrations (Saif et al. 1988b; Terrett and Saif 1987; Tsunemitsu et al. 1991). The RVC G genotypes are classified using an 85% nucleotide identity cutoff value while P genotypes use an 83% nucleotide identity cutoff value (Jeong et al. 2015; Marthaler et al. 2013). Thirteen G genotypes and eight P genotypes have been identified for RVC to date (Jeong et al. 2015; Marthaler et al. 2013; Moutelíková et al. 2015; Niira et al. 2016). Like RVB, RVC serotypes are not commonly determined due to difficulties in propagating the strains; thus only G and P genotypes are reported.

Public health

Direct transmission of RVs between animals and humans has not been shown. The detection of animal–human reassortant RVA strains in human patients has suggested a zoonotic potential for RVA (Chitambar et al. 2009; Degiuseppe et al. 2013; Hwang et al. 2012; Midgley et al. 2012; Than et al. 2013; Wilhelm et al. 2015). However, host-specific genotypes for RVB, RVC, and RVH suggest a lack of transmission between swine and humans for these RV species (Gabbay et al. 2008).

Epidemiology

RVs are ubiquitous, and every pig will experience RV infection within its lifetime, if not multiple times. Mixed infections with multiple RV strains have been reported as pigs grow older, indicating a temporal distribution of RV infectivity over a pig's lifetime (Homwong et al. 2016). The age of the pig is one of the most important factors for determining the prevalence of infection and severity of disease. Younger pigs without established immunity and piglets that have not received proper passive immunity from the sow are more susceptible to RV infections (Lecce et al. 1978). Neonatal susceptibility combined with the fact that sows shed RV while farrowing increases the chance of infection in young piglets (Benfield et al. 1982).

RV particles are shed in the feces of infected animals (Debouck and Pensaert 1983). They are highly infectious, and as few as 90 particles are sufficient to induce viral shedding and diarrhea in colostrum-deprived piglets. It is estimated each gram of fecal material contains 1×10^{10} infectious RV particles, further increasing the risk of transmission (Payment and Morin 1990). Transmission occurs by fecal–oral contact with RV-contaminated material, resulting in rapid spread within swine herds (Fu and Hampson 1989).

RV is commonly found in the environment, on fomites, and even in drinking water (Fongaro et al. 2015;

Gratacap-Cavallier et al. 2000; Lachapelle et al. 2014; Meleg et al. 2008). RV is highly stable in the environment, and complete drying will not inactivate all virions (Ward et al. 1991). Halogen (chlorine-based) or phenolic disinfectants may be helpful to control RV spread on a farm, if used consistently (Chandler-Bostock and Mellits 2015; Nemoto et al. 2014). Chlorine and glutaraldehyde are the most effective disinfectants for enteric viruses on clothing (Yeargin et al. 2016).

Since reassortment is common within each RV species, numerous G and P genotypes circulate in pig populations, and the dominant global G and P genotypes are unknown. In addition, coinfections with multiple RV strains are common in diagnostic investigations, but comprehensive studies regarding coinfections are lacking. A brief epidemiological synopsis for each RV species follows.

Rotavirus A

RVA infects the widest range of hosts, including humans (Zhang et al. 2017), cows (Komoto et al. 2016), bats (Sasaki et al. 2016), broiler chickens (Ter Veen et al. 2017), turkeys (Fujii et al. 2016), horses (Matthijnssens et al. 2015), cats (Otto et al. 2015), canines (Hoshino et al. 1982), rats (Tonietti Pde et al. 2013a), and more.

RVA has been found in pig populations on every continent. Recent epidemiological studies indicated that 4.1–89% of swine clinical samples contained RVA (Amimo et al. 2013; Chandler-Bostock et al. 2015; Lachapelle et al. 2014; Monini et al. 2015; Otto et al. 2015; Theuns et al. 2016b; Tonietti et al. 2013b). In the United States, RVA detection is most common in pigs between 21 and 55 days old, with neonatal infection occurring slightly less commonly (Homwong et al. 2016; Miyazaki et al. 2013). Risk factors associated with clinical RVA include larger herd sizes, early weaning, and "all-in/all-out" production (Dewey et al. 2003). Presumably, continuous-flow nurseries had a lower incidence of RV infection because sows were more highly exposed to RVs and, therefore, provided higher levels of maternal immunity to their piglets.

Within swine, 12 G genotypes/serotypes (G1–G6, G8–G12, and G26) and 14 P genotypes (P[1],P[5], P[6], P[7], P[8], P[11], P[13], P[14], P[19], P[23], P[26], P[27], P[32], and P[34]) of RVA have been described (Matthijnssens et al. 2011; Papp et al. 2013; Pham et al. 2014). Although P serotyping is not routinely performed or reported for swine RVA, P1A, P2A–P2C, P7, P9, P12, and P14 have been identified in pigs, and more serotypes may exist (Estes and Greenberg 2013).

Rotavirus B

RVB has been detected in cows (Tsunemitsu et al. 1999), humans (Alam et al. 2013), goats (Munoz et al. 1996), lambs (Theil et al. 1995), rats (Vonderfecht et al. 1994), and others. Of the 21 RVB G genotypes, G4 and G6–G21 have been identified in pigs (Lahon et al. 2014; Marthaler et al. 2012). Currently, information on RVB P genotypes and serotypes circulating in pig populations is lacking. While a few reports have indicated RVB as a cause of neonatal diarrhea, a lower prevalence of RVB (1.6, 4.9, and 47%) has been reported, and infections are generally associated with pigs >3 weeks old (Lahon et al. 2014; Marthaler et al. 2012, 2014a; Otto et al. 2015).

Rotavirus C

In addition to pigs, RVC can infect humans (Kumazaki and Usuku 2014), cows (Soma et al. 2013), ferrets (Wise et al. 2009), cats (Otto et al. 2015), and dogs (Marton et al. 2015), among others. In pigs, 11 RVC G genotypes (G1, G3, G5–G13) and 6 P genotypes (P[1], P[4]–P[8]) have been identified (Jeong et al. 2015; Moutelíková et al. 2015; Niira et al. 2016; Suzuki et al. 2015). Prevalence of RVC was reported as 19.5–34% in recent studies (Amimo et al. 2013; Marthaler et al. 2013; Moutelíková et al. 2014; Otto et al. 2015; Theuns et al. 2016b). In the United States, RVC is an important cause of diarrhea in neonatal pigs, especially in pigs <3 days of age (Marthaler et al. 2013, 2014a). Single infections of RVC more commonly occur in this age group, with RV coinfections occurring as pigs grow older (Homwong et al. 2016; Marthaler et al. 2014a). This age-dependent RVC pattern has yet to be identified in other countries.

Rotaviruses E and H

There is only one report of RVE in pigs (Chasey et al. 1986), and studies confirming the original observations are needed. More recently, RVH has been detected in swine (Marthaler et al. 2014b) and humans (Yang et al. 1998). In the United States and Brazil, 15 and 18%, respectively, of diarrheic samples from pigs were positive for RVH (Marthaler et al. 2014b; Molinari et al. 2016). Coinfections with other RV species are far more common and should be investigated prior to conclusively diagnosing RVH as the causative agent.

Pathogenesis

RV primarily replicates in the epithelial cells of small intestinal jejunal and ileal tissues. Replication occurs mainly in small intestinal proximal villi, resulting in villous blunting and atrophy. The main pathological lesions are likewise observed in the small intestine. RV antigen can be detected transiently in other body tissues, such as the lung, liver, spleen, or choroid plexus (Azevedo et al. 2005; Kim et al. 2013; Shaw et al. 1989; Zijlstra et al. 1997), but there is no evidence of extraintestinal replication, and lesions in extraintestinal tissues are rare.

The VP5 and VP8 subunits of the VP4 outer capsid protein bind to permissive cells by interacting with sialic

acid (Haselhorst et al. 2009; Zárate et al. 2000). There are no known universal mechanisms for cellular entry, although clathrin-mediated endocytosis appears to be important for some strains of porcine RVA (Gutierrez et al. 2010).

The widely accepted mechanism of RV-induced diarrhea is the loss of villi, leading to a deficiency in fluid absorption and subsequent malabsorptive diarrhea (Osborne et al. 1988; Ramig 2004). Other mechanisms could contribute to RV-induced diarrhea as well. After entry into permissive cells, nsp4 disrupts intracellular calcium (Ca^{2+}) regulation, resulting in increased levels of cytoplasmic Ca^{2+} (Hyser et al. 2010; Michelangeli et al. 1991; Ruiz et al. 2000). The Ca^{2+} can then act on chloride (Cl^-) secretion pathways to increase the release of Cl^- into the lumen, ultimately leading to diarrhea (Dong et al. 1997; Estes and Greenberg 2013; Ruiz et al. 2000). Diarrhea may also be caused by nsp4-mediated activation of the enteric nervous system (Lundgren et al. 2000).

Clinical signs

RV infection ranges from subclinical to severe clinical disease, depending on the RV strain, the age of the pig, immune status, overall herd health, and the presence of secondary bacterial or viral infections. The incubation period is reportedly 17–48 hours in gnotobiotic piglets and 1–4 days in conventional piglets (Torres-Medina and Underdahl 1980; Tzipori and Williams 1978). Clinical signs include profuse watery diarrhea, lethargy, vomiting, and anorexia accompanied by rapid weight loss. Feces become lighter colored or yellow, and undigested milk can be seen in fecal matter and intestines at necropsy (Bohl et al. 1982; Janke et al. 1988; Lecce et al. 1978; Lecce and King 1978; Pearson and McNulty 1977; Torres-Medina and Underdahl 1980; Tzipori and Williams 1978).

Studies involving conventionally reared piglets have reported mortality rates below 20%, but higher mortality rates have been reported in diagnostic cases (Bohl et al. 1978; Lecce and King 1978; Tzipori and Williams 1978). Mortality rates can be very high (86–100%) in gnotobiotic piglets (Bohl et al. 1982; Janke et al. 1988; Tzipori and Williams 1978). Diarrhea in pigs <7 days of age persists for 1–10 days, and pigs that recover usually rapidly return to normal body weight (Crouch and Woode 1978; Tzipori and Williams 1978). In piglets >5 days of age, less severe clinical signs and shorter disease duration are generally observed. Death is much less common in these older piglets as well (Bohl et al. 1982; Lecce et al. 1982). Although disease can be severe, subclinical RV infections have been detected, especially in pigs older than 55 days (Amimo et al. 2015; Collins et al. 2008, 2010; Steyer et al. 2008; Theuns et al. 2016a).

The severity of clinical signs can be exacerbated by several factors, including diet and coinfection with other enteric pathogens. Malnutrition correlated with longer periods of diarrhea and less complete restoration of intestinal crypt depths (Zijlstra et al. 1997). In addition to general malnutrition, vitamin A status has been proposed as an important determinant of RV infection recovery. Pigs deficient in vitamin A experienced longer episodes of more severe diarrhea, higher viral titers in feces, and more intestinal damage compared with pigs with sufficient vitamin A levels (Vlasova et al. 2013). Vitamin A deficiency may also alter B-cell immune responses after vaccination, leading to poorer immunologic protection and lower immunoglobulin levels (Kandasamy et al. 2014). Finally, coinfections with enterotoxigenic *Escherichia coli* or *Clostridium perfringens* type A can cause more severe diarrhea in piglets (Neog et al. 2011; Tzipori et al. 1980a).

Lesions

Lesions from RVA, RVB, and RVC are similar (Bohl et al. 1982; Janke et al. 1988; Marthaler et al. 2012, 2013). Small and large intestines of infected pigs are commonly dilated with excessive, watery, yellow, or gray contents. Intestinal walls are thin compared with those of noninfected individuals. The stomach can be swollen, containing undigested milk (Janke et al. 1988; Neog et al. 2011; Pearson and McNulty 1977).

Histological examination of intestinal tissues early in the course of infection reveals swelling of jejunal and ileal epithelial cells, which becomes more pronounced as infection progresses. Beginning approximately 24 hours of postinfection, epithelial cells in the ileum and jejunum slough into the intestinal lumen, leading to thinner and shorter villi (Figure 43.2). Villi are then covered by abnormal cuboidal epithelial cells (Crouch and Woode 1978; Marthaler et al. 2013; Narita et al. 1982a, b). Shortening of villi is accompanied by elongated intestinal crypts with cellular hyperplasia (Bohl et al. 1982). At 2–5 days of post inoculation, intestinal morphology begins to improve with villi returning to normal length. Despite the intestinal tissue repair, decreased villus-to-crypt length ratios were still present at 3 weeks of postinfection in inoculated pigs compared with uninfected pigs (Crouch and Woode 1978; Narita et al. 1982a).

A study of G9 genotype RVA strains reported extraintestinal lesions in the lung, liver, and nervous system, including interstitial pneumonia, hepatocyte necrosis, and degeneration of the choroid plexus, respectively (Kim et al. 2013). This highlights the significance of systemic spread and damage that occurs after infection with some RVA genotypes. However, whether this damage was due to actual viral replication was not conclusive. In RVC infections, extraintestinal RVC RNA was detected

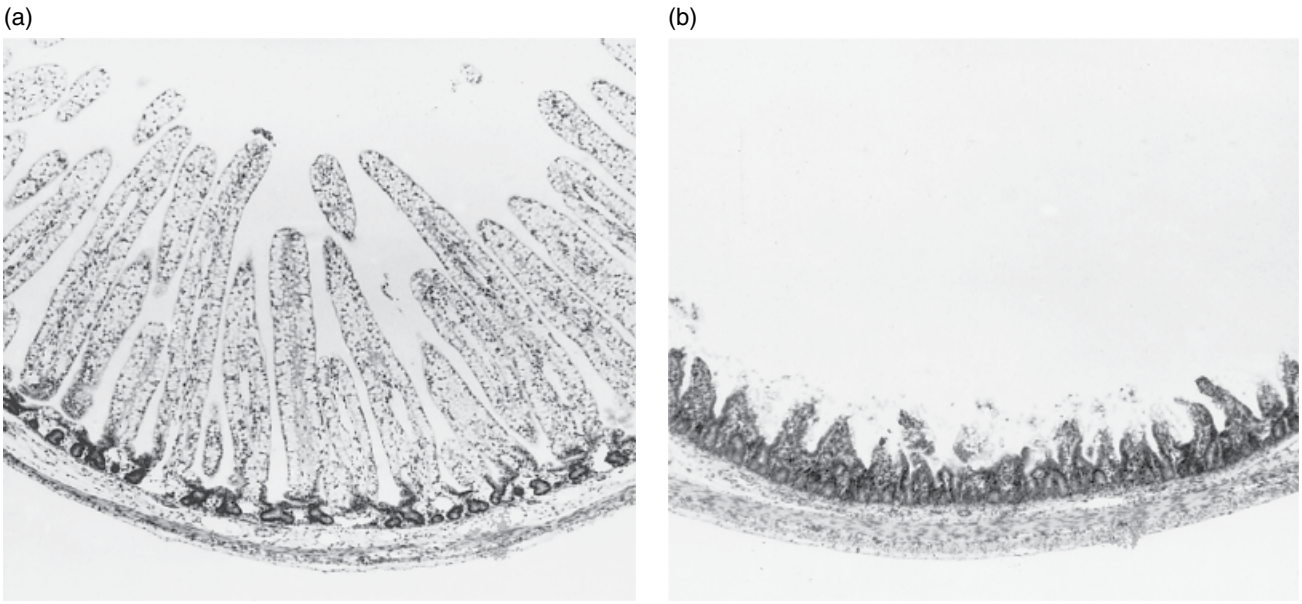

Figure 43.2 The ileum from 3-day-old gnotobiotic pigs (hematoxylin and eosin [H&E]; ×35). (a) Normal villi in an uninoculated control pig. (b) Severe villous atrophy present 18 hours of post inoculation. *Source:* Chang et al. (2012). Reproduced with permission of John Wiley and Sons.

in lung tissues, but lesions were not present and viral replication in these tissues could not be confirmed (Marthaler et al. 2013).

Diagnosis

RV primarily affects neonatal piglets, for which reason it should be included among the differentials when diagnosing enteric disease in animals of this age group. Clinical signs of RV are similar to other enteric pathogens, and, therefore, a diagnosis cannot be made without laboratory testing. However, the fact that RV can also produce subclinical infections should be a consideration when establishing a diagnosis.

Fecal or stomach content samples can be used to detect RV dsRNA and antigens. RT-PCR is the most common diagnostic method used to detect RV and, if quantitative, can determine viral concentrations within a sample (Costantini et al. 2007). The development of multiplex RT-PCR tests containing primers for several enteric viruses allows for the simultaneous detection of multiple diarrhea-causing pathogens in a clinical sample (Masuda et al. 2016; Ogawa et al. 2009; Song et al. 2006; Zhao et al. 2013). Multiplex real-time RT-PCR (rRT-PCR) methods can distinguish between RVA, RVB, and RVC (Marthaler et al. 2014a; Zhou et al. 2016). RT-PCR can also be used to identify different G and P genotypes using primers for the VP7 and VP4 gene segments (Chandler-Bostock et al. 2015; Marthaler et al. 2012; Suzuki et al. 2015; Theuns et al. 2016b).

Other methods to identify RV infection in clinical samples include immunochromatography strip tests (Kang et al. 2007), commercial ELISA kits (Brown et al. 1987; Sharma et al. 2013; Yolken et al. 1988; Zhu et al. 2013), hemagglutination inhibition tests (Eiguchi et al. 1987), cell culture immunofluorescence (Bohl et al. 1984; Terrett et al. 1987), and polyacrylamide gel electrophoresis (Markowska-Daniel et al. 1996). Postmortem diagnosis can be enhanced by the use of immunohistochemistry, *in situ* hybridization, or electron microscopy. Intestinal tissues can be stained and examined for characteristic lesions, and the use of antibodies allows visualization of virus particles within cells (Bohl et al. 1982; Crouch and Woode 1978; Zhao et al. 2013).

ELISA, enzyme-linked immunospot (ELISpot), plaque reduction neutralization (PRN), or fluorescent focus neutralization (FFN) assays are useful for testing the RV immune status of piglets or sows. Assessing levels of neutralizing antibodies against VP7 or VP4 is best done using PRN or FFN (Bohl et al. 1984; Hoshino et al. 1987; To et al. 1998). However, these assays require cultured RV, which is a challenge for some strains. ELISpot assays are useful for identifying responses of antibody-secreting cells in RV-vaccinated and RV-challenged pigs (Yuan et al. 1996, 2001). The anti-RV IgA, IgG, or IgM is quantified using ELISA with isotype-specific monoclonal antibodies (Azevedo et al. 2004).

Immunity

RV infections stimulate both systemic and local immunity, but virulent RV strains elicit stronger immune responses than attenuated strains. The immune response

produces antibodies against VP7, VP4, VP6, nsp3, and nsp4, although the strength and type of immune responses against each of these proteins vary (Chang et al. 2001; Iosef et al. 2002). While antibody-secreting cell responses and immunoglobulin production can be detected against all five proteins, only VP7 and VP4 elicit neutralizing antibody. However, serum neutralizing antibody levels are poor indicators of protective immunity (To et al. 1998).

Increased levels of RV-specific IgA in intestines and serum have been found after vaccination or exposure to virulent RV, and IgA presence is often used as a correlate of protection (Azevedo et al. 2004; Hoshino et al. 1988; To et al. 1998; Yuan and Saif 2002). Numbers of intestinal IgA antibody-secreting cells have been proposed as an even better indication of protective immunity (Chang et al. 2001; Saif et al. 1997; Yuan et al. 1996, 2001).

While there is no cross-protection between different RV species, evidence of heterotypic immunity or cross-protection against multiple genotypes of the same RV species is scarce in pigs. The best protection occurs when VP7 and VP4 segments of the vaccine strain are closely related to the challenge strain (Bishop et al. 1986; Gaul et al. 1982; Hoshino et al. 1988). In addition, RV strains belonging to different lineages within a genotype do not cross-neutralize effectively, making it difficult to conclude whether cross-protection occurs consistently (Hoshino et al. 2004). However, repeated exposure or vaccination increases the likelihood of cross-protection (Chiba et al. 1993; Gorrell and Bishop 1999). Therefore, vaccines should include the most prevalent RV genotypes in a geographic region to provide the best range of protection.

Passive immunity from sows is currently the primary method to protect piglets from RV infections. Sows provide IgG and IgA to their piglets in colostrum and milk (Gellberg et al. 1991; Ward et al. 1996). IgA is the longest-lasting immunoglobulin present in lactating sows, but antibodies taper off after farrowing and are short lived in the piglet. Levels of maternal IgG and IgM in piglets also decline over time, following the trend in the sow, until active immunity in the piglets is induced and levels of anti-RV neutralizing antibodies increase (Hess and Bachmann 1981, Tzipori et al. 1980b). Cytokines in the sow's colostrum and milk could be important in modulating immune responses, especially to activate Th2 cells and antibody production (Nguyen et al. 2007). Early weaning and lack of colostrum lead to severe RV diarrhea in piglets, demonstrating the importance of maternal antibodies in protecting piglet health (Lecce et al. 1978).

Studies in mice (Franco and Greenberg 1995; McNeal et al. 1995) and a few studies in gnotobiotic piglets (Wen et al. 2016) have looked into the relative roles of B- and T-cell immune responses against RV infection after vaccination. In the absence of B cells, T-cell populations are still able to clear RV infections, although the duration of clinical signs is prolonged. Depleting CD8 T cells in B-cell-deficient gnotobiotic pigs resulted in greater virus shedding after vaccination. However, upon challenge it appeared that CD4 T cells were able to compensate for this depletion and confer protection similar to CD8-sufficient animals (Wen et al. 2016). Not surprisingly, long-term immunity is not present in these animals, showing the importance of B-cell responses in developing immune memory.

Prevention and control

RV infections are endemic in swine populations, and elimination and eradication from swine herds is not practical. Instead, the aim is to minimize the impact of RV infections by reducing mortality and the incidence of diarrhea. Maintaining maternal immunity is key to achieving these aims. Exposure of females to infectious RV is commonly used to stimulate maternal immunity but can result in the contamination of farrowing facilities with infectious RV. Even sows with subclinical RV infections shed high amounts of virus into the environment.

Commercial vaccines are available for RVA, but not for RVB or RVC. In general, killed vaccines are not as effective as modified live or attenuated viral strains (Welter and Welter 1990). Also, maternally acquired antibodies in piglets may interfere with live RV vaccines (Hodgins et al. 1999; Parreño et al. 1999).

The most promising vaccine research involves the VP6 protein due to its strong immunogenicity and induction of high levels of both antibodies and antibody-secreting cells (Azevedo et al. 2010; Chang et al. 2001; Yuan et al. 2000, 2001). However, VP6 alone does not stimulate protective immunity. Virus-like particles containing VP6 and VP2 can be delivered intranasally and used in conjunction with attenuated RV strains to induce better immunity and protection in gnotobiotic piglets. Other potential avenues of research in vaccine development include a bicistronic plasmid vaccine system using *S. typhimurium* (Cui et al. 2013) or the use of *Lactobacillus acidophilus* as a more potent adjuvant (Wen et al. 2009; Zhang et al. 2008).

Palliative measures for RV-affected animals include maintaining adequate ambient temperature (35 °C, 95 °F) and feeding a high energy diet to weaned pigs (Steel and Torres-Medina 1984; Tzipori et al. 1980b). Fluid administration with electrolytes or L-glutamine to prevent dehydration from diarrhea and vomiting, as well as antibiotic therapy for cases with bacterial coinfections, can be helpful (Bywater and Woode 1980; Bywater 1983; Rhoads et al. 1991). Mucosal repair can be assisted by TGF-alpha administration (Rhoads et al. 1995). Dietary supplements may help treat or prevent RV infections. Extract of *Glycyrrhiza uralensis*, a plant native to Asia,

reduced levels of inflammatory cytokines in piglets with RV diarrhea, and a dose-dependent repair of histological lesions was observed (Alfajaro et al. 2012). Leucine supplementation was able to combat a decrease in mucin production in the piglet jejunal mucosa (Mao et al. 2015). *In vitro* studies suggested vitamin D3 supplementation can attenuate RV replication by modulating the RIG-I signaling pathway, which recognizes dsRNA (Zhao et al. 2015). Treating piglets with *Bifidobacteria* and *Lactobacillus* spp. probiotics may improve mucosal immune responses and reduce the severity of RV-induced disease (Kandasamy et al. 2014; Shu et al. 2001; Vlasova et al. 2016; Wen et al. 2015).

Porcine reovirus

Relevance

Porcine reovirus was discovered in pigs in 1951, but reoviruses have since been found in a large number of mammalian, avian, and reptilian species. The term "reo" is an acronym for "respiratory and enteric orphan" because the virus was thought to lack clinical significance. As reovirus research continued, its clinical significance was established, although the role of reoviruses in causing disease in pigs is still unclear.

Etiology

Mammalian reoviruses are members of the genus *Orthoreovirus*, which also includes avian reoviruses, reptilian reoviruses, etc. Reoviruses have a non-enveloped, icosahedral/spheroidal double-layered capsid 65–80 nm in diameter (Figure 43.3) and encase 10 dsRNA segments, which are separated into three categories: lambda (L), mu (M), and sigma (S). The lambda and mu categories consist of 3 segments (L1–L3 and M1–M3), while the sigma category is composed of 4 segments (S1–S4).

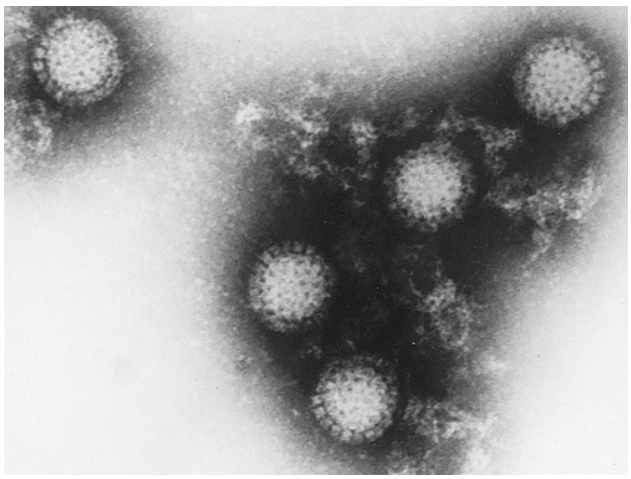

Figure 43.3 Electron micrograph of reovirus particles viewed by negative-staining EM (×115,000). *Source:* Chang et al. (2012). Reproduced with permission of John Wiley and Sons.

Nearly all mammalian species, as well as some reptilian and avian species, are susceptible to reoviruses. Unidentified reoviruses are likely present in many mammalian species but remain undetected because they do not produce clinical disease. Mammalian and avian reoviruses have specific antigen groups that distinguish them from each other. Mammalian reoviruses are currently identified by a common serotyping scheme that consists of three types (1, 2, and 3). This replaced the previous classification scheme of Lang, Jones, and Abney or Dearing (Ramig et al. 1977). A fourth (Ndelle) serotype, associated with human infection, has been proposed (Day 2009). The serotyping classification correlates to a sequenced-based subtyping of the Sigma1 (S1) segment, which encodes for the Sigma1 outer glycoprotein.

Reoviruses are stable at acidic conditions (pH 3) and resistant to many disinfectants, including ether, chloroform, and trypsin. However, the virus is sensitive to heat at 50 °C (122 °F) for 1 hour and 0.1% sodium deoxycholate (Hirahara et al. 1988). Reoviruses are resistant to extreme environmental conditions, surviving in wastewater for extended periods of time. Reoviruses are susceptible to disinfection through extended UV light exposure in a wastewater environment; however, not many chemical disinfectants have been extensively tested (Sharp et al. 1975).

Reoviruses can be propagated in multiple cells lines, including BHK-21, HEK293, MCT, HEF, Vero, and PaKiT03 (Mok et al. 2015). Mouse fibroblast L929 cells are most commonly used to isolate reoviruses and also for purification and plaque assays (Tyler 2001). In addition, reoviruses have been cultured in eggs (Narayanappa et al. 2015). While the cytopathic effects of reoviruses vary, infected cells become rounded, granular, and detached from the surface in culture. After staining with May–Grünwald–Giemsa, eosinophilic inclusion bodies can be seen in the cell cytoplasm under light microscopy (Paul and Stevenson 1999).

Public health

Reoviruses cause a wide variety of human diseases, and zoonotic transmission has been discussed, especially between bats and humans (Steyer et al. 2013). However, direct evidence of zoonotic transmission is lacking.

Epidemiology

Type 1–3 reoviruses have been found in swine populations in the United States, Europe, and China (Fukutomi et al. 1996; Tyler 2001; Yang et al. 1976). Reoviruses are transmitted via respiratory and fecal–oral routes. Immunity to reovirus infection persists for approximately

11 weeks, after which time pigs are susceptible to reinfection (Watt 1978).

Pathogenesis

While reoviruses replicate in the respiratory and intestinal systems, details on pathogenesis are lacking. Initially, cell attachment and entry into the respiratory epithelium was solely attributed to the S1 glycoprotein. A recent study suggested that S1 may not be required for cell entry, but plays a role in systemic dissemination of the virus and viremia. Once a pig is infected via the respiratory track, the virus can infect the gastrointestinal tract, the neural system, and the leukocytes (Boehme et al. 2009). Reoviruses can be detected in nasal secretions and feces as soon as 24 hours of post inoculation, and shedding may continue for 6–14 days. Hemagglutination-inhibiting antibody may be detected at 7 days of postinfection and peak at 11–21 days of postinfection (Hirahara et al. 1988).

Clinical signs

Reovirus infections (types 1–3) have been found in the respiratory, gastrointestinal, and nervous systems of healthy and diseased pigs (Elazhary et al. 1978; Kasza 1970; McFerran and Connor 1970; Robl et al. 1971). Healthy swine are commonly infected with type 2 reovirus (Fukutomi et al. 1996). Many experimental infection studies were able to produce transient febrile reactions, but not clinical disease in swine (Baskerville et al. 1971; Kasza 1970; McFerran and Connor 1970; McFerran et al. 1971; Watt 1978). In addition, reoviruses have been found in aborted fetuses (Kirkbride and McAdaragh 1978). A recent study with type 3 reovirus was able to produce gross lesions of catarrhal enteritis and intussusception in piglets with clinical signs of diarrhea, lethargy, and weight loss (Narayanappa et al. 2015), and a single report detected type 3 reoviruses in diarrheic pigs from Europe (Lelli et al. 2016). In another study, Cesarean-derived colostrum-deprived pigs and conventional pigs inoculated intranasally or exposed via aerosol to reovirus type 1 developed mild respiratory disease (pyrexia, sneezing, inappetence, and listlessness) (Hirahara et al. 1988). Reovirus was also isolated from fecal tissues and sow placenta after inoculation of reovirus via intravenous or intramuscular routes in seronegative sows between 40 and 85 days, yielding litters of mummified, stillborn, weak live-born, and normal pigs (Paul and Stevenson 1999).

Lesions

Gross lesions are rarely associated with reovirus infections in swine. Histologically, lesions of the small intestine include villous epithelial syncytia, villous blunting and fusion, multifocal necrosis of the mucous epithelium, granular cytoplasm, and vacuolation. Oral inoculation with an enteric reovirus in 1-week-old, colostrum-deprived pigs resulted in focal villous atrophy in the jejunum and ileum (Elazhary et al. 1978). Aerosol inoculation of type 1 reoviruses in 4-week-old specific-pathogen-free (SPF) pigs resulted in microscopic lung (alveoli and alveolar septa) lesions characterized by infiltration with lymphocytes and macrophages and mild peribronchiolar nodular lymphocytic hyperplasia (Baskerville et al. 1971). Intranasally inoculated respiratory type 3 reovirus in 70 kg SPF pigs yielded vesicular emphysema, lobular atelectasis, and peribronchiolar nodular lymphocytic hyperplasia, with varying intensity between lobules (Paul and Stevenson 1999). Sows inoculated via the intravenous or intramuscular routes between 40 and 85 days of gestation yielded reproductive deficits (see "Clinical Signs"), but no specific gross or histopathological lesions were observed.

Diagnosis

Since the role of reoviruses as a primary pathogen is debatable, the diagnostic investigation should assess the contributions of other respiratory and intestinal pathogens to the clinical picture. Reovirus detection relies on RT-PCR or viral isolation. Commercial antibody assays are not available for reoviruses, but viral typing can be done via virus neutralization and hemagglutination inhibition tests using reference antisera to the three reovirus types (Paul and Stevenson 1999). In addition, typing can be done by sequencing the S1 gene. More recently, whole genome sequencing of the 10 dsRNA segments has been used to subtype the virus (Narayanappa et al. 2015).

Immunity, prevention, and control

Given the lack of consistent clinical data and few clinical signs in pigs, very little information is available to understand reovirus immunity in swine. A recent study found that 5C6 and 9BG5 antibodies block reovirus binding to JAM-A, as expressed in Chinese hamster ovary cells (Dietrich et al. 2017). In addition, little emphasis is placed on prevention and control of reovirus infections.

Retroviruses

Joachim Denner

Relevance

Retroviral particles were first described in immortalized and tumor porcine cell lines (Armstrong et al. 1971; Bouilant and Greig 1975; Breese 1970; Suzuka et al. 1985). These viruses have been identified as porcine endogenous retroviruses (PERVs). It is still unknown whether PERVs cause clinical disease in swine. Rather, PERVs are important in the context of xenotransplantation. Pigs are appropriate tissue and organ donors for several reasons, including their physiological similarity to humans, the similar size of organs, the short gestation time (100 days), the high number of progeny, and the ease with which to clone and genetically modify pigs. Multiple genetic modifications have been introduced into pigs intended for xenotransplantation to prevent immunological rejection of the xenotransplant and to overcome physiological incompatibility (Niemann and Petersen 2016). Thus, swine transplants could potentially address the shortage of available human transplants (Ekser et al. 2015). However, the prospect of transplanting live pig cells, tissues, and organs into immunosuppressed humans led to careful consideration of the potential for the transmission of infectious agents from pig tissues to humans (Fishman et al. 2012; Tucker and Scobie 2012). The discovery that pig retroviruses were capable of infecting human cells *in vitro* (Patience et al. 1997) provided further motivation to study PERV and to develop strategies to prevent PERV transmission via xenotransplants (Scobie and Takeuchi 2009; Tucker and Scobie 2012; Wilson 2008).

Although endogenous retroviruses have been shown to play an important role in placentogenesis in many species including humans (Denner 2016a), it is still unknown whether PERVs play such a role in pigs (Keller et al. 2014).

Etiology

PERVs are RNA viruses in the genus *Gammaretrovirus* in the family *Retroviridae*. Retroviruses have a lipid envelope and two copies of their RNA genome. On the surface they carry "knobs" composed of trimers of the surface and transmembrane envelope protein (Figure 44.1).

Retroviruses encode for reverse transcriptase, an enzyme that transcribes the viral RNA genome into a DNA copy that will be integrated into the DNA of the host's cells (Weiss 2006). A high portion (approximately 8%) of mammalian genomic DNA is believed to be retroviral in origin (Kurth and Bannert 2009), likely resulting from the integration of DNA copies (proviruses) of ancient exogenous retroviruses into the genomes of host ancestors. PERVs are closely related to murine leukemia viruses (MuLV), gibbon ape leukemia viruses (GaLV), feline leukemia viruses (FeLV), and koala retroviruses (KoRV) (Patience et al. 2001). PERVs probably originated from a murine retrovirus that infected the ancestors of present-day pigs. At most, this occurred 7.6 million years ago, a time coincident with the separation of pigs (Suidae, *Sus scrofa*) from their closest relatives, the peccaries (Tayassuidae, *Pecari tajacu*) approximately 7.4 million years ago (Niebert and Tönjes 2005; Tönjes and Niebert 2003). In addition to the PERV sequences characterized by repeats in the long terminal repeat (LTR), proviruses without such repeats were detected and determined to have evolved approximately 3.4 million years ago, which is a phylogenetically younger structure.

The full PERV genome contains the typical retroviral coding regions of gag (group-specific antigen, encoding for the core proteins), pol (polymerase, encoding for reverse transcriptase, integrase, and protease), and env (envelope, encoding for the surface and transmembrane envelope proteins) (Figure 44.2).

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

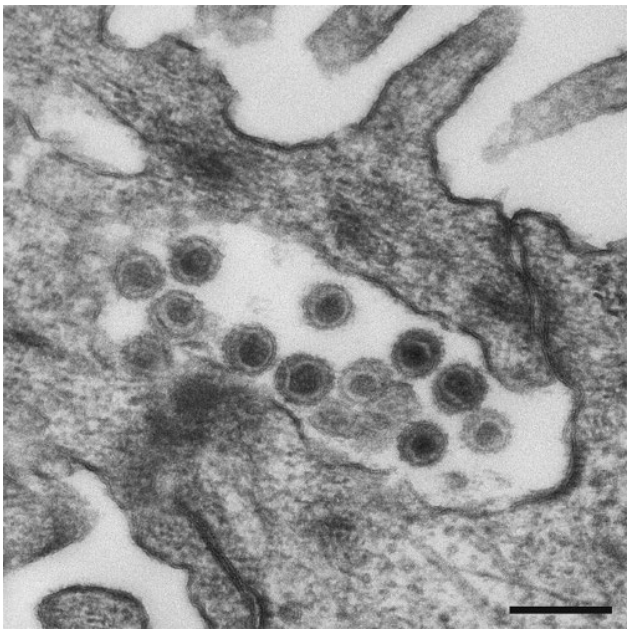

Figure 44.1 Electron microscopic presentation of PERV produced by a porcine cell line derived from a pig melanoma. *Source:* Dieckhoff et al. (2007a). Reproduced with permission of Elsevier. Bar: 200 nm. G. Holland, Dr. M. Laue, Robert Koch Institute.

Several subtypes of PERVs have been identified: PERV-A, PERV-B, and PERV-C (Takeuchi et al. 1998). PERV-A and PERV-B are present in the genome of all pigs and are able to infect human cells, as well as cells of other species (polytropic viruses), whereas PERV-C is present in most pigs and only infects pig cells (ecotropic virus). The receptors for PERV-A are known (human PERV-A receptor [HuPAR]-1 and HuPAR-2) (Ericsson et al. 2003); however, receptors for PERV-B and PERV-C are currently unknown.

Recombination between PERV-A and PERV-C has been observed; the recombinants designated PERV-A/C acquired the receptor-binding site for the receptor of PERV-A and, therefore, were able to infect human cells (Bartosch et al. 2004; Martin et al. 2006; Wilson et al. 2000; Wood et al. 2004). Interestingly, rapid passaging of a PERV-A/C on human cells was associated with an increase of such repeats in the LTR and an elevated titer of PERV in the supernatant (Denner et al. 2003). The recombinants PERV-A/C act like exogenous retroviruses, and de novo integrations into the genome of certain somatic cells were observed; however, these viruses were not found in the germ line (Denner 2008a). The recombinants PERV-A/C are characterized by a high replication rate and specific mutations in the genome (Denner et al. 2003; Harrison et al. 2004). First attempts to infect pigs with PERV-A/C failed (Kaulitz et al. 2011).

At present, the number of integrated proviruses reported in different pig breeds ranges from 1 to 114 (Denner 2016b). There are also marked differences in regard to the extent of the expression of PERVs in different pig breeds, as well as among different organs of one animal (Bittmann et al. 2012; Clemenceau et al. 1999; Dieckhoff et al. 2009; Martin et al. 1998; Moon et al. 2009). Treatment of porcine peripheral blood mononuclear cells (PBMCs) with mitogens and other agents increased the expression of PERV (Cunningham et al. 2004; Tacke et al. 2003; Wilson et al. 1998). PERVs have been isolated from pig plasma (infectious virus) and factor VII preparations (genomic RNA only) that were used for the treatment of hemophilia (Takefman et al. 2001).

Public health

There is no evidence that PERVs can be transmitted to humans by food or contact with pigs (Hermida-Prieto et al. 2007; Tacke et al. 2001). Furthermore, no PERV

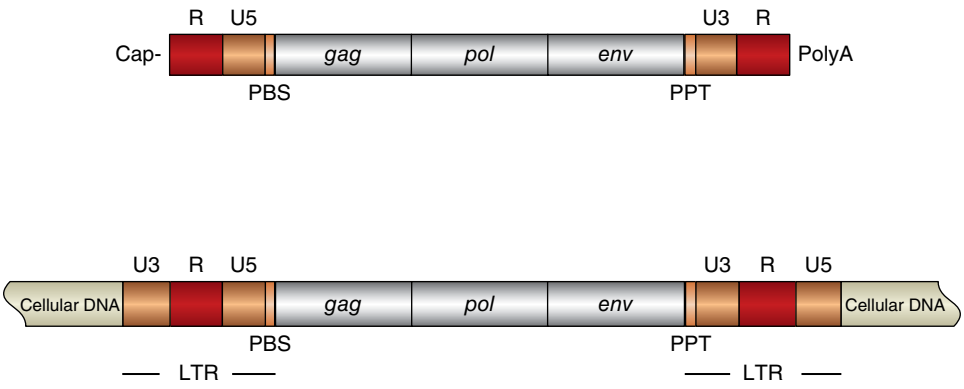

Figure 44.2 Schematic presentation of a genome and an integrated provirus of PERV. (a) The genome consists of 10Kb of RNA with a 5′ cap and a 3′ polyA tail. The viral RNA is structured as follows: R, a 5′ and 3′ direct repeat; U5 and U3, noncoding unique regions; PBS, a primer binding site; open reading frames for gag, pol, and env genes; PPT, a polypurine tract. (b) The DNA provirus with two long terminal repeats (LTRs).

transmission was observed in pig-to-small animal or pig-to-nonhuman primate experiments, either with or without pharmaceutical immunosuppression (Denner 2008b; Denner and Töenjes 2012; Specke et al. 2009). The same was true for the first clinical trials in humans (Paradis et al. 1999; Valdes-Gonzalez et al. 2010). In two more recent clinical trials, transplanting encapsulated pig islet cells for the treatment of diabetes provided a clinical benefit for the patients, and no PERV transmission was observed (Cooper et al. 2016; Matsumoto et al. 2014; Morozov et al. 2017; Wynyard et al. 2014). However, until now, no large vascularized organs have been transplanted into severely immunosuppressed patients, and, therefore, the risk posed by PERVs in the case of organ transplantation is still not fully defined.

In this context it is important to note that genetic modification of source pigs to enhance xenotransplant compatibility, either by including transgenes encoding for cell surface human complement regulatory proteins or by removing galactose-alpha-1,3-galactose epitopes recognized by human natural antibodies, resulted in released PERV particles that were protected from components of the recipient's innate immune system (Takefman et al. 2002; Weiss 1998). Since humans also contain endogenous retroviruses in their genome, it was shown that recombination or co-packaging between PERV and human endogenous retroviruses, as well as other human retroviruses (e.g. human immunodeficiency viruses), is unlikely to happen (Suling et al. 2003). Guidelines and regulations have been developed to prevent PERV transmission in future clinical xenotransplantations (Cozzi et al. 2016).

Epidemiology

Although there is evidence that PERVs may exist as exogenous retroviruses and amplify (replication and de novo integration) inside the pig (Denner 2016b), there are no data showing transmission of PERV from one pig to another. Attempts to infect pigs with a high titer PERV-A/C (Kaulitz et al. 2011) or to infect PERV-C-negative animals with PERV-C (Denner and Tönjes 2012) have failed.

Pathogenesis, clinical signs, and lesions

Retroviruses are known to induce leukemia, as in the case for the PERV-related viruses MuLV, KoRV, GaLV, and FeLV. Furthermore, retroviruses are known to induce severe immunodeficiencies. This is true for the human immunodeficiency virus 1 (HIV-1) and also for MuLV, FeLV, and KoRV (Denner 2014). There is evidence that endogenous retroviruses in mice, cats, and koalas are also associated with tumor development, partially after recombination with other endogenous sequences (Denner 2010). It is unclear whether PERVs can induce similar outcomes in pigs.

Although PERVs were expressed at higher levels in melanomas of diseased pigs compared with normal tissues and despite the fact that PERV particles were isolated from melanoma-derived cell lines (Dieckhoff et al. 2007a) (Figure 44.1), there is no evidence that these melanomas were caused by PERV. PERVs were also isolated from lymphoma cells (Moennig et al. 1974; Suzuka et al. 1985) and from radiation-induced leukemia cells (Frazier 1985); however, there is no evidence for an association with the disease.

However, a correlation was observed between PERV expression and the health status of pigs. Pigs housed in production units experiencing higher mortality and more endemic diseases showed higher levels of PERV RNA in their plasma (Harrison et al. 2010; Pal et al. 2011; Tucker and Scobie 2006). This was due to a higher PERV expression in lymphoid organs as the result of a more vigorous immune response against the endemic infections. As reported above, stimulation of pig PBMCs with mitogens (simulating an antigen response) was associated with a higher PERV expression and release (Dieckhoff et al. 2009; Tacke et al. 2003; Wilson et al. 1998).

Like most retroviruses, including HIV-1, PERVs are potentially immunosuppressive (Denner 1998). PERV contains a so-called immunosuppressive domain in the transmembrane envelope protein (Denner 2014). This domain is highly conserved in all retroviruses. It had been shown that a synthetic peptide corresponding to the immunosuppressive domain of PERV and purified PERV particles inhibited mitogen-induced proliferation and modulated cytokine release by human PBMCs (Morozov et al. 2013; Tacke et al. 2000), suggesting that PERV is immunosuppressive.

Diagnosis

Reviews describing methods for detecting PERV in donor pigs and transplant recipients are available (Denner 2011; Denner and Töenjes 2012; Godehardt et al. 2015; Herring et al. 2001). The prevalence of integrated PERV proviruses can be measured by PCR-based methods (PCR, nested PCR, and real-time PCR) or Southern blot analysis. The digital droplet PCR allows exact measurement of the copy number of PERV in the pig genome (Yang et al. 2015). PERV expression at the mRNA level can be measured by different RT-PCR methods.

Virus expression at the protein level can be measured using immunoperoxidase assays, immunofluorescence assays, Western blot analysis, immunohistochemistry, and immunogold electron microscopy. Specific antibodies against viral proteins are required for these methods.

Virus particles can be analyzed by detection of the enzyme reverse transcriptase and by scanning and transmission electron microscopy. The infectivity of the particles can be measured using infection assays. The readout of these assays may be provirus integration, mRNA or protein expression, or virus release. One of the methods to determine the release of infectious virus is co-cultivation of pig cells with human target cell lines (for testing human-tropic PERV release) or pig target cell lines (for testing ecotropic PERV release). This assay relies on the fact that retrovirus infection is more efficient via cell-to-cell contact.

Detecting PERV infections in transplant recipients requires exclusion of the presence of pig cells (so-called microchimerism) to avoid false-positive results. To detect microchimerism, PCR screening for pig genes, especially mitochondrial genes that are abundantly present, can be used (Paradis et al. 1999).

Measurement of PERV expression, including PERV release after stimulation of PBMCs with mitogens and other agents, has been used to classify pigs in high producers and low producers (Dieckhoff et al. 2009; Tacke et al. 2003). However, at present it is unclear whether this method can be used to define the expression of PERV in organs and tissues required for transplantation, since replication and de novo integrations of PERVs were observed in some, but not all organs of pigs (Denner 2016b).

No anti-PERV antibodies have been reported in pigs, because they are tolerant to their endogenous retroviruses (Keller et al. 2014). However, detection of antibodies is an efficient tool to screen for PERV infection in transplant recipients. Sensitive and specific ELISA and Western blot assays have been developed using synthetic peptides or recombinant proteins corresponding to the main core and envelope proteins of PERV (Denner and Tönjes 2012 and the references therein). Highly purified virus particles can also be used as antigens for the detection of PERV-specific antibodies (Morozov et al. 2017; Tacke et al. 2001).

Prevention and control

Unlike most infectious agents, such as herpesviruses and hepatitis E virus, PERVs cannot be eliminated by treatment, vaccination, Cesarean delivery, colostrum deprivation, early weaning, or embryo transfer because they are integrated into the genome of every pig (Denner 2015a,b; Denner and Mueller 2015; Denner and Töenjes 2012). Because PERVs were not shown to be transmitted from pig to pig or to produce clinical disease in pigs, strategies to prevent or control PERV transmission have focused on preventing transmission to humans via xenotransplantation: (1) the selection of PERV-C-negative animals to avoid recombination, (2) the selection of pigs with a low copy number and a low expression of PERV-A and PERV-B, (3) the development of transgenic pigs carrying and expressing a PERV-specific small interfering RNA to reduce the expression of PERV in all cells of the pig (Dieckhoff et al. 2007b, 2008; Karlas et al. 2004; Ramsoondar et al. 2009; Semaan et al. 2012), and (4) the concept of inactivating PERVs in pigs using gene editing techniques (Niu et al. 2017; Yang et al. 2015). If this strategy of gene editing could be used to inactivate all PERVs in viable pigs, the risk PERVs pose for xenotransplantation would be completely eliminated (Denner 2015b, 2017a). Furthermore, other tools are available to prevent transmission of PERV to the recipients such as the use of antiretroviral drugs (for review see Denner [2017b]) and vaccines based on neutralizing antibodies against the envelope proteins of PERV (Fiebig et al. 2003; Waechter and Denner 2014).

Rhabdoviruses

Sabrina L. Swenson, Daniel G. Mead, and David R. Kinker

Overview

Vesicular stomatitis viruses (VSVs) and rabies virus are members of the family *Rhabdoviridae*. VSVs belong to the genus *Vesiculovirus* and rabies virus belongs to the genus *Lyssavirus*. In general, virions are 100–180 nm in length and 45–100 nm in diameter and contain a single molecule of linear, negative-sense ssRNA (Knudson 1973; Sokol and Loprowski 1975). They are bullet shaped or cone shaped. The viruses generally have five structural polypeptides designated as L, G, N, P, and M (Dietzgen et al. 2012; Howatson 1970). Virions are composed of a host-derived plasma membrane, a phospholipid envelope, and an internal ribonucleoprotein core. After cell attachment, penetration, and uncoating, virus replication occurs in the cytoplasm of infected cells. The viral RNA-dependent RNA polymerase transcribes viral mRNAs from the viral genome (Wagner and Rose 1996). Virions are composed of between 15 and 25% lipids (McSharry and Wagner 1971a; Dietzgen et al. 2012). Generally phospholipids represent about 55–60%, and sterols and glycolipids about 35–40% of the total lipids (Dietzgen et al. 2012; Knudson 1973; McSharry and Wagner 1971b). The virions are composed of about 3% carbohydrate by weight (McSharry and Wagner 1971a). Viral RNA has a sedimentation coefficient of 42–45 Svedberg units and a buoyant density of 1.66 g/cm^3 (Hilfenhaus et al. 1979). Virion buoyant density in CsCl is 1.18–1.22 g/cm^3 and 1.17–1.19 g/cm^3 in sucrose (Fenner 1975).

Vesicular stomatitis

Relevance

Historical reports of vesicular stomatitis (VS) date back to the 1800s (Hanson 1952), but VSV was first isolated in 1925 in New Jersey and in Indiana the following year (Cotton 1927). VS in cattle and pigs resembles foot-and-mouth disease (FMD) and in pigs swine vesicular disease (SVD) or Seneca Valley virus (SVV). The presence of VS in livestock results in export restrictions on livestock from VS-affected to VS-free zones. VSV is a zoonotic virus, and appropriate personal protective equipment (PPE) should be utilized to reduce transmission from affected animals to people.

Etiology

Genetically related, but distinct, VSVs (Wunner et al. 1995) cause VS. Isolates found to be serologically distinct are classified as different serotypes: vesicular stomatitis New Jersey virus (VSNJV) and vesicular stomatitis Indiana virus (VSIV) (Cartwright and Brown 1972). Both VSNJV and VSIV serotypes are pathogenic in domestic livestock, but only VSNJV has been associated with disease in swine. Two VSIV subtypes, Cocal virus and Alagoas virus, have caused disease in livestock in South America. Virus detection is based on cell culture cultivation and/or molecular technologies. VSV may be propagated in many cell culture types, including African green monkey kidney (Vero) and baby hamster kidney (BHK-21) continuous cell lines (Swenson and Allende 2015).

Public health

Humans are susceptible to VSV and may become infected by direct contact with virus on fomites or shed by animals or by aerosolization of virus. Clinical signs in people include influenza-like symptoms and blister-like lesions appearing 1–2 days after exposure. When working with live virus, handling diagnostic specimens potentially containing VSV, or handling animals suspected of having VS, appropriate measures should be in place to prevent exposure to VSV.

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

Epidemiology

VS affects domestic livestock including cattle, horses, and swine and is the most common vesicular disease of livestock in the Americas. Antibodies to the VSVs have been found in a wide variety of wild animals, but naturally occurring clinical disease has not been reported in wildlife (Jenney et al. 1970; Tesh et al. 1970).

VS is not known to occur outside of the Americas (Swenson and Allende 2015). Within the Americas, VS, primarily caused by VSNJV and VSIV, occurs in endemic cycles in southern Mexico, Central America, and northern South America (Colombia, Venezuela, Ecuador, and Peru).

Both endemic and epidemic patterns of VS historically occurred in the United States. In the Southeastern United States, VSNJV was detected in domestic livestock almost yearly from the early 1900s to the mid- to late 1970s and in wildlife on Ossabaw Island, Georgia, from 1956 to 2007 (Killmaster et al. 2011). Based on recent negative serologic results from white-tailed deer and feral swine and the failure to isolate VSNJV from the endemic sand fly vector, *Lutzomyia shannoni*, it is possible that VSNJV is no longer present at this site (Killmaster et al. 2011). In the Western United States, epidemics of VSNJV (and VSIV to a lesser extent) generally occurred in cattle and horses at 5–10-year intervals (Rodriguez 2002). VSNJV epidemics generally affect a larger number of animals than VSIV epidemics. Naturally occurring VSNJV in domestic swine has not been reported in the United States since 1968 (Jenney and Brown 1972), and VSIV infection in swine has never been reported.

VSNJV can be transmitted via several routes, including direct animal-to-animal contact, and biologically or mechanically by insect vectors. VSNJV was efficiently transmitted among domestic swine via contact transmission (Stallknecht et al. 2001). In experimental settings, the development of vesicles in inoculated animals facilitated contact transmission. Infection in contacts ranged from subclinical to clinical.

Radeleff (1949) proposed transmission of VSNJV by arthropod vectors, but the concept remained controversial because it was not clear how vectors could acquire the infection since vertebrate hosts do not develop a detectable VSV viremia. However, Mead et al. (2000, 2004) demonstrated that (1) hematophagous insects could become infected with VSNJV when they fed on or near virus-rich vesicular lesions; (2) VSNJV could be transmitted from VSNJV-infected to uninfected black flies (*Simulium vittatum*) during the process of co-feeding on the same vertebrate host; and (3) VSNJV-infected insects transmitted the virus to livestock.

In clinically affected animals, VSV is primarily localized to areas where lesions are present. Virus can be isolated in high concentrations from vesicular fluid, throat swabs, tonsils, saliva, and the epithelium of clinically affected animals for up to 10 days post infection (range of 1–10 days), depending on the species.

Virus infectivity is stable in the pH range of 5–10 (Crimmins et al. 1983; Gaudin et al. 1993) and is rapidly inactivated by heat treatment at 56 °C (133 °F), following ultraviolet (UV) or X-ray irradiation or exposure to lipid solvents and oxidizing agents including detergents, formalin, and many common disinfectants, such as household bleach (Larghi and Nebel 1980; Zimmer et al. 2013). Under natural conditions, VSNJV can remain viable in contaminated saliva on pails or food buckets for 3–4 days (Hanson 1952) and can be recovered from plant surfaces up to 24 hours after surface inoculation at room temperature (Drolet et al. 2009).

Pathogenesis

VSV infection is localized to the site of inoculation, with occasional spread to local draining lymph nodes. Virus is not found in other tissues. Primary replication seems to occur in keratinocytes (Scherer et al. 2007).

Virulence in swine is dependent on virus strain (VSNJV is more virulent than VSIV), route of inoculation, and dose. In domestic swine, experimental inoculation of the snout with $1 \times 10^{0.7}$ median tissue culture infectious dose per ml ($TCID_{50}$) of VSNJV resulted in seroconversion without clinical disease, whereas inoculation of the snout with doses $\geq 1 \times 10^{3.3}$ $TCID_{50}$ resulted in clinical disease followed by seroconversion. VSNJV produces large vesicular lesions at the inoculation site in 1–2 days, and pigs shed high concentrations of virus for up to 7–8 days post infection. Inoculation of the oral mucosa (including tongue), snout, and coronary bands results in the development of vesicular lesions in the majority of animals. In contrast, inoculation of haired skin results only in seroconversion and subclinical disease (Howerth et al. 2006; Scherer et al. 2007; Stallknecht et al. 1999).

Naturally occurring VS in domestic swine due to VSIV has not been reported, although swine are susceptible to VSIV and develop clinical signs when the inoculation dose is $\geq 1 \times 10^{3}$ $TCID_{50}$ (Stallknecht et al. 2004). Inoculation of VSIV at doses $\leq 1 \times 10^{2}$ $TCID_{50}$ did not result in clinical signs or a detectable antibody response. Compared with VSNJV, lesions are much smaller (if present), and virus is shed at lower concentrations for 3–4 days.

The role of host factors (e.g. age and breed) in clinical disease has not been investigated, but field studies suggest that age may be associated with the outcome of infection.

Clinical signs

VS is characterized by fever, if present, from 24 to 72 hours post infection (hpi). Excessive salivation due to lesions in the mouth is usually the first sign and may be

the only sign observed. Pain associated with oral lesions can lead to anorexia and weight loss. Foot lesions and subsequent lameness are seen most frequently in swine but occur in cattle and horses as well.

The VS incubation period in domestic livestock ranges from 1 to 3 days. Viremia has never been reported in naturally infected livestock and only once under experimental conditions. In that instance, Cotton (1927) inoculated the blood of horses and cows experimentally infected with VSNJV into guinea pigs. The subsequent development of vesicular lesions in the guinea pigs at the site of inoculation (footpads) was interpreted as evidence of viremia in the horses and cows. This outcome has not been reproduced despite attempts by several investigators.

Mortality due to VSV infection is low, but morbidity rates during epidemics can be as high as 90%. VS is a self-limiting disease, and animals typically recover in 2–3 weeks if there are no complications from secondary bacterial infections (Hanson 1952).

Lesions

Noticeable vesicle formation can occur in the oral mucosa, snout, teats, and coronary bands between 24 and 72 hpi. Multiple lesions on or near the same site, or on different sites, can occur on the same animal. Lesions typically begin at the site of infection as small, in some cases pinpoint, blanched areas with raised borders. These quickly develop into 2–4 cm (0.75–1.5 in.) grayish-red vesicles. If multiple lesions develop in the same area, they may coalesce and appear as a single vesicle. Vesicles usually rupture 1–2 days after formation, releasing straw-colored, virus-rich exudates (Howerth et al. 1997). There may be extensive epidermal erosion and ulceration followed by scabbing. In severe cases, the complete tongue epithelium may slough, and if lesions develop along a coronary band, the claw may separate. Lesions typically begin to reepithelialize soon after eruption and, unless complicated by secondary infection, will completely heal in 1–2 weeks. Microscopic lesions are observed in the stratum spinosum where the virus replicates. Epithelial necrosis occurs with pleocellular inflammatory reaction in the mucosa and lamina propria (Uzal et al. 2016).

Diagnosis

Clinically, VS in swine is indistinguishable from FMD, SVD, vesicular exanthema of swine (VES), or SVV. Therefore, it is imperative to collect and submit diagnostic samples for laboratory evaluation. Rule-outs for infectious causes of vesicular disease in swine include FMDV, SVDV, VESV, SVV, porcine parvovirus, enterovirus infection, and swinepox virus. Noninfectious causes include trauma (e.g. chemical or thermal burns), course feed, toxins, plant awns, and photosensitization.

Clinical specimens for virus detection include vesicular fluid, tissue tags from ruptured vesicles, biopsies of affected areas, and swabs. To maintain virus viability, place diagnostic materials in a small volume of medium, chill to 4 °C (39 °F), and transport materials to the laboratory on ice packs. Do not freeze specimens as this can adversely affect virus detection.

Virus isolation, complement fixation (CF), antigen-capture ELISA, and reverse transcription polymerase chain reaction are used for detection of virus or viral nucleic acid (Swenson and Allende 2015). Virus isolation can be done in continuous cell lines, embryonated chicken eggs, and mice. If present in high titers, VSV can be detected in <24 hours after inoculation and within 7 days of inoculation at lower titers.

Serum antibody can be detected by virus neutralization (VN), CF, and ELISA. VN-detectable serum antibody persisted for years in experimentally infected cattle (Sorensen et al. 1958) and in naturally infected horses by the VN test and a competitive ELISA. The antibody response detected by CF is usually of shorter duration, generally months. In experimentally infected calves and ponies, the competitive ELISA detected antibody before it was detectable by CF or VN (Katz et al. 1997). Because of the long duration of antibody, a fourfold change in antibody titer (CF or VN) in paired sera collected approximately 7 days apart is required to establish VSV infection.

Immunity

The immune response to VSV infection can vary with the virus serotype, the route of exposure, method of exposure, and serologic assay used to test samples (Katz et al. 1997; Stallknecht et al. 1999). Seroconversion can be detected as early as 5 days following exposure to VSV. Maternal antibodies have been detected in offspring born to infected dams. In an experimental study, maternal antibody was demonstrated at 3 months of age, but not at 7 months of age (Sorensen et al. 1958).

The development of antibodies is associated with a decreased ability to detect viral shedding. In one study, virus was detected in 82 samples from experimentally infected pigs prior to seroconversion and in one sample following seroconversion (Stallknecht et al. 1999). However, the degree or duration of protective immunity is not fully characterized. In one study, animals reexposed to homologous virus 49–77 days after initial exposure did not shed virus and did not show a change in antibody response. In contrast, animals reexposed to a heterologous virus shed virus and responded serologically (Katz et al. 1997). All the same, field studies suggested that animals were not protected when reexposed

to homologous virus, even in the presence of neutralizing antibodies (Rodriguez et al. 1990).

Prevention and control

When vesicular disease is observed in swine, steps should be taken to stop the movement of animals and materials onto or off the premises until a diagnosis is made. The appropriate animal health authorities should be notified immediately.

As with most viral infections, treatment of VSV-infected animals is largely ineffective, except for palliative care such as feeding soft feed and providing padding for hard surfaces. Antibiotics may be useful to prevent or treat secondary bacterial infections. Treatment of vesicular lesions with topical antiseptics may promote faster healing and reduce the risk of secondary infections.

VSNJV is easily transmitted among swine by animal-to-animal contact, so affected animals and animals that may have had recent contact with them should be isolated. Minimize animal-to-animal contact to reduce transmission between animals. Disinfection of equipment, transport, and facilities occupied by infected animals is important.

Preventive measures include insect control, housing animals indoors during peak insect feeding times, and implementation of biosecurity procedures designed to avoid the introduction of VSV from affected premises via equipment, personnel, or animals. Insect repellents such as permethrin or other repellents approved for use on swine should also be considered. Vaccination with inactivated vaccines is practiced in some countries where VS is endemic.

Rabies virus

Relevance

The potential for rabies in swine is present wherever contact with wildlife or canine reservoirs is possible. The predominate rabies reservoirs are foxes in Europe; dogs and foxes in Asia; dogs, jackals, and mongooses in Africa; dogs and vampire bats in South America; and foxes, raccoons, skunks, and bats in North America. Feral and non-vaccinated cats may contract rabies from wildlife and can pose a public health risk due to their close proximity to humans.

Compared with cattle, the spillover of rabies into swine is low and probably reflects the separation between wildlife and swine that occurs with confinement operations. The United States averages about one case per year in domestic swine. In Europe, spillover to wild boars is an infrequent occurrence.

Etiology

Rabies virus is a member of the genus *Lyssavirus* in the family *Rhabdoviridae*. It is an enveloped neurotropic single-stranded RNA virus. The genus *Lyssavirus* included a number of other related viruses, including Lagos bat virus, Mokola virus, Duvenhage virus, European bat lyssaviruses, and Australian bat lyssaviruses (Gould et al. 1998).

Rabies virus is susceptible to 1% sodium hypochlorite, 2% glutaraldehyde, 70% ethanol, and formaldehyde. It is inactivated by UV radiation, heat (1 hour at 50 °C/122 °F), and lipid solvents. The virus is rapidly inactivated by sunlight and does not retain infectivity for long out of the host.

Public health

Rabies is an important zoonotic disease because of its high mortality rate in humans. However, there is little documented evidence of swine as a source of rabies for humans. Steele and Fernandez (1991) reported that of 521 people exposed to presumed rabid swine in the subcontinent of India, Pakistan, and Bangladesh from 1908 to 1972, none developed rabies. Notably, each exposed person received rabies prophylaxis.

Epidemiology

Rabies exists worldwide, except for certain islands and countries with strong geographical barriers, such as Norway and Sweden. Australia is free of rabies but does have Australian bat lyssavirus. All warm-blooded mammals are susceptible to rabies, although some appear to be more susceptible than others. The susceptibility of animals to rabies is influenced by the quantity of the virus introduced, the site of the bite, the age of the animal, and the virus strain involved. Strain differences play an important part in species susceptibility. Epidemiologic investigations may identify events that support the possible exposure of pigs to rabies-infected wildlife, such as the presence of a skunk in an outside pen.

Pathogenesis

Transmission occurs via the bite of an infected animal that has virus in its saliva. The amount and duration of virus in saliva varies significantly and is dependent on the amount of virus inoculated. In dogs, animals that received a high dose of virus died quickly with little virus in the saliva, while dogs that received lower doses of inoculums had longer incubation periods and more viruses in the saliva (Fekadu 1991). The duration of virus shedding was from 14 days before the onset of clinical signs to 4 days after onset. Studies have not been

conducted to determine the amount and duration of virus shedding in swine, but it should be assumed that virus is present when determining treatment options following human exposure.

Upon entering the body through a bite wound, rabies virus quickly enters an eclipse phase where it remains undetectable by fluorescent antibody staining or virus isolation. Murphy et al. (1973) suggested that rabies virus replicates in muscle fibers prior to invading the nervous system. They postulated that replication of the virus in muscle fibers may be a necessary amplification step prior to infection of the peripheral nervous system and may account for the long and variable incubation period of the disease. Once the virus enters the axoplasm, it travels to the dorsal root ganglia and then to the spinal cord and brain (Baer et al. 1965). As the virus spreads through the central nervous system (CNS), there is simultaneous centrifugal movement of the virus in peripheral nerves to nonnervous tissue, including the epidermis, cornea, epithelium of the mouth, nasal mucosa, intestine, lacrimal glands, pancreas, muscle fibers, myocardium, lungs, kidneys, adrenal medulla, and salivary glands.

Clinical signs

Rabies has classically been divided into furious and dumb forms. The clinical course of the disease is divided into the prodromal, excitement, and paralytic periods. During the prodromal period, there may be slight changes in temperament with a slight rise in temperature, dilation of pupils, and impaired corneal reflexes. The prominence of the excitement phase is what differentiates the furious form from the dumb form. Aggressive behavior, muscular tremors, incoordination, loss of balance, and increased salivation are common. The paralytic period, the final stage of the disease, is characterized by ascending paralysis, coma, and death.

Published reports on the clinical signs of rabies in swine are limited and, as in other species, not consistent. Sudden unexplained mortality with few clinical signs was reported in feeder pigs (Hazlett and Koller 1986). Morehouse et al. (1968) reported twitching, prostration, excessive salivation, and clonic muscle spasms. Other signs reported include uneasiness, incoordination, rapid chewing, fever, increased grunting, anorexia, marked thirst, and head and face rubbing (Dhillon and Dhingra 1973; DuVernoy et al. 2008; Merriman 1966; Morehouse et al. 1968; Yates et al. 1983).

As in other species, the incubation period in swine is variable, ranging from 17 days in a pig bitten by a skunk to 132 days in a potbellied pig bitten by a raccoon (DuVernoy et al. 2008). Baer and Olson (1972) reported the recovery of pigs from rabies. Specifically, four of six pigs developed clinical signs, including progressive paralysis, beginning 32–47 days after having been bitten by a rabid skunk. The signs subsided in 1–2 weeks with the pigs developing high antibody titers to rabies virus.

Lesions

Gross lesions, other than those caused by self-mutilation, do not occur with rabies. Microscopic changes in the CNS in swine range from mild vasculitis and focal gliosis in the brain to extensive meningoencephalitis and neuronal degeneration in the brain and spinal cord (Morehouse et al. 1968).

Diagnosis

The differential diagnosis of rabies in swine would include any disease that can mimic the neurological clinical signs associated with rabies, including pseudorabies (Aujeszky's disease), classical swine fever, Teschen disease, toxicosis, vitamin deficiencies, and congenital tremors.

The fluorescent antibody technique (FAT) for the detection of viral antigen in the brain is the preferred diagnostic test in animals, including swine, because of its speed and accuracy (Goldwasser and Kissling 1958). Antigen may also be detected in corneal impressions and in biopsies of tactile hairs in *antemortem* samples (Blenden et al. 1983; Schneider 1969).

Immunochemical (Lembo et al. 2006) and rapid immunodiagnostic (Kang et al. 2007) tests have been developed for rabies, but the results need to be confirmed by FAT. RT-PCR assays have also been developed for rabies virus, but their use is not currently recommended for routine post mortem rabies testing. Virus isolation in cell culture and the mouse inoculation test can be used to assess the infectivity of a suspension of emulsified brain tissue from a rabies suspect animal, but they are not routinely used for rabies diagnosis.

Serological methods exist, such as the rapid fluorescent focus inhibition test (RFFIT) (Velleca and Forrester 1981), but are primarily used to ensure protective vaccination titers in humans exposed or at risk of exposure to rabies virus.

Serology is less frequently used in animals for similar purposes. Serology is also not generally used for diagnosis because of the rapid progression of the disease once clinical signs are observed.

Immunity

Survival of pigs following exposure to rabies virus is common and is dependent on the site of the bite (bites around the face and neck are more likely to be fatal), the quantity of the virus introduced, the age of the animal (young animals are more susceptible), and the virus strain involved. Both humoral immunity and cell-mediated immunity are

necessary to prevent fatal infections. Once clinical signs develop, rabies is usually fatal.

Prevention and control

Because of the expense of conducting duration-of-immunity efficacy tests and the limited market, there are no licensed rabies vaccines for use in swine. Off-label use of inactivated vaccines may be justified in expensive breeding stock in rabies-endemic areas, but vaccine efficacy has not been demonstrated. Overall, the best way to prevent rabies is to control the disease in wildlife reservoirs and use physical barriers to protect swine from wildlife.

Togaviruses

Fun-In Wang, Chia-Yi Chang, and Chin-Cheng Huang

Overview

The family *Togaviridae* comprises two genera: *Alphavirus* and *Rubivirus*. The mostly arthropod-borne genus *Alphavirus* includes about 30 recognized members that can cause a variety of human and animal diseases. The genus *Rubivirus* is composed of a single member (rubella virus) pathogenic to humans. The virions are spherical, 70 nm in diameter, and consist of an envelope with fine peplomers surrounding an icosahedral nucleocapsid 40 nm in diameter. The peplomers are formed by 80 trimers of the envelope proteins E1–E2 heterodimer.

The genome is a linear positive-sense, single-stranded RNA 9.7–11.8 kb in size, arranged as 5′ m_7G-nsP1-nsP2-nsP3-nsP4 - C-E3-E2-6 K-E1-$(A)_n$ 3′. Genomic RNA serves as mRNA to translate into a polyprotein, which is processed into mature nonstructural proteins (nsP). The structural proteins are translated from a subgenomic 26S mRNA and cotranslationally processed into mature proteins (Powers et al. 2012). The E2 protein contains most neutralizing epitopes, while the E1 protein contains more conserved, cross-reactive epitopes.

Alphaviruses are stable at pH 7–8, but rapidly inactivated by very acidic pH. Virions have a half-life of 7 hours at 37 °C (98.6 °F) in culture medium, and most are rapidly inactivated at 58 °C (136 °F) with a half-life of minutes. Generally, they are sensitive to organic solvents and detergents, which solubilize their lipoprotein envelopes.

Based on serological cross-reactivity, alphaviruses are grouped into eight antigenic complexes (nine including the fish alphaviruses). Eastern equine encephalitis virus (EEEV) is in the EEEV complex, and Getah virus (GETV), Sagiyama virus (SAGV), and Ross River virus (RRV) are in the Semliki Forest complex.

Eastern equine encephalitis virus

EEEV is endemic in eastern Canada, the United States east of the Mississippi River, the Caribbean islands, and Central and South America. Ornithophilic mosquitoes (e.g. *Culiseta melanura*) maintain endemic cycles. Epidemic cycles are mediated by arthropod vectors (e.g. *Aedes* spp., *Anopheles* spp., and in some settings *Coquillettidia* spp.) that feed on both birds and mammals.

EEEV is zoonotic and causes encephalitis, fever, drowsiness, and nuchal rigidity in humans. Symptoms may progress to confusion, paralysis, convulsion, and coma.

In pigs, response to EEEV infection is age dependent. Nursing pigs are most severely affected, and infection in pigs older than 2 months is inapparent. Clinical signs include incoordination, depression, seizure, vomiting, low fever, and mortality. Growth is usually retarded in survivors. Predisposing factors, such as environmental conditions and concurrent disease(s), may contribute to higher mortality.

In 1958, serology on pigs in the states of Georgia, Massachusetts, and Wisconsin of the United States showed that prevalence ranged from 17 to 26%. In Georgia, up to 20% of domestic herds and 16% of feral swine were seropositive, with virus neutralization (VN) titers of 1 : 4–1 : 128 (Elvinger et al. 1996). VN antibody titers in domestic swine were generally lower than feral swine, and pigs from sale barns and stockyards had seropositive rates of 7%. However, a natural EEEV outbreak was not reported until 1972 in 3-week-old pigs (Pursell et al. 1972) and in 1991 in pigs under 2 weeks of age, with 80% mortality (Elvinger et al. 1994). Thus, EEEV infection in pigs is not uncommon, but clinical episodes are rare, as witnessed by no apparent increase in reports of EEEV episodes in pigs, despite the global climate extremes experienced in recent years.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

The incubation period in pigs is unknown, since most infections are subclinical, but ranged from 1 to 3 days in experimental inoculations (Elvinger and Baldwin 2006). EEEV initially replicates in regional lymph nodes and then invades extraneural tissues, resulting in high virus titers and secondary viremia. Viremia is the key to invasion of the central nervous system (CNS). Viremia lasts for 7 days post inoculation (DPI). EEEV is recoverable from oropharyngeal and rectal swabs for 4 DPI and from tonsils for 20 DPI. Potentially, infected young pigs could transmit EEEV to contacts and serve as a source of virus for vectors (Elvinger and Baldwin 2006).

Gross lesions are unremarkable. Microscopic lesions include meningoencephalitis with necrosis, microabscesses, perivascular cuffing of neutrophils (early) and lymphocytes (later), and myocardial necrosis. Pigs that die in the acute phase may not have CNS lesions (Elvinger et al. 1994).

Diagnosis by viral isolation can be done using CNS tissues and/or the specimens specified above in Vero cells or other cell culture systems, followed by identification by immunofluorescence or polymerase chain reaction (PCR) (Ostlund 2012).

There is no treatment for clinically affected pigs. Prevention is achieved by vaccination of animals at risk and/or control of the vector population. Vaccines are available for humans and horses. Vaccination may be economically justifiable in severe outbreaks or for the protection of valuable pigs. Vaccination of sows will provide protective maternal antibody to piglets.

Getah virus

GETV is present throughout Asia as far north as Russia and south to Sarawak in Malaysia. It is primarily a pathogen of horses, but the virus has been isolated from a variety of mosquito species in the vicinity of swine. *Aedes vexans nipponii, Culex tritaeniorhynchus, Culex gelidus,* and *Culex fuscocephala* are considered the main vectors, depending on the location.

GETV was first reported in swine in 1987 and in newborn piglets exhibiting depression, tremors, yellowish-brown diarrhea, and 100% case mortality (Yago et al. 1987). Subclinically infected piglets showed a transient depression in growth rate, whereas sows were unaffected. GETV has also been recovered from late-term dead fetuses from a naturally infected sow (Shibata et al. 1991). Sows inoculated before 26–28 days of gestation farrowed dead fetuses, with virus recoverable from the placenta, amniotic fluid, and fetal organs (Izumida et al. 1988), likely attributed to the presence of virus in the blood and various hematolymphoid organs (Kumanomido et al. 1988). GETV and Japanese encephalitis virus (JEV) share vector species (e.g. *C. tritaeniorhynchus*), habitats, and transmission cycles and produce similar clinical signs in pigs, and infection with GETV may be masked by coinfection with JEV (Tajima et al. 2014).

In Japan where GETV is endemic in some districts, serum antibody rates were 3–19% in domestic pigs (Hohdatsu et al. 1990) and averaged 48% in wild boar, with higher seropositive rates in adult pigs (Sugiyama et al. 2009). In areas of Sri Lanka where there is abundant rainfall and small-scale pig herds are surrounded by rice fields, there is subclinical infection with a seroprevalence of 41% compared with only 0.6% in humans (Peiris et al. 1994).

Diagnosis is done by viral isolation on rabbit kidney (RK-13) or Vero cells or by detection of viral RNA by PCR (Ogawa et al. 2009). GETV has been co-isolated with JEV, grows faster than JEV in successive passages, and produces clear plaques resembling those of alphavirus (Tajima et al. 2014). ELISA or hemagglutination inhibition (HI) is available for use in paired sera. An inactivated vaccine has been used successfully in racehorses.

Sagiyama virus

SAGV is considered a variant of GETV, but can be differentiated from GETV by complement fixation due to the presence of the amino acid leucine in the SAGV capsid protein (versus proline in GETV) (Wekesa et al. 2001). *C. tritaeniorhynchus* and *Aedes vexans* are believed to be the major vectors.

Natural subclinical infection in pigs was first reported in the 1960s, albeit the VN antibody rate in pigs was 67 versus 18% in humans living in the vicinity of infected pigs (Scherer et al. 1962). These antibody rates are higher than those reported for GETV and raise the question as to whether the presence of leucine on its capsid protein might indicate selection for more efficient transmission.

The first SAGV outbreak was reported in 2006 in 9-week-old pigs exhibiting growth retardation, panting, abdominal breathing, and arthritis (Chang et al. 2006). The clinical picture may have been affected by concurrent infection with JEV and porcine circovirus 2 (PCV2); thus, subsequent intramuscular inoculation of nursery pigs produced no specific clinical signs.

A low level of SAGV viremia occurs at 2–4 DPI, during which time virus can be recovered from the spleen, tonsil, lymph nodes, and kidney, but not from oral and nasal swabs. VN antibody can be detected by 4 DPI, and viremia is resolved by 7 DPI. SAGV is considered nonpathogenic to pigs, but concurrent infections may interact synergistically to cause more severe clinical signs.

SAGV causes CPE in swine testis (ST) (ATCC CRL-1746™, Rockville, MD), porcine kidney (PK-15),

Vero, RK-13, and baby hamster kidney (BHK-21) cells. Virus isolation is definitive, but has little diagnostic value due to the transient nature of viremia. Antibody detection is indicative of SAGV infection, in which VN antibody titers >1:48 or a seropositive rate >50% is suggestive of repeated exposures to SAGV.

There is neither treatment nor vaccine for SAGV infection, leaving vector control as the most rational form of prevention and control.

Ross river virus

RRV is endemic to Australia, Papua New Guinea, and Irian Jaya, Indonesia. Several RRV epidemics occurred in south Pacific islands in 1979–1980, but it did not become permanently established there. The main vectors are *Aedes vigilax*, *Aedes camptorhynchus*, *Aedes polynesiensis*, and *Culex annulirostris*.

RRV is regularly transmitted via a human–mosquito–macropod marsupials–mosquito–human cycle. However, in epidemics in densely populated areas, a direct human–mosquito–human route is believed to occur because of the high levels of viremia reached in humans. However, the threat may be low for RRV to emerge in areas where the macropod population and the density of major vector species are not abundant (Tompkins and Slaney 2014).

RRV is not known to cause disease in pigs. Experimental infection of juvenile domestic and feral pigs resulted in no detectable virus or only moderate viremia at 0–5 DPI (Harley et al. 2001). During epidemics, the seroprevalence in domestic pigs was 43 and 77% by HI and VN, respectively (Rosen et al. 1981). During inter-epidemic intervals, seroprevalence was 15% in feral pigs by HI (Gard et al. 1976).

In humans, RRV infection may cause symmetrical epidemic polyarthritis, predominantly involving peripheral joints, fever, skin rash, and constitutional effects like myalgia, fatigue, and malaise. Seroconversion of immunoglobulin G in paired sera as demonstrated by ELISA is indicative of a recent infection. Detection of immunoglobulin M is diagnostically unreliable, particularly in endemic areas. PCR assays have been described for human and equine sera (Sellner et al. 1995; Studdert et al. 2003) and should be used in conjunction with serology. Nonsteroidal anti-inflammatory drugs (NSAID) provide the best and most effective symptomatic relief. No vaccine is available for human use.

Section IV

Bacterial Diseases

47

Overview of Bacteria

Karen W. Post

Diseases caused by bacteria including mycoplasmas and chlamydias are all considered in this chapter. While viral diseases such as porcine reproductive and respiratory virus (PRRSV) and porcine circovirus remain as some of the greatest challenges to worldwide pork production, bacterial diseases continue to have a significant impact on the industry. Concurrent bacterial infection with lung pathogens such as *Bordetella bronchiseptica* and *Mycoplasma hyopneumoniae* has been shown to increase the severity and duration of PRRSV-induced pneumonia (Brockmeier et al. 2000; Thacker et al. 1999). Bacterial respiratory and enteric infections are among the most common and economically significant diseases facing swine producers today. A major pneumonia complex is *M. hyopneumoniae* with secondary bacterial bronchopneumonia (Straw et al. 1989). *Escherichia coli* is among the most important cause of neonatal and post weaning diarrhea in pigs (Fairbrother and Gyles 2006).

Phenotypic classification of bacteria places them into groups based upon readily identifiable characteristics, which include Gram stain reaction, microscopic cellular morphology, oxygen requirements, and ability to form endospores (Table 47.1).

The Gram stain reaction divides bacteria into gram-positive or gram-negative forms based upon differences in the composition and thickness of their cell wall. Although most of the swine bacterial pathogens are able to be Gram stained, there are notable exceptions. Even though mycoplasmas are of gram-positive lineage, their permanent lack of a cell wall precludes them from retaining the crystal violet stain. Treponemes and leptospires cannot be satisfactorily stained and observed microscopically by this method. Additionally the high lipid and mycolic acid content in the cell walls of *Mycobacterium* species may render them difficult to Gram stain.

Bacterial cellular morphology comprises cocci (spheres), bacilli (rods), and spirochetes (curved rods or spiral forms). Within these three morphologic groups, there may be considerable variability in shape and size. Cocci may be found in clusters (*Staphylococcus* species) or in long or short chains (*Enterococcus* and *Streptococcus* species). While many bacilli are considered to be regular rods (members of the genera *Escherichia, Salmonella,* and *Listeria*), others may appear coccobacillary (*Pasteurella*), pleomorphic (*Trueperella* [*Arcanobacterium*] *pyogenes* and *Actinobacillus* species), or filamentous in shape (*Haemophilus parasuis* and *Erysipelothrix rhusiopathiae*). Among the spirochetes there are those that are loosely or tightly coiled (*Brachyspira, Treponema,* and *Leptospira* species) or curved to seagull shaped (*Campylobacter* species and *Lawsonia intracellularis*). The size of the individual bacterial cell may vary depending upon its growth phase and the type of medium the organism was cultivated in or on. As a general rule, most spirochetes, *Bacillus* species, and clostridia are regarded as large. Medium-sized organisms include pseudomonads and members of the family *Enterobacteriaceae* (salmonellae and *E. coli*). *Brucella*, *Haemophilus,* and *Pasteurella* species are small in size, while mycoplasmas and chlamydias are extremely small.

Bacteria may be further categorized by their ability to utilize or tolerate oxygen. Bacteria with an absolute requirement for oxygen are called obligate aerobes. There are no genera of swine bacterial pathogens that fall into this category. Facultatively anaerobic bacteria can survive in the presence or absence of oxygen, and this category represents the majority of the swine bacterial pathogens. Microaerophilic bacteria require trace amounts of oxygen for growth but may be killed by normal atmospheric concentrations. Members of the genus *Campylobacter* best represent the microaerophiles. Obligate anaerobes are killed by even trace amounts of oxygen. Many clostridia are obligate anaerobes.

Another classification of bacteria, primarily gram-positive bacilli, is based on their ability to produce spores. Spore-forming bacteria produce a unique resting cell called the endospore when vegetative cells are deprived of a necessary growth factor or requirement.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Table 47.1 Classification of the principal bacterial pathogens of swine.

Classification	Genus/genera
Gram-positive aerobic to facultatively anaerobic cocci	*Enterococcus, Staphylococcus, Streptococcus*
Gram-positive aerobic to microaerophilic non-spore-forming bacilli	*Trueperella, Erysipelothrix, Listeria, Mycobacterium, Rhodococcus*
Gram-positive aerobic spore-forming bacilli	*Bacillus*
Gram-positive anaerobic spore-forming bacilli	*Clostridium*
Gram-positive anaerobic non-spore-forming bacilli	*Actinobaculum*
Gram-negative aerobic to facultatively anaerobic bacilli	*Actinobacillus, Bordetella, Brucella, Burkholderia, Escherichia, Haemophilus, Pasteurella, Salmonella, Yersinia*
Gram-negative microaerophilic to anaerobic curved to spiral-shaped bacilli	*Brachyspira, Campylobacter, Lawsonia, Leptospira, Treponema*
Bacteria without cell walls and obligately intracellular bacteria	*Mycoplasma, Chlamydophila*

Spores are extremely resistant to harsh environmental conditions and disinfectants. The two genera of sporeformers with veterinary medical importance are *Bacillus*, the members of which are aerobic sporeformers, and *Clostridium*, whose species are anaerobic sporeformers. Notable non-spore-forming bacilli that represent swine pathogens include *Actinobaculum suis, E. rhusiopathiae,* and *T.* (*A.*) *pyogenes*.

Knowledge of the characteristics of a given bacterium is useful to the practitioner. The Gram stain reaction of a suspected pathogen can provide information regarding which antimicrobial agent to prescribe for empiric therapy while the veterinarian is awaiting the results of culture and susceptibility testing. When carrying out primary observations on stained clinical materials, it is important to know the Gram stain and cellular morphology of the common pathogens that might be present in the specimen. Knowledge of a bacterium's oxygen requirements is an important consideration when collecting and transporting diagnostic specimens to the laboratory. Organisms that produce spores, such as *Clostridium difficile* and *Clostridium perfringens*, may be extremely difficult to eliminate from the farrowing house environment because the spores are resistant to most disinfectants, heat, and ultraviolet light. This is an important consideration for practitioners faced with the challenge of managing these infections in neonates.

The majority of swine bacterial pathogens are able to be grown on artificial culture media that provide necessary nutrients. Of these, many may form discrete colonies on plated media within 24–72 hours of inoculation. Other bacteria like *Leptospira* and *Mycobacterium* species may require several months for growth to occur in culture media. Some obligate intracellular parasites such as chlamydias and *L. intracellularis* can only be cultivated *in vivo* or in cell culture systems because they are unable to produce energy in amounts required to sustain their metabolism outside a living host.

Swine bacteria may be considered as normal flora or commensals, opportunists, or frank pathogens. Commensals live on or in the host harmlessly. Most of the aerobic and anaerobic bacteria in the porcine alimentary tract are commensals. Opportunistic pathogens cause disease when the host's innate or acquired immunity is compromised in some way. *T. (A.) pyogenes* represents one of the most common opportunists. Frank pathogens are consistently able to infect and cause disease in a percentage of healthy hosts by evading various defense mechanisms. *Bacillus anthracis* is an example of a frank pathogen.

Bacterial pathogenicity is a multifactorial process. Bacteria initially must establish an infection. This process involves bacterial attachment or other means of gaining entry into the host, evading host defenses, multiplying to significant numbers, causing damage to the host either directly or indirectly, and concluding with transmission of the agent to another susceptible host (Gyles and Prescott 2004). Host immune factors, the numbers of organisms present in the initial exposure, and the virulence attributes of the bacterium all play a role in the development of disease.

As a general rule, bacteria cause disease by two primary mechanisms: tissue invasion and toxin production (Songer and Post 2005). To invade host tissues, bacteria employ methods for adhering to and/or penetrating cells, producing extracellular substances to facilitate the process of invasion, and overcoming host defenses. Adhesins are surface proteins that cause adhesion of organisms to host cells. Many strains of pathogenic *E. coli* possess surface adhesive organelles called pili that mediate cellular attachment. *Listeria monocytogenes* and *Yersinia* species are examples of facultatively intracellular bacteria that employ invasins to gain entry into host cells (Niemann et al. 2004). Certain bacteria produce extracellular enzymes like coagulase produced by *Staphylococcus hyicus* and streptokinase produced by

beta-hemolytic streptococci that enable these agents to spread widely within host tissue. For those bacteria that cause disease through toxin production, exotoxin and endotoxin are the major types. Exotoxins are proteins released primarily by gram-positive bacteria into their extracellular environment. They vary greatly in their potency, ranging from the highly toxic botulinum toxin to the weakly toxic product released by *T. (A.) pyogenes*. Other swine pathogens that may produce exotoxins are *Clostridium perfringens*, enteropathogenic strains of *E. coli*, *Pasteurella multocida*, and *S. hyicus*. Endotoxins are the lipopolysaccharides found in the cell wall of gram-negative bacteria. These may be released from both actively growing bacterial cells and those that have been lysed as a result of the effect of certain antibiotics or through successful host defense mechanisms like lysozyme production. The release of endotoxins is a very important component of the toxicity of gram-negative bacteria and is directly responsible for many of the clinical signs produced by these pathogens including fever, shock, and disseminated intravascular coagulopathy.

Many swine bacterial diseases may be recognized by their specific clinical signs, gross postmortem lesions, or epidemiological features (Tables 47.2 and 47.3). Direct contact, close contact with infected droplets or feces, and mechanical transfer by fomites or vectors are the ways in which bacteria are commonly spread. Succeeding chapters provide in-depth coverage of bacterial diseases including relevance, potential public health significance, epidemiology, pathogenesis, clinical signs, lesions, diagnosis, immunity, and prevention and control.

Table 47.2 Gram-positive bacteria and associated swine disease(s) and/or clinical signs.

Bacterium	Disease(s) and/or clinical signs
Actinobaculum suis	Cystitis, pyelonephritis
Actinomyces hyovaginalis	Sporadic abortion, embolic pneumonia
Bacillus anthracis	Anthrax
Clostridium botulinum	Botulism
Clostridium chauvoei	Blackleg
Clostridium difficile	Neonatal colitis
Clostridium perfringens	Neonatal enteritis, pseudomembranous colitis
Clostridium novyi	Sudden death, hepatitis
Clostridium septicum	Malignant edema
Clostridium tetani	Tetanus
Enterococcus species	Enteritis
Erysipelothrix rhusiopathiae	Erysipelas
Listeria monocytogenes	Listeriosis, abortion, encephalitis, septicemia
Mycobacterium species	Tuberculosis
Mycoplasma hyopneumoniae	Enzootic pneumonia
Mycoplasma hyorhinis	Arthritis, otitis, polyserositis
Mycoplasma hyosynoviae	Arthritis
Mycoplasma suis	Anemia, infertility, decreased growth rate, pericarditis, unthriftiness
Rhodococcus equi	Granulomatous lymphadenitis
Staphylococcus aureus	Abscesses, arthritis, enteritis, mastitis, metritis, neonatal septicemia, vaginitis
Staphylococcus hyicus	Exudative epidermitis
Streptococcus dysgalactiae subsp. equisimilis	Arthritis, endocarditis, meningitis, septicemia
Streptococcus porcinus	Cervical lymphadenitis
Streptococcus suis	Septicemia, arthritis, endocarditis, polyserositis
Trueperella abortisuis	Sporadic abortion
Trueperella pyogenes	Abscesses, arthritis, endocarditis, mastitis, osteomyelitis, pneumonia

Table 47.3 Gram-negative bacteria and associated swine diseases and/or clinical signs.

Bacterium	Disease(s) and/or clinical Signs
Actinobacillus pleuropneumoniae	Pleuropneumonia
Actinobacillus suis	Pneumonia, septicemia
Bordetella bronchiseptica	Nonprogressive atrophic rhinitis, pneumonia
Burkholderia pseudomallei	Melioidosis, internal abscesses, lymph node abscesses
Brachyspira hyodysenteriae, Brachyspira hampsonii, or Brachyspira suanatina	Swine dysentery
Brachyspira pilosicoli	Porcine intestinal/colonic spirochetosis
Brachyspira murdochii or Brachyspira intermedia	Mild colitis, loose stools
Brucella suis	Brucellosis, abortion, arthritis, infertility
Campylobacter coli/Campylobacter jejuni	Subclinical enterocolitis
Chlamydia suis	Conjunctivitis, neonatal diarrhea, pneumonia, possibly abortion
Chlamydia abortus	Early embryonic death, abortion
Escherichia coli	Colibacillosis, edema disease, cystitis, enteritis, mastitis, neonatal septicemia
Haemophilus parasuis	Glässer's disease, arthritis, polyserositis
Klebsiella pneumoniae	Piglet septicemia
Lawsonia intracellularis	Porcine proliferative enteropathy
Leptospira species	Leptospirosis, infertility, stillbirths, weak piglets
Pasteurella multocida	Progressive atrophic rhinitis, pneumonia
Salmonella enterica	Enteric and septicemic salmonellosis
Treponema pedis	Cutaneous spirochetosis
Yersinia enterocolitica	Subclinical enterocolitis
Yersinia pseudotuberculosis	Diarrhea, enterocolitis

Actinobacillosis

Marcelo Gottschalk and André Broes

Actinobacillus pleuropneumoniae

Relevance

Actinobacillus pleuropneumoniae (App) (originally named as *Haemophilus pleuropneumoniae*) is the etiologic agent of porcine pleuropneumonia. An organism also isolated from porcine pleuropneumonia, originally known as "*Pasteurella haemolytica*-like," was later determined to be a nicotinamide adenine dinucleotide (NAD)-independent biotype of App (Pohl et al. 1983) and is known as App biotype II (see below).

App is one of the most important swine bacterial respiratory pathogens and is found worldwide. The most virulent strains can induce rapidly fatal fibrinohemorrhagic and necrotizing pleuropneumonia in swine of all ages. Survivors often have devitalized bacteria-laden sequestra in their lungs. The economic importance of App is mainly due to the mortality, reduced growth, veterinary costs (antimicrobials, vaccinations), and condemnations at the slaughterhouse. However, in chronically infected herds, results from studies investigating impact on average daily gain have been controversial (Andreasen et al. 2001; Hartley et al. 1988; Hunneman 1986).

Virulence of App strains varies remarkably; some strains produce high mortality, others are avirulent, and yet others are intermediate in virulence. High mortality outbreaks are now rather infrequent in the United States and Canada, but remain a problem in Latin American, Asian, and European countries (Gottschalk et al. 2003a). Certain App strains can also act as secondary pathogens contributing to increased mortality in conjunction with other viral and bacterial pathogens as a component of the porcine respiratory disease complex (PRDC).

App infections can be frustrating for swine producers and veterinarians. Many herds are infected with several strains. High virulence strains may be present in a herd for extended periods of time without evidence of clinical signs or even lesions at the slaughterhouse. The organism resides mainly in the tonsils, and carrier pigs can be difficult to detect. Outbreaks may suddenly appear in the presence of concomitant diseases or concurrent with changes in management or other significant stressors such as overcrowding. There are not readily available laboratory tests to differentiate highly virulent strains from strains of lesser virulence.

Both the organism and the disease have been studied extensively. Knowledge gained has allowed for better diagnostic tests and strategies, vaccines, and relatively effective eradication strategies. However, App remains a significant cause of economic loss to the swine industry, and there remains opportunity for improvement in control and eradication of this agent.

Etiology

App is a small, gram-negative encapsulated rod with typical coccobacillary morphology. App isolates are classified on the basis of the NAD requirement for *in vitro* growth into biotype I (NAD dependent) and biotype II (NAD independent) (Pohl et al. 1983). Biotype I strains do not grow on blood agar unless it contains NAD or unless NAD is supplied by a staphylococcal nurse streak where colonies of App grow in immediate proximity as "satellites." App forms colonies 0.5–1 mm after 24 hours of incubation and is usually beta-hemolytic. In fact, App produces an increased zone of hemolysis within the zone of partial lysis surrounding a beta-toxigenic *Staphylococcus aureus* or *Staphylococcus epidermidis* (the CAMP phenomenon) (Nicolet 1970). This CAMP phenomenon is due to secretion of combinations of the cytolysins ApxI, ApxII, and ApxIII by various strains of App (see below) (Frey et al. 1994). Additional detailed morphologic and biochemical characteristics may be found in original reports (Kilian et al. 1978). Biotype I strains should be differentiated from other NAD-dependent actinobacilli present in the upper respiratory

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

tract of swine such as *Actinobacillus minor*, *Actinobacillus porcinus*, or *Actinobacillus porcitonsillarum* (Gottschalk et al. 2003b; Kielstein et al. 2001). Definitive identification may require species-specific polymerase chain reaction (PCR) testing (Schaller et al. 2001; Tonpitak et al. 2007). Biotype II strains grow easily on blood agar plates without the presence of NAD; colonies must be differenced from those of *Actinobacillus suis* using a panel of biochemical tests or by PCR (Serrano-Rubio et al. 2008). This is especially important because *A. suis* may induce pleuropneumonia similar to App (MacInnes and Desrosiers 1999; MacInnes et al. 2008; Yaeger 1995) but has different implications for control.

App biotype I has been divided into 14 serotypes (1–12, 15, and 16) and biotype II into 2 serotypes (13–14) for a total of 16 serotypes (Blackall et al. 2002; Kamp et al. 1987; Kilian et al. 1978; Nielsen 1985a,b, 1986b; Nielsen et al. 1997; Nielsen and O'Connor 1984; Rosendal and Boyd 1982; Sárközi et al. 2015). Serotype 5 is subdivided into subtypes 5a and 5b (Nielsen 1986a); however, this subdivision has neither epidemiological nor pathological significance, and most laboratories do not perform the subtyping. The above association of serotypes and biotypes is predominant but not exclusive. Biotype II strains belonging to serotypes 2, 4, 7, 9, and 11 (normally found among biotype I strains) have been reported (Beck et al. 1994; Maldonado et al. 2009). Additionally, biotype I serotype 13 strains that are antigenically different from the reference serotype 13 biotype II strain have been isolated from the United States and Canada (Perry et al. 2012). Untypable biotype I or biotype II strains are sometimes isolated in both North America and Europe, and new serotypes will probably be described soon (Gottschalk et al. 2003a; Bossé J, unpublished observations).

Serotype specificity is considered to be conferred by the capsular polysaccharides (CPS) (Dubreuil et al. 2000). CPS are usually associated with particular cell wall lipopolysaccharides (LPS), i.e. CPS type 1 is usually associated with LPS type 1. However, some capsular serotype groups share identical O-chain LPS, thus explaining the cross-reactions observed in serological assays using LPS as antigen between serotypes 1, 9, and 11; serotypes 3, 6, 8, and 15; and serotypes 4 and 7 (Dubreuil et al. 2000; Gottschalk 2015; Perry et al. 1990). Yet, isolates with a given capsular type and a different LPS type have been sporadically reported. For example, strains of CPS/LPS serotype 1/7 and 2/7 have been reported in North America and Europe, respectively (Gottschalk et al. 2000; Nielsen et al. 1996), whereas a CPS/LPS 12/3 strain has been recently described in Japan (Ito and Matsumoto 2015). The biotype I serotype 13 strains recovered in North America are antigenically different from the biotype II serotype 13 reference strain (isolated in Europe) in that they have an LPS that cross-reacts with that from App serotype 10 (Perry et al. 2012). These strains can cause false-positive serotype 10 serologic reactions in LPS-based serologic tests (see below). It has been suggested that serotypes of App should be more rigorously defined by specifying both capsular (K) and LPS (O) antigens (Perry et al. 1990), but this nomenclature has not been widely adopted (Dubreuil et al. 2000).

Public health

App does usually not infect humans and poses no public health risk. However, necrosis from needlestick injury with live App vaccine (non-virulent strain for pigs) and the isolation of an App serotype 5 strain from a poorly healing wound of a swine producer after being bitten by a boar have been reported (Rycroft et al. 2011; R. Higgins, personal communication).

Epidemiology

Distribution of App

App is widely distributed and only infects pigs, although a recent report suggested that an App strain was able to infect poultry (Pérez Márquez et al. 2014). The primary reservoir is domestic swine, but various studies in wild boar populations in Europe, North America, and Australia showed that this species is frequently infected by App (Hälli et al. 2014; McGregor et al. 2015; Pearson et al. 2014; Reiner et al. 2010). In Canada, these populations are serologically positive for serotype 14, a capsular type not found so far in domestic pigs in North America (McGregor et al. 2015).

Outbreaks of pleuropneumonia have been reported in domestic swine from practically all European countries and from different parts of the United States, Mexico, South America, Japan, Korea, Taiwan, and Australia as well as in many other countries. Interestingly, there has been a simultaneous increase in clinical App in recent years in many European countries as reflected in increased chronic pleuritic adhesions in slaughterhouses (Hoeltig et al. 2009; Sjölund and Wallgren 2010). This is possibly due to older weaning ages mandated by new welfare laws, since App is known to be a late colonizer in piglets and earlier weaning dramatically reduces carriage rates in weaned pigs.

The distribution of serotypes involved in acute outbreaks and chronic infections in different regions of the world is radically different. Moreover, strains of a given serotype may be highly virulent in one region, and yet strains of the same serotype may be of low virulence in another region. Therefore, it is critical when testing imported pigs for App prior to introduction into a closed herd to select diagnostic tests for the most important virulent serotypes present in their region of origin.

Unfortunately, only a few reports on the distribution of serotypes recovered from diseased animals have been published during the last 25 years (Gottschalk 2015). Moreover, the relative prevalence of serotypes may dramatically change during the years as described in Korea and Canada (Gottschalk and Lacouture 2015; Kim et al. 2016). In some regions, one or more virulent serotypes predominate and cause most outbreaks – serotypes 5 and 7 in North America, serotypes 2 and 9 in many European and Asian countries, and serotype 15 in Australia, to name a few. Serotype 2 strains are highly virulent in European and Asian countries owing to secretion of two cytotoxins, ApxII and ApxIII, but serotype 2 strains in North America secrete only ApxII and are of low virulence (Gottschalk et al. 2003a). Serotype 4 is one of the most frequent virulent serotypes in Spain, but is uncommon in most other countries (Maldonado et al. 2009). This serotype was isolated once from asymptomatic animals in Canada (Lebrun et al. 1999), but there are no other reports of serotype 4 strains in North America. Serotype 15, originally described and the predominant serotype in Australia (Blackall et al. 2002), has also occasionally been reported in North and South America (Gottschalk and Lacouture 2014; Gottschalk et al. 2003a) as well as in Japan (Koyama et al. 2007). Serotype 8 is by far the predominant serotype in the United Kingdom and occasionally isolated from diseased pigs in North America and Japan (Gottschalk and Lacouture 2014; Koyama et al. 2007; Li et al. 2016).

Biotype II strains are more commonly isolated in some European countries; however, these strains are occasionally reported in North America (Frank et al. 1992; Gottschalk et al. 2003a). Biotype II strains have traditionally been considered of low virulence; however, there are reports of their isolation in several cases of fatal pleuropneumonia (Gambade and Morvan 2001). Maldonado et al. (2009) reported that 25% of isolates recovered from diseased pigs in Spain belonged to biotype II of which serotypes 7, 2, 4, and 11 were the most common.

Most conventional herds are infected with one or more serotypes of App, and although these strains are often of low virulence, high virulence strains may also be present (Gottschalk et al. 2003a). Most prevalent serotypes (detected by serology) are often different from those recovered from diseased pigs (Gottschalk 2015). In a Spanish report, almost 90% of studied herds were serologically positive for App, many of them presenting pleuritic lesions at slaughterhouse, although the distribution of involved serotypes was not studied (Fraile et al. 2010). In a Canadian study, 78% of herds were App positive based on PCR detection in the upper respiratory tract of piglets (MacInnes et al. 2008). In the same study, 70% of the herds were seropositive by LPS-ELISA with distribution of serotypes as follows: 26% were positive for serotype 7/4, 17% for 12, 15% for 3/6/8/15, 6% for 5, 4% for 2, and 2% for 1/9/11. Although serotypes 2, 12, 3, 6, 8, and 15 are usually considered as of low/intermediate virulence (Gottschalk 2015; Gottschalk et al. 2003a), serotypes 7 and 5 are currently the most common serotypes recovered from diseased pigs in Canada (Gottschalk and Lacouture 2015). Interestingly, most herds included in the study did not present clinical signs of pleuropneumonia. The somewhat paradoxical trend of high seroprevalence combined with low disease prevalence highlights a concept important in the epidemiology of App. Low virulence strains tend to be highly prevalent in herds, resulting in high seroprevalence; however, highly virulent strains are carried by a much lower proportion of animals, resulting in lower seroprevalence. This has to be taken into account when determining the number of animals to be tested in serological surveillance programs.

Strains belonging to the same serotype have been genotypically compared. Although a given genotype profile cannot be clearly related to a given serotype (Gottschalk 2015), several studies have shown a relative homogeneity within a particular serotype with one or few clones represented and this, depending on the technique used (Chatellier et al. 1999; Fussing 1998; Møller et al. 1992). Further rapid subtyping methods are needed, and a combination of different methods will have to be used to reach conclusions about epidemiological relationships (Rossi et al. 2013). Complete genome sequencing has also been used to compare different strains belonging to the same serotype (Pereira et al. 2015).

Routes and duration of shedding and transmission

With few exceptions of systemic disease (Jensen et al. 1999; Madsen et al. 2001; Ohba et al. 2008, 2010), App is essentially a swine respiratory pathogen. In peracute and acute infections, it can be found not only in pneumonic lung but also in large numbers in nasal discharges. Survivors may remain carriers for several months (Desrosiers 2004) mainly in chronic lung lesions and tonsils. Some exposed animals remain healthy and become subclinical carriers mainly in the tonsils. Less frequently, carrier animals may harbor the organism in the nasal cavity (Chiers et al. 2010). Subclinical carriage of App in tonsils occurs not only for low virulence strains but also for high virulence strains that can sometimes be present in well-managed herds for long periods without clinical signs or lesions (Gottschalk 2015). Environmental stressors or concurrent respiratory pathogens can result in sudden clinical outbreaks.

Transmission between herds occurs mainly through the introduction of carrier animals. The main route of spread is by direct nose-to-nose contact or by droplets within short distances. Moving and mixing pigs increases the risk of spread.

In acute outbreaks, infection may not occur in every pen, suggesting the possible role of aerosols and air movement in the transmission of the disease over longer

distances within buildings, or the indirect transmission of contaminated exudates from acutely infected pigs by farm personnel. Studies confirm that App may be transmitted by aerosol over short distances (Desrosiers 2004; Jobert et al. 2000). Kristensen et al. (2004b) reported that airborne transmission between closely located pig units is possible, but uncommon. In contrast, Zhuang et al. (2007) suggested that local spread of App serotype 2 from neighboring herds was a predominant factor in the contamination of Danish specific-pathogen-free (SPF) genetic herds. Introduction of the disease by artificial insemination or embryo transfer is highly unlikely, since the genital tract is not a common site of infection and antimicrobials in the semen diluent or the embryo washing procedures could possibly prevent the persistence of the organism. Birds and small rodents are unlikely to transfer App and are not considered significant sources of the infection. The role of App-contaminated fomites in the transmission of the infection is suspected but has not been studied.

In endemically infected herds, App is transmitted by infected sows to their offspring via close contact. The frequency of transmission is likely related to the amount of bacteria shed by the sow, although more quantitative studies are needed. A recent study showed that although most sows were colonized, only some litters of piglets (and some piglets within a litter) were infected (Tobias et al. 2014). It has been suggested that the level of antitoxin maternal antibodies does not influence the colonization of piglets (Tobias et al. 2014). The level of maternal antibodies against the LPS, however, seems to be positively correlated with a late colonization (unpublished results). The persistence of colostral antibody in piglets ranges from 2 weeks to 2 months of age, depending on the initial level of acquired colostral antibodies, the antigen used in the test, and the serological test used (Vigre et al. 2003; unpublished observations). Usually only a few piglets are infected from their dams during the late suckling period; then lateral spread occurs after weaning as decay of maternal immunity renders more pigs susceptible (Vigre et al. 2002) or if mixed with naïve pigs.

Survival of the organism in the environment is of short duration, especially in warm, dry conditions. However, when protected with mucus or other organic matter, it can survive for several days (even weeks), and it can survive in clean water for periods of up to 30 days at 39 °F (4 °C). Common disinfectants are effective against App when organic matter is first removed by thorough washing (Gutierrez et al. 1995).

Pathogenesis

Virulence factors and pathogenesis of the infection

The incubation period can be quite variable. Inoculation of pigs with large numbers of virulent App can lead to fatal pleuropneumonia in as few as 6 hours. Following exposure by oronasal contact or inhalation, App first colonizes the epithelial cells on the surface and later in the crypts of the palatine tonsil (Chiers et al. 1999). Colonized epithelial cells vacuolate and desquamate and, along with transmigrating neutrophils, distend tonsillar crypts. In contrast, App does not bind well to the ciliated epithelium of the trachea or bronchi (Bossé et al. 2002); an exception may be the trachea of newborns (Auger et al. 2009). When able to reach the lower respiratory tract, App is able to adhere to pneumocytes that line alveoli (Bossé et al. 2002; Van Overbeke et al. 2002).

Colonization is dependent upon bacterial-to-cell adhesion that seems to be mediated by polysaccharides and proteins (Van Overbeke et al. 2002). Evidence from other pathogen–host cell interactions suggests that adherence to host cells is a complex and multifactorial process (Bossé et al. 2002). The oligosaccharide core of LPS seems to play an important role in adherence of App to swine cells (Chiers et al. 2010). The presence of proteinaceous fimbriae and fimbrial subunits on the surface of App has been demonstrated (Zhang et al. 2000). However, their eventual role in adhesion remains to be elucidated.

Once in the respiratory tract environment, certain bacterial nutrients, particularly iron, are scarce. App expresses a number of factors that are involved in the acquisition and uptake of iron (Chiers et al. 2010; Jacques 2004). Among other mechanisms, App is capable of utilizing porcine transferrin and heme compounds including free heme, hemin, hematin, and hemoglobin as well as a siderophore (Bossé et al. 2002; Chiers et al. 2010; Jacques 2004).

In pigs that are tonsillar carriers of virulent strains of App, the mucociliary apparatus normally clears any stray bacterial cells that are inhaled. This prevents App access to and subsequent replication in alveoli, the essential step to development of pleuropneumonia. Factors that overwhelm or reduce the function of the mucociliary apparatus are necessary to deliver sufficient App to alveoli for subsequent disease development. High inhaled doses of App in finely atomized particles can result in App reaching alveoli. This is most likely during acute outbreaks when sick pigs are shedding large amounts of App. Alternatively, cilia can be damaged by colonizing *Mycoplasma hyopneumoniae* or by replication of pseudorabies (Aujeszky's) virus or influenza virus in tracheal and bronchial epithelial cells. Marois et al. (2009) showed that experimental inoculation of 10-week-old pigs with a serotype 9 strain of App produced disease only in pigs previously exposed to *M. hyopneumoniae* and not in non-exposed controls. Other factors may also impair ciliary function, like chilling or high environmental ammonia levels. It has been suggested that outbreaks of App on endemic farms could be caused by a trigger inducing pneumonia in already infected pigs (Klinkenberg et al. 2014).

Once in the alveoli, a battle ensues between host innate and acquired immune mechanisms in the alveoli and virulence mechanisms of App to overcome them, the outcome determining whether App is killed or causes pleuropneumonia. Initially LPS on the surface of App acts a potent attractor of macrophages and neutrophils as well as stimulates host alveolar macrophages to secrete inflammatory cytokines. It has been recently reported (Brogaard et al. 2015) that a local expression of proinflammatory cytokines during App infection would play an important role in the pathogenesis of swine pleuropneumonia. In fact, these cytokines would activate macrophages and increase vascular permeability, flooding alveoli with important antibacterial serum proteins including complement and anti-App IgG antibodies (maternally derived, vaccinated, or previously exposed animals). App has several strategies to resist these host responses. The polysaccharide bacterial capsule of App inhibits engulfment by phagocytes as has been demonstrated by the characterization of non-virulent isogenic non-capsulated mutants (Rioux et al. 2000). Both macrophages and neutrophils can phagocytose App only in the presence of convalescent pig serum owing to the opsonic activity of anti-App IgG (Bossé et al. 2002). App is also resistant to the action of complement (Rioux et al. 2000; Ward and Inzana 1994).

The most important factors involved in impairment of the phagocytic function of both macrophages and neutrophils are the secreted protein RTX toxins ApxI, ApxII, and ApxIII (Frey 2003). ApxI is strongly hemolytic and cytotoxic, ApxII is weakly hemolytic and moderately cytotoxic, and ApxIII is nonhemolytic but strongly cytotoxic (Frey 2003). ApxI toxin has been shown to induce apoptosis in porcine alveolar macrophages (Chien et al. 2009), whereas ApxIII is highly toxic for peripheral blood mononuclear cells. In general, strains of serotypes 1, 5, 9, and 11 produce ApxI and ApxII; strains of serotypes 2, 3, 4, 6, 8, and 15 produce ApxII and ApxIII; strains of serotypes 7, 12, and 13 produce only ApxII; and strains of serotypes 10, 14, and 16 produce only ApxI (Gottschalk et al. 2003a; Sárközi et al. 2015). It seems that strains of serotype 3 secrete low levels of ApxII. A fourth toxin (ApxIV) is produced (*in vivo* only) by all serotypes (Schaller et al. 1999). The possible role of this toxin on phagocyte damage remains to be elucidated (Frey 2003). Using an ApxIV knockout mutant, it has been reported that ApxIV would be essential for expression of full virulence of App, although more studies are needed to confirm such hypothesis.

Finally, other virulence factors have also been suggested to play important roles in the pathogenesis of the infection, such as outer membrane proteins, proteases, and many products coded by genes that are clearly upregulated during infection, although in some cases their exact function is not yet known (Chiers et al. 2010). The capacity of App to form biofilms with a certain implication during App chronic infection and/or colonization has also been suggested as being part of the pathogenesis of the infection (Roberts et al. 2015). Finally, genome sequencing and preliminary analysis of strains belonging to serotypes 2, 3, 5, 6, 7, and 8 have been reported (Foote et al. 2008; Gouré et al. 2009; Li et al. 2016; Pereira et al. 2015; Xu et al. 2008; Zhan et al. 2010). The analysis of the functions of the encoded proteins will extend current knowledge on the metabolic and virulence characteristics of this pathogen.

Tissue damage in the lung is extensive and due principally to the combined effects of the Apx cytotoxins on a variety of lung cells (Frey 2003) and the App LPS-stimulated host inflammatory response. Host phagocytes are attracted by LPS- and Apx-induced chemokines. Macrophages are activated and secrete toxic oxygen metabolites, and macrophages as well as neutrophils are killed by Apx toxins and release lysosomal enzymes, which together further damage lung cells. Damage to endothelial cells results in activation of the coagulation pathway, microthrombus formation, and localized ischemic necrosis (Bossé et al. 2002). In most fatal cases of peracute pleuropneumonia, death is caused by endotoxic shock arising from absorption of copious amounts of App-derived LPS.

Factors affecting severity of disease

Differences in virulence between serotypes or even within the same serotype have often been observed. In the field, strains of serotypes 1, 5, and 7 in North America and of serotypes 2 and 9/11 (the latter being extremely difficult to be differentiated) in Europe are generally found to be more virulent than those of other serotypes. It is suggested that such differences are due to their combination of Apx toxins/hemolysins (Frey 2003), capsular structure (Jacques et al. 1988), and LPS composition (Jensen and Bertram 1986). In addition to production of ApxIV by all strains, virulent strains seem to produce 2 (rather than 1) of either Apx I, II, or III. Interestingly, atypical strains that are either more or less virulent than others in their respective serotype have often been shown to have either added (more virulent) or lost (less virulent) an Apx toxin (Beck et al. 1994; Gottschalk et al. 2003a; Maldonado et al. 2009). However, not all differences in virulence are explained by capsule, LPS, and Apx toxin profiles as exemplified by some low virulence serotype 1 strains that have no atypical CPS, LPS, or toxin profiles (Gottschalk et al. 2003a). Attempts have been made using molecular genetic techniques directed toward Apx toxin and other gene targets to differentiate degrees of virulence in strains of App (Chatellier et al. 1999; Møller et al. 1992); however, there are currently no methods to definitively differentiate virulence levels of App strains apart from controlled animal inoculation experiments.

Outcome of infection by App and severity of outbreaks as determined by increased morbidity and mortality can be impacted by several factors. As already mentioned, strain virulence and the presence of other pathogens like *M. hyopneumoniae*, pseudorabies virus, and, likely, swine influenza virus significantly impact disease. Interestingly, serotypes considered as low pathogenic (such as serotypes 6, 8, 12, and 15, at least in North America) can sometimes induce necrotizing bronchopneumonia or pleuropneumonia, especially in the presence of these pathogens. In fact, the same strain may either behave as completely avirulent or induce serious clinical disease in the absence or presence of a *M. hyopneumoniae* coinfection (Marois et al. 2009). A synergy between PRRSV and App is controversial. Early experimental studies showed that a coinfection does not result in more severe App-induced disease (Pol et al. 1997). This is in agreement with field observations in areas of endemic PRRSV infection (such as certain regions of Canada) where the incidence of clinical pleuropneumonia has not significantly increased. Even an antiviral effect of App antigens has been reported (Lévesque et al. 2014). However, a certain effect of the coinfection has been suggested for acute and chronic (pleuritic) infections (Fablet et al. 2012; van Dixhoorn et al. 2016). Factors such as crowding and adverse environmental conditions such as rapid changes in temperature and high relative humidity coupled with insufficient ventilation also promote the development and spread of the disease and, consequently, affect morbidity and mortality. It is therefore not surprising that the highest incidence of outbreaks is observed in growing and finishing pigs, mainly in seasons with adverse weather conditions, and in herds where pigs from numerous sources are mixed.

Immune status of the animals relative to the infecting serotype of App is also important, whether passive, convalescent, or vaccinal. Animals from conventional herds that might have been in contact with low virulent serotypes of App or with *A. suis* may be more resistant to the infection from a specific strain than SPF animals that are negative to all serotypes of App (unpublished observations). However, this may depend on the ability of the previous colonizing serotypes to induce antibodies against the toxins produced by the newly infecting strain.

Immunity

Experimental or natural infections stimulate an immune response, and circulating antibodies can be detected approximately 10–14 days postinfection, depending on the serotype and the serological assay. These antibodies reach a maximum level within 4–6 weeks postinfection and may persist for many months (Desrosiers 2004). In some cases, subclinically infected animals may present low levels or absence of antibodies against toxins (Chiers et al. 2010). In fact, ELISA tests that detect antibodies against the ApxIV toxin seem to present a lower sensitivity than those detecting antibodies against LPS, especially in the absence of clinical signs (Gottschalk 2015; Opriessnig et al. 2013). However, more studies are needed to confirm this observation. Immune sows confer passive immunity to their offspring. Such colostral antibodies may persist for about 5–12 weeks (Vigre et al. 2003), but this may depend on the sensitivity of the test used to detect the antibodies and on the initial level of acquired colostral antibodies. Protection may last for as little as 3 weeks in some cases (Nielsen 1975), but this may be due to the use of a very low sensitivity test such as the complement fixation test (CFT). The antibodies are directed against a wide range of bacterial structures and products, including capsule, LPS antigens, toxins (which can be neutralized), outer membrane proteins, superoxide dismutase, and iron-binding proteins. Both local IgA antibodies and serum IgG antibodies are produced. Immunity resulting from infection is directed against the corresponding serotypes; natural cross-protection between serotypes sharing common LPS antigens has not been extensively studied.

Clinical signs

Clinical signs vary with the age of the animals, their state of immunity, the environmental conditions, and the degree of exposure to the infectious agent. The clinical course can be peracute, acute, or chronic (Gottschalk 2015). All stages of disease – from intermediate to fatal, subacute, or chronic – may develop within an affected group.

In the peracute form, one or more pigs in the same or different pens suddenly become sick with high fever to 106.7 °F (41.5 °C), apathy, and anorexia. Some pigs may vomit. The affected animals lie on the floor without distinct respiratory signs, heart rate is increased, and cardiovascular function fails. The skin on the nose, ears, legs, and later the whole body becomes cyanotic. In the terminal phase, there is a severe dyspnea with mouth breathing, animals remain in a sitting posture, and rectal temperatures drop. Shortly before death, there is usually a copious, foamy, blood-tinged discharge through the mouth and nostrils. In the peracute form, it is also common to find one or more animals dead without any premonitory signs and with typical foamy, blood-tinged nasal discharge (Figure 48.1). Experimental studies have shown that the course of the disease may be as little as 6 hours from infection to death.

In the acute form, many pigs in the same or different pens are affected. Body temperature rises to 105–106 °F (40.5–41 °C), the skin may be reddened, and the animals are depressed, are reluctant to rise, refuse food, and are reluctant to drink. Severe respiratory clinical signs with

Figure 48.1 Animal that died from peracute pleuropneumonia caused by *Actinobacillus pleuropneumoniae* presenting with typical foamy blood-tinged nasal discharge. *Source:* Courtesy of Dr. Enric Marco.

Figure 48.2 Severe diffuse fibrinonecrotic pleuropneumonia caused by *Actinobacillus pleuropneumoniae*. The lungs are rubbery and non-collapsing with florid diffuse fibrinous pleuritis, multifocal hemorrhages, and hemorrhagic interlobular edema.

dyspnea, cough, and sometimes mouth breathing are evident. The course of the disease differs from animal to animal, depending on the extent of the lung lesions and the time of initiation of therapy.

The chronic form develops after the disappearance of acute signs or when treatment or preventive measures are not able to completely control the infection and/or infections due to intermediate virulence serotypes. There is little or no fever, and a spontaneous or intermittent cough of varying intensity develops. Appetite may be reduced, and this may contribute to decreased rate of gain. The clinical signs may be exacerbated by other respiratory infections (bacterial or viral). Atypical mild respiratory signs with low mortality resembling influenza have also been reported (Tobias et al. 2009).

Less common manifestations may be seen in some outbreaks. Fatal septicemia may rarely be observed in neonatal pigs. In primary epidemics involving pregnant females, abortions (probably due to fever episodes) may be observed (Wilson and Kierstead 1976), especially when naïve sows/gilts from SPF herds are infected. Head tilt and drooping of one or both ears may be observed owing to middle ear infection associated with App infection (Duff et al. 1996).

Lesions

The gross pathological lesions are located mainly in the lungs and vary according to clinical course of disease (Sibila et al. 2014). Pneumonia can be unilateral, bilateral, lobar, diffuse or multifocal. In acute cases there is consolidation that is dark red to black, interlobular edema, and mild to severe fibrinous pleuritis (Figure 48.2).

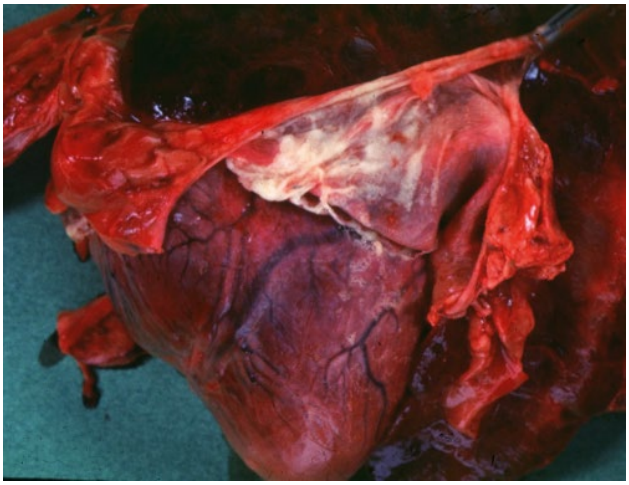

Figure 48.3 Fibrinous epicarditis and pericarditis in a pig with severe pleuropneumonia caused by *Actinobacillus pleuropneumonia*. *Source:* Courtesy of Dr. Greg Stevenson.

In peracute cases the trachea and bronchi are filled with a foamy, blood-tinged mucus exudate, and there may be few other gross changes. In slightly later peracute cases, the pneumonic areas appear dark red purple and slightly to moderately firm yet resilient with little or no fibrinous pleurisy. On cut surface there is diffuse hemorrhage, and areas of necrosis are friable.

In acute cases, layers of fibrin are obvious on the pleural surface and infrequently on the epicardium and pericardium (Figure 48.3) in animals that live for at least 24 hours after infection. The thoracic cavity usually contains a blood-tinged fluid. Affected areas of the lung are firm, rubbery, and mottled dark red purple to lighter white in areas that contain abundant fibrin. On cut surface, the parenchyma is heterogeneous (Figure 48.4).

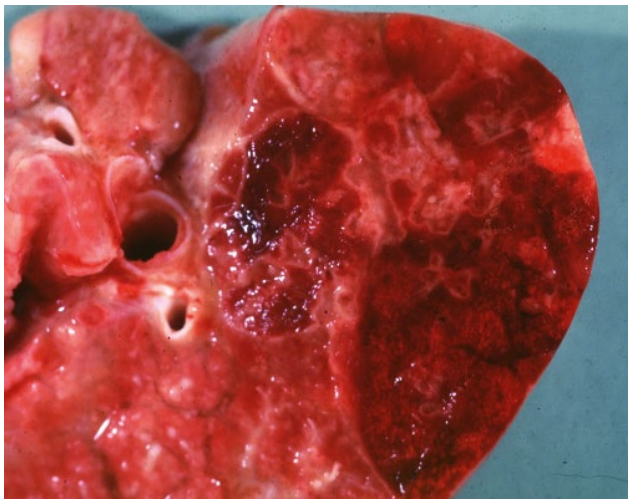

Figure 48.4 Cut surface of a lung with severe fibrinohemorragic and necrotizing pneumonia caused by *Actinobacillus pleuropneumonia*. Note the typical irregular light and dark areas that are surrounded by white lines composed of white blood cells and fibrin. *Source:* Courtesy of Dr. Greg Stevenson.

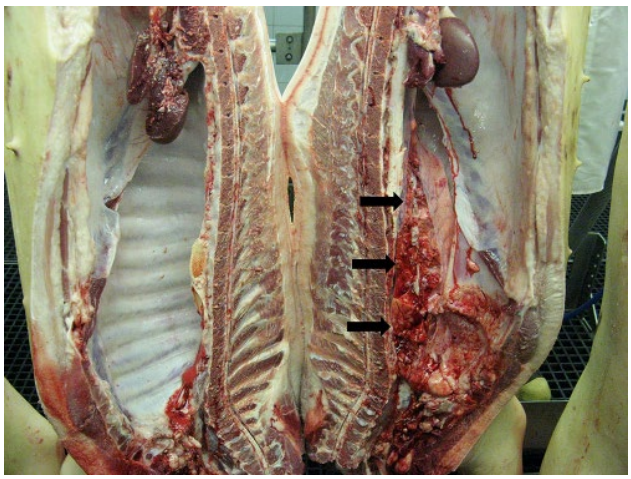

Figure 48.5 Split carcass hanging vertically. Note that the right lung remains adhered in the right thoracic cavity (arrows), whereas the left lung is removed, revealing the empty left thoracic cavity devoid of fibrous adhesions. *Source:* Courtesy of Dr. Scott Hurd.

There are areas of hemorrhage and other areas that are necrotic and friable. White lines composed of fibrin and white blood cells are observed surrounding necrotic areas and distending interlobular septa. In some areas, interlobular septa may be instead distended with hemorrhagic red fluid.

In chronic cases, fibrosis of the previously fibrinous pleuritis results in firm adhesions between visceral and parietal pleura. These areas often result in tearing of the lungs during removal at necropsy or in the slaughterhouse, leaving portions of the lung adhered to the thoracic wall (Figure 48.5). Resolution of non-necrotic areas from acute infection results in remaining cavitated necrotic foci that are surrounded by scar tissue known as sequestra. In many less severe cases, lesions in the lung parenchyma resolve, leaving only fibrous pleural adhesions. It has been demonstrated that a high prevalence of dorsocaudal pleuritis at slaughter is very suggestive of previous App pleuropneumonia (Merialdi et al. 2012; Meyns et al. 2011).

Diagnosis

Confirmation of App pleuropneumonia and typing of strains

App pleuropneumonia should be suspected when typical clinical signs and gross lesions are observed. Differentials in peracute cases where lungs are dark red and edematous should include other diseases that may produce similar lesions such as classical swine fever (Chapter 39), influenza (Chapter 36), pseudorabies (Chapter 35), septicemic salmonellosis (Chapter 59), and erysipelas (Chapter 53). In acute cases with typical fibrinohemorrhagic pleuropneumonia, *A. suis* (see below) (MacInnes and Desrosiers 1999; MacInnes et al. 2008; Yaeger 1995) and pleuritic strains of *Pasteurella multocida* (Chapter 57) should also be considered. Diagnosis is confirmed by culture, identification, and often typing of App. Lung samples for culture should come from lesioned areas of lungs collected from peracutely or acutely affected untreated animals. In chronic cases, where sequestra are in the lungs and/or fibrous pleuritis is observed at necropsy or in the slaughterhouse, App culture is usually negative. Surveillance of the herd using serology can be used to determine herd status (see below).

It is relatively easy to demonstrate App in pneumonic lesions from freshly dead animals. However, in some cases App can be overgrown by other bacteria such as *P. multocida*. Primary isolation of App from tissues and secretions may be carried out on 5% sheep blood agar with a cross-streak of *S. aureus* or *S. epidermidis*. After aerobic incubation overnight (usually in the presence of 5% CO_2), small colonies appear in the neighborhood of the streak (NAD requirement) surrounded by a clear zone of complete hemolysis. This allows a rapid presumptive bacteriologic diagnosis. For some serotypes (such as serotypes 7 and 12), the zone of hemolysis is usually less intense. Altered blood agars ("chocolate agar") or PPLO agar supplemented with NAD or yeast extract allow the growth of the organism, but colonies are less distinctive on these media. Presumptive biochemical identification can be carried out by demonstrating the CAMP phenomenon and urease activity. Usually, molecular testing will help confirm the identity of App (see below).

Most isolates recovered from acutely infected animals are typical App, and its identification is relatively

straightforward. However, when biochemically atypical isolates (for example, urease-negative isolates) (Blanchard et al. 1993), unexpected isolates recovered from the lungs without typical lesions, and/or untypable isolates are identified, the use of species-specific PCR should be used to confirm the identity of the App (Schaller et al. 2001). Biotype II (NAD-independent) isolates have been recovered more frequently in recent years (Gambade and Morvan 2001; Gottschalk et al. 2003a; Maldonado et al. 2009). These isolates might be misidentified as *A. suis*. In these cases, complete biochemical identification along with species-specific PCR tests must be done before sending the isolate for serological serotyping. *A. suis* isolates can present strong cross-reactions with rabbit sera against serotypes 3–6–8 of App, and without a correct identification, these isolates can be serotyped and reported as App (unpublished observations).

Serotyping is still of major interest for App since different serotypes have different virulence potential. In addition, serotyping is essential for choosing the most appropriate bacterins when they are used in a preventive strategy. Only biochemically (typical) or genetically (atypical) confirmed isolates should be serotyped. Although serotyping using antibodies with a variety of classical serological tests, such as agglutination, coagglutination, ring precipitation, immunodiffusion, and indirect hemagglutination, can be used, there is a need for high titer and highly specific antisera (Dubreuil et al. 2000). In addition, the presence of cross-reactions is a problem with many serotypes, and the use of two to three types of tests is usually required to identify these serotypes. In fact, serotyping by the use of polyclonal antibodies can be seriously questioned (Gottschalk 2015). Indeed, some serotypes (such as serotypes 3, 6, 8, and 15) are highly difficult to differentiate. Using serological tests the prevalence of serotype 8 has been underestimated in both the United Kingdom and North America (Gottschalk and Lacouture 2014; Li et al. 2016), since most strains had originally been typed as serotype 3 or 6 by serological methods. Serotypes 4 and 7 are also difficult to be differentiated using polyclonal antibodies (Lebrun et al. 1999). The use of monoclonal antibodies for serotyping has also been reported (Lacouture et al. 1997; Lebrun et al. 1999). These antibodies, especially those directed against the capsular epitopes, can differentiate, for example, serotype 1 from serotypes 9 and 11 and serotype 7 from serotype 4. However, monoclonal antibodies against the LPS will cross-react between serotypes sharing common LPS epitopes (Lacouture et al. 1997; Lebrun et al. 1999). Some of these monoclonal antibodies even showed that LPS epitopes are common between App serotype 7 and *Actinobacillus lignieresii* (Lebrun et al. 1999). Serotypes 9 and 11 cannot be differentiated by serological tests.

To overcome the problems of serological serotyping, several molecular techniques (mostly PCR) have been developed to serotype App from pure cultures. For a recent review on the available techniques and their advantages/disadvantages, see Gottschalk (2015). The most reliable PCR tests are based on *cps* locus genes; as it is the case with antibodies, it is important to note that serotypes 9 and 11 cannot yet be differentiated by the available PCR. Although PCR tests based on Apx toxin genes have been suggested to differentiate most serotypes, its use showed poor correlation when strains of known serotypes were tested (unpublished observations). It is important to mention that using PCR tests (many of them based on *cps* locus genes) will not identify atypical strains with a combination of a given CPS serotype and a different LPS serotype as being described in North America, Europe, and Japan (Gottschalk et al. 2000; Ito and Matsumoto 2015; Nielsen et al. 1996). Hence, there is still a need for reference laboratories using well-standardized serological techniques to confirm the identity of such atypical strains. Since PCR tests can be performed by any laboratory with minimal infrastructure and without the need of serotype-specific antisera, data on serotype distribution of isolates recovered from diseased animals in different countries will probably be available during the next years.

Although not highly useful for serotyping, PCR toxin typing (Frey et al. 1995) can be used to determine which Apx toxin genes are carried by a certain isolate, which may help to anticipate its virulence. For example, a nonvirulent serotype 1 strain recovered from healthy animals from a herd free of App-related disease was shown to produce ApxI only (Gottschalk et al. 2003b). Similarly, low virulent serotype 2 strains isolated in North America produces ApxII only, whereas highly virulent European strains produce both ApxII and ApxIII (Gottschalk et al. 2003a).

Bacteriological diagnosis of chronic disease is more complex, because it is difficult to culture App from such lungs, especially when lesions are old. In the lungs that contain sequestra, direct detection of App antigens in lung tissues can be performed by extracting antigens and testing by ring precipitation, coagglutination, latex agglutination, ELISA, and/or counterimmunoelectrophoresis (Bunka et al. 1989; Dubreuil et al. 2000). However, results should be interpreted with caution, since most of these tests have not been validated in the field. Bacterial presence can also be observed in tissues by using either a fluorescent or an immunoperoxidase antibody test (Bunka et al. 1989; Gutierrez et al. 1993). However, these tests are serotype specific, and they will not detect all App strains. Nucleic acid from App (species specific) may also be detected by labeled DNA probes in tissue (Cho and Chae 2003). Direct confirmation by PCR of the presence of App in lung tissue using

App-specific PCR (Schaller et al. 2001) is not yet routinely used, although it has been used with success in a few cases (unpublished observations). When only fibrous pleuritic lesions are present, App antigen/DNA may not be detected in the lung. Therefore, serology (see below) along with disease history in the herd of origin may be used to determine herd status.

Detection of tonsillar carriers

The detection of App from clinically healthy carrier animals is even more complex (Gottschalk 2015). This may be required in cases of equivocal serological results of seedstock introduction into negative herds or in eradication programs. Bacteria are usually localized in tonsils and, less frequently, in the nasal cavities where they must be cultured in the presence of other commensal bacteria, including several other NAD-dependent bacterial species (Gottschalk et al. 2003b; Kielstein et al. 2001). Selective media have been described (Jacobsen and Nielsen 1995), although their sensitivity is very low due to typical heavy contamination of plates. To overcome the presence of a highly contaminating flora, an immunomagnetic separation technique for the selective isolation of a given serotype of App from tonsils has been developed and applied to serotype 1 (in Canada) (Gagné et al. 1998) and serotype 2 (in Denmark) (Angen et al. 2001). Additional field studies confirmed its better sensitivity when compared with the classical bacterial isolation method (Fittipaldi et al. 2003; Gottschalk 2015). Any specific serotype can be isolated using the magnetic beads by only changing the specificity of the antibody (unpublished data). Although this test presents good sensitivity, it is time consuming and expensive. On the other hand, it allows the isolation of live App for further use in antimicrobial testing or in autogenous vaccine production. It is important to mention that the species identity of any App-like isolate recovered from a tonsil must be confirmed by PCR (Schaller et al. 2001). Due to antigenic similarities, *A. porcitonsillarum* has already been isolated using magnetic beads coated with anti-serotype 1 immunoglobulins (Gottschalk et al. 2003b).

Molecular techniques are presently used for the detection of App from tonsils. Several PCR techniques that amplify well-defined sequences of the genome have been described for rapid and affordable detection of App, and ready-to-use PCR kits have been commercialized (Gottschalk 2015). PCR tests can be directly used with swine tonsil homogenates (direct PCR to detect live and killed bacteria) or after culture of tonsils (after-culture PCR to detect only live bacteria) (Fittipaldi et al. 2003). After-culture PCR is considered to have a higher sensitivity. Although tonsil biopsies can be used, the sensitivity of this type of sample is lower than that of whole tonsils (Fittipaldi et al. 2003). Most PCR tests are specific for the species App and cannot differentiate among serotypes (Gottschalk 2015). Since most conventional herds are infected with several low virulent serotypes, the significance of a positive result is difficult to interpret. To overcome this problem, serotype-specific PCR tests have more recently been described (see above); however, most of these tests have been validated with pure cultures (with a general goal of serotyping) rather than detection of carrier animals (Gottschalk 2015). Some of these serotype-specific PCR with after-culture methods have been successfully used (unpublished observations). Finally, when detection of App is performed from tonsils collected at slaughter, results have to be interpreted with caution. Although Fittipaldi et al. (2003) did not show any cross-contamination at the slaughterhouse, another study suggested that cross-contamination principally by scald water during the slaughter process can occur (Marois et al. 2008). Finally, oral fluid has been shown to be a very low sensitive method to detect App after an experimental infection (Costa et al. 2012). An even much lower sensitivity is expected in samples from subclinically and chronically infected animals.

Serology

Serology is the preferred and most cost-effective method for App surveillance. Serological testing has been used widely for the diagnosis, management, and eradication of virulent serotypes of App. In fact, serology is the most effective tool used to detect subclinical App infections (Broes et al. 2007). For a recent review, see Gottschalk (2015). Some countries, such as Canada and Denmark, use serology for epidemiological surveillance of breeding herds on a routine basis. There are basically two types of serological tests: (1) those that detect all serotypes of App (without discrimination among serotypes) and (2) those that are serotype/serogroup specific. Commercial kits exist for both types of ELISA. There is only one test that can be considered App specific, since the antigen is produced by all App strains (with rare exceptions) and is not produced by any other bacterial species: the ApxIV ELISA test (Dreyfus et al. 2004). However, few controlled and comprehensive studies regarding its use are available. It has been recently shown that the test presents an excellent specificity but, under the conditions tested, a relatively low sensitivity, since it correctly identified less than 13% of samples from App experimentally infected pigs (Opriessnig et al. 2013), a conclusion also reached in a previous study (Eamens et al. 2008). Interestingly, an increasing detection rate was observed when animals became older (Opriessnig et al. 2013). Recently, a four-plex fluorescent microbead-based immunoassay was developed for the simultaneous detection of antibodies against ApxI, ApxII, ApxIII, and ApxIV (Giménez-Lirola et al. 2014). Using this method, and although false-positive results probably due to cross-reactions with antibodies against ApxI and ApxII were observed, a high sensitivity

was obtained with the ApxIV antigen (Giménez-Lirola et al. 2014). Interestingly, many false-negative sera previously tested by ELISA by Opriessnig et al. (2013) were positive when tested by this new highly sensitive test. Finally, interpretation of the ApxIV test must take into account that subclinically infected herds with animals harboring bacteria in tonsils only may not induce high levels of antibodies against App toxins (Chiers et al. 2002). Moreover, some strains possess insertion sequences in their genome that abolish ApxIV production. Animals infected with such strains do not produce antibodies against this toxin (Tegetmeyer et al. 2008).

Concerning the serotype/serogroup-specific tests, the CFT has been largely used in Denmark and is still used in a few US laboratories (Gottschalk 2015); in fact, this test has been clearly shown to possess a very low sensitivity (Gottschalk 2015). Amazingly, some countries (such as China and Russia) still require a negative App CFT tests for imported swine even though the low sensitivity and propensity for false positives of the CFT are well known (Gottschalk 2015). The most commonly used test in the last 20 years has been the ELISA, and among serotype/serogroup-specific antigens, purified O-chain LPS antigen (LPS-ELISA) has been the most successful (Dubreuil et al. 2000; Gottschalk 2015; Gottschalk et al. 1994; Grøndahl-Hansen et al. 2003; Klausen et al. 2007). A well-characterized O-chain LPS as a diagnostic antigen in a standardized ELISA for App was first reported in Canada in 1994 (Gottschalk et al. 1994). Serological tests for additional serotypes have subsequently been set up using similar antigens, individually or by mixing different serotypes (Gottschalk 2015; Grøndahl-Hansen et al. 2003). These ELISA tests may identify animals infected with the following serotypes/serogroups based on antigenic similarities of the O-chain LPS: 1/9/11, 2, 3/6/8/15, 4/7, 5, 10, 12, 13, and 14. Atypical biotype I North American App strains of serotype 13 present cross-reactions with serotype 10 due to a similar LPS composition (Perry et al. 2012). In fact, when the diagnosis is directed toward specific serotypes/serogroups, the LPS-ELISA seems to be the test of choice, as previously reported (Costa et al. 2011; Opriessnig et al. 2013). O-chain LPS antigens are also used in blocking/inhibition ELISA tests using polyclonal or monoclonal antibodies (Andresen et al. 2002; Stenbaek et al. 1997). It has been shown that the LPS-ELISA for serotype 1/9/11 showed low levels of cross-reactions with animals experimentally infected with high doses of *A. porcitonsillarum* (Gottschalk et al. 2003b). In addition, animals infected with one atypical strain (without O-chain LPS) did not induce antibodies detected by this ELISA (Jacques et al. 2005). However, the latter two situations are exceptional and have been observed only once (unpublished data). As for the ApxIV test, multiplex fluorescent microbead-based immunoassays for the identification of several serotypes (but identifying which ones are reacting) based on LPS and/or capsular antigens have been recently developed (Berger et al. 2014; Broes et al. 2016).

Tests detecting antibodies against specific serotype/serogroups and those detecting all serotypes of App are both useful, but they should be used appropriately (Gottschalk 2015). Although false-positive results have been exceptionally described (Broes et al. 2007), high health status herds already known to be free of all serotypes of App may decide to use the ApxIV-based test as a surveillance tool. It may be hypothesized that even though the ApxIV ELISA seems to present lower sensitivity than the LPS-ELISA (Opriessnig et al. 2013), an App strain that would have been introduced in a completely naïve herd would induce seroconversion and, depending on the strain, a relatively high seroprevalence. Under these circumstances, the ApxIV ELISA should significantly increase its sensitivity, although this remains to be demonstrated. If positive reactions are observed in herds, serological testing using antigens of different serotypes of App should be used. Otherwise, it would be extremely difficult to evaluate the level of risk of disease without knowing the serotype involved. In those cases, it is advisable to test all samples (positive and negative) with serotype/serogroup-specific ELISA to confirm the diagnosis.

Most conventional herds are infected with one or more serotypes (Gottschalk 2015). It was shown that 70% of the Canadian herds tested had antibodies against App (MacInnes et al. 2008). In some herds, sows may be infected by more than one serotype, but only one of them is consistently transmitted to offspring and found in grower–finisher animals (Broes et al. 2007). The use of the ApxIV test would not be useful in these cases, since it is not able to evaluate the risk. As mentioned above, it is important for a country to have reliable updated data regarding the most important serotypes clinically affecting animals in order to determine which serotypes (or serogroups) should be tested serologically.

Sera are still the main sample used for serology of App. LPS-ELISA tests have been used experimentally with fluids collected from muscles of pigs as well as colostrum (Desrosiers 2004; Gottschalk 2015). Oral fluid samples have not been appropriately evaluated so far. Pooling sera from different individuals may significantly reduce the sensitivity of the test, especially in subclinically infected animals, and this practice is not recommended (unpublished observations).

Even though serologic tests are valuable to identify subclinically infected herds and animals, serological testing occasionally generates ambiguous results. In such cases, molecular detection and/or bacterial isolation from tonsils could be carried out to clarify the herd status. In fact, tonsil colonization without induction of antibody response has been demonstrated (Chiers et al.

2010). App is a very dynamic pathogen, and sometimes diagnosticians and practitioners must face atypical situations. Such cases as well as diagnostic approaches have been presented by Broes et al. (2007).

Treatment

Although sporadic reports indicate a certain degree of resistance, in general, recent results of a global study across Europe showed that App is rarely resistant *in vitro* to amoxicillin (with or without clavulanic acid), cefquinome, ceftiofur, danofloxacin, enrofloxacin, marbofloxacin, florfenicol, tulathromycin, tiamulin, tilmicosin, tylosin, lincomycin, trimethoprim/sulfamethoxazole, and spectinomycin (El Garch et al. 2016). Similar high susceptibility has been observed by other studies in Europe (Hendriksen et al. 2008; Matter et al. 2007). Resistance to tetracyclines and to a lesser extent trimethoprim/sulfonamide seems to have increased in the last years (El Garch et al. 2016; Gutiérrez-Martín et al. 2006; Hendriksen et al. 2008). Recent data from North America showed high susceptibility to ceftiofur, florfenicol, enrofloxacin, erythromycin, clindamycin, trimethoprim/sulfamethoxazole, and tilmicosin. A low level of resistance was observed toward tiamulin, penicillin, and ampicillin as well as danofloxacin. On the other hand, a high level of resistance to chlortetracycline (88.4%) and oxytetracycline (90.7%) was observed (Archambault et al. 2012). Sporadic data showed a relatively high number of resistant App isolates to the beta-lactam family (penicillin, ampicillin, amoxicillin) (Dayao et al. 2016). Response of pigs with clinical App to penicillin treatment may be inconsistent (Sjölund et al. 2009). It is generally accepted that there is no clear correlation between the distribution of the antibiotic resistances and the serotypes of App (Matter et al. 2007).

The choice of the first-line antimicrobial should be based on its minimal inhibitory concentration (MIC) as well as its pharmacokinetic and pharmacodynamic (PK/PD) properties. Sjölund et al. (2009) showed that antibiotics with minimal MIC in their categories significantly varied in their capacity to control acute infection. Enrofloxacin has been shown to be particularly effective after experimental challenge (Sjölund et al. 2009). Satisfactory results in the field have been reported with tiamulin (Anderson and Williams 1990) and a combination of lincomycin and spectinomycin (Hsu 1990). Tilmicosin has also been reported as effective (Paradis et al. 2004). One study indicates that using experimentally infected animals, tulathromycin administered as a single dose at either 2.5 or 5 mg/kg body weight was at least as effective as three daily doses of ceftiofur regarding percentage of lung lesions, daily weight gain, days with clinical disease, and rectal temperature (Hart et al. 2006).

Antibiotic therapy is effective only in the initial phase of the disease, when it can reduce mortality (Desrosiers 2004). Interestingly, the success rate of an antibiotic treatment may influence the immune response of animals. In fact, highly effective antibiotics may prevent a strong antibody response, leaving animals susceptible for a later reinfection (Sjölund et al. 2009). On the other hand, the nature of the lesions means that delay in treatment can result in a degree of infarction and chronic damage, which will leave the animal as a respiratory cripple even if it recovers. Antibiotics should be given parenterally (subcutaneously or intramuscularly) and in high dosage, as affected animals may not eat or drink (Desrosiers 2004).

To ensure effective and durable blood concentrations, repeated injections may be required, depending on the pharmacokinetic properties of the antibiotic used. The success of therapy depends mainly on early detection of clinical signs and on rapid therapeutic intervention. Water treatment may be used to treat members of the affected group that are still able to drink. Feed medicated with any of the above antimicrobials may be used successfully if all pigs have a normal food and water intake. In countries where still allowed, feed and water medication can be used as prophylactic antimicrobial therapy to prevent acute outbreaks in highly infected herds. Continuous medication or pulse dosing may be practiced, but neither should be used for long, and the antimicrobial sensitivity of the organism should be regularly monitored. Where allowed, strategic medication may be targeted at periods of risk, which can be identified by routine postmortem examinations, clinical examinations, and herd antibody profiles. A combination of parenteral and oral medication in a recent outbreak often yields the best results. In spite of apparent clinical success, it must be remembered that antibiotic therapy does not eliminate infection in a herd and carrier animal may persist for a long time (Angen et al. 2008; Desrosiers 2004; Fittipaldi et al. 2005). These animals are an important source of infection for other animals. Severely affected animals may not recover even after treatment and should be euthanized.

Prevention and control

When herds are free of App, strict biosecurity measures should be applied to prevent introduction of the organism. The greatest risk is presented by introduction of potentially infected (clinically healthy) pigs. Seedstock should be purchased from herds with a history of absence of clinical sign, lesions, and negative serological testing for App. Ideally, incoming animals should also be quarantined and serologically tested as negative before introduction. If the herd where the animals will be introduced is already positive for certain serotypes known to be of

low virulence, similar precautions to introduction of serotypes known to be generally more virulent should be practiced. Introduction of animal carriers of low virulent strains of App in an SPF App-negative herd should be avoided. Indeed, most strains recovered from clinical cases and belonging to serotypes of lower virulence in Canada (serotypes 6, 12, and 15) are usually isolated in high health status herds, which were previously free of all serotypes (unpublished observations). In herds that are already infected by virulent serotypes, App-negative seedstock should be vaccinated with products appropriate for the infecting virulent serotypes according to label directions, and time should allow for development of immunity before introduction. During outbreaks of pleuropneumonia on App-infected farms, the first priority must be to control mortality by the treatment of affected individuals, usually including all contact animals in the affected pen. Treatment of animals in surrounding pens should be evaluated upon the extension of clinical disease (Desrosiers 2004); in fact, animals should be allowed to develop natural immunity (Desrosiers 2004). Generally, good environmental management minimizes outbreaks in infected herds and includes maintaining appropriate environmental temperature with minimal fluctuations, seasonally appropriate ventilation, use of solid partitions between pens, all-in/all-out movement of pigs, appropriate stocking densities, and younger weaning ages (<21 days).

A wide range of vaccines have been developed for this disease (Ramjeet et al. 2008). These vaccines can basically reduce clinical signs and lung lesions (Del Pozo Sacristán et al. 2014), but they are poorly effective in eliminating the carrier stage. Commercial vaccines fall into two main groups: killed organisms (bacterins) and subunit toxin-based vaccines. Lately, a combination of these types of vaccines (bacterins + toxins) appeared in the market (Thevenon et al. 2014). Vaccination with bacterins is serotype specific (Ramjeet et al. 2008); possible cross-immunity with cross-reacting serotypes has been suggested, although it still should be confirmed (Nielsen 1985c). The use of a bacterin should be done only in farms where the involved serotype has been identified, although animals vaccinated with bacterins will produce antibodies that might cross-react with ELISA tests that use O-LPS as antigens. However, this is not always the case: diagnostic tests have been developed to detect infected animals using highly purified antigens. Vaccination with bacterins may induce high levels of antibodies against a variety of surface antigens (including the CPS). In some cases, the level of antibodies against the O-chain LPS in vaccinated animals may not be high enough to be detected in the ELISA test: this is not an indication of failure of the vaccine on its capacity to induce antibodies. Many commercial bacterins induce protection even if they do not induce such cross-reacting antibodies detectable by the O-chain ELISA kit (unpublished observations). Finally, in some countries, autogenous vaccines are used: this approach may only be useful when serotypes involved in clinical cases are not included in available commercial bacterins. In the latter case, another option may also be the use of toxin-based vaccines that would provide protection against all serotypes.

Subunit vaccines, composed of the purified three major RTX exotoxins (ApxI, ApxII, and ApxIII) with or without a 42 kDa outer membrane protein of App, or in suspensions mixed with bacterins, have been developed and shown to give protection against all major serotypes under experimental conditions as well as in field trials (Thevenon et al. 2014; van den Bosch and Frey 2003). A potential protection conferred by the ApxIV toxin, produced by all strains *in vivo*, seems to be controversial (Liu et al. 2009; Wang et al. 2009), and it has not yet been incorporated in any commercial vaccine. Keeping in mind the very complex pathogenesis of porcine pleuropneumonia, inclusion of other bacterial virulence factors in vaccines might also be of value. A wide range of antigens administered by either parenteral, aerosol, or oral routes have been found to be experimentally protective, but none of them have been validated in the field (Ramjeet et al. 2008). Finally, live vaccines using laboratory obtained non-virulent mutants have also been developed and showed to protect against homologous and heterologous serotypes (Park et al. 2009; Ramjeet et al. 2008). Some of these live vaccines even use the differentiating infected from vaccinated animals (DIVA) concept (Liu et al. 2009). Vaccines may provide high levels of protection against morbidity in experiments, reduce mortality, reduce the number of treatments required, increase daily live weight gain, and improve feed conversion efficiency. The quality of the carcass is also improved, with fewer condemnations for pneumonia and lower slaughtering costs through reductions in pleurisy and pericarditis (Del Pozo Sacristán et al. 2014). The decision to vaccinate should be carefully evaluated; the costs of mortality alone should not be the sole consideration, because the other effects on productivity listed above contribute to the benefits of vaccination. In some cases, individual and intensified medical treatments of affected pigs may be needed to reduce the impact of App (Sjölund and Wallgren 2010). Vaccination of piglets is usually advised; animals should not receive the first dose during the first weeks of age to avoid interference with maternal antibodies. Sows can also be vaccinated without adverse effects (Kristensen et al. 2004a), and replacement animals can be vaccinated before their introduction in an infected herd. Vaccination of sows with serotype-specific bacterins may reduce/delay colonization of piglets, which may lead to a reduction, under certain circumstances, of clinical signs in

grower–finisher pigs (unpublished observations). Since antibodies against somatic antigens are needed, this effect would not be possible with exclusively toxin-based vaccines. Finally, the presence of antibodies (either natural or vaccine induced) will not eliminate the carrier state of animals at the tonsil level (Gottschalk 2015).

Eradication and regional control

Control of pleuropneumonia in a region or breeding pyramid involves health schemes aimed at pleuropneumonia-free breeding and multiplying herds, serologic monitoring, monitoring at slaughter and postmortem examination of casualties, control of management, and controlled pig traffic (serologic testing, quarantine). For herds infected with App intending to join such a scheme, an eradication program is the method of choice but requires careful evaluation of the economic consequences. Depopulation and restocking with pigs originating from certified App-free herds can be used; however, this method is expensive and may lead to the loss of important bloodlines.

Other methods that have succeeded in the past include off-site segregated medicated early weaning, at the same time supported by a program of vaccination, medication, and culling and repopulation with disease-free gilts (Larsen et al. 1990). Age of weaning and level of maternal antibodies may have an important influence on the colonization of piglets by App (Vigre et al. 2002). There are several herds that successfully eradicated App (depending on the serotype) using a medicated early weaning program (unpublished observations). Some serotypes, such as serotypes 12 and 8, are highly infective (even in the absence of clinical signs), and transmission of the infection from sows to piglets occurs relatively early and fast, preventing in some cases the success of the eradication.

Small one-site breeding herds (up to 400 sows) with a relatively low percentage of seropositive animals (up to 30%) have used the "test and removal" of seropositive sows under medication (Nielsen et al. 1976). However, the successful outcome of this method is mainly based on the serological test used: a test with low sensitivity will not eliminate all carrier sows, and a test with low specificity will eliminate healthy non-carrier animals, which could increase the cost of the program; the success of such an approach is deemed not guaranteed. A successful elimination of certain serotypes of App with partial depopulation and antibiotic treatment has been suggested (Andersen and Gram 2004). However, it has also demonstrated that antibiotic treatment cannot eliminate the pathogen from all carrier animals (Angen et al. 2008; Fittipaldi et al. 2005). So far, there is no solid proof that partial depopulation can eradicate all serotypes of App. Before an eradication program is carried out, all aspects of biosecurity and the characteristics of the farm should be taken into consideration to prevent recontamination (Zhuang et al. 2007).

Actinobacillus suis

The gram-negative bacterium *A. suis* is an ubiquitous opportunistic pathogen that colonizes the upper respiratory tract of pigs (MacInnes and Desrosiers 1999). In a Canadian survey, MacInnes et al. (2008) showed that as many as 94% of the tested herds were probably infected by *A. suis*, although no clinical cases were observed. Although originally reported as causing septicemia and death in suckling and recently weaned pigs only, disease can also be observed in fattening pigs and even adult animals, especially in high health status herds (Yaeger 1995, 1996). Prevalence of disease may be greater in new populated herds, before animals develop immunity (Wilson and McOrist 2000).

A. suis produces septicemia and localized infections and has been associated with a variety of clinical signs including sudden death, dyspnea, cough, lameness, fever, weakness, wasting, abscesses, neurological signs, abortion, cyanosis, and diffuse hyperemia. One of the most suggestive gross lesions is the presence of petechial to ecchymotic hemorrhages in the lungs, kidneys, heart, liver, spleen, skin, or intestines and petechial hemorrhages on the ears, abdomen, and skin, as well as cutaneous erysipelas-like lesions (MacInnes and Desrosiers 1999).

Yaeger (1995) reported three common forms of *A. suis* disease. First is an acute fulminant septicemic form occurring mainly in suckling and recently weaned pigs. Very often, pigs are simply found dead. Consistent gross lesions include petechial to ecchymotic hemorrhages in multiple organs and serous to serofibrinous exudates in the thoracic and abdominal cavities. Pleuritis, pericarditis, arthritis, and miliary abscesses in a variety of organs may be observed. Histologic lesions consist of foci of necrosis in multiple organs associated with bacterial thromboemboli. Differential diagnosis should include other agents of septicemia such as *Streptococcus suis* and *Klebsiella pneumoniae*.

A second form is respiratory disease mainly affecting grow–finish pigs, most commonly in high health status herds. Pigs may exhibit a cough and fever, and as with young pigs, sudden death may also be the sole sign. However, in these cases, the most remarkable gross lesions are generally a multifocal or diffuse hemorrhagic and necrotizing pneumonia or pleuropneumonia, petechial hemorrhages on the serosal surfaces of abdominal and thoracic viscera, and, in some cases, a fibrinous peritoneal exudate. Differential diagnosis should include mainly porcine pleuropneumonia caused by App (Yaeger 1995, 1996).

The third form of *A. suis* disease is acute septicemia in adult animals, also most commonly observed in high health status herds. Animals may exhibit lethargy, anorexia, fever, and red, rhomboid skin lesions resembling erysipelas. Abortions may occur and animals may also die of septicemia. Gross lesions in these cases consist of multifocal petechial hemorrhages, serofibrinous exudates in the thoracic and abdominal cavities, and occasionally small foci of hepatic necrosis. This form, particularly when skin lesions (as described above) are present, may be confused with erysipelas.

Actinobacillus suis isolates from both healthy and diseased pigs are very similar based on biochemical analysis, restriction endonuclease fingerprinting, slide agglutination, and toxin typing (MacInnes and Desrosiers 1999). The organism has genes that encode toxins that are very similar to ApxI and ApxII of App. These toxins likely contribute to the virulence of this organism. However, *A. suis* produces lower levels of Apx toxins than App, which may explain why *A. suis* is generally less virulent (MacInnes and Desrosiers 1999). On the other hand, *A. suis* is able to resist bile and serum, suggesting that it has additional, but as yet unidentified, virulence factors when compared with App. It has been shown that different serologically distinct groups of cell surface antigens exist, such as Ol/Kl, O1/K2, and O2/K2, presenting some variation in virulence (Slavic et al. 2000). However, a clear classification of serotypes and their association to virulence are not used routinely. Critical virulence factors of *A. suis* are unknown; however, an outer membrane protein and a type IVb pilus were shown to be important adhesins for swine cells (Bujold and MacInnes 2016; Ojha et al. 2010). During the last years, at least two *A. suis* strains have been sequenced, which may help, in a near future, to better understand the role of these organisms in health and disease in swine (MacInnes et al. 2012).

Preliminary diagnosis is based on typical clinical signs and gross lesions. Diagnosis is confirmed by culture and identification of *A. suis* from tissues with typical microscopic lesions. A strain-specific ELISA test has been shown to be useful to follow up maternal and active antibodies in an infected herd (Lapointe et al. 2001).

Antibiotic treatment should be applied early in the appearance of signs; ceftiofur, gentamicin, and trimethoprim/sulfadiazine seem to be the antibiotics of choice, followed by ampicillin, sulfadimethoxine, and tiamulin (MacInnes and Desrosiers 1999). There are no reports in the literature suggesting resistance of a large number of *A. suis* strains to different antibiotics. Vaccination has been implemented in some herds using autogenous vaccines, with variable results. In one of these herds, gilts and sows were vaccinated, although these animals already presented high titers of antibodies before vaccination (Lapointe et al. 2001).

Other *actinobacillus species*

Actinobacillus equuli, a primary infectious agent of horses, has been suggested as being involved in several swine infections in Europe many years ago (Ramos-Vara et al. 2008). However, most of these infections were probably caused by *A. suis*, since both pathogens are phenotypically and genetically very similar. A revised definition of actinobacilli recovered from animals (from a diagnostic point of view) has been published (Christensen and Bisgaard 2004). On the other hand, swine infection by real and confirmed *A. equuli* has been recently reported in the United States and Canada (Ramos-Vara et al. 2008; Gottschalk, unpublished observations) with, in some cases, high morbidity and mortality that required the use of autogenous vaccines. The source of the infection in most herds remains unknown, but diagnostic laboratories must be aware of the potential of *A. equuli* in pigs and clearly differentiate from *A. suis* infections (Christensen and Bisgaard 2004). A case of human infection by *A. suis* or *A. equuli* has been reported recently in Italy (Montagnani et al. 2015).

Many species of *Actinobacillus* other than App can be found in swine tonsils, such as *A. minor, A. porcinus, A. rossii*, Bisgaard Taxon 10, and *A. porcitonsillarum* (Lowe et al. 2010). As mentioned in the App section, the latter species may be easily misidentified as App. Although usually considered as non-virulent, *A. porcitonsillarum* has been recently isolated from diseased animals presenting a variety of pathologies (Martínez and Maldonado 2006; Ohba et al. 2007), and it seems to present a higher antibiotic resistance than App (Matter et al. 2007). The virulence potential of other actinobacilli has not been demonstrated (Mayor et al. 2006).

Bordetellosis

Susan L. Brockmeier, Karen B. Register, Tracy L. Nicholson, and Crystal L. Loving

Relevance

Bordetella bronchiseptica was first isolated and associated with respiratory disease in dogs in 1910 (Ferry 1910). In the 1940s it was isolated in association with swine pneumonia, and it was being investigated as a cause of atrophic rhinitis of swine by the 1950s (Phillips 1943; Switzer 1956). In swine, *B. bronchiseptica* is widespread and plays multiple roles in respiratory disease. It is the primary etiologic agent of nonprogressive atrophic rhinitis (NPAR), a mild to moderately severe, reversible condition. More importantly, nasal colonization by *B. bronchiseptica* promotes colonization by toxigenic strains of *Pasteurella multocida*, which leads to severe progressive atrophic rhinitis (PAR) (see Chapter 58). In young pigs, *B. bronchiseptica* is a primary cause of necrohemorrhagic bronchopneumonia and in older pigs can be an opportunistic pathogen contributing to the porcine respiratory disease complex (PRDC). *B. bronchiseptica* can also enhance respiratory colonization of *Streptococcus suis* and *Haemophilus parasuis*, promote disease caused by *S. suis*, and interact with porcine reproductive and respiratory syndrome virus (PRRSV) and swine influenza virus (SIV) to increase severity of respiratory disease.

Etiology

The genus *Bordetella* belongs to the class *Beta proteobacteria* and is composed of nine species. *B. bronchiseptica* is the only species of importance in swine and infects a broad range of mammals causing a spectrum of acute to chronic clinical diseases such as kennel cough in dogs, bronchitis in cats, and atrophic rhinitis and bronchopneumonia in pigs (Goodnow 1980; Mattoo and Cherry 2005).

Bordetella bronchiseptica is an aerobic, motile, gram-negative rod or coccobacillus approximately 1.0 × 0.3 mm in size. The bacterium grows slowly, but readily, on blood agar or other nonselective media as well as on MacConkey agar. Convex colonies roughly 1–2 mm in diameter, usually hemolytic on blood agar, develop after 36–48 hours at 37 °C (98.6 °F). *B. bronchiseptica* is nonfermentative but positive for oxidase, catalase, urease, and citrate.

No serotyping methodology useful for discriminating among strains or evaluating population diversity is currently available for *B. bronchiseptica*. Nearly all *B. bronchiseptica* strains express one of two antigenically distinct O-antigen serotypes, O1 or O2, that are not cross-reactive (Buboltz et al. 2009a). However, these antigens are not suitable for typing purposes since they are encoded by separate loci that may recombine (Buboltz et al. 2009a).

Researchers have turned to molecular typing methods to identify and characterize genetic relationships among strains. These include ribotyping, random amplified polymorphic DNA (RAPD) fingerprinting, pulsed-field gel electrophoresis (PFGE), and multilocus sequence typing (MLST) (Khattak and Matthews 1993; Musser et al. 1987; Register et al. 1997). Recent genome sequencing studies have generated numerous genome sequences from many *Bordetella* species, including *B. bronchiseptica* isolated from 11 different hosts (Harvill et al. 2013; Nicholson et al. 2016; Register et al. 2015). *B. bronchiseptica* can be separated into two lineages – complex I strains, which are most commonly isolated from animals, and complex IV strains, which are most commonly isolated from humans (Diavatopoulos et al. 2005).

It is well known that the consequence of colonization by *B. bronchiseptica* can vary from asymptomatic infection to lethal pneumonia (Goodnow 1980; Mattoo and Cherry 2005). Using inbred and specific-pathogen-free mice, the 50% lethal dose (LD_{50}) can differ by up to 100,000-fold between bacterial strains, suggesting that substantial differences in virulence may be due to strain variation alone (Buboltz et al. 2008; Gueirard and Guiso 1993). Recently published reports have demonstrated

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

that phylogenetic lineages can differ in virulence factor expression and virulence (Buboltz et al. 2008, 2009b). These reports support the overarching idea that the diversity of *B. bronchiseptica*-related disease and broad host range may be due, in part, to the distinct sets of virulence factors used by strains of different phylogenetic lineages (Cummings et al. 2006; Giardina et al. 1995).

Public health

Human illness resulting from *B. bronchiseptica* infection is rare but on the rise (Berkelman 2003; Brady et al. 2014; García-de-la-Fuente et al. 2015; Llombart et al. 2006; Tamion et al. 1996). Most at risk are infants and immunocompromised individuals with exposure to carrier animals; however, disease in immunocompetent adults also occurs. A variety of clinical presentations have been documented including tracheobronchitis, whooping cough, pneumonia, sinusitis, septicemia, meningitis, and peritonitis, occasionally with a fatal outcome. In many cases exposure to domesticated pets, particularly dogs, cats, and rabbits, is the presumed source of infection. No human cases related to transmission from swine have so far been reported. However, one of the few animal isolates among a genetically related group of complex IV *B. bronchiseptica* strains strongly associated with human infections is of swine origin (Diavatopoulos et al. 2005). Whether people as well as animals act as reservoirs for complex IV *B. bronchiseptica* strains, or whether people can act as asymptomatic carriers and transmitters of complex I *B. bronchiseptica* animal strains that can subsequently cause human or animal disease, is plausible but currently unknown.

Epidemiology

Bordetella bronchiseptica has a worldwide distribution and is known to infect poultry and a broad range of wild and domesticated mammalian species (Farrington and Jorgenson 1976; Goodnow 1980; Hammond et al. 2009; Heje et al. 1991; Lacasse and Gamble 2006; Ngom et al. 2006; Staveley et al. 2003). It is highly prevalent among swine and frequently isolated both from pigs with pneumonia or atrophic rhinitis as well as those that are apparently healthy (Backstrom et al. 1988; Giles et al. 1980; Kumar et al. 2014; Kureljušić et al. 2016; Palzer et al. 2008; Rutter et al. 1984; Zhao et al. 2011a).

Transmission of *B. bronchiseptica* occurs primarily by aerosol droplets. It is facilitated by close contact, but airborne transmission over short distances, including within a barn or production unit, is probable (Brockmeier and Lager 2002; Nicholson et al. 2012, 2014; Stehmann et al. 1992). Infectious aerosols generated by sneezing or coughing in pigs with active disease further promote the spread of the agent. Pigs of all ages are susceptible to infection, but many litters are colonized before weaning, most likely due to exposure from nursing sows. Antibody passively acquired by piglets from the colostrum of infected or vaccinated sows protects against turbinate lesions and pneumonia but not against infection (Kobisch and Pennings 1989; Magyar et al. 2002; Riising et al. 2002; Rutter 1981). However, vaccination of sows may delay infection for up to several weeks (Rutter et al. 1984), at which time lesions typically fail to develop or are significantly reduced in severity (de Jong and Akkermans 1986; Giles et al. 1980). *B. bronchiseptica* persists in the nasal cavity for at least several months (Backstrom et al. 1988; Riising et al. 2002; Rutter 1981) and perhaps indefinitely, and the introduction of carrier pigs is a source of infection for older animals in systems where an all-in/all-out approach is not practiced. Spread within a herd is rapid, particularly in immunologically naïve animals (Smith et al. 1982).

Newly purchased breeding stock may be a source of infection. *B. bronchiseptica* has been isolated from rodents, birds, raccoons, opossums, and other animals trapped in close proximity to swine (Farrington and Jorgenson 1976; Le Moine et al. 1987). Although so far undocumented, cross-species transmission to pigs following exposure to infected wild animals or domesticated pets, such as dogs and cats, may occur. It has been suggested that non-porcine strains are of low virulence in pigs (Ross et al. 1967), but it is unclear whether the cultures used were propagated so as to retain their original phenotypes. This conclusion should be reevaluated in light of the current understanding of virulence factor regulation in *B. bronchiseptica* and the importance of maintaining a Bvg^+ phenotype during culture (see "Pathogenesis"). A subsequent study reported no differences in the bacteriological properties of swine isolates as compared with isolates obtained from several other hosts (Bemis et al. 1977). Insect vectors may also be capable of introducing the organism into a herd or production unit (Beatson 1972). Transmission via contaminated fomites has not been evaluated but should not be excluded, given the ability of *B. bronchiseptica* to survive *ex vivo*.

The bacterium remains viable for up to 45 days in soil (Mitscherlich and Marth 1984) and for at least several weeks in lake water or non-nutritive liquid media at temperatures ranging from 50 to 98.6 °F (10–37 °C) (Porter et al. 1991; Porter and Wardlaw 1993). The half-life of aerosolized organisms at ambient temperature and approximately 75% relative humidity is 1–2 hours (Stehmann et al. 1992). *B. bronchiseptica* can be inactivated by sonication (Harris and Switzer 1972), heating to 140 °F (60 °C) (Bemis and Kennedy 1981; Lendvai et al. 1992), or treatment with formaldehyde (Jenkins 1978). It

is sensitive to several chemical disinfectants suitable for farm use (Thomson et al. 2007).

Pathogenesis

The pathogenesis of *B. bronchiseptica* is dependent on the sequential coordinated synthesis of an array of virulence factors including adhesins, toxins, and other bacterial products that may alter host functions, facilitate immune evasion, or otherwise assist in transmission or survival. Expression of most virulence genes requires coexpression of the BvgAS (*Bordetella* virulence genes) system (Beier and Gross 2008). A rise in growth temperature that occurs as the organism moves from an external environment into the tissues of the respiratory tract triggers transcription of *bvgAS* and subsequent expression of the BvgAS-inducible genes (Bvg^+ state). At temperatures of approximately 77 °F (25 °C) or lower, *bvgAS* genes are not expressed, and the resultant Bvg^- state is nonpermissive for the synthesis of toxins, adhesins, and other known or suspected virulence proteins, while there is maximal expression of motility genes, virulence-repressed genes (*vrg* genes), and genes required for the production of urease (Akerley et al. 1992; McMillan et al. 1996). Environmental cues, including a rise in growth temperature that occurs as the organism moves from an external environment into the tissues of the respiratory tract, trigger transcription of *bvgAS* and subsequent expression of the BvgAS-inducible genes (Bvg^+ state). This process, known as phenotypic modulation, is fully reversible and is an important adaptive response of the organism to changes in the environment. Previous studies involving phase-locked and ectopic expression mutants demonstrated that the Bvg^+ phase promotes respiratory tract colonization of *B. bronchiseptica*, while the Bvg^- phase promotes survival under conditions of nutrient deprivation, such as those potentially encountered in an environmental reservoir (Cotter and Miller 1994). In swine, the Bvg^+ phase is all that is required for respiratory infection and pig-to-pig transmission (Nicholson et al. 2012).

The *bvgAS* genes are also subject to phase variation, in which a small proportion of growing cells spontaneously acquire deletions or frameshift mutations that irreversibly abolish expression of all BvgAS-activated genes, regardless of the growth conditions. When subculturing *B. bronchiseptica*, it is important to pick for passage only single, well-isolated Bvg^+ colonies (small, domed, and hemolytic on blood agar) in order to avoid gradual transition of the culture to an irreversible Bvg^- state (colonies are larger, flat, and nonhemolytic on blood agar).

So-called "early" BvgAS-inducible genes, including many whose products are involved in attachment, are among the first to be activated during phenotypic modulation from Bvg^- to Bvg^+. Expression of "late" genes, including several toxins, commences only after accumulation of sufficient levels of the *bvgAS* gene products. The existence of the BvgAS system suggests that precise control of the temporal expression of virulence factors in response to a changing environment is important for optimizing the growth and survival of *B. bronchiseptica* as it cycles through transmission, colonization, growth and spread, immune evasion, and shedding.

In the initial stage of infection, *B. bronchiseptica* attaches to epithelial cells lining the nasal mucosa. Organisms display preferential adherence to ciliated cells (Duncan et al. 1966b; Yokomizo and Shimizu 1979), but attachment to nonciliated epithelia may also occur and may be important in establishing microcolonies or biofilms (Irie and Yuk 2007). Biofilms are an adherent community of microorganisms encased within a complex matrix that protects the community from a variety of environmental stresses such as shear flow forces, antimicrobial compounds, and host immune and clearance mechanisms. Biofilms are increasingly being recognized as important contributors to chronic or persistent *Bordetella* infections (Cattelan et al. 2016).

Several *B. bronchiseptica* adhesins have been characterized. Filamentous hemagglutinin (FHA) is a protein secreted by *B. bronchiseptica* and associated with the bacterial cell surface that is highly immunogenic and required for optimal colonization of the upper respiratory tract (Cotter et al. 1998; Edwards et al. 2005; Hibrand-Saint Oyant et al. 2005; Irie and Yuk 2007; Nicholson et al. 2009). At least four domains with distinct binding specificities have been identified, some of which exert immunomodulatory effects (Hannah et al. 1994; Ishibashi et al. 1994; Melvin et al. 2015; Prasad et al. 1993).

Fimbrial proteins, which form a complex of hairlike strands extending from the bacterial cell surface, possess multiple binding specificities including one that enhances FHA-mediated attachment (Geuijen et al. 1997; Hazenbos et al. 1995). Fimbriae are important for colonization and persistence in the trachea, contribute to biofilm development, and also influence the humoral and cell-mediated immune responses to infection (Edwards et al. 2005; Geuijen et al. 1997; Irie et al. 2004; Mattoo et al. 2000; Scheller et al. 2015).

The outer membrane protein pertactin also contributes to colonization, perhaps as an accessory adhesin, but its precise function remains unclear (Hibrand-Saint Oyant et al. 2005; Nicholson et al. 2009). In contrast, its importance as a protective immunogen is well established (Kobisch and Novotny 1990; Montaraz et al. 1985; Novotny et al. 1985). Sequence heterogeneity in a region comprising an immunodominant protective epitope (Boursaux-Eude and Guiso 2000; Register 2001, 2004)

may alter the specificity of host immune responses, providing a potential mechanism for immune evasion (Hijnen et al. 2007).

An additional BvgAS-regulated virulence factor of *B. bronchiseptica* is a type III secretion system (T3SS), used by the bacterium to translocate or inject protein effectors directly into the cytosol of a eukaryotic cell and whose components have immunomodulatory and cytotoxic effects (Medhekar et al. 2009). In swine, the T3SS contributes to the severity of pneumonic lesions and to the ability of the bacterium to persistently infect the lungs (Nicholson et al. 2014).

Once *B. bronchiseptica* is established within the respiratory tract, expression of toxins contributes to the progression of disease. Of central importance is the dermonecrotic toxin (DNT), a protein toxin that exerts pleiotropic effects including impairment of bone formation, that is essential for development of turbinate atrophy and pneumonia in both mice and pigs (Brockmeier et al. 2002; Horiguchi et al. 1995; Magyar et al. 2000). The DNT is primarily responsible for the sometimes fatal pneumonic lesions in suckling pigs characterized by necrosis, hemorrhage, neutrophil accumulation, and eventually fibrosis (Brockmeier et al. 2002). Swine and murine strains of *B. bronchiseptica* secrete higher levels of DNT than isolates from other host species (Okada et al. 2015), suggesting a host-specific adaptation of the bacterium.

A toxin that has both adenylate cyclase and pore-forming activities, referred to as adenylate cyclase toxin (ACT), also contributes to virulence by disrupting innate immunoprotective functions. Phagocytic cells appear to be a primary target of ACT that, in cooperation with FHA or the T3SS, modulates cytokine production and alters serum and secretory antibody responses in pigs (Harvill et al. 1999; Henderson et al. 2012; Hibrand-Saint Oyant et al. 2005; Skinner et al. 2004).

Tracheal cytotoxin (TCT) is a peptidoglycan breakdown product arising from normal bacterial cell wall remodeling during growth. Unlike most other gram-negative bacteria, *B. bronchiseptica* lacks the capability to recycle TCT (Cookson and Goldman 1987), and it is instead released extracellularly where it interacts synergistically with lipopolysaccharide to cause ciliostasis and extrusion of ciliated cells from the mucosal epithelial lining (Flak et al. 2000). TCT is likely responsible for the impairment of mucociliary clearance that occurs early in the course of infection.

Age and immune status play roles in the pathogenesis of disease with *B. bronchiseptica* as well. In the nonimmune pig, younger animals typically develop more severe disease both in regard to bronchopneumonia and atrophic rhinitis. Pigs with passive or acquired immunity from vaccination or natural infection develop less severe disease, although they may still be colonized.

Coinfection with *B. bronchiseptica* and other pathogens in the respiratory tract also affects disease severity. The ability of *B. bronchiseptica* to predispose to colonization of the upper respiratory tract with *P. multocida* leading to PAR has been well established (de Jong and Nielsen 1990; Harris and Switzer 1968; Pedersen and Barfod 1981; Rutter 1983). *B. bronchiseptica* has also been shown to predispose to disease with *S. suis* (Vecht et al. 1989, 1992). Preinoculation of pigs with *B. bronchiseptica* prior to *S. suis* resulted in increased clinical signs and fever, increased isolation of *S. suis*, increased pneumonia and disseminated lesions due to septicemic *S. suis*, and increased mortality. *B. bronchiseptica* has also been shown to enhance colonization of the nasal cavity with *H. parasuis* as well (Brockmeier 2004).

The means by which *B. bronchiseptica* exacerbates or predisposes to secondary bacterial infections is not known, but damage inflicted to innate protective mechanisms during colonization likely plays a major role. TCT causes necrosis of the ciliated respiratory epithelium that lines the nasal cavity and conducting airways, resulting in significant impairment of the clearance function of the mucociliary apparatus. *B. bronchiseptica* is also cytotoxic for swine alveolar macrophages (Brockmeier and Register 2000; Forde et al. 1999), which may result in decreased phagocytosis and killing of inhaled bacteria. Damage to turbinates by DNT may predispose to colonization by other bacteria by alteration or ablation of the normal microbiota, induction of increased mucus production, exposure of submucosal components to which other bacteria may adhere, and/or increased nutrient availability. However, a DNT-negative mutant of *B. bronchiseptica* was still capable of predisposing to infection with toxigenic *P. multocida*, and the subsequent development of atrophic rhinitis appeared unaffected (Brockmeier and Register 2007). Consequently other factors must also contribute to secondary infection and disease.

Bordetella bronchiseptica can also interact with certain swine viruses to influence the development or severity of respiratory disease. PRRSV predisposes to bronchopneumonia with *B. bronchiseptica* (Brockmeier et al. 2000). Although PRRSV alone has not been shown to enhance infection with *P. multocida*, infection with both *B. bronchiseptica* and PRRSV leads to increased pulmonary infection with *P. multocida* (Brockmeier et al. 2001). By facilitating colonization with other prevalent bacterial pathogens, *B. bronchiseptica*, in combination with PRRSV and its immunosuppressive properties, may leave pigs more susceptible to pulmonary or systemic infection with opportunistic bacteria. Coinfection with *B. bronchiseptica* and SIV or porcine respiratory coronavirus (PRCV) leads to increased severity of pneumonia with an earlier onset and longer resolution when compared with either virus alone (Brockmeier et al. 2008;

Kowalczyk et al. 2014; Loving et al. 2010). Coinfected pigs show a greater and more sustained production of proinflammatory cytokines that may contribute to the enhancement of pulmonary lesions (Brockmeier et al. 2008; Kowalczyk et al. 2014; Loving et al. 2010).

Clinical signs

Bordetella bronchiseptica is highly infectious and transmits rapidly and easily via direct contact or aerosol transmission, resulting in high morbidity but generally low mortality except in very young pigs with *B. bronchiseptica*-induced necrohemorrhagic bronchopneumonia or when complicated by certain coinfections (Brockmeier and Lager 2002). In uncomplicated disease, clinical signs typically appear around 2–3 days after infection when colonization and damage to the respiratory epithelium in the nasal cavity (rhinitis), trachea (tracheitis), and bronchi (bronchitis) leads to sneezing, nasal discharge, ocular discharge, and a dry, repeated cough. More severe signs can occur in neonatal pigs if necrohemorrhagic bronchopneumonia develops, including dyspnea, lethargy, and sometimes death. Clinical signs typically abate after a few weeks, but the respiratory tract remains colonized for months.

When *B. bronchiseptica* interacts with other pathogens to cause or enhance disease, clinical signs may include or be solely those of the other agents such as those for PAR when toxigenic strains of *P. multocida* also colonize nasal turbinates (Chapter 57), for PRRS (Chapter 41), for influenza (Chapter 36), for Glasser's disease caused by *H. parasuis* (Chapter 54), or for the various manifestations of disease caused by *S. suis* (Chapter 61).

Lesions

Bordetella bronchiseptica may colonize and cause injury throughout the entirety of the respiratory tract, but lesions are especially associated with the nasal cavity, consisting of atrophic rhinitis, and the lung, consisting of bronchopneumonia (Duncan et al. 1966a,b). Macroscopic lesions of the nasal cavity include nasal exudate and mild to moderate turbinate atrophy, which are often referred to as NPAR (Figures 49.1 and 49.2). Distortions of the nasal septum, curvature of the snout, and brachygnathia are usually not seen with uncomplicated *B. bronchiseptica* infection, but may occur in mixed infections with toxigenic strains of *P. multocida* that lead to PAR (Chapter 57). Staining or accumulation of exudate around the medial canthus of the eye often not only results from inflammation and blockage of the tear ducts but can also develop when other pathogens that cause rhinitis are

present. In most cases of uncomplicated rhinitis due to *B. bronchiseptica*, regeneration of the turbinates occurs with time, but persistent distortion of the ventral turbinates frequently results (Duncan et al. 1966b). Primary bronchopneumonia in suckling pigs when acute is necrohemorrhagic, characterized by groups of lobules in the cranial ventral lungs that are red and firm, sometimes with mild fibrinous pleuritis overlying only affected lung (Figure 49.3). Subacute lesions are yellow to gray as more leukocytes infiltrate, and chronic lesions are hard, white, and fibrotic (Figure 49.4). Opportunistic bronchopneumonia in older pigs as a component of PRDC is purulent, characterized by plum-to-gray lobular consolidation with purulent exudate in lumens of airways.

Microscopic lesions of the nasal cavity are characterized by epithelial hyperplasia to squamous metaplasia and loss of cilia, and submucosal infiltrates of neutrophils, fewer lymphocytes and macrophages, and occasional microabscesses in the epithelium (Duncan et al. 1966b). Replacement of the bony trabeculae of the turbinates with fibrous connective tissue may also occur. Microscopic lesions of the lung are characterized by hemorrhage, necrosis, and accumulation of inflammatory infiltrates, mostly neutrophils, in the airways and

alveolar spaces (Duncan et al. 1966a). Interlobular and intra-alveolar edema may also occur. Eventually fibroblastic replacement of lung parenchyma with sequestration of necrotic areas develops and may take months to completely resolve. Coinfection with other bacteria and/or viruses may change the character of the lesions, but suppurative bronchopneumonia is nearly always present.

Diagnosis

Many pathogens other than *B. bronchiseptica* often cause pneumonia in pigs. When acting as a primary pathogen, *B. bronchiseptica* alone may be isolated from pneumonic lungs. However, this organism most commonly occurs in mixed infections and is frequently found together with one or more other respiratory disease agents. In such cases, the actual contribution of *B. bronchiseptica* to clinical disease may be difficult to determine. Acute lung lesions in piglets can appear very similar to those caused by *Actinobacillus suis or Actinobacillus pleuropneumoniae*. When investigating the cause of rhinitis in young pigs, porcine cytomegalovirus and *P. multocida* should be considered in a differential diagnosis. Various grading systems for the quantitative assessment of turbinate atrophy have been used to evaluate treatment of PAR. These systems are based on transversely sectioning the snout at the level of the first or second premolar tooth and assigning a score estimating the amount of atrophy of each of the four scrolls of the ventral turbinates.

Detection of infection with *B. bronchiseptica* is typically based on isolation and biochemical testing of suspect colonies cultured from nasal swabs, post mortem lung washings, or biopsy specimens. Mini-tipped swabs are available that facilitate nasal sampling in young pigs. Swabs should be placed in a non-nutritive transport medium, such as PBS, and kept at 39 °F (4 °C) for delivery to a diagnostic laboratory, preferably within 24 hours.

Bordetella bronchiseptica grows readily on blood agar; however use of a selective medium is desirable to prevent overgrowth by other faster-growing and typically more numerous commensal and pathogenic bacteria that may be present. Many laboratories use a modified MacConkey agar with 1% glucose and 20 µg/mL furaltadone (Farrington and Switzer 1977), but a peptone agar formulation (Smith and Baskerville 1979) may be superior when the number of *B. bronchiseptica* is low. In a direct comparison, neither the modified MacConkey agar nor the peptone agar performed as well as blood agar with cephalexin for isolation of *B. bronchiseptica* from nasal swabs (Lariviere et al. 1993). Blood agar plates containing 20 µg/mL penicillin, 10 µg/mL amphotericin B, 10 µg/mL streptomycin, and 10 µg/mL spectinomycin also perform well for isolation from highly contaminated sites such as the nasal cavity (Brockmeier 1999). A blood-containing medium should be utilized for subsequent passage of primary isolates so that it is possible to evaluate and maintain the original Bvg phenotype. Although the required reagents are widely available, conventional identification methods are time consuming and suffer from poor sensitivity. A DNA probe hybridization assay using colony lifts of primary isolation plates has been described that is highly specific and more sensitive than traditional isolation and biochemical testing (Register et al. 1995). More recently a PCR target originally evaluated for use with human specimens (Hozbor et al. 1999) was found to be 100% sensitive and specific for *B. bronchiseptica* when tested with bacterial genera and species commonly found in the swine respiratory tract (Register and DeJong 2006).

Early methods employed for the serologic diagnosis of *B. bronchiseptica* infection were based on the detection of agglutinating serum antibody in assays using either tube (Jenkins 1978) or plate (Shashidhar et al. 1983) formats. ELISAs for detection of antibody in serum (Kono et al. 1994; Venier et al. 1984) or nasal secretions (Kono et al. 1994) were subsequently described. Because these assays depend solely on antibody binding and provide objective endpoints, they provide greater sensitivity and reproducibility than agglutination-based methods. Serology may be useful for monitoring the status of a herd but is rarely used routinely for diagnostic purposes.

Immunity

Studies characterizing the mechanisms of protection against bordetellosis have been carried out primarily in mice and provide useful information for understanding immunity to infection/vaccination. Studies have shown that IgA is important for clearance of organisms from the upper respiratory tract, whereas IgG is critical for clearance from the lungs; thus, vaccines that elicit strong IgA responses are critical for complete respiratory tract clearance (Kirimanjeswara et al. 2003; Wolfe et al. 2007). Infection-induced immunity, as opposed to vaccine-induced immunity, provides significant protection in the upper and lower respiratory tract. Although serum antibody titers are higher following parenteral vaccination, as opposed to mucosal infection, the antibody generated following parenteral vaccination is less effective at providing protection (Gopinathan et al. 2007). A modified live strain of *B. bronchiseptica* delivered by the intranasal route to pigs provided superior protection against challenge when compared with an inactivated vaccine, and protection was associated with mucosal *B. bronchiseptica*-specific IgA titers (Zhang et al. 2013). Together, this information suggests that immune responses elicited at the site of natural infection are likely to be the most

efficacious and live attenuated vaccines delivered intranasally are an obvious approach.

Vaccines that elicit a response to pertactin, a 68 kDa protein on the bacterial surface, have been shown to be highly protective in reducing disease severity (Kobisch and Novotny 1990; Li et al. 1992). Vaccines that induce large amounts of antibody to lipopolysaccharide appear to provide the least protection from disease (Novotny et al. 1985). Pertactin gene heterogeneity has been described (Register 2004) and is an important consideration for creating a vaccine that is efficacious against field strains. Although pertactin appears to be a primary protective antigen, reactivity to additional outer membrane proteins is important for complete protection evidenced by superior protection provided by whole-cell vaccines (Kobisch and Novotny 1990; Novotny et al. 1985). Current commercial vaccines typically contain *B. bronchiseptica* whole-cell bacterin as well as a *P. multocida* toxoid for optimal protection against PAR. Vaccination does not provide sterilizing immunity but does significantly limit or even abolish clinical disease.

Piglets may become infected with *B. bronchiseptica* prior to weaning; thus sow vaccination may be useful for preventing disease in piglets. Although sow vaccination can decrease disease severity and increase piglet performance, it does not eliminate colonization of pathogenic organisms from piglets (Riising et al. 2002). In addition, passive antibody from the sow to piglet can interfere with parenteral vaccination of the piglet (Smith et al. 1982). Vaccination of nonimmune piglets can provide protection from turbinate atrophy as piglets vaccinated with whole-cell bacterin at 1 and 4 weeks of age develop circulating antibody lasting beyond 12 weeks of age (Farrington and Switzer 1979). However, until the piglet mounts a response to the vaccine, it remains susceptible to natural infection.

Prevention and control

Bordetella bronchiseptica is largely susceptible to chlortetracycline, oxytetracycline, and enrofloxacin; all are antibiotics approved for the treatment of swine respiratory disease caused by pathogens that are often associated with *B. bronchiseptica*, such as *P. multocida*, *H. parasuis*, and *S. suis* (Kadlec et al. 2004). Tulathromycin specifically lists swine respiratory disease caused by *B. bronchiseptica* as an indicated use. *Bordetella* is largely resistant to ampicillin and cephalosporins such as ceftiofur, which is approved for treatment of swine respiratory disease of mixed bacterial etiology (Dayao et al. 2014; Pruller et al. 2015; Zhao et al. 2011). Accordingly, ceftiofur is not the optimal choice when treating mixed infections that include *B. bronchiseptica* as a component. Antibiotics may alleviate pneumonia and reduce clinical signs, but total clearance of *Bordetella* from the upper respiratory tract is difficult. Normally the need for treatment of atrophic rhinitis arises when there are signs of PAR in the herd, which almost always involves coinfection with toxigenic strains of *P. multocida*. Use of antibiotics to control cases of atrophic rhinitis includes administration by feeding or parenteral route to sows and piglets around the time of farrowing/weaning in an effort to limit the extent of colonization in young pigs. Tetracyclines and trimethoprim–sulfonamide preparations have historically been successfully used for this purpose, but examining susceptibility profiles of porcine pathogens coming out of diagnostic laboratories indicates there is significant resistance of *B. bronchiseptica* to trimethoprim-sulfonamide combinations (de Jong and Oosterwoud 1977). Treatment of older pigs probably has limited efficacy on the disease progression of atrophic rhinitis.

Most vaccine studies have examined efficacy in terms of prevention of atrophic rhinitis, but since *B. bronchiseptica* predisposes to infection with other respiratory pathogens, vaccination or elimination from a herd may have broader effects on respiratory health. Vaccines for *B. bronchiseptica* largely consist of whole-cell bacterins often in combination with *P. multocida* whole-cell bacterins and/or toxoids for control of atrophic rhinitis, but there are a few attenuated intranasal vaccines available as well. When using vaccination to prevent PAR, the *P. multocida* toxin (PMT) is an important component of the vaccine, and those with added PMT toxoid offer superior protection (Foged et al. 1989; Hsuan et al. 2009; Nielsen et al. 1991; To et al. 2005; Voets et al. 1992). Vaccination of sows around 6 weeks and again around 2 weeks prior to farrowing appears to work well to protect piglets and minimize transmission (Riising et al. 2002). Protection of piglets, whether through antibiotic treatment, passive antibody through sow vaccination, or a combination of both, during the first few weeks of life appears to be an important factor in the control of atrophic rhinitis (Pejsak et al. 1994). Vaccination of piglets around 2 and 4 weeks of age has had mixed results; when less favorable results occur, it is probably due to the occurrence of maternal antibody interference and/or prior colonization of young piglets before an immune response has developed (Farrington and Switzer 1979; Smith et al. 1982). Bacterins provide protection against disease manifestations such as turbinate atrophy but typically fail to protect animals from colonization. Thus vaccinated animals can still serve as subclinical carriers that continue to shed and transmit *B. bronchiseptica* to cohorts.

Attenuated live vaccines are usually given intranasally within a few days of birth in an attempt to prevent colonization with virulent strains of *B. bronchiseptica* by competitive exclusion and to induce a mucosal immune response. Previous studies have shown a resistance to

reinfection in animals naturally infected with *B. bronchiseptica*, indicating a mucosal response may be important for clearance of *B. bronchiseptica* from the respiratory tract (Gopinathan et al. 2007; Harris and Switzer 1969). Results with attenuated vaccines have been mixed, possibly because of maternal antibody interference or due to the nature of the attenuated strain (de Jong 1987; Pejsak et al. 1994). *B. bronchiseptica* attenuated via mutation of the *bvg* locus is avirulent but poorly colonizes the respiratory tract and would not be expected to elicit a robust immune response. Strains defective only in DNT production have been engineered and are greatly attenuated but may not be desirable for vaccine use since, like wild type, they predispose to colonization with *P. multocida* (Brockmeier and Register 2007). Recently an attenuated strain of *B. bronchiseptica* based on deletion of *aroA* that was administered intranasally to pigs provided superior protection against challenge when compared with an inactivated vaccine, and protection was associated with mucosal *B. bronchiseptica*-specific IgA titers (Zhang et al. 2013).

Attempts to control *B. bronchiseptica* infection in swine herds are usually instituted when PAR is severe and *B. bronchiseptica* is confirmed as a component along with toxigenic strains of *P. multocida*. Measures to control or eliminate PAR from a herd include combinations of improved husbandry, such as improved air quality/ventilation and pig flow (all-in/all-out management with proper cleaning and disinfection between groups), medicated early weaning, and vaccination of the breeding herd and/or pigs. Intensive use of these methods has been shown to reduce the bacterial burden of both *B. bronchiseptica* and *P. multocida* and, in combination with nasal swab testing and elimination of positive animals, has even been able to eliminate toxigenic *P. multocida* from herds. *B. bronchiseptica* is a ubiquitous pathogen that is highly infectious. Whether or not *B. bronchiseptica* can be totally eliminated by these methods remains unclear.

Brucellosis

Steven C. Olsen, Paola Boggiatto, Pauline Nol, and Luis Samartino

Relevance

Swine are the reservoir host for *Brucella suis*, the predominant cause of swine brucellosis. However, *Brucella abortus* and *Brucella melitensis* can also infect swine in regions where they are endemic in their respective reservoir hosts (cattle and small ruminants). In swine and other livestock hosts, *Brucella* can produce pregnancy loss, stillbirths, and infertility in females, and epididymitis and orchitis in males after localizing in reproductive tissues of sexually mature animals (Corbel 2006). Uncommon clinical signs can occur in swine due to *B. suis* localization in a variety of tissues, with lameness following localization in joint(s) or bone being most common. *B. suis* is separated into 5 biovars. Biovars 1, 2, and 3 are reported to infect swine, and only biovars 1 and 3 are reported in domestic or feral swine in the United States.

B. suis remains endemic in swine populations in many parts of the world where it causes clinical disease in swine and humans. Human brucellosis, also known as undulant fever, is most commonly contracted through direct or indirect contact with infected animals or their products (Corbel 2006; Franco et al. 2007). Many species of *Brucella* can cause disease in humans, with *B. suis* and *B. melitensis* being the more virulent human pathogens. Brucellosis is the world's most common bacterial zoonosis, with over half a million new cases annually and prevalence rates in some countries exceeding 10 cases per 100,000 population (Pappas et al. 2006). The highest prevalence of human brucellosis occurs in regions where *Brucella* spp. are endemic in reservoir hosts. For example, the highest prevalence of *B. melitensis* infections in humans are in regions with high populations of small ruminants (sheep and goats), especially countries along the Mediterranean Sea and in Central Asia. *B. suis* can be an important cause of human brucellosis in areas where pigs are raised in significant numbers and the disease is present in domestic or wild populations. For example, the high prevalence of *B. suis* (biovar 1) infections in feral swine in Australia is associated with numerous reports of brucellosis in humans and animals (Massey et al. 2011; Mor et al. 2016).

Human brucellosis is the primary basis for control or eradication programs targeting *Brucella* spp. in domestic livestock hosts. Control or eradication programs are justified by data, which indicates that addressing the disease in livestock reservoirs is the most efficient and economical approach for reducing human brucellosis (Jelastopulu et al. 2008; Roth et al. 2003; Zinsstag et al. 2007). Prior to the initiation of the eradication program in the United States in 1959, the number of reported human cases in the United States peaked at 6321 in 1949 with most cases attributed to infections with *B. abortus* and *B. suis* (Pappas et al. 2006). Following a rapid decline in *B. abortus* and *B. suis* in livestock in the United States due to eradication efforts, human infections have been reduced to an average of 159 human cases per year since 1973. These human cases are mostly due to *B. melitensis* imported through the US–Mexican border in infected dairy products (Pappas et al. 2006) or international travel, and occasionally due to *B. suis* contracted by hunters of feral swine.

Due to the success of regulatory programs in many developed countries, increased use of confinement operations, and changes in swine management practices, feral swine or wild boar is the predominant reservoir host for *B. suis* in a number of countries (Australia, United States, Canada, Western and Central Europe, and others). In the United States, the highest disease prevalence is in feral pigs in south central and southeastern states. Not only can feral swine transmit brucellosis to domestic swine raised outside of containment, but people involved in hunting feral swine or wild boar are also at risk for infection (CDC 2009; Garin-Bastuji et al. 2006; Irwin et al. 2009; Lagier et al. 2005; Robson et al. 1993).

In most European countries, brucellosis in domestic swine is almost exclusively in swine raised outdoors and

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

related to spillover of *B. suis* biovar 2 from wild boars (*Sus scrofa scrofa*) or wild hares (*Lepus europaeus*, *Lepus capensis*) (Cvetnic et al. 2003; Godfroid et al. 2005; Godfroid and Käsbohrer 2002). Venereal transmission is proposed as the main route of transmission of *B. suis* biovar 2 from wild boars to domestic swine, whereas transmission from brown hares is probably through oral consumption. Disease prevalence in Eurasian wild boar is high with estimates ranging from 8 to 32% throughout continental Europe (Al Dahouk et al. 2005; Cvetnic et al. 2003; Garin-Bastuji and Delcueillerie 2001).

In Central and South America, biovar 1 of *B. suis* is predominantly reported in domestic swine in a number of countries including Argentina, Brazil, Columbia, Cuba, Chile, Honduras, Paraguay, and Peru (Luna-Martínez and Mejía-Terán 2002; Poester et al. 2002; Samartino 2002). Although feral swine are present in parts of these regions, prevalence of brucellosis among them is currently unknown.

Biovars 1 and 3 of *B. suis* have also been reported in domestic swine in many parts of Central and Southeast Asia including China, India, Indonesia, the Philippines, Taiwan, French Polynesia, Malaysia, Tonga, and other islands in the Pacific (Fahrion et al. 2014; Olsen and Tatum 2016; Praud et al. 2013; Quance et al. 2016; Tay et al. 2016). There has also been one report of a seropositive wild boar in Japan (Watarai et al. 2006). The economic impact of swine brucellosis in Asia is probably greatest in China due to high levels of swine production, sporadic reports of epidemics of *B. suis* in swine, and reports of zoonotic infections in humans. At least one country in Central Asia, Turkey, has reported human infection with biovar 1 of *B. suis* (Kutlu et al. 2016). Porcine brucellosis is also believed to be widespread across sub-Saharan Africa although data is limited and populations of swine are relatively small (McDermott 2002). However *B. suis* biovar 1 has been isolated from cattle in Egypt and Zimbabwe, suggesting that the disease may be endemic in those countries (McDermott 2002; Menshawy et al. 2014).

Etiology

Brucellosis is an infectious disease caused by bacteria in the genus *Brucella*, with 10 species recognized (*B. abortus*, *B. canis*, *B. ceti*, *B. melitensis*, *B. ovis*, *B. microti*, *B. neotomae*, *B. inopinata*, *B. pinnipedialis*, and *B. suis*) that have different preferred hosts (Table 50.1 [Alton 1990]) and that differ by molecular and microbiological characteristics. In addition several new species are under consideration for inclusion in the genus *Brucella*. For *B. suis*, microbiologic, serologic, and molecular tests have further divided the species into 5 biovars (Table 50.2 [Alton 1990]). Biovars 1, 2, and 3 are associated with infections in swine, biovar 4 is almost exclusively limited to reindeer and wild caribou in subarctic areas, and biovar 5 has only been recovered from rodents in the former USSR (Olsen and Tatum 2016). While domestic swine (*Sus scrofa domesticus*) are primarily reservoir hosts for *B. suis*, swine may also be infected by *B. abortus* and *B. melitensis* in areas where brucellosis is enzootic in cattle and small ruminants, respectively (Lucero et al. 2008; Stoffregen et al. 2007). *B. microti* and the cattle vaccine, *B. abortus* strain 19, have also rarely been recovered from feral swine. The remainder of this chapter will primarily focus on infection of swine by *B. suis* biovars 1, 2, and 3.

Like other species of *Brucella*, *B. suis* organisms are gram-negative coccobacilli measuring 0.6–1.5 μm length and 0.5–0.7 μm width. In nature, *B. suis* almost exclusively occurs in the smooth form that express the O side chain on the lipopolysaccharide (LPS). Colonies of *B. suis* cannot be visually differentiated from other smooth *Brucella* species. Since *Brucella* spp. are potent human pathogens, manipulation of cultures or contaminated material from potentially infected animals should be done under Biosafety Level 3 (BSL-3) laboratory conditions.

Complete genomes of the different *Brucella* species have been fully sequenced with more than 59 *B. suis* genomes currently available in GenBank (NCBI – NIH). With the exception of *B. suis* biovar 3 that has a single chromosome of approximately 3.1 Mbp, all other biovars have two circular chromosomes encoding approximately 2.1 and 1.2 Mbp. *Brucella* spp. have no known natural plasmids with which to transfer genetic material or antibiotic resistance (Bavishi et al. 2010). With the exception of biovar 5, genomes of *B. suis* isolates cluster together. A recent analysis of published *B. suis* genomes identified 16,756 single nucleotide polymorphisms (SNPs) between strains, including biovar-specific SNPs that may have value as diagnostic targets (Sankarasubramanian et al. 2016). Currently available polymerase chain reaction (PCR) assays and pipelines for analysis of whole genome sequencing data can be used to differentiate *Brucella* by species, biovars, and strains and to facilitate understanding of strain lineages and epidemiologic relationships (Di et al. 2016; Duvnjak et al. 2015; García-Yoldi et al. 2007; Garin-Bastuji 2008; Kamath et al. 2016; López-Goñi et al. 2008, 2011; Mayer-Scholl et al. 2010; Sankarasubramanian et al. 2016).

Epidemiology

In general, environmental persistence of *B. suis* is of low epidemiological importance. Maintenance of *B. suis* is in infected populations of domestic or feral swine and requires continued infection of susceptible hosts. Direct

or close contact is required for disease transmission. However, *Brucella* can survive in a cold moist environment for up to several months in infected aborted fetuses or fluids. Bacteria may also survive in contaminated materials such as feed, bedding, equipment, and clothing (Olsen et al. 2012).

Ingestion of aborted uterine contents or discharges is probably the main route of transmission of *B. suis*, but infection across the conjunctiva or penetration through breaks in the epidermis may also be routes of infection. Unlike most other brucellae, *B. suis* can also be spread venereally, which appears to be important for transmission within and between herds. Shedding in semen of boars is sporadic and of long duration as a consequence of *B. suis* containing granulomas in male reproductive organs. Transplacental infection can result in infected live-born pigs, and piglets can also be infected through consumption of infected milk. Neonatal infection may lead to a latent carrier state that could result in disease transmission in the absence of clinical and immunological signs of brucellosis (Acha and Szyfres 2003; Olsen et al. 2012).

When first entering a naive herd, *B. suis* can quickly spread from a single infected animal resulting in infection rates of up to 70–80% in the early stages of outbreaks (Beer 1980; Olsen et al. 2012; Szulowski 1999). In

epidemically infected herds, pregnancy loss, increased perinatal mortality, and infertility are common; however, in endemically infected herds, only mild to moderate clinical signs are observed, and infection often goes undetected. Large numbers of *B. suis* can be shed in uterine fluids and fetal tissues following reproductive failure. Although uterine infection and vaginal shedding is cleared in most females by 30–40 days after pregnancy loss, a small percentage of females can maintain a persistent uterine infection. This results in temporary or permanent infertility and vaginal shedding of *B. suis* for up to 36 months (Manthei and Deyoe 1970). Data suggests that the majority of live-born pigs infected *in utero* clear the *B. suis* infection by 6 months of age; however, in one study, 8% of 230 pigs were blood culture positive beyond 3 months of age, and 2.5% were tissue positive at slaughter at 2 years of age (Manthei et al. 1952). If infected after sexual maturity, the course of infection appears to be longer, with greater chronicity associated with males as compared with females. In mature boars, *B. suis* was recovered from tissue samples of 66.7% at 6 months after experimental infection with 50% remaining culture positive at 42 months. In females, approximately 25% of those experimentally infected were culture positive between 6 and 42 months after experimental infection (Deyoe 1972). Infection can persist for up to 3–4 years in male reproductive tissues (Manthei 1964).

The main risks for the introduction of porcine brucellosis into pig herds are through addition of infected animals, via contact with infected feral pigs and/or European hares, and by infected semen introduced through natural service or artificial insemination (Alton 1990). Feeding uncooked kitchen waste or garbage containing uncooked meat to pigs could also potentially spread swine brucellosis. The possibility of transmission of *B. suis* to swine through environmental contamination or infection of other mammalian vectors has been suspected but never documented (Komendy and Nagy 1982; Repina et al. 1993). Other mammals uncommonly infected with *B. suis* include dogs, cattle, sheep, horses, opossums (*Didelphis marsupialis*), red foxes (*Vulpes vulpes*), roe deer (*Capreolus capreolus capreolus*), armadillos (*Chaetophractus villosus*), capybara (*Hydrochaeris hydrochaeris*), and collared peccaries (*Tayassu tajacu*) (Barr et al. 1986; Bhongbhibhat et al. 1970; Cook and Kingston 1988; Corbel 2006; Cutler et al. 2005; Ewalt et al. 1997; Garin-Bastuji and Delcueillerie 2001; Hofer et al. 2010; James et al. 2017; Komendy and Nagy 1982; Lord and Flores 1983; Lord and Lord 1991; Lucero et al. 2008; Mor et al. 2016; Olsen and Tatum 2016; Ramamoorthy et al. 2011).

Throughout continental Europe, *B. suis* biovar 2 prevalence in Eurasian wild boar (*S. scrofa scrofa*) is high with estimates ranging from 2 to 55% (Al Dahouk et al. 2005; Cvetnic et al. 2003; Garin-Bastuji and Delcueillerie 2001; Grégoire et al. 2012; Hubálek et al. 2002; Koppel et al. 2007; Leuenberger et al. 2007; Montagnaro et al. 2010; Muñoz et al. 2010; Pilo et al. 2015; Wu et al. 2011). Studies have shown that *B. suis* biovar 2 strains isolated from wild boar and domestic swine in various parts of Europe are closely related, strongly suggestive of cross-transmission (Duvnjak et al. 2015; Krezinger et al. 2014; Muñoz et al. 2010). At least in France, Portugal, and Italy, transmission from wild boars to domestic swine is believed to be through the venereal route with many premises reporting the birth of striped piglets (Barlozzari et al. 2015). The European hare (*L. europaeus*) is a source of biovar 2 infections in domestic swine in Europe through natural ingestion of dead hares in pastures or via swill feeding containing offal from hunted infected hares (Olsen et al. 2012). Biovar 2 isolates from European hares are genetically unique when compared with isolates from wild boars in Europe, indicating separate lineages in each host and no evidence of cross-species infection (Krezinger et al. 2014; Lavín et al. 2006; Muñoz et al. 2010).

Public health

B. melitensis and *B. suis* are generally more virulent human pathogens than other *Brucella* species (Corbel 2006). *B. suis* biovars 1, 3, and 4 are pathogenic in humans, and current data suggests that biovar 2 of *B. suis* is a very rare human pathogen occurring only in immunocompromised hosts (Garin-Bastuji et al. 2006; Lagier et al. 2005; Paton et al. 2001).

Human brucellosis due to *B. suis* is most frequently a disease of farmworkers, veterinarians, and abattoir employees, but it can also be contracted through hunting or other associations with feral swine (CDC 2009; Robson et al. 1993). Transmission of *B. suis* from swine to humans primarily occurs by direct contact with infected animals or contact with materials associated with abortion. Routes of entry include aerosol, oral, or through breaks in epidermal integrity. Processing of infected swine through an abattoir setting is associated with a high risk for infection of human workers (Hendiricks et al. 1962; Huddleson et al. 1933; Trout et al. 1995), most likely through aerosol exposure. Some data suggests that zoonotic infection with *B. suis* can result from handling or consumption of infected raw or undercooked pork (Hutchings et al. 1951). Swine can also transmit *B. suis* to cattle where it has a predilection for localization in mammary tissues and shedding in milk (Ewalt et al. 1997). A number of reports have documented zoonotic transmission of *B. suis* to groups of people through consumption of unpasteurized bovine milk (Beattie and Rice 1954; Borts et al. 1943). Person-to-person transmission of

human brucellosis is extremely rare and reported primarily for *B. melitensis* (Corbel 2006).

Human brucellosis is also known as "undulant fever" due to the single consistent symptom of fever that waxes and wanes. It is associated with a wide spectrum of nonpathognomonic clinical manifestations depending on which organs or tissues it localizes in, including the more common osteoarticular, nervous, pulmonary, and mucocutaneous tissues (Franco et al. 2007). Clinical disease typically begins as an acute febrile illness with nonspecific flu-like symptoms such as headache, malaise, back pain, myalgia, and generalized aches. Drenching sweats can occur, particularly at night. Acute disease is associated with an incubation period of 2–3 weeks, yet in half of human patients the onset is insidious with symptoms developing over a period of weeks to months after exposure (Corbel 2006). In the absence of specific treatment, infection may persist for weeks or months (Ariza et al. 2007). Relapse of infection after treatment is not uncommon, usually within 6 months, and not usually associated with emergence of antibiotic-resistant strains (Corbel 2006). The duration of human illness and its long convalescence mean that brucellosis is not only a medical problem but also an economic issue related to loss of productivity or inability to work.

Pathogenesis

B. suis generally causes prolonged infections characterized by granulomatous inflammation in a variety of organs. Localization in male and female reproductive organs is responsible for the predominant clinical signs of fetal loss and infertility as well as being the predominant route for shedding and disease transmission. The capacity of *Brucella* spp. to invade, survive, and proliferate within cells, especially macrophages and placental trophoblasts, is important for its pathogenesis.

The minimum infectious dose of *B. suis* is not well characterized, but doses of 10^{3-4} are probably capable of infecting swine (Alton 1990; Teske et al. 2011). Infection depends on strain virulence, dose, and route of infection as well as host susceptibility and immunologic status (Enright 1990). *B. suis* typically enters by penetration of mucous membranes or, less commonly, through breaks in the epithelium. Location of entry is determined by route of exposure (i.e. oral, venereal, or contact with skin). Initial localization and replication is in lymphoreticular tissues draining the site of exposure/infection. Studies with *B. abortus* suggest that penetration of the mucosa occurs preferentially through follicle-associated epithelial cells such as M cells and/or via uptake by intraepithelial phagocytes, which may also aid in transport to submucosal lymphoid patches or regional lymph nodes (Ackermann et al. 1988).

Bacteremia follows initial replication, either due to free bacteria or *B. suis*-laden phagocytes, resulting in systemic dissemination to a variety of lymphoid and nonlymphoid organs. Bacteremia usually lasts an average of 5 weeks but can extend up to 34 months in sows (Deyoe 1967, 1972). Lymph nodes believed to be preferential sites include mandibular, gastrohepatic, internal iliac, suprapharyngeal, and supramammary although localization may be influenced by route of exposure (Deyoe and Manthei 1967). Nonlymphoid tissues commonly infected include mammary gland, placenta, and synovial tissues. Less commonly, seminal vesicles, prostate, epididymides, testes, uterus, oviducts, liver, spleen, bones, tendon bursae, and brain can also be affected (Alton 1990; Rosenbusch 1951).

Once in the host, *Brucella* resists destruction by extracellular and intracellular host mechanisms designed to eliminate bacterial infection. Exact mechanisms by which *Brucella* avoids elimination are only partially understood. The O side chain on the LPS of virulent smooth strains is important for extracellular survival as it has low immunogenicity and is relatively resistant to both complement- and cationic peptide-mediated bactericidal functions (Allen et al. 1998; Lapaque et al. 2005). Additional details of mechanisms used by *Brucella* spp. to inhibit host innate and adaptive immune response will be discussed in the section on immunology below.

After internalization by phagocytic cells, primarily macrophages, *Brucella* spp. adapts to survival within the harsh intracellular environment of the host. The capacity of antibody- and complement-opsonized as well as nonopsonized *Brucella* to modify their intracellular environment and maintain long-term residence within macrophages is the basis for the establishment and maintenance of chronic infections (Baldwin and Goenka 2006; Roop et al. 2003). Non-opsonized *Brucella* entry into cells is mediated by lipid rafts (Naroeni and Porte 2002), a process that does not cause significant activation of host cells and may contribute to their intracellular survival. Once inside the host cell, *Brucella* reside in a compartment termed the *Brucella*-containing vacuole (BCV), which interacts with components of the endocytic and secretory pathways.

The majority of BCV (75–80%) merge with phagolysosomes and the bacteria are killed. The remaining 20–25% of BCV undergo a maturation process and acquire markers of early and late endosomes. As maturation proceeds, acidification of BCV is an important step for *Brucella* survival. A drop in pH induces the expression of genes required for virulence, including the *virB* operon, which encodes a type IV secretion system (T4SS) (Boschiroli et al. 2002). Induction of T4SS inhibits BCV fusion with lysosomes and facilitates fusion with the endoplasmic reticulum (ER), creating the "brucellasome" (Celli 2006). The brucellasome is a favorable intracellular

niche where *Brucella* replicate, accumulate, and ultimately lyse the host cell to repeat the cycle.

Survival of *Brucella* in brucellasomes is enhanced by the use of stationary-phase physiology and siderophores to scavenge iron and by their ability to resist oxidative killing (Roop et al. 2003). Additionally *Brucella* spp. can directly interfere with host cell signaling pathways, including Toll-like receptor (TLR) signaling (Cirl et al. 2008; Salcedo et al. 2008) and programmed cell death pathways (He et al. 2006; Gross et al. 2000; Tolomeo et al. 2003). Interference with these pathways decreases immune recognition and enhances long-term intracellular survival.

Clinical signs

Most swine infected with *B. suis* are clinically normal with normal leukograms during acute and chronic infections. Prior to the onset of sexual maturity, clinical signs are generally limited to occasional swollen joints and lameness. In sexually mature swine, brucellosis is characterized by fetal loss, stillbirth, and infertility in sows and orchitis, epididymitis, and infertility in boars with clinical signs that mimic other bacterial and viral diseases. Although *B. suis* is often considered to be an abortifacient bacterium, abortion is generally a minor component of the clinical presentation under field conditions.

Epidemic infection of naïve swine herds results in rapid transmission throughout the herd and fetal loss at all stages of gestation. Infection of sows by natural breeding or artificial insemination or by other routes near the time of conception results in fetal death by 21–27 days that is usually recognized as irregular returns to estrus at 30–45 days after breeding (Manthei and Deyoe 1970). Infection of sows later in gestation results in abortion of fetuses of various sizes, stillborn pigs, or infected live-born pigs that exhibit increased neonatal mortality rates (Hutchings et al. 1946b). Placental retention, metritis, vaginal discharges, and poor subsequent fertility may be observed in sows that have aborted. Infertility is directly related to the duration of infection and the severity of uterine lesions (Manthei and Deyoe 1970; Thomseon 1934).

In endemically infected herds, only mild to moderate clinical signs are typically observed. Pregnancy rates may be decreased due to chronic uterine infection and consequent infertility in a portion of sows (Manthei and Deyoe 1970; Thomseon 1934). When infected boars are used for natural service, depending on whether testicular or epididymal damage is uni- or bilateral, libido and fertility can be decreased, resulting in reduction in conception rates and litter size (Hutchings and Andrews 1946; Manthei and Deyoe 1970). Irregularity in contour and size of testes and epididymides may be observed or palpated in some affected boars. Venereal transmission to naïve females can also result in early pregnancy loss and irregular returns to estrus. Apart from pregnancy loss in females and reduced libido in boars, most immature and mature pigs will typically appear clinically normal. Swollen joints and tendon sheaths accompanied by lameness and incoordination can occasionally occur in both males and females. Less commonly, posterior paralysis resulting from lumbar abscesses or spondylitis may occur (Enright 1990).

Lesions

In the uterus and uterine tubes, multifocal, miliary, 2–3 mm yellow nodules develop in the mucosa that may contain purulent or caseous exudate. These nodules may coalesce to form plaques and are often associated with thickening of the mucosa. In the uterine tubes, the nodules can lead to obstruction and pyosalpinx. The endometrium may be expanded by lymphoid and plasma cell infiltrates including some hyperplasic lymphocytic nodules. Suppurative infiltrates may be present in superficial endometrial glands and in the uterine lumen. Partial desquamation or squamous metaplasia, including rete pegs and intercellular bridges, may be observed in the endometrial epithelium or superficial glands. Uterine ligaments often contain small and irregular granulomas on their surface (Schlafer 2007).

In the pregnant uterus, miliary lesions are superimposed on a diffuse, mucohemorrhagic endometritis with the catarrhal mucosal exudate containing large numbers of bacteria. Lesions in placenta and aborted fetuses are uncommon, but may include patchy placental thickening caused by necrosuppurative placentitis and mild suppurative fetal bronchopneumonia (Manthei and Deyoe 1970).

In intact males, orchitis caused by *B. suis* results in multiple granulomas accompanied occasionally by fibrinopurulent or hemorrhagic periorchitis. Testes may be enlarged or atrophic. Granulomas in the testes or epididymis have a caseous core surrounded by epithelioid macrophages, multinucleate giant cells, lymphocytes, and plasma cells and may be encapsulated in fibrous connective tissue. Infection of accessory glands may be associated with vesicular gland hypertrophy and microabscesses or granulomas in vesicular glands, prostate, or bulbourethral glands (Foster 2007). Calcified foci may also be in the testes and accessory sexual glands and organs, particularly in the epididymis and seminal vesicles. Fibrosis may result in adhesions between the two layers of the tunica vaginalis (Foster 2007).

Articular lesions are characterized by purulent or fibrinopurulent synovitis affecting the joints of the limbs. Osteomyelitis is typically observed in the lumbar vertebra

and commonly is associated with destruction of the intervertebral cartilages. Bone lesions are usually granulomatous with dry caseous necrosis but can become suppurative, leading to paravertebral abscesses (Thompson 2007). Abscesses and/or granulomas may also develop in other tissues with *B. suis* localization, particularly the lymph nodes, spleen, liver, kidneys, joint capsules, tendon sheaths, bones, mammary gland, urinary bladder, and brain.

Diagnosis

Direct diagnosis

Bacterial culture is the definitive method for confirming brucellosis in swine. Due to the lack of sensitivity and specificity of current serologic tests in swine, bacterial culture from lymph nodes is as likely to detect infection as serologic diagnosis (Alton 1990; Rogers et al. 1989). However, the slow growth of *Brucella in vitro*, the tendency for reduced recovery of isolates from chronically infected swine, high costs, and biosafety concerns make diagnosis by bacterial culture unfeasible in some situations.

A presumptive diagnosis of brucellosis in pigs can be made by microscopic examination of Stamp's stained smears from vaginal swabs, placentas, and/or aborted fetuses. However, this testing lacks sensitivity and specificity and should be supported by direct culture techniques to ensure an accurate diagnosis. For direct culture, preferred samples include vaginal secretions (swabs), milk, semen, fetal membranes, and samples from aborted fetuses including stomach contents, spleen, and lung. At necropsy, spleen, cervical lymph nodes, mammary gland, uterus, testes, epididymis, vesicular glands, prostate, and bulbourethral glands are good samples for direct culture.

Recovery of *B. suis* can be done at 37 °C without a 5–10% CO_2 atmosphere using multipurpose basal culture media without serum. Due to the possible overgrowth of bacterial contaminants, use of selective media (Alton 1990) containing serum is recommended in addition to incubation of plates at 37 °C with 5–10% CO_2. These *in vitro* conditions will also maximize the ability to isolate other species of *Brucella* that might be present. Farrell's and modified Thayer-Martin's media (Marín et al. 1996) should be utilized when *B. suis* biovar 2 may be present due to the greater sensitivity of this biovar to antibiotics contained in common *Brucella* selective medias. *Brucella* isolates are generally slow growing with colonies not being visible until 3–4 days. To maximize recovery cultures should be incubated for at least 8 days.

B. suis biovars 1, 2, and 3 may be presumptively identified by slide agglutination with monospecific antiserum combined with additional bacteriological tests (Alton 1990). The precise differentiation of biovars depends on susceptibility to specific phages, ability to produce hydrogen sulfide (H_2S), and growth in the presence of thionin or basic fuchsin dyes (Table 50.2). Oxidative metabolic tests can be used in identification of biovars but are cumbersome and rarely performed. Interpretation of test results may be subjective, and differentiation of biovars 1, 2, and 3 may require additional testing and should therefore be conducted by a brucellosis reference laboratory. Some automated identification systems may misidentify *B. suis* isolates as *Ochrobactrum* due to the high homology between genera (Bartham et al. 1993; Vila et al. 2016).

A number of PCR-based protocols are reported that allow direct diagnosis of *B. suis* from samples (Bounaadja et al. 2009; Huber et al. 2009; López-Goni et al. 2011; Ratushma et al. 2006). The sensitivity of these methods is currently significantly lower than culture methods for some samples due to the presence of DNA inhibitors that interfere with PCR.

Indirect diagnosis

The diagnostic value of serological tests for brucellosis in swine is only at a herd basis rather than an individual basis. None of the conventional serological tests used for the diagnosis of brucellosis in domestic ruminants have adequate sensitivity and specificity for the diagnosis of swine brucellosis in individual pigs. A recent study found that a panel of serologic tests were only able to identify 52% of naturally infected feral swine as seropositive (Pedersen et al. 2014) and 17% of culture-positive swine were negative on all serologic tests (Ferris et al. 1995). In herds with positive serologic test results, *B. suis* infection should be confirmed using bacteriologic isolation and/or molecular assays that detect *Brucella* DNA.

The major antigen involved in the serological response against *in vivo* infection with smooth strains of *Brucella* is the smooth LPS. Antisera developed against the smooth LPS of *B. abortus* (A dominant) and *B. melitensis* (M dominant) are available for diagnostic use. Although there is some variation between strains, the smooth LPS of *B. suis* is recognized by monoclonal antibodies specific for either the A or M antigens and by antibodies against common LPS epitopes shared by *B. abortus* and *B. melitensis* (Douglas and Palmer 1988). The majority of standard brucellosis serologic tests were developed for detection of *B. abortus* in cattle and use the polysaccharide O side chain of the *B. abortus* smooth LPS as antigen. This may be one explanation for observed reductions in sensitivity and specificity of these tests for detection of *B. suis* in swine as compared with their use to detect *B. abortus* infections in cattle. An explanation for their lower specificity in swine

is the similarity of the structural component of the *B. abortus* LPS O side chain (repeated residues of 4-formamindo-4,6-dideoxymannose linked in α-1,2 or α-1,3 conformation) to the LPS of other bacteria, including *Yersinia enterocolitica* O:9 and *Escherichia coli* O:157 (Bundle et al. 1989). *Y. enterocolitica* O:9 infection in pigs is widespread in many countries and is believed to be the major source of false-positive serological reactions in standard brucellosis serologic tests. Tests using *Brucella* protein extracts free of the LPS O side chain (gel immunodiffusion, indirect enzyme-linked immunosorbent assays (ELISAs), counterimmunoelectrophoresis, and latex agglutination) are less likely to result in false-positive results than tests that depend on the LPS O side chain as antigen (Rose Bengal plate test [RBT], ELISAs, and fluorescence polarization assay [FPA]) (Dieste-Perez et al. 2015a; McGiven et al. 2012).

Sensitivity and specificity estimates for serologic tests are typically related to the "gold standard" of bacterial culture, and *B. suis* is typically cultured from a greater proportion of acute than chronic infections. This may explain the great variation in published estimates of sensitivity and specificity for these tests in swine. Ranges for estimates of sensitivity of standard tests are standard tube (SAT; 51.1–100%), mercaptoethanol (38.5–100%), Rivanol (23.1–100%), complement fixation test (CFT) (49.1–100%), card test (RBT; 20–100%), buffered plate antigen (61–77.1%), and FPA (63–98.9%). Estimates of specificity ranges are serum tube agglutination test (SAT) (62–100%), mercaptoethanol (81.1–100%), Rivanol (74–100%), CFT (86–100%), RBT (76–92%), buffered plate agglutination (90–95.9%), and FPA (55–99.9%) (Ferris et al. 1995; García-Carillo et al. 1971; Hutchings et al. 1946a; Lord et al. 1997; Nielsen et al. 1999; Paulo et al. 2000; Rogers et al. 1989). Some data has suggested higher sensitivity and specificity for detecting pigs infected with *B. suis* by use of competitive ELISAs as compared with indirect ELISA, FPA, and the RBT (Praud et al. 2012, 2013). However, in pigs naturally infected with *B. suis* biovar 2, a competitive ELISA was comparable in performance with the RBT, indirect ELISA, and a blocking ELISA (Muñoz et al. 2012). Others have proposed using a combination of the c-ELISA, indirect ELISA, and FPA for maximizing specificity and sensitivity of serologic detection of brucellosis in swine (Di Febo et al. 2012).

Because swine serum may sometimes contain nonspecific antibodies thought to be IgM, the specificity of the SAT is reduced, and this test should not be used for diagnosis of brucellosis in pigs. In addition, swine complement interacts with guinea pig complement to produce anticomplementary activity that reduces the sensitivity of the CFT test, causing its sensitivity to be significantly lower than that of the RBT (Ferris et al. 1995; Rogers et al. 1989). Despite reduced sensitivity, the CFT has high specificity for identifying true infected herds when interpreted on a collective basis.

The delayed-type hypersensitivity (DTH) reaction based on the use of smooth LPS-free *Brucella* cytoplasmic proteins (widely known as brucellin), extracted from rough *B. melitensis* strain B115 (Bhongbhibhat et al. 1970), is of diagnostic value due to reductions in false-positive responses. The brucellin DTH test is currently the only indirect diagnostic test capable of discriminating between *B. suis* infections and infections caused by cross-reacting bacteria. Although developed for use in ruminants, it has been used in swine in the EU for brucellosis diagnosis at the herd level (Dieste-Perez et al. 2015b; EFSA 2009).

Immunity

The central role of interferon gamma (IFN-γ)

The most extensive characterization of the host immune response to *Brucella* spp. has been performed in the murine model. These studies demonstrate that T helper (T_{H-1}) responses, characterized by production of interferon gamma (IFN-γ) from $CD4^+$ and $CD8^+$ T cells are required for the control of *Brucella* infection (Araya et al. 1989; Fernandes et al. 1996). Production of IFN-γ is a critical component of immunity against intracellular pathogens, including *Brucella* spp., as *in vitro* studies have shown that this cytokine activates infected macrophages to inhibit intracellular replication and mediates intracellular killing (Jiang and Baldwin 1993). This important role of IFN-γ in suppressing *Brucella* infection is confirmed *in vivo*, both experimentally and clinically. Mice deficient in IFN-γ production are unable to control systemic bacterial replication and succumb to *B. abortus* infection (Murphy et al. 2001). In humans, polymorphisms in IFN-γ (and other proinflammatory cytokines) contribute to susceptibility to brucellosis (Karaoglan et al. 2009), and chronicity of infection is associated with reduced production of IFN-γ (Rafiei et al. 2006).

Inhibition of the host immune response by *Brucella*

Brucella have several mechanisms to inhibit or avoid components of the host immune responses, allowing them to evade detection and clearance. The host innate immune response depends on pattern recognition receptors (PRR) found on host cell and endosomal membranes and within the cytosol to detect pathogen-associated molecular patterns (PAMPs). Binding of a specific PAMP to host cell PRR stimulates various cellular antibacterial activities. PRR include TLR, nucleotide-binding oligomerization

domain-like receptors (NLR), C-type lectins, and retinoic acid-inducible gene-I-like (RIG-I-like) receptors. LPS produced by *Brucella* spp. has multiple features that allow it to limit its detection by TLR4, a specific TLR. While the LPS lipid A moiety of other bacterial pathogens contain short fatty acid residues (C12–C16), *Brucella* LPS lipid A is longer (C28), which results in greatly reduced TLR4 agonist responses (Barquero-Calvo et al. 2007; Lapaque et al. 2006). In addition, the O-antigen moiety of LPS is typically a target for complement component C3 deposition. However, *Brucella* LPS resists C3 deposition, resulting in decreased generation of anaphylatoxins C3a and C5a, further dampening proinflammatory responses (Barquero-Calvo et al. 2007; Hoffmann and Houle 1983). The unusual composition of the LPS O chain of smooth *Brucella* strains also resists degradation by macrophages, and the accumulation of undigested O chain directly inhibits antigen presentation by infected macrophages to T cells via the MHC class II pathway (Forestier et al. 2000).

Brucella also suppresses innate immune responses by decreasing overall TLR signaling through production of a protein that contains a Toll/interleukin-1 receptor (TIR) domain. This protein ultimately results in inhibition of both TLR2 and TLR4 signaling (Cirl et al. 2008; Salcedo et al. 2008). Dendritic cell (DC) maturation and production of inflammatory cytokines such as IL-12 and TNF-α are inhibited following *Brucella* infection, mediated by the inhibition of TLR signaling (Salcedo et al. 2008).

Brucella have also developed mechanisms to avoid the adaptive immune response. DC play a critical role in bridging innate and adaptive immunity. Infection and proliferation of brucellae within DC has been reported both *in vitro* and *in vivo* (Archambaud et al. 2010; Salcedo et al. 2008). By infecting DC, *Brucella* not only target a replicative niche, but they also hinder the priming of adaptive immune responses. *In vitro B. abortus* 2308 and *B. suis* 1330 inhibit DC maturation and function via decreased surface expression of major histocompatibility complex (MHC) class II, CD80, and CD86, decreased secretion of IL-12 and TNF-α, and poor antigen presentation to naïve T cells (Billard et al. 2007). Similarly, *B. abortus*-infected macrophages have been shown to have reduced major MHC class I and class II expression (Barrionuevo et al. 2008, 2013), further interfering with antigen presentation to $CD8^+$ and $CD4^+$ T cells.

Adaptive host immune response to *Brucella*

Despite these evasion mechanisms, most smooth strains of *Brucella* induce an immune response after infection. However, the chronic nature of *Brucella* infections indicates that these immune responses are often insufficient to eliminate *Brucella* from their intracellular niche for extended periods of time (Olsen and Hennager 2010).

The LPS and other antigens of *Brucella* are highly immunogenic in eliciting humoral responses in infected swine. The LPS of *Brucella* is a prototypical T-cell-independent antigen because it can directly activate B cells to produce antibody without the aid of helper T cells. Antibodies are beneficial against intracellular pathogens through opsonization, complement activation, antibody-dependent cellular cytotoxicity, and binding to bacterial receptors to prevent adherence of bacteria to host tissues. In swine, the pattern of antibody production following *B. suis* infection has not been properly established. However, it should be similar to that induced by other *Brucella* infections with IgM antibodies predominating in the first 2 weeks after infection and IgG isotypes increasing slowly during the first 3 weeks of infection. However, antibodies are not as important for long-term protection as cellular immunity.

Cell-mediated immune responses to *B. suis* infection in swine have not been fully characterized. Both $CD4^+$ and $CD8^+$ T cells from pigs experimentally infected with *B. suis* produce IFN-γ and proliferate in response to *in vitro* stimulation (Riber and Jungersen 2007). Similarly, vaccination of pigs with *B. suis* strain 353–1 results in peripheral blood mononuclear cell (PBMC) proliferation and IFN-γ production in response to antigen stimulation (Stoffregen et al. 2013). It is known that the release of IFN-γ by *Brucella*-specific $CD4^+$ and $CD8^+$ T cells augments bactericidal function of macrophages and that *Brucella*-specific $CD8^+$ T cells are capable of killing infected macrophages via cell-mediated cytotoxicity. However, studies with the intracellular pathogens *Mycobacterium bovis* and *Leishmania major* have demonstrated that measurement of IFN-γ production is not sufficient to predict protective immunity (Elias et al. 2005; Gicheru et al. 2001). A more ideal assessment of the quality of a cellular immune response is the measurement of antigen-specific polyfunctional phenotype (i.e. the ability to produce multiple cytokines including IL-2, TNF-α, and IFN-γ) (Thakur et al. 2012). Currently, the quality of the cellular immune response as assessed by the polyfunctional effector phenotype in swine brucellosis remains uncharacterized.

Despite the initial presence of a proinflammatory response early in disease, studies of chronic brucellosis in mice have demonstrated that the initial anti-*Brucella* T_H1 proinflammatory environment switches to an immunosuppressive state. Similarly, during chronic human brucellosis, the initial T_H1 response is dampened over time and gains effector functions associated with T_H2 responses such as increased production of IL-13 (Rafiei et al. 2006). It is likely that a suppression of cell-mediated immunity occurs in brucellosis in swine as has been demonstrated in mice and humans, thus explaining the chronic nature of the disease.

Prevention and control

There are currently no commercially available vaccines for protecting domestic or feral swine against *B. suis* infection. Although initial reports were promising, currently available data suggests that the oral *B. suis* strain 2 vaccine developed in China (Deqiu et al. 2002) and the *B. abortus* strain RB51 vaccine (Edmonds et al. 2001) do not adequately protect swine against *B. suis* infection (Stoffregen et al. 2007). Recently a rough *B. suis* strain that functions as a differentiating infected from vaccinated animals (DIVA) vaccine was demonstrated to have efficacy after oral or parenteral delivery to domestic or feral swine (Stoffregen et al. 2013). Commercial development of this vaccine is not eminent.

Currently, the only effective strategy to maintain *B. suis*-free status of a swine herd or system is excellent biosecurity. Principal components must include testing to ensure *B. suis*-free status of any source of purchased semen or seedstock prior to herd entry and installation of adequate fencing when husbandry practices allow potential contact with wildlife reservoirs.

Given the few and nonspecific clinical signs in endemically *B. suis*-infected pig herds and the degree of transport and intermingling of pigs in most countries, introduction of *B. suis*-infected pigs in seedstock farms or boar studs could rapidly disseminate the disease. This is true for swine herds in all regions that have *B. suis*-infected feral reservoirs or *B. suis*-infected domestic swine herds, but even more so for Europe and similar regions having a high simultaneous prevalence of feral reservoirs and open-air swine rearing systems (EFSA 2009).

Since serologic surveillance is best performed in swine on a herd basis, regulatory efforts to control or eradicate *B. suis* in domestic swine should be directed toward herds rather than individual animals (Olsen and Tatum 2016). Proximity to an infected herd is also a risk factor; therefore, elimination of brucellosis from a farm may only be transient if neighboring farms remain infected (Acha and Szyfres 2003) and rigorous biosecurity measures are not in place to prevent reinfection.

Test and removal strategies are not economically feasible under all circumstances, so a number of studies have evaluated the ability of antibiotic treatment to control brucellosis in host species, including swine (Bunnell et al. 1947; Radwan et al. 1993). These studies found that although disease prevalence was reduced, cost of treatment and persistence of infection in some treated animals made long-term antibiotic therapy nonviable as a regulatory strategy. More recently, a small study of naturally infected swine (n = 8/treatment) found that oral treatment with oxytetracycline (20 mg/kg/daily for 21 days) eliminated *B. suis* biovar 2 infection from only 50% of infected swine. In contrast, when oral oxytetracycline therapy was combined with the macrolide antibiotic tildipirosin (4 mg/kg administered IM on days 1 and 10), the authors were unable to recover *B. suis* from treated swine at 21 days (Dieste-Perez et al. 2015c). In a larger field study, oral treatment of naturally infected swine (*B. suis* biovar 2) with oxytetracycline (20 mg/kg/daily) was not sufficient to eradicate brucellosis in infected herds (Dieste-Perez et al. 2016). However, when combined with removal of infected animals as identified by one of three diagnostic tests (brucellin DTH or Rose Bengal and indirect ELISA serologic tests), brucellosis was eradicated from infected herds in approximately 16 months.

With the exception of increasing hunting pressure to reduce population densities, no measures are currently available to reduce or eliminate *B. suis* infection in wildlife reservoirs. The risk of disease transmission from wildlife reservoirs to domestic swine is unlikely to diminish in the near future. Current research in swine evaluating immunocontraception, toxin containing baits, and orally deliverable vaccines may eventually provide needed tools to help in managing the disease in free-ranging feral swine (Snow et al. 2016).

Clostridial Diseases

Francisco A. Uzal and J. Glenn Songer

Introduction

Members of the genus *Clostridium* are mainly anaerobic, gram-positive spore-forming rods. However, there are a few clostridia that stain gram-negative and others that tolerate oxygen (Rood 2016). *Clostridium perfringens* type C, *Clostridium difficile*, *Clostridium septicum*, *C. perfringens* type A, *Clostridium tetani*, *Clostridium botulinum*, and, rarely, *Clostridium chauvoei*, *Clostridium novyi* type A, and *Clostridium sordellii* are the main clostridial pathogens that affect pigs (Diab 2016; Silva et al. 2016; Songer and Uzal 2005). Broadly, clostridial diseases of pigs and other animal species are classified into enteric, histotoxic, and neurotoxic infections (Table 51.1).

Enteric infections

Clostridial enteric infections in pigs are mainly caused by *C. perfringens* type C *and C. difficile. C. perfringens* is divided into seven toxinotypes (A through G) based on production of six so-called major toxins (i.e. alpha [CPA], beta [CPB], epsilon [ETX], iota [ITX], enterotoxin [CPE] and necrotic enteritis B like toxin [NetB]) (Theoret and McClane 2016; Rood et al. 2018) (Table 51.2). Colonies of most *C. perfringens* strains have a typical appearance in blood agar characterized by a double halo of hemolysis produced by CPA and perfringolysin (Figure 51.1).

Clostridium perfringens type C and *C. difficile* are well-established enteric pathogens of suckling pigs. The role of *C. perfringens* type A in enteric disease in pigs is less clear, there being abundant testimonial association with disease but very little experimental evidence supporting *C. perfringens* type A as a cause of enteric disease in mammals (Uzal 2016; Uzal et al. 2016).

Clostridium perfringens type C enteritis

Infection with *C. perfringens* type C occurs worldwide (Azuma et al. 1983; Barnes and Moon 1964; Diab 2016; Field and Gibson 1955; Hogh 1965; Matthias et al. 1968; Morin et al. 1983; Plaisier 1971; Szent-Ivanyi and Szabo 1955). In swine *C. perfringens* type C causes fatal necrohemorrhagic enteritis mostly in neonates.

Etiology and epidemiology

Clostridium perfringens type C is a primary pathogen that produces CPA and CPB, CPB being the main virulence factor (Fisher et al. 2006; Sayeed et al. 2008). *C. perfringens* type C may be found, albeit rarely, in low numbers as a component of normal swine microflora (Songer and Uzal 2005). Neonatal suckling pigs are infected primarily by exposure to sow feces but may also be infected by lateral transmission from infected littermates (Songer and Uzal 2005; Uzal et al. 2016) or from spores ingested from a contaminated environment. Infected suckling pigs act as "enrichment vessels" where *C. perfringens* type C outcompetes other bacteria, multiplying to high levels and producing disease. This may be strain dependent as there is also a large variation in CPB production and virulence between different strains of *C. perfringens* type C (Fisher et al. 2006). Vegetative bacterial cells are shed in feces in low numbers by healthy sows and in high numbers by diseased pigs where they may sporulate. Spores are resistant to heat, disinfectants, and ultraviolet (UV) light (Diab 2016) and may serve as a source of infection for successive litters if the farrowing environment is not sufficiently cleaned and disinfected.

Disease may appear as early as 12 hours after birth but is most common in 3-day-old piglets. Onset is rare in pigs older than one week (Bergeland et al. 1966; Diab 2016; Matthias et al. 1968; Meszaros and Pesti 1965; Uzal et al. 2016). Type C enteritis may occur as epidemics in non-vaccinated populations (Bergeland et al. 1966) and can reach a prevalence of 100% of litters. As dams

Table 51.1 Major clostridial infections and associated syndromes affecting swine.

Type of infection	Syndrome	*Clostridium* species
Enteric	Neonatal hemorrhagic and necrotic enteritis	*C. perfringens* type C
	Necrotizing enteritis (presumptive)	*C. perfringens* type A
	Neonatal necrotic enterotyphlocolitis	*C. difficile*
Histotoxic	Gas gangrene	*C. septicum*, *C. perfringens* type A, *C. novyi* type A, *C. chauvoei*, *C. sordellii*
	Blackleg (presumptive)	*C. chauvoei*
Neurotoxic	Tetanus	*C. tetani*
	Botulism	*C. botulinum*

Table 51.2 Production of so-called major toxins by toxinotypes of *Clostridium perfringens* and associated diseases in humans and animals.

	Major toxins						
Toxinotype	Alpha (CPA)	Beta (CPB)	Epsilon (ETX)	Enterotoxin (CPE)	Iota (ITX)	Necrotic Enteritis like Toxin (NetB)	Major diseases
A	+	–	–	–/+	–	–	Gas gangrene in humans[a] and animals, yellow lamb disease in sheep, necrotic enterocolitis in neonatal pigs (presumptive)
B	+	+	+	–/+	–	–	Lamb dysentery, hemorrhagic enteritis in cattle and possibly horses
C	+	+	–	–/+	–	–	Necrotic and/or hemorrhagic enteritis in neonatal pigs, horses, cattle, sheep, and goats Acute enterotoxemia ("struck") in adult sheep
D	+	–	+	–/+	–	–	Enterotoxemia in sheep, goats, and cattle
E	+	–	–	–/+	+	–	Role in animal disease not fully determined
F	+	–	–	+	–		Food poisoning in humans; role in animal disease not fully determined
G	+	–	–	–/+	–	+	Necrotic enteritis of poultry

[a] Human gas gangrene is mediated by CPA acting synergistically with perfringolysin (PFO).

Figure 51.1 *Clostridium perfringens* colonies on blood agar. Observe the double halo of hemolysis surrounding the colonies, characteristic of this microorganism.

develop immunity and provide protective lactogenic immunity to their suckling piglets, disease becomes endemic. When endemic, peracute and acute fatal clinical disease is observed predominantly in litters of nonimmune dams, usually gilts. The case fatality rate varies, but 100% mortality in litters of nonimmune gilts is not unusual. Total herd mortality may be as high as 60% but is usually lower (Bergeland et al. 1966; Hogh 1967). A more protracted chronic form of disease occurs in individual pigs receiving insufficient lactogenic immunity, usually due to insufficient milk intake or in litters of dams providing partially protective lactogenic immunity.

Pathogenesis

Clostridium perfringens has a very short generation time, allowing type C organisms to multiply to 10^8–10^9 cells/g

of intestinal content in only a few hours (Ohnuna et al. 1992). Attachment to intestinal epithelial cells has been suggested (Arbuckle 1972; Walker et al. 1980), but definitive evidence of this is lacking. The CPB toxin has been confirmed as the main virulence factor of *C. perfringens* type C in animal experiments using CPB toxin mutants in rabbits, mice, and goats (Garcia et al. 2012; Sayeed et al. 2008; Uzal et al. 2009). The CPB toxin is exquisitely trypsin sensitive, and low trypsin levels in the intestine of neonatal animals and/or of animals fed trypsin inhibitors are critical in the pathogenesis of type C disease. The high susceptibility of neonatal animals to type C disease is thought to be a consequence of trypsin inhibition by colostrum, a mechanism apparently important for protection of colostral immunoglobulins (Uzal et al. 2016). Experimentally, inoculation of *C. perfringens* type C in combination with a trypsin inhibitor produces acute necrohemorrhagic enteritis and/or enterotoxemia in piglets, guinea pigs, rabbits, lambs, and goats (Garcia et al. 2012; Sayeed et al. 2008; Uzal et al. 2009, 2016).

It is generally assumed that the initial effect of CPB produced in the intestinal contents occurs on enterocytes (Uzal et al. 2016). Recently CPB binding to endothelial cells in the small intestinal mucosa of piglets with type C infection was demonstrated, and it was suggested that CPB-induced endothelial cell damage plays an important role in the early lesion development (Schumacher et al. 2013). However definitive evidence to support this claim is lacking. The CPB toxin has also been detected in peritoneal fluid of affected pigs, suggesting that systemic toxemia along with local intestinal damage and dysfunction causes death. In addition to primary replication in intestine, *C. perfringens* type C can also function as an opportunist, colonizing intestinal mucosal lesions induced by *Isospora suis* (coccidiosis; Chapter 66) and other causes of villous atrophy including rotaviruses (Chapter 43) and coronaviruses (Chapter 31) (Songer and Uzal 2005). *Clostridium perfringens* beta-2 toxin (CPB2) is a minor toxin distinct from CPB that has been suggested to play a role in the pathogenesis of *C. perfringens* type C (and type A)-associated enteric diseases in piglets (Bueschel et al. 2003; Songer and Uzal 2005). However little scientific evidence is available to support these claims.

Clinical signs and lesions

Clinical signs may be peracute, acute, or chronic, varying with immune status and age of affected piglets and perhaps the virulence of strain of *C. perfringens*. Peracutely affected piglets develop hemorrhagic diarrhea that begins 8–22 hours after exposure to *C. perfringens* type C (Songer and Uzal 2005; Uzal et al. 2016). They are weak, are reluctant to move, and become rapidly moribund. Rectal temperature falls to 35 °C (95 °F) or below, and abdominal skin may darken before death. Many piglets are found dead without clinical signs being observed (Songer and Uzal 2005). Acutely affected piglets may survive for 1–2 days after onset of clinical signs. They have reddish-brown diarrhea containing gray shreds of tissue debris and may be dehydrated. Perineal scalding may occur, with adherent reddish feces. Nursing is minimal, and these piglets rapidly become gaunt and weak and then die (Songer and Uzal 2005). Chronically affected pigs usually have intermittent diarrhea for more than a week. Feces are yellow to gray and mucoid, and tail and perineum may be fecal stained. These piglets remain alert but may die after several weeks or be euthanized due to unthriftiness.

Lesions have been well described (Cho et al. 1991; Niilo 1988; Songer and Uzal 2005; Uzal et al. 2016) and are usually segmental in the small intestines, but occasionally may include or be exclusively seen in the spiral colon. The character of lesions is the same regardless of location. Gross lesions in peracute disease include transmural intestinal hemorrhage and emphysema (Figure 51.2) and mucosal fibrinonecrotic exudate. There may also be variable serosanguinous abdominal fluid containing strands of fibrin, fibrinous adhesions between intestinal loops, and reddened mesenteric lymph nodes. Lesions in acute disease may include segments with acute lesions as well as segments of thickened and yellow or grayish intestine with a longitudinal striped appearance, sometimes referred to as "tiger striping," that have mucosa markedly thickened by an adherent fibrinonecrotic diphtheritic membrane (Figures 51.2 and 51.3). Deposition of urate crystals in kidney is common. Gross lesions in chronic disease are limited to segmental mucosal diphtheritic membranes with or without mural thickening and rarely mucosal fibrosis.

Histologically, the hallmark of peracute disease is hemorrhagic necrosis of the intestinal wall that starts in the mucosa but usually progresses to affect most or all layers of the intestine (Cho et al. 1991; Niilo 1988; Songer and Uzal 2005; Uzal et al. 2016). Thick bacilli with square

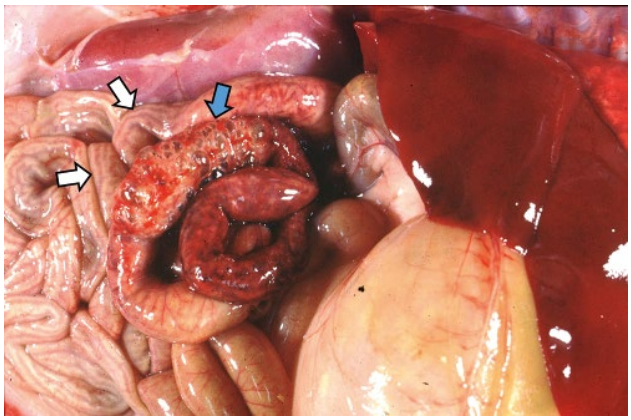

Figure 51.2 Lesions of *C. perfringens* type C enteritis in a neonatal piglet. Peracute mural hemorrhage and emphysema (blue arrow) and acute thickening with longitudinal stripes ("tiger striping") of segments of the jejunum (white arrows) are observed. *Source:* Courtesy of Dr. Mark Anderson.

Figure 51.3 Chronic *C. perfringens* type C enteritis in a neonatal piglet. The small intestinal mucosa is covered by a thick fibrinonecrotic diphtheritic membrane. *Source:* Courtesy of Dr. Pat Blanchard.

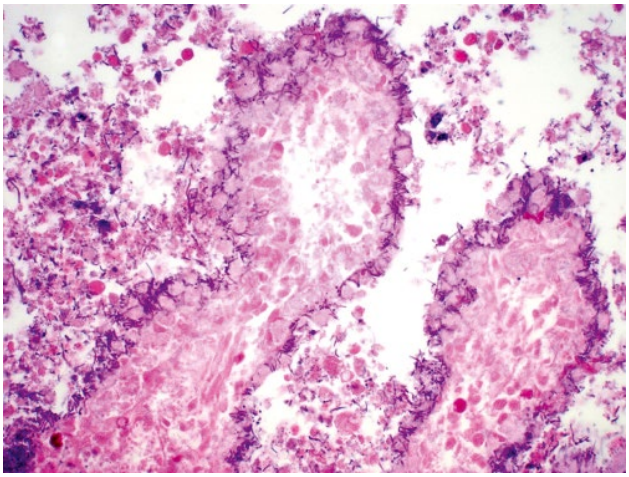

Figure 51.4 Peracute *C. perfringens* type C infection in a neonatal piglet. Association of *C. perfringens*-like organisms with the basement membrane of denuded necrotic villi and accumulation of large numbers of organisms in jejunal lumen. *Source:* Courtesy of Dr. Greg Stevenson.

ends are observed singly or in clusters in intestinal contents or on the luminal interface with necrotic mucosa (Figure 51.4). The superficial mucosa is necrotic, being effaced by necrotic cellular debris, neutrophils, fewer lymphocytes, plasma cells and macrophages, fibrin, and thick bacilli with square ends and rare subterminal spores (Figure 51.5). A few bacilli might also be observed in intestinal crypts and the submucosa. Fibrin thrombi are common in blood and lymphatic vessels of the mucosa and less common in the submucosa. Subserosal vessels are severely congested, and there is diffuse edema in viable layers of the intestine. Specific microscopic changes are not usually observed outside the gastrointestinal (GI) tract, although systemic capillary thrombosis can uncommonly be observed in the lungs, kidney, spleen, and liver as a consequence of terminal disseminated intravascular coagulation (Uzal et al. 2016).

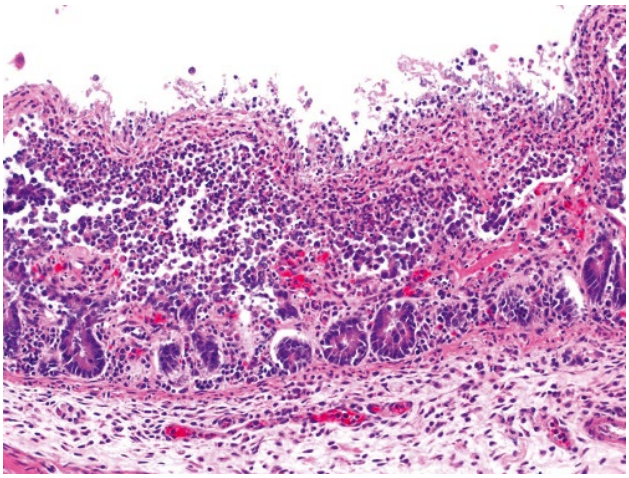

Figure 51.5 Peracute *C. perfringens* type C enteritis in a neonatal piglet. Observe severe mucosal necrosis and pseudomembrane covering the mucosa. HE, 250×.

Lesions are similar in pigs with acute or chronic clinical disease, but the necrosis in intestinal segments extends deeper to encompass the entire mucosa and sometimes the submucosa. Uncommonly, fibrosis will be observed at the interface between viable and necrotic tissue and on the serosal surface.

Diagnosis

Typically, hemorrhagic diarrhea and rapid death in neonatal piglets that have gross lesions of segmental necrohemorrhagic or fibrinonecrotic enteritis are sufficient bases for a presumptive diagnosis of type C enteritis (Songer and Uzal 2005; Uzal et al. 2016). Under field conditions, examination of smears of intestinal mucosa for abundant large gram-positive rods adds confidence to the presumptive diagnosis. Confirmation of the disease relies on detection of CPB in intestinal contents and/or feces (Diab 2016). However, because this toxin is so sensitive to trypsin and it tends to break down soon after being produced in the intestine, failure to detect CPB in intestinal contents does not preclude a diagnosis of *C. perfringens* type C infection. Detection of CPB toxin is most commonly performed by antigen immunoassays that are commercially available. Freezing of and/or adding trypsin inhibitor to intestinal contents or fecal samples prevents proteolysis of CPB for several weeks, allowing shipment to a laboratory for testing (Macias Rioseco et al. 2012).

Culture of *C. perfringens* type C supports a diagnosis of type C disease, but it is not diagnostic since it can be found, rarely and in low numbers in the intestines of healthy pigs (Songer and Uzal 2005). *C. perfringens* is not an efficient sporulator, but ovoid to eccentric spores may be observed. Colonies after 24 hours of incubation on horse or bovine blood agar are usually 3–5 mm in diameter, grayish, and circular. The organism usually produces an inner complete zone of hemolysis, caused by

PFO, and a less complete outer zone caused by CPA (Figure 51.1). Following culture, genotyping of isolates using a multiplexed PCR test to detect genes for the major toxins is the nearly universal method to determine *C. perfringens* type (Buogo et al. 1995; Meer and Songer 1997; Songer and Meer 1996).

Treatment and prevention

Treatment is of little value in animals with clinical signs (Hogh 1967; Szabo and Szent-Ivanyi 1957), and prophylaxis is the preferred approach. In an outbreak, passive immunization with equine-origin antitoxin can protect piglets in litters of nonimmune sows for up to 21 days (Ripley and Gush 1983). Antitoxin should be injected parenterally as soon after birth as possible. Oral antimicrobials such as ampicillin or amoxicillin can also be given prophylactically, beginning immediately after birth and continuing daily for 3 days. There are reports of antimicrobial resistance in *C. perfringens*, and tetracycline resistance plasmids have been identified (Rood et al. 1985). However, the organism remains uniformly susceptible to penicillins. Ceftiofur may be an alternative for treatment of piglets, and bacitracin methylene disalicylate can be administered to sows before and after farrowing to decrease the likelihood of infection of piglets.

Prevention is best achieved by vaccination of sows with type C toxoid at breeding or mid-gestation and at 2–3 weeks before farrowing (Kennedy et al. 1977). Commercial toxoid vaccines are quite effective, and vaccination usually eliminates the disease within one farrowing cycle.

Ten-fold reductions in mortality are common (Ripley and Gush 1983), assuming normal responses of the sow to vaccination (Matishek and McGrinley 1986) and ingestion by piglets of adequate amounts of colostrum. Booster injections of vaccine should be given about 3 weeks before subsequent farrowings.

Clostridium perfringens type A

There is very little information available about the role of *C. perfringens* type A in diarrheal disease of pigs. Although this microorganism has been associated with neonatal diarrhea and many swine practitioners are confident of its role (Chan et al. 2013), disease has not been reproduced in inoculation studies in suckling pigs. This confusion is fueled by the ease with which *C. perfringens* type A is cultured from diarrheic and clinically normal neonatal pigs, since it is well established as normal intestinal microbiota (Diab 2016; Mansson and Smith 1962; Uzal et al. 2016) and by lack of specific and/or consistent associated microscopic lesions (Collins et al. 1989). Lacking clear criteria for definitive diagnosis, attempts have been made to identify other toxins or virulence traits that could be used as diagnostic markers in strains of *C. perfringens* type A cultured from diarrheic pigs that would distinguish them from so-called nonpathogenic strains. These attempts have so far failed. Early studies reported that nearly all type A strains isolated from pigs with enteric disease carried the *cpb2* gene for CPB2 toxin compared with a lower proportion of clinically normal pigs (Bueschel et al. 2003; Waters et al. 2003); however, recent studies found no such correlation (Chan et al. 2012; Farzan et al. 2013). In addition, CPB2-associated enteric diseases of pigs have not been reproduced experimentally.

Etiology and epidemiology

Clostridium perfringens type A resembles type C in culture, but it produces CPA as its sole major toxin. This toxin and *C. perfringens* type A are very frequently found in the intestine of healthy animals and the environment, which complicates significantly the diagnosis of enteric disease associated with this microorganism (see below; Uzal et al. 2016). *C. perfringens* enterotoxin (CPE) that is produced by some type A strains and by type F strains (Rood et al. 2018) is a common cause of food poisoning in humans characterized by abdominal cramping, nausea, and diarrhea. The CPE toxin has also been evaluated as a possible virulence factor for type A-associated diarrhea in pigs. However, presence of CPE-producing strains in animal disease is uncommon (Collins et al. 1989; Estrada Correa and Taylor 1989; Miwa et al. 1997; Uzal et al. 2016; van Damme-Jongsten et al. 1990).

Recently two novel toxins are described, NetB produced by type G strains, and NetF produced by certain type A strains (Mehdizadeh Gohari et al. 2015; Rood et al. 2016). The NetB toxin has been shown to be responsible for cases of necrotic enteritis in poultry (Rood et al. 2016), while some evidence suggests a possible causal relationship between NetF and enteritis of foals and dogs (Mehdizadeh Gohari et al. 2015). It is therefore possible that some strains of *C. perfringens* type A produce one or more yet unidentified virulence factors that are responsible for enteric disease in pigs. This, however, is speculative, and until more is known about type A strains possibly associated with enteric diseases in pigs, no final conclusions can be drawn about the role of this microorganism on such diseases.

Putative type A diarrheal disease in pigs occurs during the first week of life, and sows are the likely source of infection. However, diagnosis is complicated by the fact that differentiation between normal flora and disease-causing strains is not possible, and it may be that under appropriate conditions, any strain of *C. perfringens* type A can cause disease (Uzal et al. 2016). Thus, discussion of the epidemiology of type A enteric infections is highly speculative.

Public health

The CPE produced by some strains of *C. perfringens* type A and by all type F strains is a leading cause of foodborne illness in humans that is characterized by

abdominal cramping, nausea, and diarrhea. It usually occurs when CPE-producing strains that contaminate meats proliferate in meats that are poorly refrigerated or are cooled slowly after cooking. Livestock, including pigs, have been traditionally implicated as the primary source of CPE type F strains through fecal contamination of meat during slaughter. However, the proportion of type F strains in pigs is low (Kanakaraj et al. 1998; Miwa et al. 1996, 1997), and recent evidence also implicates human fecal contamination of meat during handling as a common source (Lindström et al. 2011). Direct contact with swine poses no public health risk associated with *C. perfringens* type A.

Pathogenesis

CPB2 is a so-called minor toxin distinct from CPB that has been suggested to play a role in the pathogenesis of *C. perfringens* type A-associated enteric diseases in piglets (Bueschel et al. 2003; Songer and Uzal 2005). However little scientific evidence is available to support these claims. Recent evidence suggests that the number of *cpb2*-positive *C. perfringens* strains in the intestinal contents is not useful for making a diagnosis of type A enteritis in diarrheic piglets (Farzan et al. 2013).

The pathogenesis of *C. perfringens* type A enteric disease in pigs is poorly established. Association by culture of type A from diarrheic pigs in the absence of other known causes of diarrhea or lesions is often the criteria for diagnosis. This, however, is inadequate since *C. perfringens* type A is normal intestinal flora. No direct information implicates specific toxins in pathogenesis of this condition, including CPB2, CPE, NetB, and NetF (see above) as well as CPA. Studies in ligated gut loops found no consistent changes in loops inoculated with purified CPA when compared with control loops (Johannsen et al. 1993).

Clinical signs and lesions

No consistent and few inconsistent lesions are reported in *C. perfringens* type A-associated diarrheal disease in neonatal pigs. Collins et al. (1989) reported intestinal villi of normal length and morphology with few neutrophil aggregates occasionally observed in the apical lamina propria and large numbers of *C. perfringens*-like bacilli in the lumen. Songer and Uzal (2005) described small intestinal mucosal necrosis with villous atrophy and a fibrinonecrotic pseudomembrane and occasional serositis in low proportion of affected pigs.

Diagnosis

Currently no criteria are available to establish a definitive diagnosis of type A enteritis in pigs. It has been suggested, however, that non-hemorrhagic diarrhea of otherwise unexplained origin and isolation of large numbers of *C. perfringens* type A from affected jejunum or ileum are strongly suggestive of type A disease (Collins et al. 1989). Detection of CPA in gut contents is nondiagnostic because this toxin can be found in the intestinal content of healthy pigs. Currently, no commercial assays are available to detect CPB2, and the significance of finding this toxin in the intestine of pigs is uncertain.

Clostridium difficile-associated disease (CDAD)

Clostridium difficile-associated disease (CDAD) affects numerous animal species with expanded large bowels, including gerbils, guinea pigs, hamsters, horses, rabbits, pigs, and others (Diab et al. 2016). In domesticated animals, CDAD is typically referred to as necrotizing enterotyphlocolitis and, with a few exceptions (notably pigs), is antibiotic associated. In humans, the nature of the typical lesion gives rise to the common name of pseudomembranous colitis. In pigs, CDAD is not antibiotic associated and typically presents at 1–7 days of age as diarrhea and rarely as respiratory distress or sudden death.

Etiology and epidemiology

Clostridium difficile is in cluster XIa (*Peptostreptococcaceae*). It is a gram-positive strict anaerobic rod, and its highly resistant spores are ubiquitous in the environment, being responsible for its long-term survival, transmission, and, to an extent, pathogenesis. *C. difficile* appears as rods, approximately 1.2 µm × 8 µm, that occasionally occur in short chains. Spores are oval and subterminal. *C. difficile* is well known for its widespread contamination of human and animal hospitals and other medical facilities but can be found in surprisingly large numbers in any environment subject to fecal contamination. It is common in the large intestine and feces of domestic animals (particularly herbivores and swine) and, in consequence, can also be found in large numbers in manured soil. It is also common in meats and in vegetables that have been subjected to fecal contamination (Diab et al. 2016; Songer and Uzal 2005).

The vegetative forms of *C. difficile* die readily in an aerobic environment. However, the vegetative cells sporulate readily and the spores are highly resistant to oxygen. In addition, the spores of *C. difficile* are resistant to most common disinfectants, which makes them a sturdy environmental contaminant (Diab et al. 2016).

In pigs, *C. difficile* causes disease mostly between 1 and 7 days of age. The primary source of infection for newborn pigs is spores shed in sow feces or in the contaminated local environment. Route of infection is mostly oral, but spores have also been found in air samples in swine farms, suggesting that inhalation is possible. The prevalence of *C. difficile* is high in neonatal pigs, significantly decreases with age, and is unaffected by antimicrobial use in any age pigs. It can be isolated from

intestinal content of piglets as early as 1 hour after birth with 100% of piglets positive by 3 days postpartum (Songer JG and Post KW, unpublished observations). The prevalence decreases dramatically in nursery-age and older pigs, ranging between 3 and 9%.

Public health

CDAD is the leading cause of antibiotic-associated diarrhea in humans, characterized by syndromes from mild diarrhea to fatal pseudomembranous colitis. Infants are at low risk for disease and can be colonized with either toxigenic or nontoxigenic strains at variable rates worldwide from 4 to 48%, highest among neonates with extended hospitalization. Colonization as an infant can be protective against CDAD later in life. Adults can be colonized without disease. Most cases were previously thought to be nosocomial (i.e. hospital or clinic associated), but with the advent of whole genome sequencing, it is evident that a majority (65%) are community acquired (Warriner et al. 2016). Risk factors for community-acquired CDAD (CA-CDAD) differ from nosocomial CDAD. CA-CDAD occurs in young persons without contact with hospital or clinical environments, but with frequent use of proton inhibitors to reduce stomach acid (Freeman et al. 2010). Source of infection in CA-CDAD is usually unknown. Recent attention has focused on zoonotic or foodborne sources. Toxigenic strains of *C. difficile* are common in pigs, cattle, poultry, dogs, and a variety of other mammals. Contamination of carcasses at slaughter is uncommon and foodborne transmission is unlikely (Warriner et al. 2016). Direct transmission from human carriers or from infected animals has also not been confirmed as a direct cause of CDAD.

Pathogenesis

The pathogenesis of *C. difficile* infections are mediated by toxins A (TcdA) and B (TcdB), both members of the family of large clostridial toxins. A role for a separate ADP-ribosylating toxin (CDTa) also seems likely. The genes for these toxins (*tcdA*, *tcdB*, and *cdtA*) are located chromosomally (Songer et al. 2016). Contrary to CDAD in most animal species, antibiotic administration does not seem to be a significant risk factor in pigs (Diab et al. 2016). Following ingestion spores of *C. difficile* are resistant to the acidity of the stomach, and when they reach the small intestine, bile salts stimulate germination. They subsequently colonize the large intestine, and in some pigs TcdA, TcdB, and CDTa are secreted in amounts sufficient to induce colonic damage and disease.

Clinical signs and lesions

Piglets 1–7 days of age usually present with a history of early-onset scours and rarely with respiratory distress, mild abdominal distension, scrotal edema, or sudden death (Diab et al. 2016).

Figure 51.6 *Clostridium difficile* infection in a neonatal piglet. Edema of the mesocolon. *Source:* Courtesy of Dr. Darin Madson.

Gross lesions are nonspecific. Common lesions include a flaccid cecum and colon filled with fluid or pasty yellow to brown contents and edema of the mesocolon (Figure 51.6). The mucosa of the cecum and colon may be unremarkable or have multifocal-to-coalescing erosions or ulcers with attached fibrinonecrotic exudate. Less commonly, systemic lesions may include ascites, hydropericardium, and hydrothorax and scrotal edema (Bakker et al. 2010; Diab et al. 2016; Hunter et al. 2010; Uzal et al. 2016; Waters et al. 1998; Weese et al. 2010; Yaeger et al. 2002).

Microscopic lesions of CDAD in pigs are limited to the cecum and colon and may be very characteristic, but are not specific. In most piglets there is necrosuppurative or erosive/ulcerative colitis and typhlocolitis. Multifocal erosions of the luminal epithelium are observed in the cecum and colon through which fibrin and neutrophils exude, resembling volcanic eruptions, so-called volcano lesions characteristic of CDAD (Figure 51.7). Similar exudate may be observed in the subjacent lamina propria, and necrosis sometimes extends to involve all layers of the wall in severe cases. The mesocolon may be expanded by clear or pale blue staining fluid and few neutrophils (Songer et al. 2000; Songer and Uzal 2005; Uzal et al. 2016).

Diagnosis

A presumptive diagnosis of CDAD in pigs can be established based on a compatible clinical history, clinical signs, and gross and microscopic findings. Among the latter, mesocolonic edema and necrosuppurative typhlocolitis are highly suggestive of CDAD in piglets. However, a definitive diagnosis of *C. difficile* infection must be based on detection of TcdA and/or TcdB in feces or colonic contents. The reference method is measurement of neutralizable cytotoxicity in monolayers of Chinese hamster ovary or other cells, but most laboratories now use commercially

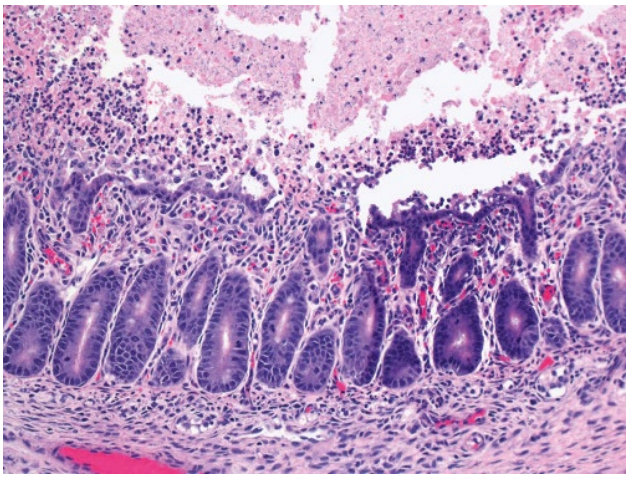

Figure 51.7 *Clostridium difficile* infection in a neonatal piglet. Central erosion of luminal epithelium with fibrinopurulent erupting exudation, so-called volcano lesion; exudate blends with diffuse fibrinosuppurative mucosal exudate.

available enzyme immunoassays (Diab et al. 2016; Songer and Uzal 2005). The finding of toxins must be coupled with compatible clinical signs and postmortem findings because TcdA and/or TcdB have been inconsistently found in the intestinal tract of normal piglets.

Culture of *C. difficile* is of little diagnostic significance because the prevalence of *C. difficile* in the intestinal tract of healthy piglets is relatively high. Culture for *C. difficile* can be somewhat challenging, in that this organism is more strictly anaerobic than some clostridia (Post et al. 2002; Songer et al. 2000). Isolation from feces or other specimens is effective using solid media containing cefoxitin, cycloserine, and fructose, often with taurocholate to initiate spore germination. Colonies are chartreuse under long-wave UV illumination. Most isolates are fully toxigenic, but some produce only TcdB or no toxins at all, and isolation should be followed by toxinotyping of the isolates, usually by PCR.

Treatment and prevention

Immunoprophylaxis of CDAD in domestic animals has not been studied, but precedent in other species suggests that immunity will be antitoxic. Antibodies against TcdA (Allo et al. 1979) and TcdB (Kink and Williams 1998; Viscidi et al. 1983) prevent toxin binding in mouse and hamster models, eliminating secretion, inflammation, and clinical disease. Results of *in vitro* antimicrobial susceptibility testing suggest that tylosin may be effective in treatment of piglets.

Histotoxic infections

Histotoxic clostridial infections are sporadic in swine and are usually exogenous, being associated with wound infections, especially contaminated injection sites, and are collectively known as gas gangrene. However, a small portion caused by *C. chauvoei* (blackleg) or *C. perfringens* type A appear spontaneously and are thought to be endogenous, resulting from oral exposure, where organisms may lie dormant in various tissues until a microenvironment favorable for their growth is generated. Histotoxic clostridial diseases of swine are not zoonotic, hence there is no public health concern.

Gas gangrene

Clostridial wound infections have received different names in the past including gas gangrene, malignant edema, and cellulitis. Because these seem to be variations of the same or similar conditions, in this chapter they will all be dealt here under the generic name of gas gangrene.

Gas gangrene is observed sporadically in pigs and is mostly associated with *C. septicum*, *C. perfringens* type A, *C. novyi* type A, *C. chauvoei*, and *C. sordellii*, acting alone or in combination.

Etiology and epidemiology

C. septicum is the most common etiologic agent of gas gangrene in swine. It is an anaerobic, gram-positive rod that forms oval subterminal spores, is found in soil and feces (Finegold et al. 1983; Kahn 1924; Princewill 1985; Princewill and Oakley 1976; Silva et al. 2016), and is a frequent postmortem invader (MacLennan 1962). Incidence of gas gangrene is particularly high on certain premises that have had large populations of livestock for many years, suggesting that there is a buildup of spore numbers in the environment of these farms. Alpha toxin (ATX), a β-pore-forming member of the aerolysin family, is considered the main virulence factor of *C. septicum* (Silva et al. 2016). The ATX is not related to the alpha toxins (CPA) of *C. perfringens* despite sharing the same name.

Clostridium perfringens type A is among the main etiological agents of gas gangrene in humans. With the use of reverse genetics, it has been demonstrated that CPA and to a lesser extent PFO are the major virulence factors responsible for gas gangrene (Awad et al. 2000). CPA and PFO play local and systemic synergistic roles in myonecrosis produced by *C. perfringens* type A (Awad et al. 2000) as determined from studies in laboratory mice. However, very little is known about the pathogenesis of *C. perfringens* type A-associated gas gangrene in spontaneous infections of animals.

Clostridium novyi type A is a large, strict anaerobic gram-positive rod with subterminal spores. The microorganism produces several toxins, of which alpha toxin (TcnA) is thought to be mainly responsible for the role of this microorganism in gas gangrene (Popoff 2016c). TcnA is not related to ATX of *C. septicum* or CPA of *C. perfringens* type A.

Clostridium chauvoei is a pleomorphic, anaerobic, gram-positive rod that readily forms central of subterminal spores. It causes blackleg (Abreu and Uzal 2016; Burke and Opeskin 1999; Kuhnert et al. 1996), an emphysematous necrotizing myositis that resembles malignant edema mostly in cattle. This microorganism is also a component of the gas gangrene complex in cattle and several other species, including pigs (Silva et al. 2016). Among its several virulence factors, CctA seems to be most important in virulence (Popoff 2016c).

Clostridium sordellii is another pleomorphic, anaerobic, gram-positive rod that readily forms central of subterminal spores. It produces several toxins of which the lethal toxin (TcsL) and hemorrhagic toxin (TcsH) seem to be the most important virulence factors (Popoff 2016c).

Pathogenesis

Most cases of gas gangrene originate from wounds, injection sites being among the most common type, and local tissue damage favors establishment of the infection. Source of the offending *Clostridium* spp. in injection sites can be contaminated syringes, needles, or skin or uncommonly reuse of contaminated injectable products. Lesions are largely the result of the necrotizing effect of ATX of *C. septicum*, CPA of *C. perfringens* type A, TcnA of *C. novyi*, CctA of *C. chauvoei*, and/or TcsL and TcsH of *C. sordellii* (Silva et al. 2016). Hyaluronidase may cause disappearance of the endomysium (Aikat and Dible 1960), which may aid spread of the infection through the muscle. Toxemia is probably the ultimate cause of death.

It has been suggested that as in the case of blackleg, the source of infection in cases of *C. perfringens* type A gas gangrene is in many cases endogenous (i.e. the result of organisms lying dormant in tissues that proliferate when the local environment is favorable), with most cases preceded by localized trauma. However, final evidence to support this claim is lacking. High intraherd incidence of *C. perfringens* type A-associated gas gangrene in young piglets is often a complication that follows injection of iron-containing preparations for prevention of nutritional anemia. Anecdotal evidence supports a view that such injections create a tissue microenvironment that favors growth of *C. perfringens* (Jaartsveld et al. 1962; Taylor and Bergeland 1992) in pure or mixed culture. The case fatality rate approaches 50%.

Clinical signs and lesions

Gas gangrene is nearly always acute and is often fatal in less than 24 hours, although some animals may live longer or survive. Hemorrhage, edema, and necrosis develop as the infection spreads along muscular fascial planes. Common sites include the inguinal and ventral abdominal region, the head and ventral cervical area, and the shoulder. Animals are reluctant to bear weight on affected limbs, and skin overlying the swollen area has a blotchy reddish-purple discoloration (Figure 51.8). Tissues that are initially painful and warm, with pitting edema, become rapidly crepitant and cold. In the terminal stage, affected swine lie in lateral recumbency and commonly groan during forced expiration.

Swelling at the primary infection site overlies subcutaneous edema that may be colorless or tinted with sanguineous fluid. Adjacent skeletal muscle may be edematous, with essentially normal color, or may be black, dry, and crepitant (Figure 51.9). Regional lymph nodes are typically enlarged and hemorrhagic and emphysematous. Acute fibrinohemorrhagic peritonitis is common, the spleen may be slightly enlarged, and there may be moderate pulmonary edema and congestion. Varying amounts of blood-tinged fluid and fibrin may be found in the pleural cavity and pericardial sac. Postmortem accumulation of subcutaneous gas may progress until the subcutis of the entire carcass is emphysematous (Silva et al. 2016). Animals that survive the

Figure 51.8 *Clostridium septicum* gas gangrene in a pig. Observe clearly demarcated dark discoloration of the skin. *Source:* Courtesy of Dr. Greg Stevenson.

Figure 51.9 *Clostridium septicum* gas gangrene in a pig. Diffuse necrotizing and emphysematous myositis. *Source:* Courtesy of Dr. Greg Stevenson.

acute infection may show loss of skin and subcutaneous tissue with exposure of underlying muscle.

Microscopically, the edematous subcutis contains large numbers of degenerating acute inflammatory cells and few to many bacteria. Septic thrombi in subcutaneous veins and lymphatics are commonly found. Affected skeletal muscle fibers undergo coagulation necrosis with fragmentation and lysis, and bacteria are readily found between degenerating muscle fibers (Silva et al. 2016).

Clostridium perfringens type A-associated uterine gangrene and decomposition of its contents may follow dystocia and attempts to assist with delivery. Foul-smelling, reddish watery vulvar discharge may be seen, and death ensues in 12–24 hours. The uterus is usually dark green or black, is malodorous, and contains gas bubbles. There may be foul-smelling reddish fluid in the peritoneal cavity. Decomposition of the remainder of the carcass is rapid, and lesions are rarely identified in other sites.

Diagnosis

A presumptive diagnosis is based upon typical history of rapid progression and gross lesions. Laboratory confirmation is achieved by detection of the microorganisms involved by any of the methods described below. Bacteria can be observed in direct smears of affected subcutis or muscle, and fluorescent-labeled antibody staining is a rapid and accurate method to positively identify the species of clostridia present (Batty and Walker 1963; Silva et al. 2016). Bacteriologic culture is an effective alternative confirmatory method if done by a qualified veterinary microbiologist. However, culture can be time consuming (Martig 1966). For culture, care must be exercised in collection of samples to prevent fecal contamination as clostridia originating from the intestine may overgrow primary pathogens and/or result in false-positive tests. Also, swarming of *C. septicum* may cause small numbers of the organism to appear predominant, resulting in a false-positive diagnosis. Confirmation can also be by immunohistochemistry for each of the *Clostridium* spp. that can be performed on formalin-fixed, paraffin-embedded tissues. Polymerase chain reaction is a very sensitive and specific diagnostic test that can be performed on fresh or formalin fixed tissues.

Treatment and prevention

Prevention is preferred to treatment, given the fulminant clinical course. Sanitary procedures should be followed when making injections or performing surgery, and housing and equipment should be maintained free of exposed sharp objects. Immunization against toxin antigens provides lifelong immunity (Green et al. 1987), and use of vaccines may be considered on premises where the disease recurs. Treatment with antimicrobials may be successful if applied early (Zeller 1956). Experimental prophylactic use of tetracyclines, penicillin, or chloramphenicol prevents disease in mice (Taylor and Novak 1952).

Blackleg

Blackleg is a disease typically described in young cattle and rarely in other animal species, with an endogenous pathogenesis and produced exclusively by *C. chauvoei* (Abreu and Uzal 2016). There have been very few substantiated reports of blackleg in swine (Eggleston 1950; Gualandi 1955; Sterne and Edwards 1955), and information about the condition in this species is minimal.

Etiology and pathogenesis

Blackleg is produced exclusively by *C. chauvoei*. See section on gas gangrene for a brief description of this microorganism and its virulence factors. Pathogenesis of *C. chauvoei* infection in pigs has been little explored. It is believed that infection may be by the oral route rather than beginning as a wound infection as in the case of gas gangrene. If this is the case, the organisms may lie dormant in various tissues until a microenvironment favorable for their growth is generated; this microenvironment is thought to be induced by localized trauma. The disease has occurred in swine kept under poor hygienic conditions on premises with previous losses of cattle from blackleg (Gualandi 1955; Sterne and Edwards 1955). Disease may follow consumption by swine of meat from blackleg-affected calves (Eggleston 1950), and in these cases swelling of the face and throat is prominent.

The roles of toxin A (TccA), which is necrotizing, hemolytic, and lethal, and beta toxin, a DNase (Ramachandran 1969), have not been fully defined. Flagellar expression is associated with virulence, and phase variation occurs in motility and flagellation (Tamura et al. 1995). Flagella are apparently immunogenic (Kojima et al. 2000; Verpoort et al. 1966).

Clinical signs and lesions

Signs include high fever, anorexia, depression, and lameness, with crepitant lesions and sudden death. Lesions are thought to be more common in legs (Mavenyengwa and Matope 1995). Gross lesions are often dry and emphysematous at the center, but edematous, hemorrhagic, and necrotic at the periphery. Microscopically, lesions are similar to those described in cattle and consist of myofiber necrosis with little leukocytic infiltration (Abreu and Uzal 2016).

Diagnosis, treatment, and prevention

A diagnosis of blackleg can be made only by bacterial identification, due to similarities in the clinical presentation and pathology of other histotoxic clostridial infections. The fluorescent antibody test, applied to impression smears of infected tissue, is a rapid and practical method of identification (Batty and Walker 1963; Uzal et al. 2016). Bacterial isolation may be difficult in

decomposing specimens, since *C. chauvoei* is easily overgrown by other bacteria, including *C. septicum*. Polymerase chain reaction is also available to detect this microorganism on fresh or formalin fixed tissues.

Prevention of *C. chauvoei* infection requires minimizing exposure. *C. chauvoei* is not known to be a common soil organism, but anecdotal evidence suggests that keeping swine on known contaminated premises or allowing them to eat carcasses of ruminants dead of blackleg are risk factors.

Neurotoxigenic clostridia

Neurotoxic clostridial diseases include tetanus caused by *C. tetani* and botulism caused by *T. botulinum*. Neither disease is zoonotic; hence there is no public health concern.

Tetanus

Clostridium tetani causes tetanus, characterized by toxin-mediated, uncontrollable spasms of voluntary muscles. Swine of all ages may be affected, but most cases involve young pigs and originate with castration wounds or umbilical infection (Popoff 2016b).

Etiology and epidemiology

Clostridium tetani is a slender, anaerobic, gram-positive rod. It forms terminal spores that are ubiquitous in the environment. Spores often enter via traumatic wounds, including, but not limited to, those from tail docking and castration (Popoff 2016b). Sows may be infected by contamination of uterine prolapses.

Pathogenesis

Development of tetanus depends upon the presence of *C. tetani* in a tissue environment that will support spore germination, vegetative cell growth, and toxin production. Spores usually gain entrance via a deep penetrating wound. Spore germination is facilitated by the presence of foreign bodies or facultative anaerobes that reduce oxygen tension in tissues. Bacterial multiplication and production of the primary toxin tetanospasmin (TeNT) is enhanced by tetanolysin, a cholesterol-binding toxin that inhibits neutrophil and macrophage chemotaxis and causes local tissue necrosis. Spores may remain latent in healed wounds for 10 years or more. *C. tetani* is not invasive and remains localized at the primary site of infection (Popoff 2016b).

Toxin-containing vesicles pass by retrograde axonal transport along the motor nerve fibers from neuromuscular junctions at the site of the infection, acting eventually on the inhibitory neurons in the ventral horn of the spinal cord. The TeNT cleaves synaptobrevin, a protein involved in the exocytosis of neurotransmitters by neurons, resulting in tetany.

Clinical signs and lesions

Tetanus is characterized by generalized skeletal muscle spasms. The incubation period ranges from several days to several weeks. In general, shorter incubation periods are associated with a more acute and fulminating course and a higher fatality rate.

The earliest sign is a stiffened gait, and disease progresses rapidly over 1–2 days. Ears become erect, the tail extends straight out, the head is slightly elevated, and the nictitating membrane may protrude. The pig becomes incapable of walking, and the skeletal muscles are very firm on palpation. Ultimately, the pig lies in lateral recumbency in opisthotonus, with front and rear legs extended posteriorly. Tetanic spasms proceed from periodic to continuous and are noticeably heightened by sudden sensory stimuli. Tachycardia and increased respiration rate are common terminal signs, and white froth may be present around the mouth and external nares (Popoff 2016b).

In acute cases, respiratory failure resulting from severe skeletal muscle spasms is likely to be the single most important cause of death. Prolonged recumbency and nutrient deprivation may be factors contributing to death in animals with a relatively long survival time. Animals dying of tetanus do not show specific gross or microscopic lesions. Deep wounds associated with the port of entry may be found; although these support the diagnosis, they are not diagnostic in themselves.

Diagnosis

Diagnosis is based upon typical clinical signs. An obvious area of infection (e.g. a castration wound or umbilical abscess) may be apparent. Identification of typical rods with terminal spores on Gram-stained smears of a wound lends credibility to a diagnosis of tetanus (Popoff 2016b). The organism may be isolated by bacteriologic culture or identified by immunofluorescence (Batty and Walker 1963) from suspect wounds, but this is usually not necessary if there is adequate antemortem clinical observation of the affected animals.

Treatment and prevention

There is no practical way to eliminate spores from soil, so control is directed toward prevention of wound contamination by soil or feces. Good sanitation in the farrowing house, treatment of umbilical cords with antiseptics soon after birth, sanitary practices for castration and other surgeries, and treatment of wounds with antiseptics and affected animals with prophylactic parenteral antibiotics are recommended preventive measures against tetanus. Sharp objects that may cause wounds should be removed from the environment.

Passive immunization with tetanus antitoxin, prophylactic use of antibiotics, and/or active immunization with tetanus toxoid may be indicated. Prophylactic use of

large doses of long-acting penicillin or tetracyclines may be superior to antitoxin in preventing experimental tetanus if treatment is instituted within a few hours after infection (Veronesi 1966). Active immunity may be obtained from a single injection of alum-precipitated tetanus toxoid, and excellent protection for a year or more can be expected if three doses are given several weeks apart.

With even moderate clinical tetanus, prognosis is poor, and there is little evidence that treatment is of real benefit. Various suggested treatments include reopening castration wounds and flushing them with hydrogen peroxide, administration of antitoxin to neutralize toxin not already fixed by nervous tissue, administration of antibiotics, and the use of tranquilizers or barbiturates as muscle relaxants.

Botulism

Botulism is mostly produced by *C. botulinum*. This microorganism may produce seven botulinum neurotoxins (BoNTs), which are different protein neurotoxins that are immunologically distinct and are identified by letters from A to G. A novel type, BoNT/H, which seems to be a hybrid between BoNT/F and BoNT/A, has been reported but awaits further characterization (Popoff 2016a). Nevertheless, all BoNTs cause the typical flaccid paralysis of botulism in experimental animals, similar to that observed in humans and domestic and wild animals suffering from botulism (Popoff 2016a). Each of the BoNTs has unique geographic distribution and species susceptibility patterns (CDC 1998; Hatheway 1990, 1995; Shapiro et al. 1998; Smith 1977; Smith and Milligan 1979). Swine are susceptible to botulism but are in general considered to be among the least susceptible domestic animals.

Etiology and epidemiology

C. botulinum is strictly anaerobic and gram positive (Smith and Holdeman 1968) and forms oval, usually subterminal, spores. Growth is optimal at about 86 °F (30 °C). Spores are ubiquitous in soil throughout the United States (Kelch et al. 2000; Smith 1979; Whitlock and Williams 1999).

Botulism in swine is rare, so there are few recorded organism or toxin sources, but disease in swine due to consumption of dead fish (Beiers and Simmons 1967) and decomposing brewers' waste (Doiurtre 1967) has been reported. Disease in other species is associated with contaminated forage (Franzen et al. 1992; Kelly et al. 1984; Kinde et al. 1991; Le Maréchal et al. 2016; Popoff 2016a; Ricketts et al. 1984; Whitlock 1997; Wichtel and Whitlock 1991), contamination of grain by decomposing animal carcasses (Divers et al. 1986; Enfors et al. 1975; Galey et al. 2000; Whitlock and Williams 1999), or transport of BoNT by ravens or crows feeding on a decomposing carcass (Schoenbaum et al. 2000). Type D botulism has been linked to pica, in which phosphorus-deficient animals consume bones of carcasses of animals dead of botulism (Dobereiner et al. 1992).

Eating habits of non-confined pigs should make them likely candidates for botulism, but there appears to be innate resistance to toxin administration by the oral route. The swine GI tract may have a low permeability for botulinum toxin (Dack and Gibbard 1926; Scheibner 1955; Smith et al. 1971).

Pathogenesis

Potency of botulinum toxin varies among toxin types, and amount of toxin produced varies with strain. Botulism occurs after ingestion of preformed BoNT or by dissemination of toxin from an infected wound or focus of clostridial multiplication in the GI tract or elsewhere (Bernard et al. 1987; Hatheway 1995; Swerczek 1980). Absorption varies among species and with different areas of the GI tract (May and Whaler 1958).

Botulinum toxin is composed of an enzymatic light chain (a zinc-dependent endopeptidase) and a heavy chain that binds to receptors and facilitates internalization. The light chain cleaves proteins involved in exocytosis of neurotransmitters by neurons. Toxin types B, D, and F cleave synaptobrevin, types A and E act on SNAP-25, and type C toxin acts on syntaxin at the myoneural junction, preventing muscular contraction. Death is generally ascribed to asphyxia resulting from paralysis of the muscles of respiration.

Clinical signs and lesions

The latent period between consumption of toxic material and onset of signs ranges from 8 hours to 3 days or more, largely determined by the amount of toxin consumed (Beiers and Simmons 1967; Smintzis and Dunn 1950). Initial signs are weakness, incoordination, and staggering, with weakness appearing first in the forelegs, followed by involvement of the hind legs and general motor paralysis and dilation of the pupils (Smith et al. 1971). The clinical effect is progressive flaccid paralysis of voluntary muscles, which manifests in the end as lateral recumbency with complete flaccidity. Other clinical signs include anorexia, reduced vision or complete blindness, aphonia, excessive salivation, involuntary urination, and deep labored breathing (Beiers and Simmons 1967; Smintzis and Dunn 1950). There are no specific gross or microscopic lesions.

Diagnosis

A diagnosis of botulism should be considered in afebrile, alert animals with progressive weakness and recumbency. Because the pig apparently is quite highly resistant to botulism, a diagnosis should be made only after

thorough investigation and exclusion of other possible diagnoses (Beiers and Simmons 1967). Confirmation of the diagnosis should be based on detection of BoNT in feed, GI contents, liver, or serum. Mouse bioassay is still the test most frequently used around the world, although the sensitivity of the test is usually low. The sensitivity of this test for mammals is highest for feed, intermediate for GI content and liver, and lowest for serum (Le Maréchal et al. 2016; Muller 1967; Narayan 1967; Yamakawa et al. 1992).

Treatment and prevention

If botulism is suspected, an effort should be made to find the toxin source and prevent further consumption of suspect material by the herd. Antitoxin is the only specific treatment for botulism, and it has been effective in reducing mortality in humans after consumption of toxin-containing food (Lamanna and Carr 1967; Le Maréchal et al. 2016). Polyvalent antitoxins incorporating the types most commonly present in a geographic area are required for therapy in animals. Therapy aimed at reducing continued absorption of toxin from the intestine (administration of magnesium sulfate) might be helpful.

Prevention requires eliminating opportunities to consume potentially toxic material such as spoiled garbage and decomposing animal tissue. Prophylactic immunization with toxoids is not practical in swine because of the infrequent occurrence of the disease.

Colibacillosis

John M. Fairbrother and Éric Nadeau

Relevance

Diseases caused by *Escherichia coli* have been a recognized problem for as long as pigs have been raised. Early work in the 1960s and 1970s elucidated the pathogenic mechanisms of *E. coli*-induced neonatal diarrhea and led to the development of sow vaccines that effectively control this form of the disease by passive immunity. However, maternal vaccination does not protect pigs against the diarrhea and edema disease (ED) that occur in the post weaning period.

More recent advances in our understanding of how *E. coli* cause disease have led to a better classification of pathogenic strains based on the presence of virulence factors, permitting much more accurate diagnostic strategies, as opposed to traditional serotyping identifying the *E. coli* O and H types. Antimicrobial resistance is at a crisis point for pig producers because of limited treatment options and an increased public health concern due to the potential transfer of drug resistance genes directly by contact and indirectly into the food chain, water, manure, etc. This has provided the impetus to find alternative control strategies such as novel vaccines for weaned pigs.

All over the world, *E. coli* is an important cause of a wide range of diseases in pigs, including neonatal diarrhea, post weaning diarrhea (PWD), ED, septicemia, polyserositis, coliform mastitis (CM), and urinary tract infection (UTI). In particular, diarrhea and ED due to *E. coli* may result in significant economic losses due to morbidity, mortality, decreased weight gain, and cost of treatment, vaccinations, and feed supplements. *E. coli* PWD is also called post weaning enteric colibacillosis. Edema disease is also known as "bowel edema" or "gut edema" because edema of the submucosa of the stomach and the mesocolon is often a prominent feature of the disease. *E. coli* PWD and ED may occur independently, but they may also occur together in a single outbreak or in the same pig. PWD is endemic in many farms and its prevalence fluctuates over time and across regions. A more severe form of enteric *E. coli* infection may be observed at 2–3 weeks following weaning and is manifested as sudden death or severe diarrhea.

Postpartum dysgalactia syndrome (PPDS) or mastitis–metritis–agalactia (MMA) is an economically important disease complex characterized by reduced milk production postpartum, leading to pig starvation (see Chapter 18 for a more detailed discussion of this syndrome). Mastitis is the most important component, and coliforms, predominantly *E. coli*, are the most frequently isolated bacteria in affected sows. The term "coliform mastitis" is used to refer to puerperal mastitis in the pig.

UTI is present whenever microbes colonize any of the typically sterile sections of the urinary tract. It may or may not be accompanied by clinical or subclinical disease. In the pig, specific UTI caused by *Actinobaculum suis* (Chapter 64) is distinguished from nonspecific UTI caused by a variety of microbes, the subject of this chapter. According to Liebhold et al. (1995), a nonspecific UTI often predisposes for *A. suis* infection.

Certain *E. coli*, particularly those of serotype O157:H7, serogroup O26, and other non-O157 *E. coli*, may be present sporadically in the intestines and feces of normal pigs and are considered as zoonotic.

Etiology

Taxonomy, morphology, and laboratory cultivation

The genus *Escherichia* is named after the German pediatrician Theodor Escherich (1857–1911). It is classified with the family *Enterobacteriaceae*, which consists of gram-negative facultatively anaerobic rods. The species *E. coli* includes normal inhabitants of the gastrointestinal tract and strains causing a broad variety of intestinal and extraintestinal diseases in swine.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Escherichia coli are gram-negative, peritrichously flagellated rods of variable length and with a diameter of about 1 µm. Colonies on solid media reach their full size within 1 day of incubation and vary from smooth to rough or mucoid. A wide range of selective media is available for growth of *E. coli*. Hemolysis, although not itself a significant virulence factor in enterotoxigenic *E. coli* (ETEC) and edema disease *E. coli* (EDEC), is frequently used as a marker for pathogenicity in isolates of these pathotypes producing the F4 (K88) or F18 adhesin and certain isolates producing F6 (987P). All other ETEC and an increasing number of ETEC isolates producing F4 from pigs are nonhemolytic.

Species identification may be on biochemical characteristics, although there is no differentiating biochemical test for which 100% of strains give a positive reaction. Commercially available identification kits therefore make use of up to 50 tests to achieve a high level of accuracy. Many larger diagnostic laboratories now use MALDI-TOF mass spectrometry that generates a spectral signature that is compared with a database for the identification of the microorganism. The determination of DNA relatedness, the scientific base of discrimination between species, is restricted to research laboratories.

Classification

Over the decades, several classification systems have been developed to subdivide the species into types. Serotyping is an established typing system to identify pathogenic *E. coli* strains, and serotypes have shown good association with certain virulence traits. Complete serotyping includes determination of the surface O (somatic; polysaccharide), K (capsular or microcapsular), H (flagellar), and F (fimbrial) antigens. Unlike salmonellae, only a small percentage of *E. coli* isolates are typable with available antisera, since serotyping has been limited to isolates of proven or suspected pathogenicity. Presently, at least 188 O, 103 K, 56 H, and over 20 F antigens are officially recognized. A serogroup refers to strains that share only one of these antigens (e.g. serogroup O149), whereas a serotype refers to strains sharing a combination of these antigens (e.g. serotype O149:H10). Although certain porcine pathogenic *E. coli* belong to a limited number of serotypes, serotyping is less used today for diagnostic purposes having been replaced by direct detection of genes coding for bacterial traits involved in pathogenesis of disease, called virulence factors. The term pathotype is used to identify types of *E. coli* on the basis of their virulence mechanism as indicated by the presence of particular virulence factor combinations, which characterize the way in which disease is caused. This system identifies broad classes or categories of pathogenic *E. coli*, such as ETEC; Shiga toxin-producing *E. coli* (STEC), which includes the EDEC and enterohemorrhagic *E. coli* (EHEC); enteropathogenic *E. coli* (EPEC); and extraintestinal pathogenic *E. coli* (ExPEC) (Gyles and Fairbrother 2010). Detection of virulence factors is important for the identification of pathogenic *E. coli*, and the term virotype is now used to refer to the combination of these factors for a particular isolate. Table 52.1 summarizes important pathotypes of *E. coli*

Table 52.1 Important pathotypes, adhesins, toxins, and serogroups of pathogenic *E. coli* in pigs.

Pathotype	Adhesins	Toxins	O serogroups	Diseases
ETEC	F5(K99), F6(987P), F41	STa	O8, O9, O20, O64, O101	Neonatal diarrhea
	F4(K88)	STa, STb, LT, EAST1, α-hemolysin	O8, O138, O141, O145, O147, O149, O157	Neonatal diarrhea Diarrhea in young pigs preweaning
	F4(K88), AIDA, unknown	STa, STb, LT, EAST1, α-hemolysin	O8, O138, O139, O141, O147, O149, O157, O?:K48	Post weaning diarrhea
	F18, AIDA	STa, STb, LT, Stx(VT), EAST1, α-hemolysin	O8, O138, O139, O141, O147, O149, O157	
EPEC	Eae (intimin)		O45, O103	
STEC (VTEC)	F18, AIDA	Stx2e(VT2e), EAST1, α-hemolysin	O138, O139, O141, O147	Edema disease
	Eae (intimin)	Stx1 and/or Stx2	O157	None in pigs, bloody diarrhea and hemolytic uremic syndrome in humans
ExPEC	P, S	CNF	O6, O8, O9, O11, O15, O17, O18, O20, O45, 060, O78, O83, O93, O101, O112, O115, O116	Colisepticemia/polyserositis
	P, S	CNF	O1, O4, O6, O18	Urogenital infection

and their common virulence factors and serogroups as well as diseases they cause.

Enterotoxigenic *E. coli* (ETEC)

ETEC is the most important pathotype in pigs and includes strains that elaborate one or several enterotoxins that induce secretory diarrhea (Fairbrother et al. 2005; Gyles and Fairbrother 2010). Two major classes of enterotoxin are produced by porcine ETEC: heat-stable toxin (ST) and heat-labile toxin (LT). Heat-stable toxin has been further divided into STa (also called STI, ST1, or STaP) and STb (also called STII or ST2) based on solubility in methanol and biological activity. Likewise, two subgroups of LT, LTI and LTII, have been described. The enteroaggregative heat-stable toxin 1 (EAST1) is widespread among porcine ETEC. The role of this toxin in porcine diarrhea remains controversial as, alone, EAST1 does not seem capable to produce disease, but together with LT it is efficient in producing diarrhea. The *E. coli* enterotoxins and their activity have been reviewed in detail elsewhere (Dubreuil et al. 2016; Gyles and Fairbrother 2010).

ETEC must attach to the apical surface of small intestinal mucosal epithelial cells or the adjacent mucus layer in order to colonize and produce a combination of enterotoxins in the microenvironment of the glycocalyx. The level of intestinal colonization determines whether or not disease will result from infection. Bacterial cells attach by fimbrial adhesins that are hairlike appendages composed of protein subunits, extending from the bacterial cell (Figure 52.1). Fimbriae are classified by serologic reactivity and over 20 types have been identified. Of these, F5 (K99), F6, and F41 are generally isolated from neonatal diarrhea, F4 from both neonatal diarrhea and PWD, and F18 from PWD and ED.

Figure 52.1 Electron micrograph of fimbrial attachment typical of enterotoxigenic *E. coli* (ETEC) in the intestine. Hairlike fimbriae extend from the surface of bacterial cells that are located approximately half a bacterial width away from the microvilli of intestinal epithelial cells.

Neonatal ETEC

ETEC that cause neonatal diarrhea usually produce only STa and may have one or more of the fimbriae F4, F5, F6, and F41. The prevalence of F4-, F5-, and F6-fimbriated ETEC from neonatal diarrhea cases from various studies was recently reviewed, showing both temporal and geographic variations (Dubreuil et al. 2016). Of these, the F4-ETEC most often belong to the serogroups O149, O8, O147, and O157, and the F5-ETEC, F6-ETEC, and F41-ETEC to serogroups O8, O9, O64, and O101 (Gyles and Fairbrother 2010).

Post weaning ETEC

ETEC that cause diarrhea in post weaning or older suckling pigs typically produce one or more of the enterotoxins including STa, STb, LT, and EAST-1 (Zhang et al. 2007). These PWD strains usually have either F4 or F18 as fimbrial adhesin (Fairbrother et al. 2005; Francis 2002; Frydendahl 2002; Luppi et al. 2016; Mainil et al. 2002; Zhang et al. 2007). However, some F4- and F18-negative PWD virotypes have been identified, the most important of which are shown in Table 52.2 (Do et al. 2006; Frydendahl 2002; Jahanbakhsh et al. 2016; Liu et al. 2014; Wang et al. 2011). The role of these F4- and F18-negative virotypes in the development of diarrhea has not yet been established. ETEC isolates of the STb or STb:EAST-1 virotypes from weaned pigs may also produce a non-fimbrial adhesin involved in diffuse adherence (AIDA-I) (Mainil et al. 2002; Ngeleka et al. 2003), originally detected in *E. coli* isolates from humans with diarrhea.

The fimbriae F4 and F18 have several variant subtypes based on antigenic differences. For F4 variants ab, ac, and ad have been described. However, almost all belong to F4ac and are often referred to simply as F4. For F18 there are two known variants, ab and ac. Though early studies associated the F18ac variant with ETEC causing PWD and F18ab with F18-ETEC causing ED, with some exceptions, a more recent report showed that both variants may be involved in causing PWD or ED in pigs (DebRoy et al. 2009). At present in PWD, most F4-positive isolates

Table 52.2 Common serovirotypes of pathogenic *E. coli* from pigs with post weaning diarrhea or edema disease.

Fimbrial adhesin	Serovirotypes
F4	O149:LT:STb:EAST-1, O149:LT:STa:STb:EAST-1, O149:LT:STb, O?:STa:EAST-1:Stx2e
F18	O149:LT:STb:EAST-1, O138:STa:STb, O138:LT:STb:EAST1:Stx2e, O139: Stx2e:(AIDA), O147:STa:STb:AIDA, O?:STa:STb, O?:STa:STb:Stx2e
Not known	O?:STa:STb, O?:STb:EAST-1:AIDA, O?:LT:STb:EAST-1:AIDA, O45/O?:Eae:(EAST-1)

Note: Virulence factors in parentheses are not always present when tested and are not always tested for in all laboratories.

are O149, whereas F18 isolates are more heterogeneous and include serogroups O139, O138, O141, O147, and O157. Common serovirotypes of pathogenic ETEC from pigs with PWD are listed in Table 52.2.

Certain strains produce enterotoxins and Stx2e (see STEC below), as well as either of the fimbrial variants F18ab and F18ac. These strains are classified as ETEC rather than STEC, since they produce clinical PWD more than ED. Mixed infections of F18-STEC and F4-ETEC may be observed. In these cases, the predominant clinical sign is often diarrhea caused by the F4-ETEC, although histopathological evidence of ED may be present. Mixed infections of F18-ETEC and F4-ETEC are also observed.

ETEC may also be associated with secondary septicemia, particularly in older piglets. These isolates most frequently belong to the serovirotypes listed in Table 52.2.

Enteropathogenic *E. coli* (EPEC)

Another pathotype of *E. coli* found in pigs with PWD is known as EPEC. EPEC were initially associated with diarrhea in children, especially in developing countries. These bacteria do not attach by fimbria; rather they have a complex secretion system that injects over 20 effector proteins into the host enterocyte, leading to intimate adherence of the bacteria to the host intestinal epithelium and to development of a characteristic "attaching and effacing" (AE) lesion (Figure 52.2). EPEC, which induce formation of AE lesions, are called attaching and effacing *E. coli* (AEEC). EPEC from different animal species may have different virulence factors, but all possess a variant of the AE factor Eae or intimin, a bacterial outer membrane protein adhesin that is responsible for intimate attachment. Hence, the presence of Eae (intimin) is indicative of an EPEC. EPEC do not possess any virulence factors of classic ETEC PWD or ED strains (Zhu et al. 1994).

Figure 52.2 Electron micrograph of intimate attachment by enteropathogenic *E. coli* (EPEC) and typical attaching and effacing (AE) lesions. Bacteria attach intimately to the apical intestinal epithelial cell membrane, induce dense regions in the apical cell cytoplasm, and efface cell microvilli.

Shiga toxin-producing *E. coli* (STEC), edema disease *E. coli* (EDEC), and enterohemorrhagic *E. coli* (EHEC)

STEC produces one or more of a family of cytotoxins that are known as Shiga toxins (Stx) or verotoxins (VT) (Mainil 1999). The two names are used interchangeably in the literature. Many STEC without fimbriae are probably not pathogenic, but are present in the normal intestinal microbiota in pigs. In pigs the most important STEC are those that cause ED; these are known as EDEC. These strains produce the Shiga toxin variant Stx2e (VT2e) and may possess the fimbrial variant F18ab or F18ac (DebRoy et al. 2009). Common serovirotypes of EDEC are listed in Table 52.2. Another subgroup of STEC, also known as EHEC, is highly pathogenic in humans (e.g. O157:H7). Most EHEC are AE, also possessing Eae and the same secretion system as EPEC.

Some zoonotic EHEC are occasionally recovered, at a low rate, from pigs (see section "Public Health").

E. coli causing fatal shock

Enteric colibacillosis complicated with shock also occurs in young pigs before and after weaning. *E. coli* associated with this disease are usually F4-ETEC (serogroup O149, O157, or O8) (Faubert and Drolet 1992) or Stx2e-producing *E. coli* that are associated with ED.

Extraintestinal pathogenic *E. coli* (ExPEC)

ExPEC are a heterogeneous group of *E. coli* so named because their normal habitat is in the intestinal tract yet they are able to invade, cause bacteremia, and induce septicemia or localized extraintestinal infections such as meningitis or arthritis (Fairbrother and Ngeleka 1994). In contrast to ETEC, EPEC, and STEC, they are not characterized by a constant group of virulence factors. Rather they possess a large number of virulence factors that vary greatly between strains. They often possess fimbrial antigens of the P, S, and F1C families that contribute to bacterial colonization (Dozois et al. 1997) as well as cytotoxins such as hemolysin and cytotoxic necrotizing factor (CNF). They usually contain one and sometimes several iron capturing systems, such as aerobactin, which permit them to survive in the blood and other tissues outside the intestines (Gyles and Fairbrother 2010). ExPEC possess lipopolysaccharides (LPS) (O-antigen) and capsules (K-antigens), which protect the bacteria against killing by serum complement and phagocytes.

Serogroups O6, O8, O9, O11, O15, O17, O18, O20, O45, O60, O78, O83, O93, O101, O112, O115, and O116 have most commonly been identified in isolates associated with septicemia (Gyles and Fairbrother 2010).

Coliform mastitis (CM) *E. coli*

CM in sows appears to be from fecal contaminants and is noncontagious. Multiple serological types of *E. coli* isolates from cases of mastitis may be found within a herd, between distinct glands of one sow, or even between subcomplexes within one gland (Awad-Masalmeh et al. 1990; Morner et al. 1998). Heterogeneity of mastitis isolates has also been demonstrated by random amplified polymorphic DNA genotyping (Ramasoota et al. 2000). This great variety of coliform bacteria associated with CM indicates an abundant reservoir of potentially pathogenic bacteria. One study demonstrated the presence of ExPEC virulence genes in *E. coli* isolates from both CM cases and healthy sows, suggesting a role for other factors in CM (Gerjets et al. 2011).

Nonspecific urinary tract infection (UTI) *E. coli*

One or more of a number of bacterial species may cause nonspecific UTI, including *E. coli*. *E. coli* isolates from UTI in pigs have not been well characterized. Isolates from pyelonephritis in pigs differ from those of human uropathogenic isolates with respect to virulence profile, being rarely hemolytic and less frequently possessing P and F1C fimbriae (Krag et al. 2009).

Genetics of virulence

In most *E. coli* diseases, virulence genes determine pathogenicity and are encoded by plasmids, bacteriophages, or pathogenicity islands (PAIs) (Gyles and Fairbrother 2010). These genes are plasmid-encoded for enterotoxins and fimbriae or pili, phage-encoded for Stx, and PAI-encoded for the AE lesion. In strains from most extraintestinal infections, however, the genes encoding for fimbriae, cytotoxins, and hemolysin are chromosomally located. In the laboratory plasmids can easily be transmitted from donor to recipient strains. However, such exchanges of genetic material do not appear to play a major role in the field as the genetic makeup of pathogenic *E. coli* strains is remarkably stable. This may be because a whole set of virulence factors is involved in the virulence of a particular strain, and certain recipient strains may not express transmitted plasmid-determined functions. The clinically important development of antimicrobial resistance is an exception to this observation.

Public health

Certain EHEC, particularly EHEC O157:H7, O26, and other non-O157 serogroups, may be present sporadically in the intestines and feces of normal pigs and are zoonotic, as they may cause bloody diarrhea, hemorrhagic colitis, and/or hemolytic uremic syndrome in humans infected through food or water contaminated by animal feces (Fairbrother and Nadeau 2006). Pigs are not considered a major source of O157 EHEC, the prevalence rate being usually very low. Cattle and other ruminants are the main reservoir of zoonotic EHEC. ED bears some similarity to the human diseases caused by EHEC, which produce closely related Shiga toxins. However, the human EHEC strains colonize the intestine by a mechanism distinct from EDEC, and the Shiga toxins target different organs (Gyles and Fairbrother 2010). Serotypes associated with ED are also different from those of EHEC that cause disease in humans.

Escherichia coli of the intestinal ecosystem, both commensal and pathogenic, may acquire antimicrobial resistance following administration of antimicrobials, whether in the feed, water, or by injection, for the purpose of promoting growth, improving feed efficiency, preventing diseases (prophylaxis), or as treatment, including metaphylaxis, for bacterial infections. These strains may be resistant to antimicrobials that are preferred treatments for serious infections in humans and

for which limited alternatives are available, referred to as critically important or very high importance antimicrobials, such as third- and fourth-generation cephalosporins (e.g. ceftiofur) and fluoroquinolones (e.g. enrofloxacin). Such strains constitute a public health threat when they enter the food chain.

Epidemiology

Escherichia coli infections are widespread, occurring in both industrialized and developing countries and in temperate, subtropical, and tropical climates. Diarrhea (neonatal ETEC, PWD ETEC, and EPEC), ED due to EDEC, systemic infections due to ExPEC, CM, and UTI occur in pigs in all countries where pigs are raised commercially.

The primary habitat of *E. coli* in the pig is the gastrointestinal tract, and *E. coli* is the dominant aerobe in this habitat. *E. coli* populations in the pig fecal microbiota and in the farm environment are highly dynamic and show high levels of diversity (Marchant and Moreno 2013). Dominant strains change at intervals from 1 day to several weeks, leading to successive waves of dominant strains (Katouli et al. 1995). It has been reported that the *E. coli* microbiota is highly structured, and that different compartments of the gut are preferentially colonized by distinct phylogenetic *E. coli* clones (Dixit et al. 2004), though another study suggested that porcine *E. coli* populations might not be as structured (Schierack et al. 2007). Numbers in the large intestine average around 10^7 colony-forming units (CFU)/g of contents; however, *E. coli* contribute less than 1% to the total bacterial count.

Escherichia coli are found in fecal-contaminated feed, water, soil, and the environment of the pig barn. Long survival times in the environment are promoted by low temperature and sufficient moisture, among other factors. In slurry samples, a porcine *E. coli* O139:K82 strain remained viable for more than 11 weeks (Burrows and Rankin 1970). The spread of pathogenic *E. coli* is presumed to mainly occur via other pigs and contaminated barn environment, but also via aerosols, contaminated feed and water, contaminated trucks that transport pigs, other vehicles, and possibly other animal species. Airborne transmission between pigs in wire cages 1.5 m apart was repeatedly observed in transmission experiments with an F4-ETEC strain (Wathes et al. 1989).

Intestinal infections caused by ETEC, EDEC, and EPEC are considered contagious. The same strain is usually found in many sick pigs and often in consecutive batches of pigs. A more recent phenomenon is the emergence in sick pigs of a more pathogenic Stx-producing F18-ETEC lineage demonstrating a high level of multidrug resistance, thus representing a high risk to swine production (Kusumoto et al. 2016). In contrast, infections caused by ExPEC and *E. coli* causing CM and UTI do not behave as communicable diseases. Mixed infections by more than one strain are frequent and are acquired by invasion of preexisting intestinal bacteria in the case of ExPEC and from fecal and/or environmental contamination of teats and the urethra in the case of CM and UTI.

Routine cleaning and disinfection are usually insufficient to break the cycle of infection by *E. coli* (Hampson et al. 1987). Under experimental conditions, however, transmission can be prevented by strict hygienic measures (Kausche et al. 1992).

There are only limited data on the susceptibility of *E. coli* isolates to commonly used disinfectants. According to a Danish study, *E. coli* fecal isolates from livestock did not appear to have developed resistance to benzalkonium chloride, H_2O_2, chlorhexidine, formaldehyde, or zinc chloride (Aarestrup and Hasman 2004). However, Beier et al. (2005) demonstrated that reduced chlorhexidine susceptibility in virulent *E. coli* isolates from newborn pigs with diarrhea correlated with resistance to gentamicin and streptomycin. These findings underline the potential for transfer of this resistance and the possible impact of environmental contamination.

Neonatal *E. coli* diarrhea

Neonatal *E. coli* diarrhea is observed most commonly in pigs aged from 0 to 4 days and is caused by ETEC. The newborn pig, on leaving the uterus and before reaching the teats of the sow, encounters the heavily contaminated environment of the farrowing crate and the skin of the dam, resulting in ingestion of microbes from the intestinal microbiota of the sow. In conditions of poor hygiene or in a continuous-farrowing system, buildup of pathogenic strains increases risk for an outbreak.

Pathogenesis

In the presence of the appropriate predisposing environmental conditions and host factors, ETEC proliferate in the intestine and cause disease by means of specific virulence factors (Table 52.1; see also etiology above). Risk factors for the development of various *E. coli* diseases in pigs are summarized in Table 52.3. ETEC must be able to adhere to and colonize the intestinal mucosa to permit the release of sufficient enterotoxin to cause diarrhea. Adherence to specific receptors on mucosal epithelial cells and in the adjacent mucus layer is mediated by fimbria on the bacterial surface (Figure 52.1).

ETEC affecting neonates mostly colonize the posterior jejunum and ileum. Piglets are most susceptible to infection with F5-ETEC and F6-ETEC during the first several days of life and subsequently become more resistant. This susceptibility could be related to a reduction of the

Table 52.3 Risk factors for development of *E. coli* diseases.

	Etiology	Risk factors		
Diseases	***E. coli* pathotype + others**	**Host**		**Environment**
Neonatal diarrhea	F4(K88)-, F5(K99)-, F6(K987P)-, F41-ETEC	• Susceptibility to F5(K99) and F6(987P) high; decreases with age • Susceptibility to F18 low; increases with age • No effect of age on susceptibility to F4(K88) • First gestation: low levels of colostral antibodies		Ambient temperature less than 25 °C (77 °F)
Septicemia	ExPEC	• Low transfer of colostrum		
Young pig diarrhea	F4(K88)-ETEC, rotavirus, coccidia, TGE virus			
Enteric colibacillosis complicated by shock	F4(K88)-ETEC	• Some pigs resistant to F18 due to lack of receptor		
Edema disease	F18-STEC	• Up to 50% of pigs may be resistant to F4 due to lack of receptor • Earlier weaning age • Stress • Loss of specific antibodies from milk	Rapidly growing pigs	• High protein diet • Transportation • Mixing of pigs • Diet changes • Diet elements – Low level of milk and other products of animal source – Certain ingredients such as soybeans – Presence of other infections, such as PRRSV or PRV
Post weaning diarrhea	F4(K88)-, F18-ETEC AIDA-ETEC, EPEC, mixed *E. coli* pathotypes			
Urogenital infection	ExPEC	• Last period of pregnancy • Parturition • Trauma at coitus		

number of receptors present on intestinal epithelial cells with age or inhibition of colonization by preferential binding of bacteria to F6 receptors present in the mucus rather than to those on the intestinal epithelium. Not all pigs have epithelial cell receptors for F4 and are thus resistant to infection by F4-ETEC (van den Broeck et al. 1999). This genetic resistance is inherited in a simple Mendelian way with the allele for the receptor being dominant. A similar genetic resistance has not been observed for the other fimbriae (F5, F6, F41) of neonatal porcine ETEC.

ETEC adhering to the intestinal mucosa produce enterotoxins that change the water and electrolyte flux of the small intestine and may lead to diarrhea if the excess fluid from the small intestine is not absorbed in the large intestine. Excessive net secretion leads to dehydration, metabolic acidosis, and eventually death. Most strains of neonatal ETEC produce STa, which is active in the intestine of infant mice and young piglets of less than 2 weeks of age, but is less active in older pigs. This could be due to differences in the concentration of intestinal receptors with age. Based on the concentration and affinity of the STa receptors, the posterior jejunum appears to be the major site of hypersecretion in response to STa.

In suckling pigs, the severity of ETEC-induced disease depends on antibody titers in the milk of the sow (Sarmiento et al. 1988b). The colostrum and the milk may contain nonspecific bactericidal factors and specific antibody (mainly IgG and IgA, but also IgM) that inhibit the adherence of pathogenic *E. coli* to the intestine. If the dam has not been vaccinated or exposed to the pathogenic *E. coli* present in the environment of the piglets, specific antibodies are not present in the colostrum and the milk, and suckling piglets are susceptible to intestinal infection. Similarly when individual piglets do not have access to colostrum, due to injury or inability to compete or due to agalactia or insufficient teats of the sow, they are more susceptible to infection.

Low ambient temperatures in the farrowing house also impact severity of disease. In pigs kept at temperatures of

less than 25 °C (77 °F), intestinal peristaltic activity is greatly reduced, and passage of bacteria and protective antibodies through the intestine is delayed (Sarmiento 1983). Increased numbers of pathogenic *E. coli* in the intestinal tract of these pigs result in a more severe diarrhea than in pigs kept at 30 °C (86 °F).

Clinical signs

Clinical signs and age most commonly affected are summarized for the various diseases caused by *E. coli* in Table 52.4. Neonatal diarrhea may first be observed 2–3 hours after birth and may affect one or a few pigs or whole litters. Gilt litters are more often affected than sow litters. Morbidity in an affected herd is extremely variable. The average is 30–40%, but may be as high as 80% in some herds. Mortality can reach 70% in affected litters. In a low proportion of pigs, the infection may be so rapid that death occurs before the development of diarrhea.

Diarrhea may be very mild with no evidence of dehydration or may be clear, watery, and profuse. The feces vary in color from clear to whitish or various shades of brown. In very severe outbreaks, a small proportion of affected animals may vomit. In severe cases, 30–40% of total body weight may be lost and result in signs of dehydration. Abdominal musculature may be flaccid, pigs may be sluggish with sunken eyes, and skin may be bluish gray in color and parchment-like in texture. The loss of fluid and weight results in the exaggeration of bony prominences. These animals usually die. In more chronic or less severely affected cases, the anus and perineum may be inflamed from contact with the alkaline diarrheic fecal material. Pigs with less severe dehydration may continue to drink and, if treated appropriately, recover with only minimal long-term effects.

Lesions

Few specific lesions are observed. Gross lesions may include dehydration, dilation of the stomach (which may contain undigested milk curd), venous infarcts on the greater curvature of the stomach, and dilation of the small intestine with some congestion of the small intestinal wall.

Microscopically, layers of *E. coli* may be observed adhering in patches to the mucosal epithelial cells of the jejunum and ileum. Adhering bacteria may be found only in the crypts of Lieberkühn, or more often covering the crypts and the tips of the villi. Other lesions sometimes observed include vascular congestion in the lamina propria with hemorrhages into the intestinal lumen, increased numbers of neutrophils and macrophages in the lamina propria, and mild villous atrophy.

Table 52.4 Association of clinical signs, prevalence, and age with various clinical diseases due to *E. coli*.

	Age period[a]				
Clinical disease	**Newborn[b]**	**Suckling**	**Post weaned**	**Grow–finish**	**Adult**
Neonatal diarrhea[c] Severe watery diarrhea, dehydration, mortality up to 70% in affected litters	■				
Septicemia Shock, depression, death, polyarthritis	■				
Young pig diarrhea Low mortality, diarrhea of moderate severity, decreased weight gain		■			
Enteric colibacillosis complicated by shock Rapid death, cyanosis of extremities, diarrhea		■			
Edema disease[c] Sudden death, possibly paralysis, and eyelid edema, sporadic mortality up to 65%			■	■	
Post weaning diarrhea[c] Initially deaths, with severe to moderate diarrhea, decreased weight gain, mortality up to 25% in untreated animals			■	■	
Urogenital infection Sporadic cystitis often after mating, pyelonephritis 2 weeks postpartum					■
Coliform mastitis First several days following farrowing, generally short duration. Clinically similar to lactational failure					■

[a] Most commonly affected age periods shaded.
[b] First several days.
[c] Most important clinical diseases.

Diagnosis

Neonatal diarrhea caused by ETEC must be differentiated from other common infectious causes of diarrhea including *Clostridium difficile* and *Clostridium perfringens* types A and C (Chapter 51); transmissible gastroenteritis virus (TGEV) (Chapter 31); porcine epidemic diarrhea virus (PEDV) (Chapter 31); rotavirus groups A, B, and C (Chapter 43); and PRRSV (Chapter 41). In suckling pigs 5 days and older, *Isospora suis* (Chapter 66) must also be considered. It may be helpful to determine fecal pH as ETEC produces alkaline feces, whereas malabsorptive diarrheas produced by TGEV, PEDV, and rotaviruses produce acidic feces.

Diagnosis of neonatal ETEC is based on clinical signs, microscopic lesions, and the presence of small gram-negative rod-shaped bacteria colonizing the small intestinal mucosa. Colonization can be visualized in formalin-fixed, paraffin-embedded tissues by routine histopathology, or *E. coli* organisms can be definitively identified and visualized using immunohistochemistry or in frozen sections using indirect immunofluorescence. This diagnosis is strengthened by the isolation from rectal swabs or intestines of *E. coli* possessing appropriate virulence factors. Criteria used to identify causative *E. coli* in diarrhea in pigs are summarized in Table 52.5.

Swabs or samples of intestinal contents should be inoculated onto blood and MacConkey agar or other media, which are selective for *Enterobacteriaceae* and allow differentiation of lactose fermenting from lactose-non-fermenting gram-negative enteric bacilli. Use of transport medium such as alginate swabs or Stuart's medium should be considered if isolation could not be done within 24 hours.

Morphology and lactose fermentation on MacConkey agar are a first indication of potential *E. coli*. To identify the species as *E. coli*, it is essential to determine the capacity of colonies to transform indole, since 99% of *E. coli* strains are indole positive. Identification can be completed by the citrate assay (*E. coli* are not able to use citrate as the only carbon source) and by the methyl red assay.

A diagnostic laboratory can use OK typing sera (serotyping) against serogroups most prevalent in its geographical region to obtain a rapid presumptive diagnosis. Common O serogroups associated with disease in pigs are shown in Table 52.1. Complete O and H serotyping can only be carried out in a few reference laboratories.

The use of serotyping for primary identification of porcine pathogenic *E. coli* is less relevant today because of the presence of non-typable (NT) pathogenic strains, not all strains of a given serotype are pathogenic, the need of large number of reference antisera, and the growing availability of efficient genetic methods to identify virulence factors. Virotyping, or determination of the virulence factors, is thus a more definitive way of identifying pathogenic *E. coli* (Table 52.1).

The presence of enterotoxins and cytotoxins may be detected by tests for biological activity, which are no longer commonly used in routine diagnosis. Antigen ELISA tests have been developed for the detection of Stx-producing cultures or for direct detection of the Stx-producing bacteria in the feces and may be used more widely in diagnostic laboratories.

Slide agglutination, with or without latex particles, is a simple and easy method to determine the presence of fimbrial adhesins of ETEC, which are expressed in culture media, except F18, which is rarely expressed *in vitro*. This method is commonly used for the identification of F4-ETEC. Antigen ELISA is also used to determine the presence of adhesins. However, bacteria must be grown on the appropriate media for detection of F5 and F41, which are only well expressed in culture media low in glucose or alanine. Other fimbriae, such as F1 and F6, undergo phase variation and may be very poorly expressed after several passages in the laboratory.

Currently, genotypic analysis is more commonly used to define the virotypes involved in an infection. Techniques include colony or DNA hybridization and polymerase chain reaction (PCR) for the detection of genes encoding for virulence factors such as toxins and

Table 52.5 Criteria used to identify causative *E. coli* in diarrhea.

	Pathogenic *E. coli* identified						
	ETEC						
Criterion	F4(K88)	F18	F5(K99), F6(987P), F41	AIDA	F18-STEC	EPEC	ExPEC
Hemolytic colonies	All (not discriminatory)		None		All	None	Some
OK serotyping	Most (some non-ETEC identified)			Not known	Most	Few	Some
F adhesin serotyping	All	Not reliable	Most (not reliable)	Not done	Not reliable	Not done	
Virotyping	All						Some

adhesins (Francis 2002; Frydendahl 2002; Harel et al. 1991; Wray and Woodward 1994). PCR may also be used to detect pathogenic *E. coli in situ* in formalin-fixed, paraffin-embedded tissues.

Immunity

Immunity to enteric *E. coli* infections is humoral and is initially provided through passive immunity via the maternal colostrum and lactogenic antibodies in the milk of the sow and subsequently by active local intestinal immune responses. The concentration of IgG in colostrum is severalfold higher than in sow plasma and declines rapidly during the first 24 hours of secretion, with IgA becoming the dominant immunoglobulin class in milk (Rooke and Bland 2002). The latter protects the gut against *E. coli* infection. Protective immunity is based on the presence of antibodies to surface antigens, especially the fimbrial adhesins F4, F5, F6, and F41. Antibodies to the polysaccharide capsule of ETEC may also be protective. Anti-fimbriae and anti-capsular antibodies function by preventing attachment of the ETEC to enterocytes. Infection with ETEC positive for fimbriae, for example, F5, is unlikely to result in cross-protection against infection with ETEC positive for another fimbria such as F4 or F41 unless some protection is conferred by antibodies against shared capsular antigens.

Prevention and control

Treatment with antimicrobials at the earliest sign of diarrhea may be on an individual or litter basis, by mouth or parenteral injection. It is important to confirm the diagnosis of *E. coli* infection by culture and to perform antimicrobial sensitivity tests because antimicrobial sensitivity varies greatly among *E. coli* isolates. *In vitro* resistance of *E. coli* isolates to a wide range of antimicrobial agents has dramatically increased over the last several years. Commonly used antimicrobials are ampicillin, apramycin, ceftiofur, gentamicin, neomycin, spectinomycin, furazolidone, and potentiated sulfa drugs. An alternative approach to the antibiotic treatment of enteric *E. coli* infection is the use of bacteriophages, an approach that has been successful experimentally (Jamalludeen et al. 2009) but has not been extensively applied in the field.

Fluid therapy, consisting of electrolyte replacement solutions containing glucose given orally, is useful for the treatment of dehydration and acidosis. Drugs that inhibit the secretory effects of enterotoxin, such as chlorpromazine and berberine sulfate, may be useful for the treatment of diarrhea, although many of these drugs have undesirable side effects. The use of such antisecretory drugs as bencetimide and loperamide, alone or in combination with antibacterial agents, has also been suggested (Solis et al. 1993).

The principles of control of *E. coli* neonatal diarrhea revolve around hygiene and management strategies to reduce the buildup of the causative *E. coli* and increasing immunity in sows and piglets. A program for prevention of enteric *E. coli* infection should be aimed at reduction of numbers of pathogenic *E. coli* in the environment by good hygiene, maintenance of suitable environmental conditions, and provision of a plentiful supply of colostrum at birth and a high level of immunity. Strategies commonly used for the control of enteric *E. coli* infections are summarized in Table 52.6.

One of the most important factors in prevention of enteric *E. coli* infection and septicemia is the maintenance of piglets at an adequate environmental temperature, free of drafts, and on a low-heat-conducting floor. This is particularly true for piglets of below average weight, which lose heat more rapidly because they have a greater skin surface area per unit body weight.

Stringent biosecurity should be used to control the introduction of different *E. coli* virotypes or other infectious agents into the herd. Animals in the herd will have little immunity to *E. coli* fimbrial antigens with which they have not had contact.

Good hygiene in the farrowing area leads to a reduction in the numbers of *E. coli* presented to the piglet to a level that it is able to control through its own defense mechanisms. Farrowing crates should be thoroughly cleaned and disinfected between litters, and farrowing rooms should be managed as all-in/all-out with thorough disinfection between farrowing groups. Sow fecal material should be minimized in farrowing crates by sizing crates to sow size that minimize area of fecal contamination and by utilizing perforated flooring that allows fecal material to drop through. Litters farrowed onto such floors have a noticeably lower incidence of diarrhea than those on solid concrete floors.

A dry, warm environment reduces the moisture available for survival and growth of *E. coli*. This is largely affected by ventilation rates, although if room temperature is too high, sows tend to try and spread water over their lying area to cool themselves, thereby defeating other hygienic procedures. The sow should be at a temperature of approximately 22 °C (72 °F), necessitating a warmer creep area for the piglets. It is important to ensure that younger piglets are maintained at a constant temperature of 30–34 °C (86–93 °F) to prevent chilling, which predisposes to neonatal colibacillosis.

Maternal vaccination has been one of the most effective ways of preventing neonatal ETEC diarrhea in piglets. One of the earliest vaccination techniques consisted of taking the small intestinal contents (or scour) from a piglet with diarrhea, culturing it in milk, and feeding the culture to pregnant sows, usually about a month before parturition (Kohler 1974). This technique is effective, conferring an immunity lasting

Table 52.6 Strategies commonly used for the control of enteric *E. coli* infections.

	Strategies that result in:	
	Reduced number of pathogenic *E. coli*	**Increased resistance of animals to infection**
Preweaning diarrhea	• Warmth • Hygiene • Gate and floor design • Quarantine • All-in/all-out • Farrowing	• Maternal vaccination – F4(K88), F5(K99), – F6(987P), F41 • Pig hyperimmune – γ-globulin
Post weaning diarrhea and edema disease	• Increase weaning age • Warmth • Diet – Highly digestible – Milk-based protein – Restricted feed intake • Hygiene • Water additive – Organic acids • Feed supplements – Organic acids – ZnO – Spray-dried plasma – Probiotics • Antimicrobial peptides	• Live oral nontoxigenic F4(K88) and F18 *E. coli* vaccines • Oral powdered egg yolk from F4(K88)- and F18-immunized hens • Stx2e toxoid vaccine (edema disease) • Selection of F4(K88)- and F18-resistant animals

throughout the suckling period, and is still used, particularly in the United States.

Commonly used commercially available vaccines are given parenterally and may be killed whole cell bacterins or purified fimbrial vaccines, with or without LT toxoid. Both types of vaccines appear to work equally well. Bacterins usually contain strains representing the most important serogroups and producing the fimbrial antigens F4, F5, F6, and F41 (Gyles and Fairbrother 2010). Two doses are usually given parenterally at 3 or 4 weeks apart, the second generally administered 2–3 weeks prior to parturition. Most vaccines comprise antigens for other pathogens, such as for *C. perfringens*, and rotavirus. Some vaccines may include antigens for the different F4ab, F4ac, and F4ad variants. However, it is not clear that these vaccines would be more efficient than others including only F4ac since most cases are due to F4ac-ETEC and immunologic cross-reactivity between the three variants is reported. One sow vaccine including also bacterins of F18ab and F18ac *E. coli* has been recently approved in several European countries. In cases where vaccination is ineffective, it is important to identify the serotype of the isolated causative strain for possible inclusion in an autogenous bacterin. Further characterization of these isolates may identify new or variant fimbrial adhesins important in the pathogenesis of ETEC diarrhea.

Post weaning *E. coli* diarrhea and edema disease

Escherichia coli PWD and ED are treated in one section because they often both occur in the same age group of pigs, the causative bacteria share certain virulence factors, and some strains of *E. coli* can cause both diseases. There are also important differences in the two diseases.

Lactogenic passive protection decreases with aging of suckling piglets, and older unweaned piglets can be affected by *E. coli* diarrhea and ED as levels of protective antibody wane in maternal milk; however, loss of milk antibodies at weaning contributes significantly to susceptibility of pigs to PWD and ED (Deprez et al. 1986; Sarmiento et al. 1988b). As a result, most disease is observed post weaning.

PWD and ED are caused by strains of *E. coli* that possess adhesion factors enabling the bacteria to colonize the small intestine and that elaborate one or several protein exotoxins. They may occur independently, but PWD and ED may also occur in a single outbreak or in the same pig.

PWD is most commonly caused by ETEC and mediated by enterotoxins but can also be caused by EPEC that do not possess any virulence factors of classic PWD or ED strains. Common PWD and ED serovirotypes are summarized in Table 52.2, and virulence factors are listed in Table 52.1 and described in the etiology section above. PWD ETEC strains usually have either F4 or F18 variants F18ac or F18ab as fimbrial adhesins, although some F4- and F18-negative virotypes exist. Most PWD F4-positive isolates are serogroup O149, and F18 isolates are O139, O138, O141, O147, or O157. PWD ETEC are observed in pigs worldwide, and in a given geographical area, certain serovirotypes predominate (Do et al. 2010; Fairbrother et al. 2000; Francis 2002; Frydendahl 2002; Liu et al. 2014; Wang et al. 2011). Outbreaks of F4-positive *E. coli* disease tend to involve only one strain at any one time. Occasionally, two potential pathogens are isolated, but one usually predominates in any given outbreak. Exceptionally, in one case, multiple outbreaks in herds involving different serogroups were detected in 47% of 84 herds (Awad-Masalmeh et al. 1988). Mortality is often 1.5–2% of pigs and can reach 25% if no treatment is given.

ED is caused by EDEC that colonize the small intestine and elaborate a Shiga toxin, Stx2e, which enters the bloodstream and damages vessel walls, resulting in edema in targeted tissues. Most notably, cerebral edema leads to the predominant nervous signs characteristic of the disease. Both F18ab and F18ac variants may be involved (DebRoy et al. 2009). Most ED strains belong to serogroups O138, O139, O141, and O147. ED most often manifests as sporadic cases or small outbreaks limited to a specific age group. The case mortality rate ranges from 50 to over 90%, and the course of the disease in the herd varies from 4 to 14 days. The disease typically disappears as abruptly as it appears. Recurrence on the same site is common.

Some F18ab- and F18ac-positive strains of *E. coli* produce both enterotoxins and Stx2e. Pigs infected by one of these strains generally exhibit clinical PWD more than ED. Outbreaks of disease may also be caused by mixed infections of both ETEC and EDEC strains. When this occurs, clinical diarrhea usually predominates even though microscopic lesions of ED may be present.

The age group primarily affected by PWD and/or ED varies based on absolute pig age and diet. There are some differences between *E. coli* with F4 and those with F18. Receptors for F4 are fully expressed on enterocytes of pigs from birth to adult age, rendering pigs of all ages potentially susceptible to infection. F4-positive strains most often cause outbreaks of PWD in the very first days after weaning.

In contrast F18 receptors important in ED and some PWD are expressed age dependently. It was first reported that the F18 receptors are not yet fully expressed by piglets under about 20 days of age (Nagy et al. 1992). However, a more recent study reported that the expression of the F18 receptors in the intestines was found from 10 days of age, increasing gradually with age in the suckling period, and then maintained highly expressed from about 3 weeks of age (Coddens et al. 2007). Hence, *E. coli* with F18 fimbriae do not cause diarrhea or ED in neonatal pigs and usually cause ED or PWD between 5 and 14 days after weaning or after introduction to fattening herds. Fimbrial receptors are subject to modulation by feed lectins such as constituents of leguminous plants (Kelly et al. 1994). It is speculated that feed-induced changes of the receptor are involved in the observed reduction in colonization by F18-positive *E. coli* in the first days after weaning (Bertschinger et al. 1993).

Older suckling pigs may acquire F18 *E. coli* infection from previously contaminated farrowing crates or their dam and develop disease and/or carry it into the weaner unit. The contaminated environment of the weaner unit appears to be also an important source of pathogenic *E. coli* strains. Intestinal infections caused by *E. coli* are contagious and are transmitted to other pigs by the oral route via fecal–oral transmission, contaminated immediate environment, contaminated feed and drinking water, handlers, or aerosol. The same strain is usually found in many sick pigs and often in consecutive batches of pigs (Jorsal et al. 1996). These strains are usually only shed for a few days after infection, probably due to the development of immunity. Not all infected pigs develop disease; the degree of colonization determines whether disease results from infection.

Pathogenesis

Colonization

When ingested in sufficient numbers, *E. coli* causing PWD and/or ED colonize and then proliferate rapidly to attain massive numbers to the order of 10^9/g of contents. For ETEC and EDEC, colonization requires attachment of fimbrial adhesins (mainly F4 and F18) to complementary receptors on the small intestinal epithelium or in the mucus coating in the mid-jejunum to ileum. On the other hand, for EPEC, the eae adhesin (intimin) binds to its complementary receptor on the apical surface of host epithelial cells in the small and large intestines, with heaviest colonization in the duodenum and cecum.

Epithelial cell receptors for pathogenic ETEC and EDEC are not present in every pig. Certain pigs do not have receptors for F4 and are thus resistant to infection by F4-ETEC. Receptors are prerequisite for both the development of clinical signs and immune responses with F4-positive *E. coli* (van den Broeck et al. 1999). This genetic resistance to infection is inherited in a simple Mendelian way, and the allele for the receptor is dominant. Subsequent studies have demonstrated up to eight

pig phenotypes (A to H) based on susceptibility of brush borders of different pigs to adherence of isolates, producing the variants F4ab, F4ac, and F4ad (Baker et al. 1997; Hu et al. 1993; Li et al. 2007). The F4 receptors per se are still unknown, and different receptor types have been proposed to play a role in the binding of F4 to enterocytes (Nguyen et al. 2013). The loci encoding porcine intestinal receptors for F4ab and F4ac are closely linked on chromosome 13 (Edfors-Lilja et al. 1995). Susceptibility of pigs to F4ab/ac -ETEC diarrhea has been linked to a polymorphism on MUC4 gene (Goetstouwers et al. 2014). However, the correlation between MUC4 polymorphism and F4 susceptibility is not completely consistent, particularly for resistance, a proportion of pigs with a MUC4-resistant genotype showing intestinal adhesion of F4ac *E. coli* and/or becoming seropositive after immunization with F4 (Goetstouwers et al. 2014; Nguyen et al. 2013; Rasschaert et al. 2007). This strongly suggests the presence of other receptor(s) for F4ac. Other genes on pig chromosome 13 have attracted scientific interest as F4ab/ac receptor, including MUC13, MUC20, and TFRC (reviewed by Xia et al. 2015). It has been shown that pigs carrying F4ab/ac receptors had greater average daily weight gain than pigs exempt of these receptors (Yan et al. 2009).

Specific intestinal receptors for F18 have not yet been fully identified. However, the importance of F18 receptor in colonization of F18 *E. coli* and development of disease was demonstrated; the susceptibility to colonization by F18 *E. coli* is controlled by a dominant allele and resisted by a recessive allele (Bertschinger et al. 1993; Frydendahl et al. 2003). The receptor for F18 fimbriae is controlled in a single locus on chromosome 6 close to the locus for stress susceptibility. Pigs with at least one copy of the dominant allele for the receptor are susceptible to intestinal colonization. Susceptibility to F18 *E. coli* infections was reported to be dependent on the activity of the FUT1 gene, encoding the alpha(1,2)-fucosyltransferase. The association between FUT1 M307 genotypes and adhesion phenotypes was reported to be very strong for both F18ab and F18ac (Frydendahl et al. 2003). The complexity of the F18 receptor expression was recently demonstrated by differential gene expression analysis (Dong et al. 2016).

Other factors may also effect bacterial colonization and severity of disease. Low room temperature in the weaner rooms appears to be responsible for a more severe course of PWD (Wathes et al. 1989). This is likely because chilling reduces intestinal peristaltic activity and enhances bacterial colonization. In contrast, under experimental conditions, ED is not aggravated by cold stress (Kausche et al. 1992). Endogenous as well as orally administered proteases may reduce the receptor activity for F4 fimbriae (Mynott et al. 1996), thus reducing the severity of F4-mediated diarrhea. Several predisposing factors, such as a weaner diets containing soya and field peas or PRRSV infection, may enhance bacterial colonization and development of the AE lesions of EPEC (Neef et al. 1994).

Mechanisms of ETEC post weaning diarrhea

Like neonatal ETEC, post weaning ETEC adhere to the intestinal mucosa and produce enterotoxins, which change the water and electrolyte flux of the small intestine. Excessive secretion leads to dehydration, metabolic acidosis, and possibly death.

Post weaning ETEC strains produce one or more of the enterotoxins STa, STb, LT, and EAST-1. STb is antigenically and genetically unrelated to STa and is poorly immunogenic. LT is a highly immunogenic molecule, and recent studies have shown that LT also promotes adherence of ETEC *in vitro* and *in vivo* (Fekete et al. 2013).

EAST-1 is commonly found in F4-ETEC strains from pigs with diarrhea and in F18:Stx2e strains from pigs with ED (Choi et al. 2001). The mechanism of action of EAST-1 is proposed to be identical to that of STa. Overall, most studies suggest that EAST1 toxin alone does not induce diarrhea in the animals tested (Dubreuil et al. 2016).

Mechanisms of EPEC post weaning diarrhea

EPEC use a type III secretion system (T3SS) to translocate bacterial effectors directly into the intestinal epithelial cells. Porcine EPEC attach to the intestinal mucosa and cause lesions similar to those observed for EPEC isolated from human infantile diarrhea (Hélie et al. 1991). They attach intimately to the intestinal epithelial cell membrane by means of a bacterial outer membrane protein termed "EPEC attaching and effacing factor" (Eae) or "intimin." Eae is the product of a chromosomal PAI in EPEC composed of over 40 genes that code for proteins involved in intimate adherence to and signal transduction within the host cell (Dean and Kenny 2009; Nataro and Kaper 1998). One of these proteins is the "translocated intimin receptor" (Tir) that is injected into the host cell cytoplasm where it reappears on the host cell surface and acts as receptor for the bacterial intimin (Gyles and Fairbrother 2010). Attached EPEC efface the microvilli and sometimes invade the epithelial cells (Figure 52.2) (Zhu et al. 1994). The mechanisms by which EPEC induce diarrhea are poorly understood. Effacement of microvilli and the consequent loss of absorptive surface area may lead to malabsorptive diarrhea. The rapid onset of diarrhea suggests a more active secretory mechanism that may be due to EPEC signaling activity on intracellular mediators (Gyles and Fairbrother 2010). Other possible mechanisms include an increased permeability of tight junctions between epithelial cells, a localized inflammatory response at the lesion site, or chloride

secretion following polymorphonuclear (PMN) leukocyte transmigration. The clinical outcome of the infection is difficult to evaluate, as mixed infection, such as with F4-ETEC, often occurs.

Mechanisms of edema formation by edema disease *E. coli* (EDEC)

ED is a Stx2e toxemia that results in severe edema in specific sites in pigs that have absorbed Stx2e from the intestine following colonization by an EDEC. Highly purified Stx2e induces a dose-dependent disease indistinguishable from ED when administered intravenously to pigs (MacLeod and Gyles 1990). Colonization by EDEC develops over 3–6 days on the tips and sides of villi in the distal jejunum and ileum and is mediated by plasmid-encoded F18ab or F18ac fimbriae. It has been reported that F18-STEC infection results in a slower colonization of the gut than F4-ETEC, the latter showing a peak of fecal excretion at 2 days postchallenge compared with 3–5 days for F18-STEC (Verdonck et al. 2002).

The Stx2e toxin is part of the AB_5 toxin family and binds to globotriaosylceramide (Gb3) or preferably to globotetraosylceramide (Gb4) receptors. The Stx2e produced by EDEC in the intestine is absorbed into the circulation and causes vascular damage in target organs. The toxin also binds to Gb4 on red blood cells. Thus, vessels are subjected to prolonged toxin exposure (Boyd et al. 1993). The toxin can be detected in endothelial cells of small blood vessels of the intestine and in microvillous membranes of enterocytes at the base of the villi by immunological methods (Waddell et al. 1996). The Stx2e toxin does not appear to be absorbed from the intestine under normal conditions, but the addition of deoxycholate to the intestine allows absorption of Stx2e to occur (Waddell and Gyles 1995), and it is possible that bile could influence absorption. Strains of EDEC may pass from the intestine to the mesenteric lymph nodes and produce Stx2e toxin there, providing another mechanism for absorption of toxin into the blood.

The most consistent injury observed in field cases, after injection of partially purified toxin (Gannon et al. 1989) and in pigs inoculated orally with live EDEC (Kausche et al. 1992), is a degenerative angiopathy of small arteries and arterioles. The edema fluid found in various tissues is low in protein and is the result of a mild increase in vascular permeability.

A distinct type of ED is characterized by terminal bloody diarrhea and hemorrhagic lesions in the cardiac region of the stomach, the ileum, and the large intestine (Bertschinger and Pohlenz 1983). Gannon et al. (1989) observed acute hemorrhagic gastroenteritis in some of the pigs to which a high dose of Stx2e was administered. Epithelial necrosis secondary to necrosis of small arteries and arterioles may be responsible for luminal hemorrhage.

Clinical Signs

Post weaning diarrhea

Diarrhea in pigs from late suckling through the post weaning period is similar to that observed in neonatal piglets but tends to be less severe. Diarrhea is seen as yellowish or grey fluid, lasting up to a week and causing dehydration and emaciation. Over several days, most of the pigs in a group may be affected, and mortality of up to 25% may be observed. Peaks of diarrhea vary between farms but are generally seen in the first 3 weeks after weaning. Severe cases have been observed at 6–8 weeks after weaning when the pigs enter the growing barns.

Edema disease

ED mostly occurs during the first few weeks after weaning, although cases may be observed through to the grower barns. The disease may be sporadic or may affect an entire herd and may be first recognized as sudden death without signs of sickness. Some affected pigs become inappetent, develop swelling of the eyelids and forehead (Figure 52.3), emit a peculiar squeal, and show incoordination and respiratory distress. Some of these pigs will soon become recumbent and die. There is usually no diarrhea or fever. In mild cases, subcutaneous edema is accompanied by pruritus, which disappears after recovery. In some pigs with or without dyspnea, respiration is accompanied by a snoring sound. Watery diarrhea with clots of fresh blood may appear in a few pigs at the terminal stage.

Subclinical ED may occur where pigs are clinically normal but develop vascular lesions and may have a decreased growth rate. Chronic ED occurs in a low proportion of pigs recovering from acute attacks of ED or *E. coli* PWD caused by strains that also produce Stx2e. This condition was called cerebrospinal angiopathy before its association with ED became apparent. For periods varying from days to several weeks after intestinal infection, growth stops, and sick pigs often show unilateral

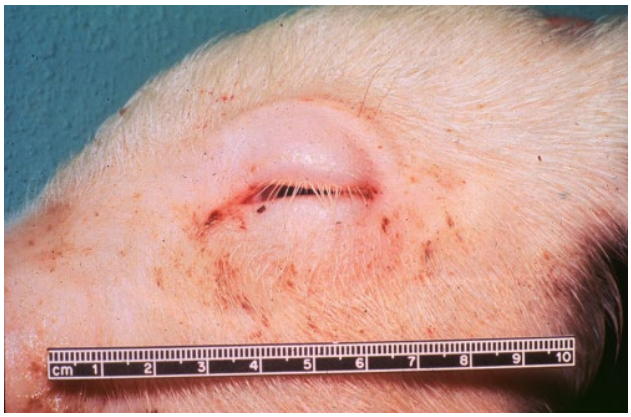

Figure 52.3 Edematous swelling of eyelids in a pig with edema disease. *Source:* Courtesy of Dr. Greg Stevenson.

nervous disturbances such as circling movements, twisting of the head, or atrophy of limb muscles with progressive weakness. Subcutaneous edema is rare.

Lesions

Post weaning diarrhea

Pigs dead from *E. coli* PWD are generally in good condition but severely dehydrated with sunken eyes and some cyanosis. The stomach is often distended with dry feed. The gastric fundus is variably hyperemic. The small intestine is dilated, slightly edematous, and hyperemic. The contents vary from watery to mucoid, with a characteristic smell. The mesentery is heavily congested. Contents of the large intestine most often are light greenish or yellowish and are mucoid to watery. Pigs dying late in an outbreak look emaciated and exhibit a strong smell of ammonia. There are irregularly shaped superficial ulcerations in the gastric fundus and large intestine. The feces may look yellow and pasty. If the causative strain of ETEC also produces Stx2e, lesions typical of ED (see below) are mild or absent.

Microscopic lesions in pigs with ETEC PWD are few. Bacterial layers (gram-negative rods) may be observed in patches on the apical surface of villous epithelial cells in the ileum and, less consistently, jejunum (Sarmiento et al. 1988a), although absence of this observation does not exclude ETEC infection. The mucosa and the epithelium remain normal in appearance; however, increased numbers of neutrophils may be observed in the superficial lamina propria.

Microscopically in pigs infected with EPEC, a multifocal colonization of the brush border of mature enterocytes by *E. coli* arranged in palisades with enterocyte degeneration and light to moderate inflammation of the lamina propria is observed, the latter being mostly in the ileum (Hélie et al. 1991). Colonization is most intense in the duodenum and cecum, bacteria are sometimes observed in intracytoplasmic vacuoles in enterocytes, and colonized enterocytes swell and slough, resulting in mild to moderate villous atrophy in the small intestine. On transmission electron microscopy, bacteria are intimately attached to the cytoplasmic membrane of mature enterocytes and arranged in regular palisades, parallel to the microvilli, with effacement of adjacent microvilli. The bacterial cell wall and the apical cell membrane of the enterocyte are separated by a narrow regular gap of 10 nm at the cupping pedestal, and apical dense regions are seen at attachment sites (Figure 52.2).

Edema disease

Pigs dying of ED are mostly in good condition. Edema is variable in specific sites of predilection and may be absent in some animals. Subcutaneous edema may occur and is most often in the eyelids and face (Figure 52.3). Gelatinous edema that is barely detectable up to 2 cm in thickness in the submucosa of the gastric cardia and occasionally fundus is characteristic. The mesocolon is commonly edematous, and edema of the small intestinal mesentery and gallbladder is sometimes observed. The mesenteric and colic nodes may be swollen, edematous, and congested. Pericardial, pleural, and peritoneal cavities sometimes contain a slight increase of serous fluid that contains strands of fibrin.

The stomach is typically full of dry, fresh-looking feed, and the small intestine is relatively empty. Some think that this is a manifestation of delayed gastric emptying, since some animals have a period of anorexia before death. Colonic contents may be diminished in amount and some pigs may be constipated. There may be varying degrees of pulmonary edema and a characteristic patchy, sublobular congestion. In some cases, this may be the only observable lesion. Cases with laryngeal edema have also been observed. A few epicardial and endocardial petechiae may occur. This lesion must not be confused with mulberry heart disease (Chapter 14) where hemorrhages are also throughout the myocardium.

In some pigs with ED, a form of hemorrhagic gastroenteritis occurs, which is quite different from that described with *E. coli* PWD. In addition to marked edema, the edematous submucosa of the cardiac region of the stomach and the mucosa of the lower small and upper large intestine show extensive hemorrhage. Watery diarrhea with clots of coagulated blood occurs shortly before death in some of these pigs.

Microscopically, patchy layers of bacteria are adherent to the distal jejuna and ileal mucosa early in the course of ED (Bertschinger and Pohlenz 1983). Contrasting with *E. coli* PWD, the colonization has often disappeared when pigs with ED become moribund (Bertschinger and Pohlenz 1983).

The hallmark microscopic lesion of ED is a degenerative angiopathy affecting small arteries and arterioles with associated edema of surrounding tissues (Clugston et al. 1974). Sites of predilection are those mentioned above where edema is observed as well as in the brain. The dense arterial network in the mesocolon adjacent to the colic lymph nodes is frequently affected. Vascular lesions may be subtle, affecting only some segments of arterioles, and difficult to detect in acute cases, but are more readily apparent in surviving pigs or those affected subclinically (Kausche et al. 1992).

Acute changes include necrosis of smooth muscle cells in the tunica media evidenced by pyknotic and karyorrhectic nuclear debris and hyaline change in cytoplasm (Figure 52.4). In the walls of some affected vessels, fibrinoid material is deposited. Endothelial cells may also be swollen. In acute experimental cases, edema of the leptomeninges and perivascular spaces has been demonstrated. Affected vessels in the brain may be surrounded

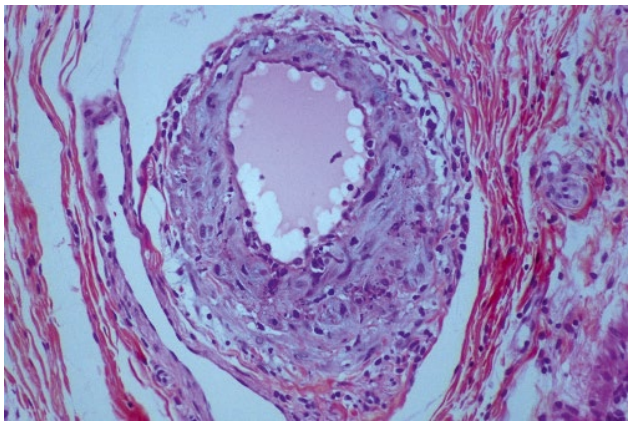

Figure 52.4 Necrosis of smooth muscle cells of the tunica media of a small arterial blood vessel in a pig with edema disease. Note pyknosis and karyorrhexis of smooth muscle nuclei. *Source:* Courtesy of Dr. Richard Drolet.

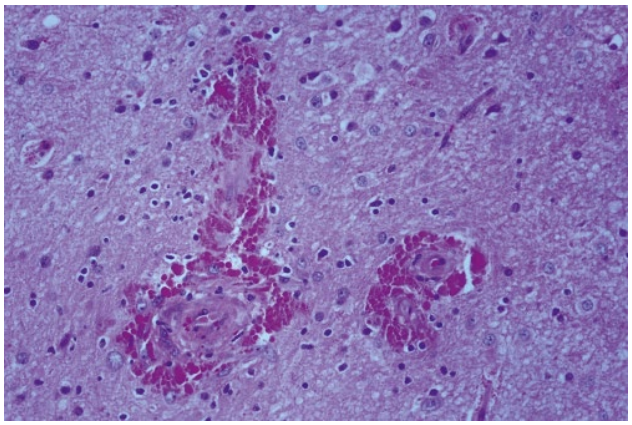

Figure 52.5 Cerebrospinal angiopathy in a pig with edema disease. Note hyaline degeneration of arteriolar walls with perivascular eosinophilic droplets. *Source:* Courtesy of Dr. Richard Drolet.

by eosinophilic, periodic acid–Schiff (PAS)-positive droplets (Bertschinger and Pohlenz 1974) (Figure 52.5). In older lesions, there may be proliferation of adventitial and medial cells. Thrombosis is not usually a feature of uncomplicated naturally occurring ED.

In cases of ED where hemorrhagic gastroenteritis is observed, vessels in affected areas of the gastric, lower small intestinal, and upper colonic wall have changes strikingly similar to those observed in human hemorrhagic colitis caused by EHEC. These include swelling, vacuolation and proliferation of endothelial cells, subendothelial fibrin deposition, medial necrosis, perivascular edema, and microthrombus formation.

In pigs that have recovered from natural outbreaks or survived for several days following acute signs, there may be multifocal encephalomalacia in the brain stem together with typical lesions in the small arteries and arterioles (Kausche et al. 1992). Malacia is thought to be due to ischemia secondary to vascular injury.

Diagnosis

In enteric post weaning *E. coli* infections, a presumptive diagnosis is made based on clinical presentation of diarrhea early after weaning (or sometimes later as previously described), marked dehydration, and low to moderate mortality. Mild diarrhea may be the only clinical presentation in less severe cases. The gross lesions, including the characteristic smell, are also helpful. Differentials should include other common infectious causes of non-bloody diarrhea in weaned pigs including rotaviruses (Chapter 43), TGEV (Chapter 31), salmonellosis (Chapter 59), PEDV (Chapter 31), and, in older weaned pigs, proliferative enteropathy (Chapter 58).

Likewise in ED, a presumptive diagnosis is made based on the sudden appearance of neurologic disease in thriving pigs in the first weeks after weaning. Partial ataxia or a staggering gait is the most consistent sign, and subcutaneous edema in the palpebrae and over the frontal bones is also a cardinal sign when present. Sudden death without clinical signs has been observed in some cases. Characteristic lesions of edema in gastric mucosa and mesentery are helpful when present, but may be absent in a significant number of cases, especially when severe diarrhea has preceded ED. Differentials should include other common causes of nervous signs in weaned pigs including pseudorabies (Chapter 35), teschoviral encephalitis (Chapter 40), *Streptococcus suis* (Chapter 61)- or *Haemophilus parasuis* (Chapter 54)-induced meningitis, and water deprivation/salt intoxication (Chapter 68). ED should be included in the differential diagnostic when sudden death is observed in the first weeks after the weaning.

Definitive diagnosis of ETEC or EPEC PWD and ED is based on the presence of typical lesions and culture of the causative *E. coli* along with confirmation of appropriate virulence factors (Tables 52.1 and 52.2). Criteria used to identify causative *E. coli* in diarrhea in pigs are summarized in Table 52.5. Serotyping continues to be used today in some laboratories, but virotyping (identification of virulence factors) should be performed to confirm the case. Colonization can be visualized in formalin-fixed, paraffin-embedded tissues by routine histopathology, or *E. coli* organisms can be definitively identified and visualized using immunohistochemistry or in frozen sections using indirect immunofluorescence. However, absence of observed colonization does not exclude ETEC or EDEC. Methods for culture and serovirotyping are discussed previously in the section on diagnosis of neonatal ETEC.

Culture of the small intestine in ETEC and small intestine and colon in EPEC and ED usually yields pure or

nearly pure cultures of hemolytic (ED and ETEC) or nonhemolytic (EPEC) *E. coli*. However in ED bacterial numbers may have declined in more protracted cases (Bertschinger and Pohlenz 1983); therefore, a negative bacteriologic result does not exclude the diagnosis of ED. Because all F18 and most F4 *E. coli* causing ED and ETEC PWD are hemolytic, the presence of hemolytic colonies is often used as a rapid means for confirming a presumptive diagnosis of these conditions. However, this method would exclude EPEC and an increasing number of F4-ETEC that produce nonhemolytic colonies on blood agar. This may be an important consideration when putting into place prevention strategies, such as vaccination. In addition, in cases of diarrhea with mixed infections of hemolytic and nonhemolytic ETEC, the assumption that the presence of hemolytic colonies indicated that F4- or F18-ETEC was the only causative agent may result in the nonhemolytic ETEC remaining undetected. Likewise, in cases of diarrhea mixed with subclinical ED, this assumption would result in the ED remaining undetected. These are important considerations in light of the increasing prevalence of mixed pathogenic *E. coli* infections associated with cases of diarrhea, particularly later in infection or in groups with a more endemic presentation.

In cases of subacute or chronic ED or of ED in adults, culture is of little value since causative EDEC are typically no longer a dominant strain in the intestines. Subacute or chronic ED is diagnosed by lesions, especially by the demonstration of subacute to chronic arteriopathy and possibly lesions of focal encephalomalacia. Diagnosis of ED in adult pigs may require additional effort, often requiring postmortem examination and histopathology of more than one pig. Death of adults is occasionally caused by cerebral hemorrhage (stroke) from rupture of severely damaged arterioles, with an apparent affinity for the basal ganglia, especially the corpus striatum.

Immunity

Protective acquired immunity is based on the presence of mucosal secretory antibodies, first IgM and then IgA, to fimbrial adhesins, particularly F4 and F18, in weaned pigs. There are differences in kinetics of infection and immunity in weaned pigs infected with F4- and F18-ETEC (Verdonck et al. 2002). Infection with F4-ETEC results in a more rapid intestinal colonization, induction of anti-fimbrial antibodies, and switch from IgM to IgA and IgG than for F18-ETEC. There are conflicting results concerning cross-protection between strains with fimbrial variants F18ab and F18ac, a first study showing evidence of crosswise anti-colonization immunity between F18ab and F18ac *E. coli* (Sarrazin and Bertschinger 1997), and another one concluding heterologous protection may not be very effective (Bertschinger et al. 2000). However, effective cross-protection has been demonstrated with an oral commercial live vaccine recently approved in Europe. This vaccine comprising a live nonpathogenic F18ac *E. coli* showed protection against a challenge with an F18ab-ETEC.

Protective acquired antibodies are produced against Stx2e in pigs that survive ED. Weiler et al. (1995) showed that pigs that had survived an outbreak of ED had antibodies reacting in an antigen ELISA to the B subunit of Stx2e. Vaccine studies using various forms of Stx2e toxoid have demonstrated protection in ED models (see section on active and passive immunization below).

Prevention and control

Treatment

In post weaning colibacillosis, treatment with antimicrobials and electrolytes should be administered. Sick pigs must be treated parenterally as they eat and drink very little. Subsequently the antimicrobial may be given in the water or feed or as metaphylaxis treatment. Attractive rehydration fluid should be offered to counteract dehydration and acidosis or injected intraperitoneally if the pig is anorectic. Such fluids may contain glucose, glycine, citric acid, and potassium dihydrogen phosphate in an isotonic solution (Bywater and Woode 1980). Uptake should be equal to the loss (i.e. up to 25% of the body weight).

Control of bacterial proliferation therapeutically is much more effective in *E. coli* PWD than in ED, because in ED Stx2e has already been absorbed into the circulation and been bound to receptors when clinical signs become visible. In general, pigs showing neurological signs have a poor prognosis. The development of bacterial resistance against a wide range of antimicrobial drugs makes the efficacy of antimicrobial therapeutics uncertain. Antimicrobial susceptibility testing is indispensable for selection of effective drugs. Antimicrobials that reach therapeutic concentrations in the intestinal lumen, such as amoxicillin/clavulanic acid, fluoroquinolones, cephalosporins, apramycin, ceftiofur, neomycin, or trimethoprim, must be selected. However, antimicrobials identified as "Critically important in human medicine," such as fluoroquinolones and cephalosporins of third and fourth generations, should be used only as a last resort.

For groups of pigs during outbreaks of ED, withholding the feed is thought to impair colonization and is a valuable measure still recommended to prevent new clinical cases. In-feed or water medication, selected by sensitivity testing of isolated EDEC, administered a few days before the onset of ED can reduce the outcome of the outbreak.

Preventive husbandry

Nurseries should be managed as all-in/all-out facilities and should be thoroughly cleaned of organic matter and disinfected prior to use. Water lines and water systems should likewise be disinfected using shock chlorination or a similar chemical process. Management of the weanling pig should minimize environmental and other forms of stress such as unnecessary mixing of litters, chilling, transportation, and assignment to new pens. Recently weaned pigs should be housed in a draft-free environment at a constant temperature of about 29.5 °C (85 °F).

Passive and active immunoprophylaxis

Various strategies involving passive immunity for the prevention of PWD and ED have been used with varying success. An improved weight gain and lower frequency of diarrhea were observed in early weaned (10 days of age) pigs fed a spray-dried porcine plasma-based diet, partly due to the presence of specific anti-ETEC antibodies (Owusu-Asiedu et al. 2002). Similarly, spray-dried porcine plasma had an inhibitory effect on *E. coli* enterotoxemia that lasted only as long as the plasma was fed (Deprez et al. 1990). However, the potential link between spray-dried porcine plasma products and PEDV transmission in North America led to a ban, or voluntary removal, of these products in several North American and European areas (Opreissnig et al. 2014). Passive immune protection against colonization with F4- and F18-positive *E. coli* may be attained by feeding eggs from vaccinated hens or IgY from egg yolk, although effectiveness is not always observed in challenge studies (Li et al. 2015). Antiserum produced by injecting a horse with Stx2e toxoid was effective in protecting pigs from ED in two Danish herds with this disease (Johansen et al. 2000).

Several commercial vaccines are now available for the prevention of *E. coli* PWD and ED. Vaccination against ETEC in pigs has been recently reviewed (Melkebeek et al. 2013). Injectable vaccines, such as those administered to sows for the prevention of neonatal diarrhea, stimulate mostly systemic rather than mucosal immunity, giving rise to circulating antibodies, which do not reach intestinal bacteria in high enough levels to be very effective (Van den Broeck et al. 1999). Such vaccines may even suppress the mucosal immune response upon subsequent oral infection with a pathogenic *E. coli* (Bianchi et al. 1996). Though systemic induction of serum IgA by parenteral vaccines may result in the presence of secretory IgA in the intestinal tract, the latter would be present only as long as the systemic response persists, as no antigen-specific IgA antibody-secreting cells are present in the gut-associated lymphoid tissue (GALT) (Melkebeek et al. 2013). A new vaccine comprising different *E. coli* bacterins was recently approved in some European countries for vaccination of sows and gilts for the passive immunization of piglets in order to prevent neonatal diarrhea and to reduce mortality and clinical signs due to PWD (up to 21 days of age) and to ED (up to 28 days of age).

Live attenuated and wild-type avirulent *E. coli* vaccines have been shown to be an effective approach to prevent and control F4 and F18 pathogenic *E. coli*. Live nonpathogenic *E. coli* vaccine strains carrying fimbrial adhesins may be administered to weaned piglets in the drinking water or to unweaned piglets by oral drenching at least one week prior to the expected onset of diarrhea. Oral administration of a live nonpathogenic F4 *E. coli* vaccine to 17- to 18-day-old pigs immediately following weaning induced a significant protection after challenge with a F4-ETEC strain administered at 7 and 21 days after vaccination and resulted in reduction of clinical signs of PWD, ileal colonization and fecal shedding of F4-ETEC, and normal growth rates after challenge (Fairbrother et al. 2017). Live nonpathogenic F4 *E. coli* vaccines are commercially available (Europe and North America), and a bivalent live vaccine comprising a F4 nonpathogenic *E. coli* strain and a F18 nonpathogenic *E. coli* strain has been recently approved in Europe and Canada for immunization of pigs against F4- and F18-positive *E. coli* PWD.

Another approach is the oral administration of purified F4 and/or F18 fimbriae as a vaccine for the control of outbreaks of *E. coli*-associated diarrhea in weaned pigs (reviewed by Melkebeek et al. 2013). The use of such experimental subunit vaccines, with or without the mucosal adjuvant CT, results in a specific intestinal mucosal immune response and a significant reduction in fecal excretion of the pathogenic F4 *E. coli*. Contrary to F4, oral delivery of purified F18 could not induce a protective response against pathogenic F18 *E. coli* challenge infection (Verdonck et al. 2007).

Several approaches for the control of ED have been investigated. A genetically modified Stx2e toxoid was found to prevent overt and subclinical ED when vaccinated pigs were challenged with EDEC (Bosworth et al. 1996). In two Danish herds with persistent ED problems, vaccination with a Stx2e toxoid almost totally eliminated mortality due to ED (Johansen et al. 1997). A commercial injectable vaccine based on genetically modified recombinant Stx2e that showed reduction of mortality due to ED (Fricke et al. 2015) is now licensed in Europe and Canada.

As with ETEC PWD, live avirulent F18-positive *E. coli* strains have been orally administered to pigs at least 1 week prior to the expected onset of ED. Commercial oral live vaccines comprising an avirulent F18 *E. coli* are available in North America for immunization of recently weaned pigs against ED, but no efficacy studies are yet published. The abovementioned bivalent F4/F18 live vaccine comprising a F4 and a F18 nonpathogenic strain has been recently licensed in Canada for immunization of pigs against F4-PWD, F18-PWD, and F18-ED.

Antimicrobial prophylaxis

At present preventive feed medication with antibiotics is widely practiced in most countries despite serious drawbacks such as nonacceptance by the consumer, impaired buildup of immunity, and selection of resistant bacteria. Resistance is often induced within days or a few weeks. Isolates from *E. coli* PWD and ED show the highest rate of resistance within porcine *E. coli*. In addition to the classes of antimicrobials mentioned above for parenteral therapy, aminoglycosides and colistin are widely used for chemoprophylaxis. However, colistin resistance in pigs has been increasingly reported worldwide in the last several years (Rhouma et al. 2016). In addition, since the first description of the plasmid-mediated colistin resistance *mcr-1* gene in food animals, food, and humans in China in November 2015 (Liu et al. 2016), the number of reports in animal sources rapidly increased. Recently, the European Antimicrobial Advice Ad Hoc Expert Group of the European Medicines Agency recommended that colistin should be classified as "Critically important antimicrobial" (category 2), reserved for situations when there is no affective alternative.

Dietary preventive measures

A number of nutritional strategies appear promising as alternative means of maintaining performance and controlling PWD in weaned pigs without using in-feed antimicrobials and have been reviewed elsewhere (Heo et al. 2013; Kil and Stein 2010; Thacker 2013).

Restriction of feed intake, high fiber diets, and ad libitum feeding of fiber have been reported as effective deterrents to the development of ED and PWD (Bertschinger et al. 1978). The nutritive value of the feed may be reduced by increasing fiber content to 15–20% and reducing crude protein and digestible energy to one-half of the normal values. The addition of fiber to normal diets or feeding high-quality alfalfa coupled with restriction of daily feed intake may be beneficial. A low protein diet with amino acid supplementation may decrease production of toxic protein metabolites and reduce PWD (Heo et al. 2013). Animal source proteins seem to provide protection against PWD. Addition of dairy products to feed delayed the occurrence of PWD and reduced mortality (Tzipori et al. 1980), possibly due to greater digestibility or stimulation of higher feed intake (Lalles et al. 2007).

A lower mortality due to *E. coli* enterotoxemia and improved weight gains were reported after introduction of rations with a reduced acid-binding capacity. A similar effect is ascribed to organic acids. Organic acids contribute to the maintenance of an acidic gastrointestinal tract, which may control potentially pathogenic bacteria. However, mortality due to ED was not reduced by the inclusion of a mixture of organic and inorganic acids in the feed (Johansen et al. 1996). This result is not surprising in view of the highly regulated pH close to the mucosal surface (McEwan et al. 1990).

Zinc oxide may offer an alternative to antimicrobials. Feeds with contents between 2400 and 3000 ppm of zinc reduce diarrhea and mortality and improve growth. The prevention of disease in piglets improves growth and feed conversion efficiency. Positive response at 1500 ppm has been reported using growth rate as an indicator. The protective effects of zinc oxide may be due not to antibacterial activity but to a protection of intestinal cells from ETEC infection by inhibition of bacterial adhesion and internalization and modulation of cytokine gene expression (Roselli et al. 2003). However, care must be taken to avoid overdose or feed pigs for a too long period since toxicity has been reported. Environmental considerations should be included in discussions of zinc oxide at such high levels. Recently, different studies suggest that therapeutic doses of zinc co-select for antibiotic resistance development in weaned pigs, though further research is needed to confirm the link between the use of zinc and antimicrobial resistance (Vahjen et al. 2015).

Several successful dietary supplements have been reported. Oral administration of immunostimulatory beta-glucans from the cell wall of yeasts reduces the susceptibility of weaned piglets to F4-ETEC infection (Stuyven et al. 2009). Exogenous as well as endogenous proteases lower the activity of intestinal F4 receptors. Bromelain, a protease from pineapple stems, administered orally to pigs reduced the binding of F4-ETEC to brush borders in a dose-dependent manner (Mynott et al. 1996). Wide ranges of antimicrobial peptides, which are components of the host defense system, have been identified, which may potentially replace antibiotics (Thacker 2013). Other alternatives include clay minerals, essential oils, and recombinant enzymes, although most of these compounds produce inconsistent results and they are rarely as effective as antibiotics.

Addition of colicin E1, a member of a class of bacteriocins produced by and effective against *E. coli*, in the diet of young pigs decreased the incidence and severity of PWD caused by F18-ETEC and improved the growth performance of the piglets (Cutler et al. 2007).

Prebiotics selectively stimulate the proliferation of potentially beneficial microorganisms in the gastrointestinal tract. For example, administration of a heat-killed and dried *Enterococcus faecalis* strain significantly reduced the incidence of clinical signs due to STEC (Tsukahara et al. 2007).

Some promising results have been obtained using probiotics, potentially beneficial microorganisms. Feeding of a diet supplemented with a *Lactobacillus sobrius* strain isolated from the pig intestine resulted in a significant decrease in ETEC numbers and increased daily weight gain in weaned pigs challenged with an F4-ETEC (Konstantinov et al. 2008). *Lactobacillus plantarum*,

given to piglets in early life, improved performance and effectively prevented the diarrhea in young piglets induced by F4-ETEC challenge by improving function of the intestinal barrier by protecting intestinal morphology and intestinal permeability (Yang et al. 2014). The administration of *Pediococcus acidilactici* or *Saccharomyces cerevisiae boulardii* was effective in reducing F4-ETEC attachment to the ileal mucosa, and at least the presence of *P. acidilactici* resulted in the modulation of the expression of intestinal inflammatory cytokines, in pigs challenged with F4-ETEC (Daudelin et al. 2011). On the other hand, others reported no efficacy of feeding of *Lactobacillus* spp., *Enterococcus faecium*, and *Bacillus cereus* strain "toyoi" to experimentally and/or naturally infected pigs (De Cupere et al. 1992).

Feeding of a diet supplemented with fermented soybeans (especially *Rhizopus*-fermented soybean, but also *Bacillus*-fermented soybean) reduced the excretion of ETEC and the incidence, severity, and duration of diarrhea in weaned pigs (Kiers et al. 2003).

Breeding of resistant pigs

Augmentation of the presence of both the F18 and F4 resistance loci in the pig population through breeding is an attractive approach to prevent PWD and ED. However, it will be important to avoid co-selection of unwanted traits closely linked with loci coding for the F18 and F4 receptors. It cannot be predicted if additional types of adhesive fimbriae or new variants of known types will emerge, which could bind to yet unidentified receptors. Availability of techniques for large-scale selection of resistant animals remains an important challenge.

A few genetic markers are used by some genetic and breeding companies to increase the proportion of F4- and F18-resistant pigs. A PCR-RFLP test detecting FUT1 M307 polymorphism, correlated with the gene controlling expression of the *E. coli* F18 receptor, could be a simple and inexpensive method for large-scale selection of animals (Frydendahl et al. 2003).

The transmembrane mucins MUC13 and MUC4 provide potential markers for selection of ETEC F4ab/ac-resistant animals, although it is probable that other receptors are involved (Rasschaert et al. 2007; Zhang et al. 2008). However Rasschaert et al. (2007) calculated the sensitivity and specificity for the *in vitro* villous adhesion test, with MUC4 genotyping as the gold standard, as 100 and 24%, respectively. Low specificity was evidenced by a high proportion of pigs identified as genetically resistant showing adhesion of F4ac *E. coli* on the intestine. On the other hand, the immunity aspect should be considered if breeding for resistance becomes available for F4-ETEC, as resistant sows (F4 receptor-negative sows) do not develop and transfer F4-specific antibodies in their colostrum. Thus, heterozygous piglets are not passively protected from development of neonatal diarrhea due to these strains.

E. coli causing fatal shock

Enteric colibacillosis complicated with shock occurs in young pigs before and after weaning. *E. coli* associated with this disease are F4-ETEC (serogroup O149, O157, or O8) or Stx2e-producing *E. coli* that are associated with ED.

In these cases of ETEC or ED, infection progresses so rapidly that death occurs due to shock before diarrhea is observed or before diarrhea proves fatal in the case of ETEC or before cerebral edema proves fatal in ED. This phenomenon is probably due to the rapid release of large amounts of LPS by the colonizing ETEC. The lipid A portion of LPS stimulates the overproduction of mediators of inflammation including tumor necrosis factor (TNF)-α, interleukin (IL)-1, and IL-6. Aggregation and subsequent degranulation of neutrophils activated by these mediators causes damage to the vascular endothelium, loss of fluid, and hypovolemic shock. Modulation of the coagulation pathway also leads to fibrin deposition and clot formation.

Clinical signs are minimal. Apparently healthy young pigs die suddenly or decline rapidly with cyanosis of the extremities. A yellowish to brownish diarrhea is sometimes observed.

Characteristic gross lesions include marked congestion of the small intestinal and stomach walls and blood-tinged intestinal contents (Figure 52.6). Microscopically, severe congestion of the gastric and small intestinal mucosae is commonly associated with microvascular fibrinous thrombi. Necrosis of villi with marked infiltration of neutrophils occurs in severe cases. There is only occasional hemorrhage in the lamina propria of the jejunum and the ileum (Faubert and Drolet 1992).

Immunity, diagnosis, prevention, and control are as described for EPEC and ED.

Systemic *E. coli* infections

E. coli may induce systemic infections, such as septicemia, or localized extraintestinal infections, such as meningitis or arthritis, resulting from bacteremia (Gyles and Fairbrother 2010). Primary septicemia due to *E. coli* occurs sporadically or rarely as small outbreaks predominantly in newborn to 4-day-old pigs; septicemia can be secondary to diarrhea or other compromising diseases in young and even weanling pigs (Fasina et al. 2015).

Piglets lacking immunity due to an absence of ingested colostrum or to ingestion of colostrum lacking specific antibody are most at risk for primary septicemia. Agalactia in sows, low birth weights, an inadequate number of functional nipples, or any other factor that reduces consumption of colostrum may result in susceptible piglets. Although these piglets usually develop septicemia within the first few days of life, cases may occur throughout the suckling period, or exceptionally in pigs up to 80 days of age. Poor environmental temperature control and inadequate hygiene increase the risk of systemic infection. The intestine is considered as the major route of *E. coli* invasion. The disease can be experimentally induced by oral or intragastric inoculation (Ngeleka et al. 1993). Bacterial invasion may also be via the respiratory tract or contamination of the umbilicus. Strains involved are known as ExPEC and are a heterogeneous group that possesses a large number of virulence factors (discussed in the section on etiology above). Nevertheless, only a limited number of serogroups are represented (Table 52.1).

Secondary septicemia may develop after invasion by ETEC. The ETEC serovirotypes most often involved are listed in Table 52.2. Older suckling piglets suffering from secretory diarrhea caused by ETEC are most often affected. Sows may also be affected soon after farrowing. Other risk factors may include enteric viruses that damage the intestine and alter the bacterial environment or infection by PRRSV that results in immunosuppression, permitting invasion by ETEC leading to death (Nakamine et al. 1998).

Pathogenesis

Bacteria pass through the mucosa of the alimentary tract, probably by endocytic uptake into intestinal epithelial cells or through the intercellular spaces formed by lateral plasma membranes of adjacent epithelial cells, to locate in the mesenteric lymph nodes before entering the bloodstream. Bacterial invasion may result in a generalized infection (septicemia, polyserositis) with bacteria disseminated in various extraintestinal organs such as the lung, liver, spleen, kidney, and brain or in a localized infection (meningitis or arthritis).

The exact role of each virulence factor in the pathogenicity of ExPEC is not always clear, although it appears that the greater number of virulence factors present in an ExPEC isolate, the greater its pathogenic potential. LPS, K-antigen of the capsule and O-antigen, and production of siderophores such as aerobactin are thought to allow the bacteria to invade the host and escape its defense mechanisms. These determinants increase bacterial resistance to the bactericidal effect of complement and to phagocytosis and allow bacterial growth in body fluids with low concentrations of free iron (Ngeleka et al. 1992). Fimbriae appear to be important for the survival and spread of bacteria within the host and subsequent bacterial pathogenicity, in part by promoting bacterial resistance to the bactericidal effects of phagocytosis (Ngeleka et al. 1994).

Clinical signs

Clinical signs of septicemia include depression, lameness, reluctance to move, anorexia, rough hair coat, and labored respiration, due in part to the effect of bacterial endotoxin or cytotoxins or to the effects of inflammatory cytokines induced by these bacterial products (Jesmok et al. 1992; Nakajima et al. 1991). The affected piglets may show sternal recumbency and the abdomen may be somewhat distended. Sometimes piglets become unconscious, with convulsions and paddling movements; they may be in good bodily condition, but cyanosis of the extremities may be observed. Some piglets are found dead, whereas others are comatose without any sign of diarrhea. These clinical signs may develop within 12 hours after birth, and piglets can die within 48 hours. In older piglets, the clinical signs may include periodic diarrhea or other clinical signs, which precede the onset of acute septicemia with clinical signs resembling those in the newborn pigs.

Lesions

In acute primary septicemia, there may be no gross lesions other than congestion of the intestine, the mesenteric lymph nodes, and the extraintestinal organs. In subacute cases, subserous or submucosal hemorrhages and fibrinous polyserositis (Figure 52.7) with gross signs of pneumonia are usually observed, often accompanied by fibrinopurulent arthritis and meningitis. Histological examination of the lung reveals expansion of alveolar septa with edema and neutrophilic infiltration, but alveoli are mostly free of exudates.

In secondary septicemia resulting from enteric colibacillosis, icterus, petechial hemorrhages in the serosal membranes, and splenomegaly accompanied by severe diarrhea and dehydration may be observed. In many cases of secondary systemic *E. coli* infection, presumably occurring in the terminal stages of the underlying disease, lesions attributable to systemic ETEC are slight or no lesions at all are recorded.

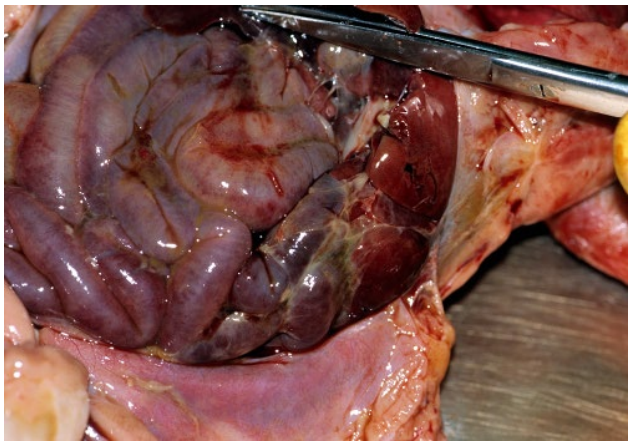

Figure 52.7 Fibrinous peritonitis in a 2-day-old piglet with polyserositis due to *E. coli* (ExPEC). *Source:* Courtesy of Dr. Richard Drolet.

Diagnosis

Systemic colibacillosis should be suspected with the appearance of the clinical signs and lesions described above, especially when observed in pigs under 4 days of age. Differentials should include other causes of systemic bacterial infections. In older suckling and especially weanling pigs with polyserositis, differentials should include *H. parasuis* (Chapter 54), *Mycoplasma hyorhinis* (Chapter 56), and *S. suis* (Chapter 61).

Positive blood culture results are essential to make the diagnosis of bacteremia. However, treatment cannot be delayed until the results of blood cultures are obtained. Blood must be withdrawn from the vein aseptically and deposited into both aerobic and anaerobic blood culture bottles. Diagnosis is confirmed by the isolation in pure culture or by the predominance in extraintestinal organs such as the spleen, liver, brain, lungs, and pericardial, pleural, and peritoneal fluids of one of the typical *E. coli* serovirotypes associated with primary septicemia (Table 52.1) or, for secondary septicemia, one of the ETEC serovirotypes listed in Table 52.2. Methods used to isolate, identify, and serovirotype are as described in the diagnostic section for neonatal *E. coli* diarrhea.

Prevention and control

In septicemia, treatment may be useful in subacute cases of infection but is mostly ineffective after the appearance of clinical signs. However, the remaining unaffected littermates and adjacent litters should be treated prophylactically with antibiotics. Vaccination is rarely considered for the control of septicemia due to *E. coli*. However, in the case of small outbreaks of septicemia, careful monitoring of the causative serogroup(s) and autovaccination of the pregnant sows might be beneficial. The most effective prevention is in ensuring that piglets consume adequate colostrum by focusing on management practices that enable optimal lactation and suckling. Additionally, facility design and husbandry practices to minimize environmental contamination by feces will reduce exposure and transmission of offending strains of *E. coli* to suckling pigs.

Coliform mastitis

The term "coliform mastitis" is used to refer to mastitis in swine, underlining the parallel of this disease with CM in the cow. Up to 80% of dysgalactic sows may have gross lesions of mastitis (Ross et al. 1981). Wegmann et al. (1986) reported that *E. coli* or *Klebsiella pneumoniae* were isolated from 79% of mammary complexes in sows with mastitis. Mortality among affected sows is low, but in piglets nursing multiparous sows with PDS, it has been reported to be as high as 55.8%, compared with 17.2% in piglets nursing healthy sows (Bäckström et al. 1984).

The fecal microbiota is a reservoir for extraintestinal coliform infections such as mastitis and UTI. Various coliform strains are found in the intestine of each individual pig, and mixed infections of more than one strain are often found in any one pig. In about one-third of the sows with mastitis, identical isolates were found in mastitic glands, the uterine contents, and the urinary bladder (Bertschinger et al. 1977a). The intestinal microbiota of the sow, the oral microbiota of the neonatal piglet, and environmental bacteria may significantly contribute to contamination of the nipples. Awad-Masalmeh et al. (1990) found identical O serogroups of *E. coli* in mammary secretion and in feces of about one-fourth of sows with CM. The bedding of the sow is very important, permitting feces and urine to contaminate the udder (Muirhead 1976). *Klebsiella* spp. may also originate from wood shavings used for bedding. Counts of coliform bacteria on teat ends and incidence of intramammary *E. coli* infections were considerably greater in sows farrowing in conventional farrowing crates as compared with those observed in sows farrowing in pens where they could lie down in a clean resting area (Bertschinger et al. 1990).

A great heterogeneity of isolates, evidenced by multiple serological types and by random amplified polymorphic DNA genotyping, may be cultured in cases of mastitis within a herd, between distinct glands of one sow, or even between subcomplexes within one gland (Awad-Masalmeh et al. 1990; Morner et al. 1998; Ramasoota et al. 2000).

Pathogenesis

Mastitis has been reproduced in the sow by intramammary instillation of as few as 120 organisms of a strain of *K. pneumoniae*. External contamination of the nipples

was as successful on gestation day 111 as at 2 hours after completion of farrowing (Bertschinger et al. 1977b). However, it is not clear when spontaneous invasion of the cistern takes place. Significant numbers of coliform bacteria have been observed in about one-fourth of mammary glands cultured immediately prior to parturition (McDonald and McDonald 1975). New infections seem to most commonly occur from before the birth of the piglets to 2 days postpartum (Bertschinger et al. 1990).

The bacteria are located in the ductular and alveolar lumina, either free or within phagocytic cells. Little adhesion to surfaces is observed. At postmortem examination the causative bacteria are frequently isolated from regional lymph nodes, whereas isolations from the liver, spleen, or kidney are rare (Ross et al. 1981).

Multiplication of bacteria in the mammary secretion is controlled by antimicrobial mechanisms, including a variety of inhibitors acting in concert and conferring on the dry udder a nearly total resistance to coliform proliferation. A lower opsonic activity observed in mammary secretions of sows at parturition (Osterlundh et al. 1998) as well as a lower phagocytic capacity of PMN cells in colostrum as compared with milk (Osterlundh et al. 2001) may explain the increased susceptibility to the development of CM at parturition. CM is a self-limiting disease. The bacteria generally disappear between 1 and 6 days after parturition (Bertschinger et al. 1990), but in severe cases they may persist in necrotic foci throughout lactation (Löpfe 1993).

CM in the sow is associated with massive accumulation of neutrophils in the lumina of affected glands and may be accompanied by a severe leukopenia (Bertschinger et al. 1977b). Severe reaction is the consequence of massive and persistent multiplication of inoculated bacteria, susceptibility to infection being associated with impaired function of circulating neutrophils (Löfstedt et al. 1983). The cause of the impaired neutrophil function is not well understood. Magnusson et al. (2001) showed that sows were more susceptible to experimental infection immediately prior to parturition than at 4 days before parturition, the number of neutrophils in the blood being greater in the former. These findings suggest a role for the number of circulating neutrophils at the time of infection in the development of clinical CM in the sow. Nevertheless, Osterlundh et al. (2002) have shown in experimental inoculation studies that impaired chemotactic or phagocytic capacity of blood granulocytes does not appear to be involved in susceptibility of sows to develop clinical CM at parturition.

The systemic signs of CM are induced by bacterial endotoxin (Bertschinger et al. 1990). The development of clinical signs of CM, like high fever, is associated with the degree of local expression of regulatory cytokines such as IL-1 and IL-6 (Zhu et al. 2008).

Clinical signs

In CM, the initial signs are most often detected on the first or second day and more rarely on the third day after farrowing, although they may be observed as early as during parturition. The first clinical signs are pyrexia, listlessness, weakness, and loss of interest in the piglets. Affected sows prefer sternal recumbency. In severe cases they become stiff, do not stand, and may even become comatose. Consumption of feed and water is either reduced or absent. Body temperature is moderately elevated and only rarely exceeds 42 °C (107 °F). Afebrile cases have been reported. On the other hand, many normal sows will have rectal temperatures that exceed the 39.7 °C (103 °F) limit on the day of parturition and for 2 days thereafter. In affected sows, respiratory and heart rates are increased. In general, clinical signs do not last for more than 2–3 days.

The clinical findings in sows with proven CM may be quite similar to those in sows with lactational failure. Interpretation of clinical parameters is also rendered difficult by the presence of subclinical CM in apparently healthy sows. The behavior of the piglets is very helpful in the early detection of lactational failure. Undernourished piglets look gaunt. They frequently try to suck, move from nipple to nipple, nibble at litter, and lick urine from the floor. If the sow gives access to the nipples, the periods of suckling are shortened. After suckling, the piglets wander instead of resting in close contact with their littermates.

Precise localization of mammary lesions is often not possible because reddening and heat of the skin extend over several subcomplexes. The reliable clinical assessment of the state of the mammary tissue is difficult because of subcutaneous fat and considerable subcutaneous edema. If palpable, the mastitic tissue is firmer and palpation may cause pain. The red color of the skin is blanched by finger pressure, which causes a depression of the tissue lasting for some time due to edema. Mere clinical examination will at best detect only a portion of the affected subcomplexes (Persson et al. 1996). The inguinal lymph nodes may be swollen.

Lesions

Lesions of CM are confined to the mammary glands and regional lymph nodes. Grossly, the exudate from inflamed subcomplexes resembles serous to creamy pus. It may contain clots of fibrin or blood. The subcutaneous tissue may be edematous over affected parts of the udder. Irregularly scattered foci of mastitis may be detected in different subcomplexes. The appearance of affected mammary tissue varies from slightly increased firmness and grayish discoloration to sharply demarcated, red-mottled, hard, and dry areas.

Microscopically, an acute purulent exudative mastitis with congestion is observed. The severity varies greatly, both between and within subcomplexes, ranging from a small number of neutrophils in the alveolar lumina to severe purulent infiltration with necrosis. Acute purulent lymphadenitis may be present in the inguinal and iliac lymph nodes. Large necrotic foci surrounded by fibrous tissue may persist through the lactation in severe cases (Löpfe 1993).

Diagnosis

Any hypogalactia at the beginning of lactation arouses suspicion of CM. The diagnosis may be supported by fever, anorexia, reluctance to stand, lying on the gland, and disinterest in the piglets. In severe cases some affected glands may be reddened, swollen, and firm, and the secretion may look abnormal.

A reliable rapid test for use on the farm is not available. Due to the normal higher cell content of sow milk compared with cow milk, tests developed for use with the cow cannot be recommended. Bacteriological and cytological examinations of the secretion are only valuable if all glands are sampled or if affected glands are known. The pH is of limited diagnostic value (Persson et al. 1996), but cytological examination allows differentiation between healthy and mastitic complexes at least during the first 48 hours after parturition (Wegmann and Bertschinger 1984). Because mastitis is a local process, samples must be taken from individual complexes and not pooled. A suggested threshold value for the total cell count is 5×10^6 cells/mL of milk and fewer than 70% PMN. Culture of the secretion may be necessary in unclear cases. Methods for culture are as described for neonatal *E. coli* diarrhea.

Immunity

An episode of CM apparently does not result in protection against homologous reinfection (Bertschinger and Bühlmann 1990). Ringarp (1960) reported a higher incidence in sows than in gilts, as well as repeated occurrence, up to 10 times, in individual sows.

Prevention and control

In CM, therapeutic measures are usually not undertaken before the sow shows signs of dysgalactia. Thus treatment may at best shorten the period of underfeeding of the piglets. Antimicrobial therapy is complicated by the heterogeneous pattern of antimicrobial susceptibility of individual isolates not only within a herd but also within a sow. Therefore sensitivity testing is of little value in individual cases.

Much attention should be given to the piglets. They may either be fostered by other sows or remain with their mother and receive a milk substitute. A sterile 5% glucose solution can be repeatedly injected intraperitoneally every several hours, or a more concentrated solution may be administered intragastrically. When the piglet obtains insufficient amounts of milk, protection against chilling is particularly important.

Strategies for prevention of CM include protection of the teats from bacterial contamination (Muirhead 1976). Optimal prophylaxis is achieved by designing farrowing accommodation in which the sow is prevented from lying down in her own feces. When this is not possible, periodic washing and disinfection of contaminated pens and of the newly housed sows are not highly effective prophylactic measures. If cases of CM accumulate, the bedding materials should be checked. Drastic reduction of the sow's ration shortly before parturition is a widespread practice. Reduction of the daily feed allowance may substantially lower the incidence of agalactia (Persson et al. 1989).

Chemoprophylaxis appears to be the most promising method of control for CM where accommodation cannot be improved. The prevalence of drug resistance and the wide variety of bacteria associated with the disease in a herd must be considered when the drug is selected. Feed medication should be replaced by individual application of the drug in a small amount of feed because the feed consumption of the sow in the periparturient period is quite variable. Minimizing the period of treatment helps to postpone the emergence of drug resistance. Antimicrobials demonstrating some effectiveness include a combination of trimethoprim, sulfadimidine, and sulfathiazole; apramycin; and enrofloxacin.

Nonspecific urinary tract infection

Like CM, nonspecific UTI behaves like a noncontagious infectious disease of endogenous origin. The fecal microbiota is a reservoir for extraintestinal infections such as mastitis and UTI. Contamination and ascent of the urethra by fecal microbiota is more likely in females than males. Under intensive confinement conditions, vulvas of sows are often placed in direct contact with feces (Smith 1983). The dog-sitting position helps to force fecal material into the vagina. Sows resting for long periods of time void urine at longer intervals, and urinary stasis favors bacterial ascent in the urethra and proliferation in the bladder. However, housing conditions have not been studied with respect to UTI. The age distribution of UTI favors the concept of continuous exposure to fecal contamination, since the prevalence of UTI increases with sow parity and increasing parity is associated with greater vulvar and urethral trauma and laxity (Becker et al. 1985). Low water consumption may also have a role in predisposing to UTI.

Pathogenesis

In humans and in dogs, colonization of the lower genital tract and of the urinary tract by uropathogenic *E. coli* is greatly facilitated by fimbrial adhesins, particularly type 1 and P fimbriae (Gyles and Fairbrother 2010). Similarly, P fimbriae and mannose-sensitive hemagglutination indicative of type 1 pili were found in *E. coli* isolates from the urine of pigs with bacteriuria (de Brito et al. 1999). Serovirotypes of *E. coli* commonly isolated from UTI are listed in Table 52.1. Bacteria most likely ascend through the urethra. Invasion is favored by the short wide urethra of the female pig, the relaxation of the sphincter muscle in late pregnancy and puerperium, trauma to the urethra and bladder at coitus and parturition, abnormal bacterial colonization of the sinus urogenitalis and the genital organs, incomplete closure of the vulva, and catheterization of the bladder. Asymptomatic bacteriuria may result in cystitis with spontaneous remission. Nonspecific infection may promote colonization of the bladder by *A. suis* (Liebhold et al. 1995). Bacterial colonization may lead to shortening and deformation of the ureteric valve, promoting vesicoureteric reflux (Carr et al. 1990).

UTI may predispose to MMA due to ascending invasion of the uterus at parturition and of the mammary glands from contamination of the lying area. Identical OK serotypes of *E. coli* have been found in the urinary bladder and uterus or bladder and mammary gland of sows with MMA (Bertschinger et al. 1977a).

Clinical signs

In the vast majority of nonspecific UTI cases, there are no clinical signs. Sows with a significant bacteriuria tend to wean small litters, have increased intervals between litters, show a lower fertility rate, and exhibit an inferior body condition (Akkermans and Pomper 1980). Sows with cystitis may void urine in small quantities with straining or be observed in a dog-sitting position (Becker et al. 1988).

Vulvar discharge may appear as dried deposits around the vulva, on the underside of the tail, or more often as a pool on the floor underneath the sow (Dial and MacLachlan 1988a). The discharge may be mucoid, mucohemorrhagic, or purulent and is observed most often during the final phase of urination. However, discharge may result from inflammation of any part of the urogenital tract. Significant discharge is more often the consequence of endometritis than of UTI.

Severe pyelonephritis becomes clinically manifest during the first 2 weeks postpartum in 40% of the cases (Stirnimann 1984). Typical cases exhibit a rectal temperature below 38 °C (100 °F), a heart rate over 120, polypnea, cyanosis, ataxia, and more rarely generalized tremor. The blood concentrations of urea and creatinine are higher than normal.

Lesions

The gross lesions of cystitis begin as focal or diffuse mucosal hyperemia (Dial and MacLachlan 1988b). Subsequently, there may be mucosal ulceration with fibrinopurulent exudate over affected areas. The bladder wall becomes thickened. Similar lesions occur in the ureters and the renal pelvis if infection ascends the urinary tract. In pyelonephritis the inflammatory process extends into the renal parenchyma. Multiple unevenly distributed foci of inflammation mostly affecting the renal poles are observed (Isling et al. 2010). Wedge-shaped foci extend from the distorted pelvis to the cortex. Fibrosis of the kidneys may occur with time.

Microscopic bladder lesions can be found even in sows with nonspecific UTI and no proteinuria. They consist of a prominent goblet cell proliferation and of intraepithelial cysts containing a few granulocytes. The epithelial layer is infiltrated with neutrophils, whereas mononuclear cells dominate in the lamina propria (Liebhold et al. 1995). In kidneys, tubulointerstitial infiltration with neutrophils and mononuclear cells and tubular destruction are the main findings (Isling et al. 2010).

Diagnosis

Clinical examination of the animal is of little value in the diagnosis of UTI. Bacterial culture of the urinary tract is complicated by the presence of the normal microbiota colonizing the vagina and the distal part of the urethra. Therefore, distinction between contamination and infection is based on the number of bacteria in the urine. A viable count of 10^5 CFU/mL is interpreted as indicative of infection and 10^4 CFU/mL as suspicious. Catheterization of the sow is possible but does not circumvent contamination and involves the risk of setting up a new UTI.

Immunity

Serum antibody against the infecting *E. coli* strain can regularly be detected in sows with pyelonephritis, less often in sows with cystitis, and rarely in sows with asymptomatic bacteriuria (Wagner 1990). *E. coli* strains may persist in the urinary tract despite high antibody concentrations in the urine.

Prevention and control

Treatment of urogenital infections of swine is frustrating (Dial and MacLachlan 1988b). For UTI, therapy with broad-spectrum or combined antimicrobials, such as trimethoprim/sulfonamides, is recommended due to the variable susceptibilities of the diverse bacteria involved and the frequent acquisition of resistance (Berner 1990). Prolonged parenteral treatment may be recommended, although

subclinical UTI often persists after treatment (Becker et al. 1988). Treatment of affected sows with specific antimicrobial drugs before parturition may be helpful.

Strategies for control of UTI include decreasing environmental exposure by improving fecal drainage and housing conditions. Frequency of urination may be increased by giving access to an exercise yard and by increasing water intake, being achieved by a salt content of 1% in the diet (Smith 1983). Water accessibility and flow rates in water lines and nipples should also be evaluated. Decreased water consumption can also be caused by poor palatability.

Erysipelas

Tanja Opriessnig and Tania A. Coutinho

Relevance

The causative agent of erysipelas, *Erysipelothrix rhusiopathiae*, was first isolated from a pig in 1882 by Louis Pasteur and was first characterized in experimentally infected pigs in 1886 by Friedrich Löffler. Erysipelas occurs sporadically in the pig population, but there is evidence that more severe and prevalent outbreaks occur in recurring intervals of approximately 10 years. Several recent reports of swine erysipelas outbreaks in countries with relevant pig production raise concerns on reemergence of this disease (Bender et al. 2010; Coutinho et al. 2011; Ding et al. 2015; To et al. 2012).

Swine erysipelas, when uncontrolled, is economically significant and capable of affecting all stages of pork production. The greatest losses can be attributed to cases of sudden death and acute septicemia in grow–finish pigs. A frequent sequel of surviving an acute infection is chronic lameness and arthritis, which results in poor growth and abattoir condemnations. *E. rhusiopathiae* is also relevant from a public health perspective, albeit infections in humans are rare (Reboli and Farrar 1989).

Etiology

Erysipelothrix rhusiopathiae belongs to a group of bacteria that represent a new class, *Erysipelotrichia*, in the phylum *Firmicutes* (Ogawa et al. 2011). The genus *Erysipelothrix* comprises seven species to date: *E. rhusiopathiae* (Migula 1900; Skerman et al. 1980), *Erysipelothrix tonsillarum* (Takahashi et al. 1987), *Erysipelothrix* sp. strain 1, *Erysipelothrix* sp. strain 2, *Erysipelothrix* sp. strain 3 (Takahashi et al. 2008), *Erysipelothrix inopinata* (Verbarg et al. 2004), and *Erysipelothrix larvae* sp. nov. (Bang et al. 2015). The most relevant species for pigs is *E. rhusiopathiae*, though strains of *E. tonsillarum* have been isolated from cases of chronic arthritis and vegetative valvular endocarditis (Bender et al. 2011; Takahashi et al. 1996).

Erysipelothrix spp. are nonmotile, non-sporulating, non-acid-fast, facultatively intracellular gram-positive rods that are facultative anaerobes and grow between 41 °F (5 °C) and 111 °F (44 °C), with optimal growth occurring between 86 °F (30 °C) and 98.6 °F (37 °C) (Carter 1990). On agar media, colonies of *Erysipelothrix* spp. are clear, circular, and small (0.1–0.5 mm in diameter) after 24 hours of incubation at 95 °F (35 °C) or 81 °F (27 °C), with increased size (0.5–1.5 mm in diameter) after 48 hours, and they are either smooth or rough, being slightly larger with an irregular edge. Most strains induce a narrow zone of partial hemolysis on blood agar media, usually with a greenish color. Rough colonies are not typically associated with hemolysis. *E. rhusiopathiae* is relatively inactive in commonly used biochemical tests, producing acid but no gas from certain fermentable carbon compounds and hydrogen sulfide in triple-sugar iron agar (Carter 1990).

Based on heat-stable cell wall antigens, *Erysipelothrix* spp. strains can be differentiated by precipitation reactions using hyperimmune rabbit antiserum into at least 28 serotypes, 1a, 1b, 2–26, and N, the latter referring to strains lacking these antigens (Kucsera 1973; Wood and Harrington Jr 1978) (Table 53.1). Cases of clinical erysipelas are predominantly caused by serotype 1a, 1b, or 2 (Wood and Harrington Jr 1978).

Public health

Though human infections by *E. rhusiopathiae* are rarely reported, this bacterium has long been recognized as zoonotic (Rosenbach 1909). Most human cases are a consequence of occupational exposure (butchers, abattoir workers, veterinarians, farmers, fishermen, fish handlers, and housewives) to infected animals or their tissues (Reboli and Farrar 1989) and occur via scratches

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Table 53.1 Characteristics of strains associated with different *Erysipelothrix* spp.

Species	Isolated from	Pathogenic to pigs	Serotypes	Surface protective antigen type
E. rhusiopathiae	Terrestrial and marine mammals, birds, reptiles, fish, and arthropods	Yes	1a, 1b, 2, 4, 5, 6, 8, 9[a], 11, 12, 15, 16, 17, 19, 21, N	A, B, C, or combinations
E. tonsillarum	Terrestrial mammals and fish	Variable	3, 7[a], 10[a], 14, 20, 22, 23, 25, 26	None
Erysipelothrix sp. strain 1	Pigs	Yes	13	None
Erysipelothrix sp. strain 2	Pigs	Yes	9[b], 10[b], 18	C
Erysipelothrix sp. strain 3	Pigs	Yes	7[a]	None
E. inopinata	Sterile-filtered vegetable broth[c]	No	Not determined	Not determined
E. larvae sp. nov.	Beetle	No	Not determined	Not determined

or traumatic penetration of the skin. Not accidentally the most common clinical manifestation in humans is known by names such as "whale finger," "seal finger," "speck finger," "blubber finger," "fish poisoning," "fish handler's disease," and "pork finger" (Reboli and Farrar 1989) since cutaneous infections are usually confined to the extremities. The clinical form in humans is called erysipeloid and manifests as acute localized cellulitis with skin reddening. Additional clinical presentations include a generalized cutaneous form and a septicemic form, with endocarditis present in about one-third of the patients (Principe et al. 2016). These conditions should not be confused with "human erysipelas," which refers to a skin infection caused by mainly group A and G streptococci (Bläckberg et al. 2015). Human-to-human transmission of *E. rhusiopathiae* has not been established to date (Reboli and Farrar 1989).

Epidemiology

Erysipelothrix rhusiopathiae is worldwide in distribution and is ubiquitous. The domestic pig is considered the most important reservoir. Besides pigs, a variety of vertebrate and invertebrate species are known to harbor the organism providing a broad reservoir (Wang et al. 2010).

Approximately 30–50% of apparently healthy pigs harbor *E. rhusiopathiae* in their tonsils and other lymphoid tissues (Stephenson and Berman 1978). Carriers and pigs with acute erysipelas can shed the organism in their excretions (urine, feces) and secretions (saliva, nasal mucus) for extended periods of time. The bacterium can be isolated from oral fluid of an acutely infected population for 1–3 days and demonstrated by real-time PCR for 1–9 days (Giménez-Lirola et al. 2013). Transmission of *E. rhusiopathiae* is believed to occur directly via oronasal secretions and feces and indirectly via environmental contamination (Wood and Harrington Jr 1978). While there is no evidence of *E. rhusiopathiae* growth in the environment, its presence in facilities and on equipment is well documented (Bender et al. 2010; Reboli and Farrar 1992). Pigs can be infected by ingestion of contaminated feed or water and through contamination of skin wounds. Pigs less than 3 months of age (due to a protective effect of passively acquired immunity) or pigs older than 3 years of age (due to repeated subclinical disease) are generally least predisposed to erysipelas.

Survival of *E. rhusiopathiae* in soil is less than 35 days, with no evidence of establishment of stable populations (Wood 1973). *E. rhusiopathiae* is inactivated by moist heat at 131 °F (55 °C) but is resistant to salting and many other food preservation methods (Conklin and Steele 1979). It may remain viable for 12 days under direct exposure to sunlight and for months in unburied carcasses or in carcasses buried to a depth of 7 ft (2.13 m) (Reboli and Farrar 1989). *Erysipelothrix* spp. are inactivated by commonly available disinfectants (Conklin and Steele 1979).

Pathogenesis

The route of exposure to *E. rhusiopathiae* in pigs is primarily oral with initial infection of the tonsils or gastrointestinal mucosa. Cytokeratin 18 positive cells of tonsillar crypt epithelium are likely the main invasion sites of *E. rhusiopathiae* (Harada et al. 2013). The bacterium is able to survive and replicate within macrophages (Ogawa et al. 2011; Shimoji 2000) and is consistently

detected within peripheral tissues (Harada et al. 2013). Bacteria may also enter through skin abrasions or via mechanical vectors such as arthropod bites (Chirico et al. 2003). Usually, bacteremia develops within 24 hours in the absence of an effective immune response. Subsequent septicemia results in distribution of the organisms throughout the body. In the early septicemic stage, damage occurs to capillaries and venules of most body organs and synovial membranes (Schulz et al. 1975a). At 36 hours after subcutaneous inoculation, endothelial swelling, monocyte adherence to vascular walls, and hyaline thrombosis occur (Schulz et al. 1975b). This process is referred to as a shock-like generalized coagulopathy that leads to fibrinous thrombosis, diapedesis, invasion of vascular endothelium by bacteria, and deposition of fibrin in perivascular tissues (Schulz et al. 1975a, 1976a). Eventually, there is connective tissue activation in predisposed sites of infection including the joints, heart valves, and skin (Schulz et al. 1976b). Hemolysis and ischemic necrosis can occur in severe cases. Sequestration of *E. rhusiopathiae* in the cytoplasm of chondrocytes of articular cartilage has been reported (Franz et al. 1995) and likely provides protection from host immunity, contributing to chronic arthritis.

Marked differences in virulence among strains of *E. rhusiopathiae* exist and may be modulated by virulence factors (Wang et al. 2010). Important virulence factors include neuraminidase, capsular polysaccharides, and surface proteins. Neuraminidase is an enzyme that cleaves sialic acids from glycoproteins, glycolipids, and polysaccharides on host cell walls, providing bacterial nutrients and aiding in bacterial adhesion and tissue invasion (Schauer 1985). The amount of secreted neuraminidase is proportional to the degree of virulence in *E. rhusiopathiae* strains (Krasemann and Müller 1975); none is secreted by nonpathogenic *E. tonsillarum* (Wang et al. 2005). The polysaccharide capsule of *E. rhusiopathiae* provides resistance to phagocytosis by leukocytes and intracellular killing by macrophages (Shimoji 2000). The *E. rhusiopathiae* capsule plays a major role in bacterial adherence and immune evasion. Its phosphorylcholine component, along with surface protective antigen A (SpaA), has been demonstrated to be involved in bacterial adherence to endothelial cells in the absence of platelet-activating factor receptor mediation *in vitro* (Harada et al. 2014). Although SpaA, a choline-binding protein, is expressed in higher amounts in highly virulent strains (Galán and Timoney 1990) and has long been known to be a major protective antigen of *E. rhusiopathiae* (Makino et al. 1998), the extent of its contribution to bacterial virulence is unknown. Other bacterial surface proteins that may contribute to virulence include novel adhesins RspA and RspB (Shimoji et al. 2003), which are important in early biofilm formation.

Experimental evidence linking susceptibility to swine erysipelas with host genetics is lacking. Sudden changes in weather, especially hot summer weather, or other stressors have been implicated in increased incidence of the disease.

Clinical signs

Three clinical forms of swine erysipelas – acute, subacute, and chronic – have been described (Conklin and Steele 1979; Grieco and Sheldon 1970). The acute form is septicemic disease that manifests as sudden onset of acute death, abortions, depression, lethargy, pyrexia (104–108 °F [40–42 °C] or greater), withdrawal, lying down, painful joints evidenced by stiff stilted gait, reluctance to move and/or vocalization during movement, partial or complete inappetence, and characteristic pink, red, or purple raised firm rhomboid or squared "diamond skin" lesions. In dark-skinned animals, the skin lesions are best appreciated by palpation or by observing areas with raised hairs. In nonfatal cases, the skin lesions will gradually disappear within 4–7 days.

The subacute form is clinically less severe than the acute form. Animals do not appear as sick, temperatures are not as high or persistent, appetite may remain unaffected, skin lesions may be few in number or absent, mortality will be lower, and animals will recover more rapidly. There may be infertility, litters with increased numbers of mummies or of small size, and pre- or postparturient vulvar discharges. Some cases may be so mild that they remain unnoticed (subclinical).

Chronic erysipelas follows acute, subacute, or sometimes subclinical erysipelas in a proportion of surviving animals. The most economically significant form is chronic arthritis that may appear as soon as 3 weeks after the initial outbreak. Affected animals are mildly to markedly lame with associated reduction in feed intake. Firm enlargement of hock, stifle, or carpal joints may be observed. Chronic erysipelas can also manifest as respiratory distress, lethargy, cyanosis, or sudden death as consequences of vegetative valvular endocarditis that may lead to cardiac insufficiency and pulmonary edema.

Morbidity and mortality vary depending on the immune status of a herd. In outbreaks of acute swine erysipelas in naïve herds, mortality can quickly rise to 20–40%. In subclinically or chronically affected herds, the morbidity and mortality associated with *Erysipelothrix* spp. vary and are dependent on herd management, environment, and other concurrent infections.

Lesions

The nearly pathognomonic gross lesions of acute swine erysipelas consist of multifocal pink to purple rhomboid (diamond-shaped) slightly raised skin lesions (Figure 53.1) predominately around the snout, ears, jowls, throat, abdomen, and thighs. The skin of extremities can also be purple. In addition to skin lesions, other typical lesions of septicemia include enlarged and congested lymph nodes, enlarged spleen, and edematous and congested lungs. Petechiae and ecchymosis may be found in the renal cortex (Figure 53.2), the heart (epicardium and atrial myocardium), and occasionally elsewhere. Joints may be slightly enlarged, and the synovium and periarticular tissues are typically distended by serofibrinous exudates that may also fill the joint cavity. In some outbreaks, fattening hogs may be found dead without any gross lesions.

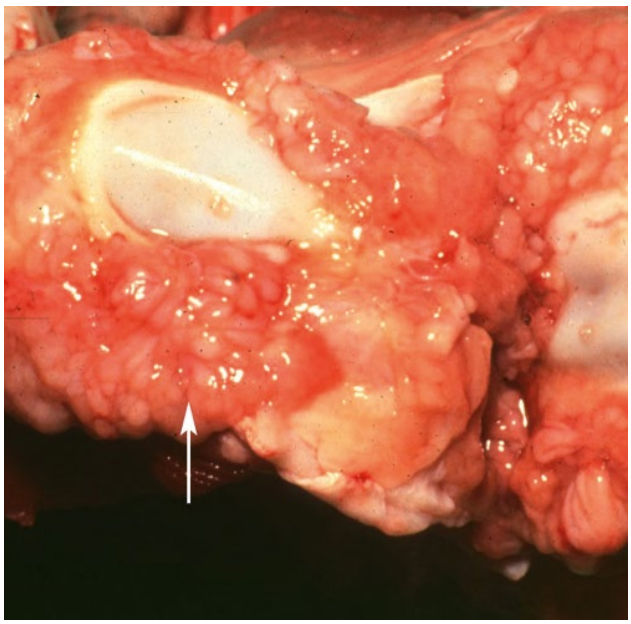

Figure 53.3 Proliferative synovitis in the stifle from a pig with swine erysipelas. *Source:* Courtesy of Dr. Greg Stevenson.

Chronic lesions may include chronic arthritis often involving joints of one or more legs or the intervertebral articulations. Proliferative synovial membranes (Figure 53.3) and serosanguinous effusion in the joint cavity are also observed. The joint capsule is often

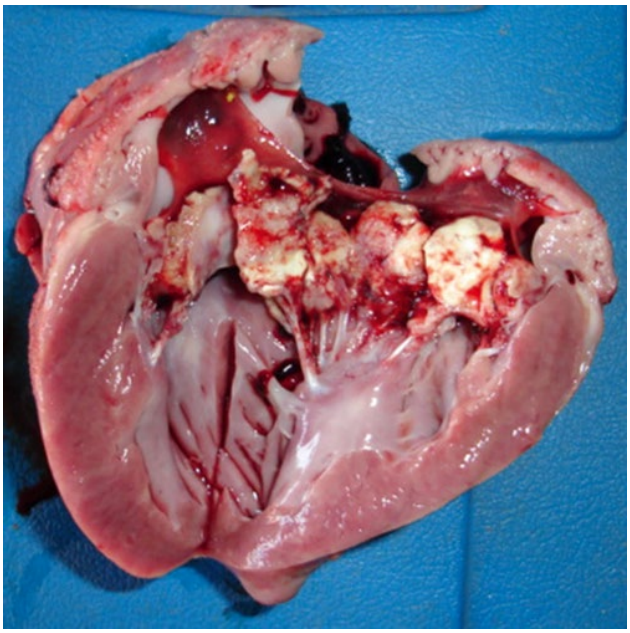

Figure 53.4 Valvular endocarditis in a pig with naturally occurring swine erysipelas. Note the proliferative granular growth on the heart valve. *Source:* Courtesy of Dr. João Gomes-Neto.

Figure 53.5 Ischemic necrosis of the skin on extremities in an 8-week-old pig with swine erysipelas. Note the dark dry partially detached skin. *Source:* Courtesy of Dr. Greg Stevenson.

hyperemic. There may be proliferation and erosion of the articular cartilage that lead to fibrosis, ankylosis, and spondylitis. Valvular endocarditis (Figure 53.4) can be seen as proliferative granular growth on the heart valves (mitral valve most common). Ischemic necrosis of the rhomboid skin lesions and of skin on the extremities is also observed as dry, dark, and sometimes partially detached skin (Figure 53.5).

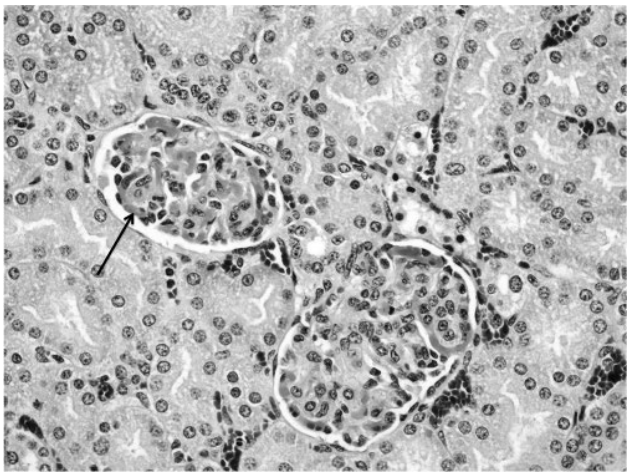

Figure 53.6 Changes in glomeruli in a kidney from a pig 2 days after experimental infection with *Erysipelothrix rhusiopathiae*. Note the inflammatory changes and congestion.

Microscopic lesions in acute erysipelas are predominantly in blood vessels, resulting in associated ischemia and necrosis. Capillaries and venules in the dermis are often dilated and congested. Microthrombi and bacterial emboli may occlude vessels, leading to circulatory stasis and focal necrosis (Figure 53.6). Neutrophils infiltrate the affected dermis. Similar hyperemia, vasculitis, neutrophilic infiltrates, and focal necrosis can also be observed in the brain, heart, kidneys, lungs, liver, spleen, and synovial membranes. Consequences of alveolar septal vessel damage include acute interstitial and exudative pneumonia characterized by serous exudates expanding alveolar septa and flood alveoli that also often contain aggregates of macrophages. Damage to glomerular vessels may result in hemorrhages that are grossly visible on the renal cortex. Affected lymph nodes are hyperemic, hemorrhagic, and infiltrated with neutrophils. Segmental hyaline and granular necrosis of muscle fibers followed by fibrosis, calcification, and regeneration also occurs. As lesions become subacute, infiltrates of monocytes, lymphocytes, and macrophages accumulate in sites of inflammation.

Chronic arthritis is characterized by marked hyperplasia of synoviocytes, resulting in thickened villous proliferations on synovial membranes that also have stromal thickening due to infiltrates of lymphocytes, plasma cells, and macrophages as well as neovascularization. In later stages, marked fibrosis may be observed in synovial membranes and periarticular tissues. Articular cartilage may be focally to extensively necrotic with associated fibrinous to fibrinopurulent exudates. Vegetative valvular endocardial lesions are composed of irregular fibrin lamina comprising fibrin, necrotic cellular debris, mixed inflammatory cells, bacterial colonies, and granulation tissue.

Diagnosis

Timely and accurate diagnosis of erysipelas is important since effective treatments are available and there are a wide variety of conditions that may be confused with swine erysipelas. Differentials for acute swine erysipelas include septicemia and sudden death in grow–finish pigs due to *Salmonella* Choleraesuis (Chapter 59), *Actinobacillus suis* or *Actinobacillus pleuropneumoniae* (Chapter 48), *Haemophilus parasuis* (Chapter 54), *Streptococcus suis* (Chapter 61), and other bacteria. Skin lesions resembling swine erysipelas can also be observed with classical swine fever virus (Chapter 39), porcine dermatitis and nephropathy syndrome (Chapter 30), or *A. suis* (Chapter 48) septicemia. For diagnosis of *Erysipelothrix* spp., a variety of tests are available (Table 53.2). Selection of diagnostic assays should be based on cost, required turnaround time, and availability in different geographic regions.

Isolation of *Erysipelothrix* spp. from tissues with morphological lesions provides a definitive laboratory diagnosis. Direct culture from non-contaminated specimens is usually fast and easy and can be conducted using basic laboratory equipment. Chronic cases and contaminated specimens often require prior selective enrichment methods (Bender et al. 2009; Harrington Jr and Hulse 1971; Wood 1965). Other gram-positive, non-sporulating rod-shaped bacteria that can be confused with *Erysipelothrix* spp. include members of the genera *Brochothrix*, *Corynebacterium*, *Lactobacillus*, *Listeria*, *Kurthia*, and *Vagococcus* (Bender et al. 2009).

To overcome the difficulties of bacterial isolation from specimens of antimicrobial-treated pigs or chronically affected pigs, an immunohistochemical assay has been developed and found to be highly sensitive and specific when compared with direct culture techniques (Opriessnig et al. 2010). In contrast the use of fluorescent antibodies in frozen tissue sections was found less sensitive compared with culture methods (Harrington Jr et al. 1974).

Several polymerase chain reaction (PCR) methods have been developed for the rapid detection of *Erysipelothrix* spp. Among PCR assays, genus-specific methods (Makino et al. 1994; Shimoji et al. 1998a), a multiplex PCR assay capable of differentiating between *E. rhusiopathiae* and *E. tonsillarum* (Yamazaki 2006), a species-specific PCR assay capable of distinguishing four *Erysipelothrix* species (Takeshi et al. 1999), a single nucleotide polymorphism-based PCR assay able to differentiate a Japanese live vaccine strain from field isolates (Shiraiwa et al. 2015), and a quantitative real-time multiplex assay capable of detecting and differentiating *E. rhusiopathiae*, *E. tonsillarum*, and *Erysipelothrix* spp. strain 2 (Pal et al. 2009) have been described.

Serological assays including plate, tube, and microtitration agglutination, passive hemagglutination, hemagglutination inhibition, complement fixation, enzyme-linked immunosorbent assays (ELISA), and indirect immunofluorescence assays have been used to detect antibodies against *E. rhusiopathiae* in pigs (Imada et al. 2003; Wang et al. 2010). However, since 30–50% healthy pigs are carriers and serum antibody responses to *E. rhusiopathiae* infection can persist for days, weeks, or even throughout the life of the pig, serology assays are most useful to evaluate vaccination success in breeding herds.

Genetic or antigenic properties of *Erysipelothrix* spp. isolates can be utilized to gain insight into the origin and relatedness of individual isolates. Methods include serotyping, genomic fingerprinting, and pulsed-field gel electrophoresis (PFGE). The standard serotyping method

Table 53.2 Application of different diagnostic assays for identification of *Erysipelothrix* spp.

utilizes a double agar-gel precipitation test with type-specific rabbit antisera and antigen (Imada et al. 2004; Kucsera 1973); its execution depends on availability of antiserum and requires about 3 days for completion. Genomic fingerprints can be created for species for which minimal information is available by random amplified polymorphic DNA (RAPD) analysis (Okatani et al. 2000, 2004; Imada et al. 2004). Among the current DNA-based typing methods, PFGE has been considered the gold standard by some (Olive and Bean 1999), and using restriction enzyme *Sma*I resulted in distinct PFGE patterns, allowing differentiation among *Erysipelothrix* isolates (Coutinho et al. 2011; Okatani et al. 2001; Opriessnig et al. 2004); however, the turnaround time of this assay is 3–4 working days.

Immunity

Both humoral immunity and cell-mediated immunity play a role in host defense against *E. rhusiopathiae* infection. Therapy with antiserum has been widely used as treatment for acute septicemia. *E. rhusiopathiae* bacteria opsonized with immune serum are readily eliminated by neutrophils, peripheral mononuclear cells, or macrophages, suggesting a type I phagocytosis mediated by IgG antibodies (Shimoji 2000) and participating antigens, notably Spa proteins (Imada et al. 2003; Makino et al. 1998). The presence of cellular immunity against *E. rhusiopathiae* was confirmed in mice experimentally immunized with acapsular *E. rhusiopathiae* (Shimoji et al. 1998b); however, its relative contribution to protection and involved bacterial antigens are presently unknown.

A significant level of cross-protection is observed among different *E. rhusiopathiae* strains. Pigs vaccinated with a live serotype 2 vaccine were protected against clinical erysipelas when challenged with serotypes 1a, 1b, 2, 5, 8, 11, 12, 18, 19, and 21 but developed local dermal lesions after serotype 9 and 10 challenge (Takahashi et al. 1984). Cross-protection is best understood when focusing on the Spa proteins, which are known to elicit highly protective antibodies (Galán and Timoney 1990). Three Spa proteins have been identified to date, namely, SpaA, SpaB, and SpaC (Makino et al. 1998; To and Nagai 2007) (Table 53.1), and appear not restricted to certain serotypes (Ingebritson et al. 2010). In the mouse model, homologous cross-protection of recombinant SpaA, SpaB, or SpaC proteins was confirmed, but heterologous cross-protection varied (To and Nagai 2007). Furthermore, mice immunized with an *E. rhusiopathiae* serotype 2 SpaA strain were protected when challenged with homologous Spa-type strains; however, protection varied against heterologous Spa strains (Ingebritson et al. 2010). Since Spa classifications are predictive of cross-protection, a new classification scheme for *E. rhusiopathiae* isolates based on Spa genes has been suggested (Ingebritson et al. 2010).

The degree and duration of passively acquired immunity are thought to be related to the immune status of the dam and colostrum uptake of the offspring. Sows are routinely vaccinated against *E. rhusiopathiae*, and maternally derived antibodies in their offspring are generally considered protective for up to approximately 8 weeks of age (Pomorska-Mól et al. 2012).

Prevention and control

Antimicrobial therapy early in the course of *E. rhusiopathiae* infection usually results in a good response in affected pigs within 24–36 hours. The bacterium is highly susceptible to penicillin, which remains the treatment of choice (Chuma et al. 2010; Coutinho et al. 2011; Ding et al. 2015; Zhang et al. 2015). Most *E. rhusiopathiae* strains are also susceptible to cephalosporins, lincosamides, macrolides, quinolones, and tetracyclines; however, antimicrobial susceptibility should be carefully evaluated on a case-by-case basis due to the emergence of resistant isolates (Chuma et al. 2010; Coutinho et al. 2011). The mechanisms by which *E. rhusiopathiae* strains develop resistance to antibiotics remain unclear, though resistance genes located in the chromosome (Zhang et al. 2015) and a small plasmid (Xu et al. 2015) have been described.

Prevention of swine erysipelas is best accomplished by immunization programs. Current vaccines are based on *E. rhusiopathiae* serotypes 1 or 2 and are either inactivated bacterins for intramuscular injection or attenuated (avirulent live) vaccines designed for whole herd mass treatment via the drinking water. Most bacterins are serotype 2 (Eamens et al. 2006), while most attenuated live vaccines contain serotype 1a isolates (Opriessnig et al. 2004). Vaccination is generally effective in preventing swine erysipelas, and the duration of immunity varies between 6 and 12 months for both correctly administered bacterins and avirulent vaccines (Swan and Lindsey 1998). Vaccination may not be as effective in preventing chronic arthritis since sequestration of *E. rhusiopathiae* in the cytoplasm of chondrocytes of articular cartilage may provide protection from host immunity. Vaccination of breeding animals reportedly reduces the incidence of periparturient vulvar discharge, decreases farrowing intervals, and increases the numbers of live-born pigs in clinically affected herds (Gertenbach and Bilkei 2002). Immunization programs can target growing pigs, breeding herds, or both.

Negative herds can be established by Cesarean derivation or medicated early weaning. However, given the ubiquity of *E. rhusiopathiae*, it is unlikely that negative herds can be maintained for extended periods of time.

Glässer's Disease

Virginia Aragon, Joaquim Segalés, and A.W. (Dan) Tucker

Relevance

In 1910 K. Glässer discovered a bacillus in exudates from pigs with fibrinous polyserositis. The isolation and characterization of this fastidious bacillus required several years, and, after some changes, it was named *Haemophilus parasuis*. The disease caused by *H. parasuis* is characterized by fibrinous polyserositis and arthritis and is known as Glässer's disease.

Glässer's disease occurs in swine populations around the world irrespective of health status, and outbreaks of this economically significant disease may be linked to stress-associated events including coinfections and moving and commingling animals (Brockmeier et al. 2014). In the United States it is considered one of the main infectious problems in the nursery, also affecting growing pigs and sows (Holtkamp et al. 2007).

Etiology

The etiological agent of Glässer's disease was formally identified in 1931 by Lewis and Shope as *Haemophilus influenzae* (variety *suis*), due to the similarity to the human pathogen *H. influenzae*. Later, Biberstein and White (1969) determined that contrary to *H. influenzae*, the swine bacterium did not require the X factor (hemin) to grow. Following the standard nomenclature in this group of microorganisms, *H. influenzae* (variety *suis*) was renamed *H. parasuis*.

Haemophilus parasuis is a gram-negative bacterium and member of the family *Pasteurellaceae*. Revision of the classification of some members of this family is ongoing, and reclassification of *H. parasuis* as a different genus has been proposed (Inzana et al. 2016). In addition, high diversity in 16S rRNA gene sequence within the *H. parasuis* species and segregation into two distinct clusters have been reported (Angen et al. 2007).

Classification of *H. parasuis* strains

Haemophilus parasuis strains are heterogeneous in phenotypic and genotypic traits, including virulence. Strains are classified into 15 serovars (Kielstein and Rapp-Gabrielson 1992), although non-typable isolates represent a high percentage. Serotyping can be performed by agar-gel precipitation test (AGPT) (Kielstein and Rapp-Gabrielson 1992) or by indirect hemagglutination (del Rio et al. 2003b; Tadjine et al. 2004). *H. parasuis* serovars 4 and 5, along with non-typable isolates, are reported as the most prevalent in different countries (Angen et al. 2004; Cai et al. 2005; Oliveira et al. 2003a; del Rio et al. 2003b; Rubies et al. 1999; Tadjine et al. 2004; Turni and Blackall 2005). Discrepancies in serotyping results are reported (Turni and Blackall 2005) and are probably due to differences in methods, antisera, and reacting antigens. Recently, the analysis of loci encoding capsular polysaccharides from the 15 serovar reference strains has allowed design of polymerase chain reactions (PCRs) for molecular serotyping (Howell et al. 2013). These PCRs represent an invaluable tool for implementation of serotyping in many laboratories while reducing the number of non-typable isolates and the inconsistency of results.

Several studies have attempted to correlate serovar and virulence, but a strict relationship between these two traits has not been demonstrated (Table 54.1). As an example, serovar 7 strains were thought to all be non-virulent, but some serovar 7 strains have been isolated from systemic lesions of Glässer's disease, and disease has been reproduced with one of them (Aragon et al. 2010).

In order to increase the discrimination capacity of the typing methods, several genotyping methods have been used to classify *H. parasuis* strains. *H. parasuis* was first genotyped using fingerprinting methods, such as restriction endonuclease pattern, also known as restriction fragment length polymorphism (RFLP) (Smart et al. 1988) and enterobacterial repetitive intergenic consensus (ERIC)-PCR (Oliveira et al. 2003a; Rafiee et al. 2000).

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Fingerprinting results are useful for local studies but are difficult to share and compare among laboratories. To facilitate the exchange of genotyping information, multilocus sequence typing was later developed (Olvera et al. 2006; Mullins et al. 2013). Genotyping methods confirmed the high heterogeneity of *H. parasuis*, allowed the identification of several *H. parasuis* strains in a single animal or farm, and established that strains isolated from systemic and respiratory sites represented two distinct groups.

There is no direct association between genotype and serovar (Oliveira et al. 2003a; Turni and Blackall 2010a). Lack of association between genotype and serovar has also been confirmed by three different RFLP-PCR protocols using *tbpA* (de la Puente Redondo et al. 2003) and *aroA* genes (del Rio et al. 2006).

Since the first report of the genome sequence of *H. parasuis* (Yue et al. 2008), the number of strains whose genome has been sequenced has increased quickly. Comparison of the genome of more than 200 clinical and nonclinical isolates allowed the detection of 48 putative virulence factors, including some factors identified by independent methods, such as the virulence-associated trimeric autotransporters (VtaAs), the cytolethal distending toxin (CDT), a *tonB*-dependent protein, and a serine protease (Howell et al. 2014).

Laboratory cultivation

Haemophilus parasuis is a small, nonmotile, pleomorphic (from single coccobacilli to filamentous chains) gram-negative bacterium in the family *Pasteurellaceae*, which requires V factor, nicotinamide adenine dinucleotide (NAD), but not X factor, hemin, for growth. In the laboratory *H. parasuis* grows on enriched chocolate agar, but not on blood agar. However it can also be cultured on blood agar with a *Staphylococcus* nurse streak as a source of V factor, showing the characteristic satellitic growth. *H. parasuis* requires 1–3 days to produce small brown-to-gray colonies on chocolate agar plates or small translucent nonhemolytic colonies on blood agar.

Epidemiology

Haemophilus parasuis is a member of the normal respiratory microbiota and is ubiquitous in swine herds worldwide. Colonization of the upper respiratory tract of piglets by *H. parasuis* occurs soon after birth through contact with the sow. However *H. parasuis* is not always detected in the nasal cavity of dams (Cerdà-Cuéllar et al. 2010), probably due to low quantity of bacteria in these animals. Attempts to isolate *H. parasuis* from the vagina of the sows have failed. This is in agreement with the production of *H. parasuis*-free piglets by snatch farrowing and subsequent artificial feeding. Snatch-farrowed colostrum-deprived piglets have been useful to experimentally reproduce disease with *H. parasuis* (Blanco et al. 2004; Oliveira et al. 2003b).

Haemophilus parasuis has been detected in nasal swabs of piglets with a maximum prevalence of colonization occurring at 60 days of age (Angen et al. 2007; Cerdà-Cuéllar et al. 2010). Different strains of *H. parasuis* can be isolated from the nasal cavities of piglets, and a single animal can carry more than one strain. Four to five strains can be isolated from a herd at a given time, and up to 16 different strains were isolated in a single farm during one production cycle (Cerdà-Cuéllar et al. 2010; Oliveira et al. 2003a; Olvera et al. 2006, 2007b). In spite of the variety of strains within a herd, usually one prevalent strain is associated with an outbreak (Rafiee et al. 2000).

Colonization of nasal mucous membranes by *H. parasuis* usually develops when piglets are still protected from Glässer's disease by circulating maternal IgM and IgG antibodies that are protective only for the strains to which each dam has been exposed. Disease may occur in pigs at different ages based on a number of factors including decay of maternal immunity, exposure to other strains by contact with other litters, mixing at weaning, or introduction of new stock. Additionally, immunity may be suppressed by porcine reproductive and respiratory syndrome virus (PRRSV) destruction and/or induced dysfunction of macrophages or by less defined mechanisms involving other pathogens, chilling, crowding, or other stressful events.

Domestic pig and wild boar are the only known hosts for this bacterium. *H. parasuis* has been isolated (Olvera et al. 2007a), and specific antibodies have been detected (Vengust et al. 2006) in wild boar, but only one case of Glässer's disease has been reported in this animal (Cuesta Gerveno et al. 2013).

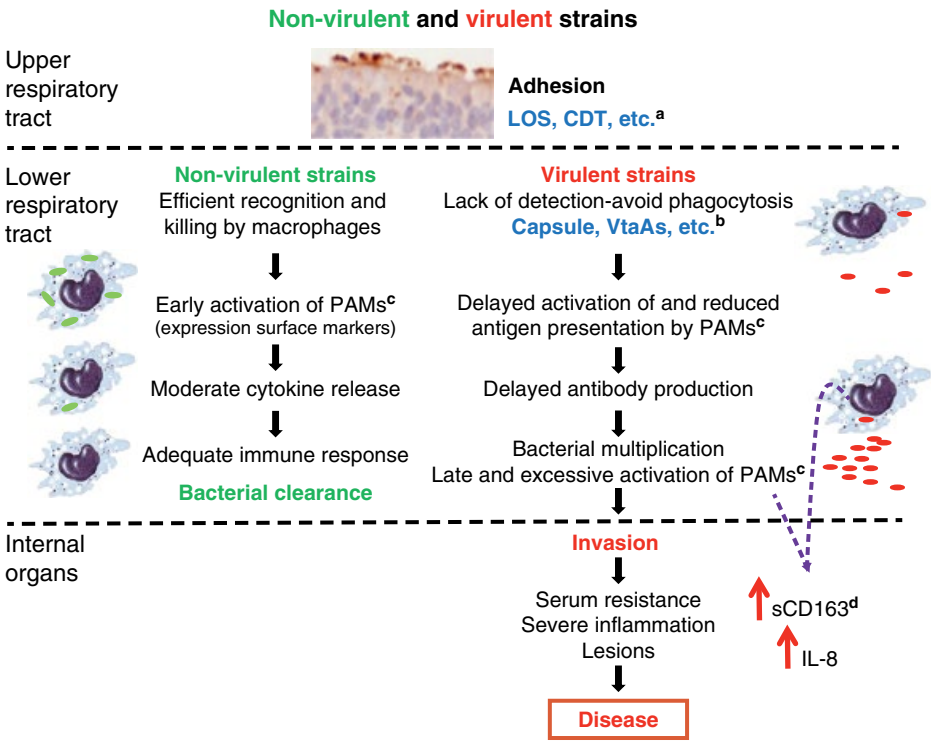
Transmission of *H. parasuis* occurs through contact of carrier or diseased pigs with susceptible animals. Thus, mixing pigs from different origins and ages is a risk factor for transmission. *H. parasuis* is very labile in the environment. Although there are not many studies on its resistance to disinfectants, efficacy of several formulations, including chloramine-T and quaternary ammonium compounds, has been reported (Rodríguez-Ferri et al. 2010).

Pathogenesis

Haemophilus parasuis pathogenesis requires entry into the host, evasion of host defenses, bacterial multiplication, and damage to tissues (Figure 54.1). Disease caused by *H. parasuis* has been reproduced with virulent strains by different inoculation routes (Amano et al. 1994; Blanco et al. 2004; Palzer et al. 2015a). After intranasal inoculation *H. parasuis* was detected in the nasal mucosa where suppurative rhinitis and epithelial cell degeneration were observed (Vahle et al. 1997). Induction of adhesins and biofilm formation may play an important role at this stage, especially in the normal colonization by non-virulent strains (Bello-Ortí et al. 2014b; Jin et al. 2006). Bacterial adhesion to and invasion of epithelial cells, induction of apoptosis, and cytokine release can also be important events for *H. parasuis* colonization (Bouchet et al. 2009; Frandoloso et al. 2012a). CDT and sugar residues of the lipooligosaccharide (LOS) are involved in the interaction with epithelial cells (Xu et al. 2013; Zhang et al. 2012b, 2013, 2014; Zhou et al. 2016). After nasal colonization, the bacterium is isolated from lung and later only virulent strains from internal organs after a short passage through blood (Vahle et al. 1995). In the lung, virulent strains of *H. parasuis* survive the phagocytic activity of porcine alveolar macrophages (PAMs) and can be detected in the lung tissue by immunohistochemistry (IHC). In contrast non-virulent strains are efficiently cleared from the lung by PAMs and are retained in the upper respiratory tract (Bello-Orti et al. 2014a; Olvera et al. 2009). Macrophage activation is delayed by virulent strains, and lung infection is established (Costa-Hurtado et al. 2013). Phagocytosis resistance is likely associated with the expression of capsule (Olvera et al. 2009), as well as with other genes, including two virulence-associated trimeric autotransporters (*vtaA*), VtaA8 and VtaA9 (Costa-Hurtado et al. 2012). In agreement, several genes with homology to putative virulence factors, such as several *vtaAs* and *siaB* (involved in sialic acid utilization), or a protease, were expressed *in vivo* in the infected lung (Bello-Ortí et al. 2015; Jin et al. 2008). Survival in the lung by virulent strains is accompanied by changes in bacterial metabolism, including upregulation of iron uptake genes (Bello-Ortí et al. 2015). Besides, *H. parasuis* possess a neuraminidase that operates as scavenger of sialic acid for nourishment or modification of the bacterial surface to evade the immune system (Martínez-Moliner et al. 2012; Perry et al. 2013).

Haemophilus parasuis invades endothelial cells and induces apoptosis and production of proinflammatory interleukin-6 (IL-6) and interleukin-8 (IL-8) (Bouchet et al. 2008; Frandoloso et al. 2013). These phenomena may play a role in the passage to the blood and across the blood–brain barrier. LOS has a partial role in endothelial adhesion and induction of inflammation (Bouchet et al. 2008; Zhang et al. 2013, 2014). Virulent strains are able to survive the bactericidal effect of the blood complement (Cerdà-Cuéllar and Aragon 2008) and can reach systemic sites. Several bacterial factors are involved in serum resistance, including the polysaccharide biosynthesis protein CapD (Wang et al. 2013) and the outer membrane protein P2 (Zhang et al. 2012a). Systemic spread of *H. parasuis* induces a severe increase in proinflammatory IL-8 and soluble CD163 in blood (Costa-Hurtado et al. 2013), with the subsequent inflammation and production of the characteristic lesions of Glässer's disease in serosae. In the spleen of infected pigs, genes involved in immune response were differentially expressed and included inflammatory molecules, acute-phase proteins, adhesion molecules, complement, and genes with functions in antigen processing and presentation (Chen et al. 2009).

Severity of disease depends on the virulence of the *H. parasuis* strain, the immunity of the piglets, the concomitant presence of other pathogens in the herd, and the genetic resistance of the host. *H. parasuis* can act as primary or secondary pathogen. Immunosuppressive events, such as viral infections that alter the immune system, allow *H. parasuis* strains that are usually restricted



[a] Sugar residues of the capsular lipooligosaccharide (LOS) and bacterial cytolethal distending toxin (CDT) are important in adhesion to host epithelial cells
[b] Bacterial capsule and two virulence-associated trimeric autotransporters (VtaA8 and VtaA9) interfere with phagocytosis by host leukocytes
[c] Pulmonary alveolar macrophages (PAMs)
[d] During tissue invasion, the number of activated macrophages increases with an associated increase in proinflammatory cytokines sCD163 and interleukin-8

Figure 54.1 Main events in *Haemophilus parasuis* pathogenesis. Virulent strains delay activation of alveolar macrophages, survive in the lung, and invade systemic organs, while non-virulent strains are cleared from the lung by alveolar macrophages and remain in the upper respiratory tract. Invasion of virulent strains induces severe inflammation and the characteristic lesions of Glässer's disease. Blue represents some virulence factors.

to the respiratory tract to invade and be isolated from systemic sites (Olvera et al. 2009). An epidemiological association between *H. parasuis* infection and PRRSV, porcine circovirus type 2 (PCV2), and influenza virus has been reported (Kim et al. 2002; Li et al. 2009; Palzer et al. 2015b; Unterweger et al. 2016). Exacerbation of disease by *H. parasuis* with PRRSV was experimentally confirmed by concurrent infection with both agents (Yu et al. 2012), although earlier studies failed to find such association (Solano et al. 1997). A work by Brockmeier (2004) linked higher nasal colonization by *H. parasuis* to prior colonization by *Bordetella bronchiseptica*. The influence of genetic background on resistance to *H. parasuis* systemic infection has been evaluated. Blanco et al. (2008) reported that piglets obtained from six different sire boars significantly varied regarding their resistance, which was associated with higher levels of antibacterial activity in the lung (Wilkinson et al. 2010). Some genetic markers (BAT2, Mx1, and EHMT2 variations) have been also associated with the risk of infection by *H. parasuis* (Wang et al. 2012).

Even though domestic pig and wild boar are the only natural hosts for *H. parasuis*, the guinea pig model is suitable to reproduce lesions (Morozumi et al. 1982; Rapp-Gabrielson et al. 1992), and the mouse model has been proven useful to study the protective capacity of experimental vaccine candidates (Zhou et al. 2009).

Clinical signs

Clinical signs are mainly observed in 4- to 8-week-old pigs, although the age of affected animals may vary, depending on the level of acquired maternal immunity and colonization. Also, Glässer's disease cases can be sporadically observed in adult pigs. Based on experimental

infections using *H. parasuis*-free piglets (Aragon et al. 2010), the incubation period varies depending on the infecting strain and ranges from less than 24 hours to 4–5 days post inoculation.

Peracute disease has a short course (<48 hours) and may result in sudden death without characteristic gross lesions (Peet et al. 1983). The typical clinical signs of acute Glässer's disease include high fever (41.5 °C), coughing, abdominal breathing, swollen joints with lameness, and central nervous signs such as lateral decubitus, paddling, and trembling (Vahle et al. 1995). These signs may be seen jointly or independently. Animals with mild to moderate clinical signs usually survive the acute phase of disease and may develop a chronic stage characterized by rough hair, reduced growth rate, and lameness. Dyspnea and coughing have also been described together with *H. parasuis* isolation from lungs with cranioventral consolidation (Little 1970). Other very sporadic clinical outcomes have been associated with *H. parasuis* infection, such as acute myositis of the masseter muscles in gilts (Hoefling 1991).

Morbidity and mortality rates associated with Glässer's disease in affected farms have been traditionally very variable, but they usually vary from 5 to 10% in conventional farms. Concomitant stressors, mainly viral infections that alter the immune system, also modulate disease prevalence. As stated above an increase of Glässer's disease prevalence has been described in farms affected by other pathogens, such as PRRSV, PCV2, and influenza.

Lesions

Peracutely diseased pigs usually die without characteristic gross lesions, but may show petechial hemorrhages in some tissues (Peet et al. 1983). Histologically, those pigs show septicemia-like microscopic lesions such as disseminated intravascular coagulation and micro-hemorrhages (Amano et al. 1994). Increased serosanguinous fluid in the thoracic and abdominal cavities, without fibrin, can also be seen in peracute cases of *H. parasuis* infection.

Acute systemic infection is characterized by the development of fibrinous or fibrinopurulent polyserositis, polyarthritis, and meningitis (Figure 54.2). The fibrinous exudate can be observed on the pleura, pericardium, peritoneum, synovia, and meninges and is usually accompanied by an increased amount of fluid (Oliveira et al. 2003b; Vahle et al. 1995). Fibrinous

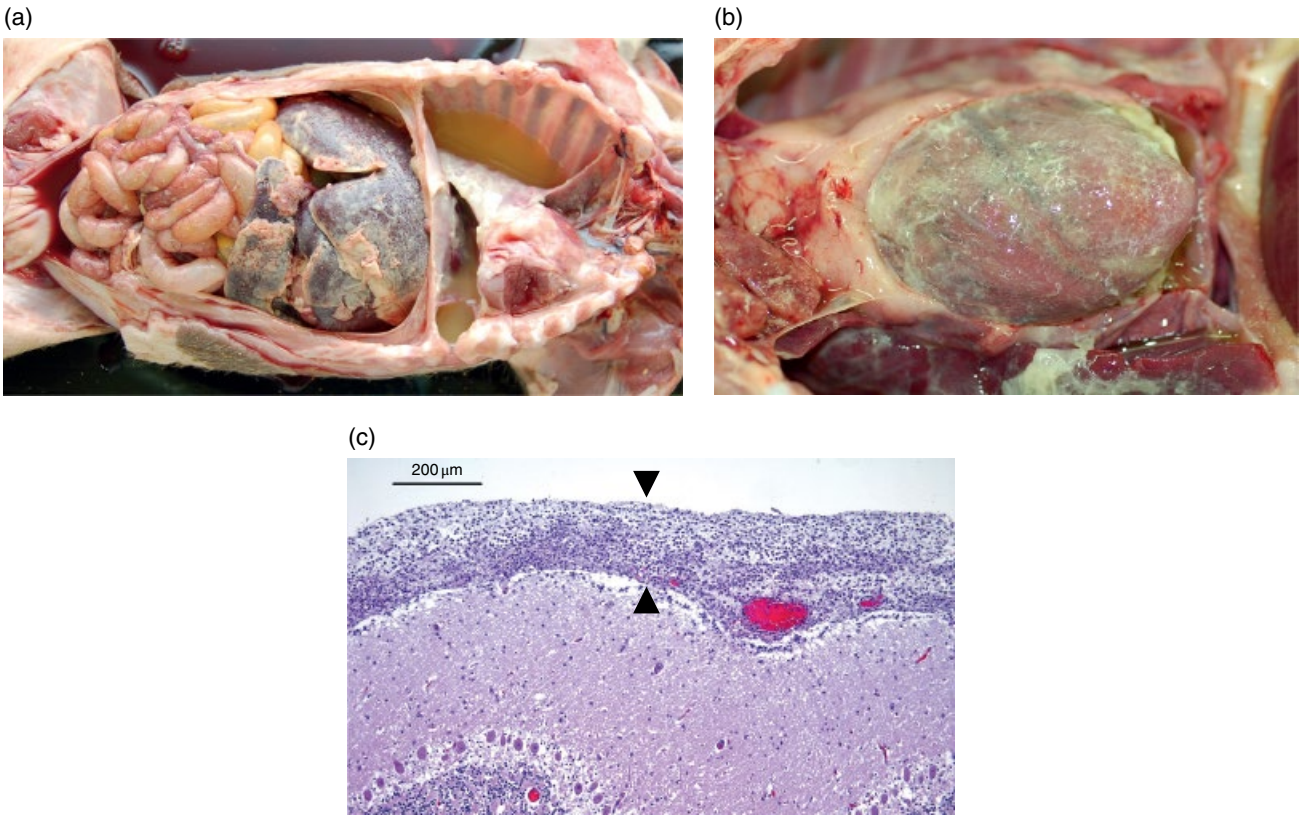


Figure 54.2 Gross and microscopic lesions found in *Haemophilus parasuis* systemic infection. (a) Polyserositis characterized by fibrinopurulent exudate on serosal membranes in peritoneal and thoracic cavities. Note the significant amount of fluid in the thorax. (b) Fibrinopurulent exudate on pericardial surface. (c) Brain, fibrinopurulent meningitis.

pleuritis may be found with or without cranioventral consolidation due to catarrhal purulent bronchopneumonia (Little 1970). Lack of characteristic gross lesions is also common in a number of pigs showing neurological clinical signs. Histopathological examination of typical Glässer's disease reveals fibrinous to fibrinopurulent serositis and usually does not contribute additional useful information to the diagnosis except the detection of potential fibrinopurulent meningitis (Figure 54.2c). Recently, pyelitis has been described as a consistent histopathological finding in experimentally infected conventional pigs with *H. parasuis* serovar 5 (Palzer et al. 2015a).

Chronically affected animals usually show severe fibrosis of the pericardium, pleura, and/or peritoneum, as well as chronic arthritis.

Diagnosis

The clinical signs and lesions described for *H. parasuis* systemic infection are not pathognomonic of this agent, and other agents must be included in a differential diagnosis. Fibrinous polyserositis may be caused by other gram-negative bacteria such as nonhemolytic *Escherichia coli* (Chapter 52). Polyserositis caused by nonhemolytic *E. coli* is sporadic and usually affects suckling piglets (Nielsen et al. 1975). Beta-hemolytic Shiga toxin 2e (Stx2e)-positive *E. coli* can cause central nervous system signs in recently weaned pigs (edema disease) similar to those observed with *H. parasuis* systemic infection. However, these pigs do not develop fibrinopurulent meningitis typical of *H. parasuis* (Moxley 2000). *Mycoplasma hyorhinis* is another important cause of fibrinous polyserositis in nursery pigs, and it is frequently found coinfecting pigs with *H. parasuis* (Chapter 56; Palzer et al. 2015b). *Streptococcus suis* usually affects pigs at the same age as *H. parasuis* and may cause similar lesions (Chapter 61; Reams et al. 1994). Other agents involved in development of lameness and arthritis include *Erysipelothrix rhusiopathiae* (Chapter 53) and *Mycoplasma hyosynoviae* (Chapter 56). However, both agents are more likely to cause chronic non-purulent arthritis in finishing pigs (Hariharan et al. 1992).

Considering that *H. parasuis* is a colonizer of the upper respiratory tract of healthy pigs, detection of this microorganism in the nasal cavity and trachea does not imply disease development. Systemic isolates are more likely to carry important virulence factors, and, therefore, those isolates should be pursued for laboratory confirmation of morbidity and mortality caused by this agent.

Haemophilus parasuis can be isolated from the fibrinous exudate and parenchyma of affected internal organs and from lung lesions in pneumonia cases. It is recommended to take several samples from the same animal. *H. parasuis* is a fastidious microorganism with limited survival at room temperature and special requirements for *in vitro* growth. The chances of isolating *H. parasuis* can be considerably improved by utilizing swabs with Amies transport media and submitting samples under refrigeration to the laboratory (del Rio et al. 2003a). Although *H. parasuis* isolation can be a difficult task, it is important to obtain an isolate for antibiotic sensitivity assessment and typing.

H. parasuis can also be detected directly in the lesions of affected tissues by IHC (Amano et al. 1994; Bello-Orti et al. 2014a; Vahle et al. 1995) or *in situ* hybridization (ISH) (Jung et al. 2004). However the specificity of these techniques is not fully clarified, and their uses have been restricted to research activities.

PCR is a sensitive and specific method to detect *H. parasuis*. Several methods are described in the literature, varying from conventional gel-based tests to real-time detection (Angen et al. 2007; Jung et al. 2004; Oliveira et al. 2001; Turni et al. 2010b). PCR detects *H. parasuis* even when the organism is no longer viable, and it represents a great advantage in sensitivity compared with bacterial isolation. A real-time PCR showed a detection limit of 0.83–9.5 CFU per reaction and was more sensitive and specific than previously reported gel-based methods (Turni et al. 2010b). PCR can be used also for differentiation between virulent and non-virulent isolates. A multiplex test based on the detection of a fragment of *vtaA*s can be used to further characterize isolates regarding invasiveness potential (Olvera et al. 2012). This information is relevant, especially when selecting isolates for antibiotic sensitivity or autogenous vaccine production.

ELISA can detect antibodies against *H. parasuis*, although this technique has mostly been used for research purposes. Whole cell indirect ELISAs have been used to characterize the transfer of maternal immunity from sows to piglets and to demonstrate seroconversion post-vaccination (Baumann and Bilkei 2002; Cerdà-Cuéllar et al. 2010; Solano-Aguilar et al. 1999). Blanco et al. (2004) utilized a commercial ELISA to characterize the decay of maternal antibodies and identify a window of susceptibility in conventional pigs for experimental infection. The specificity of experimental and commercially available *H. parasuis* ELISAs has not been extensively evaluated, and their ability to detect antibodies against different *H. parasuis* serovars and strains has been poorly characterized.

Immunity

Both innate and acquired immune responses are important in *H. parasuis* infection. Although phagocytosis, antibody opsonization, and complement attack were

previously recognized as key defenses, new information on the interplay between pathogen and host humoral and cellular immune responses is emerging.

Immune responses

IHC and ISH methods have demonstrated that following infection *H. parasuis* is phagocytosed by neutrophils and macrophages and can be found as degenerated bacteria in dilated phagosomes (Amano et al. 1994; Segales et al. 1999). PAMs promptly phagocytose non-virulent strains, whereas virulent strains show resistance to phagocytosis. Once opsonized by antibodies, these virulent strains can be successfully internalized and killed by PAMs (Olvera et al. 2009). Virulent strains appear to be resistant to complement-mediated killing, while non-virulent strains are susceptible to complement activation and killing via the non-antibody-mediated pathway (Cerdà-Cuéllar and Aragon 2008).

H. parasuis stimulates the production of proinflammatory cytokines IL-8 and IL-6 by porcine airway epithelial cells upon adhesion (Bouchet et al. 2009; Chen et al. 2015). IL-8 is a potent chemoattractant for leukocytes, whereas IL-6 is an important mediator in the development of acute-phase response. Increased levels of IL-1α have been reported in pigs undergoing severe disease following experimental infection, whereas IL-4, IL-10, tumor necrosis factor-alpha (TNF-α), and interferon gamma (IFN-γ) were expressed in significantly higher levels by survivors (Martín de la Fuente et al. 2009a). Swift-onset global changes in circulating immune cell populations have been described following *H. parasuis* challenge including a rapid increase in CD163+ monocyte lineages alongside a depletion of gamma/delta TCR+ T cells (Frandoloso et al. 2012b).

Development of antibodies against *H. parasuis* following exposure or vaccination has been demonstrated in colonized, convalescent, and vaccinated pigs. Pigs exposed to *H. parasuis* live cultures or vaccinated with killed bacterins generate a transient IgM response followed by a solid and progressively increasing IgG antibody response. Pigs with high IgG titers are protected against challenge (Martín de la Fuente et al. 2009b). Pigs exposed to live *H. parasuis* cells develop antibodies against specific surface proteins, including VtaAs and oligopeptide permease A (OppA), which are not always elicited by killed vaccines (Macedo et al. 2016; Olvera et al. 2010). The role of CD8+ cytotoxic T cells, which rapidly increase in numbers in challenged pigs, is not fully understood but is proposed to be linked to MHC class I presentation based on the ability of *H. parasuis* to penetrate epithelial and endothelial cells (Frandoloso et al. 2012b).

Protective immunity and cross-protection

Protective immunity against *H. parasuis* infection has been linked mainly to the development of specific antibodies, which are known to successfully opsonize *H. parasuis* and facilitate phagocytosis by PAMs (Olvera et al. 2009). Complete protection against challenge is usually obtained with homologous vaccination, whereas partial protection is generally observed with heterologous challenges (Martín de la Fuente et al. 2009b; Miniats et al. 1991; Nielsen 1993; Takahashi et al. 2001).

Exposure and colonization with live *H. parasuis* cells are also known to generate protective immunity. Pigs exposed by aerosol to different live *H. parasuis* strains developed circulating antibodies and resisted challenge with virulent heterologous strains (Brockmeier et al. 2013; Nielsen 1993). However, pigs colonized with virulent strains serve as reservoirs for transmission to naive pigs (Brockmeier et al. 2013) and constitute a risk for disease.

Cross-protection between different serovars and even within the same serovar is variable and difficult to predict (Rapp-Gabrielson et al. 1997). The design of new universal vaccines has exploited immunoproteomic approaches to identify secreted and surface proteins with protective potential (Li et al. 2015; Olvera et al. 2011; Zhou et al. 2009). Most promising among these approaches is the demonstration of protection from *H. parasuis* challenge after immunization using a mutated transferrin-binding protein (TbpB) cloned from a virulent strain of *H. parasuis* – with evidence of a robust TH2 response (Martínez-Martínez et al. 2016).

Maternal immunity

Maternal antibodies are an important source of protective immunity for susceptible piglets. Pigs lacking maternal immunity are susceptible to systemic infection using low doses of *H. parasuis*, whereas pigs with maternal antibodies are protected against challenge (Blanco et al. 2004; Oliveira et al. 2003b).

Levels of maternal antibodies directly influence the susceptibility of the offspring to *H. parasuis* systemic infection. Solano-Aguilar et al. (1999) demonstrated that pigs from vaccinated gilts had significantly higher maternal antibody titers compared with those from non-vaccinated gilts. Pigs from vaccinated gilts were protected against challenge at 28 days of age, whereas pigs from non-vaccinated gilts were fully susceptible to systemic infection at 21 days of age. More recently Cerdà-Cuéllar et al. (2010) found that maternal immunity decayed by 20 days in pigs from non-vaccinated sows but not until 60 days in those from vaccinated sows. These timings coincided with high levels of isolation and detection of *H. parasuis* in the nasal cavities of these pigs. Pigs from

vaccinated sows tended to have a lower amount and reduced variety of *H. parasuis* strains compared with pigs from non-vaccinated sows. Maternal immunity can interfere with piglet vaccination, measured as antibody induction (Pomorska-Mól et al. 2011), although this interference was not observed when vaccination was performed during an acute outbreak of Glässer's disease (Oh et al. 2013).

Prevention and control

Antibiotics are widely used to prevent and control *H. parasuis* disease, but increasing pressure to reduce reliance on antibiotics, particularly for population-level prophylaxis, puts more emphasis on vaccination strategies to prevent systemic infection and mortality.

Antibiotic treatment remains an essential control measure in the face of severe outbreaks of *H. parasuis* systemic infection. Injectable treatments tend to be more effective than water or feed medication, since pigs clinically affected by *H. parasuis* systemic infection are less likely to ingest the required antibiotic dose via food and water intake. Nonsteroidal anti-inflammatory treatment may assist recovery (Viehmann et al. 2013).

Antibiotic susceptibility profiles are variable in different countries and reflect the selection of drugs used in each region. For example, Danish, British, and Australian isolates are reported as broadly susceptible to most antibiotics, whereas high rates of resistance to commonly used antibiotics are reported for Chinese and Spanish isolates (Aarestrup et al. 2004; Dayao et al. 2014; El Garch et al. 2016; Martín de la Fuente et al. 2007; Zhou et al. 2010). Resistance to tetracycline and beta-lactam antibiotics has been linked to the presence of resistance genes in plasmids carried by *H. parasuis* (Lancashire et al. 2005; Moleres et al. 2015). Recent data indicate that low variability in the composition of the nasal microbiota at weaning, a condition that may be associated with antibiotic use, is a predisposing factor for disease development by *H. parasuis* (Correa-Fiz et al. 2016).

Haemophilus parasuis is a commensal of the upper respiratory tract and colonizes virtually every pig. The early colonization of pigs with virulent strains in the presence of maternal immunity actually prevents disease and mortality post weaning (Oliveira et al. 2004). However, natural colonization during the suckling period usually is not protective against the wide variety of strains circulating in different swine populations owing to poor heterologous protection (Oliveira et al. 2004). Therefore, commingling of pigs from different sources and ages is an important cause of increased mortality due to Glässer's disease and should be avoided when possible. Although elimination of *H. parasuis* from a herd is difficult due to early maternal colonization of neonatal piglets, it may be achieved through Cesarean derivation into pig-free premises. However, except in circumstances where standards of biosecurity are exceptional, elimination is not recommended because such herds are highly susceptible to severe outbreaks if exposed to virulent *H. parasuis* due to a lack of immunity. Strict biosecurity that forbids introduction of *H. parasuis*-positive swine or fomites is essential to prevent high mortality in such cases.

Vaccination is an effective measure to prevent mortality. Commercially available bacterin vaccines are based on serovar 5, combined serovars 4 and 5, or combined serovars 1 and 6 for use in sows and pigs. All these products show limited cross-protection to heterologous strains. Studies have failed to show interference from maternal antibody where sow and piglet vaccination are practiced concurrently in acute disease contexts (Oh et al. 2013). More recently, a live attenuated serovar 5 strain has become available in North America with cross-protection claimed for serovars 4 and 13 (Oliveira et al. 2013). Autogenous vaccines are highly effective in protecting susceptible pigs (McOrist et al. 2009), but it is essential to use typing methods to ensure that the appropriate systemic isolate is incorporated into the vaccine preparation by sampling from systemic rather than respiratory locations.

Leptospirosis

Zbigniew J. Arent and William A. Ellis

Relevance

Leptospirosis is a cause of reproductive loss in breeding herds and has been reported in swine from all parts of the world; however, knowledge of the incidence and economic impact of the disease is largely confined to Argentina and Brazil and to the intensive pig industries of the Northern Hemisphere, Australia, and New Zealand, where its importance has apparently declined.

Endemic infection in a herd of swine may produce little evidence of clinical disease, but when it is first introduced into a susceptible breeding herd, or during periods of waning herd immunity, it can cause very appreciable losses through infertility, abortion, and the full-term birth of dead pigs or weak pigs of reduced viability.

Leptospires persist in the kidneys and female and male genital tracts of carrier swine and are excreted in urine and genital fluids. Survival outside the host is favored by warm moist conditions. Transmission is by direct or indirect contact with a carrier pig or other animal. Interruption of transmission from infected pigs or other hosts to susceptible pigs is the critical factor in control.

Etiology

Leptospirosis of swine is a disease caused by a variety of morphologically similar but antigenically and genetically distinct, small, motile, aerobic spirochetes belonging to the genus *Leptospira*. They are thin helical motile, gram-negative organisms that are often hooked at one or both ends. They range in length from about 6 to 20 µm, with amplitude of approximately 0.1–0.15 µm and a wavelength of about 0.5 µm. Under adverse nutritional conditions, leptospires may be greatly elongated, while under conditions such as high salt concentrations, aging culture or in tissues, leptospires may form coccoid cells of about 1.5–2 µm diameter. They divide by binary fission and stain poorly with aniline dyes. Unstained cells are visible only by dark-field microscopy. In a suitable liquid environment, motility is accomplished by rotating along the long axis, but an undulating action is observed in semisolid media. Culture requires special media containing mammalian serum or albumin for cultivation (Faine et al. 1999).

The major structural components are an outer membrane that surrounds a double-membrane structure in which the cytoplasmic membrane and peptidoglycan cell wall are closely associated. Two flagella with polar insertions are located in the periplasmic space and are responsible for motility (Adler and de la Peña-Moctezuma 2010). Within the outer membrane, lipopolysaccharide (LPS) constitutes the main antigen for *Leptospira*. In addition to LPS, structural and functional proteins form part of the leptospiral outer membrane. A large proportion of such proteins are lipoproteins with LipL32, LipL41, LipL21, and Loa22 (probable lipoproteins) being the most abundant on the cell surface (Cullen et al. 2005; Haake and Zückert 2015). Integral membrane proteins such as the porin OmpL1 are also located in the outer membrane (Shang et al. 1995).

The genus *Leptospira* includes both saprophytic and pathogenic species. The pathogenic family consists of 14 pathogenic species: *Leptospira alexanderi*, *Leptospira alstonii*, *Leptospira borgpetersenii*, *Leptospira broomii*, *Leptospira inadai*, *Leptospira interrogans*, *Leptospira fainei*, *Leptospira kirschneri*, *Leptospira kmetyi*, *Leptospira licerasiae*, *Leptospira noguchii*, *Leptospira santarosai*, *Leptospira weilii*, and *Leptospira wolffii*, with more than 260 serovars. There are seven saprophytic species (Levett 2015). There are differences in the global distribution of some of the *Leptospira* species: *L. interrogans*, *L. borgpetersenii*, and *L. kirschneri* have a worldwide distribution, whereas *L. noguchii* and *L. santarosai* are found mainly in North and South America, while *L. weilii* is found mainly in China and Eastern Asia. Strains that cause disease in pigs are found mainly in the *L. interrogans* and *L. borgpetersenii* species.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

At the subspecies level, serovar classification of *Leptospira* is still widely used as it facilitates serodiagnostic, epidemiology, and prevalence studies. It is based on the expression of the surface-exposed epitopes in a mosaic of the LPS antigens, while the specificity of these epitopes depends on their sugar composition and orientation (Adler and de la Peña-Moctezuma 2010). In addition, the concept of serogroups that clusters antigenically related strains is still used as the basis of selecting cross-reactive strains for serological tests.

Public health

Leptospirosis is a potential occupational zoonosis of those who work with pigs in regions in which infection in swine is common, especially farmers, veterinarians, and abattoir workers (Faine et al. 1999). Infection is by direct or indirect contact of mucous membranes or skin wounds with the urine of an infected pig. A majority of cases are asymptomatic or present as sudden onset of an approximately weeklong febrile sickness with any combination of chills, conjunctival suffusion, severe headache, myalgia of lower back and legs, abdominal pain, vomiting, and diarrhea. In approximately 5–10% of cases, the clinical course progresses rapidly to include icterus, renal failure, cough, dyspnea, and hemoptysis that may be fatal.

Epidemiology

The epidemiology of swine leptospirosis is potentially very complicated, since swine can be infected by any of the pathogenic serovars. Fortunately, only a small number of serovars are endemic in any particular region or country. Furthermore, leptospirosis is a disease that shows a natural nidality, and each serovar tends to be maintained in specific maintenance hosts. Therefore, in any region, pigs are infected by serovars maintained by pigs or by serovars maintained by other animal species present in the area. The relative importance of these incidental infections is determined by the opportunity that prevailing social, management, and environmental factors provide for contact and transmission of leptospires from other species to pigs.

Pigs act as maintenance hosts for serovars belonging to the Pomona and Australis serogroups, while Icterohemorrhagiae, Grippotyphosa, and Tarassovi serogroups are among the more commonly identified incidental infections in swine.

Pomona infection

Leptospira serovars belonging to serogroup Pomona are one of the most commonly identified types of *Leptospira* in livestock. The classical serological identification of Pomona serogroup members has been very difficult because of very close antigenic relationships between strains. Taking into account genotypic classification, the members of serogroup Pomona are found in four Leptospira species, namely, *L. interrogans*, *L. kirschneri*, *L. noguchii* and *L. santarosai*, but only two of them, namely, *L. interrogans* with serovar Pomona and *L. kirschneri* with serovar Mozdok, have been the most commonly isolated from pigs worldwide. Introduction of genetic methods demonstrated strain differences at the subserovar level and some types within the serovar Pomona such as type Pomona (sensu stricto), Kennewicki and Monjakov.

Infections with these serovars have been extensively studied and provide a suitable model with which to illustrate general concepts of swine leptospirosis. Many strains of serovars Pomona types Pomona and Kennewicki, especially those found in the United States and Canada, are adapted to swine. They have been the cause of widespread clinical disease in swine in North and South America, Australia, New Zealand, parts of Asia, and Eastern and Central Europe and are endemic in many of these regions. There is now evidence of high levels of infection in parts of Africa (Agunloye 2001) and Southeast Asia (Al-Khleif et al. 2009). Such strains are apparently absent from the more westerly parts of Europe where the rodent-maintained serovar Mozdok may cause occasional outbreaks of clinical disease (Barlow 2004; Rocha 1990; Zieris 1991).

In parts of North America, the prevalence of Pomona infection in pigs has declined markedly from the high levels observed in the 1950s and early 1960s. No carriers were detected in a 1989 meat plant survey carried out in Iowa (Bolin and Cassells 1992). In contrast, Baker et al. (1989) recovered serovar Pomona type Kennewicki from almost 10% of pigs in a small survey in Canada.

Leptospires have a particular affinity for the kidneys of infected pigs, where they persist, multiply, and are voided in urine. This characteristic is very important in the transmission of infection.

Infection is introduced into a susceptible herd by three possible routes: the introduction of infected stock, exposure to a contaminated environment, or contact with an alternative infected animal vector. Carrier pigs are probably the most common route of introduction. Replacement gilts or infected boars have been identified as important means of introducing infection (Ellis 2006).

The importance of free-living species as possible sources of Pomona infection of pigs depends on geographical location. In North America, the skunk has been incriminated as a source of Pomona outbreaks in pigs (Mitchell et al. 1966), and the move to indoor housing has reduced the opportunity for skunk-to-pig transmission.

Once Pomona has been introduced into a pig population, a high prevalence of infection is established. Only low infective doses are required to transmit infection (Chaudhary et al. 1966a,b). If direct contact is prevented, indirect contact through contaminated effluent, water, or soil ensures transmission. The presence of moisture is critical for indirect transmission. The organisms cannot withstand desiccation, but when infected urine is deposited in damp soil or water with a neutral or slightly alkaline pH, the organisms may survive for extended periods (Ellis 2006).

During the initial herd infection, clinical disease may occur in all ages of sows. Following the initial establishment of infection, an endemic cycle typical of that in a maintenance host population is set up (Hathaway 1981). Piglets are passively protected in the first weeks of life by colostrum-derived immunoglobulins from infected dams (Bolt and Marshall 1995a; Fish et al. 1963). The duration of this passive protection depends primarily on the quantity of immunoglobulins received in colostrum (Chaudhary et al. 1966b). A study of grower pigs in New Zealand has shown that *Leptospira* infection becomes apparent in piglets from 12 weeks of age and by slaughter up to 90% may be infected. The intensity of shedding in urine is greatest in the first 3–4 weeks of infection after which it declines and becomes intermittent (Bolt and Marshall 1995a,b). Infection between groups of fattening pigs is often by urine-contaminated effluent from a common drainage system (Buddle and Hodges 1977). In herds with endemic infection, clinical disease is usually restricted to gilts that have either been reared in isolation since weaning and reintroduced into the herd or more commonly brought in from an uninfected herd.

Australis infection

Serovar Bratislava and to a lesser extent the closely related serovar Muenchen have emerged as major swine-maintained leptospiral infections but remain poorly understood due to difficulties in culturing these strains. Serologic data has indicated widespread infection in Europe, the United States, Canada, Australia, Brazil, South Africa (Ellis 2006), Nigeria (Agunloye 2001), Korea (Choi et al. 2001), and Japan, (Kikuchi et al. 2009) among others.

In contrast to the high seroprevalences reported worldwide, serovar Bratislava has only been recovered from pigs in a few countries, namely, the Netherlands (Hartman et al. 1975), the United Kingdom (Ellis et al. 1991), the United States (Bolin and Cassells 1990, 1992; Ellis and Thiermann 1986), Germany (Schonberg et al. 1992), and Vietnam (Boqvist et al. 2003).

The epidemiology of these strains is poorly understood. There are specific pig-adapted strains; other strains that are maintained by pigs, dogs, horses, and hedgehogs; and other strains that are found only in wildlife. Among the pig strains there are genotypes that are more likely to be associated with disease (Ellis et al. 1991; Ellis unpublished data).

Two very distinct serological profiles may be seen in endemically infected herds. In indoor sow units infected with pig-adapted strains of Bratislava, the prevalence of sows with antibody titers of greater than 1:100 in the microscopic agglutination test (MAT) is usually very low, although many sows will have titers of less than 1:100. This is thought to result from infection primarily due to venereal transmission. In contrast in units where the sows are kept outside, the seroprevalences (≥1:100) may be greater than 50%. This is thought due to systemic infection as a result of exposure to infected rodent urine.

Although the renal carrier state does become established, urinary excretion is poor compared with Pomona, and transmission within the fattening house is inefficient. Important additional carrier sites have been identified, namely, the upper genital tracts of sows and boars (Bolin and Cassells 1992; Ellis et al. 1986b,c; Power 1991). Venereal transmission is thought to play an important role in the spread of Bratislava infection. Boars are frequently the only new animals introduced into pig breeding units and are clearly a potential means of introducing *Leptospira* infections.

Tarassovi infection

There is much less information available on the epidemiology of Tarassovi infection in pigs. The pig was previously thought to act as a maintenance host for some strains of Tarassovi found in Eastern Europe and Australia, but declining seroprevalences would suggest that this is not so (Wasinski 2005). High seroprevalences associated with reproductive failure have recently been reported from Vietnam (Boqvist et al. 2007).

Many strains of Tarassovi have been recovered from free-living animals, further supporting the view that Tarassovi infections are incidental infections of pigs resulting from wildlife contact. Work in the United States supports this view. Tarassovi has not been recovered from swine, but there is serologic evidence of infection in pigs in the southeastern states (Cole et al. 1983) where it has been isolated from raccoons, skunks, and opossums (McKeever et al. 1958; Roth 1964).

Canicola infection

Although organisms belonging to this serogroup have been recovered from swine in a number of countries, little is known of the epidemiology of serovar Canicola infection in pigs. Conventional wisdom has been that infection is acquired from dogs, the recognized maintenance host for this serovar, although wildlife may also be

a source (Paz-Soldan et al. 1991). The long period of urine shedding observed in infected pigs (at least 90 days) and the ability of Canicola to survive for up to 6 days in undiluted pig urine (Michna 1962) suggest that intraspecies transmission could occur.

Icterohemorrhagiae infection

Serologic evidence of Icterohemorrhagiae serogroup infection has been reported in many countries, but few isolations have been made from pigs. Both serovars Copenhageni and Icterohemorrhagiae may be involved and are probably introduced to susceptible stock via an environment contaminated with infected urine from the brown rat (*Rattus norvegicus*), the maintenance host for these serovars. Urinary excretion is less than 35 days (Schnurrenberger et al. 1970), and intraswine transmission is inefficient (Hathaway 1985). It is believed, in the absence of supporting isolation data, that vaccine-induced antibodies are responsible for the seroprevalences to Icterohemorrhagiae observed in the United States. High seroprevalences to Icterohemorrhagiae associated with clinical disease have been detected in some pig populations in Brazil (Osava et al. 2010).

Grippotyphosa infection

Serovar Grippotyphosa infection is maintained by wildlife hosts, and incidental infection of pigs gives rise to low prevalences of antibodies in swine in various regions, particularly Eastern and Central Europe and the United States, and it has been recovered from pigs in Russia and the United States in the past (Ellis 2006). A high seroprevalence has been reported in Thailand (Puchadapirom et al. 2006).

Hardjo infection

Serovar Hardjo infection is maintained by cattle worldwide, and where cattle and pigs come in close contact, the opportunity arises for infection in pigs to occur. There have been reports of the isolation of Hardjo from pigs in the United Kingdom (Ellis et al. 1986a; Hathaway et al. 1983) and the United States (Bolin and Cassells 1992), but persistence in renal tissue was not a feature of experimental infection (Hathaway et al. 1983), suggesting that intraspecies transmission is unlikely.

Pathogenesis

The most important route of natural infection has not been determined. It is thought to be via the mucous membranes of the eye, mouth, or nose. Infection via the vaginal route is also possible, and transmission through milk from an infected dam has been demonstrated experimentally. A period of bacteremia, which may last for a week, begins 1 or 2 days after infection. During this period leptospires can be isolated from most organs of the body and also from cerebrospinal fluid (Ellis 2006). This primary bacteremic phase ends with the appearance of circulating antibodies, which are detectable usually after 5–10 days (Hanson and Tripathy 1986). A secondary bacteremic period (after 15–26 days) has been reported in experimental Hardjo infection (Hathaway et al. 1983).

Antileptospiral agglutinins appear at detectable levels in the blood at approximately 5–10 days after infection and reach maximum levels at around 3 weeks. Peak titers vary considerably (1:1,000 to 1:100,000 in the MAT), and these may be maintained for up to 3 weeks, after which a subsequent gradual decline occurs. Low titers may be detectable for several years in many animals.

Following the period of leptospiremia, leptospires localize in the proximal renal tubules where they multiply and are voided in the urine. The duration and intensity of urinary shedding varies from pig to pig and with the infecting serovar. In the case of Pomona infection, the intensity of excretion is highest during the first month of shedding, when more than a million leptospires may be present in each milliliter of urine; urine shedding is very constant during this period. A variable period of intermittent, low-intensity leptospiruria then ensues, and this may last for up to 2 years in some cases.

Leptospires also localize in the uterus of pregnant sows, and abortion, production of stillborn pigs, and neonatal disease frequently result from intrauterine infections occurring in the last half of the gestation period. Abortions and stillbirths usually occur 1–4 weeks following infection of the gilt or sow (Hanson and Tripathy 1986), by which time most sows have developed detectable antibody titers. Since pig fetuses are capable of producing antibodies during the latter stages of gestation, some stillborn piglets will have detectable titers.

The pathogenesis of reproductive disease is poorly understood, but some authors believe that transplacental infection, occurring during the very limited period of maternal leptospiremia, is the sole cause. While this may be true for systemic infections such as Pomona, the low antibody titers detected in sows aborting Bratislava-infected fetuses has led to the hypothesis that infection occurs as a result of waning uterine immunity being unable to prevent transplacental infection by leptospires present in the genital tract. Horizontal transmission to littermates not infected during the period of maternal leptospiremia may also occur. Once the placental barrier is breached, septicemia results in large numbers of leptospires in all fetal tissues (Ellis 2006).

An additional feature seen in Bratislava infection but not reported for the other swine leptospiral infections is the persistence of leptospires in the oviduct and uterus of nonpregnant sows and in the seminal vesicles, bulbourethral glands, prostate, and testes of boars (Ellis 2006; Oliveira et al. 2007).

Clinical signs

The vast majority of swine leptospiral infections are subclinical. Two groups of pigs are most likely to experience clinical infections: the young piglet and the pregnant sow.

Acute leptospirosis

This phase usually coincides with the period of bacteremia. In experimental infections, many pigs exhibit transient anorexia, pyrexia, and listlessness at this time (Hanson and Tripathy 1986). However, the mild nature of these signs means that in natural infections, especially in endemically infected herds where perhaps only one or two animals may be affected, this phase of infection usually goes unrecognized.

There have been a few reports of jaundice and hemoglobinuria in naturally occurring outbreaks (Ferguson et al. 1956), particularly in cases of infection in piglets under 3 months of age by Icterohemorrhagiae (Field and Sellers 1951; Modric et al. 2006). A high proportion of these undergo spontaneous recovery within a week of when clinical signs develop. The small number of such reports suggests that this more severe form of disease is rare.

Chronic leptospirosis

Abortions, stillbirths, the birth of weak piglets of reduced viability, and reduced litter size are primary signs of chronic leptospirosis, particularly Pomona infection. It is this aspect of leptospirosis that can cause considerable economic loss (Azevedo et al. 2008; Ellis 2006).

Information as to the importance of leptospirosis as a cause of abortion in national swine herds is not available. If it were, it would vary from country to country depending on prevalence as well as epidemiologic and management factors, including the implementation of control measures. From the limited and dated information available, it would appear that even in countries where vaccination has been widely practiced, leptospirosis is a common cause of swine abortion. In Ontario, for example, 6% of swine abortions were attributed to Pomona infection (Anon 1986). Endemic Tarassovi infection was considered to be the cause of a 3% abortion rate in herds in Poland (Wandurski 1982). Fearnley et al. (2008) found 4 of 24 fetal diagnostic submissions from the United Kingdom to be polymerase chain reaction (PCR) positive. Acute outbreaks can still give rise to severe losses; Saravi et al. (1989) described an outbreak in a herd in which 19% of pregnant sows aborted, while the proportion of stillborn per litter rose from 8% prior to the outbreak to 28% during the outbreak. Differences in strain pathogenicity also contribute to different prevalences of clinical abortion in infected herds (Nagy 1993).

A very high prevalence of serovars belonging to the Australis serogroup in aborted pig litters has been observed in part of the United Kingdom (Ellis et al. 1986a). Similar strains have also been recovered from aborted piglets in the United States (Bolin and Cassells 1990; Bolin et al. 1991). Rehmtulla et al. (1992) reported fetal Bratislava infection following abortions in 16% of sows in a herd in Ontario. Egan (1995) reported FAT positive prevalences ranging from 5 to 23% in diagnostic submissions in Ireland. Published experimental evaluations of the significance of such microbiological findings are not available. There has, however, been an absence of significant isolations of other abortifacient agents from these cases, and the farrowing rate and the number of live piglets born/sow improves significantly following either Bratislava vaccination (Frantz et al. 1989) or the use of an antibiotic medication program (Ellis et al. 1989).

Following abortions due to Pomona, there does not appear to be any subsequent limitation on reproductive performance, even in pigs that remain infected for long periods (Ferguson and Powers 1956; Kemenes and Suveges 1976; Mitchell et al. 1966).

Infertility is a feature of Bratislava infection (Hathaway and Little 1981; Jensen and Binder 1989; Van Til and Dohoo 1991). Split-herd trials, carried out using a Bratislava bacterin, have demonstrated significant improvements in sow fertility (Frantz et al. 1989).

Lesions

The main pathological changes are essentially the same for all infections, with the primary lesion being damage to the membranes of the endothelial cells of small blood vessels.

In acute leptospirosis there are no pathognomonic gross changes. Pathologic changes in acute Pomona infection are very limited, reflecting the mild nature of acute clinical disease. Hanson and Tripathy (1986) reported little gross or histopathologic change in swine killed during the acute phase of leptospirosis. Burnstein and Baker (1954) reported that petechial and ecchymotic hemorrhages could be seen in the lungs of some pigs, and histologic examinations have revealed minor renal tubular damage, focal liver necrosis, lymphocytic infiltration of the adrenal

glands, and meningoencephalitis with perivascular lymphocytic infiltration (Burnstein and Baker 1954; Chaudhary et al. 1966a; Sleight et al. 1960).

In chronic leptospirosis, gross lesions are confined to the kidneys and consist of scattered small gray foci, often surrounded by a ring of hyperemia. Microscopic examination reveals progressive multifocal interstitial nephritis (Burnstein and Baker 1954; Cheville et al. 1980; Langham et al. 1958). The renal interstitium contains focal-to-coalescing aggregates of lymphocytes, macrophages, and plasma cells. Some glomeruli may be swollen, atrophic, or fibrotic. Bowman's capsule may be thickened, containing eosinophilic granular material (Langham et al. 1958). Renal tubular epithelial cells may be degenerate and sloughing, resulting in necrotic cellular luminal debris, or they may be hyperplastic. Older lesions mainly consist of fibrosis and interstitial inflammatory cell infiltrations. Chronic lesions with accompanying acute inflammatory changes are still noticeable as long as 14 months' postinfection (Morter et al. 1960).

Experimental studies indicate that leptospires can invade the mammary gland of pigs and produce mild focal nonsuppurative mastitis (Tripathy et al. 1981).

The gross pathology of fetuses aborted as a sequela of Pomona infection is nonspecific and probably due to intrauterine autolysis, and includes edema of various tissues, serous or bloodstained fluid in body cavities, and sometimes petechial hemorrhages in renal cortices (Fennestad and Borg-Petersen 1966; Ryley and Simmons 1954a,b; Wrathall 1975). Jaundice may be seen in some aborted piglets (Hathaway et al. 1983). Multifocal hepatic necrosis, presenting as small grayish-white spots, may be a frequent finding (Fennestad and Borg-Petersen 1966; Fish et al. 1963; Ryley and Simmons 1954a,b). Microscopic examination may reveal small foci of interstitial nephritis and multifocal hepatic necrosis. Placentas from aborted fetuses are grossly normal (Fennestad and Borg-Petersen 1966; Fish et al. 1963).

Diagnosis

A diagnosis of clinical or subclinical leptospirosis in swine may be required for a variety of reasons, including (1) confirmation of clinical disease, (2) assessment of herd infection and/or immune status for control or eradication on a herd or national basis, or (3) determination of the status of individual animals for introduction into a closed herd or for trade.

The mild, often inapparent clinical signs of acute leptospirosis make clinical diagnosis difficult, and the lack of specificity of lesions makes pathological diagnosis difficult; therefore, diagnosis is usually based on the results of laboratory tests. Laboratory tests for leptospirosis fall into two groups: (1) indirect serologic tests that assess antibody levels and (2) direct tests that detect the organism. The selection of tests depends on the purpose for testing and availability of tests.

Serologic tests

Serologic testing is the most widely used method for diagnosing leptospirosis, and MAT (OIE 2008) is the standard serologic test. The minimum antigen requirements are that the test should employ representative strains of all the serogroups known to exist in the particular country, plus those known to be maintained by pigs elsewhere.

MAT is used primarily as a herd test. To obtain useful information, at least 10 animals or 10% of the herd, whichever is the greater, should be tested. A retrospective diagnosis of both acute leptospirosis and Pomona abortion may be made when the majority of affected animals have titers of 1 : 1000 or greater. Increasing the sample size and sampling a number of different cohorts markedly improves epidemiologic information, investigations of clinical disease, assessments of vaccination needs, and public health tracebacks.

As an individual animal test, MAT is very useful in diagnosing acute infection; rising antibody titers in paired acute and convalescent serum samples are diagnostic. The presence of antibody in fetal serum is diagnostic of leptospiral abortion.

MAT has severe limitations in the diagnosis of chronic infection in individual pigs, both in the diagnosis of abortion and in the identification of renal or genital carriers. Infected animals may have MAT titers below the widely accepted minimum significant titer of 1 : 100 (Ellis et al. 1986b,c). In these cases a competitive ELISA has proved useful (Frizzell et al. 2004).

Tests that detect leptospires

Confirmation of leptospires in the internal organs (such as the liver, lung, and brain) and body fluids (blood, cerebrospinal, thoracic, peritoneal) of clinically affected animals gives a definitive diagnosis of acute clinical disease or, in the case of a fetus, a diagnosis of leptospiral abortion and probable chronic infection of its mother.

Confirmation of leptospires in the male or female genital tract, the kidney, or urine, in the absence of evidence of generalized infection, is diagnostic of chronic infection. Failure to demonstrate leptospires in the urine of a pig does not rule out the possibility of the animal being a chronic renal carrier; it merely indicates that the pig was not excreting detectable numbers of leptospires at the time of testing.

Bacterial culture

Culture, especially from clinical material, is difficult and time consuming and is a job for laboratories specializing in the identification of isolates. Culture from renal carriers is very useful in epidemiologic studies to determine which serovars are present in an animal species or in a particular group of animals or geographic location.

Culture is the most sensitive direct method provided that antibiotic residues are absent, that tissue autolysis is not advanced, and that tissues for culture have been stored at a suitable temperature of 4 °C (39 °F) and, in the case of urine, at a suitable pH.

Culture should be carried out in a semisolid (0.1–0.2% agar) bovine serum albumin medium containing either Tween 80 (Johnson and Harris 1967) or a combination of Tween 80 and Tween 40 (Ellis 1986) and preferably with a small amount of fresh rabbit serum (0.4–2%). A dilution culture method should be used (Ellis 1986). Contamination may be controlled by a variety of selective agents including 5-fluorouracil, nalidixic acid, fosfomycin, and a cocktail of rifamycin, polymyxin, neomycin, 5-fluorouracil, bacitracin, and actidione. Culture media containing 5-fluorouracil at levels between 200 and 500 µg/mL should be used as transport media for the submission of samples (Ellis 1990). Cultures should be incubated at 29–30 °C (84–86 °F) for at least 12 weeks, preferably for 26 weeks (Ellis 1986). They should be examined by dark-field microscopy every 1–2 weeks.

Other methods to detect leptospires

Leptospires do not stain satisfactorily with the aniline dyes, and silver staining techniques lack sensitivity and specificity (Baskerville 1986). Dark-ground microscopy of fetal fluids or urine leads to false-positive diagnoses and should be avoided.

The demonstration of leptospires by immunochemical tests (immunofluorescence, immunoperoxidase, immunogold) is more suited to most laboratory situations; however, these tests are "number-of-organisms" dependent and lack the sensitivity of culture. They provide no information as to the infecting serovar (Ellis 1990) and require as reagent high IgG titer antileptospire sera. Immunofluorescence is the method of choice for the diagnosis of fetal leptospirosis.

Identification of leptospiral DNA by PCR should be the most sensitive method of detecting leptospires in tissues and fluids since PCR is not dependent on viable organisms. There have been few reported uses of PCR as a tool in the diagnosis of swine leptospirosis, and poor correlations with culture have been reported (Miraglia et al. 2008), but some studies have shown promise (Oliveira et al. 2007).

Prevention and control

Interruption of transmission from infected pig or other infected host to susceptible pig is the critical factor in control. Control of leptospirosis is dependent on the combined use of three strategies: antibiotic therapy, vaccination, and management. Unfortunately, not all these options are available in every country. Vaccines are not available in many Western European countries, while problems of antibiotic residues may make the use of antibiotic therapy difficult in other situations. In the United States, the most useful antibiotic for leptospiral control/treatment programs, streptomycin, is no longer available for veterinary use. Control programs must therefore be modified to meet local conditions.

Vaccination induces immunity of relatively short duration. Immunity to infection is probably never 100% and, at best, lasts little more than 3 months (Ellis et al. 1989; Kemenes and Suveges 1976). Immunity to clinical disease is believed to last somewhat longer, although exact duration is not known. Vaccination markedly reduces the prevalence of infection in swine herds (Kemenes and Suveges 1976; Wrathall 1975) but will not eliminate infection (Cargill and Davos 1981; Edwards and Daines 1979; Hodges et al. 1976). Improvements in bovine leptospirosis vaccines have resulted in protective immunity lasting approximately 12 months. There is a need for the development of similar vaccines for swine that should contain appropriate serovars of pig-maintained strains plus strains maintained by other regional hosts. Mixed genotype infection of serovar Bratislava indicates that natural infection by one genotype may not always confer immunity to infection by the heterologous genotype of the same serovar (Arent et al. 2016).

Antibiotics alone will not eliminate pig-maintained leptospiral infections from individual carriers or control infection in herds. Despite claims by some authors that either systemic streptomycin at 25 mg/kg body weight (Alt and Bolin 1996; Dobson 1974) or oral tetracyclines at levels of 800 g/ton of feed (Stalheim 1967) will eliminate carriers, others have reported that these regimes do not work (Doherty and Baynes 1967; Hodges et al. 1979). Work on the use of alternative antibiotic therapy regimes indicates that oxytetracycline (40 mg/kg for 3 or 5 days), tylosin (44 mg/kg for 5 days), or erythromycin (25 mg/kg for 5 days) may be effective in eliminating Pomona from the kidneys of experimentally infected pigs (Alt and Bolin 1996).

The main management factor in the control of leptospirosis is the prevention of direct or indirect contact with free-living vectors or other domestic stock. Strict biosecurity should be implemented, including stringent rodent control programs. When faced with an outbreak of clinical disease, the best option is to treat both affected and at-risk stock with streptomycin at

25 mg/kg body weight, to immediately vaccinate the at-risk stock, and then to introduce a regular vaccination program. If vaccination is not an available option, then a feed medication program, using either chlortetracycline or oxytetracycline at 600–800 g/ton of feed, should be introduced. This ration is fed either continuously or on a 1-month-on/1-month-off basis. Alternatively, it may be fed for two periods of 4 weeks in the year, preferably one in the spring and the other in the autumn.

The use of artificial insemination is an important tool in the control of Bratislava infection.

Mycoplasmosis

Maria G. Pieters and Dominiek Maes

Overview

Pathogenic and nonpathogenic *Mycoplasma* spp. have been identified in swine. Four species are responsible for nearly all diseases. *Mycoplasma hyopneumoniae* causes enzootic pneumonia (EP) and is an important primary pathogen in the porcine respiratory disease complex (PRDC). *Mycoplasma hyorhinis* most commonly causes polyserositis and arthritis in nursery-age pigs. *Mycoplasma hyosynoviae* causes arthritis in grow–finish pigs, and *Mycoplasma suis*, formerly *Eperythrozoon suis*, causes infectious anemia in pigs.

Mycoplasmas are classified within the phylum *Tenericutes*, class *Mollicutes*, order *Mycoplasmatales*, and family *Mycoplasmataceae* (Nowak 1929). They are the smallest and simplest known self-replicating organisms, phylogenetically related to gram-positive bacteria. They are distinguished from other eubacteria by lacking a cell wall (Neimark 1986) and by having cholesterol in the plasma membrane, a low genomic G+C content, and unique usage of the UGA codon for tryptophan. Mycoplasmas likely evolved by degenerative, reductive, and regressive evolution, ending with a very small genome of 580–1380 kbp (Razin 1992). This small genome results in a slow growth rate due to an inability to rapidly synthesize ribosomes and dependence on host-derived nutrients. Most *Mycoplasma* spp. attach to and replicate on epithelial cells that line the respiratory and urogenital tracts, as well as the mucous membranes of the conjunctiva, the digestive tract, mammary glands, and joints. In contrast, *M. suis* attaches to and invades and replicates on and in red blood cells (RBCs).

Mycoplasma hyopneumoniae

M. hyopneumoniae infects only pigs and is ubiquitous, found worldwide in nearly all countries and pig farms where the organism has not been intentionally eliminated. It is the essential causative agent of a chronic insidious bronchopneumonia known as EP. It produces long-term colonization of ciliated respiratory epithelium in the conducting airways where it suppresses innate and acquired pulmonary immunity. This allows upper respiratory commensal bacteria such as *Pasteurella multocida*, *Streptococcus suis*, *Haemophilus parasuis*, and others to proliferate in the lungs and contribute to disease. EP is characterized by its chronic nature, high morbidity, low mortality, and decreased performance. The economic impact of EP is significant and primarily related to decreased average daily gain, increased feed conversion ratio, and increased number of days to reach market weight. EP occurs primarily in grower–finisher pigs in age-segregated production systems or sometimes in younger nursery-age pigs in continuous-flow systems. In addition to EP, *M. hyopneumoniae* can also contribute to PRDC through its potentiation of respiratory disease caused by certain viral pathogens, including porcine reproductive and syndrome virus (PRRSV) and porcine circovirus type 2 (PCV2). Although most swine herds are endemically infected with *M. hyopneumoniae*, when it is introduced into negative naïve herds, it can produce epidemics affecting all ages of pigs simultaneously.

Etiology

M. hyopneumoniae was first isolated over half a century ago (Goodwin et al. 1965; Mare and Switzer 1965) and was established as the agent causing EP. It is difficult to grow *in vitro* due to demanding nutritional requirements, slow growth rate, and overgrowth with other bacteria, especially *M. hyorhinis*. The medium universally employed for *M. hyopneumoniae* culture was developed by Friis (1975) and contains a wide array of compounds including antibiotics, serum of swine and equine origin, yeast extract, and a pH indicator. Recently Cook et al. (2016) claim to have optimized the original medium by inclusion of kanamycin to inhibit the growth of *M. hyorhinis*. Careful sample selection and handling to ensure that a significant amount of

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

M. hyopneumoniae is inoculated into media improves isolation rates (Anderson et al. 2016a).

M. hyopneumoniae grows more slowly in culture than other mycoplasmas, and isolation is often unsuccessful. Culture is typically attempted when a certain isolate of *M. hyopneumoniae* is needed, but not as a routine diagnostic method. Optimum samples for culture include typical pneumonic lesions and the surrounding normal-appearing lung, and bronchial swabs. Following inoculation of Friis broth medium, the medium is serially diluted, and dilutions are monitored for 3–30 or more days for growth. Growth is typically evidenced by color change but can be accurately measured using an ATP luminometry method (Calus et al. 2010). Broth growth is plated to solid agar media to clone. Growth may require days to weeks and colonies are best visualized using a stereoscopic microscope. Individual colonies are identified as *M. hyopneumoniae* by PCR (Stakenborg et al. 2006a) or are grown back in Friis broth for identification by other methods or for harvest and storage.

Strains of *M. hyopneumoniae* are antigenically and genetically diverse. The lack of clonality of *M. hyopneumoniae* was suspected and initially demonstrated by serological methods (Ro and Ross 1983), fingerprinting (Kokotovic et al. 1999), clinical presentation (Vicca et al. 2003), and *in vitro* growth (Meyns et al. 2007). Efforts to characterize *M. hyopneumoniae* at the molecular level are based on sequencing of a specific VNTR in the gene encoding the major adhesion protein P146 (Mayor et al. 2007), the length of fragments after digestion with restriction enzymes (Kokotovic et al. 1999; Stakenborg et al. 2006b), or the analysis of VNTR patterns in various loci (Dos Santos et al. 2015b; Nathues et al. 2011; Stakenborg et al. 2005b; Vranckx et al. 2011). Strains of *M. hyopneumoniae* differ in virulence, with high virulence strains inducing more severe pneumonia in a larger proportion of infected pigs (Meyns et al. 2007; Vicca et al. 2003; Woolley et al. 2012). Higher pathogenicity in high virulence strains is attributed to a higher capacity to multiply in the lungs and induction of a more severe inflammatory process (Meyns et al. 2007).

Epidemiology

Infections caused by *M. hyopneumoniae* are virtually present in every country where pigs are raised. Prevalence levels are likely high, but there is little published prevalence data. Switzerland is an exception where the prevalence is under 1% after completing an eradication program at national level (Stärk et al. 2007). However *M. hyopneumoniae* infections in wild boar and domestic swine are sporadically detected in Switzerland (Kuhnert and Overesch 2014; Kuhnert et al. 2011). Cross-transmission between domestic and feral swine has not been documented.

Swine of all ages are susceptible to colonization by *M. hyopneumoniae* on the epithelium of their nasal cavity and conducting airways. *M. hyopneumoniae* is shed in nasal secretions of infected animals (Goodwin 1972), and the most common mode of transmission occurs via close, usually nose-to-nose, contact between infected and susceptible pigs (Calsamiglia and Pijoan 2000; Rautiainen and Wallgren 2001). However nose-to-nose transmission is inefficient and spread is slow. Studies have demonstrated that 1 infected nursery-age pig will transmit *M. hyopneumoniae* to 1–2 naïve pigs during 4–6 weeks of continuous contact (Meyns et al. 2004; Roos et al. 2016; Villarreal et al. 2011). Colonization of pigs persists for long periods, typically 7–8 months (Pieters et al. 2009). Colonized pigs may or may not develop clinical pneumonia during this period, depending on a variety of factors, including strain virulence, infectious dose, host immunity, concurrent bacterial, viral, or other infections, and environment, among others (see section "Pathogenesis"). Colonized pigs appear to be infectious to other animals during the entire duration of infection, although consistency of shedding and concentration of *M. hyopneumoniae* shed may vary over time. Naïve contact pigs develop a higher rate of colonization when exposed to *M. hyopneumoniae*-infected pigs with clinical EP compared with lower rates when exposed to subclinically *M. hyopneumoniae*-infected pigs in the later months of their infection (Pieters et al. 2009).

M. hyopneumoniae is most commonly introduced into naïve populations by direct transmission via close contact through the introduction of infected pigs. However, airborne transmission of *M. hyopneumoniae* has been suspected for decades (Goodwin 1985) and has been confirmed over short distances (Fano et al. 2005). Otake et al. (2010) showed that air samples containing *M. hyopneumoniae* recovered from as far as 9.2 km from an infected farm remained infectious to inoculated animals. A number of studies of the Danish specific-pathogen-free (SPF) systems found that herd reinfections with *M. hyopneumoniae* often occurred in the autumn and winter when atmospheric conditions favored aerosol transmission (Jorsal and Thomsen 1988). *In utero* transmission of *M. hyopneumoniae* is not known to occur, and the role of vectors in transmission is considered to be minimal.

Once *M. hyopneumoniae* is introduced, a swine herd typically remains endemically infected. Infection is maintained in breeding herds by the constant introduction of naïve replacement animals, which allows for continuous pathogen transmission among resident females and incoming purchased or self-reared replacement gilts. Dams transmit *M. hyopneumoniae* via nasal secretions to their progeny during the suckling period (Calsamiglia and Pijoan 2000; Fano et al. 2007; Rautiainen and Wallgren 2001). The proportion of sows that shed

M. hyopneumoniae decreases by parity. In one study, 73% of parity 1, 42% of parity 2–4, 50% of parity 6–7, and 6% of parity 8–11 were shedding the organism (Calsamiglia and Pijoan 2000). In another study, 33% of pigs from parity 1 to 2 sows were *M. hyopneumoniae* positive at weaning compared with 21% from 3+ parity sows (Fano et al. 2006). Management practices at the sow and the piglet level seem to be risk factors for piglet colonization. Increasing risk of infection at weaning is associated with a higher proportion of positive dams, higher numbers of replacement gilts in the breeding herd (presumably affecting the proportion of positive dams), larger farrowing rooms, lower ambient temperatures in the suckling piglet nesting area, and longer lactation periods (Nathues et al. 2013a, 2013b; Pieters et al. 2014; Vangroenweghe et al. 2015). Cross-fostering of piglets would also likely increase prevalence of *M. hyopneumoniae* at weaning. Prevalence of colonization at weaning varies widely but in most reports is 0–15%.

Following weaning, infected pigs are mixed with larger cohorts of naïve pigs, increasing the potential for transmission. The prevalence of piglet colonization at weaning age has been proposed as a predictor of disease severity in the finishing phase (Fano et al. 2007; Sibila et al. 2007b). For example, with a 1:1 transmission ratio every 4 weeks, a 2% prevalence of infection at a 1-month weaning age would result in 4, 8, 16, and 32% prevalence of infection in the weaned cohort at 2, 3, 4, and 5 months of age, compared with a 6% prevalence of infection at weaning that would result in 12, 24, 48, and 96% prevalence of infection at the same ages in the finishing barn. In a continuous-flow system, transmission is further enhanced by direct contact or indirect exposure via a shared airspace with older pigs having a higher prevalence of infection (Giacomini et al. 2016; Vranckx et al. 2012). In age-segregated 2- or 3-site systems, EP is usually manifest in the mid- to late finishing phase; however, in continuous-flow systems, EP may be observed as early as 8 weeks of age. Investigation of differences between farms and production systems has identified numerous factors important in the dynamics and severity of *M. hyopneumoniae* disease on a herd level, including housing styles, ventilation systems, stocking densities, climatic conditions, and the type of system, i.e. age-segregated or continuous-flow 1-, 2-, or 3-site production systems (Sibila et al. 2004b; Vicca et al. 2002). Additionally, the presence of other infectious or toxic agents impact expression of disease (see section "Pathogenesis").

The application of molecular methods has allowed the differentiation of *M. hyopneumoniae* strains and their epidemiologic study in the field. In areas with low swine density or low prevalence of *M. hyopneumoniae*-positive herds, a single strain of *M. hyopneumoniae* has typically been detected in infected herds (Mayor et al. 2007; Vranckx et al. 2012). In contrast in swine-dense areas, multiple strains of *M. hyopneumoniae* have been frequently detected in individual swine herds (Michiels et al. 2017; Nathues et al. 2011). One study suggests that herds infected with larger numbers of strains have more severe lesions of EP at slaughter (Michiels et al. 2017).

Pathogenesis

The pathogenesis of *M. hyopneumoniae* is complex and involves long-term colonization of airway epithelium, stimulation of a prolonged inflammatory reaction, suppression and modulation of the innate and adaptive immune responses, and interaction with other infectious agents.

M. hyopneumoniae replicates nearly exclusively on ciliated respiratory epithelial cells lining the nasal cavity and conducing airways of pigs. However, it has rarely been isolated from the liver, spleen, and kidneys of experimentally inoculated pigs where no lesions or alterations in organ function are reported (Le Carrou et al. 2006; Marchioro et al. 2013; Marois et al. 2007).

Upon inhalation, *M. hyopneumoniae* organisms penetrate the mucus layer of the respiratory mucosa (Jenkins et al. 2006; Wilton et al. 2009), and within one day they are adherent to cilia of epithelial cells of the trachea, bronchi, and bronchioles (Tajima and Yagihashi 1982). The process of adherence to the cilia is complex and mediated between adhesins of the mycoplasma cells and receptors on the membrane of the cilia. A number of adhesins have been identified including Mhp182 (P102), Mhp183 (P97), Mhp 684 (P146), Mhp 493 (P159), Mhp 494 (P216), Mhp 683 (P135), Mhp 271, Mhp 107, and Mhp 108 (P116). Adherence is largely mediated via interactions of members of the P97 and P102 adhesin families and P159 with glycosaminoglycans and fibronectin that decorate the surface of ciliated respiratory epithelial cells (Adams et al. 2005; Hsu and Minion 1998; Seymour et al. 2012; Wilton et al. 2009).

Members of the P97 and P102 adhesin families and P159 are large-mass (>100 kDa), modular, multifunctional molecules that are cleaved at multiple sites, generating a complex mixture of cleavage fragments that remain attached on the extracellular membrane surface of *M. hyopneumoniae*. In the P97/P102 adhesin families, posttranslational cleavage is extensive and unorthodox (Jarocki et al. 2015; Tacchi et al. 2016). The resulting diversity of surface proteins is thought to regulate adhesion to the host tissue, potentiate host cell invasion, and avoid immune clearance (Bogema et al. 2012). Cleavage fragments derived from these adhesins bind heparin (Burnett et al. 2006; Deutscher et al. 2010), fibronectin (Deutscher et al. 2010; Seymour et al. 2011, 2012), and plasminogen (Robinson et al. 2013; Seymour et al. 2010, 2011, 2012). Binding of plasminogen facilitates conversion to plasmin by mammalian plasminogen activators

(Seymour et al. 2012). Plasmin functions as a proinflammatory agonist and likely facilitates tissue invasion, inflammatory lesions, and systemic infection (Bogema et al. 2012).

The conducting airways, especially in the apical and cardiac lobes, are progressively colonized by *M. hyopneumoniae* with corresponding damage to the mucociliary apparatus (Bendjennat et al. 1999; Blanchard et al. 1992). Within hours after the adherence of *M. hyopneumoniae* to the cilia, damage to cilia gives way to cilia loss and ultimately disruption of the epithelial cells (Blanchard et al. 1992; Park et al. 2002). This results in a reduced clearing capacity by the mucociliary apparatus and increases susceptibility to secondary bacterial and viral respiratory infections (Ciprian et al. 1994; Park et al. 2016).

M. hyopneumoniae has a modulating effect on the inflammatory response and the immune system. *M. hyopneumoniae* organisms stimulate alveolar macrophages and lymphocytes to produce proinflammatory and immunoregulatory cytokines that play a role in inducing lung inflammation and lymphoid hyperplasia (Meyns et al. 2007; Rodriguez et al. 2004), the primary features of lesions observed in EP. On the other hand, there is also evidence for the induction of anti-inflammatory cytokines that suppress the function of neutrophils (Asai et al. 1996) and macrophages (Caruso and Ross 1990), this likely aiding persistent infection by *M. hyopneumoniae* and opportunistic infection by other bacterial and viral agents. See more on modulation of the inflammatory and immune response in section "Immunity."

Not all respiratory infections with *M. hyopneumoniae* result in clinical pneumonia. Development of clinical pneumonia is dependent on the number of organisms in the respiratory tract, the virulence of the infecting strain(s) of *M. hyopneumoniae*, and the involvement of other respiratory pathogens. The number of organisms colonizing a pig is likely dependent on cumulated infectious doses, capacity of the *M. hyopneumoniae* strain(s) to multiply in the lungs, and time. Infection with *M. hyopneumoniae* often has its greatest economic significance due to interaction with other respiratory pathogens.

Pulmonary colonization by *M. hyopneumoniae* predisposes pigs to respiratory infections with opportunistic bacteria, typically upper respiratory commensals. This is due to reduced pulmonary clearance induced by *M. hyopneumoniae* through damage to cilia, induction of excessive thick mucus, reduction in phagocytic efficiency of neutrophils and macrophages, and likely other mechanisms. Combined experimental infections with *M. hyopneumoniae* and either *P. multocida* (Amass et al. 1994) or *Actinobacillus pleuropneumoniae* (Marois et al. 2009) result in more severe lesions compared with the single infections. Coinfections with *P. multocida* and *A. pleuropneumoniae* and with other bacteria such as *Bordetella bronchiseptica*, *H. parasuis*, *Trueperella pyogenes*, or streptococci are commonly found in field outbreaks of EP.

Infection with *M. hyopneumoniae* also potentiates some viral infections. An initial study focusing on the interaction between *M. hyopneumoniae* and PRRSV did not demonstrate a potentiating effect of either pathogen (Van Alstine et al. 1996). Later studies confirmed that *M. hyopneumoniae* significantly prolongs and increases the severity of PRRSV-induced pneumonia (Thacker et al. 1999). Similar studies demonstrated only transitory and/or inconsequential potentiation of influenza viral pneumonias (Deblanc et al. 2012; Thacker et al. 2001; Yazawa et al. 2004). Studies using dual *M. hyopneumoniae* and PCV2 challenge models indicated that *M. hyopneumoniae* infection potentiates the severity of PCV2-associated lung and lymphoid lesions and increases the amount and prolongs the presence of PCV2 antigen (Opriessnig et al. 2004; Seo et al. 2014). Additionally, the incidence of post weaning multisystemic wasting syndrome in pigs was also found to be increased (Opriessnig et al. 2004). Sibila et al. (2012) however could not demonstrate an interaction between *M. hyopneumoniae* and PCV2 infection. In herds facing concurrent infections with *M. hyopneumoniae* and PCV2, studies have confirmed that vaccination against PCV2 alone or in combination with vaccination against *M. hyopneumoniae* is more effective in preventing potentiation of lung lesions than *M. hyopneumoniae* vaccination alone (Raith et al. 2015; Seo et al. 2014).

Finally, some cofactors potentiate lesions of EP in *M. hyopneumoniae*-infected pigs. Lesions typical for EP have higher prevalence and are more severe in pigs that are concurrently infected with migrating *Ascaris suum* larvae (Flesja and Ulvesaeter 1980) or in pigs receiving feed contaminated with fumonisin B (Pósa et al. 2013).

Immunity

Innate as well as adaptive humoral and cellular immune responses are elicited in *M. hyopneumoniae*-infected pigs. Although the immune response prevents significant systemic spread of *M. hyopneumoniae*, it is unable to rapidly clear pulmonary infection resulting in persistent colonization of airways for up to 7 months. This results in a prolonged localized inflammatory and cellular immune response that is responsible for the majority of gross and microscopic lesions.

M. hyopneumoniae both stimulates and inhibits the innate immune response. Colonization by *M. hyopneumoniae* induces localized tissue histiocytes to secrete inflammatory cytokines that, in turn, induce a localized inflammatory response. This results in an influx of neutrophils and macrophages that predominate early in infection. Clearance of *M. hyopneumoniae* and other bacterial and viral agents is impaired by *M. hyopneumoniae*-induced damage to cilia, induction of excessive

mucus, and reduction in phagocytic efficiency of neutrophils and macrophages. The secretion of inflammatory cytokines increases as colonization by *M. hyopneumoniae* progresses, due to increasing numbers of accumulating inflammatory cells. Toll-like receptors 2 and 6 recognize lipoproteins in *M. hyopneumoniae*, inducing cytokine production (Muneta et al. 2003; Régia Silva Sousa et al. 2011). The extent of the cytokine induction can vary between strains of infecting *M. hyopneumoniae* (Meyns et al. 2007). The cytokine profile during infection with *M. hyopneumoniae* is contradictory. Proinflammatory cytokines like IL-1, IL-2, IL-6, IL-8, IL-12, IL-18, INF-γ, and TNF-α (Asai et al. 1993, 1994; Muneta et al. 2006; Thacker et al. 2000a; Thanawongnuwech et al. 2004), as well as anti-inflammatory cytokines like IL-10, have been measured in *M. hyopneumoniae*-infected pigs (Thanawongnuwech and Thacker 2003).

Shortly after neutrophils and macrophages arrive at sites of *M. hyopneumoniae* colonization, peribronchiolar and adjacent perivascular connective tissues are infiltrated by both B and T lymphocytes, leading to the production of *M. hyopneumoniae*-specific antibodies and the development of a cell-mediated immune response. Helper (CD4+) T cells are more prevalent than cytotoxic (CD8+) T cells (Sarradell et al. 2003). Over time lymphoid nodules with germinal-like centers form. Cell-mediated immunity (CMI) may be important in limiting spread of *M. hyopneumoniae* to other organs, but it is also responsible for enhancing lesions. Tajima et al. (1984) demonstrated in thymectomized pigs treated with antithymocyte serum and inoculated with *M. hyopneumoniae* that lesions of EP were less severe than in controls but that *M. hyopneumoniae* was isolated from the spleen of one of the thymectomized pigs but not in control pigs.

Antibodies against *M. hyopneumoniae* are detected in the serum and in the lower respiratory tract of infected pigs. Immunoglobulins M, G, and A have been measured in the lung (Messier et al. 1990) and IgG and IgA in tracheobronchial secretions of naturally and experimentally infected animals (Messier et al. 1990; Redondo et al. 2009; Rodriguez et al. 2004; Suter et al. 1985). Studies confirm a lack of correlation between the level of serum antibodies and protection from infection (Djordjevic et al. 1997).

Antibodies and immune cells specific for *M. hyopneumoniae* can be transferred from the dam to the baby pig via colostrum. Bandrick et al. (2008) demonstrated the transfer of CMI in a newborn piglet model in a *M. hyopneumoniae* endemically infected farm. Later, Bandrick et al. (2011) showed that the transfer of the *M. hyopneumoniae*-specific immunity was affected by time after birth for antibodies and was time and source dependent in the case of CMI. The effect of maternally transferred immunity has been a cause of debate. Maternal interference with the pig immune response to infection, or vaccination, has been demonstrated in terms of antibody levels, but interference is not evidenced for maternal CMI (Bandrick et al. 2014).

Clinical signs

Two clinical forms of *M. hyopneumoniae*-induced disease occur in swine herds: epidemic and endemic. Epidemics are uncommon, occurring only when *M. hyopneumoniae* enters a noninfected, immunologically naive herd. The spread of the disease occurs rapidly, and all age groups may be affected. Coughing, acute respiratory distress, fever, and deaths may occur. Typically, infection transitions to an endemic pattern in the herd within 2–5 months.

The endemic form of disease known as EP is the common form of disease and is observed in continuously infected herds. The most obvious clinical sign is nonproductive coughing in nursery, grower, and/or finisher pigs. Onset is insidious, affecting at first a few animals and slowly spreading to involve a considerable percentage of the pigs. Coughing may disappear after 2–3 weeks but can also persist throughout the entire finishing period. Under experimental infections, clinical signs are mainly characterized by slight fever, followed by dry coughing. Coughing appears from 10 to 14 days post inoculation, reaches a maximum peak at about 4–5 weeks, after which it disappears gradually (Arsenakis et al. 2016; Garcia-Morante et al. 2016; Vicca et al. 2003). Under field conditions, most infections with *M. hyopneumoniae* are complicated by coinfection with other opportunistic bacteria or with respiratory viruses. In this case, clinical signs are more severe and may include severe respiratory distress, fever, labored breathing, prostration, reduced appetite, and eventually mortality.

Lesions

Macroscopic lesions in the lungs of pigs infected with *M. hyopneumoniae* are found bilaterally in the apical, cardiac, and intermediate lobes and sometimes in the anterior parts of the diaphragmatic lobes. In inoculation studies they can be detected 7–10 days post infection (Kobisch et al. 1993; Underdahl et al. 1980) and reach their maximal extension 2–4 weeks post infection. The lesions are fawn/pink or plum colored and demarcated from normal tissue (Rodríguez et al. 2016). When the affected lung is incised, the consistency is moderately firm, and the cut surface is moist. The bronchial and mediastinal lymph nodes are enlarged. During the chronic stages, the lesions are deeper red. Recovering lesions consist of fissures of collapsed alveoli (interlobular scar retractions) and remain 2–4 months after infec-

tion (Kobisch et al. 1993; Sorensen et al. 1997). They are located mainly in the cardiac lobes. Although gross lesions are suggestive of EP, they are not pathognomonic for *M. hyopneumoniae*, as other organisms like swine influenza virus or the combination of *P. multocida* and Aujeszky's disease virus may produce similar lesions (Done 1991; Fuentes and Pijoan 1987).

Microscopic lesions can be staged depending on the duration of the disease. Early microscopic lesions consist of limited accumulations of neutrophils in the lumens and around the airways as well as in alveoli. Few lymphocytes are in the adventitia of arterioles and venules and around the airways. Second-stage lesions occur between 7 and 28 days post infection and are characterized by marked accumulation of neutrophils, fluid, and macrophages in alveoli; proliferation of type II alveolar pneumocytes; increasing accumulation of lymphocytes, histiocytes, and plasma cells around blood vessels and conducting airways; and development of peribronchial lymphoid nodules. Bronchial epithelium may be partially denuded of cilia or partially desquamated (Blanchard et al. 1992). Established third-stage lesions occur 17–40 days post infection and are characterized by progressive peribronchial lymphoid hyperplasia, increased perivascular mononuclear cell accumulation, and progressive development of alveolar pneumonia. Late and recovering fourth-stage lesions occur 69–210 days post infection. Large numbers of lymphocytes and fewer plasma cells form extensive peribronchial cuffs that also contain many large lymphoid nodules that may compress bronchial lumens. Scoring systems have been used to quantify microscopic lesions (Morris et al. 1995; Villarreal et al. 2009).

Lesions are often complicated by additional features characteristic of concurrent bacterial or viral infectious agents.

Diagnosis

M. hyopneumoniae does not cause pathognomonic clinical signs or lesions. Diagnosis of EP should include typical clinical signs, epidemiology, typical lesions, and confirmation of *M. hyopneumoniae* infection.

Nonproductive cough and/or decreased growth rate is suggestive of *M. hyopneumoniae*. Traditional methods to quantify coughs have proven valuable to indicate disease onset (Nathues et al. 2012). The use of computerized cough monitoring systems coupled with microphones physically located in the barns have been proposed as means to detect increases in cough activity and to trigger disease investigations (Guarino et al. 2008).

Typical microscopic lesions should be confirmed in lungs having suggestive gross lesions of EP. Several samples should be collected from areas with gross lesions, focusing on areas toward the middle and base of lung lobes and avoiding lung margins. Samples should be placed in fixative as soon as possible after death. When possible, several lungs should be sampled.

The traditional gold standard method for confirmation of *M. hyopneumoniae* infection is culture using Friis media (Friis 1975); however, slow growth, frequent overgrowth by other bacteria, high cost, and low sensitivity of the method limit usefulness. Culture is typically employed only when a bacterial isolate is needed.

Direct detection of the antigen or nucleic acid can be performed in the airway epithelium and lung tissue. Fluorescent antibody (FA) or immunohistochemistry (IHC) tests use specific antibodies to detect antigen in thin frozen sections or fixed sections of tissue, and *in situ* hybridization (ISH) uses specific nucleic acid probes to detect specific nucleic acids in thin fixed tissue sections (Boye et al. 2001). FA and IHC tests have been widely used but require high-quality *M. hyopneumoniae*-specific antibodies that are sometimes unavailable. Among these, IHC and ISH have the advantage of allowing visualization of *M. hyopneumoniae* antigen in conjunction with microscopic lesions, conferring a high level of confidence in a diagnosis of EP. However, all three methods suffer from several disadvantages. They cannot be used on antemortem samples. Since they require intact *M. hyopneumoniae*-colonized bronchial epithelial cells in the sections of tested lungs, samples from carcasses with postmortem degeneration or that have passed through a scalding process at slaughter can result in false-negative tests. Because colonization of lungs is nonuniform, several sections from each lung should be tested, or false negatives may result. Finally, the technologies employed are less sensitive than PCR, which has become the most widely used confirmatory test.

Various PCR assays have been developed and validated, including gel based, nested, and real time (Dubosson et al. 2005; Strait et al. 2008). High accuracy, fast turnaround, high throughput, and utility for use with tissue samples collected postmortem or clinical samples collected from live pigs have made real-time PCR the most used confirmatory test. Sample selection for *M. hyopneumoniae* detection by PCR can be challenging. The most sensitive samples are of lung exhibiting typical gross lesions and that include bronchi, i.e. not along lung margins. Clinical samples can also be used, including oral fluids, nasal swabs, tonsillar swabs, laryngeal swabs, tracheobronchial swabs, and tracheobronchial lavages, among others (Anderson et al. 2016a,b; Calsamiglia et al. 1999; Fablet et al. 2010; Pieters et al. 2017; Sibila et al. 2004a). The sensitivity of the sample types varies, with samples collected toward the lower respiratory tract exhibiting higher sensitivity. However, care should be exercised when interpreting PCR results, as the potential

for cross-contamination exists, and viable and nonviable cells will be equally detected.

Evaluation of lungs at slaughter has been used to collect samples for confirmatory testing of *M. hyopneumoniae* infection and to quantify prevalence and severity of lesions suggestive of EP. Prevalence of EP can be overestimated since similar lesions of other respiratory diseases can be misclassified as EP. To prevent this, samples should be collected for histopathology and confirmatory testing. Prevalence can also be underestimated since lesions of EP can be resolved by slaughter age in some herds and/or animals, depending on the epidemiology of EP in the herd, as it is influenced by the interaction of various herd-specific housing, pig flow, gilt acclimation, vaccination, and other factors. Lack of lesions at slaughter should not be considered proof of absence of EP in the herd without further careful clinical examination.

The serological response to *M. hyopneumoniae* is frequently measured for diagnostic purposes. Various ELISA assays are commercially available for detection of *M. hyopneumoniae*-specific IgG in serum samples. Assays differ based on type (i.e. direct, indirect, or blocking) and by type of antigen used (i.e. whole cell or individual proteins). The overall accuracy of various commercial ELISA assays has been investigated, and significant differences have not been documented (Erlandson et al. 2005; Pieters et al. 2017). However occasionally the number of false-positive results in known negative populations exceeds that expected based on published test accuracy. Data from Petersen et al. (2016) supports the hypothesis that infections with other nonpathogenic mycoplasmas, like *Mycoplasma flocculare*, could be the cause of unexpected false-positive rates. Western blot analysis has been proposed as means to sort out apparently false-positive findings (Ameri et al. 2006), but results obtained using this method have not been consistent.

There are several considerations when interpreting *M. hyopneumoniae* serological data in EP investigations. Antibodies to *M. hyopneumoniae* are detectable in pigs generally after 3–8 weeks post exposure, and seroconversion does not typically occur in all infected animals. Moreover, antibodies are not detectable during the entire duration of infection (Pieters et al. 2009). Maternally derived antibodies, antibodies generated after infection, and antibodies generated after vaccination are indistinguishable. For these reasons, serology is a useful diagnostic method mainly in populations and when vaccination status is known.

Treatment, control, and eradication

Treatment

Tetracyclines and macrolides are frequently used to treat and control *M. hyopneumoniae* infections in pigs. Other potentially effective antimicrobials include lincosamides, pleuromutilins, fluoroquinolones, florfenicol, aminoglycosides, and aminocyclitols (Hannan et al. 1997a; Inamoto et al. 1994; Ter Laak et al. 1991). Since *M. hyopneumoniae* lacks a cell wall, it is insensitive to antibiotics that interfere with the polymerization of cell wall precursors, such as beta-lactam antibiotics (e.g. penicillin, cephalosporin), and to polymyxin, oleandomycin, erythromycin, rifampicin, streptomycin, neomycin, trimethoprim, and sulfonamides. Sulfonamides have little influence on *M. hyopneumoniae*, although they are widely used for control of secondary bacterial infections associated with EP.

Acquired antimicrobial resistance of *M. hyopneumoniae* has been documented but is not currently pervasive enough to constitute a major problem for treatment. Inconsistent results have been reported in susceptibility testing of tetracyclines (Etheridge et al. 1979; Williams 1978). Inamoto et al. (1994) reported acquired antimicrobial resistance to tetracyclines (chlortetracycline and oxytetracycline) occurring in *M. hyopneumoniae* field strains isolated in Japan between 1970 and 1990. However, high MIC values for chlortetracycline should be interpreted with care because of the instability of the molecule in the culture medium (Pommier 2006). Studies have also reported acquired antimicrobial resistance of field strains to macrolides (tylosin, tilmicosin), lincosamides (lincomycin), and fluoroquinolones (enrofloxacin, flumequine) (Le Carrou et al. 2006; Stakenborg et al. 2005a; Tavío et al. 2014; Thongkamkoon et al. 2013; Vicca et al. 2007). Resistance against other antimicrobials has not yet been detected. The susceptibility to valnemulin and tiamulin has decreased in 1997 (Hannan et al. 1997b) to 2013 (Tavío et al. 2014; Thongkamkoon et al. 2013).

Many studies have assessed the efficacy of various antimicrobials used for the treatment and control of *M. hyopneumoniae* infections (Mateusen et al. 2002; Pallarés et al. 2015; Vicca et al. 2005). An overview of studies performed under experimental or field conditions is available (Del Pozo Sacristán 2014). For most tested antimicrobials, treated pigs had improved performance and decreased lesions and clinical signs of EP. The success of therapy under field conditions is also determined by other concurrent respiratory bacterial pathogens. Antimicrobial medication of weaned pigs (Pallarés et al. 2015; Vicca et al. 2005) and sows (Thacker et al. 2006) reduced the number of *M. hyopneumoniae* organisms in the respiratory tract.

Diseased pigs and pen mates should be treated immediately with antibiotics active against *M. hyopneumoniae*. Pigs with severe clinical signs should receive medication by injection, followed by oral medication. The use of anti-inflammatory drugs can be helpful in severely affected pigs. Although treatment may lead to

clinical improvement, clinical signs of EP and shedding of *M. hyopneumoniae* typically reappear after cessation of therapy.

Control

Improvement of management practices is essential to the control of *M. hyopneumoniae* infections. Environmental and management factors impacting control of respiratory disease in pigs, including EP, have been reviewed by Maes et al. (2008). Management practices that reduce spread of *M. hyopneumoniae* or decrease lung damage by other pathogens lead to considerable improvement. These include all-in/all-out production, proper gilt acclimation, stabilization of herd immunity, optimal stocking densities, prevention of other respiratory diseases, and optimal housing and climatic conditions. Use of early weaning strategies where pigs are weaned at 7–10 days of age and removed to an isolated site significantly reduces but does not always completely eliminate vertical transmission from sows (Dritz et al. 1996).

Gilt acclimation prior to introduction into breeding herds is critical to control of EP. The goal is the introduction of immune gilts that are not shedding *M. hyopneumoniae*. This is challenging since vaccination does not prevent infection or shedding of *M. hyopneumoniae*. Pieters and Fano (2016) proposed a method of gilt development and acclimation using strategic exposure of gilts to *M. hyopneumoniae* at an early age, with the aim that gilts will clinically recover, develop immunity, and cease shedding prior to entry to the sow farm. Early exposure of gilts at approximately 50 days of age is key to success as *M. hyopneumoniae* persistence is extremely long.

Strategic and pulse medication with antibiotics in chronically infected herds has also been used to control EP. For strategic medication, antibiotic is administered at treatment levels for 1–2 weeks, commencing some days prior to the predicted onset of EP. Pulse medication implies that antibiotic is provided intermittently during critical production stages of the pigs to prevent EP. It has been beneficial, but the results were less effective than other control measures (Le Grand and Kobisch 1996). Strategic and pulse medication strategies are discouraged due to the increased risk of development of antimicrobial resistance and the risk for antimicrobial residues in the pig carcasses at slaughter.

Vaccination is widely applied worldwide to control *M. hyopneumoniae* infections. Commercial vaccines mostly consist of inactivated, adjuvanted whole cell preparations that are administered intramuscularly. Vaccination improves daily weight gain (2–8%), feed conversion ratio (2–5%), and sometimes mortality rate. Additionally, shorter time to reach slaughter weight, reduced clinical signs and lung lesions, and lower treatment costs are observed (Maes et al. 1998, 1999). The financial benefit of vaccination depends on herd factors and also market conditions (Maes et al. 2003). Although protection against clinical pneumonia is often incomplete and vaccination does not prevent colonization, currently used vaccines reduce the number of organisms in the respiratory tract (Meyns et al. 2006; Vranckx et al. 2012; Woolley et al. 2014) and decrease the prevalence of infection in a herd (Sibila et al. 2007b). However, vaccination does not significantly reduce the transmission of *M. hyopneumoniae* (Meyns et al. 2006; Pieters et al. 2010; Villarreal et al. 2011).

The exact mechanisms of protection from vaccination are not fully understood. Studies suggest that systemic CMI is important for protection (Marchioro et al. 2013; Thacker et al. 2000b). Results indicate a considerable variation among individual pigs. Both endogenous CMI and maternally derived CMI contribute to the generation of primary and secondary *M. hyopneumoniae*-specific CMI responses. Bandrick et al. (2014) showed that neonatal piglet vaccination against *M. hyopneumoniae* produces CMI responses that are not hindered by the presence of maternally derived *M. hyopneumoniae*-specific CMI.

The importance of local mucosal antibodies remains unclear. Djordjevic et al. (1997) and Thacker et al. (1998) found that antibody concentrations in respiratory tract washings did not correlate with protection, whereas opposite results were obtained by Thacker et al. (2000b) and Sarradell et al. (2003). Commercial vaccines also induce serum *M. hyopneumoniae*-specific antibodies. The percentage of animals seroconverting after vaccination ranges from 30 to 100% and serological responses differ among vaccines (Thacker et al. 1998). Antibody titers following vaccination may, in the absence of natural infections that boost the immune system, decrease below detection limits 1–3 months after vaccination (Maes et al. 1999). It is generally accepted that levels of serum antibodies do not predict protective immunity, since no direct correlation could be demonstrated between serum antibody concentration and protection against *M. hyopneumoniae* challenge (Djordjevic et al. 1997; Thacker et al. 1998).

Different vaccination strategies have been adopted, depending on type of herd, production system and management practices, infection pattern, and preferences of the pig producer. Since colonization with *M. hyopneumoniae* may already occur during the first weeks of life (Sibila et al. 2007a,b; Vicca et al. 2002; Villarreal et al. 2010), vaccination of piglets is most commonly used. The efficacy has been demonstrated in numerous studies under experimental as well as field conditions (Jensen et al. 2002). Vaccination of suckling piglets (early vaccination; <4 weeks of age) is more common in single-site herds, whereas vaccination of nursery/early fattening pigs (late vaccination; between 4 and 10 weeks) is more often practiced in two- or three-site systems where late

infections are more common. Originally, double vaccination was the most frequent practice. Currently, one-dose vaccination with products licensed for single-dose application is more frequently used, mainly because it requires less labor and it can be implemented more easily in routine management practices on the farm (Baccaro et al. 2006). Single vaccination at either 7 or 21 days of age was equally efficacious in a pig herd with clinical respiratory disease during the second half of the fattening period (Del Pozo Sacristán et al. 2014). Arsenakis et al. (2016) showed vaccinating piglets 3 days prior to weaning conferred slightly better results than vaccination at weaning.

Vaccination of sows at the end of gestation is less commonly practiced. It aims to both reduce transmission of *M. hyopneumoniae* from sow to offspring and potentially protect the piglets against infection via maternally derived immunity. Ruiz et al. (2003) and Sibila et al. (2008) showed that vaccination of sows 5 and 3, and 6 and 3 weeks before farrowing, respectively, resulted in a lower number of positive piglets at weaning.

Vaccination of replacement gilts is recommended in endemically infected herds to avoid destabilization of the breeding stock immunity (Bargen 2004). This is particularly important when gilts are purchased from herds that are free from *M. hyopneumoniae* or from herds with a low infection level.

Although vaccination confers beneficial effects in most infected herds, the effects are variable between them. This may be due, among other factors, to improper vaccine storage conditions and administration, vaccination compliance, infection level, diversity of *M. hyopneumoniae* strains, and coinfections. The influence of maternally derived antibodies on vaccine responses in piglets is not fully elucidated. Martelli et al. (2006) showed that maternally derived antibodies have little or no effect on vaccine-induced priming or on subsequent anamnestic response.

Preliminary studies have shown that genetic selection for disease resistance in pigs may be helpful in the control of *M. hyopneumoniae* infections (Borjigin et al. 2016a), although positive effects are not consistent (Borjigin et al. 2016b).

Eradication

The ultimate means to control *M. hyopneumoniae* infection is elimination. Originally pioneered in small herds in Europe in the 1980s, a program using partial depopulation consisting of a 2-week period during which no animals younger than 10 months were allowed on the farm has been successful in Switzerland, Denmark, Sweden, and Finland (Baekbo et al. 1996; Heinonen et al. 1999, 2011; Rautiainen et al. 2001; Zimmerman et al. 1989). Since then, *M. hyopneumoniae* elimination programs have evolved and have been adapted to current swine production systems around the globe. Besides depopulation and repopulation, which can be successfully applied for *M. hyopneumoniae*, given that a source of negative replacement gilts is secured, partial depopulation (Swiss method), herd closure and medication, and herd medication without herd closure are practiced nowadays (Holst et al. 2015). Herd closure and medication seem to provide high success rate in North America. Holst et al. (2015) have described protocol details and compared different medication options. Reservations on elimination decisions are mostly based on the perceived risk for reinfection. Nevertheless, diagnostic data from *M. hyopneumoniae*-negative flows raised in pig-dense areas have instilled trust in the likelihood for success and overtime perseverance of the elimination efforts (Yeske, personal communication).

Mycoplasma hyorhinis

Although *M. hyorhinis* is considered a commensal bacterium in swine, it is well established as a cause of polyserositis and polyarthritis primarily in nursery-age pigs. It has also infrequently been incriminated in pneumonia, otitis, conjunctivitis, and abortion.

Etiology

Initially described by Switzer (1955), *M. hyorhinis* is a bacterium that grows well in enriched media and exhibits its morphological features less than 1 week after culture in agar (Kobisch and Friis 1996). It has the ability for uptake and metabolism of a wider range of carbohydrates than other porcine mycoplasmas (Ferrarini et al. 2016). This may explain its ability to invade tissues beyond the respiratory tract in pigs, potentially infect other mammals, and thrive as a common contaminant of cell cultures.

The complex system of membrane lipoproteins of *M. hyorhinis* was described by Rosengarten and Wise (1990) and is the basis of remarkable membrane lipoprotein diversity. A combination of multiple coding sequences and mutations results in variable protein expression and size, thought to be important for pathogenesis and immune evasion (Citti et al. 2000; Rosengarten and Wise 1990, 1991; Yogev et al. 1995).

Various methods have been employed to demonstrate variability among *M. hyorhinis* strains. Typing methods based on multilocus sequence and multiple-locus variable number tandem repeat analysis (MLVA) have been recently developed (Dos Santos et al. 2015a; Tocqueville et al. 2014). To date, complete sequencing of various *M. hyorhinis* strains, obtained from several host tissues and cell culture, has been completed and is in the public domain (Calcutt et al. 2012; Dabrazhynetskaya et al. 2014; Goodison et al. 2013).

Public health

The ubiquity of *M. hyorhinis* is supported by common findings of contamination of a wide variety of cell cultures derived from multiple mammalian species (Robinson and Wichelhausen 1956). *M. hyorhinis* is one of the most important bacterial considerations when evaluating cell culture purity, yet contamination of animal and human biologics has been reported. Huang et al. (2001) found a high association between the presence of *M. hyorhinis* and a variety of human carcinomas, but causality of *M. hyorhinis* in human disease is not established.

Epidemiology

Data on the prevalence of *M. hyorhinis* in swine at the country level is generally not available. However, it is considered to have worldwide distribution and be prevalent even in herds where *M. hyopneumoniae* has been eradicated (Luehrs et al. 2017). In recent years, *M. hyorhinis* has been recognized as an emerging pathogen in the United States and other countries. Whether there is a true increase in disease prevalence or the perceived increase is the result of improved diagnostic assays is uncertain. There is poor understanding of the epidemiology of *M. hyorhinis* due to its relatively recent recognition as an economically significant swine pathogen.

The main expressions of disease caused by *M. hyorhinis* are polyserositis and polyarthritis in recently weaned pigs up to 8–10 weeks of age (Gois et al. 1977). Older pigs affected with *M. hyorhinis* typically exhibit mild arthritis (Potgieter and Ross 1972); thus age susceptibility is suspected (Gois and Kuksa 1974). Acute arthritis has been observed up to 2 months after experimental inoculation with *M. hyorhinis*, and the bacterium can persist in joints up to 8 months after inoculation (Barden and Decker 1971).

Eustachitis and otitis (Kazama et al. 1994; Morita et al. 1995, 1998, 1999), abortions (Shin et al. 2003), and pneumonia (Lin et al. 2006) have also been suggested to be the result of *M. hyorhinis* infections. The capability of *M. hyorhinis* to cause pneumonia is controversial. Colonization can induce subtle microscopic lesions in the respiratory epithelium (Lee et al. 2016). However, detection in the lungs of healthy pigs is common, and Luehrs et al. (2017) found no correlation between detection of *M. hyorhinis* in the lungs and coughing or pneumonic lesions.

M. hyorhinis is considered a commensal, colonizing the tonsils and respiratory epithelium of the nasal cavity and conducting airways (Friis and Feenstra 1994; Gois and Kuksa 1974). A majority of colonized pigs have no apparent clinical disease. Like most other *Mycoplasma* species affecting swine, *M. hyorhinis* is thought to be transmitted in nasal secretions by direct contact among pen mates and in the farrowing house from colonized dams to piglets (Friis and Feenstra 1994; Kobisch and Friis 1996). The speed of transmission among pigs has not been investigated. Ross and Spear (1973) isolated the organism from nasal secretions of 10% of sows and 30–40% of weanling pigs. Clavijo et al. (2017) detected *M. hyorhinis* in nasal swabs by PCR in slightly more than 10% of suckling pigs. The level of bacterial colonization increases rapidly in piglets after weaning, and almost 100% detection at the group level has been reported at the end of the nursery period (Clavijo et al. 2017; Roos and Pieters 2017). These high levels of colonization with *M. hyorhinis* appear to remain through the finishing phases. Anderson et al. (2016c) showed that the bacterium can be detected in herds even after undergoing elimination efforts including herd closure and antibiotic treatment.

Molecular characterization of *M. hyorhinis* has been performed with MLST (Tocqueville et al. 2014) and MLVA typing (Dos Santos et al. 2015a). However, applied epidemiological investigations at the molecular level are lacking for *M. hyorhinis*.

Pathogenesis

M. hyorhinis binds to the ciliated respiratory epithelium of the nasal cavities and conducting airways via a family of variable lipoproteins that are embedded in the bacterial cell membrane (Xiong et al. 2016a, b). Inoculation of pigs with *M. hyorhinis* resulted in colonization of the respiratory epithelium, damaged cilia, reduced epithelial thickness, and increased numbers of goblet cells; however, gross and microscopic lesions of pneumonia were not produced (Lee et al. 2016). Systemic invasion from sites of mucosal colonization and development of systemic disease are well documented, but the mechanism of invasion is unknown. Friis and Feenstra (1994) suggest that damage to the respiratory tract by other pathogens favors systemic spread. In experimental models in pigs of *M. hyorhinis*-induced polyserositis and/or arthritis, the incubation period is 3–10 days post inoculation (Kobisch and Friis 1996). The surface lipoproteins of *M. hyorhinis* have been suggested as the main cause of inflammatory reactions as they stimulate cytokine production by macrophages (Muhlradt et al. 1998).

M. hyorhinis is more common in lungs of pigs with PRDC than those without PRDC, suggesting a possible role in pathogenesis (Kawashima et al. 1996; Kobayashi et al. 1996b). Co-inoculation with *M. hyorhinis* and PRRSV or PCV2 resulted in more severe lesions of PRRSV-like or PCV2-like interstitial pneumonia, respectively, but did not result in enhanced *M. hyorhinis*

systemic disease (Chen et al. 2016; Lee et al. 2016). At least under the conditions of these studies, *M. hyorhinis* augmented lesions of PRRSV- or PCV2-induced interstitial pneumonia, but neither virus enhanced *M. hyorhinis* invasion, spread, and production of polyserositis and/or arthritis.

Immunity

A humoral immune response is elicited following *M. hyorhinis* infection. Circulating *M. hyorhinis*-specific antibodies are primarily IgG (Gois et al. 1972; Ross et al. 1973) and can be detected 2 weeks post inoculation by latex agglutination (Gois et al. 1972) or ELISA (Gomes Neto et al. 2014) tests. Antibodies peak at 12 weeks and decrease to non-detectable by approximately 26 weeks post infection (Ross et al. 1973). Antibodies can also be detected in synovial fluids in higher concentrations than serum for up to 1-year post inoculation (Ross et al. 1973).

Clinical signs

Pigs 3–10 weeks of age are typically affected with *M. hyorhinis*-induced polyserositis and/or arthritis, although they may not exhibit clinical signs (Friis and Feenstra 1994). A portion of affected animals may exhibit lethargy, fever, and anorexia. Respiratory distress characterized by labored breathing and dyspnea can be observed in pigs with pleuritis. Swelling of one or more joints and lameness are frequently observed in pigs with arthritis (Barden and Decker 1971).

Lesions

Macroscopically, fibrinous serositis involving the pleura, pericardium, and/or peritoneum is most commonly observed in *M. hyorhinis* infections (Gois et al. 1977). Microscopic lesions include infiltration of lymphocytes, plasma cells, and macrophages in serosal connective tissues and variable amounts of fibrin containing neutrophils on serosal surfaces (Roberts et al. 1963). In joints affected with *M. hyorhinis*, synovial membranes are edematous with fibrinosuppurative exudate adherent to synoviocytes (Ennis et al. 1971) and expansion of the synovial stroma by infiltrates of lymphocytes, plasma cells and macrophages, and fewer neutrophils (Duncan and Ross 1969; Ennis et al. 1971). Synovial fluid contains fibrin, neutrophils, erythrocytes, and platelets (Duncan and Ross 1969). Protein titers in the synovial fluid are higher than those in serum and seem to be the result of local immunoglobulin production (Barden and Decker 1971; Barthel et al. 1972), even if the microorganism cannot be isolated from joints (Barden and Decker 1971; Ennis et al. 1971).

Diagnosis

Fibrinous polyserositis and/or arthritis in nursery-age pigs can also be caused by *H. parasuis* (Chapter 54), *S. suis* (Chapter 61), *Actinobacillus suis* (Chapter 48), or *M. hyosynoviae* (arthritis only; see below). Confirmation of *M. hyorhinis* as a cause of polyserositis and/or arthritis requires demonstration of characteristic lesions, confirmation of infection in the systemic site of the observed lesions, and elimination of other potentially causal agents by negative tests. Because *M. hyorhinis* is a commensal in the tonsil, nasal cavity, and lung, confirmation of infection in any of these sites does not confirm it as cause of disease in systemic sites (Friis and Feenstra 1994; Gomes Neto et al. 2012; Rovira et al. 2010).

Confirmation of *M. hyorhinis* is typically performed by culture and/or PCR. Appropriate samples for confirmation of disease include fibrin or swabs collected from serosal surfaces or joints with lesions or fluid from the pleural, pericardial, peritoneal, or joint cavities where lesions are present. Useful samples for epidemiologic studies may also include nasal swabs, tonsillar swabs, and tracheobronchial swabs (Friis and Feenstra 1994; Gois et al. 1969; Gomes Neto et al. 2012; Makhanon et al. 2012).

Bacterial isolation can be performed using enriched media such as the one described by Hayflick and Chanock (1965), although *M. hyorhinis* can be cultured in media used to grow *M. hyopneumoniae* (Friis 1975), in which case *M. hyorhinis* will overgrow other *Mycoplasma* species. Initial culture in broth or agar needs to be further confirmed with PCR or bacterial sequencing. Frequently, several passages and single-colony cloning are needed before an isolate can be obtained.

DNA hybridization (Taylor et al. 1984, 1985) and conventional, multiplex, and real-time PCR assays have been developed for detection of *M. hyorhinis* nucleic acid (Caron et al. 2000; Clavijo et al. 2014; Gomes Neto et al. 2015; Kang et al. 2012; Lin et al. 2006; Stakenborg et al. 2006a; Stemke et al. 1994; Timenetsky et al. 2006). The overall accuracy of PCR-based tests is high.

M. hyorhinis detection can also be achieved by immunofluorescence assays, although test accuracy may be low (Binder et al. 1989; Jansson 1974; Potgieter and Ross 1972). ISH assays have been developed for *M. hyorhinis* detection in fixed tissue, but are not routinely used for diagnostic testing (Boye et al. 2001; Kim et al. 2010; Resende et al. 2017).

Serology is not generally used for diagnosis. Efforts have been made to adapt at least a small proportion of the various research-based ELISAs for manufacturing (Binder et al. 1989; Duncan and Ross 1973; Friis and Feenstra 1994; Gois et al. 1972; Gomes Neto et al. 2014;

Kawashima et al. 1996), but commercial serologic tests are generally unavailable. Serologic response would not likely differentiate localized commensal infection from systemic disease-inducing infection.

Prevention and control

Due to the high prevalence of infection and lack of understanding of epidemiology and strain virulence, measures to eliminate or control herd infection are generally not considered. Efforts are primarily focused on mitigation of clinical disease through antibiotic therapy and, sometimes, vaccination to reduce or prevent disease.

Due to the lack of a cell wall, *M. hyorhinis* is naturally resistant to β-lactams. *M. hyorhinis* is generally susceptible to macrolides, lincomycin, and tetracyclines (Aarestrup et al. 1998; Ogata et al. 1971; Williams 1978; Wu et al. 2000). Decreased susceptibility or resistance to certain antimicrobial drugs has been suggested (Kobayashi et al. 1996a, 2005).

Commercial vaccines for *M. hyorhinis* are unavailable. Autogenous vaccines for *M. hyorhinis* have gained popularity among certain production systems, but efficacy evaluations of such products have not been performed or are not in the public domain.

Published reports of successful elimination of *M. hyorhinis* from swine herds are not available. Methods used in Switzerland to eliminate *M. hyopneumoniae* from the national swine herd did not eliminate *M. hyorhinis*.

Mycoplasma hyosynoviae

M. hyosynoviae, also belonging to the class *Mollicutes*, infects only swine. It is a commensal of the tonsils, nasal cavity, and conducting airways and occasionally invades systemically to produce acute arthritis in growing- and finishing-age swine.

Etiology

Originally described by Ross and Karmon in 1970, *M. hyosynoviae* was characterized from cultures obtained from swine joints, nose, and tonsils. Comparable with other *Mycoplasma* species, *M. hyosynoviae* requires enriched media for growth. A medium containing PPLO broth, mucin, and turkey serum has been employed to increase growth and potentiate virulence of *M. hyosynoviae*. Overgrowth with other swine *Mycoplasma* species, like *M. hyorhinis*, is a common problem in culture. In solid media *M. hyosynoviae* exhibits the typical *Mycoplasma* "fried egg" colony morphology within 3–4 days of incubation (Ross and Karmon 1970).

Epidemiology

Information is lacking on the prevalence of *M. hyosynoviae* around the globe, but it is thought to occur worldwide. Infections due to *M. hyosynoviae* have been documented in the United States, England, Denmark, Australia, Japan, Thailand, and Canada, among others. Clinical and diagnostic investigations from many other countries also confirm arthritis typical of *M. hyosynoviae*. An increase in detection of *M. hyosynoviae* in submissions to diagnostic laboratories in the United States in recent years (Gomes Neto et al. 2012) is presumably due to improved diagnostic capabilities and not increased prevalence.

Like other respiratory mycoplasmas, *M. hyopneumoniae* and *M. hyorhinis*, *M. hyosynoviae* is shed in nasal secretions and transmitted by close contact or presumably short distances by aerosol. The bacterium seems to be introduced to herds by persistently colonized replacement gilts (Ross and Spear 1973). Transmission among pen mates is thought to occur, although information on the speed of transmission and risk factors for colonization and/or infection have not been clearly identified. It has been proposed that bacterial shedding occurs during the acute (Ross and Spear 1973) and the chronic phase of infection (Hagedorn-Olsen et al. 1999).

Transmission from infected dam to piglet during the lactation period occurs but does not seem to be as frequent as for *M. hyopneumoniae* or *M. hyorhinis*. Early reports suggested that transmission did not take place in piglets younger than 4–8 weeks of age (Ross and Spear 1973). Subsequent studies confirmed tonsillar colonization of younger suckling pigs (Hagedorn-Olsen et al. 1999; Schwartz et al. 2014). In general, prevalence of colonization is low at weaning and typically peaks sometime between 10 and 16 weeks of age (Roos et al. 2016; Ross and Spear 1973; Schwartz et al. 2014). Lameness and lesions of arthritis are produced in only a portion of colonized pigs.

Pathogenesis

The conditions that trigger systemic spread of *M. hyosynoviae* from its commensal habitat on the respiratory mucosa and in tonsils are unknown as are risk factors for disease development. An inoculation study in 6- and 13-week-old naïve pigs resulted in similar prevalence and severity of clinical lameness and arthritis, suggesting that naïve pigs younger than those typically observed with disease in the field are susceptible (Lauritsen et al. 2008). Infection and disease have been characterized in naïve pigs in multiple studies utilizing intravenous or intranasal inoculation or by direct contact with *M. hyosynoviae*-infected seeder pigs (Gomes Neto et al. 2016; Hagedorn-Olsen et al. 1999). Detection of *M. hyosynoviae*

in the blood has been as early as 2 days post inoculation. Incubation period to lameness and arthritic lesions has been consistently determined to be 4–10 days post inoculation/exposure, with 30–75% of inoculated/exposed pigs developing disease. *M. hyosynoviae* can be detected in blood for only a few days post inoculation, from joints typically up to 21 days, and from tonsils for longer in both diseased and non-diseased pigs.

Virulence factors are unknown for *M. hyosynoviae* as are mechanisms of tissue damage. Strains are thought to differ in virulence (Gomes Neto et al. 2016), but convincing documentation is lacking.

Immunity

The immune response against *M. hyosynoviae* is not well characterized. A recent study by Lauritsen et al. (2017) suggests that maternally transferred antibodies are detectable in piglets and confer partial protection. Gomes Neto et al. (2014) followed a cohort of experimentally infected pigs, and at least until the last day of sampling (66 days post inoculation), only one of four inoculated animals had seroconverted to *M. hyosynoviae*.

Clinical signs

The main clinical sign associated with *M. hyosynoviae* infection is acute lameness affecting one or more joints in pigs 3–5 months of age. Involvement of stifle and/or hock joints can result in a dog-sitting posture. Lameness may last for only a few days or for an extended time. It typically decreases with time until there is full recovery unless complicated by conditions like osteochondrosis that can aggravate and extend lameness. As a consequence of pain, pigs can exhibit lack of appetite or reluctance to move, which ends up in weight loss and poor body condition. Thus, infections with *M. hyosynoviae* can be a significant welfare issue in the swine industry and contribute to the general culling and mortality observed in finishing pigs (Kobisch and Friis 1996; Nielsen et al. 2001).

Lesions

M. hyosynoviae causes lesions in one or more joints, while no joint-specific tropism has been demonstrated (Gomes Neto et al. 2016). In acute infections, the synovial stroma is expanded by serofibrinous effusion and sparse aggregates of lymphocytes and plasma cells, resulting in grossly moist swollen synovial membranes. Fibrin and few neutrophils may be adherent to synoviocytes and, along with blood, may create turbidity and variable color from yellow to red to brown in joint fluid (Hagedorn-Olsen et al. 1999; Nielsen et al. 2001). As lesions become subacute to chronic, the fibrin and neutrophilic infiltrates resolve, large numbers of lymphocytes and plasma cells expand the synovial stroma, and there is proliferation of synoviocytes, resulting in grossly proliferative synovial villi. The turbidity and coloration of the synovial fluid may remain or resolve with a more normal synovial fluid observed.

Diagnosis

M. hyosynoviae should be suspected in cases of acute lameness in finishing pigs over 10 weeks of age, along with other causes of lameness including *M. hyorhinis*, *E. rhusiopathiae* (Chapter 53), *H. parasuis* (Chapter 54), and *S. suis* (Chapter 61). Noninfectious causes such as osteochondritis dessicans and nutritional deficiencies/excesses as well as genetics, trauma, management practices, and facilities design, among others, should be evaluated as part of an exhaustive investigation (Chapter 19). Diagnosis requires demonstration of characteristic lesions and confirmation of *M. hyosynoviae* infection in affected joints. Acutely lame non-medicated pigs should be selected for sampling, and joints on affected legs should be examined and sampled. Joint fluid and/or synovial membranes should be collected for confirmation of infection, and synovial membranes should be fixed for histopathologic examination (Gomes Neto et al. 2012).

Gross and microscopic lesions in synovial membranes are sufficiently specific to strongly suggest *M. hyosynoviae*, but not pathognomonic, and must be accompanied by confirmation of infection. Confirmation by culture is only practiced in selected diagnostic laboratories, due to the intrinsic lack of sensitivity, and has been rapidly replaced by detection with highly accurate PCR-based tests (Gomes Neto et al. 2015; Makhanon et al. 2012). DNA identification in tissue can also be performed via ISH (Boye et al. 2001), but is not used as a routine diagnostic test. ELISA-based antibody tests have been developed (Nielsen et al. 2005), but are not commercially available for evaluation of the humoral immune response.

Prevention and control

Preventative measures for *M. hyosynoviae* infection are not routinely employed. Vaccines for *M. hyosynoviae* are not commercially available. Autogenous vaccines are applied in the field, although public data evaluating the efficacy of such products is generally lacking.

Antimicrobial treatments are the most common strategy for disease control. A large number of studies have shown the *in vitro* and field efficacy of macrolides, quinolones, and to a lesser extent tetracyclines (Burch and Goodwin 1984; Cooper et al. 1993; Friis et al. 1992; Hannan et al. 1989, 1997a,b; Kobayashi et al. 1996b; Schultz et al. 2012). Occasionally, reduced susceptibility

to antibiotics has been reported. Treatment early in the course of infection is crucial for effectiveness.

Mycoplasma (Eperythrozoon) suis

M. suis, formerly *E. suis*, is classified as a member of the family *Mollicutes* based on the physical characteristic of the organism and the 16S ribosomal RNA (rRNA) gene sequences (Neimark et al. 2002; Peters et al. 2008). It is a hemotrophic mycoplasma and causes infectious anemia in pigs.

Etiology

Hemotrophic mycoplasmas were previously classified in the genera *Eperythrozoon* and *Haemobartonella*. Based on 16S rRNA gene phylogenetic analysis, they were reclassified to the genus *Mycoplasma*, family *Mycoplasmataceae*, order *Mycoplasmatales*, and class *Mollicutes* (Messick et al. 2002; Neimark et al. 2001, 2002; Rikihisa et al. 1997). Hemotrophic mycoplasmas are clustered in the "pneumoniae" group (Neimark et al. 2001; Peters et al. 2008; Rikihisa et al. 1997); however, their tropism for RBCs and only moderate sequence similarity (77–83%) to any other *Mycoplasma* spp. (Uilenberg et al. 2004) have made their taxonomic classification uncertain.

M. suis is round to oval and 0.2–2 µm in diameter, and it adheres to the surface of erythrocyte membranes (Liebich and Heinritzi 1992). It may also invade erythrocytes, residing in membrane-bound vacuoles or free in the cytoplasm (Groebel et al. 2009), or adhere to endothelial cells (Sokoli et al. 2013). The organism cannot be cultured in cell-free media to date.

Epidemiology

Infections with *M. suis* have been reported worldwide. The use of PCR and serology based on recombinant antigens has improved knowledge of the distribution and prevalence of *M. suis* infections. Using PCR, the prevalence in feeder pigs (20–30 kg) in Germany was 14%, with 40% of the farms having positive animals (Ritzmann et al. 2009). In Brazil 18% of sows and 40% of piglets (9–30 days of age) were positive (Guimaraes et al. 2007). Song et al. (2014) used serology to assess the prevalence and risk factors in 69 pig farms from different provinces in China. Overall, 96% of the farms tested positive. The prevalence was higher in breeding animals (44–48%) than in suckling (13%), weaned (11%), and growing–finishing pigs (25%). The prevalence was significantly higher in summer and autumn than in other seasons. Antimicrobial treatment (odds ratio of 0.24) and frequency of disinfection (odds ratio of 0.23) were associated with a lower prevalence. The presence of mosquitoes and flies (odds ratio of 5.99) was associated with a higher prevalence. Using PCR, the prevalence in wild boar in Germany was 10% (Hoelzle et al. 2010), and the prevalence in pigs raised under extensive conditions in Brazil was 76% (Toledo et al. 2016).

The natural transmission routes of *M. suis* are largely unknown. Experimental transmission via intraperitoneal, oral, subcutaneous, and intravenous inoculation of infected blood has been described (Hoelzle 2008). Therefore, it is likely that an iatrogenic blood transfer due to contaminated instruments or small skin lesions due to fighting play an important role. Other described potential transmission routes include transplacental transmission (Henderson et al. 1997), blood-contaminated semen, and transmission by bloodsucking arthropods (Neimark et al. 2001; Prullage et al. 1993). Dietz et al. (2014) found shedding in saliva, in nasal and vaginal secretions, and in urine upon experimental infection. They suggested that blood-independent transmission as well as indirect transmission via environmental contamination could also play a role in the epidemiology of *M. suis* infections.

Pathogenesis

The pathogenesis of *M. suis*-induced disease is complex, and the organism has a repertoire of mechanisms to induce clinical signs and establish persistent infections (Hoelzle et al. 2014). Adhesion of *M. suis* to RBCs results in mechanical and/or osmotic damage that triggers extravascular hemolysis in the spleen, liver, lungs, and bone marrow, resulting in anemia (Groebel et al. 2009; Guimaraes et al. 2011). At least two proteins of *M. suis*, MSG1 and α-enolase, are involved in adhesion, and both also serve as enzymes in carbohydrate metabolism (Oehlerking et al. 2011; Schreiner et al. 2012a,b).

M. suis may also invade RBCs using an endocytosis-like invasion mechanism. Membrane-adhered *M. suis* induces through unknown mechanisms invagination and pinching-off of the RBC membrane, resulting in *M. suis* in intracellular vacuoles (Groebel et al. 2009; Guimaraes et al. 2011). The life span of parasitized RBCs is reduced through several mechanisms. *M. suis* scavenging of glucose and amino acids (Guimaraes et al. 2011) in RBCs likely leads to reduced energy production and oxidative stress. *M. suis*-induced damage of the RBC membrane (Zachary and Basgall 1985) is thought to induce eryptosis, the process of programmed cell death of RBCs (Lang et al. 2006; Felder et al. 2011). Eryptosis results in conformational and biochemical changes in the RBC membrane, leading to subsequent recognition and phagocytosis by macrophages (Felder et al. 2011; Lang et al. 2006). The occurrence and frequency of eryptosis depends on the virulence of the *M. suis* strain, whether pigs are splenectomized, and the phase of infection.

Autoimmune mechanisms also contribute to the development of *M. suis*-induced anemia. Both cold (IgM) and warm (IgG) reactive autoimmune antibodies targeting RBC antigens lead to extravascular and intravascular hemolysis. Cold autoreactive antibodies (so-called cold agglutinins) are found mainly during the chronic phase of the disease (Felder et al. 2010), and warm autoreactive IgG occurs mainly during the acute phase at the time of peak *M. suis* bacteremia (Felder et al. 2010; Hoelzle et al. 2006).

M. suis is also able to attach to endothelial cells (Sokoli et al. 2013), either singly or as biofilm-like microcolonies. This may contribute to persistence of infection by preventing phagocytosis by macrophages in major organs operative in extravascular hemolysis. *M. suis*-induced endothelial damage may also compound clinical anemia by causing coagulopathy, vascular thrombosis, and hemorrhagic diathesis (Sokoli et al. 2013).

Clinical signs

The incubation period and clinical signs after experimental infection with a virulent and RBC invasive strain depend on whether pigs are splenectomized. Splenectomized pigs develop severe anemia and massive hypoglycemia 5–8 days post infection, and most pigs need to be euthanized. By contrast, non-splenectomized pigs develop mild anemia, massive skin alterations with petechiae, and hemorrhagic diathesis between days 6 and 21 and seroconvert within 35 days post infection (Stadler et al. 2014). When using less virulent strains, infection in non-splenectomized pigs leads to none or marginal clinical symptoms or alterations in blood parameters (Heinritzi et al. 1990a,b).

The incubation period in naturally infected animals is highly variable with some infected pigs never exhibiting clinical disease. Infected animals can remain normal for months prior to exhibiting clinical disease, which is often related to stress, or individual susceptibility. *M. suis* infection under field conditions can cause acute hemolytic disease and death in young pigs, prepartum sows, and stressed weaned and feeder pigs. Pallor, fever, occasional icterus, and cyanosis of the extremities, especially the ears, are observed during the acute phases of the disease. More commonly, mild anemia, increased mortality, and poor growth rates are observed in suckling, weaned, and feeder pigs. Infection of sows may result in fever, anorexia, lethargy, dysgalactia, and poor maternal behavior (Strait et al. 2012). Clinical disease in sows typically occurs within 3–4 days of introduction to the farrowing room or immediately after farrowing. Chronic infections in animals with low or undetectable numbers of parasites result in unthriftiness, pallor, and occasionally skin hypersensitivity characterized by urticaria. In sows, chronic *M. suis* infection has been associated with decreased reproductive efficiency, although Zinn et al. (1983) found no appreciable impact on sow reproductive performance.

In all cases, simultaneous infections with other pathogens, poor management such as overcrowding, poor environmental conditions, and the presence of parasites may contribute to the severity of disease associated with *M. suis* infection.

Diagnosis

Diagnosis is based on clinical signs, hematology results, and the demonstration of the organism. PCR assays are available, are more sensitive for detection of *M. suis* than blood smears (Hoelzle et al. 2007b), and are effective in detection of *M. suis* in pigs that are carriers or subclinically infected (Hoelzle et al. 2003; Messick et al. 1999). A sensitive and specific real-time PCR assay is currently the best assay for detecting the organism. Other more recently developed tests include a specific and highly sensitive multiplex microbead immunoassay (Guimaraes et al. 2014) and a colloidal gold-based immunochromatographic assay for rapid detection (<10 minutes) of *M. suis* in porcine plasma (Meng et al. 2014).

Detection of serum antibodies is also possible. Mostly, ELISAs based on recombinant antigens such as rMSG1, rHspA1, or rPPA are used (Hoelzle et al. 2007a; Liu et al. 2012). The production of antibodies occurs in waves, with each reinfection or recrudescent episode resulting in the production of new antibodies. However, the antibody titers may persist only 2–3 months, resulting in frequent false-negative results (Heinritzi 1999).

Treatment and prevention

Treatment

The treatment of choice for infection is oxytetracycline at a dose of 20–30 mg/kg administered parenterally (Heinritzi 1999). Acutely diseased pigs require parenteral treatment due to lack of adequate feed consumption. Administration of oxytetracycline at times of stress or treatment in infected herds may help to prevent acute disease. However, treatment does not necessarily eliminate the organism from the pig, as *M. suis* may reside intracellularly in RBCs. Chlortetracycline fed to the entire sow herd at 22 mg/kg/d for 2 weeks resulted in a near-complete disappearance of dysgalactia in sows farrowing within 5 weeks after the start of treatment (Strait et al. 2012).

Supportive therapy and iron injections (200 mg iron dextran/pig) will help recovery and minimize mortality. Feeding affected sows multiple times a day to maintain blood glucose can help prevent acute death and dysgalactia.

Strategies for elimination of *M. suis* from infected herds are not available.

Prevention

Stopping the spread of the organism and preventing reinfection are critical to controlling the herd infection status. Transmission by needles and surgical instruments must be minimized by changing needles between sows and litters. No vaccine is currently available, and vaccine development is complicated by the lack of ability to culture *M. suis* and knowledge of the virulence factors. An attempt to produce a vaccine from a recombinant protein produced in *E. coli*, while inducing a humoral and cellular immune response, failed to protect against challenge (Hoelzle et al. 2009). If a herd is *M. suis*-free, new additions should also be from herds negative for the organism.

Other *mycoplasma* spp. in swine

Other mycoplasmas in swine are generally nonpathogenic and without consequence. They include species typically found in other animals and acholeplasmas that are common in a wide variety of animals and plants.

M. flocculare (Friis 1972) is nonpathogenic but of importance because of its similarity to *M. hyopneumoniae* (Petersen et al. 2016). It is widely distributed in swine where it is a commensal in the nasal cavities and lungs. Similarity of *M. flocculare* and *M. hyopneumoniae* in culture, antigenically and genetically, has made their differentiation difficult until recently. They share approximately 78% of coding DNA sequences and greater than 90% of predicted surface proteins (Siqueira et al. 2013). In recent years PCRs have been developed that can differentiate the two species (Blank and Stemke 2001; Stakenborg et al. 2006a; Strait et al. 2008a).

Little information is available on infection of the genitourinary tract with mycoplasmas in swine. Shin et al. (2003) demonstrated a cytopathic species of *M. hyorhinis* that was thought to be a cause of abortions in sows. Other species of mycoplasmas that have been isolated from swine include *M. sualvi*, *M. hyopharyngis*, *M. arginini*, *M. bovigenitalium*, *M. buccale*, *M. gallinarum*, *M. iners*, *M. mycoides*, and *M. salivarium*. In addition to mycoplasmas, acholeplasmas have occasionally been isolated from the respiratory tract of swine. Acholeplasmas differ from mycoplasmas by having a larger genome and are capable of growing in media that lacks sterols. No importance in their presence in pigs has been demonstrated.

Pasteurellosis

Karen B. Register and Susan L. Brockmeier

Relevance

The importance of *Pasteurella multocida* as a respiratory disease agent in pigs has been recognized for more than 130 years, yet this bacterium continues to significantly impact swine health worldwide as a cause of progressive atrophic rhinitis (PAR) and pneumonia.

Atrophic rhinitis in pigs, characterized by stunted development or total disappearance of the nasal turbinates, was first reported in 1830 in Germany (Franque 1830). Following debate for more than a century regarding the precise etiology of the disease, it is now known that a severe and often irreversible form, referred to as progressive atrophic rhinitis, is caused by toxigenic strains of *P. multocida* either alone or in combination with *Bordetella bronchiseptica* (de Jong and Nielsen 1990). PAR may negatively affect growth rate and the efficiency of feed conversion (Pedersen and Barfod 1981; Riising et al. 2002), and moderate to severe outbreaks may have a substantial economic impact (Muirhead 1979; Pedersen and Nielsen 1983). *B. bronchiseptica* alone may also cause rhinitis and turbinate atrophy in young pigs accompanied by minor effects on growth, but this reversible condition, known as nonprogressive atrophic rhinitis (NPAR), is distinct from PAR (see Chapter 49).

Pneumonic pasteurellosis is a purulent bronchopneumonia that results from opportunistic *P. multocida* infection of the lung following primary infections by predisposing bacterial and viral pathogens. *P. multocida* is among the most common and costly components of porcine respiratory disease complex (PRDC). In the United States pneumonia is the leading cause of death in nursery, grower/finisher, and wean-to-finish pigs (USDA 2015). Reduced weight gain and the cost of treating sick animals add further to the economic impact. *P. multocida* is among the bacterial agents most frequently isolated from pneumonic lungs with a particularly high prevalence in finishing pigs (Choi et al. 2003; Fablet et al. 2012; Opriessnig et al. 2011; Pors et al. 2011).

Sporadic outbreaks of fatal acute septicemia in farmed and wild pigs have also been attributed to *P. multocida* in Europe, Asia, and Australia (Cameron et al. 1996; Cardoso-Toset et al. 2013; Kalorey et al. 2008; Mackie et al. 1992; Risco et al. 2013; Townsend et al. 1998b; Ujvári et al. 2015).

Etiology

Pasteurella multocida includes three subspecies: *P. multocida*, *P. septica*, and *P. gallicida*. The vast majority of swine isolates appear to be *P. multocida* subsp. *multocida*, but other subspecies are occasionally reported (Blackall et al. 2000; Bowles et al. 2000; Cameron et al. 1996; Davies et al. 2003; Varga et al. 2007).

Pasteurella multocida is a nonmotile gram-negative rod or coccobacillus approximately 1.0–2.0 µm in length. Initial or low-passage isolates may exhibit a distinct bipolar staining not usually observed following serial subculture. The bacterium is a facultative anaerobe and grows well at 98.6 °F (37 °C) in most enriched media. On blood agar plates it forms grayish, nonhemolytic colonies, often mucoid, with a characteristic "sweetish" odor. It does not grow on MacConkey agar, is oxidase and catalase positive, and produces indole.

Five capsular serotypes – A, B, D, E, and F – are recognized (Carter 1955; Rimler and Rhoades 1987) with A and D comprising most swine isolates. A small proportion of isolates from the respiratory tract are noncapsulated and, therefore, untypable. Serotype A is most commonly cultured from pneumonic lungs, while most PAR isolates are serotype D, but either serotype may be isolated from either condition, and serotype F has also rarely been recovered (Bethe et al. 2009; Davies et al. 2003; Ewers et al. 2006; García et al. 2011; Peng et al.

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

2017; Varga et al. 2007). The most prevalent capsular serotype associated with acute septicemic pasteurellosis in swine is B, but types D and A have also been reported (Cameron et al. 1996; Kalorey et al. 2008; Mackie et al. 1992; Townsend et al. 1998b).

In addition to capsular serotyping, an additional somatic serotyping method was later developed to further distinguish isolates on the basis of lipopolysaccharide (LPS) antigens (Heddleston et al. 1972). There are 16 known somatic serotypes, designated 1–16. Historically, types 3, 5, and 12 predominated among swine isolates, but present-day information is sparse. The combined results of capsular and somatic serotyping have traditionally been the basis for characterization of isolates, but the difficulty of generating consistent, high-quality, and readily available antisera led to the development of PCR assays that type isolates on the basis of differences in the organization of the genes responsible for capsule and LPS synthesis (Harper et al. 2015; Townsend et al. 2001).

A classification scheme based on carbohydrate fermentation and enzyme production is also sometimes used, with most pig isolates represented by 2 of the 14 defined biovars (García et al. 2011). Alternative typing techniques based on pattern analysis of genomic DNA fragments or PCR amplicons have also been employed (Dziva et al. 2008). A significant limitation of those methods is the lack of standardization and the associated difficulty in comparing data across laboratories.

Multilocus sequence typing (MLST), based on DNA sequences obtained from short fragments of a defined set of housekeeping genes, has been used to investigate the population structure and evolution of *P. multocida* (Bisgaard et al. 2013). MLST provides definitive and objective results that are easily evaluated, compared, and archived. Because relatively few isolates from pigs have been analyzed, it is yet unclear whether the method is sufficiently discriminatory for use as an epidemiologic tool in swine.

Genome sequences for nearly 100 isolates of *P. multocida* are now available, but only a few are of swine origin, representing capsular types A, D, and F (Okay and Kurt Kızıldoğan 2015; Peng et al. 2017). Comparative analyses suggest that allelic heterogeneity and differences in gene complement are more closely tied to disease syndrome than to host specialization. Insights provided by comparative genomics with respect to disease in swine will be relatively limited until genomes from additional isolates that more fully represent the diversity of strains infecting pigs are sequenced.

Public health

Pasteurella multocida is an important zoonotic agent and is responsible for most human infections related to animal bites or scratches. Dogs and cats are the predominant source, but infection following bites from pigs, rabbits, rats, and various wild animals has been reported (Wilson and Ho 2013). Human pasteurellosis most often presents as skin or soft tissue infection, typically with rapid onset, characterized by inflammation, swelling, and purulent exudate. More serious manifestations generally limited to immunocompromised patients include septicemia, osteomyelitis, endocarditis, pneumonia, meningitis, and peritonitis.

Pasteurella multocida is not a usual constituent of the human upper respiratory tract, but strains genetically identical to those found in swine are frequently isolated from pig farmers and from inhabitants of regions with intensive pig breeding (Donnio et al. 1999; Marois et al. 2009). Water from scalding tanks is a potential source of exposure for abattoir workers (Marois et al. 2008). Most human carriers remain healthy, but *P. multocida* may also be associated with acute or chronic respiratory disease. It has been proposed that pneumonic pasteurellosis be considered an occupational disease. Appropriate precautions should be observed by immunocompromised persons who have contact with swine infected with *P. multocida*.

Epidemiology

Pasteurella multocida has been isolated throughout the world from a wide array of wild and domesticated mammals and birds, including aquatic mammals (Smith et al. 1978). It causes acute or chronic disease of importance in poultry, cattle, water buffalo, swine, sheep, and rabbits. *P. multocida* often occurs as part of the normal flora, and clinically inapparent infections that spark disease outbreaks in immunologically naïve animals are common in many hosts. It has no known environmental reservoir.

The epidemiology of *P. multocida* in swine is not well understood. In many herds the organism is detectable in the nose and tonsils of healthy animals and may persist for months or even years with little evidence of disease. Although the bacterium may occasionally be spread via aerosols, nose-to-nose contact is the common route of infection. Introduction of *P. multocida* into a herd is usually by introduction of infected swine. Spread within a herd occurs rapidly both vertically from infected dam to suckling piglets and horizontally between infected and uninfected animals (Dritz et al. 1996; Fablet et al. 2011; Zhao et al. 1993). Spread related to contaminated fomites or intermediate hosts has been suggested (Desrosiers 2011; Goodwin et al. 1990), and there is some evidence consistent with occasional interspecies transmission of avian, bovine, ovine, and porcine strains (Davies et al. 2004). Rodents, cats, dogs, and other hosts that commonly carry *P. multocida* should be considered possible sources of exposure for pigs. Whether healthy human carriers can transmit *P. multocida* to swine is unknown.

Molecular typing techniques have been used to better understand the epidemiology of *P. multocida* in pigs, but comparisons among studies are problematic because there is no widely adopted and standardized method and many studies fail to provide a quantitative measure of diversity. Among pneumonic isolates, one or a few strains often predominate in closed herds or in those with minimal introductions, although strains differ between operations (Blackall et al. 2000; Marois et al. 2009; Rúbies et al. 2002; Zhao et al. 1993). Multiple strains are more likely to be involved in herds where pig movement occurs (Bowles et al. 2000). It has been hypothesized that highly pathogenic clones preferentially cause pneumonia, but this seems doubtful since no traits associated exclusively with virulence have been identified and commensal isolates from healthy and diseased pigs possess a similarly limited degree of genetic heterogeneity (Bethe et al. 2009; Ewers et al. 2006). Only a few investigations using DNA-based typing methods have evaluated strains associated with PAR, and these reveal relatively limited genetic diversity. Results of restriction endonuclease analysis and ribotyping demonstrated that multiple PAR strains may be found within a herd and that single strains may be found in more than one herd (Bethe et al. 2009; Gardner et al. 1994; Harel et al. 1990).

Pasteurella multocida survives for approximately 1 week at 39 °F (4 °C) following growth in liquid or on solid medium but may remain viable for up to several months when stored at 59 °F (15 °C) or 98.6 °F (37 °C). It is culturable for up to 6 days in pig slurry and more than 49 days in nasal washings obtained from piglets, with maximal survival at 59 °F (15 °C) or higher (Thomson et al. 1992). Aerosolized organisms suspended in nasal washings remain viable for at least 45 minutes. The half-life of *P. multocida* in a rotating aerosol chamber at 73 °F (23 °C) and 75% relative humidity is 21 minutes (Müller et al. 1992).

Several disinfectants suitable for farm use are bactericidal for *P. multocida*, some under high organic matter conditions (Thomson et al. 2007). The bacterium is inactivated by overnight incubation at 39 °F (4 °C) in 0.5% phenol or 0.2% formalin or, when not protected by organic material, heating to 140 °F (60 °C) for 10 minutes.

Pathogenesis

Colonization

Pasteurlla multocida poorly colonizes the swine respiratory tract in the absence of preexisting damage to the mucosa (Pedersen and Elling 1984). *In vitro* studies using swine turbinate explants or epithelial cells from the nasal cavity or trachea consistently demonstrate little or no attachment (Chung et al. 1990; Frymus et al. 1986; Jacques et al. 1988; Nakai et al. 1988).

Pasteurella multocida can bind to components of porcine respiratory tract mucus (Jacques et al. 1993; Letellier et al. 1991). When mucociliary clearance is compromised, interaction of bacteria with extracellular mucus may facilitate colonization of the mucosal epithelium. Attachment of *P. multocida* to porcine tracheal rings previously infected with *B. bronchiseptica* increased by several orders of magnitude as compared with tracheal rings infected with *P. multocida* alone (Dugal et al. 1992). Enhanced binding was credited to *B. bronchiseptica*-induced mucus accumulation and ciliostasis. This phenomenon was observed with numerous *P. multocida* isolates from healthy and diseased pigs representing capsular type A and type D with or without toxin production.

LPS, a major component of the *P. multocida* outer membrane, has been implicated in attachment. LPS purified from a toxigenic type D swine isolate binds to porcine respiratory tract mucus and blocks adherence of the bacterium to porcine tracheal rings (Jacques et al. 1993). Elimination of the capsule by serial passage *in vitro* significantly increased the number of adherent organisms to trachea, suggesting that the type D capsule may interfere with binding. The authors hypothesized that during the early stages of infection, organisms express a minimal amount of capsular material, thereby exposing otherwise masked outer membrane components (LPS and perhaps others) involved in attachment. A later study showed that cells grown under iron-restricted conditions, such as those encountered *in vivo*, are covered by a thinner layer of capsular material and display increased adherence to porcine respiratory tract mucus and to frozen sections of porcine lung and trachea as compared with cells cultivated under iron-replete conditions (Jacques et al. 1994).

Homologues of the outer membrane proteins OmpA and OmpH, known or putative adhesins in other pathogens, have been identified in swine isolates of *P. multocida* (Davies et al. 2003; Lugtenberg et al. 1986; Marandi and Mittal 1996). Whether they similarly function as adhesins during colonization of the swine respiratory tract is unknown.

Many isolates of *P. multocida* have hemagglutinating activity, but there is no correlation with *in vitro* binding or *in vivo* colonization (Fortin and Jacques 1987; Pijoan and Trigo 1990; Vena et al. 1991). Likewise, fimbriae are produced by many toxigenic and nontoxigenic capsular type A and D strains but appear to play no role in adherence to cells or tissues of swine origin (Isaacson and Trigo 1995; Pijoan and Trigo 1990).

Although there is a general association of toxigenic type D strains with PAR in the upper respiratory tract and of nontoxigenic type A strains with pneumonic

pasteurellosis in the lower respiratory tract, there is little evidence that strains of different capsular types employ distinct adherence strategies (Dugal et al. 1992; Frymus et al. 1986; Letellier et al. 1991; Pijoan and Trigo 1990; Vena et al. 1991). Neither does there appear to be a relationship between toxigenicity and differential attachment. Interestingly, in a study of 158 swine isolates, Davies et al. (2003) found that most pneumonic isolates share outer membrane profiles distinct from those shared among PAR isolates, irrespective of capsular type. However, it is unknown whether any of the discriminatory outer membrane proteins has a role in attachment or colonization.

The tonsil, particularly the tonsillar crypt, appears to be the preferred habitat of *P. multocida* in swine and may protect bacteria from inflammatory cells or act as a physical barrier to removal by swallowing (Ackermann et al. 1994). Colonization of the tonsil by type A and type D strains in the absence of prior mucosal damage and persistence for up to 60 days post infection has been reported in experimentally infected piglets (Ono et al. 2003; Pijoan and Trigo 1990). The bacterial products essential for colonization of this site are unknown, but the tonsil may serve as a reservoir from which strains capable of causing PAR or pneumonia subsequently spread when innate defenses of the upper or lower respiratory tract are weakened or incapacitated.

Progressive atrophic rhinitis

The common predisposing factor in pigs naturally affected by PAR is prior infection with *B. bronchiseptica* (Pedersen and Barfod 1981). The mechanism facilitating colonization by *P. multocida* is unproven, but a tracheal cytotoxin released by *B. bronchiseptica* that causes ciliostasis and destruction of the mucosal epithelium is likely of primary importance (Dugal et al. 1992; Flak et al. 2000). Other toxins and effectors produced by *B. bronchiseptica* also probably play a role (see Chapter 49).

Elaboration by *P. multocida* of a 146 kDa protein toxin, referred to as *P. multocida* toxin (PMT), is the essential virulence factor for the pathogenesis of PAR. PMT produces progressive snout shortening and turbinate atrophy when given to pigs intranasally (Il'ina and Zasukhin 1975) and by a variety of parenteral routes (Rutter and Mackenzie 1984). It produces lesions in the turbinates, liver, and urinary tract characterized by degenerative and hyperplastic changes. The toxin interferes with normal remodeling and formation of bone in the turbinates (Dominick and Rimler 1988; Foged et al. 1987; Martineau-Doizé et al. 1990) and can decrease physeal area in the long bones of pigs (Ackermann et al. 1996), which perhaps contributes to slow growth associated with PAR. PMT may have direct access to the turbinates when toxigenic strains are growing in the nasal cavity, but the capacity to act systemically suggests that its effects may also be exerted by bacteria colonizing the tonsil or other anatomical sites.

The structure of PMT and its molecular mechanism of action have been intensively investigated (reviewed in Orth and Aktories 2012). It interferes with G-protein- and Rho-dependent signaling pathways and stimulates mitogenesis. The biologically active region has been localized to the C-terminus, while a cell-binding and/or internalization domain resides in the N-terminus. PMT is encoded by the *toxA* gene (Petersen and Foged 1989), which has a G + C content significantly different than that of the *P. multocida* genome, indicating that it may have been horizontally acquired. Further study by Pullinger et al. (2004) revealed that the gene is located within an inducible prophage. PMT lacks a typical signal sequence and is not secreted during growth *in vitro*, leading to the suggestion that, like some other bacterial toxins, phage-induced cell lysis triggered by contact with host cells or by some environmental factor encountered *in vivo* is the mechanism of export. Phage-mediated transduction could potentially lead to acquisition and expression of *toxA* by nontoxigenic strains of *P. multocida*, or even other bacteria, but whether this occurs is not known.

Several environmental, management, and husbandry factors can influence the occurrence and presentation of PAR. More severe disease is generally associated with intensive indoor production systems that have high stocking density, poor hygiene, and poor ventilation. Exposure to high levels of dust and ammonia may facilitate colonization of the upper respiratory tract by *P. multocida* and/or exacerbate disease (Andreasen et al. 2000; Hamilton et al. 1999). Continual pig throughput and frequent moving and mixing of pigs are also predisposing factors.

Pigs infected within the first few weeks of life with toxigenic *P. multocida* are the most severely affected with PAR, but mild to moderate turbinate lesions occur in those infected as late as 16 weeks of age (Rutter et al. 1984). Apparently healthy 3-month-old pigs can develop PAR when introduced into a production unit where severe disease is occurring (Nielsen et al. 1976). Age-dependent disease severity may be partly related to changes in the amount and type of mucins present in the nasal cavity and altered cellular distribution within the nasal epithelium that occur as pigs mature (Larochelle and Martineau-Doizé 1990, 1991). The impact of aerial pollutants may also be greatest in young pigs (Robertson et al. 1990).

Feed consumption may be influenced by PAR, since piglets with an acute rhinitis may accept feed less readily and become stunted and weak. Growing pigs with conchal damage may also have reduced feed intake.

Pneumonia

The virulence factors of *P. multocida* that contribute to the development of pneumonia are unknown and may differ depending on the number and identity of other agents present in the lung. Studies comparing the prevalence of potential virulence genes in swine isolates from the nasal cavity of healthy animals with those from pneumonic lungs failed to reveal a specific genotype correlated with virulence (Bethe et al. 2009; Ewers et al. 2006). There is no convincing evidence in support of a role for PMT, but some investigators have reported an unusually high percentage of toxigenic strains from the lung (Høie et al. 1991; Iwamatsu and Sawada 1988), sometimes preferentially associated with acute cases (Kielstein 1986). Nonetheless, nontoxigenic strains continue to comprise the majority of lung isolates (Bethe et al. 2009; García et al. 2011).

Coinfection with other respiratory disease agents is the most significant factor contributing to swine pneumonic pasteurellosis. Implicated agents include *Mycoplasma hyopneumoniae* (Amass et al. 1994; Ciprián et al. 1988) and pseudorabies virus (Carvalho et al. 1997; Fuentes and Pijoan 1987); a synergistic effect with a hog cholera vaccine has also been demonstrated (Pijoan and Ochoa 1978). Coinfection with *Actinobacillus pleuropneumoniae* permits colonization of the lung by *P. multocida*, perhaps by interfering with the ability of porcine alveolar macrophages to phagocytose and kill the bacterium (Chung et al. 1993), but the ensuing disease may be no more severe than that resulting from only *A. pleuropneumoniae* (Little and Harding 1980). Porcine reproductive and respiratory syndrome virus (PRRSV) alone appears not to interact with *P. multocida*, but prior infection with both PRRSV and *B. bronchiseptica* leads to colonization of the lung and induction of pneumonia by nontoxigenic *P. multocida* upon subsequent exposure (Brockmeier et al. 2001; Carvalho et al. 1997). Prior infection with only *B. bronchiseptica* results in colonization of the nasal cavity and tonsil without overt disease, and this could be a means by which healthy carrier pigs arise undetected. Long-term carriage of nontoxigenic strains in the tonsil may lead to pneumonia in the face of other predisposing factors that arise at a later time.

The capsule may contribute to virulence in swine pneumonic pasteurellosis, but its precise role is not fully understood. Swine alveolar macrophages poorly phagocytose encapsulated organisms (Chung et al. 1993; Fuentes and Pijoan 1986), and the capsule also interferes with uptake by swine neutrophils (Rimler et al. 1995). Yet, an antiphagocytic role is called into question by the demonstration that little capsular material is produced under iron-limiting growth conditions expected to mimic the environment *in vivo* (Jacques et al. 1994). The degree to which these data can be extrapolated is unclear since little is known about conditions that exist in the microenvironments to which *P. multocida* is exposed during various stages of pulmonary infection and disease. Growth conditions may vary significantly within different tissues or even within different substructures of a single tissue and further depend on the degree of host cell damage locally present.

Some strains of *P. multocida* produce pleuritis and abscessation (Pijoan and Fuentes 1987; Pors et al. 2011). The factors that distinguish these strains from less virulent pneumonic strains are not defined. However, there is some suggestion that PMT may be involved in the formation of pulmonary abscesses (Ahn et al. 2008; Iwamatsu and Sawada 1988; Kielstein 1986).

Large swine herds with high stocking density and poor air quality are associated with a higher prevalence of pneumonia (Done 1991). Excessive aerial ammonia was reported to facilitate pulmonary infection of unweaned piglets with *P. multocida* (Neumann et al. 1987). Other investigators have reported little effect of ammonia on the development of lung lesions in pigs coinfected with *M. hyopneumoniae* and *P. multocida* but noted lower slaughter weights in those exposed to higher concentrations (Andreasen et al. 2000; Diekman et al. 1993). Oral exposure to endotoxin or fumonisins has also been shown to potentiate pneumonia in pigs infected with *P. multocida*, with or without *B. bronchiseptica* (Halloy et al. 2005a,b; Pósa et al. 2011).

Septicemic pasteurellosis

On the basis of several genetic and phenotypic characteristics, capsular type B *P. multocida* isolates associated with swine septicemic pasteurellosis appear to be more closely related to isolates causing hemorrhagic septicemia in other hosts than to isolates from swine PAR or pneumonia (Cardoso-Toset et al. 2013; Townsend et al. 1998b; Ujvári et al. 2015). Hematogenous spread of type A or type D isolates may, in some instances, be an extension of pneumonic pasteurellosis (Pors et al. 2011). There is little known regarding the identity or role of virulence factors potentially contributing to systemic spread and related disease.

Clinical signs

Progressive atrophic rhinitis

Sneezing in baby pigs is often the first clinical sign of PAR but also results from infection with other pathogens that produce acute rhinitis. Pigs with PAR may continue to sneeze, snuffle, and snort throughout the growing period, and a variable amount of serous to mucopurulent nasal and ocular discharge may be observed. Tear staining that

radiates from the medial canthus of the eye as a result of nasolacrimal duct occlusion may be present in either NPAR or PAR, but epistaxis is typically observed only in PAR. Also specific to PAR is ensuing snout deformation that becomes apparent when pigs are 4–12 weeks of age. The most common visible manifestation of PAR is brachygnathia superior, in which the upper jaw is shortened in relation to the lower, giving the nose a pushed-up appearance with the skin on the dorsum typically thrown into folds (Figure 57.1). Lateral deviation of the snout may be evident when more extensive deformation of the bone occurs on one side of the head than the other (Figure 57.2). This may vary in severity from a barely perceptible misalignment to obvious twisting. The prevalence of snout distortion varies among outbreaks, and not all pigs with significant turbinate atrophy develop marked distortions. In severe outbreaks of PAR, growth retardation and a reduction in the efficiency of feed utilization may occur.

Pneumonia

Pneumonic pasteurellosis most commonly occurs in grower- and finisher-age swine where it exacerbates PRDC that is initiated by one or more primary respiratory pathogens. These polymicrobial disease processes typically cause high morbidity and variable mortality and can greatly lengthen the time to market and increase the number of culls. Clinical signs can vary depending on the pathogens involved and stage or severity of the disease but often include coughing, intermittent fever, depression, anorexia, reduced growth rate, labored breathing or thumping, and in severe cases cyanosis or blue discoloration, especially in the tips of the ears. More severe disease and clinical signs may be associated with certain strains of *P. multocida* that produce abscesses and pleuritis.

Figure 57.1 A 17-week-old pig with clinical progressive atrophic rhinitis showing marked brachygnathia superior, wrinkling of the skin on the dorsum of the nose, and tear staining.

Figure 57.2 The head of a 15-week-old pig with clinical progressive atrophic rhinitis showing severe lateral deviation of the snout. The anatomy of the skull is distinctly abnormal due to a failure of normal bone development.

Septicemic pasteurellosis

Septicemic pasteurellosis typically has a sudden onset and acute progression of disease with high morbidity and mortality. Clinical signs include high fever, severe dyspnea, cyanosis of the ventrum and ears, anorexia, weakness, and prostration. One of the most striking features is edema and hemorrhage of the ventral neck that may become necrotic (Cardoso-Toset et al. 2013; Ujvári et al. 2015). Clinical signs consistent with pneumonic pasteurellosis have also been noted in some cases.

Lesions

Progressive atrophic rhinitis

The gross lesions of PAR are restricted to the nasal cavity and adjacent structures of the skull although in advanced cases pigs may also be stunted. Atrophy of the ventral and dorsal turbinates, present in variable degrees, is the hallmark lesion. In mild to moderate cases, the ventral scrolls are by far the most consistently and extensively affected; severe cases may progress to total loss of the turbinates and deviation of the nasal septum (Figures 57.3–57.7). Mucopurulent exudate may be found in the nasal cavity, occasionally with associated

Figure 57.3 Cross section of the snout of an 18-week-old pig showing normal anatomy of the turbinates.

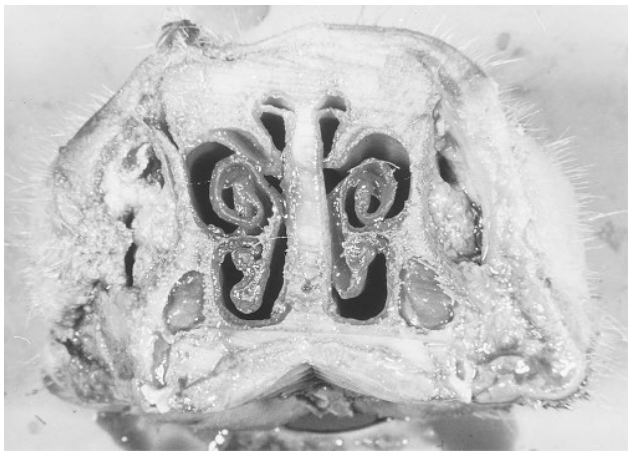

Figure 57.4 Cross section of the snout of an 18-week-old pig. Slight distortion of the ventral scrolls of the turbinates is present, a common finding.

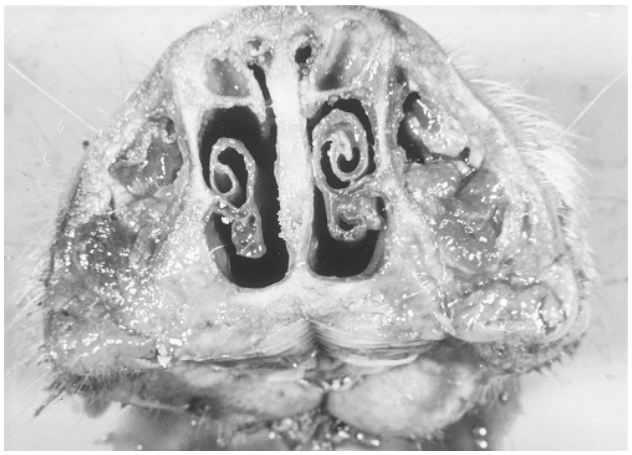

Figure 57.5 Cross section of the snout of an 18-week-old pig showing modest but definite turbinate atrophy.

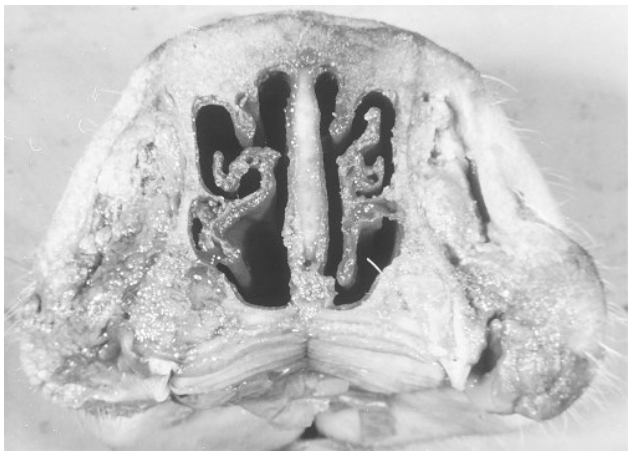

Figure 57.6 Cross section of the snout of an 18-week-old pig showing severe bilateral turbinate atrophy.

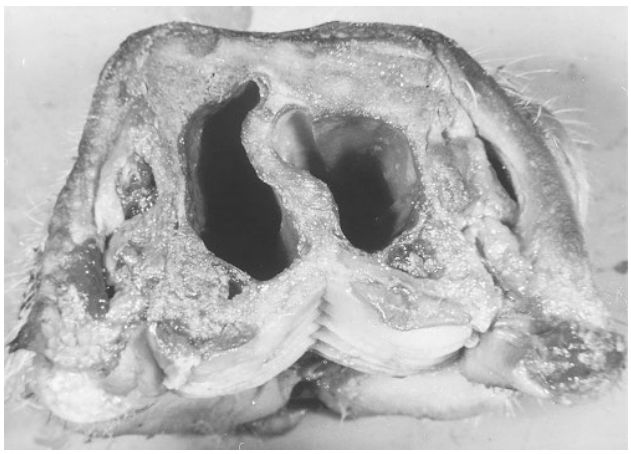

Figure 57.7 Cross section of the snout of a 22-week-old pig showing total atrophy of all turbinate structures with severe bending of the nasal septum.

hemorrhage. Many studies suggest that lesions of PAR are irreversible, but Magyar et al. (2013) have recently reported that turbinate structure may return to normal by approximately 18 weeks post infection in high health status pigs.

Depending on the stage of disease at the time of necropsy, acute, subacute, or chronic histologic changes may be observed. The principal microscopic lesion of PAR is replacement of the bony trabeculae of the nasal turbinates with fibrous connective tissue (Pedersen and Elling 1984). Increased numbers of osteoclasts are observed contributing to this process. The degree of epithelial damage or inflammation depends on the stage of disease and whether coinfection with *B. bronchiseptica* is present (Duncan et al. 1966; Elling and Pedersen 1985). Subacute cases in conventional pigs will show various mixtures of degenerative, inflammatory, dystrophic, and reparative processes.

Pneumonia

Pneumonic lesions vary since *P. multocida* is often only one component of a complex infection. Macroscopic lesions include typical red-to-gray firm consolidation with a cranial ventral well-demarcated lobular distribution and purulent exudate in lumens of conducting airways and alveoli characteristic of acute to chronic bacterial bronchopneumonia (Figure 57.8). Abscesses, pleuritis with visceral and parietal pleural adhesions, and pericarditis also occasionally occur (Figures 57.9 and 57.10). Microscopic lesions consist of suppurative bronchopneumonia characterized by neutrophil infiltration of bronchial and alveolar spaces and interstitial thickening (Pors et al. 2011). Fibrinosuppurative pleuritis and fibrous encapsulation of necrosuppurative areas will be seen in cases where pleuritis and abscesses are present. Additional lesions may be apparent depending on the other agents involved. For example, peribronchiolar lymphocyte infiltration may be seen when *Mycoplasma* is present, while interstitial pneumonia or necrotizing bronchiolitis may be features when PRRSV or swine influenza virus is a component.

Figure 57.8 Pneumonic pasteurellosis. Lung consolidation is anteroventral with a clear demarcation line between affected and healthy tissue.

Figure 57.9 Pleural adhesions of lung to the thoracic wall in a case of pleuritic pasteurellosis. Note that the pleura has a translucent, dry aspect.

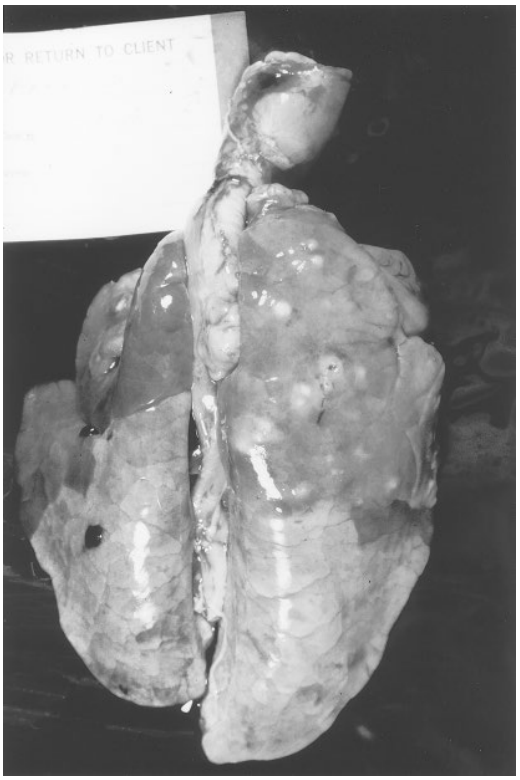

Figure 57.10 Lung from a case of pleuritic pasteurellosis. Note anteroventral well-demarcated lesions with multiple abscesses and extensive interlobar adhesion.

Septicemic pasteurellosis

Subcutaneous hemorrhagic edema is often seen in cases involving capsular type B strains (Cardoso-Toset et al. 2013; Ujvári et al. 2015). Other lesions associated with septicemic pasteurellosis include edema of the pharynx and trachea, pulmonary edema and hemorrhage with or without pulmonary consolidation, enlarged edematous and hemorrhagic lymph nodes, and congestion and

hemorrhage of the visceral organs, occasionally with fibrin deposition in the peritoneal and pleural cavities (Mackie et al. 1992). Microscopically, intravascular thrombosis and changes consistent with widespread vascular damage, such as edema, hemorrhage, and necrosis, are present in tissues, and bacteria can often be observed in the vessels and throughout affected tissues. Purulent inflammatory exudates in multiple organs and fibrinous serositis may also be present.

Diagnosis

Progressive atrophic rhinitis

A definitive diagnosis of PAR depends on clinical and pathological observations and demonstration of toxigenic *P. multocida*. A preliminary diagnosis of PAR can be made based on a pattern of typical clinical signs. Animals showing lateral deviation of the snout and/or marked brachygnathia superior almost always have pronounced turbinate atrophy, but snout deformation alone is not pathognomonic. When these signs are not apparent or are of decreasing prevalence (e.g. following treatment), it is not possible for even experienced observers to assess the extent of turbinate atrophy in the live animal. Radiography (Done 1976) and computed tomography (Magyar et al. 2003) can provide objective observations from live animals and are noninvasive but require that pigs be sedated or physically immobilized. Tomography reveals more subtle changes that may not be apparent by radiography.

The prevalence and severity of turbinate atrophy are best estimated by examination of nasal turbinates during regular slaughter checks. Snouts should be transversely sectioned at the level of the first/second upper premolar; sectioning cranial to this may give a false-positive result. Atrophy may be scored subjectively by various systems (Cowart et al. 1990). Although there may be considerable interobserver variation within a system, subjective scoring is highly useful for monitoring herd status and evaluating treatment. Objective methods better suited for data analysis are also available (Gatlin et al. 1996). Samples from the tonsils and nasal cavity should be evaluated for the presence of toxigenic *P. multocida* to ensure a proper diagnosis. When severe PAR is first detected, infection may have actually occurred weeks or months earlier, and evidence of toxigenic *P. multocida* may be difficult to obtain. In such cases it is recommended to also examine and culture less severely affected (usually younger) pigs.

Tonsil swabs or biopsies provide the highest isolation rates for *P. multocida* (Ackermann et al. 1994), but nasal swabs suffice. Live pigs should be adequately restrained, and the external nares cleaned. Swabs with flexible shafts are preferred to avoid breakage in the event of sudden movements of the animal. Mini-tipped swabs are available that facilitate sampling in young pigs. The surface of the tonsil should be swabbed, or, when sampling the nasal cavity, a single swab should be inserted with slight rotation deep into both sides of the nasal cavity. Swabs should be transported to the laboratory within 24 hours, preferably in a transport medium under cooled conditions (39–46 °F [4–8 °C]). Nutrient transport media that support the growth of fast-growing contaminants are best avoided; sterile phosphate-buffered saline is preferable.

Toxigenic and nontoxigenic strains of *P. multocida* share many cross-reacting antigens, and there are no satisfactory serological tests for identification of animals infected with only toxigenic strains. PMT-specific enzyme-linked immunosorbent assays (ELISAs) designed for use with the bacterium (Bowersock et al. 1992; Foged et al. 1988) can be adapted for use with serum, but in naturally infected pigs PMT is a weak immunogen and PMT-specific antibodies are often undetectable. Use of toxoid-containing vaccines limits the diagnostic value of this approach to herds with no history of vaccination or to detection of vaccine response in immunized herds.

Sneezing in young pigs occurs in active PAR, but also during infection with *B. bronchiseptica* or porcine cytomegalovirus, both widely prevalent. Brachygnathia superior develops naturally in certain lines of the Large White/Yorkshire breed but can generally be distinguished from PAR by the absence of turbinate atrophy. Sows and gilts kept in stalls often bite, chew, or play with bars or drinkers, and this can give rise to asymmetric bone development causing protrusion of the lower jaw or mandibular misalignment. These conditions can be confused with the facial deformity of PAR, especially in the older pig, but careful inspection should reveal that the lower jaw is abnormally placed rather than that the snout is shortened or laterally deviated. The presence of mild turbinate atrophy in a herd may represent either NPAR or developing PAR. Definitive diagnosis requires culture.

Pneumonia

Lung lesions caused by *P. multocida* are not pathognomonic and cannot be used as the only criteria to establish a definite diagnosis. The history of the outbreak, histopathology, and isolation of the organism should be used to confirm the original presumptive diagnosis.

Optimal specimens include swabs of tracheobronchial exudate and affected lung tissue obtained from the border area between affected and normal tissue. Swabs should be immersed in an appropriate transport medium, such as Stuart's. Lung samples should be obtained as

aseptically as possible. All samples should be refrigerated (but not frozen) until cultured. There is no serologic test routinely available to assist in the diagnosis of *P. multocida* lung infection.

Differential diagnosis should include other causes of purulent bronchopneumonia or pleuropneumonia such as *B. bronchiseptica*, *M. hyopneumoniae*, *Streptococcus suis*, *Haemophilus parasuis*, *Trueperella pyogenes*, *Salmonella choleraesuis*, *Actinobacillus suis*, and *A. pleuropneumoniae*. Accurate clinical differentiation is often difficult, requiring bacterial culture, histopathology, and other testing as needed for a definitive diagnosis.

Septicemic pasteurellosis

Diagnosis depends on detection of *P. multocida* in blood and affected tissues, the presence of multifocal thrombosis and necrosis, and the absence of other agents causing sudden death.

Identification and characterization of *p. Multocida*

Culture and phenotypic methods

Pasteurella multocida grows readily on blood agar, but nonselective media are appropriate only when specimens are obtained aseptically from a normally sterile site, for example, the lung. For most specimens a selective medium is preferred to prevent masking of colonies by overgrowth of other bacteria often present in higher numbers. Various formulations have been used, but comparison of studies in the literature indicates that the highest isolation rates are obtained with modified Knight medium (Lariviere et al. 1993) or blood agar plates containing certain antimicrobials (Ackermann et al. 1994). A selective medium for simultaneous isolation of both *P. multocida* and *B. bronchiseptica* from swine has also been described (de Jong and Borst 1985). Once isolated, conventional biochemical tests can be used to identify suspect colonies, although reliability varies among methods and PCR (see below) may be superior (García et al. 2011; Townsend et al. 1998a).

Capsular typing of *P. multocida* is useful for epidemiologic purposes. Serotyping by indirect hemagglutination has traditionally been used (Carter 1955), but the hyaluronidase test (Carter and Rundell 1975) and acriflavine test (Carter and Subronto 1973) are simpler methods for the detection of type A and D strains, respectively.

Classification of *P. multocida* as PMT positive or negative is critical for a diagnosis of PAR and may also be informative in other disease manifestations. Tests based on dermonecrotic or lethal effects of PMT toxin in rodents were initially used, but toxigenicity can be more easily and humanely demonstrated *in vitro* by assessing cytopathic effects in embryonic bovine lung cells or Vero cells (Chanter et al. 1986; Pennings and Storm 1984). ELISAs based on the use of PMT-specific monoclonal antibodies have now generally replaced biological assays and are more rapid, sensitive, and specific (Bowersock et al. 1992; Foged et al. 1988).

DNA-based methods

Several species-specific PCRs for detection of *P. multocida* have been developed, but relatively few have been evaluated for use with swine isolates (Dziva et al. 2008). On the basis of published reports, the PCR of Townsend et al. (1998a), which targets the predicted esterase/lipase gene *kmt1*, appears to be most widely used and offers both high specificity and sensitivity. The *kmt1* gene has also been successfully used as a target for loop-mediated isothermal amplification (Sun et al. 2010). This easy-to-perform method has the potential to be used as a screening assay in the field since a thermal cycler is not required and the amplification products can be visualized directly without the need for electrophoresis.

A multiplex capsular PCR (Townsend et al. 2001) has largely replaced serological capsular typing methods. It has a high correlation with serological results, with the exception of antigenically related types A and F for which PCR typing was shown to be more accurate. Because there is often a reduction or complete loss of capsular material when *P. multocida* is passaged on media, fewer isolates may be untypable by PCR than by serology (Arumugam et al. 2011). However, false-positive PCR results may arise from strains that fail to synthesize a capsule due to point mutations or other minor changes in the DNA sequences targeted by the primers.

A number of PCRs perform well for detection of toxigenic swine isolates (Kamp et al. 1996; Lichtensteiger et al. 1996; Nagai et al. 1994). A multiplex PCR for simultaneous identification of *B. bronchiseptica* and both toxigenic and nontoxigenic *P. multocida* is also useful for investigating the etiology of atrophic rhinitis or pneumonia (Register and DeJong 2006).

Immunity

Progressive atrophic rhinitis

PMT is the major protective antigen in PAR, and immunization with PMT toxoid alone alleviates the associated lesions (Foged et al. 1989). Antibody appears to be important in immune defense as evidenced by passive transfer experiments (Chanter and Rutter 1990) and protection of piglets via antibody passively acquired from vaccinated sows (Foged et al. 1989). It is important to provide maternal colostral protection of piglets since exposure most often occurs during the first few weeks of life. Bacterins made from toxigenic strains of

P. multocida elicit antibacterial antibodies but vary in efficacy since they often fail to induce adequate toxin-specific antibodies (Chanter and Rutter 1990). Therefore, vaccines with added toxoid are superior to bacterins alone. Because PMT is difficult to purify and attenuate in large quantities, methods of producing recombinant detoxified PMT have been developed that rely on either truncation (Nielsen et al. 1991) or genetic modification via amino acid substitution at two key sites for detoxification (To et al. 2005). Vaccines for PAR often contain both *B. bronchiseptica* and *P. multocida* to protect against the combined effects of these pathogens. Vaccination does not provide sterilizing immunity but will reduce the pathogen load and significantly diminish or abolish clinical disease and lesions associated with PAR (Riising et al. 2002). A live attenuated strain of *Salmonella typhimurium* engineered to express antigens from PMT and other putative virulence factors of *P. multocida* and *B. bronchiseptica* has recently been developed as a potential vaccine for pneumonic pasteurellosis and PAR (Hur et al. 2014). A protective immune response was achieved in mice following intranasal administration, but the vaccine has yet to be evaluated in pigs.

Pneumonia

Identification of immunogens or immune responses important for protection against pneumonic pasteurellosis in swine has been elusive. Studies comparing parenteral and aerosol delivery of vaccines indicate that a respiratory mucosal immune response is important for clearance of the organism and protection from pulmonary lesions (Müller et al. 2000). Much of the research devoted to vaccines for pneumonic pasteurellosis has been performed in hosts other than swine. The absence of a reliable pulmonary disease model in pigs makes vaccine efficacy difficult to assess. Maternally derived immunity is probably not as important as an adaptive immune response for protection against pneumonia caused by *P. multocida* since this is typically a disease of older swine. Overall, the effectiveness of vaccines in controlling pneumonic pasteurellosis in swine is questionable.

Prevention and control

Progressive atrophic rhinitis

Effective treatment of PAR requires a selected combination of management, environmental, chemotherapeutic, and vaccination procedures. No single approach is equally applicable to all affected herds. The overall aims of treatment are threefold. The first aim is to reduce the prevalence and load of *P. multocida* in young pigs, with or without *B. bronchiseptica*, by sow vaccination, medication of feed, and antibiotic treatment of piglets. The second aim is to treat growing pigs suffering from acute rhinitis in order to reduce the burden of infection and severity of the hypoplastic changes as well as to maintain efficient growth and feed utilization. The final aim is to manipulate housing, ventilation, and management to improve the overall environment.

To reduce vertical transmission from infected dams to suckling offspring, the sow's feed can be medicated during the final month of gestation. Sulfonamides and tetracyclines are most widely used. Increasing resistance to some sulfonamides has been reported for both *B. bronchiseptica* and *P. multocida*, as has an increase in resistance of *P. multocida* to oxytetracycline (El Garch et al. 2016; Furian et al. 2016). Thus, determining the antibiotic susceptibility profile for isolates from a particular herd is prudent. Suckling piglets are best medicated by strategic injections of antibacterial agents in therapeutic dosages through the first 3–4 weeks of life. Drugs used commonly for treatment of *P. multocida* are ampicillin, ceftiofur, enrofloxacin, and tulathromycin. However, because of resistance, ampicillin and ceftiofur should not be the first choice if *B. bronchiseptica* is a factor in PAR. PAR in weaned pigs that leads to marked turbinate atrophy at slaughter can be controlled to some extent by medication of rations or drinking water with tetracyclines, tilmicosin, and trimethoprim/sulfa. Such medication also assists in the maintenance of growth and feed efficiency in the face of active PAR. Medication is most effective when environment and management are improved and vaccination is employed.

Sow vaccination induces a significant degree of passive colostral protection against PAR (Riising et al. 2002). Vaccines often contain a combination of *B. bronchiseptica* and *P. multocida* bacterins. PMT is an important component of vaccines for PAR, and those with added PMT toxoid offer superior protection (Foged et al. 1989; Hsuan et al. 2009; Nielsen et al. 1991; To et al. 2005). Two doses given to sows, the first at 4–8 weeks prior to initial farrowing and the second at 2–4 weeks prior, followed by revaccination 2 weeks before each subsequent farrowing, is an effective means for controlling disease. Vaccination of nonimmune piglets from unvaccinated dams at 1 and 4 weeks of age can be of value; however, passive antibody from the sow can interfere with parenteral vaccination of the piglet. Vaccination of older pigs undoubtedly produces an active humoral response, but its value is debatable since the main effects of the infection occur in younger animals.

Medication and vaccination should never be introduced without concurrent attempts to improve management and husbandry. All-in/all-out systems are favored for farrowing, weaner, and preferably fattener units. Stocking density should be reduced, strict hygiene measures should be implemented, and

ventilation rates should be maintained to reduce airborne bacteria, noxious gases, and dust. The age of the sow herd can be allowed to rise to avoid the introduction of large numbers of infected gilts. Steps should also be taken to reduce stress in young pigs, including minimization of temperature variations, chilling, and drafts. Infection can be eradicated by depopulation and restocking, and clean herds may be maintained free from PAR by isolation, herd monitoring, and the use of clean breeding stock.

Pneumonia

Treatment of pulmonary *P. multocida* infections with antibiotics is challenging because of the difficulty of achieving therapeutic concentrations in consolidated pneumonic lungs. Parenteral antibiotics are preferable including ampicillin, ceftiofur, enrofloxacin, and tulathromycin. In-feed antibiotics, such as chlortetracycline and tilmicosin, are best used on a preventative basis.

Under field conditions the effectiveness of vaccination against pneumonia with *P. multocida* is dubious. Since pneumonic pasteurellosis is often the final stage of enzootic pneumonia or PRDC, which are polymicrobial infections, control of the primary pathogens such as *M. hyopneumoniae*, *B. bronchiseptica*, or PRRSV through vaccination, medication, or management practices may be the most efficient method of controlling the disease. Management changes that reduce the spread of the pathogens involved may have value in decreasing the incidence of pneumonia. These include segregated early weaning, all-in/all-out production, limiting the introduction of outside pigs and determining the health status of the farm from which they are purchased, minimizing mixing and sorting, reducing the size of buildings and pens in which pigs are housed, and reducing animal density.

Proliferative Enteropathy

Fabio A. Vannucci, Connie J. Gebhart, and Steven McOrist

Relevance

Proliferative enteropathy (PE), also known as ileitis, is an infectious disease caused by the obligate intracellular bacterium *Lawsonia intracellularis*. It is characterized by thickening of the intestinal mucosa due to intestinal crypt epithelial cell proliferation (McOrist et al. 1995a). Lesions are most often in the ileum but may also be in the jejunum and colon. Crypt epithelial cell proliferation is directly associated with intracytoplasmic *L. intracellularis* infection and replication. Mild to severe diarrhea and weight loss are the major clinical signs observed in clinically affected animals. Subclinical infection (i.e. lacking diarrhea) is common in which infected pigs have less extensive lesions that are associated with a commensurate retardation in growth rates (Jacobson et al. 2003).

Two major clinicopathologic forms of PE have been recognized, acute and chronic (Rowland and Lawson 1975). Proliferative hemorrhagic enteropathy (PHE) is an acute form of disease that may be associated with bloody diarrhea and high mortality, and that is characterized by mucosal proliferation and hemorrhage. Porcine intestinal adenomatosis (PIA) is uncomplicated chronic PE characterized by marked corrugated thickening of the mucosa. Chronic PE that is complicated by opportunistic bacteria resulting in fibrinonecrotic exudate adherent to thickened corrugated mucosa is known as necrotic enteritis (NE).

PE is a common and an important enteric disease worldwide. Globally, it is estimated that 96% of farm sites are infected, with approximately 30% of weaner-to-finisher pigs having lesions of variable severity and duration (McOrist et al. 2003; Stege et al. 2000). Biester and Schwarte (1931) first described lesions of PE in pigs. By studying field outbreaks of PE, Rowland and Lawson (1974) found that intracellular bacteria were consistently observed within the abnormal proliferating mucosal epithelial cells by silver staining or ultrastructural methods. The identity of these bacteria and their etiologic role in PE were resolved in 1993 with successful co-culture of the intracellular organism in a rat enteric cell line and subsequent reproduction of the disease by inoculation of pigs with a pure culture of the organism (Lawson et al. 1993; McOrist et al. 1993). Its taxonomic position was clarified by phenotypic and genetic characterization (Gebhart et al. 1993), a new genus and species were established, and the organism was named *Lawsonia intracellularis* (McOrist et al. 1995a).

Economic losses due to PE have been estimated from its negative impacts on slaughter weight, feed conversion efficiency, space utilization, breeding problems and morbidity–mortality effects, totaling from US $1 to $5 per affected growing pig (McOrist 2005; McOrist et al. 1997b; Veenhuizen et al. 2002). The impact is likely higher since estimates are based on clinical cases and do not include subclinical cases.

Etiology

Lawsonia intracellularis is the sole species in the bacterial genus *Lawsonia* (McOrist et al. 1995a) and the only cause of PE. It is an obligate intracellular bacterium that grows *in vivo* in the cytoplasm of intestinal epithelial cells and *in vitro* in cultures of intestinal and fibroblast-derived cell lines (Guedes and Gebhart 2003a; Lawson et al. 1993). It has not been cultivated in cell-free media probably due to unique metabolic requirements that are not well understood (Schmitz-Esser et al. 2008).

Lawsonia intracellularis is an obligately intracellular, gram-negative, non-spore-forming, microaerophilic, curved or vibroid-shaped rod (Figure 58.1). It is 1.25–1.75 µm in length and 0.25–0.43 µm in width and has a trilaminar outer envelope (McOrist et al. 1995a). It has a unipolar flagellum and exhibits darting motility *in vitro* upon escape from infected enterocytes (Lawson and Gebhart 2000). *In vivo* it locates in the apical cytoplasm of intestinal epithelial cells and is commonly associated

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

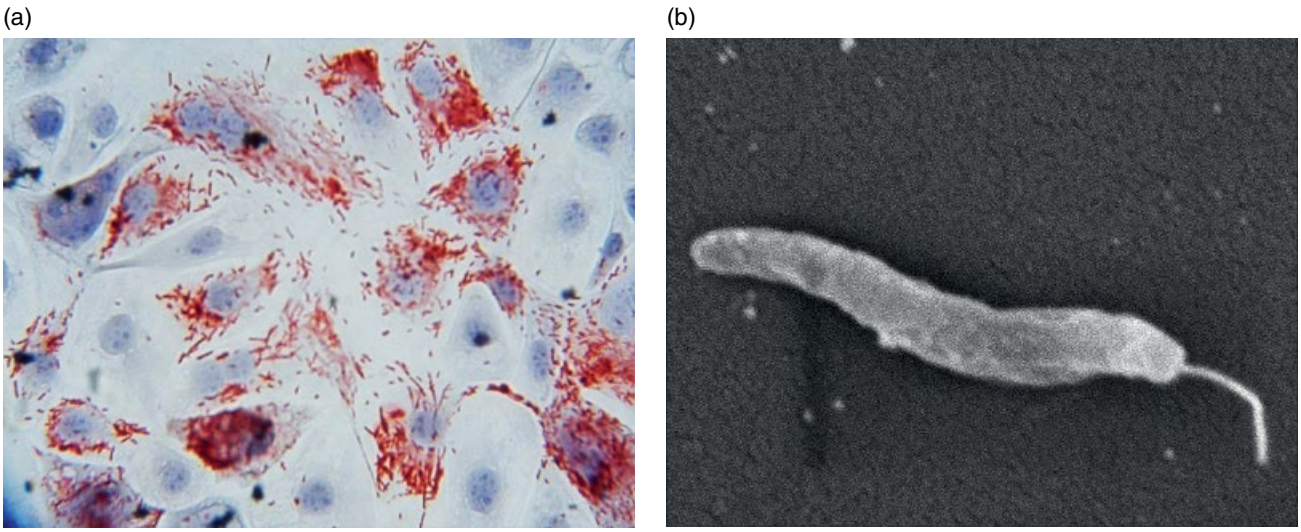

Figure 58.1 *Lawsonia intracellularis*. (a) Immunocytochemistry. Co-culture of intestinal porcine enterocyte cells (IPEC-J2) in adherent monolayer and intracytoplasmic *L. intracellularis*. (b) Scanning electron microscopy. Vibroid-shaped rod morphology and unipolar flagellum of *L. intracellularis*.

with free ribosomes and mitochondria (Johnson and Jacoby 1978).

Lawsonia intracellularis is classified as a member of the family *Desulfovibrionaceae* in the delta subdivision of *Proteobacteria* (Gebhart et al. 1993). Based on the DNA sequence of the 16S ribosomal gene, it is most closely related to *Bilophila wadsworthia*, a free-living anaerobic human pathogen (Sapico et al. 1994), and to *Desulfovibrio desulfuricans*, a sulfate-reducing bacterium (Gebhart et al. 1993). Evolutionary analysis suggests that *L. intracellularis* has gained cell-dependent respiration and lost its sulfate reduction capacity (Schmitz-Esser et al. 2008). The bacterium has a small chromosome and three plasmids, totaling 1.72 million bp and 1324 protein encoding regions. It possesses low G + C% content and significant presence of heat shock proteins that are common in other symbiont intracellular bacteria (Dale et al. 1998).

Since the first reports of cultivation and maintenance of *L. intracellularis in vitro* (Lawson et al. 1993), various cell lines have been shown to support growth, including insect and avian cells (Guedes et al. 2002a; McOrist et al. 1995b). Regardless of the cell lineage, the bacteria require dividing cells in a specific microaerophilic atmosphere for cultivation (Lawson et al. 1993; Vannucci et al. 2012c). Culture attempts have regularly been more successful from PHE cases than from chronic PE cases, likely due to the lower numbers of contaminating enteric organisms present in the affected ilea. Cultivation of *L. intracellularis* has been conventionally achieved in a static adherent monolayer in a humidified tri-gas incubator with 83.2% nitrogen, 8.8% carbon dioxide, and 8% oxygen at 37 °C (Lawson et al. 1993; McOrist et al. 1995b). Suspension cultures have also been used for large-scale cultivation for vaccine production (Kroll et al. 2004).

Clinical disease and lesions typical of PE have been reproduced reliably in pigs given oral inocula consisting of pure cultures of *L. intracellularis* derived at low passages (4–20 times) in cell culture (Guedes and Gebhart 2003b; McOrist et al. 1993, 1996b; Vannucci et al. 2013a), but not when given cultures passed 40 times *in vitro* (Vannucci et al. 2013a). It is therefore suggested that attenuation of virulence factors within *L. intracellularis* occurs between passages 20 and 40, probably due to gene deletions or mutation. However standard DNA-based typing techniques such as pulsed-field gel electrophoresis (PFGE), multilocus sequence typing (MLST), and variable number tandem repeat (VNTR) have shown identical genotypes in homologous isolates at low and high passages, so the exact type of gene modification in high-passage isolates is not known.

Public health

There is no evidence of *L. intracellularis* infection in humans. A surveillance study in children living on European pig farms failed to find *L. intracellularis* DNA in their fecal samples (Jacobson et al. 2007). Investigations of Crohn's disease and other mucosal inflammatory conditions of humans have consistently failed to find typical PE lesions or *L. intracellularis* (Crohn and Turner 1952; Michalski et al. 2006).

Epidemiology

PE is endemic in domesticated swine herds and has also been described in feral swine populations worldwide (Baroch et al. 2015; McGregor et al. 2015; Tomanova et al. 2002; Yeh 2014; Zlotowski et al. 2008). Epidemiological modeling has assessed the risk of introduction of PE from feral swine into commercial herds as being greatest in free-range production systems (Pearson et al. 2016), but transmission has not been documented.

Lawsonia intracellularis infection and proliferative intestinal lesions have been occasionally reported in other species, including hamsters (Cooper et al. 1997b), rabbits (Umemura et al. 1982), ferrets (Fox et al. 1994), guinea pigs (Elwell et al. 1981), foxes (Landsverk 1981), dogs (Collins et al. 1983), rats (Vandenberghe and Marsboom 1982), mice (Abshier et al. 2001), sheep (Cross et al. 1973), deer (Drolet et al. 1996), emus (Lemarchand et al. 1997), ostriches (Cooper et al. 1997b), turkeys (Moura-Alvarez et al. 2014), chickens (Ohta et al. 2016), and nonhuman primates (Klein et al. 1999). The presence of *L. intracellularis* in fecal samples of various wild species such as jackrabbits, skunks, opossums, raccoons, and coyotes has also been reported (Hossain et al. 2016; Pusterla et al. 2008). While PE has been only sporadically described in a wide range of species, patterns of disease similar to those observed in pigs have been widely reported in laboratory hamsters and have increasingly been reported in young foals (Pusterla et al. 2009).

The role of other animal species as potential sources of *L. intracellularis* for infection and disease in swine is unclear. Very high degrees (>99%) of similarity among isolates from different animal species have been demonstrated based on 16S ribosomal DNA sequences (Cooper et al. 1997a). However, there is some data that suggest the potential for animal species-adapted subtypes of *L. intracellularis* (Vannucci et al. 2012b). Typical proliferation of *L. intracellularis*-infected intestinal epithelial cells has been reproduced in a variety of animal species by inoculation with species-specific *L. intracellularis* isolates (Jacoby 1978; McOrist et al. 1993; Pusterla et al. 2010). However the clinicopathology of disease varies between some animal species (Deprez et al. 2005; Duhamel and Wheeldon 1982; Frazer 2008; Jacoby et al. 1975; Vannucci et al. 2010). Differences in virulence have been reported when one animal species is inoculated with an *L. intracellularis* isolate from another species (Jasni et al. 1994a; Murakata et al. 2008; Vannucci et al. 2012b; Viott et al. 2013). Recently a genomic island associated with the presence of a prophage has been detected in a non-extensive sampling of porcine but not equine isolates (Vannucci et al. 2013c), confirming a potential difference in genotypes of *L. intracellularis* isolated from these animal species. Taken together, these data suggest that there may be species-adapted genotypes or subspecies of *L. intracellularis*. More work is needed to determine the extent of interspecies differences in *L. intracellularis* and the potential impact on cross-species transmission and disease.

High prevalence of *L. intracellularis* is reported in commercial swine herds mainly by serology and fecal PCR. Transmission is by the fecal–oral route from infected pigs or contaminated environs to noninfected pigs. The infectious dose is relatively low (Guedes et al. 2003; McOrist et al. 1993), and fecal excretion may be high in infected pigs (Guedes et al. 2002a; Smith and McOrist 1997). Disease manifests differently between farms, based on management systems as they impact primarily dose and immunity in exposed pigs. On farms with a continuous pig flow between different pig ages/farm areas/housing locations, infection usually occurs a few weeks after weaning, presumably when maternal antibodies fade. This dynamic can be delayed by the use of effective antimicrobials in the first weeks post weaning. In these cases, clinical disease is usually later in the growing and finishing phases. Once infection starts in a population, it amplifies through fecal–oral cycling (Stege et al. 2004). When organic bedding is used and/or there is group housing of breeding animals, infection may amplify faster.

An intermittent pattern of PE occurs in weaner and grower/finishers on farms with periodic oral antibiotic usage. On farm systems with distinct separation of groups of post weaning and breeding pigs by age and site (all-in/all-out multisite systems), *L. intracellularis* infection is usually delayed in grower/finishers until they are 14–20 weeks of age and occurs rarely in breeding stock (Bronsvoort et al. 2001; Marsteller et al. 2003). This pattern is accentuated in the United States, where weaner–nursery pigs may receive quinoxaline antimicrobials, forestalling early infections. Application of strict disinfection protocols and all-in/all-out procedures are critical to decrease the prevalence of PE (Dors et al. 2015).

It is likely that the environment of most pig farms contains a sustained level of *L. intracellularis* in the residual fecal material or organic bedding in buildings or on equipment or other fomites. *L. intracellularis* can remain viable in feces at 5–15 °C (41–59 °F) for 2 weeks (Collins et al. 2000). This may act to reintroduce the infection to new groups of pigs. The infection can build up slowly or quickly, with variations in the time of disease onset on different farms and importantly on the same farm between different groups in the same building or pens (Hammer 2004; Philips et al. 1998). Transmission of fecal matter from contaminated areas to other areas of a farm, such as those containing breeding animals, would be expected to occur more commonly on single-site farms. Modes of this transmission probably include transfer of feces on boots or other fomites as well as possible transfer via insects and rodents in contact with pig feces

(Friedman et al. 2008). A recent study experimentally demonstrated subclinical infection in pigs exposed to fecal samples from infected mice (Gabardo et al. 2016). Therefore, rodents in particular may have a critical role in introduction and maintenance of *L. intracellularis* in swine herds (Backhans et al. 2013; Collins et al. 2011). Application of rodent control strategies is an important factor in controlling PE. Studies tracking PE infection on breeding farms have indicated that infected gilts or sows do not readily transmit the infection to their progeny in the farrowing area (Guedes et al. 2002a; Jacobson et al. 2010).

Acute and chronic PE continue to be an important problem in herds with high health status. The absence of clinical PE in conventional swine herds, even over a period of years, is no guarantee of freedom from *L. intracellularis* infection. Animals from such herds may be responsible for the introduction of PE into a hitherto uncontaminated environment or naïve population, often followed by an explosive outbreak of acute hemorrhagic PE and later by endemic chronic PE. Examples where this has typically occurred include boar and gilt performance testing stations, gilts within breeding programs that involve transportation to new units, and the movement and mixing of boars and gilts into breeding groups (Friendship et al. 2005). However, these outbreaks have become noticeably less common following the wide usage of a live attenuated *Lawsonia* vaccine in breeding-age pigs prior to mixing or moving.

Pathogenesis

Experimental infections using pure cultures of porcine-origin *L. intracellularis* as oral inocula for conventional pigs or gnotobiotic pigs pre-dosed with a minimal bacterial flora of nonpathogenic enteric species have resulted in reproduction of the specific and characteristic lesions of PE (McOrist et al. 1993, 1994). Pathogenesis of PE has been studied using *in vitro* and *in vivo* experimental models. However, the typical proliferation of *L. intracellularis*-infected intestinal epithelial cells observed *in vivo* has not been reproduced in any cell type *in vitro* (Lawson et al. 1993; Vannucci et al. 2012c). Therefore, comprehensive studies on the progression of lesions of PE have been conducted in experimental infection models primarily in pigs and hamsters (Guedes and Gebhart 2003a; Jasni et al. 1994b).

Exposure of pigs to crude or partially filtered, homogenized diseased mucosa resulted in reproduction of specific intestinal lesions and clinical disease in some early disease reproduction trials (Mapother et al. 1987; McOrist and Lawson 1989; Roberts et al. 1977). The difficulties in routine culture of *L. intracellularis* have resulted in this strategy continuing as a model for reproduction of PE in conventional pigs (Boutrup et al. 2010; Guedes and Gebhart 2003b; Winkelman et al. 2002).

Naïve pigs of a wide age range (neonates to grower/finishers) are susceptible to oral challenge. In typical oral inoculation studies in naïve pigs inoculated with approximately 10^8 *L. intracellularis* bacteria/mL, infection, proliferative lesions, and fecal shedding begin at 1 week, peak at 3 weeks, and persist for approximately 4 weeks in most pigs (Figure 58.2). In some, fecal shedding may persist for 12 weeks (Guedes et al. 2002a; Smith and McOrist 1997). Lesions in the large intestines appear 1–2 weeks after those in the small intestines (Guedes and Gebhart 2003b).

Lawsonia intracellularis organisms have the ability to infect mature enterocytes as well as immature crypt epithelial cells. They are first observed in the cytoplasm of mature enterocytes on the tips of small intestinal villi 12 hours following oral inoculation but are observed as a persistent infection in the cytoplasm of the poorly differentiated crypt cells from 5 to 28 days post infection (Boutrup et al. 2010). These infected crypt epithelial cells continue to proliferate and fail to mature, resulting in the characteristic adenomatous proliferation of an immature mucosa that is the hallmark of PE. In general, no significant inflammatory response occurs while the bacteria persist within the intestinal epithelium. Loss of body protein and amino acids into the intestinal lumen and the reduced nutrient absorption by the intestinal mucosa lacking mature enterocytes are the likely causes of the reduction in weight gain and feed conversion efficiency seen in pigs and hamsters affected with chronic uncomplicated PE lesions (Gogolewski et al. 1991; Rowan and Lawrence 1982; Vannucci et al. 2010).

During the first 12 hours after infection, before the bacteria reach the enterocyte, *L. intracellularis* must survive low gastric pH. Functional analysis of the *L. intracellularis* genome revealed the genes of two systems known to play a crucial role in the maintenance of pH homeostasis, the glutamate decarboxylase (GAD) system and the F0F1-ATPase operon (Vannucci et al. 2013c). There is currently no mechanistic evidence demonstrating the activity of these acid-tolerant systems in *L. intracellularis*; however, their roles in responding to acid stress has been well described among other enteric pathogens (Bearson et al. 1997).

Survival of *L. intracellularis* in the intestinal microenvironment is influenced by the intestinal microbiota. Germ-free pigs are not susceptible to infection using pure cultures of *L. intracellularis* (McOrist et al. 1994), whereas pigs exposed to intestinal material from infected animals develop the disease (McOrist and Lawson 1989). Diet composition may also influence infection in hamsters and pigs (Boesen et al. 2004; Jacoby and Johnson 1981). Pelleted diets are associated with higher levels of *L. intracellularis* in ileal microbiota compared with

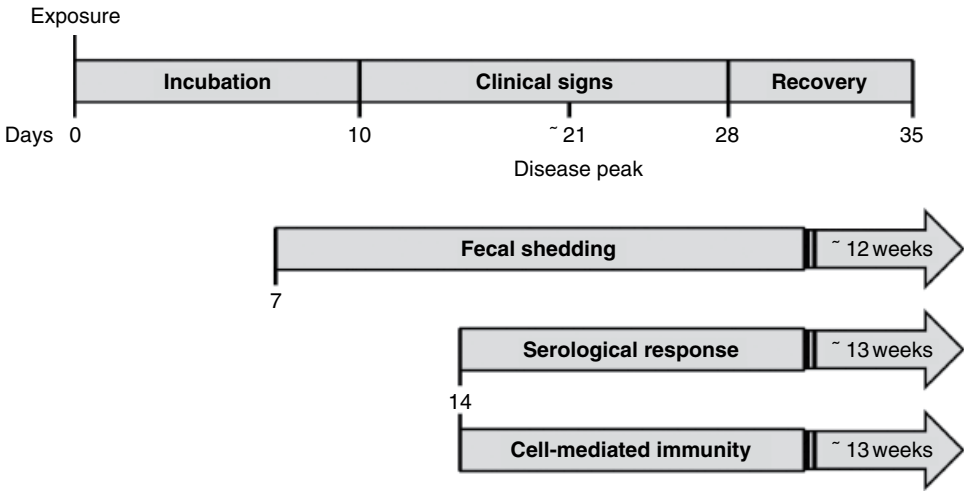

Figure 58.2 Porcine proliferative enteropathy. Typical clinical course, fecal shedding, and immune response of proliferative enteropathy in naïve pigs experimentally infected with *L. intracellularis*. *Source:* Adapted from Gebhart and Guedes (2010). Reproduced with permission of John Wiley and Sons.

non-pelleted diets (Mølbak et al. 2008). The mechanisms by which diet or intestinal microbiota influences *L. intracellularis* remain unclear.

Internalization of *L. intracellularis* has been described *in vitro*. The bacterium is found in close association with the cell surface after 10 minutes, internalized within transient membrane-bound vacuoles by 3 hours, and released from the vacuoles to live and proliferate in the apical cytoplasm thereafter (Johnson and Jacoby 1978; McOrist et al. 1995b). Inhibitors of host cell growth reduce bacterial multiplication *in vitro*, suggesting that actively dividing cells enhance bacterial replication (Lawson et al. 1995).

Virulence factors associated with adhesion and entry into enterocytes have not been characterized. However, bacterial invasion does not depend on the viability of the *L. intracellularis* cells. Cell entry may be partially mediated or enhanced by a type III secretion system, of which the genes and associated proteins are characterized and conserved among *L. intracellularis* isolates (Alberdi et al. 2009).

The microaerophilic properties of *L. intracellularis* and its proximity to the host mitochondria create a paradox for intracellular survival of the bacterium due to the oxidative phosphorylation supported by the continuous transport of oxygen through the mitochondrial membrane (Koyama et al. 1989). In order to survive in this microenvironment, *L. intracellularis* harbors a sophisticated oxidative protection mechanism involving Cu–Zn superoxide dismutase and dioxygenases (Vannucci et al. 2012a, 2013b). Additionally *L. intracellularis* seems to take advantage of this oxidative intracellular microenvironment while utilizing the host energy by expressing ATP/ADP translocase (Schmitz-Esser et al. 2008). This enzyme catalyzes the exchange of bacterial ADP for host ATP and allows the bacterium to exploit its hosts' energy pool, a process referred to as energy parasitism. Intracellular survival and/or pathogenesis of *L. intracellularis* may also be aided by high levels of *in vivo* expression of genes sharing homology with the *Salmonella* pathogenicity island 2 (Vannucci et al. 2013b), known to be pivotal to the intracellular survival and virulence of *Salmonella* in mammals.

Lesions of PE are restricted to the intestinal epithelium, and the dissemination of active infection to other organs has not been reported. The primary mode of cell-to-cell transmission of *L. intracellularis* is by the proliferation of *L. intracellularis*-infected crypt cells, resulting in infected progeny cells that continue the cycle (Jacoby and Johnson 1981; Vannucci and Gebhart 2014). Detection of bacterial antigens in mesenteric lymph nodes and tonsillar crypt cells has been demonstrated but attributed to the carriage of *L. intracellularis* antigens by infected macrophages (Gebhart and Guedes 2010). Movement of *L. intracellularis* through the lamina propria has been speculated as an additional route for spreading infection from crypt to crypt in the intestinal tract (Boutrup et al. 2010; Jensen et al. 2006).

The intriguing mechanisms whereby intracytoplasmic *L. intracellularis* causes infected cells to fail to mature and to undergo mitosis and form the hyperplastic to adenomatous crypts are not fully understood. Activation of DNA transcription, protein biosynthesis, and genes acting on the G_1 phase of the host cell cycle have been identified in infected cells *in vivo* and are potentially involved on the pathogenesis of PE (Vannucci et al. 2012a). Cell proliferation during *L. intracellularis* infection showed no association with an observed concurrent reduction of apoptosis (Guedes et al. 2017).

The dominance of the immature phenotype of proliferating crypt epithelial cells in PE, with their characteristic morphology and staining, means that fewer membrane transporters related to digestion and nutrient acquisition are operative (Jacobson et al. 2011; Vannucci et al. 2013a). This lack of membrane transporters in *Lawsonia*-infected enterocytes includes those involved in the absorption of carbohydrates, amino acids, lipids, and vitamin B_{12}. Thus reduced nutrient absorption by the immature intestinal mucosa is likely a significant cause of reduction in weight gain and feed conversion efficiency seen in PE-affected pigs (Gogolewski et al. 1991; Grützner et al. 2015; Rowan and Lawrence 1982; Vannucci et al. 2010).

Degenerative, necrotic, and reparative changes may superimpose the primary lesion of crypt epithelial proliferation over time. The acute form of PE, PHE, is marked by severe bleeding into the lumen of the intestine, but with typical underlying cell proliferation typical of PE. Hemorrhage occurs concurrently with the widespread degeneration and desquamation of many epithelial cells and leakage from the capillary bed. The pathogenesis of this more acute lesion is not well characterized.

Lawsonia intracellularis may also modulate the immune response, facilitating chronic infection of intestinal epithelial cells (see discussion in immunology section below).

Clinical signs

Three clinically different forms of PE are observed most commonly: acute, chronic, and subclinical. The acute form (PHE) occurs more commonly in young adults 4–12 months of age, such as breeding gilts. Clinical presentation is mainly characterized by sudden death associated with anemia and hemorrhagic diarrhea. Black tarry feces are often the first visible clinical sign and these may become loose. However, some animals die without fecal abnormality and show only marked pallor. Around half of the animals clinically affected may die with the remainder recovering over some weeks. Pregnant animals that are clinically affected may abort within 6 days of the onset of clinical signs (McOrist et al. 1999).

The chronic form of PE (PIA) is the most common and is observed predominantly in weaned pigs 6–20 weeks of age. Affected pigs have mild to moderate loose-to-watery grey-green diarrhea, variable anorexia, and failure to sustain growth despite normal feed intake. Fecal blood and mucus are not observed. Within the same groups, there are typically subclinically affected pigs that have normal stools, reduced weight gain, and less severe microscopic mucosal proliferative lesions.

Severe chronic cases can be complicated by opportunistic bacterial infections resulting in NE. These animals display a remarkable loss of condition and persistent diarrhea, sometimes with liquid feces containing fibrinonecrotic casts. Necrotic enteritis occurs more often in conditions that facilitate fecal–oral cycling, such as use of straw bedding or solid flooring with poor sanitation, thus increasing the likelihood of complicating opportunistic diseases such as enteric salmonellosis.

In most cases of uncomplicated PE, recovery occurs around 5 weeks after the onset of clinical signs with a return of appetite and growth rate to normal levels. Although these pigs usually progress to slaughter weight despite having PE lesions (Suto et al. 2004), average daily weight gain and feed efficiency are typically reduced, and days to market are increased. Chronically affected pigs have an average reduction in daily weight gain of 6–20% (Gogolewski et al. 1991; McOrist et al. 1996b, 1997a).

Lesions

Thickening of the intestinal mucosa due to crypt epithelial cell proliferation is the primary and most remarkable gross lesion of PE. In chronically affected growing pigs (PIA), gross lesions are most commonly observed in the terminal ileum and cecum, and with increasing severity, they typically extend to include the jejunum, cecum, and spiral colon. In mild cases, the earliest distinguishable gross lesions are often in the terminal ileum, approximately 10 cm oral from the ileocecal valve. Uncommonly, lesions may be localized to only one or more foci in the jejunum. Regardless of location, affected mucosa is variably thickened and thrown into longitudinal-to-transverse folds resembling cerebral cortex (i.e. cerebriform) with a moist but not mucoid surface (Figure 58.3). In severe areas, the intestinal wall is obviously thickened when viewed externally, and the overall intestinal diameter is increased. In some cases, there may be sparse multifocal adherent fibrinonecrotic mucosal exudate. Careful examination is required since contracted intestines due to post mortem peristalsis may result in relative thickening of the mucosa that can be easily misinterpreted as mild PE. Additionally, nonspecific submucosal edema found in many types of enteritis can enhance the normal mucosal folds, especially overlying Peyer's patches, and also be misinterpreted as mild PE.

Necrotic enteritis may be observed as a loosely or tightly adherent fibrinonecrotic membrane on the surface of the proliferated intestinal mucosa (Figure 58.3). Occasionally, this membrane may detach and be found intact (a cast) or in pieces in the contents of the large intestines or in diarrheic feces.

In acute hemorrhagic cases (PHE), the intestine is dilated and the wall is thickened by serosal edema and mucosal proliferation. The lumen of the ileum usually contains one or more formed blood clots combined with fibrinonecrotic debris (fibrinohemorrhagic cast;

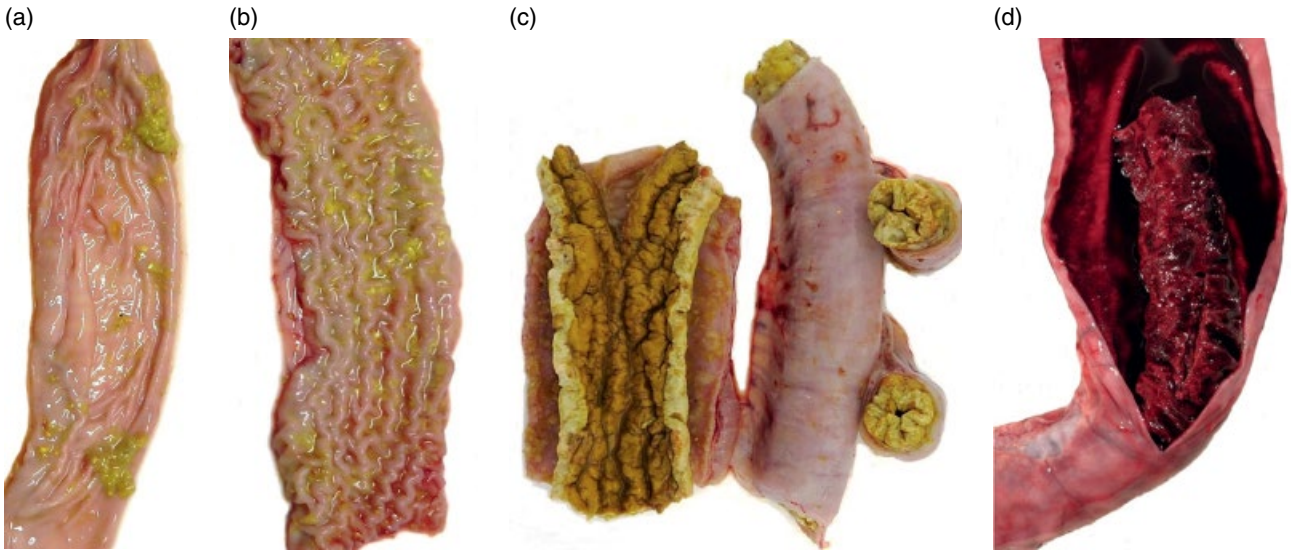

Figure 58.3 Porcine proliferative enteropathy, macroscopic lesions. (a) Normal small intestine. (b) Typical chronic porcine intestinal adenomatosis (PIA) characterized by thickening and corrugation of the intestinal mucosa. (c) Necrotic enteritis due to opportunistic bacterial aggravation of the chronic intestinal adenomatosis. (d) Proliferative hemorrhagic enteropathy (PHE) with fibrinohemorrhagic cast in the intestinal lumen.

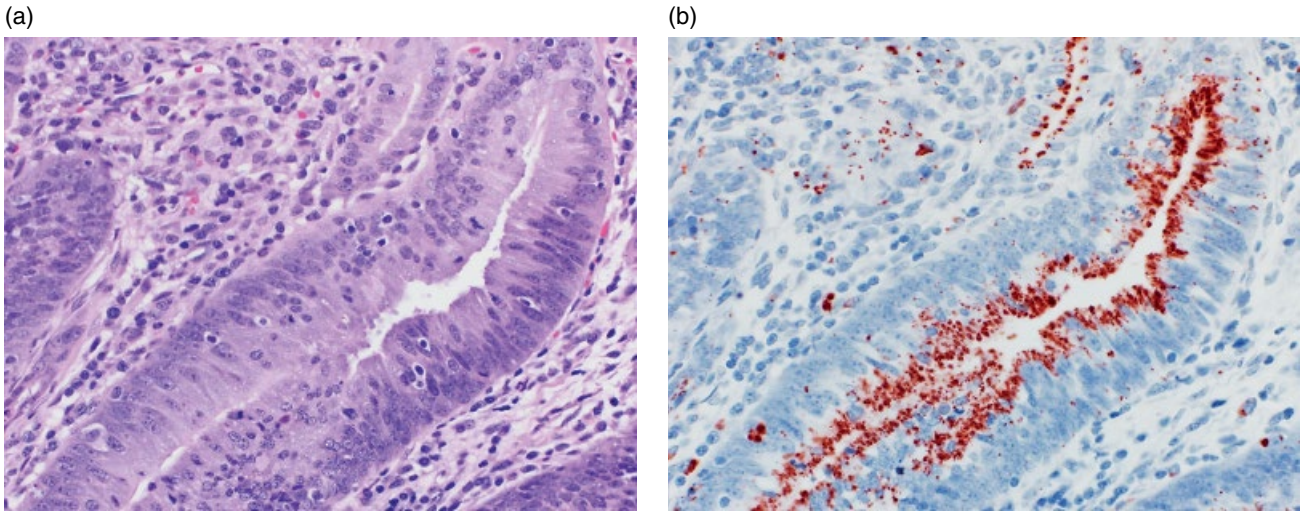

Figure 58.4 Porcine proliferative enteropathy, microscopic lesions. (a) H&E stain. Marked enlargement of an affected intestinal crypt composed of multiple epithelial layers and lacking goblet cells (400× magnification). (b) Immunohistochemistry. Affected intestinal crypt showing large numbers of *L. intracellularis*-specific antigen (maroon staining) predominantly in the apical cytoplasm of proliferative enterocytes (400× magnification).

Figure 58.3) (Lawson et al. 1979; Rowland and Lawson 1975). The rectum may contain black tarry feces of mixed blood and digesta. The mucosa of the affected portion of intestine has few lesions except proliferation typical of chronic PE (PIA). No petechial hemorrhages, erosions or ulcers typically are observed.

The hallmark microscopic lesion in all forms of PE is mucosal thickening produced by proliferation of immature crypt epithelial cells that form hyperplastic and dysplastic crypts (Lomax and Glock 1982; Rowland and Lawson 1974). The normal single layer of simple columnar crypt epithelial cells is replaced by 2 or more irregular pseudostratified layers containing numerous mitotic figures (Figure 58.4). This results in enlarged crypts with irregular outlines that are often branched and that lack goblet cells present in crypts of normal swine intestine. Reappearance of goblet cells in deep glands is an indication of impending resolution. Infiltration of inflammatory cells is minimal or absent and only evident in late-stage lesions or in lesions complicated by other opportunistic infections (McOrist et al. 2006).

Specific immunostains or electron microscopy of affected intestinal sections reveals intracellular *L. intracellularis*, often in considerable numbers, lying in the apical cytoplasm of the affected crypt epithelial cells (Figure 58.4). In recovering lesions, the organisms may be either in extruded degenerate cells in the lumen or in cytoplasmic vacuoles within activated macrophages in the lamina propria. Recovering lesions of PE are notable for resumption of development of a population of mature epithelium through the crypt–villus axis, reappearance of goblet cells, and reestablishment of normal mucosal thickness and morphology (McOrist et al. 1996a).

In cases of NE, the superficial mucosa is effaced by coagulative necrosis, fibrin, and degenerative inflammatory cells. Typical proliferated *L. intracellularis*-infected crypt epithelium can be observed in deeper non-necrotic mucosa. Histological lesions in acute hemorrhagic cases (PHE) are characterized by variably severe mucosal proliferation typical of PE, fibrinohemorrhagic luminal clots or fibrinonecrotic and hemorrhagic luminal casts, and accumulation of bloody cellular debris containing numerous *L. intracellularis* organisms on the surface of the affected mucosa and in the lumen of affected intestinal crypts. In most cases, relatively minimal mucosal hemorrhage is observed relative to the large amount of accumulated blood in the intestinal lumen.

Diagnosis

The clinical diagnosis of PE has been historically based on clinical and pathological characteristics of the *L. intracellularis* infection. The differential diagnosis for clinical cases of PE varies with the particular form of the disease.

Pigs affected with PHE may have acute red-tinged loose-to-watery diarrhea or may be found dead with no prior clinical signs detected and with fecal staining of the skin in the perianal region. Differential clinical diagnosis should include acute swine dysentery (Chapter 62), gastric ulceration, and hemorrhagic bowel syndrome (Chapter 15).

Pigs affected with PIA predominantly exhibit diarrhea, anorexia, and poor growth. This form of PE is most likely confused clinically with endemic forms of coronaviruses (Chapter 31), rotaviruses (Chapter 43), brachyspiral colitis (Chapter 62), enteric salmonellosis (Chapter 59), porcine circovirus-associated enteritis (Chapter 30), enterotoxigenic colibacillosis (Chapter 52), and some nutritional diarrheas (Chapter 15). Porcine circovirus infections may produce grossly evident mucosal thickening of the intestines, but distinctive systemic lesions of PCVAD and granulomatous (non-adenomatous) enteritis differentiate it from PE (Jensen et al. 2006).

Confirmation of PE has typically relied on the observation of characteristic gross and microscopic lesions with detection of *L. intracellularis* infection by one or more methods. The difficulty in routinely culturing *L. intracellularis* has led to several alternative methods for confirmation of *L. intracellularis* infection. Immunohistochemistry or, less commonly, *in situ* hybridization can confirm the organism by visualization within the microscopic lesions. PCR assays have been widely used to confirm *L. intracellularis* DNA in fecal or intestinal mucosal samples (Jacobson et al. 2004; Jones et al. 1993).

Immunohistochemical staining using *L. intracellularis*-specific antibody has been the gold standard for specific identification of the bacterium in PE lesions (Guedes and Gebhart 2003a; Ladinig et al. 2009; McOrist et al. 1987). Immunohistochemistry can also be used to estimate the level of infection based on the amount of labeled *L. intracellularis*-specific antigen present in the intestinal mucosa (Guedes and Gebhart 2003a).

In situ hybridization assays can also specifically detect *L. intracellularis* nucleic acids in PE lesions (Gebhart et al. 1994; Jensen et al. 2010; Weissenböck et al. 2007); however, they are uncommonly used for routine diagnostics. Silver staining techniques are nonspecific in that they allow visualization of intracellular bacteria typical of *L. intracellularis* within lesions of PE, but they do not allow specific identification. Given the unique features of PE and the unique intracellular location of *L. intracellularis*, visualization with silver staining in typical PE lesions is essentially diagnostic. Where electron microscopic facilities are available, the presence of typical curve-shaped intracellular organism can be confirmed.

The sensitivity of PCR techniques for *L. intracellularis* has increased considerably over the last decade mainly due to development of real-time assays, including commercial kits with multiple sequence targets, and optimization of DNA extraction methods. Many PCR assays can detect as low as 100 organisms per gram of feces. Because of this high sensitivity, the mere demonstration of *L. intracellularis* in feces by PCR may not indicate economically significant PE at a herd level. Caution should also be exercised when interpreting negative IHC results since they are often based on microscopic evaluation of few sections of the small intestine. Considering the inexact segmental distribution of the PE lesions, examination of more segments of intestine may well demonstrate *L. intracellularis* infection within typical localized microscopic lesions.

The *antemortem* diagnosis of chronic or subclinical PE, without the aid of histopathology, can be challenging (Jacobson et al. 2003). A comprehensive investigation focusing on apparent wasting animals with intermittent diarrhea and variable weight gain is warranted along with serial fecal sampling for PCR testing from suspect groups. Records should be carefully examined to detect changes in average weight gain and feed conversion efficiency in the post weaned group (Gogolewski et al. 1991;

Roberts et al. 1979). A correlation should be evident between levels of *L. intracellularis* fecal shedding and diarrheic disease and growth performance. As an example, Burrough et al. (2015) published findings of a study that sought to correlate results of a semiquantitative real-time PCR test for *L. intracellularis* run on feces of diarrheic pigs with the presence of typical PE lesions and positive IHC tests. The authors found that Ct values of 29–32 or lower in the evaluated PCR test represented approximately 10^4 organisms/g of feces or more and that these Ct values were predictive of finding lesions of PE and detection of *L. intracellularis* by IHC. Given this correlation, Ct values below 30 in this particular test on fecal samples from diarrheic pigs could be interpreted as indicating that *L. intracellularis* is at least partially the cause of diarrhea and that the sampled pig could reasonably be expected to have typical lesions. These findings would need to be confirmed on an appropriate number of animals if a conclusion were to be made about the population as a whole.

The challenge in measuring the economic impact of subclinical cases of PE has motivated discussions questioning their importance, especially after observing positive fecal PCR tests from apparently healthy animals. This debate is primarily fueled by the growing number of countries adopting policies to restrict the usage of antimicrobials in swine production. It has been questioned whether the simple detection of *L. intracellularis* in feces should justify antimicrobial therapy. Consequently there is increasing concern to better define a protocol for therapeutic intervention for PE control. A PCR threshold has been investigated as an indicator of clinically significant fecal shedding that would merit treatment (Pedersen et al. 2012). Regardless of specific levels of fecal shedding, increasing numbers of *L. intracellularis* in feces of individuals over time have been strongly correlated with a decreasing average daily gain. More specifically, a $\log_{10}$ unit increase in *L. intracellularis* fecal load (around 3 Ct values) increases by 2 the odds ratio of a pig having a low growth rate (Johansen et al. 2013).

The use of oral fluid samples has been explored for detection of *L. intracellularis* DNA by PCR (Frana et al. 2014; LaVigne et al. 2013) and antibodies (IgA and IgG) by immunoperoxidase monolayer assay (IPMA) (Gabardo et al. 2014) and blocking ELISA (Johnson et al. 2011). Detection of *L. intracellularis* by PCR from oral fluids results from the behavior of pigs in which infected fecal matter is transported through the animal's mouth from the ground to the ropes used for oral fluid collection. These samples then represent a pool of feces from animals grouped in a pen. Therefore, a potential reduction on the sensitivity should be considered due to the dilution factor intrinsic to the pooling approach. The IPMA technique for IgG and IgA detection from oral fluids has shown high specificity and moderate sensitivity (Gabardo et al. 2014). Based on the endemic scenario of PE in swine herds worldwide, the diagnostic value of positive results by either PCR or serology in oral fluids is questionable. However, these diagnostic tools may be useful for diagnosis in herds with high health status or in naïve populations.

Serological tests for detection of IgG specific for *L. intracellularis* using whole bacterial antigen such as indirect immunofluorescence assay (Knittel et al. 1998) and IPMA (Guedes et al. 2002b) have been well validated. Several ELISA assays have been described incorporating differing antigen extracts (Boesen et al. 2005; Collins et al. 2012; Kroll et al. 2005; Watarai et al. 2004). Serologic assays have documented systemic IgM and IgG responses to *L. intracellularis*. Local intestinal IgA response has been detected by IPMA from intestinal lavage (Guedes and Gebhart 2010). Antibody responses usually have a good correlation with the presence of lesions. But exposure may not necessarily induce significant seroconversion in all cases. Although blood collection can be more time consuming than feces collection, the serological tests are cheaper to perform than individual fecal PCR tests.

Immunity

Humoral and cell-mediated immune responses are first detected two weeks after challenge of pigs with pure culture of *L. intracellularis* and persist in some animals for 13 weeks after exposure (Figure 58.2; Guedes and Gebhart 2003b). Macrophage ingestion of *L. intracellularis* in developing lesions probably leads to a predominant typical Th1 type immune cell response in the lamina propria (MacIntyre et al. 2003; McOrist et al. 1992). Serological IgG peaks near the end of the third week after infection and then drops gradually (Knittel et al. 1998). Naturally infected pigs showed a large accumulation of total IgA in the apical cytoplasm of proliferating enterocytes (McOrist et al. 1992). *Lawsonia*-specific IgA was detected in intestinal lavage of experimentally infected pigs three weeks after infection (Guedes and Gebhart 2010). Pigs rechallenged with *L. intracellularis* after recovering from previous exposure were protected from recolonization and clinical disease (Collins and Love 2007). *Lawsonia*-specific immune response appears to correlate with long-lasting (at least 10 weeks) protective immunity to reinfection (Cordes et al. 2012; Kroll et al. 2004; Riber et al. 2011). Progeny from acutely affected breeding stock is not fully protected from PE (Guedes et al. 2002a; Jacobson et al. 2010). The cell-mediated immune response mediated through CD8+ effector T cells is likely primarily responsible for protective immunity (Cordes et al. 2012).

Some data indicates that *L. intracellularis* modulates the immune response, enabling persistent infection of crypt epithelial cells. Early observations that well-developed typical PE lesions lacked significant inflammatory or immune cellular infiltrates led to the suggestion of immunomodulation (Rowland and Rowntree 1972). This has been confirmed by numerous *in vivo* studies that have consistently shown downregulation of genes related to the immune response, including those typically induced by intracellular pathogens such as tumor necrosis factor (Jacobson et al. 2011; Vannucci et al. 2012b). Reduction in the numbers of T cells and B cells in heavily infected pigs has also been demonstrated (MacIntyre et al. 2003).

Prevention and control

Improved farm hygiene measures will reliably reduce levels of PE. Quaternary ammonium-based compounds have effective anti-*Lawsonia* disinfectant activities (Collins et al. 2000; Wattanaphasak et al. 2010), but isolates appeared somewhat resistant to phenolic or iodine-based mixtures. Rigorous washing and cleaning of feces from all parts of pig pens, facilities, boots, and equipment on both single-site and multisite farms, as well as insect and rodent control, are likely to be more effective at reduction of PE than reliance on slatted floors and sunken pits for feces removal (Bronsvoort et al. 2001; Smith et al. 1998).

Limited *in vitro* studies have compared the minimum inhibitory concentrations of different classes of antimicrobials with potential activity against *L. intracellularis* (McOrist et al. 1995c; Wattanaphasak et al. 2009; Yeh et al. 2011). These *in vitro* evaluations corroborate results of controlled *in vivo* studies in commercial herds. Overall, macrolides and pleuromutilins are the most effective antibiotics when given at an adequate dosage rate per kg of body weight (McOrist et al. 1996b, 1997a; Pommier et al. 2008; Schwartz et al. 1999; Walter et al. 2001). In the United States quinoxalines (such as carbadox) are also available and effective. Acquired resistance by *L. intracellularis* to these active drug groups has not been demonstrated (McOrist 2000). Although tetracycline demonstrated only intermediate effectiveness *in vitro* (Wattanaphasak et al. 2009), medication via water using tetracycline and its derivative, doxycycline, demonstrated reduction in fecal shedding of *L. intracellularis* under field conditions (Larsen et al. 2016; Weber et al. 2017).

Apparent medication failures with antimicrobials known to be effective are most likely due to subtherapeutic dosages. Antimicrobials known to be ineffective against *L. intracellularis* in clinical PE include penicillins, bacitracin, and aminoglycosides such as neomycin, virginiamycin, and ionophores. Non-antibiotic therapies such as copper or zinc compounds or feed acidifiers are generally ineffective.

Effective medication protocols vary depending on the time course of the disease and the age of pigs involved. Controlled field trials suggest that incorporation of in-feed or water-soluble antibiotics for control achieves best results if given early in the course of infection. Treatment of PHE in breeding herds requires a vigorous approach, medicating both clinically affected and in-contact animals (which may include whole herd treatment). A preferred strategy would be tiamulin (120 ppm), tylosin (100 ppm), or tylvalosin (100 ppm) for 14 days, delivered orally via a water-soluble formulation or an in-feed premix or by intramuscular injection of an equivalent dose. Severe PIA manifested as wasting pigs will often be moderated by the use of tiamulin, tylosin, tylvalosin, or carbadox. The removal of affected animals to separate pens, with supportive therapy, may also limit losses.

Medication of older pigs (i.e. breeding stock) is not likely to eliminate the infection. Partial depopulation and medication-based eradication attempts have been largely unsuccessful. Since PE can vary in the time of onset on different farms and between batches of pigs within the same farm, in-feed antimicrobials added too late may not adequately reduce the clinical signs or improve performance (Hammer 2004). Conversely, antimicrobials added too early may prevent exposure and subsequent development of active immunity. These pigs may remain naïve and susceptible to exposure later and thus experience the acute hemorrhagic form (PHE).

A modified live vaccine has been widely used with demonstrated effectiveness in preventing PE. It has provided protection against subsequent challenge with virulent heterologous *L. intracellularis* when administrated either by individual oral drench or drinking water delivery to a group of pigs (Kroll et al. 2004). Vaccinated animals showed reduced PE lesions and fecal shedding of *L. intracellularis* along with better cell-mediated immune responses upon challenge (Nogueira et al. 2013; Riber et al. 2015). Specific IgG and IgA responses and cytokine production in the ileal mucosa were also observed in vaccinated pigs (Nogueira et al. 2015). Field studies confirm that vaccination results in improved rate of gain and economic benefits (i.e. return of investment) (Hardge et al. 2004; McOrist and Smits 2007; Park et al. 2013). Additionally, vaccination has resulted in reduced antibiotic usage in PE-affected herds (Bak and Rathkjen 2009).

A particular concern regarding the use of an avirulent live vaccine is the concurrent administration of some antimicrobials that inactivate the live *L. intracellularis* vaccine. This scenario may prevent production of IFN-γ, important for a specific cell-mediated immune response. Temporary removal of most medications from feed is recommended at least 3 days

before and 3 days after vaccination (Kolb and Sick 2003). The concurrent use of in-feed administration of colistin at 30 g/ton or virginiamycin at 11 g/ton has not demonstrated interference with the effectiveness of the modified live oral vaccine (Beckler et al. 2013; Liesner et al. 2012).

In 2016 an injectable killed vaccine became commercially available in the United States. The label recommends a single intramuscular dose in pigs at 3 weeks of age or older. A study conducted by the manufacturer showed specific serological response (humoral IgG) along with reduced PE lesions and fecal shedding of *L. intracellularis* in vaccinated pigs challenged 20 weeks after vaccination (Roerink et al. 2016). Presently, there is no published information on the effect of this injectable bacterin on growth performance or mucosal immune responses in vaccinated pigs.

Vaccination is particularly important in nucleus herds and for introduction of replacement breeding stock into commercial farms. Acclimation and medication programs, without vaccination, for naïve gilts may result in PE outbreaks.

Salmonellosis

Ronald W. Griffith, Steven A. Carlson, and Adam C. Krull

Relevance

Members of the genus *Salmonella* are notorious for their ability to infect a broad range of hosts. Taylor and McCoy (1969) observed that salmonellae have been isolated from virtually all vertebrate hosts from which they have been sought. Many of the more than 2400 *Salmonella* serotypes have a broad host range, but several serotypes are quite adapted to a single host species including *S.* Typhi (humans), *S.* Dublin (bovine), *S.* Gallinarum (poultry), and *S.* Choleraesuis (swine).

Salmonella infections of swine are of concern for two major reasons. The first is clinical disease in pigs (salmonellosis), and the second is that swine can be infected with a broad range of *Salmonella* serotypes that can potentially contaminate pork products and pose a threat to human health.

Etiology

There has been considerable disagreement over the nomenclature of the genus *Salmonella*, and several proposals for altering it have been made. Convention has been to refer to each of the over 2400 distinct serotypes as though it is a species. *Salmonella enterica* has been designated as the type species for the genus *Salmonella*, and approximately 60% of all *Salmonella* serotypes belong in the subspecies *enterica* including the vast majority of pathogens. Not italicizing the serovar names and capitalizing the first letter in recognition that they are not species names has been widely accepted. For simplicity, serovar names will be shortened in this chapter to *S.* Choleraesuis, *S.* Typhimurium, etc.

Disease in swine has historically been almost always caused by either *S.* Choleraesuis variety Kunzendorf or by *S.* Typhimurium. The former produces septicemia with lesions in a variety of organs and has historically been and may continue in some parts of the world to be the most frequent serotype causing disease in swine (Lawson and Dow 1966; Levine et al. 1945; Mills and Kelly 1986; Morehouse 1972; Schwartz and Daniels 1987; Wilcock et al. 1976). An emerging concern is illustrated by a recent study that identified a multiple antibiotic resistant isolate of *S.* Choleraesuis exhibiting hypervirulence after the bacterium has escaped from waterborne protozoa (Xiong et al. 2010). However, the National Animal Disease Laboratories (NADL) report that *S.* Choleraesuis is no longer in the top 10 serovars identified by their laboratory from swine in the United States (personal communication, 2017).

Salmonella Choleraesuis *had diminished and S.* Typhimurium had emerged as the most frequently isolated serotype from diseased swine in North America at the time of publication of the previous (10th) edition of *Diseases of Swine* (Foley et al. 2008). *S.* Typhimurium causes diarrheal disease as a consequence of enterocolitis. Disease caused by *S.* Typhimurium occurs with greater than expected frequency in what could be considered unusually clean herds such as purebred breeding herds (Gooch and Haddock 1969; Heard et al. 1968; Lynn et al. 1972) because of introduction into a previously immunologically naïve population. This organism is also frequently isolated as a sequel to other enteric or debilitating diseases. As with *S.* Choleraesuis, some multiresistant *S.* Typhimurium can be hypervirulent following exposure to common waterborne protozoa (Xiong et al. 2010).

Salmonella I 1,4,[5],12 : i:- is antigenically similar to *S.* Typhimurium but lacks the second-phase flagellar antigens (Moreno Switt et al. 2009; Soyer et al. 2009). It is considered to be a serologic variant of *S.* Typhimurium. It has been identified for many years but has been increasingly seen as a cause of clinical disease in humans and animals. In 2012 and 2013, this variant was ranked by NADL in the top five causing clinical disease in swine. In 2014–2016, this organism was the leading cause of clinical salmonellosis in swine in the United States.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Clinical disease and lesions caused by infection with this serovar appear to be identical to those caused by infection with *S.* Typhimurium (Krull 2017, unpublished data). There has also been a steady increase over time in the percentage of isolates with ampicillin, streptomycin, sulfonamide, and tetracycline (ASSuT) antimicrobial resistance. Approximately 38% of isolates at the Iowa State University Veterinary Diagnostic Laboratory in 2016 expressed ASSuT resistance (Krull 2017, unpublished data).

Localized epidemics of disease caused by the biochemically atypical *S.* Typhisuis have been historically reported in the American Midwest (Andrews 1976; Barnes and Bergeland 1968) and Europe (Barnes and Sorensen 1975). This organism grows poorly in standard selective media for *Salmonella* isolation, but the disease produced by *S.* Typhisuis is so characteristic that outbreaks are not likely to remain unnoticed (Barnes and Bergeland 1968). This serotype was demonstrated to be able to subsist on antibiotics as a sole carbon source (Barnhill et al. 2010), a concern given the potential for antibiotics present in manure lagoons.

Other serotypes are occasional causes of disease in swine but are usually transient and associated with predisposing factors including debilitation, immunocompromise, other intestinal disturbances, or circumstances, which allow immunologically naïve pigs to be exposed to very large doses. *S.* Heidelberg has been associated with post weaning diarrhea with mild lesions more typical of enterotoxigenic diarrheal disease than of the typical fibrinonecrotic enterocolitis observed with *S.* Choleraesuis or *S.* Typhimurium (Reed et al. 1985). *S.* Dublin (Lawson and Dow 1966; McErlean 1968) and *S.* Enteritidis (Reynolds et al. 1967) have been rarely reported as causes of meningitis in suckling pigs.

Public health

Non-typhoidal salmonellosis is a worldwide health problem and is the leading cause of foodborne illnesses in the United States and many parts of the world. The topic has been recently reviewed (Doyle et al. 2009; Foley et al. 2008; Foley and Lynne 2008). Although less common than contaminated food, direct contact with clinically or subclinically infected animals can also be a source of human infection (Hoelzer et al. 2011). Among the top 20 *Salmonella* isolated from diseased humans, 5 are commonly isolated from swine (i.e. *Salmonella* I 1,4,[5],12 : i:-, *S.* Typhimurium, *S.* Heidelberg, *S.* Agona, and *S.* Infantis). Even so, human salmonellosis is more commonly acquired in the United States through consumption of contaminated poorly cooked poultry, eggs, or beef than by consumption of pork or direct contact with pigs. *S.* Choleraesuis is an uncommon human pathogen in the United States, but the non-Kunzendorf variety is a cause of human disease in other countries.

Non-typhoidal human salmonellosis usually manifests as self-limiting diarrhea, abdominal cramps, vomiting, and fever that begins 6–12 hours after oral exposure and resolves after 2–7 days. In a low percentage of affected individuals, septicemic disease develops, leading to osteomyelitis, pneumonia, or meningitis that require antibiotic therapy. An exception is *S. Choleraesuis* that consistently produces severe septicemic disease. Mortality may result from dehydration or effects of septicemic disease. Severe disease and mortality are most common in infants, the elderly, or immunocompromised individuals.

Epidemiology

The reservoir for salmonellae is the intestinal tract of warm- and cold-blooded animals. Salmonellae have virtually all of the attributes necessary to ensure wide distribution, including abundant reservoir hosts, efficient fecal shedding from carrier animals, persistence within the environment, and the effective use of transmission vectors (feed, fomites, vehicles, etc.). Inapparent, long-term carriers that can shed salmonellae in feces continuously or intermittently, often in high numbers, are common in most host species. Shedding of the organism can be exacerbated by a long list of stressors, including commingling of pigs, transportation, concurrent diseases, antibiotic therapy, and food deprivation.

Infection of swine with persistent shedding by one or more serotypes is common, but primary clinical disease caused by serotypes other than *S.* Typhimurium or the *S.* I 1,4,[5],12 : i:- variant is uncommon. Put differently, clinically normal swine may be infected and shed a variety of serotypes that pose little threat to pigs but may pose risk for humans through direct exposure or contamination of pork products. Thus, shedding of salmonellae by clinically and subclinically infected pigs has implications both for contamination of pork carcasses and foodborne human illness and for the development of clinical salmonellosis in swine populations.

Salmonellae in pork

Although much of the *Salmonella* contamination of pork products occurs by fecal contamination during slaughter within abattoirs, infected pigs leaving the farm are considered the original source of abattoir contaminations. The stress of transport and feed deprivation increases shedding from inapparent carriers, which then contaminate the environment of the truck and abattoir (Isaacson et al. 1999; Williams and Newell 1970). The prevalence of infection within the group continues to increase with

increasing length of stay in the pens prior to slaughter, rising by about 50% for each 24 hour period (Craven and Hurst 1982; Morgan et al. 1987).

Although *Salmonella* contamination of poultry and beef products exceeds that of pork, *Salmonella* control programs in swine will continue to be a primary focus of food safety initiatives. *Salmonella* reduction programs are becoming commonplace in some regions, with long-range goals to include the production and marketing of salmonellae-free pork products. Numerous dynamic programs are in place utilizing hazard analysis and critical control point principles. Those programs that have been in place for a sufficient period of time, such as the Danish program, have significantly reduced the rate of *Salmonella* contamination in pork products (Nielsen et al. 1995). Fortunately, most of the methods useful for preharvest *Salmonella* reduction in swine populations are related to sound management practices that also improve the overall health of a swine operation. The Danish program, which uses serology to identify *Salmonella*-infected herds and therefore control the introduction of shedding swine into the abattoir, has not been as successful as originally hoped.

Salmonellosis in swine

Most salmonellosis outbreaks occur in intensively reared weaned pigs, and although disease in adults and suckling pigs is infrequent, infection is not (Gooch and Haddock 1969; Wilcock et al. 1976). The low frequency of salmonellosis in suckling pigs presumably results from lactogenic immunity, since naïve neonatal swine are susceptible to oral challenge with salmonellae and develop a disease comparable with that in weaned pigs (Wilcock 1978). Disease occurs worldwide but varies markedly in estimated prevalence, morbidity, and mortality.

Host-adapted *S.* Choleraesuis is isolated almost exclusively from diseased swine and is usually manifested as septicemia. Midwestern US veterinary diagnostic laboratories and veterinarians reported an increasing frequency of salmonellosis due to *S.* Choleraesuis from 1981 to 1990 and a decreasing frequency from 1991 to 2016 (Krull 2017, unpublished data; Schwartz 1997). The decrease starting in the mid-1990s is likely due to improvements in swine management and husbandry and the advent of efficacious attenuated live vaccines. Immunization of swine against *S.* Choleraesuis is no longer a routine practice in many operations.

Salmonella Typhimurium and its variant *S.* I 1,4,[5],12 : i:- have worldwide distribution, are not host specific, and have become the most frequently isolated serotypes from clinically ill pigs in the United States (Foley et al. 2008; Krull et al. 2017, unpublished data). Clinically ill pigs develop enterocolitis and exhibit diarrhea and dehydration. Disease most commonly develops in pigs with concurrent debilitating diseases, in conditions of poor hygiene that allow exposure to high doses of the organism, or in immunologically naïve pigs. The latter are frequently encountered in modern production systems utilizing age-segregated production.

Caution should be exercised before incriminating other serotypes as primary pathogens. Most other serotypes are transient, sporadic causes of disease, and often disease cannot be reproduced experimentally without unique qualifying criteria. *S.* Heidelberg has been implicated in watery diarrhea in recently weaned pigs thought to be caused by an enterotoxin-mediated secretory mechanism and associated with only mild catarrhal enterocolitis (Reed et al. 1985). This is in sharp contrast to the severe lesions of fibrinonecrotic enterocolitis observed in *S.* Typhimurium-associated disease.

Sources of infection

The number of potential sources of *Salmonella* infection for a population of swine is seemingly endless. A task force study in the United States did not reach a consensus as to the most important source of salmonellae for pigs (Bixler 1978), in large part due to the diversity and the biology of the genus *Salmonella*. *S.* Choleraesuis used to be a frequent isolate from clinically ill pigs, but was always a very infrequent isolate from pig feeds or non-porcine *Salmonella* reservoirs. Vertical (dam to offspring) and horizontal transmission both occurred. Pigs may also be the likely source for *S.* Derby, which seems to be very common in some abattoir surveys of swine.

The source of infection for other serotypes is less clear since the host and vector range for salmonellae is broad and they have amazing capability to persist in environments outside the host. There are generally low numbers of various *Salmonella* serotypes present in feed, water, or litter contaminated by birds, rodents, or other animals. Evidence linking sources of contamination to primary clinical outbreaks, without other concurrent diseases or predisposing conditions, is generally lacking. Feed containing ingredients of animal origin is widely accepted as a source of *Salmonella* infection to herds, but it should be emphasized that ingredients of vegetable origin can also be a source of salmonellae-contaminated feed. Water is not as likely a source of infection unless surface water is used for consumption or pigs have access to recycled lagoon water. Birds, insects, rodents, and pets can all act as carriers, as can bedding and litter (Allred et al. 1967; Nape and Murphy 1971; Williams et al. 1969). The isolation of salmonellae from feed was significantly associated with the lack of bird proofing, with on-farm feed preparation, and with the housing of pigs in facilities other than total confinement, for all stages of production.

Transmission, shedding, and carrier state

Definitive statements regarding the transmission, shedding, and carrier states of salmonellae are difficult due to the dynamic and complex relationships between salmonellae, hosts, and environment. *Salmonella* transmission and shedding within differing populations of animals in an endless variety of environmental, feeding, and management situations result in countless unique situations that cannot be experimentally reproduced.

In general, fecal–oral transmission is the most likely mode of transmission of virulent salmonellae. *Salmonella* can be recovered from the intestinal tract of pigs within several minutes of oral exposure. Transmission can occur from pig to pig, contaminated environment to pig, or dam to offspring. Oropharyngeal secretions may contain salmonellae, largely due to the fact that tonsils become rapidly contaminated with salmonellae following oral transmission. This may allow nose-to-nose transmission. Aerosolized secretions, feces, or contaminated dust particles make the potential for aerosol transmission for short distances quite real. In fact, experimentally esophagostomized pigs can acquire systemic *Salmonella* following aerosol introduction of the pathogen (Fedorka-Cray et al. 1995).

Salmonella infection of swine herds is much more common than disease. Longitudinal studies in the Netherlands suggest that about 25% of herds are never infected, 24% are constantly infected, and 50% are infected most of the time. There appear to be infection cycles, with the endemic salmonellae having an ecological advantage over newly introduced *Salmonella* serotypes. Infection occurs in the first weeks after arrival or commingling and reaches a maximum of 80–100% prevalence within another 2–3 weeks. About 5–30% of the pigs are still excreting salmonellae at the end of the finishing period. In 2006, the National Animal Health Monitoring System (NAHMS) reported that 52.6% of herds sampled across the United States were *Salmonella* positive, up from data obtained in 1995 (38.2%) and 2000 (32.8%). The 2012 NAHMS survey reported on the percentage of grower/finisher sites listing salmonellosis as a disease problem. Grower/finishers with <2000 hogs reported 3.1% of sites with salmonellosis. Grower/finishers with >5000 head reported 18.8% of sites with salmonellosis.

During acute disease, pigs will shed up to 10^6 *S.* Choleraesuis per gram feces (Smith and Jones 1967) or 10^7 *S.* Typhimurium per gram of feces (Gutzmann et al. 1976). The minimum disease-producing dose of either serotype has not been established in field situations, but disease is difficult to reproduce experimentally at low doses. There is one report of moderate disease following oral inoculation of 10^6 microbes (Dawe and Troutt 1976), but most authors report successful experimental disease production with doses of 10^8–10^{11} organisms unless pigs are artificially stressed by injection of dexamethasone or in some other manner. Pigs infected with 10^3 organisms remained clinically normal, but uninoculated pigs in the same pen did become clinically ill (Gray et al. 1996). It is likely that dose (and perhaps virulence) is magnified when pigs are infected and sequential (pig-to-pig) transmission occurs in field situations so that the initial infective dose in the field is considerably less than that required in experimental situations. High animal density, stress of transport, and intercurrent nutritional or infectious disease are assumed to increase the shedding by carriers as well as the susceptibility of exposed pigs. Pigs with nondetectable shedding of salmonellae can begin shedding within hours of an applied stress. The transmission demonstrated between feeder pigs also occurs between pigs during market transport and lairage at abattoirs, with infection rates proportional to time spent in transport and lairage (Hurd et al. 2001a,b). It is likely that catecholamines are released in association with stress, resulting in decreased gastric acid production and increased intestinal motility. Increases in stomach pH increase the likelihood that salmonellae will survive passage through the stomach and will access and replicate in the intestine and colon.

Outbreaks of salmonellosis are usually characterized by spread from pen to pen. Situations of spread from pen to distant pen are likely because of vectors or caretaker transmission. When all animals sicken simultaneously, a common source such as feed, bedding, water, or a contaminated environment should be suspected. *Salmonella* infections tend to be more prevalent in continuous-flow systems than in barns managed by principles of all-in/all-out. Prevalence is also higher in barns with open flush gutters than in those with slotted floors, with the highest rates of infection observed in outdoor finishing systems (Davies et al. 1997).

Numerous studies in a variety of host species with a variety of serotypes have demonstrated prolonged carrier states following infection. The pattern of shedding and the duration of the carrier state after clinically apparent disease have been studied only in group-housed pigs with no barrier to repeated reinfection (Wilcock and Olander 1978; Wood et al. 1989). After experimental infection, *S.* Typhimurium was isolated from feces daily during the first 10 days postinfection and frequently during the next 4–5 months. When slaughtered 4–7 months after initial infection, over 90% of pigs were positive for *S.* Typhimurium in the mesenteric lymph node, tonsil, cecum, or feces (Fedorka-Cray et al. 1994; Wilcock and Olander 1978; Wood et al. 1989; Wood and Rose 1992). *S.* Newport has been shown to persist in mesenteric lymph nodes for 28 weeks. Infection of individual animals may be relatively short lived (less than 8 weeks), but organisms may circulate

within a population and between pigs and the environment for extended periods of time. *S.* Choleraesuis has been shown to persist for at least 3 months in wet feces and 6 months in desiccated feces.

The influence of antibiotics on the frequency and duration of shedding of salmonellae in pigs has received little attention. In human enteric salmonellosis, the use of antibiotics has long been recognized to prolong the carrier state (Aserkoff and Bennett 1969; Dixon 1965). In pigs with enterocolitis, antibiotics do not reduce the duration or the magnitude of fecal shedding, but neither are they reported to prolong or intensify shedding (Degeeter et al. 1976; Finlayson and Barnum 1973; Gutzmann et al. 1976; Jacks et al. 1988; Jones et al. 1983; Wilcock and Olander 1978). In contrast, vigorous antibacterial therapy early in the course of septicemia caused by *S.* Choleraesuis may significantly reduce the magnitude and duration of fecal shedding (Jacks et al. 1981).

Pathogenesis

The clinical and pathological features of *Salmonella* infections are extremely variable. Severity is influenced by serotype, virulence, natural and acquired host resistance, and route and quantity of the infective dose. Over 200 virulence factors have been associated with salmonellae, but few have been completely characterized. Generally, those that promote virulence in pathogenic salmonellae are involved in adhesion, invasion, cytotoxicity, and resistance to intracellular killing, often working in combination to promote disease.

Although large doses (greater than 10^7 microbes) are required to induce disease experimentally, intraluminal replication may be important with small inocula. Disease is facilitated by factors such as peristaltic impairment, interference with intestinal flora, and elevation of gastric pH (Clarke and Gyles 1993). Replication to about 10^7 organisms per gram of intestinal content is required for lesion production in pigs infected with *S.* Typhimurium, a finding that probably also applies to other serotypes causing enterocolitis. Alterations in normal intestinal defenses by antibiotic-induced changes in normal flora or cold-induced alteration in intestinal motility may reduce the amount of replication required for disease or increase the ease of *Salmonella* replication (Bohnhoff et al. 1954).

The ability to invade is a requirement for pathogenesis and is encoded by a serotype-specific plasmid (Helmuth et al. 1985). Removal of this plasmid results in a lack of ability to invade but has no effect on ingestion or killing by murine macrophages, LPS production, or serum resistance (Gulig and Curtiss 1987). During the invasion process there is induction of synthesis of new proteins that enhance intracellular survival (Finlay et al. 1989). While many epithelial cell types (enterocytes, M cells, goblet cells) in the jejunum and ileum may be invaded, the predominant portal of entry into the submucosa may occur at Peyer's patches (Meyerholz et al. 2002; Meyerholz and Stabel 2003; Schauser et al. 2004). *S.* Choleraesuis locates preferentially in the colon on the luminal surface of ileal M cells of Peyer's patches (Pospischil et al. 1990). Invasion into M cells appears to be the preferred route given the shorter glycocalyx that coats these cells. Attachment of the bacteria to epithelial receptors triggers microfilament-controlled uptake, vacuole formation, vacuole transport through the cell cytoplasm, and entry into the lamina propria via exocytosis through the basement membrane (Takeuchi 1967; Takeuchi and Sprinz 1967). Passage through the epithelium causes mild and transient enterocyte damage. Salmonellae can synthesize over 30 proteins that are selectively induced during infection of macrophages, making them facultative intracellular bacteria (similar to *Brucella*, *Mycobacterium*, and *Listeria* species) that can survive within macrophages and neutrophils in the lamina propria (Roof et al. 1992a,b). Spread to mesenteric lymph nodes is rapid, occurring within 2 hours of inoculation of ligated intestinal loops or 24 hours after oral challenge (Reed et al. 1985, 1986). Knockout mice ($CD18^-$) have been used to show that $CD18^+$ phagocytes are important in the dissemination of the organism to the spleen and liver (Vazquez-Torres et al. 1999). Two leading cell candidates for this systemic transport are macrophages and dendritic cells (Vazquez-Torres et al. 2000). Recent *in vitro* work has suggested that dendritic cells are capable of producing tight junction proteins to penetrate the epithelium and sample luminal bacteria including *Salmonella* (Rescigno et al. 2001). Concurrent with bacillary spread is the appearance of an acute predominantly macrophagic inflammatory reaction and prominent microvascular damage with thrombosis within the lamina propria and submucosa. Non-enteric routes of systemic invasion may be important since *S.* Choleraesuis demonstrated primary colonization of the lung within 4 hours after intranasal administration to esophagostomized pigs (Fedorka-Cray et al. 1995; Gray et al. 1995).

Early intestinal inflammation is considered a key feature of pathogenesis for enteric forms of salmonellosis. Neutrophil recruitment and transmigration across the epithelium is considered the most significant component (McCormick et al. 1995). Host-derived caspase-1 can act as a proinflammatory agent by cleaving interleukin-1 beta and interleukin-18 into active molecules (Fantuzzi and Dinarello 1999). SipA, a protein that *Salmonella* injects into host cells, has also been shown to contribute to the inflammatory response by activation of phospholipase C (Lee et al. 2000). *Salmonella*-induced activation

of inflammatory mediators such as nuclear factor-kappa B and phosphokinase C results in basolateral secretion of interleukin-8 and apical secretion of pathogen-elicited epithelial chemoattractant (Eaves-Pyles et al. 1999; Lee et al. 2000). These molecules act as chemokines promoting the transepithelial migration of neutrophils into the intestinal lumen (Gewirtz et al. 1999). In contrast, several studies using rabbits, monkeys, calves, or pigs have demonstrated fluid secretion independent of mucosal necrosis or inflammation (Clarke and Gyles 1987; Giannella et al. 1973; Kinsey et al. 1976; Rout et al. 1974). These studies present evidence that, at least early in the disease, diarrhea is the result of decreased sodium resorption and increased chloride secretion due to cholera-like and Shiga-like enterotoxins. Secretion stimulated by prostaglandins elaborated by endotoxin-stimulated neutrophils may also be important (Stephen et al. 1985). Toxic effects of certain *Salmonella* outer membrane proteins, as well as lipid A associated with the LPS, are also important mediators of cell damage. Survival within phagocytes is an important attribute of virulent salmonellae, the mechanism of which is not clear. Salmonellae that possess smooth LPS, O side chains, and a complete LPS core are more resistant to phagocyte killing.

Mucosal inflammation and necrosis, as well as septicemia, occur in concert with the diarrhea but perhaps independently of this response. Microvascular thrombosis and endothelial necrosis in the submucosa and lamina propria are consistent early lesions in porcine salmonellosis (Brown et al. 2007; Lawson and Dow 1966; Reed et al. 1986; Wilcock et al. 1976), probably in response to locally produced endotoxin. Salmonellae are not directly associated with the damaged vessels but direct the events from the protected intracellular niche of macrophages in the surrounding submucosa or lamina propria (Takeuchi and Sprinz 1967). Mucosal ischemia as a result of the microvascular thrombosis is probably a major contributor to the mucosal necrosis so typical of salmonellosis in all species. The second major contribution to mucosal necrosis is probably from the chemical products of mucosal inflammation. The systemic signs and lesions of septicemic salmonellosis are most commonly attributed to endotoxemia from bacterial dissemination. The complex biology of endotoxin is beyond the scope of this chapter, and readers should consult Cybulsky et al. (1988), Elin and Wolff (1976), or Wolff (1973). Briefly, endotoxin initiates inflammation and fever. Most of the effects are mediated by interleukin-1, a lymphokine produced by macrophages stimulated by the endotoxin (Rubin and Weinstein 1977). Endotoxins have either direct effects on tissue or effects via an array of cytokine mediators that are likely a result of interactions with Toll-like receptor 4 (McGettrick and O'Neill 2010).

Clinical signs

Salmonella typhimurium and the *S.* I 1,4,[5],12 : i:- Variant

Clinical signs of *S.* I 1,4,[5],12 : i:- infection in swine are essentially indistinguishable from those of *S.* Typhimurium. The initial clinical sign in pigs is watery yellow diarrhea initially without blood or mucus. The disease may spread rapidly to involve most pigs in a pen within a few days. The initial diarrhea in an individual pig usually lasts 3–7 days, but it typically may recur for second and third bouts, giving the impression of a waxing and waning diarrheal disease of several weeks' duration. Blood may appear sporadically in the feces but rarely with the profuseness typical of swine dysentery or hemorrhagic porcine proliferative enteropathy. Affected pigs are febrile, have decreased feed intake, and are dehydrated, paralleling the severity and duration of the diarrhea. Mortality usually is low and occurs only after several days of diarrhea, presumably as the result of hypokalemia and dehydration. Most pigs make complete clinical recovery, but a portion may remain as carriers and intermittent shedders for at least 5 months. A few pigs may remain unthrifty and chronically waste. Occasional pigs may develop rectal strictures, resulting in obstipation and marked distension of the abdomen. Rectal strictures have been ascribed to defective healing of ulcerative proctitis caused by *S.* Typhimurium (Wilcock and Olander 1977a,b). The stricture reportedly represents fibrosis in an area of persistent ischemia, with the rectum predisposed because of a normally precarious blood supply.

Salmonella choleraesuis

Septicemic salmonellosis caused by *S.* Choleraesuis is most often observed in weaned pigs less than 5 months of age but may be seen occasionally in market swine, suckling piglets, or adult breeding stock. Clinical signs observed are initially from generalized sepsis and later may be from localization in one or more organs/systems. Initially affected animals are inappetent, lethargic, and febrile with temperatures of 40.5–41.6 °C (105–107 °F) and may have a shallow, moist cough with slight expiratory dyspnea. Icterus may be apparent. The first evidence of disease may be finding pigs reluctant to move, huddled in the corner of a pen, or even dead, with cyanosis of extremities and abdomens (Figure 59.1). Diarrhea is not usually a feature of septicemic salmonellosis until the third or fourth day of disease, when watery yellow feces may be seen. Infrequently, nervous signs may be observed that resemble *Streptococcus suis* meningitis, classical swine fever, or pseudorabies (Reynolds et al. 1967; van der Wolf et al. 2001; Wilcock and Olander 1978) as a

Figure 59.1 *Salmonella* Choleraesuis. Lethargic, gaunt, and cyanotic extremities. *Source:* Courtesy of Dr. Greg Stevenson.

result of necrotizing and histiocytic vasculitis leading to encephalitis and/or meningitis. In pregnant sows, abortions may be observed. In most outbreaks, the case fatality rate is high, while morbidity is variable but is usually less than 10%. The duration of the disease in individual pigs, as well as the duration and severity of each epidemic, is unpredictable but will be prolonged without successful intervention.

Other serotypes

Salmonella Typhisuis is an infrequent cause of chronic diarrhea and wasting with characteristic caseating lesions in affected pigs. *S.* Heidelberg has been infrequently associated with outbreaks of acute watery diarrhea in weaned pigs. *S.* Dublin and *S.* Enteritidis rarely cause nervous signs in suckling pigs as a consequence of suppurative meningitis.

Lesions

Salmonella typhimurium

The most consistent gross lesion in pigs suffering from *S.* Typhimurium is enterotyphlocolitis most often involving the ileum, cecum, and spiral colon and occasionally extending to involve the descending colon and rectum. Affected segments typically have thickened edematous walls, and the mucosa is red and roughened with a granular appearance and may have multifocal or coalescing erosions and ulcers that are covered with adherent gray-yellow fibrinonecrotic debris (Figure 59.2). Sharply delineated deep button ulcers may be observed in more chronic lesions (Figure 59.3). Mesenteric lymph nodes, especially ileocecal nodes, are consistently markedly enlarged, congested, and moist (Figure 59.4). Stomach and intestinal contents are usually scant and bile stained.

Figure 59.2 *Salmonella* Typhimurium. Spiral colon. Thickened turgid wall and hyperemic and thickened mucosa with adherent yellow-tan fibrinonecrotic exudate. Lesions are typical of acute colitis caused by *S.* Typhimurium, *S.* I 1,4,[5],12 : i:-, and *S.* Choleraesuis. *Source:* Courtesy of Dr. Darin Madson.

Figure 59.3 *Salmonella* Choleraesuis. Spiral colon. Multifocal-to-coalescing well-demarcated "button" ulcers covered by yellow fibrinonecrotic exudate. Lesions are typical of chronic colitis caused by *S.* Choleraesuis, *S.* Typhimurium, and *S.* I 1,4,[5],12 : i:-. *Source:* Courtesy of Dr. Greg Stevenson.

Often cecal and colonic contents contain black or sand-like gritty material. Of note is that the ileal mucosa in uncomplicated cases of *S.* Typhimurium is usually reddened and slightly roughened with occasional adherent fibrin. It should not be confused with the markedly thickened and necrotic ileal mucosa that was observed in the historic condition known as "necro" and is now known to most commonly be a sequel to proliferative enteropathy (see Chapter 59). Rarely, there is a stricture in the intrapelvic rectum associated with mural fibrosis and distension of the more proximal colon (and sometimes small intestines) with impacted feces.

Microscopic lesions are most consistent in the cecum and spiral colon but may be also in the ileum, descending colon, and rectum and include focal to diffuse necrosis of

Figure 59.4 *Salmonella* Choleraesuis. Mesenteric lymph node is congested, moist and enlarged typical of *S*. Choleraesuis, *S*. Typhimurium, and *S*. I 1,4,[5],12 : i:-. *Source:* Courtesy of Dr. Greg Stevenson.

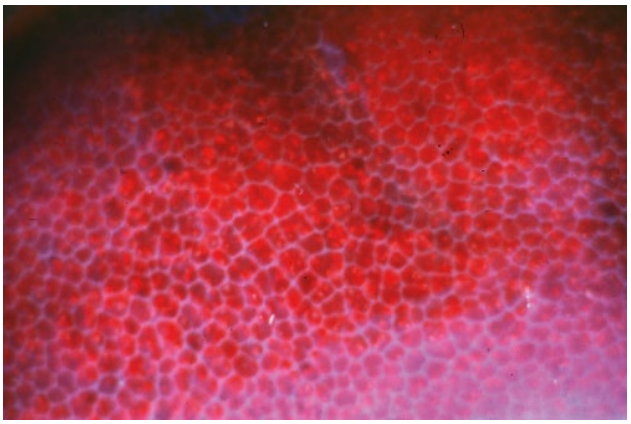

Figure 59.5 *Salmonella* Choleraesuis. Capsular surface of the liver. Visible through the capsule amid the normal lobular pattern of the porcine liver are many small variably sized white-to-pink foci of hepatic parenchymal necrosis. *Source:* Courtesy of Dr. Greg Stevenson.

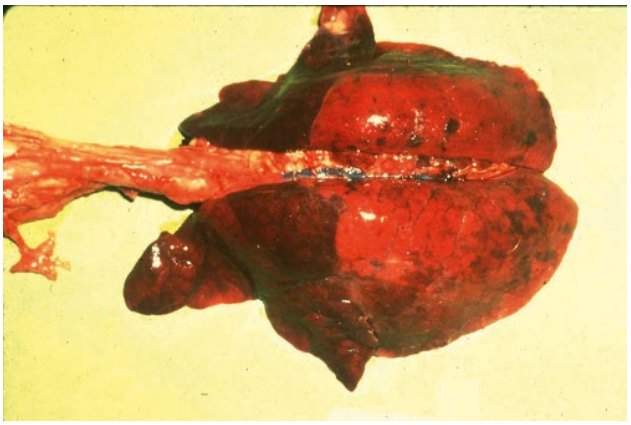

Figure 59.6 *Salmonella* Choleraesuis. Dorsal caudal lung is slightly firm, moist, resilient, and non-collapsing and has interlobular hemorrhagic edema and multifocal ecchymoses typical of acute *S*. Choleraesuis-induced interstitial pneumonia. Cranial ventral lung is dark purple, firm, and non-collapsing with focal fibrinous pleuritis, typical of subacute *S*. Choleraesuis-induced bronchopneumonia. *Source:* Courtesy of Dr. Greg Stevenson.

crypt and surface epithelial cells. The lamina propria and submucosa are typically infiltrated first by neutrophils followed by predominantly macrophages and fewer lymphocytes by the second day. Fibrin thrombi are frequently observed in capillaries of the lamina propria and are less frequent in larger vessels in the submucosa. Necrosis, likely a sequel to infarction, sometimes extends through the mucosa into the submucosa and lymphoid patches, creating grossly visible ulcers. Fibrinonecrotic debris that may contain myriad opportunistic bacteria and numerous *Balantidium coli* organisms is often adherent to the luminal surface of damaged epithelium. Submucosal lymphoid patches may be necrotic in acute disease, but later in pigs dying of the naturally occurring disease, lymphoid hypertrophy or even regenerative hyperplasia is more common. Regional lymph nodes are typically edematous and contain neutrophils acutely and predominantly macrophages by day 2–3 in sinuses. In some nodes, there may be focal necrosis. More complete discussions of lesions are available (Brown et al. 2007; Wilcock et al. 1976).

Salmonella choleraesuis

Gross lesions in pigs dying in the acute phase of septicemia include cyanosis of ears, feet, tail, and ventral abdominal skin (Figure 59.1). Lymph nodes, especially the gastrohepatic and mesenteric, are typically enlarged, moist, and congested (Figure 59.4), and the spleen is enlarged, dark purple, and pulpy. The liver may be slightly enlarged with scattered small 1–2 mm foci of parenchymal necrosis (Figure 59.5), and the wall of the gallbladder may be thickened and edematous. There are often renal cortical petechia and ecchymoses. Acute interstitial pneumonia evidenced by moist, slightly firm, resilient non-collapsing lungs that often have red (hemorrhagic) fluid separating lobules is usually observed (Figure 59.6). The gastric mucosa is often markedly congested. Additionally, in pigs that survive a few days, there may be infarction of the skin on the tips of ears that appears dry and dark purple, sometimes with portions that slough (Figure 59.7). Icterus is inconsistently severe. Bronchopneumonia may be observed as consolidation of cranial ventral lungs with purulent exudate in airways (Figure 59.6). The gastric fundic mucosa may be infarcted, appearing dark purple. Enterocolitis may be present and is identical to that described for *S*. Typhimurium (Figures 59.1 and 59.2).

Microscopic lesions are extensive and involve many organs. The most unique and diagnostic lesions are randomly scattered foci of coagulative necrosis in the liver

Figure 59.7 *Salmonella* Choleraesuis. Cyanosis of the skin on the snout, shoulders, and legs with ischemic necrosis of skin on the ears evidenced by dark purple-black discoloration. *Source:* Courtesy of Dr. Greg Stevenson.

that are variably infiltrated with neutrophils and histiocytes (Lawson and Dow 1966), so-called paratyphoid nodules. Similar coagulative necrosis may be randomly scattered in spleen or observed in lymph nodes. Other lesions typical of salmonellosis include fibrinoid thrombi in venules of gastric mucosa, in cyanotic skin, in glomerular capillaries, and less regularly in pulmonary vessels. There is hyperplasia of reticular cells of spleen and lymph nodes as well as generalized swelling of endothelial cells and histiocytosis typical of gram-negative sepsis. Diffuse histiocytic interstitial pneumonia or suppurative bronchopneumonia is often observed. Segmental necrotizing vasculitis with perivascular histiocytic infiltrates, sometimes with localized necrotizing encephalitis, is uncommonly observed. Lesions in small and large intestines are the same as for *S.* Typhimurium and are described below. More complete discussions of the pathology of septicemic salmonellosis are available (Brown et al. 2007; Lawson and Dow 1966).

Other serotypes

Lesions observed in wasting pigs infected with *S.* Typhisuis are characteristic (Andrews 1976; Barnes and Bergeland 1968; Fenwick and Olander 1987). Chronic ulcerative colitis is observed with deep multifocal-to-coalescing mucosal ulcers that have caseous necrotic material in their centers. Likewise, regional lymph nodes are enlarged and contain caseous necrotic debris, forming the base. Bronchopneumonia with caseous abscesses, resembling tuberculosis, may also be observed.

Lesions in weaned pigs with diarrhea associated with *S.* Heidelberg are mild or absent. Small and large intestines are typically fluid filled, and the mucosa may have sparse to moderate amounts of adherent mucus. In the few reports of nervous disease in suckling pigs infected with *S.* Dublin or *S. Enteritidis*, the leptomeninges are distended by fibrin and aggregates of neutrophils and fewer macrophages.

Diagnosis

Clinical signs and lesions may lead to a presumptive diagnosis of salmonellosis, but are insufficient for confirmation given the number of other diseases that resemble the various forms of salmonellosis. The clinical signs observed with *S.* Choleraesuis are similar to other septicemias such as caused by *Erysipelothrix rhusiopathiae* (Chapter 53), *S. suis* (Chapter 61), or *Actinobacillus suis* (Chapter 48) or to those observed with classical swine fever (Chapter 39). Lesions in lungs may resemble those of or *Actinobacillus pleuropneumoniae* (Chapter 48). Gross lesions of splenomegaly, hepatomegaly, lymphomegaly, interstitial pneumonia, and focal hepatic necrosis are very suggestive of septicemia by *S.* Choleraesuis, but are not seen in every case and closely resemble lesions of classical swine fever.

Likewise the differential diagnosis of diarrhea in weaned pigs, in addition to *S.* Typhimurium and *S.* I 1,4,[5],12 : i:-, should include swine dysentery (Chapter 62), proliferative enteropathy (Chapter 58), rotaviruses (Chapter 43), coronaviruses (Chapter 31), circovirus type 2 (Chapter 30), colibacillosis (Chapter 52), and trichuriasis (Chapter 67). Combined infections in diarrheal disease are commonplace. Gross lesions in enteric salmonellosis, swine dysentery, and proliferative enteropathy are similar in that all three may present as fibrinonecrotic typhlocolitis. However, presumptive differentiation at necropsy is possible in many cases by recognition of differences in lesion distribution. Salmonellosis is usually in the spiral colon and occasionally small intestine, may be focal or diffuse, may include mucosal ulcers, and always involves marked mesenteric lymphadenopathy. The lesion of swine dysentery is diffuse and shallow (no deep ulceration) and restricted to the cecum and spiral colon. In addition, lymph node enlargement is absent or mild. In proliferative enteropathy, ileal involvement usually overshadows the milder colonic lesions, and the mucosa underlying any fibrinonecrotic exudate is markedly hyperplastic.

The lesions of caseating button ulcers in the spiral colon, caseous lymphadenitis, and bronchopneumonia with caseating abscesses in wasting pigs with chronic diarrhea are strongly presumptive of infection with *S.* Typhisuis. However the intestinal lesions may heal in some pigs, leaving the lymphoid and pulmonary lesions to be distinguished from tuberculosis and infection with *Trueperella pyogenes* (Barnes and Sorensen 1975).

A definitive diagnosis of salmonellosis is confirmed by bacterial culture and identification in conjunction

with demonstration of compatible lesions. The wide distribution of environmental salmonellae and the incidence of subclinical infection and shedding of various *Salmonella* serotypes make culture of intestinal lesions or contents alone unreliable for disease diagnosis. Positive cultural identification should always be supported by appropriate lesions before a diagnosis of salmonellosis is made.

To culture *S.* Choleraesuis from suspected cases of septicemia, samples of lung, liver, or spleen often yield pure cultures of the organism on brilliant green, bismuth sulfite, blood agar, or MacConkey agar. Enrichment techniques are seldom required unless the organs have been contaminated by feces or careless handling or have autolysis, in which case tetrathionate broth at 107.6–109.4 °F (42–43 °C) is the enrichment medium of choice. Selenite broth is inhibitory for *S.* Choleraesuis and should be avoided (Edwards and Ewing 1972). Attempts to isolate salmonellae from animals that have received antimicrobial therapy are often unrewarding. Intestine or feces are not reliable specimens for isolation of *S.* Choleraesuis in pigs with acute septicemia (Schwartz 1991).

In cases of diarrhea in which S. Typhimurium or the I 1,4,[5],12 : i:- variant is suspected, a pool of ileum, colon, and ileocecal lymph node should enable detection of virtually all active or recently recovered cases, although tissues such as tonsil or cecal wall will usually yield positive cultures as well (Wilcock et al. 1976; Wood et al. 1989). From live animals, large (10 g) aliquots of feces or pharyngeal tonsil scrapings are preferable to rectal swabs for isolation, with tetrathionate enrichment the method of choice.

Other tests using more sophisticated technology, including polymerase chain reaction (PCR), are not required for routine diagnosis. PCR currently has value as a screening tool in populations but has a relatively high cost and currently lacks sensitivity without preenrichment. PCR-based detection of salmonellae does not constitute diagnosis of salmonellosis since this assay can detect DNA from dead *Salmonella* and the organism may be present without causing clinical disease.

Serology is becoming increasingly available, usually in the form of an ELISA test. Most tests use surface antigens such as LPS. These tests, some of which use mixed antigens containing both LPS and antigens from several serotypes, thus far appear to lack specificity and sensitivity for individual animal diagnosis but are useful for herd screening (Baum et al. 1996). A mixed ELISA test using meat juice at slaughter to detect antibody to a broad range of serotypes has been useful in categorizing the level of *Salmonella* infection in herds in Denmark (Mousing et al. 1997; Nielsen et al. 1995).

Prevention and control

Prevention

Infection does not necessarily result in disease, and pigs may not sicken with disease until severely stressed long after initial exposure. The control of disease expression rests on efforts to minimize the exposure dose and stress and to maximize pig resistance. Carrier pigs and contaminated feed or environment are the most significant sources of infection to pigs, and pigs are most likely to develop disease during periods of stress or when exposed to massive numbers of salmonellae. The commingling and transport of weanling pigs from different sources to finishing farms enhance activation of latent carriers and ensure exposure of stressed pigs to salmonellae (Allred 1972). The source of host-adapted *S.* Choleraesuis, which is rarely isolated from feed or feed ingredients, would seem to be limited to carrier pigs and facilities previously contaminated with this serotype. The fact that many outbreaks occur in facilities with good sanitation suggests that other stresses probably contribute to occurrence of the disease. Management practices that allow filling of grower and finishing rooms with single-source and single-age pigs are beneficial. Minimizing the variety of stresses often involved in acute outbreaks requires constant attention to details of management and husbandry, including proper animal density, dry, comfortable pens and temperatures, and adequate ventilation. On farms with endemic disease, modifications to the facility and environment as well as implementation of management practices that emphasize all-in/all-out production should precede a prophylactic drug program. Antibiotics are probably useful as aids in preventing occurrence of disease when used prophylactically, but their use will not prevent infection and when relied upon for prevention of disease will eventually fail.

As with other facultative intracellular bacteria, live vaccines that stimulate cell-mediated immunity are the most likely to be protective for salmonellae in swine. Historically, an attenuated live *S.* Choleraesuis vaccine was used widely in the United Kingdom for many years but was withdrawn when *S.* Choleraesuis infection decreased in that country to negligible proportions. Introduction of effective and safe modified live attenuated vaccines for *S.* Choleraesuis has been credited with a major reduction in the occurrence of systemic salmonellosis in North America. The isolates used in these vaccines are either naturally occurring avirulent *S.* Choleraesuis or are derived from repeated passage through porcine neutrophils, the product of which was demonstrated to have been cured of a 50 kb virulence plasmid necessary for intracellular survival (Kramer et al. 1987, 1992; Roof et al. 1992b). When given at weaning, vaccine protected pigs for at least 20 weeks (Roof

and Doitchinoff 1995) against homologous serotypes, with some cross-protection suggested with heterologous serotypes. A vaccine containing *S.* Choleraesuis and *S.* Typhimurium is also available.

Partial protection can be obtained with bacterins, primarily because of the nonspecific mitogenic and immunostimulant effect of LPS (Fenwick et al. 1986) and the immunodominance of *Salmonella* O antigens. Killed vaccines for *S.* Typhimurium are safe, but the bulk of the evidence suggests that they have little efficacy in preventing disease following strong challenge because resistance to disease rests primarily on cell-mediated immunity (Collins 1974; Davies and Kotlarski 1976). Extrapolation of information from experience in humans (Hornick et al. 1970; Welliver and Ogra 1978) and calves (Bairey 1978) suggests, however, that use of a potent killed vaccine may increase the dose necessary to cause disease and may offer some protection from septicemic salmonellosis, in which humoral immunity may play a role.

Monitoring herds for salmonellae has not been commonly practiced. The detection of carrier animals is difficult because of the unpredictability of fecal shedding. The detection of salmonellae by bacterial culture of feces and tonsils of diarrheic pigs in the nursery would likely be the most rewarding for identification of infected herds. However, even repeated negative fecal or tonsillar cultures do not guarantee that a herd or individual is not a *Salmonella* carrier and thus a potential shedder. The use of *Salmonella* serology can determine if an animal has had previous exposure to salmonellae, but this has little relevance to the carrier status or to the probability of shedding. Food safety concerns have stimulated renewed interest in serology as a method to determine the *Salmonella* infection status of groups of market swine. This technology offers the possibility of sensitive and specific methods to identify infected herds, but it is not yet useful for determining the infection status of individual pigs.

Control

With either septicemic or enteric salmonellosis, the goals of treatment in an outbreak of salmonellosis are to minimize the severity of clinical disease, prevent spread of infection and disease, and prevent recurrence of the disease in the herd. With salmonellosis the attainment of these goals is particularly difficult. Salmonellae are often resistant *in vitro* to many antibacterial agents used in swine (Barnes and Sorensen 1975; Blackburn et al. 1984; Krull 2017, unpublished data; Schultz 1989; Schwartz 1997; Wilcock et al. 1976). During clinical disease, the organism inhabits a protected intracellular niche inaccessible to many common antibacterials. The use of various antibiotics to treat enteric salmonellosis is widely advocated (Barnes and Sorensen 1975; Morehouse 1972; Radostits et al. 2007), but much of the information to support this recommendation has been taken from trials designed to test the prophylactic efficacy of drugs, not their therapeutic efficacy. Thus pigs on medicated feed when inoculated orally with salmonellae have the antibiotic already present in the gastrointestinal tract to interact with the salmonellae, resulting in milder disease because of what amounts to a decreased inoculum. In the few trials designed specifically to test antibacterial drug efficacy against clinical enteric salmonellosis, such therapy was considered to have little merit (Gutzmann et al. 1976; Heard et al. 1968; Olson et al. 1977; Wilcock and Olander 1978). Although not therapeutic, oral medications may decrease efficiency of transmission and have a prophylactic effect on pigs not yet affected. Antimicrobials are ordinarily administered at maximum permissible levels in feed or, preferably, water. Ideally, the choice of antibacterial agent should be based on *in vitro* susceptibility testing of isolates from each outbreak. Since medication often must be initiated before such results are available, choices must be based on previous experience and results of controlled trials.

In contrast, vigorous therapy early in the course of septicemia caused by *S.* Choleraesuis has been reported to significantly reduce the duration and severity of disease (Jacks et al. 1981). In that report, therapy was initiated after inoculation but prior to the onset of clinical signs. Evaluation of efficacy under field conditions is difficult because of the unpredictability of the disease and because husbandry changes often accompany the use of antibacterials in an outbreak. Reports and practitioner communications from the American Midwest, however, suggest that visibly affected animals respond to aggressive therapy with parenteral antimicrobials (Schwartz 1991). Mass medication of the population at risk to decrease severity of disease and transmission of salmonellae is also widely practiced. The choice of an appropriate antimicrobial is aided by antibiograms and previous herd experience. In the absence of either, amikacin, gentamicin, apramycin, ceftiofur, and trimethoprim/sulfonamide have been effective *in vitro* against most isolates (Barnes and Sorensen 1975; Mills and Kelly 1986; Schultz 1989; Schwartz 1997; Wilcock et al. 1976). The increase in incidence of ASSuT resistance in *S.* Typhimurium and the *S.* I 1,4,[5],12 : i:- variant increases the need for isolation, identification, and susceptibility testing. Anti-inflammatory agents are sometimes administered to critically ill animals to combat the effects of endotoxin (Schultz 1989; Schwartz and Daniels 1987). Dipyrone was the anti-inflammatory of choice in swine, but this drug is now banned in food-producing animals. Flunixin is approved for use in swine and this drug has potent antiendotoxin effects. Meloxicam is another NSAID that has been used in swine (Pairis-Garcia et al. 2015).

Most *Salmonella* antimicrobial resistance is plasmid mediated. Of concern is the recent emergence of a *S.* Typhimurium definitive type 104 (DT104), isolated primarily from bovine and human populations, that has chromosomally integrated multiple antimicrobial resistance (Low et al. 1997). This isolate has a higher morbidity and mortality in humans than other *S.* Typhimurium organisms and was, until recently, increasing in prevalence in human and bovine populations. Xiong et al. 2010 identified a DT104-like resistance gene cassette in *S.* Choleraesuis exhibiting hypervirulence *in vivo*. However, this isolate has yet to be implicated in field outbreaks of swine salmonellosis. The *S.* I 1,4,[5],12 : i:- variant of *S.* Typhimurium is the result of a full or partial deletion of the fljB gene responsible for expression of flagellar antigen 2 (Foley et al. 2008)

In addition to antimicrobial therapy, the successful treatment of salmonellosis relies heavily on routine husbandry procedures recommended for control of infectious diseases. The diarrheic pig contaminates its environment and is the single most important source of infection for other pigs. Removal and isolation of sick animals, minimizing exposure to infective material by scrupulous pen sanitation, frequent cleaning of water bowls, and restriction of animal or staff movement from potentially contaminated to clean areas are necessary. Efforts to modify management and environment to decrease crowding and stress and increase pig comfort are essential adjuncts to specific therapy.

Staphylococcosis

Timothy S. Frana and Samantha J. Hau

Staphylococci are essentially ubiquitous in pigs and swine facilities. Diseases in pigs are commonly caused by *Staphylococcus hyicus*, the cause of exudative epidermitis (EE), and *Staphylococcus aureus* that causes abscesses and other conditions. Occasionally other staphylococcal species such as *Staphylococcus chromogenes, Staphylococcus epidermidis, Staphylococcus sciuri, Staphylococcus warneri*, and *Staphylococcus xylosus* may be isolated from lesions, but their role as primary pathogens should be assessed with caution.

Staphylococcus hyicus: exudative epidermitis

EE, also known as greasy pig disease, occurs worldwide and is the most common staphylococcal skin disease in swine. EE occurs most frequently and is most severe in pigs from approximately 3–32 days of age where affected pigs develop generalized nonpruritic exudative dermatitis–epidermitis. Affected pigs fail to thrive, and loss of body fluid may lead to dehydration and death. Localized milder forms of EE affecting ear tips, head, flanks, and extremities occur primarily in older animals. *S. hyicus* has also been infrequently associated with polyarthritis and reproductive failure (Duncan and Smith 1992; Hill et al. 1996).

Etiology

Although EE was described nearly 170 years ago by Spinola (1842), it was not until 1953 that the cause was attributed to *Micrococcus hyicus* (Sompolinsky 1953). *M. hyicus* was placed in the *Staphylococcus* genus in 1965 (Baird-Parker 1965) and was later divided into subspecies *S. hyicus* and *S. chromogenes* (Devriese et al. 1978). Elevation in 1986 of *S. hyicus* subsp. *chromogenes* to *S. chromogenes* resulted in *S. hyicus* as a singular species (Hajek et al. 1986). *S. hyicus* is a gram-positive coccus. Colonies of *S. hyicus* on blood agar appear non-hemolytic, creamy white, convex, and circular. Biochemically, *S. hyicus* is catalase positive, oxidase negative, and Voges–Proskauer negative. *S. hyicus* produces DNase, phosphatase, hyaluronidase, gelatinase, and lecithinase. Some strains produce coagulase that is enhanced by porcine plasma (Lammler 1991). Aerobic fermentation of fructose, glucose, lactose, mannose, and trehalose occurs with most strains (Lammler 1991). A small zone of hemolysis occurs on chocolate agar, and a CAMP-like zone of complete lysis in the zone of incomplete lysis of the staphylococcal beta-lysine occurs on sheep blood agar (Lammler 1991). Expression of protein A-like receptors for IgG is common in porcine strains (Lammler 1991). Although *S. hyicus* does not form spores, it is resistant to drying and can remain viable in the environment for long periods.

Strains of *S. hyicus* vary in virulence. Virulence is closely associated with the production of exfoliative toxins (Andresen et al. 1997; Futagawa-Saito et al. 2007; Sato et al. 1991b; Wegener et al. 1993). At least six exfoliative toxins – ExhA, ExhB, ExhC, ExhD, ShetA, and ShetB – are described in *S. hyicus* strains from diseased pigs (Ahrens and Andresen 2004; Andresen 1998; Andresen et al. 1997; Leekitcharoenphon et al. 2016; Sato et al. 2000; Watanabe et al. 2000). These toxins target epidermal cells of the stratum granulosum and stratum spinosum. Prevalence studies indicate that toxigenic *S. hyicus* is found more commonly from EE-affected pigs than healthy pigs (Andresen 2005; Kanbar et al. 2008). However there was no clear pattern as to which toxins are most common in strains causing EE, and regional differences apparently exist.

Several other virulence factors are described for *S. hyicus*. A homologue of *S. aureus* protein A with multiple binding sites for IgG helps the bacterium resist phagocytosis (Rosander et al. 2011). Coagulase aids in the formation of a fibrin clot that can protect the *S. hyicus* from host defenses. Surface fibronectin-binding proteins are

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

likely important in bacterial adhesion to fibronectin (Lammler et al. 1985). Additionally *S. hyicus* produces staphylokinase and excretes lipase that cleave proteins and phospholipids, respectively. The exact role of these factors in enhancing virulence is unclear.

Certain strains of staphylococcal species other than *S. hyicus* appear capable of causing EE in pigs. A strain of *S. sciuri* carrying the ExhC exfoliative toxin gene was reportedly isolated from a diseased piglet with EE (Chen et al. 2007). A toxin similar to ExhB was also identified in a strain of *S. chromogenes*, and this strain was able to induce clinical signs of EE in experimentally inoculated pigs (Andresen et al. 2005). Additionally, methicillin-resistant strains of *S. aureus* have been associated with EE (van Duijkeren et al. 2007). Whether these findings represent emerging EE pathogens or isolated instances of non-*S. hyicus*-induced EE has yet to be determined.

Virulent and avirulent strains of *S. hyicus* can be found on the skin of EE-affected animals as well as healthy pigs (Devriese 1977; Park 1986; Wegener et al. 1993), indicating that cofactors in addition to strain virulence are required for expression of disease.

Public health

Staphylococcus hyicus causes no disease in humans.

Epidemiology

Staphylococcus hyicus is distributed globally and infects most pig herds. In the United States it was reported to cause sickness or mortality in 27.5% of sites with nursery-age pigs (USDA 2007) and 16.5% of pig herds in the United Kingdom (Taylor 2004). *S. hyicus* is considered normal bacterial flora on the skin of adult swine and is present in many herds without causing disease. It can be recovered from multiple skin sites on healthy pigs (Hajsig et al. 1985), most commonly from young pigs, and from the environment in swine facilities of infected herds. Infected pigs are the nearly exclusive source of infection for uninfected individuals and herds. Although *S. hyicus* has been isolated from cattle, goats, horses, and chickens (Birgersson et al. 1992; Devriese et al. 1983; Jarp 1991; Kibenge et al. 1983; Myllys 1995; Takeuchi et al. 1985), these animal species are not considered sources of *S. hyicus* for pigs. Species-specific differences in *S. hyicus* apparently render these strains incapable of causing EE in pigs (Devriese et al. 1978; Shimizu et al. 1987, 1997; Takeuchi et al. 1987).

Transmission is primarily by direct contact and can be lateral, between pigs in the same cohort, or vertical by contact of suckling pigs with their infected dam. Vertical transmission may also occur at birth as pigs contact *S. hyicus* while transiting an infected vagina. *S. hyicus* strains isolated from the skin of piglets within 24 hours after birth were the same type as their dams and identical to strains isolated from the same litter 3 weeks later (Wegener and Skov-Jensen 1992).

Expression of disease in herds infected with virulent strains of *S. hyicus* varies and is impacted by the interaction of other cofactors of disease. These include immune status, genetic susceptibility, and a variety of other factors that have in common damage to the epidermis. These include physical, chemical, or solar trauma, viral infections, ringworm, pityriasis rosea, ectoparasitism, and excessive moisture via poor hygiene or poor ventilation.

Inadequate or absent maternal immunity is likely the most important cofactor in the majority of outbreaks that commonly occur in pigs under 8 weeks of age. EE is observed more frequently in piglets born to gilts in start-up herds or born to gilts introduced to an infected herd or environment without adequate time to develop immunity prior to farrowing. Entire litters or cohorts may be affected with high mortality. In contrast, offspring from infected carriers or animals where *S. hyicus* is endemic are generally unaffected, suggesting transfer of protective maternal immunity. Outbreaks are usually self-limiting and generally last 2–3 months but may persist for 12–18 months. Cessation is likely due to development of acquired immunity in a majority of dams prior to farrowing.

The cofactors operative in outbreaks of EE in older animals in endemically infected herds, presumed to have maternal or acquired immunity, are often less certain. Limited outbreaks may occur when colonization by *S. hyicus* coincides with decay of maternal immunity. In most of these outbreaks, damage to the epidermis by one or more of the aforementioned factors allows virulent strains of *S. hyicus* to penetrate to deeper layers of the epidermis beyond the superficial stratum corneum where it colonizes. Common causes include trauma due to fighting and persistent skin moisture due to poor ventilation and/or hygiene. Epizootic or limited endemic infection with certain viruses that damage skin has also been implicated including porcine parvovirus (Kresse et al. 1985; Whitaker et al. 1990), porcine circovirus 2 (Wattrang et al. 2002), or both (Kim and Chae 2004). Ages and numbers of animals with epidermis so damaged by predisposing cofactors determine the extent of the EE outbreak. In summary, development of EE likely involves interplay of immune status, prior exposure, nutrition, housing conditions, and commitment disease, combined with strain virulence and skin entry site.

Pathogenesis

Exudative epidermitis, as the name implies, is primarily a disease of the epidermis. The epidermis wraps the body in an effective barrier to microbial invasion and fluid

transit, preventing dehydration or overhydration from the ambient environment. The outer layer of the epidermis most responsible for these functions is the stratum corneum. The stratum corneum is composed of dead keratinocytes, essentially bricks of the fibrous protein keratin that are bonded together by a complex hydrophobic lipid mortar. The tensile strength of the epidermis is due to a variety of intercellular adhesive structures, most importantly desmosomes, in the stratum spinosum and stratum granulosum. *S. hyicus* colonizes the surface of the stratum corneum, likely aided by secretion of staphylokinase and lipase that cleave proteins and phospholipids, respectively. Although *S. hyicus* may directly penetrate the skin, a breach of the stratum corneum by one or more cofactors is the most common inciting factor for EE in susceptible pigs. Once *S. hyicus* gains access to the underlying stratum granulosum and stratum spinosum, secreted exfoliative toxins cause extensive damage, enabling *S. hyicus* to proliferate within the epidermis, causing extensive damage.

Exfoliative toxins are the most important virulence factor in the development of EE in pigs. In 1979, Amtsberg demonstrated that a culture filtrate of *S. hyicus* could cause exfoliation in the skin of piglets and suggested this was due to exotoxin production. So far six exfoliative toxins have been identified in *S. hyicus*: EhA, EhB, EhC, EhD, SHETA, and SHETB (Ahrens and Andresen 2004; Andresen 1998; Andresen et al. 1997; Sato et al. 2000; Watanabe et al. 2000). Toxins EhA–EhD and SHETB are similar to serine proteases ETA, ETB, and ETD that are produced by *S. aureus* and cause staphylococcal scalded skin syndrome and bullous impetigo in humans (Ahrens and Andresen 2004). The target for this group of toxins is desmoglein (Dsg1), a component of desmosomes (Fudaba et al. 2005). Cleavage of extracellular domains of Dsg1 leads to cell separation in the stratum granulosum and stratum spinosum, exfoliation of the outer layers of the epidermis, and serous exudation. Subcutaneous injection of purified exfoliative toxins from *S. hyicus* caused exfoliation in piglets and chickens (Sato et al. 1991a; Tanabe et al. 1993). Additionally, piglets experimentally inoculated with toxin-producing strains of *S. hyicus* developed local erythema, exfoliation, exudation, and crusting, while those inoculated with non-toxin-producing strains developed only local erythema that disappeared within 48 hours (Tanabe et al. 1996).

Dissolution of desmosomes in the stratum granulosum causes clefts that soon fill with serum filtrates and neutrophils, resulting in subcorneal vesicles, pustules, and erosions. As bacteria multiply, desmosomes are dissolved deeper in the stratum spinosum, and greater inflammation is induced, resulting in dermal and epidermal edema, intraepidermal leukocytosis, and exudation on skin surfaces. The loss of fluids and electrolytes leads to dehydration and death in severely affected piglets. Older animals may develop subcutaneous abscesses, polyarthritis, and necrosis of the ears and tail.

Clinical signs

Disease is most severe with highest mortality when in young suckling pigs. Piglets as young as 3–4 days may develop severe acute EE. Red glistening moist areas of the skin are first observed on the head and on non-haired skin on the medial aspect of legs. Ulcers may develop on the tongue or in the mouth (Andrews 1979). Lesions rapidly spread to the ventral abdomen, coronets, and then the entire body within 24–48 hours. Pigs are listless and anorexic, but are not pruritic and do not have elevated body temperature. The affected skin is soon covered by a thick tenacious brown crust. Some pigs can die within 24–48 hours. Others survive longer; the skin becomes thickened and wrinkled, and the crust dries and cracks. In the deep portion of the wrinkles, the skin is moist and red. Protracted anorexia results in weight loss. Death usually follows in 3–10 days.

A less severe localized more protracted form of disease that is less often fatal occurs when onset is in older, usually recently weaned pigs. Skin lesions are less severe and often confined to the head and consist of erythema and waxy brown exudate. Affected pigs suffer reduced weight gains relative to peers. In some pigs, lesions may generalize and result in fatality. In others, recovery may require several weeks. Adult swine occasionally have a few brown exudative lesions on the back and flanks, usually unrelated to outbreaks in younger pigs. Other reported outcomes of *S. hyicus* infection include polyarthritis (Hill et al. 1996) and abortion (Duncan and Smith 1992).

Lesions

Gross lesions begin most commonly around eyes, mouth, and ears, in axilla and groin, and in areas of trauma. The affected skin is first erythematous and moist, having a scalded appearance. Lesions spread and coalesce, and exudate quickly accumulates as a greasy brown film, then as bacteria and dirt accumulate, a thick malodorous brown crust forms (Figures 60.1 and 60.2). Below the crusty layer, the skin is erythematous and/or grossly thickened and wrinkled. At necropsy, dehydration and emaciation are evident. There may be linear streaks on renal papillae and accumulation of cellular debris in the ureters and pelvis of kidneys. Lymph nodes draining the skin are swollen and edematous.

Microscopically, subcorneal vesicle and pustules that may extend to include follicular infundibula are the earliest lesions. As lesions progress, there are spongiosis, increased numbers of intraepithelial leukocytes, spongiotic pustules, and accumulation of crust composed of

Figure 60.1 Generalized exudative epidermitis in a 3-week-old piglet. *Source:* Courtesy of Dr. Bruce Janke.

serum, exfoliated stratum corneum, large numbers of neutrophils, necrotic cellular debris, and large numbers of staphylococci. The dermis is expanded by edema, perivascular-to-generalized neutrophilic accumulations, and congested vasculature. As lesions become chronic, orthokeratosis and parakeratosis contribute to a thickened crust, generalized epidermal proliferation results in acanthosis and generalized epidermal thickening, and cellular infiltrates in the dermis transition to predominantly histiocytes, lymphocytes, and plasma cells. In addition to lesions in the skin, suppurative lymphadenitis in subcutaneous lymph nodes and renal lesions are common. Acute renal lesions are likely due to damage by excreted exfoliative toxins of *S. hyicus* on tubular and transitional epithelial cells. Cells lining collecting ducts and the renal pelvis become vacuolated and are later shed, sometimes forming casts that obstruct tubules in the renal pelvis or, in severe cases, the ureters (Blood and Jubb 1957). Purulent pyelonephritis can also develop in pigs with EE that are bacteremic.

Diagnosis

Clinical signs and lesions are characteristic if not pathognomonic for EE in young piglets. Diagnosis of EE in adults or animals with local lesions secondary to trauma is more difficult. Confirmation requires demonstration of typical microscopic lesions and isolation of *S. hyicus* or rarely *S. aureus*, *S. chromogenes*, or *S. sciuri*. Isolation of *S. hyicus* during outbreaks is important for antimicrobial susceptibility testing. Ideal samples for culture are swabs of moist, affected areas of skin taken after removing the overlying crust and enlarged superficial lymph nodes in areas of affected skin.

Staphylococcus hyicus grows well on sheep or bovine blood agar; however, secondary organisms such as *Pseudomonas*, *Proteus*, and other *Staphylococcus* species may also be isolated from EE lesions. Selective media containing potassium thiocyanate (Devriese 1977) or less than 10% NaCl may aid isolation. *S. hyicus* can be identified by using conventional biochemical tests or panel identification systems or by matrix-assisted laser desorption/ionization time of flight (MALDI-TOF). Toxigenic and nontoxigenic strains can be isolated from the same lesion. A method of phage typing *S. hyicus* has been described, which aids in differentiating virulent from avirulent strains (Wegener 1993). An indirect ELISA test for detection of toxins ExhA, ExhB, and ExhC was developed as an alternative to phage typing (Andresen 1999). Additionally identification and toxin profiling with polymerase chain reaction and dot blot hybridization is possible (Andresen and Ahrens 2004; Onuma et al. 2011; Voytenko et al. 2006). However tests for toxin identification are not in widespread use in veterinary diagnostic laboratories.

Other skin diseases may look similar to EE. Swinepox (Chapter 42) has localized lesions and is rarely fatal. Mange (Chapter 65) is pruritic, and mites can be demonstrated in skin scrapings. Ringworm (Chapter 17) has typical expanding superficial lesions in which dermatophytes can be demonstrated by culture or microscopic examination. Pityriasis rosea (Chapter 17) has expanding nongreasy erythematous circular lesions and is self-limiting and nonfatal. Zinc deficiency (Chapter 68) causes parakeratosis that appears as symmetrical dry lesions in 2- to 4 month-old pigs. Finally, dermatosis vegetans (Chapter 17) is a rare inherited disease in Landrace, which also causes a fatal pneumonitis.

Treatment and prevention

Early treatment following onset of disease provides best chance of success, but severely affected animals may not

respond. Antimicrobial drugs are commonly used to treat EE. However, reports indicate that *S. hyicus* is resistant to many antimicrobial agents (Aarestrup and Jensen 2002; Park et al. 2013a; Teranishi et al. 1987; Wegener et al. 1994; Werckenthin et al. 2001). A study comparing antimicrobial susceptibility profiles of toxigenic and nontoxigenic *S. hyicus* isolates concluded that there was not a significant correlation between toxin gene carriage and antimicrobial resistance (Futagawa-Saito et al. 2009). Although regional differences exist, resistance to penicillin, erythromycin, streptomycin, sulfonamides, and tetracycline is a frequent occurrence. In addition, genetic elements conferring methicillin and zinc resistance have been reported in *S. hyicus* (Park et al. 2013b; Slifierz et al. 2014). Therefore antimicrobial susceptibility testing of isolates recovered from EE lesions is recommended to provide evidence of the appropriate treatment. In the absence of drug susceptibility results, ceftiofur, enrofloxacin, and combination of trimethoprim/sulfamethoxazole and lincomycin are best choices. Injection of the antimicrobial is recommended, but it may be given orally in less severe cases. Other treatments include spraying the pigs several times with skin disinfectants such as novobiocin in mineral oil, chlorhexidine, Virkon® (Durvet), or dilute tamed iodine. Fluid and electrolyte replacement is important in severely affected piglets and may be administered orally.

Cross-suckling of gilt piglets with older sows may provide some passive protection. Alternatively autogenous vaccines using strains isolated from the affected herd may be helpful in protracted disease situations. Newly acquired sows or gilts vaccinated prior to farrowing will provide some colostral protection to offspring and help ward off severe forms of EE. Efforts should be made to minimize skin trauma by clipping needle teeth, removing abrasive surfaces, and treating for mange if present. Thorough cleaning and disinfection of facilities should be carried out between farrowings, and sows entering facilities should be washed and disinfected. Control of EE may depend largely on preventing trauma and improving the environment with better ventilation, cleaner and drier pens, controlled humidity, and reduced stocking density.

Staphylococcus aureus

Staphylococcus aureus is the only staphylococcal species apart from *S. hyicus* to be consistently isolated from lesions in pigs. Besides skin infections, *S. aureus* has been associated with septicemia, mastitis, vaginitis, metritis, osteomyelitis, and endocarditis. Although commonly found in the swine facilities and on the skin of healthy pigs, *S. aureus* is not a common pathogen and is not associated with herd outbreaks.

Etiology

Like all staphylococci, *S. aureus* is positive on Gram stain, and it forms white to golden opaque colonies with a double zone of hemolysis on sheep blood agar. The inner zone of complete hemolysis is caused by alpha-hemolysins, while the outer zone of incomplete hemolysis is caused by beta-hemolysins. *S. aureus* grows best under aerobic conditions at 95–98.6°F (35–37°C). It tends to form grape-like clusters of coccoid organisms best observed from solid media. Besides hemolysins, the organism variably produces a number of substances, which may be considered virulence factors. Among these are protein A, teichoic acids, coagulase, staphylokinase, DNase, lipase, hyaluronidase, leukocidin, enterotoxins, and exfoliative toxins.

Public health

Recently there has been a public health concern regarding swine as a reservoir for methicillin-resistant *S. aureus* (MRSA). *S. aureus* in humans is a frequent cause of localized skin infections as well as life-threatening septicemia, pneumonia, endocarditis, and other soft tissue and bone infections (Falcone et al. 2009). MRSA strains emerged in the 1960s and are of great concern given their poor response to treatment and consequent higher mortality rates. Traditionally most MRSA disease has been health-care-associated MRSA (HA-MRSA), being acquired through contact with a health-care setting or health-care personnel (Tiemersma et al. 2004). More recently, MRSA-associated disease has emerged in people in the community apart from health-care-associated risk factors, so-called community-associated MRSA (CA-MRSA) (Vandenesch et al. 2003). Specific genotypes predominate in HC-MRSA and CA-MRSA infections, which assist in distinguishing infection sources (Bal et al. 2016).

Colonization by MRSA has also been reported in livestock including pigs (van Loo et al. 2007), so-called livestock-associated MRSA (LA-MRSA). Studies in Europe, North America, and elsewhere have demonstrated that nasal and skin colonization without clinical infection in pigs is common and caused by the multilocus sequence types ST398, ST9, and ST5 (Armand-Lefevre et al. 2005; Frana et al. 2013; Smith et al. 2009; Smith and Pearson 2011; Wagenaar et al. 2009; Weese et al. 2010). A limited number of reports implicate ST398 and ST9 isolates in a range of human disease conditions similar to other *S. aureus* strains, but these strains may not cause disease as frequently in colonized people as other human MRSA strains (Cuny et al. 2009; Smith and Pearson 2011; van Loo et al. 2007). This difference is likely due to adaption in pigs leading to a reduction in pathogenicity in humans. This is due to a reduced

capacity for adherence to human skin (Uhlemann et al. 2012) and the near absence of human-specific *S. aureus* virulence factors (Hau et al. 2015; Price et al. 2012). While ST398 and ST9 are considered livestock-adapted lineages, the ST5 lineage has historically been a well-adapted HA-MRSA clone and may indicate an increased risk posed to exposed individuals colonized through contact with swine (Bal et al. 2016).

People who spend considerable time in contact with infected pigs are at significantly increased risk for testing positive for LA-MRSA from nasal swabs relative to the general population (Smith et al. 2009; Voss et al. 2005). In one study isolates from pigs and people from the same farm were indistinguishable, suggesting inter-transmission (Khanna et al. 2008). However, the persistence of LA-MRSA in humans is dependent on intensity of animal contact (i.e. contamination of nasal mucus is probably more frequent than true colonization of nasal mucosa), and short-term carriage after animal contact has been described (Frana et al. 2013; Graveland et al. 2011). Transmission from ST398 MRSA-positive farmworkers to family members not in contact with swine has been reported, but spread into the general community seems to be infrequent (Cuny et al. 2009; Graveland et al. 2011). Many unanswered questions remain about LA-MRSA colonization in both humans and swine that need to be addressed prior to implementing a successful bacterial prevention or control strategy on farms or in the community.

Pathogenesis

Damage to skin and mucosal surfaces can predispose to localized *S. aureus*-induced skin lesions similar to EE caused by *S. hyicus*. Some strains of *S. aureus* can produce exfoliative toxins that are similar to those found in *S. hyicus*. *S. aureus* may also invade causing bacteremia that can evolve to life-threatening septicemia in neonates. More often bacteremia leads to abscesses in bones, joints, heart valves, liver, kidney, lymph nodes, and other internal organs. Abscesses may be observed at slaughter in otherwise normal pigs. Ascending infections may lead to mastitis, vaginitis, metritis, and umbilical abscesses.

Clinical signs and lesions

Because *S. aureus* is associated with numerous diseases and other agents can cause similar diseases, clinical signs are not predictive of this organism as the causative agent. Most cases occur in individual animals, and animal-to-animal spread is rare. Neonatal septicemia may be fatal or result in stunted piglets at 7–10 days of age. Umbilical abscesses, polyarthritis, and vegetative endocarditis with cardiac enlargement may also occur, or animals may be found dead with no gross lesions. Chronic infections appear as abscesses of the skin, umbilicus, bones, joints, mammary glands, and internal organs. Osteomyelitis may lead to pathologic fractures particularly in vertebrae. Bone and joint infections in the feet are most often due to extension of skin infections initiated by trauma. Abscesses typically contain creamy white or bloodstained pus and are often surrounded by thick fibrous capsules. Pus may also be in the peritoneal cavity, the pericardial sac, or the lumen of the uterus. A white, non-odorous purulent vaginal discharge occurs with endometritis (Roberson et al. 2007). *S. aureus* may cause sporadic abortions (Kohler and Wille 1980) and has also been rarely isolated from cases of enteritis where enterotoxins may be contributory (Taylor et al. 1982).

Diagnosis and treatment

Diagnosis of *S. aureus* is based on culture from suggestive lesions. Aerobic growth on sheep blood agar of small (1–2 mm diameter), yellow to white opaque colonies with double-zone hemolytic pattern is highly indicative of *S. aureus*. Further identification is accomplished by Gram stain and biochemical testing or MALDI-TOF. *S. aureus* is positive for catalase, coagulase, mannitol, and Voges–Proskauer reagent. These tests should differentiate *S. aureus* from other abscess-causing bacteria such as *Arcanobacterium pyogenes* and streptococci. In the past further identification of *S. aureus* isolates for public health significance was accomplished by phage typing or plasmid profiling. These have largely been replaced by other methods such as multilocus sequence typing (MLST) or protein A gene sequence typing (*spa* typing).

Treatment of individual abscesses can be accomplished by surgical drainage and antimicrobial therapy. Prompt parenteral treatment is recommended to minimize development of extensive and fatal abscess development. Susceptibility testing for appropriate antimicrobial agent is recommended since many isolates are resistant to common drugs such as penicillin, ampicillin, chlortetracycline, oxytetracycline, and spectinomycin. Ceftiofur, enrofloxacin, and trimethoprim/sulfamethoxazole are good choices in the absence of individual isolate testing. Since *S. aureus* infection is an individual animal problem, there is usually no need to treat the whole group. The use of bacterins has been described, but they are not widely available or extensively used. Environmental cleaning of heavily contaminated areas is prudent. *S. aureus* is somewhat resistant to disinfectants especially when protected by organic materials, but it is sensitive to disinfectants, such as phenols, hypochlorites, iodine, and iodophors.

Streptococcosis

Marcelo Gottschalk and Mariela Segura

Relevance

Several streptococcal species reside in tonsils, intestines, and/or genital tract of clinically healthy pigs, and some are potential pathogens. *Streptococcus suis, Streptococcus porcinus*, and *Streptococcus dysgalactiae* subsp. *equisimilis* are generally found in tonsils (Devriese et al. 1994b; Vieira et al. 1998). *Streptococcus hyointestinalis*, *Streptococcus alactolyticus* (*Streptococcus* intestinalis) and *Streptococcus bovis*, and possibly *S. suis* are considered part of the intestinal microflora (Devriese et al. 1994b). *Streptococcus orisuis* and streptococcal mutans-like strains are normal inhabitants of the oral cavities of pigs (Takada and Hirasawa 2007; Takada et al. 2008). Vaginal microflora may include some of the aforementioned species (such as *S. suis*), as well as *Streptococcus hyovaginalis* and *Streptococcus thoraltensis* (Devriese et al. 1997, 1988).

Streptococcus suis is the most important streptococcal swine pathogen worldwide, causing septic diseases mostly in 5- to 10-week-old pigs characterized by septicemia and acute death, meningitis, polyarthritis, polyserositis, and valvular endocarditis. It is also important as a zoonotic agent. Other less common *Streptococcus* spp. isolated from a variety of lesions/disease conditions are discussed, including *S. porcinus* (Lancefield groups E, P, U, and V) and S. dysgalactiae subsp. *equisimilis* (Lancefield groups C, G, and L), among others.

Streptococcus suis

Etiology and prevalence

Streptococcus suis is an encapsulated gram-positive coccus. It was first reported by Jansen and Van Dorssen in the Netherlands (1951) and by Field et al. (1954) in England and was officially recognized as a new species in 1987 (Kilpper-Balz and Schleifer 1987). Since then *S. suis* has been reported globally in both traditional and modern intensive swine operations. Some confusion existed in the original studies regarding early Lancefield groups R, S, and T and their relationship with group D streptococci and the different *S. suis* capsular serotypes. The terminology of Lancefield groups R, S, RS, and T, sometimes employed in papers describing human *S. suis* infections, should not be used to avoid confusion (Gottschalk et al. 2010; Okura et al. 2016).

Nine serotypes, 1–8 and 1/2, were originally described based on antigenicity of capsular polysaccharides (CPS) (Perch et al. 1983). In the following years, a total of 26 additional serotypes, 9–34, were described (Gottschalk et al. 1989, 1991; Higgins et al. 1995). Reference strains originated mostly from diseased pigs, although some originated from clinically healthy pigs, a diseased human, diseases calves, or a diseased lamb. Subsequent phylogenetic analyses of the 16S rRNA and chaperonin 60 (cpn60) genes showed that the reference strains of serotypes 32 and 34 should have been classified as *Streptococcus orisratti* (Hill et al. 2005). More recently, sequence analyses of species-specific genes (*sodA* and *recN*) indicate that the reference strains of serotypes 20, 22, 26, and 33 should also be taxonomically removed from the *S. suis* species (Okura et al. 2016). It has been proposed that serotypes 20, 22, and 26 belong to a new species (*Streptococcus parasuis*) (Okura et al. 2016). However, more extensive studies using a higher number of *S. suis* and *S. suis*-like strains will provide additional insights into the classification of these strains and make the species boundaries clearer (Okura et al. 2016). In fact, all 35 serotypes of *S. suis* (or *S. suis*-like strains) are isolated from diseased pigs (Gottschalk and Segura 2015), and, from the clinical point of view, most laboratories still identify the 35 serotypes.

A majority of *S. suis* strains isolated from diseased pigs belong to serotypes 1–9 (Goyette-Desjardins et al. 2014). Serotype 2 is considered the predominant and most virulent serotype in most Eurasian countries (Berthelot-Hérault et al. 2000; Goyette-Desjardins

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

et al. 2014; Wei et al. 2009; Wisselink et al. 1999). However, serotype 9 is most frequently isolated from diseased pigs in Spain, Germany, and the Netherlands (Goyette-Desjardins et al. 2014; Vela et al. 2005). The situation seems to be different in North America. Although serotypes 2 and 3 are the most prevalent in diseased pigs, serotype 2 has a prevalence typically below 20% in Canada (Gottschalk and Lacouture 2015) and in the United States (Fittipaldi et al. 2009). Strains of lower virulence are present in North America when compared with those from Europe (Fittipaldi et al. 2011). Untypable isolates are recovered mostly from sporadic occurrences of disease (Gottschalk and Lacouture 2015). Some of them are nonencapsulated, hence impossible to serotype using antisera. The use of multiplex PCR for serotyping (Okura et al. 2014) can sometimes identify the serotype of such strains. Some of these strains remain untypable even by PCR due to mutations or even loss of *cps* loci (Zheng et al. 2017). New novel cps *loci*, which would represent new serotypes, have been lately described within strains isolated either from healthy Chinese (Qiu et al. 2016) or diseased Canadian (Zheng et al. 2017) pigs. The use of PCR tests that identify these new novel cps *loci* may significantly reduce the number of untypable isolates.

Genetic diversity exists among *S. suis* isolates within and between serotypes (Princivalli et al. 2009). Though different methods based on DNA have been used for *S. suis* surveillance, they are only effective for short-term epidemiology as they are based on non-characterized genomic differences between isolates. It has been reported that the genetic diversity of *S. suis* is better evidenced by multilocus sequence typing (MLST), mainly for serotype 2 strains. Using this technique, different sequence types (ST) have been identified. Serotype 2 ST1 strains are mostly associated with high virulence and disease in both pigs and humans in Europe, Asia, Africa, and South America (Segura et al. 2017). Serotype 2 ST7, a single locus variant of ST1, is mostly endemic to mainland China (see below). North American serotype 2 strains are mainly ST25 and ST28, with the presence of a low percentage of ST1 strains. The original hypothesis of lower virulence of North American serotype 2 strains (Gottschalk and Segura 2000) was confirmed by experimental infection of animals that demonstrated that ST1 European strains are significantly more virulent than ST28 strains, while ST25 strains are intermediate in virulence (Fittipaldi et al. 2011). Differences in strain virulence belonging to the same ST have also been revealed (Athey et al. 2015).

Public health

Streptococcus suis is an emerging zoonotic agent that has increased in importance in the last 10 years. Serotype 2 is the most common cause of human disease; serotypes 5, 14, and others are also uncommonly reported (Callejo et al. 2016; Goyette-Desjardins et al. 2014; Wertheim et al. 2009).

Meningitis is the most common manifestation evidenced clinically by headache, fever, vomiting, and nervous signs and later by hearing loss. Some patients exhibit signs of sepsis including cutaneous petechiae, ecchymoses, and purpura (Wertheim et al. 2009). Less commonly, endocarditis, arthritis, and endophthalmitis are reported (Doube and Calin 1988; Huang et al. 2005; McLendon et al. 1978; Vilaichone et al. 2002; Voutsadakis 2006). In recent outbreaks in China of unusually high morbidity and mortality, sepsis with a toxic shock-like syndrome is described (Tang et al. 2006; Yu et al. 2006). Case fatality rates vary from less than 3% in most Western countries to 26% in some Asian countries (Gottschalk et al. 2010).

In Western countries where human *S. suis* has been reported, it is rare, usually involving a single person, and is highly occupationally associated in pig farmers, veterinarians, abattoir workers, people who transport pork, meat inspectors, and butchers. Infection is primarily through direct contact of small skin wounds with *S. suis*-infected pigs or contaminated pork, although in some cases no wound is obvious (Gottschalk et al. 2010; Segura et al. 2016). The incubation period with directly infected skin wounds is typically a few hours but may be up to several days (Wertheim et al. 2009). Humans in at-risk occupations also may have asymptomatic *S. suis* colonization of tonsils (Gottschalk et al. 2010; Segura et al. 2016) or nasal mucosa (Bonifait et al. 2014) and may be seropositive (Robertson and Blackmore 1989; Smith et al. 2008). The significance of these findings relative to risk of disease is unknown.

Disease in humans in Southeast Asia can be different. Although sporadic individual cases of disease occur as in the West, albeit more frequently, there have also been two major outbreaks in China in 1998 and 2005 where in each more than 50 people died of toxic shock-like septic disease with relatively low incidence of meningitis (Gottschalk et al. 2010; Tang et al. 2006; Yu et al. 2006). In other Asian countries, such as Vietnam and Thailand, human *S. suis* is among the most frequent causes of bacterial meningitis in adults (Gottschalk et al. 2010). In these countries, *S. suis* is a frequent foodborne disease (Segura et al. 2016) as well as a disease of direct contact with infected swine or contaminated pork. This is likely due to cultural and other factors. There is a high rate of *S. suis* contamination of pork as indicated by a high percentage of positive pork samples in Asian markets (Cheung et al. 2008). The well-documented risk of consuming contaminated undercooked pork is compounded by the common practice of consuming raw pork in Vietnam, Laos, and Thailand (Gottschalk et al. 2010). Since *S. suis* can survive in carcasses at 4°C (39°F) for

6 weeks, contaminated chilled or frozen meat poses risk long after being butchered. In addition to foodborne risks, larger numbers of people in Southeast Asia are at risk by direct contact with *S. suis*-infected pigs compared with the West. In these countries, backyard pig production is common, often including slaughter and processing, and living conditions frequently place pigs and humans in close contact.

Differences between the West and Southeast Asia may also be due to differences in *S. suis* strain virulence or prevalence. It has been proposed that a highly virulent *S. suis* ST7 strain unique to China was responsible for the toxic shock-like outbreaks. However, fatal toxic shock-like cases have occurred in many Western countries where this ST7 strain has never been isolated (Gottschalk et al. 2010; Mancini et al. 2017). Recent information clearly indicates that serotype 2 strains differ in virulence for swine (and probably for humans) according to different geographic regions (see above). Because serotype 2 strains predominate in human cases, it may be that a lower prevalence of virulent serotype 2 in pigs in North America translates to lower transmission to humans and lower prevalence of human disease. In Argentina where virulent European-like serotype 2 ST1 strains are frequently isolated from diseased pigs, a high number of human cases have been reported, a surprising fact for a country with still limited swine production (Callejo et al. 2016).

Finally, a reason for very low prevalence of human *S. suis* in North America and low prevalence in Europe may be partially due to underdiagnosis. *S. suis* is a pathogen very well known by laboratories of human disease in Asia, relatively well known in Europe, and generally poorly known in America. Many diagnostic laboratories working in human diseases in Western countries have misidentified it as enterococci, *Streptococcus pneumoniae, S. bovis*, other streptococci, or even *Listeria* (Gottschalk et al. 2010).

Epidemiology

Natural habitat

The natural habitat of *S. suis* is the upper respiratory tract, particularly the tonsils and nasal cavities, as well as the genital and possibly alimentary tracts of pigs (Devriese et al. 1994b; Hogg et al. 1996). It is easily detected in almost all pigs of any age (MacInnes et al. 2008). Virulent serotype 2 strains can also be carried subclinically by healthy pigs, but in few herds that remain entirely subclinical and in only a low proportion of pigs within these herds (Marois et al. 2007; Monter Flores et al. 1993). In herds with clinical signs, the number of *S. suis* serotype 2 carrier animals is usually higher (Marois et al. 2007). Serotypes 9–34 (as well as untypable strains) are more likely to subclinically colonize the nasal cavities and vagina than to cause disease (Hogg et al. 1996). Individual pigs are usually colonized by more than one *S. suis* serotype (Monter Flores et al. 1993).

Wild boars are known to carry *S. suis*, even to suffer from fatal disease, and may be an important reservoir in some countries (Baums et al. 2007; Risco et al. 2015). In Spain, serotype 9, the most important serotype isolated from clinical disease in domestic pigs, was also shown to be widely present in wild boars (Sánchez del Rey et al. 2014). *S. suis* has also uncommonly been confirmed in cattle (Okwumabua et al. 2017), lambs (Muckle et al. 2014), wild rabbits (Sánchez del Rey et al. 2013), and a dog (Muckle et al. 2010), suggesting that these could serve as unlikely sources for pigs. Additional mammals and birds might also carry *S. suis* (Devriese et al. 1994a), but these isolates need to be confirmed as *S. suis* using current discriminatory methods.

Transmission

Transmission of virulent strains between herds usually occurs by the movement of healthy carrier animals. The introduction of carrier pigs harboring virulent strains (breeding gilts, boars, weaners) into a noninfected recipient herd may result in the subsequent onset of disease in weaners and/or growing pigs. Sows infect their piglets during birthing via contamination from vaginal colonization and probably through the respiratory route (Amass et al. 1997; Cloutier et al. 2003; Robertson et al. 1991; Segura et al. 2016). Although most weaned piglets carry *S. suis* strains, few carry virulent strains capable of inducing the disease (Cloutier et al. 2003; Marois et al. 2007). Even though different serotypes and strains within the same serotype are present in a herd, a single strain usually causes most disease (Cloutier et al. 2003; Marois et al. 2007). However, when predisposing factors are present in a herd that can lower immunity or otherwise lower resistance to *S. suis* invasion (see below), multiple strains of *S. suis* may cause disease in a herd. Horizontal transmission is important, especially during outbreaks, when diseased animals shed higher numbers of bacteria, thereby increasing transmission by direct contact or aerosol (Cloutier et al. 2003). Aerosol transmission without nose-to-nose contact has been confirmed for *S. suis* serotype 2 (Berthelot-Hérault et al. 2001). Another study showed that although prevention of direct contact by spatial separation of pigs reduces the rate at which susceptible pigs become colonized, such intervention measures would not prevent *S. suis* spread in a farm (Dekker et al. 2013).

The importance of environmental contamination, fomites, and insect vectors in transmission of *S. suis* is uncertain. *S. suis* has been isolated from feed troughs of piglets and sows (Robertson et al. 1991), confirming environmental contamination. However, the oral route of infection is not yet been proven, and recent studies suggested that *S. suis* is not able to survive in feed (fine

pellet or crumb feed, with or without formic acid) or in the stomach contents (Warneboldt et al. 2016). *S. suis* may also be transmitted via fomites (Dee and Corey 1993; Robertson et al. 1991) and flies (Enright et al. 1987), although the importance of such vectors has still to be confirmed.

Survival in the environment

The durability of *S. suis* in various environmental conditions has been studied using serotype 2 strains. Viability in water at 39 °F (4 °C) is retained for 1–2 weeks. In experimentally inoculated feces, *S. suis* survives at 32 °F, (0 °C) 48 °F (9 °C), and 72–77 °F (22–25 °C) for 104, 10, and 8 days, respectively. In dust survival at 32 °F (0 °C), 48 °F (9 °C), and 72–77 °F (22-25 °C) is for 54, 25, and 0 days, respectively. Thus, at a summertime or nursery temperature of 72–77 °F (22–25 °C), the organism could survive about 8 days in feces but less than 24 hours in dust (Clifton-Hadley and Enright 1984). Viability is retained in rotting pig carcasses for 6 weeks at 39 °F (4 °C) and for 12 days at 72–77 °F (22–25 °C), proving a potential source for spread by birds, rats, mice, dogs, or other species (Clifton-Hadley and Enright 1984).

Disinfectants commonly used in piggeries can kill *S. suis* in less than 1 minute, even at concentrations less than those recommended by the manufacturers (Clifton-Hadley and Enright 1984; Robertson et al. 1991). Organic matter reduces effectiveness of chemical disinfectants and should be completely removed with thorough washing prior to application. Even though *S. suis* survives in water up to 2 hours at 122 °F (50 °C) but only 10 minutes at 140 °F (60 °C), use of heated pressure washers compared with non-heated is of limited value since water cools rapidly on surfaces, negating potential benefit (Clifton-Hadley and Enright 1984).

Virulence factors

Nearly all studies on virulence factors, pathogenesis, mechanisms of protection, and animal models of disease have used ST1 Eurasian and/or ST7 Chinese serotype 2 strains (Fittipaldi et al. 2012; Segura et al. 2017). Extrapolation of findings to other serotypes or even to other serotype 2 strains such as ST25/ST28 North American strains should be done with caution. Interpretation of the collective results of studies on virulence factors and protection is hampered by variation in experimental designs. There is no generalized agreement among investigators in the *S. suis* field about what defines a strain as virulent, and, on many occasions, strains have been defined as virulent or avirulent solely on the basis of the clinical condition of the animal from which the strain was recovered and/or the site of recovery. For example, not all strains isolated from tonsils of clinically healthy pigs are avirulent, since pigs may be tonsillar carriers of virulent strains without being ill (Segura et al. 2017). Additionally, experimental infection models to evaluate virulence are not readily comparable. There are models in pigs; strains of inbred and outbred mice, rabbits, and zebrafish; and unicellular eukaryotes such as an amoeba (Segura et al. 2017).

The pig remains the most valuable model, but *S. suis* experimental models are not easily standardized. Variations in the type (traditional or minipigs), genetic background, age, health status of the herd of origin, and route of infection further complicate *S. suis* pathogenesis studies in the natural host (Segura et al. 2017). To reproduce disease in a relatively natural way by the respiratory route, intranasal or aerosol routes of inoculation have been used. However, results have not always been positive or reproducible. In most models, prior to *S. suis* exposure, preconditioning the nasal mucosa to favor bacterial invasion is usually needed. These methods include preinfection with other toxin-producing pathogens such as *Bordetella bronchiseptica* (Vecht et al. 1985, 1991) or direct mucosal irritation with acetic acid (Pallarés et al. 2003). Yet these methods may work with very virulent serotype 2 strains, but not with less virulent strains or serotypes (Segura et al. 2016). In fact, there is not a sure way to determine the level of virulence for a given strain of *S. suis*. As a consequence, important discrepancies exist in the literature regarding even the virulence of the same strain (Berthelot-Hérault et al. 2005). Nevertheless, it is clear that differences in virulence exist among serotype 2 strains (Fittipaldi et al. 2011; Gottschalk and Segura 2000).

Difficulties with reliable experimental models of *S. suis* disease have also confounded studies aimed at identification of critical virulence factors. Recent literature is replete with new putative critical virulence factors, confusion, and controversy. For a critical evaluation, readers are invited to consult the studies compiled by Segura et al. (2016, 2017).

The best validated *S. suis* virulence factor is the CPS that plays an important role in bacterial resistance to phagocytosis by leukocytes. The CPS chemical structure of only a few serotypes is known (van Calsteren et al. 2016). The CPS seems to be a necessary but not sufficient virulence factor as most low virulence strains are encapsulated, indicating that additional virulence factors are necessary for full virulence. Unencapsulated strains can also occasionally invade host tissue and cause disease, mainly endocarditis (Lakkitjaroen et al. 2011).

Bacterial cell wall components may be surface exposed even in encapsulated strains, inducing an exaggerated inflammatory response of the host. Among these, peptidoglycan and teichoic and lipoteichoic acid components have been implicated as virulence factors, mainly involved in resistance to killing by phagocytic cells, adherence to host cells, resistance against cationic

antimicrobial peptides, and/or induction of exaggerated inflammation (Fittipaldi et al. 2008a,b). Also, several proteins with a C-terminal cell wall sorting signal including LPXTG or related motifs are thought to be important in virulence when compared to isogenic mutants lacking some of these factors (Segura et al. 2016, 2017).

Products secreted by *S. suis* are also suggested as virulence factors. Of these the hemolysin suilysin (SLY) is the best characterized being toxic to epithelial, endothelial, and phagocytic cells (Gottschalk and Segura 2000; Tenenbaum et al. 2016).

Although the bulk of literature may not confirm some putative virulence factors as significant, some of them may still serve as virulence markers and/or be useful for phenotypic comparison of strains. Examples include the proteins muramidase-released protein (MRP), extracellular factor (EF) (Smith et al. 1997; Vecht et al. 1991), and SLY (Tenenbaum et al. 2016). Although isogenic mutants lacking either MRP or EF proteins or SLY were shown to be as virulent to pigs as the respective parent strains (Allen et al. 2001; Smith et al. 1997), there is a positive association between the presence of these proteins and strain virulence in European and Asiatic countries (Silva et al. 2006; Wei et al. 2009). For example, there is a positive correlation between ST1 virulent strains and the presence of these three factors (Fittipaldi et al. 2011; Callejo et al. 2016). Avirulent *S. suis* serotype 2 strains possessing MRP, EF, and SLY have so far not been described (Fittipaldi et al. 2012). However, the absence of any or all of these proteins is not necessarily associated with a lack of virulence. Most North American and some European and Asian virulent isolates do not produce all these factors (Berthelot-Hérault et al. 2000; Fittipaldi et al. 2009). In North America, ST28 low virulence strains are MRP+, whereas higher virulent ST25 strains are negative for this marker. In both cases these strains are negative for both EF and SLY (Fittipaldi et al. 2011).

Pathogenesis of the infection

Virulent strains of *S. suis* can colonize the tonsils and, to a lesser extent, the respiratory mucosal surfaces in a low number of pigs without producing disease (see above). Colonization is thought to be the requisite first step to subsequent invasion, hematogenous and/or lymphogenous dissemination, and systemic disease (Madsen et al. 2002; Segura et al. 2016). However the exact mechanism(s) of invasion of mucous membranes is (are) unknown. Damage to the mucosal epithelium is thought to play a role, supported by the fact that colonization of the nasal mucosa by *B. bronchiseptica* and its ability to damage the mucosal epithelium by elaboration of dermonecrotic toxin (DNT) predisposes to *S. suis* invasion and septic diseases (Vecht et al. 1985, 1991).

The gastrointestinal tract cannot be excluded as a secondary site of infection in piglets. Studies have shown that *S. suis* is able to translocate from the intestine via the bloodstream to different tissues and cause disease. However, these studies used *S. suis* protected within gastric acid-resistant capsules (Segura et al. 2016). Experimental infection of weaned piglets through the oral route with either virulent serotype 2 or serotype 9 strains did not induce disease (Warneboldt et al. 2016). The conditions leading to sufficient passage of *S. suis* through the stomach are still unclear and might differ in neonatal, suckling, or weaning periods. Further studies on oro-gastrointestinal *S. suis* infections are required (Segura et al. 2016). The intestinal route of infection is, however, very common in humans (Segura et al. 2016).

The pathogenesis of *S. suis* infection is summarized in Figure 61.1. Survival of the organism in the bloodstream may be facilitated by the CPS and cell wall components that efficiently hamper phagocytosis (Fittipaldi et al. 2008a,b, 2012; Smith et al. 1999). The role of host complement in bacterial killing, mediated by opsonophagocytosis, is still controversial (Segura et al. 2016). Bacteria then travel in the bloodstream either free in circulation or attached to the surface of monocytes (Fittipaldi et al. 2012; Gottschalk and Segura 2000). SLY that is produced by some strains seems to contribute to the ability of encapsulated *S. suis* to resist killing by porcine phagocytes in the presence of complete serum lacking specific antibodies (Benga et al. 2008; Tenenbaum et al. 2016).

The mechanism(s) by which *S. suis* is able to cross the blood–brain barrier is only partially understood. Brain microvascular endothelial cells together with choroid plexus epithelial cells constitute the structural basis of the blood–brain barrier. *S. suis* adheres to and invades brain microvascular endothelial cells with or without cytotoxicity (Vanier et al. 2004). It also affects porcine choroid plexus epithelial cell barrier function and integrity through cell death that is predominantly due to necrosis, but apoptosis may also contribute. These and probably other mechanisms facilitate *S. suis* invasion of the CNS (Fittipaldi et al. 2012; Tenenbaum et al. 2016).

Inflammation plays an important role in the pathogenesis of *S. suis*-induced septicemia and meningitis. Bacterial cell wall components are known to induce the production of proinflammatory cytokines by murine, human, and swine cells (Gottschalk and Segura 2000; Fittipaldi et al. 2012). High levels of cytokines are also produced after *in vivo* infections that may lead to sudden death of animals (Domínguez-Punaro et al. 2007). Likewise, and shortly after *S. suis* invasion of the CNS by *S. suis*, there are transcriptional activation of proinflammatory cytokines and chemokines and induction of inflammation that causes CNS clinical signs. Cases in humans and pigs with presence of a shorter incubation

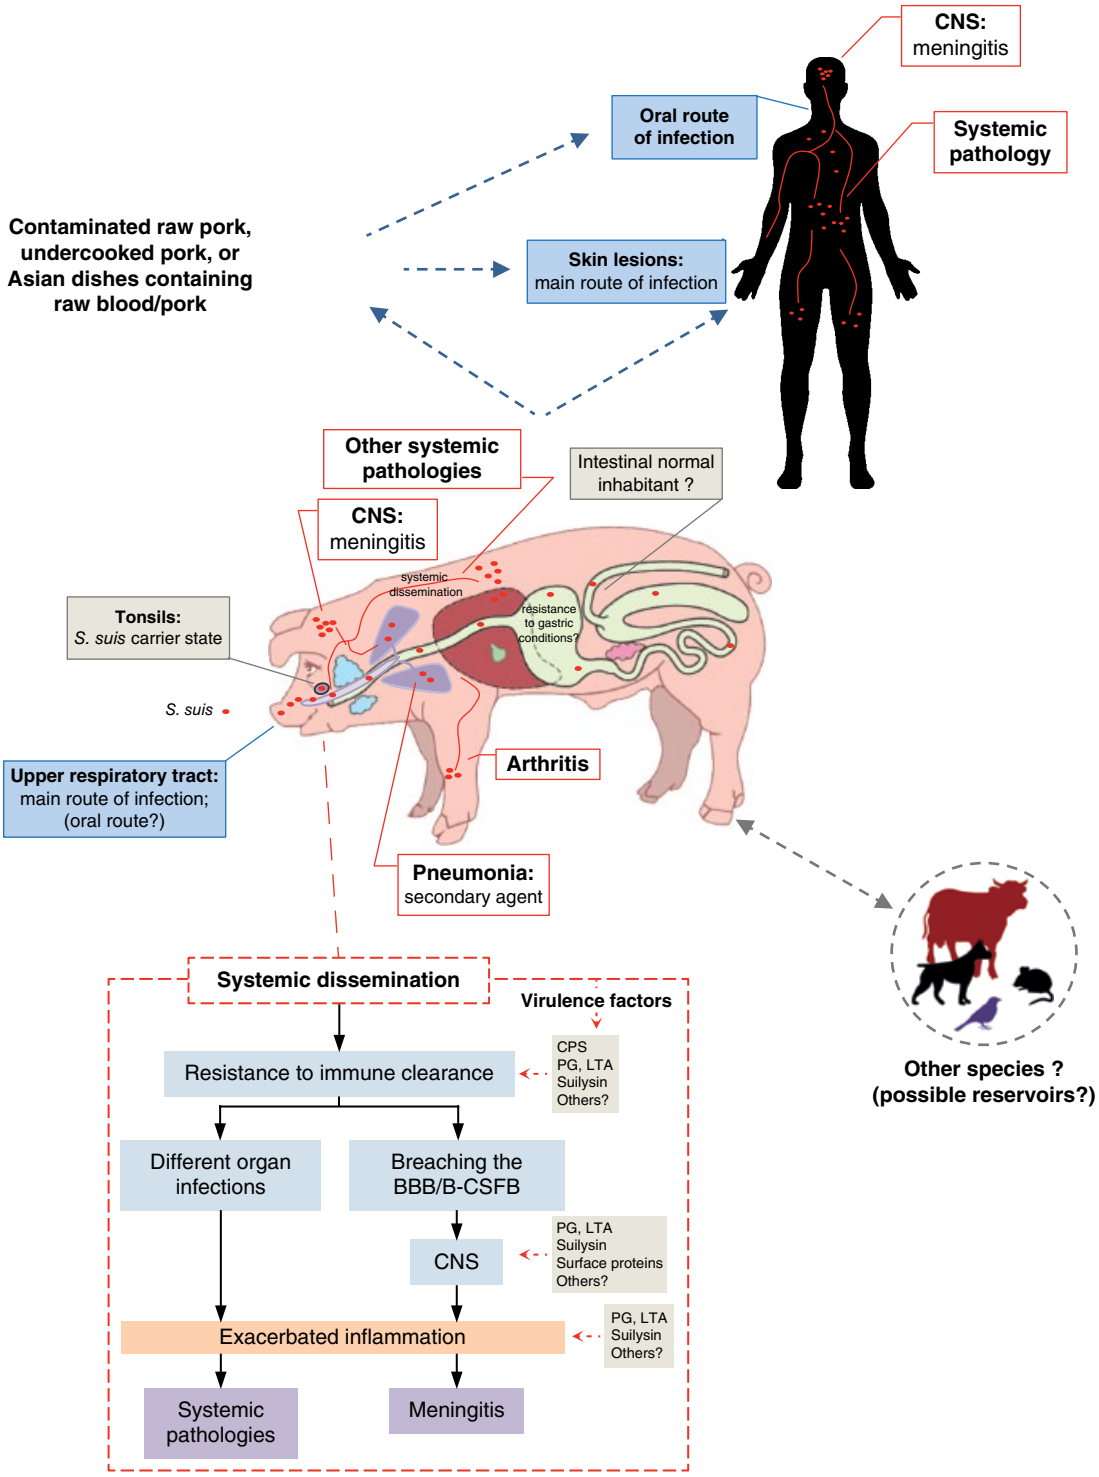

Figure 61.1 Pathogenesis and epidemiological features of *Streptococcus suis*-induced disease. The main route of entry of *S. suis* in pigs is the upper respiratory tract, whereas in humans it enters via skin wounds (handling of infected animals or meat) or the oral route (ingestion of raw or undercooked contaminated pork-derived products). After breaching the mucosal (respiratory, intestinal) or skin barriers, *S. suis* invades different organs and tissues through hematogenous and/or lymphogenous dissemination, leading mainly to meningitis, arthritis, and/or other multiple systemic pathologies (such as septic shock with sudden death, polyserositis, and endocarditis). Access to the central nervous system (CNS) is gained by crossing of the blood–brain barrier (BBB) and/or the blood–cerebrospinal fluid barrier (B-CSFB), leading to severe meningitis. During systemic dissemination, *S. suis* resists the attack of the host innate immune system by avoiding phagocytosis, possibly reducing complement activation, reducing cell activation, and/or inducing the death of leukocytes by means of multiple virulence factors. These include capsular polysaccharide (CPS), suilysin, and/or modifications of chemical properties of the cell wall components peptidoglycan (PG) and lipoteichoic acid (LTA). Several possible mechanisms might be used by *S. suis* to cross the BBB or the B-CSFB, including increased barrier permeability by direct induction of necrosis/apoptosis or indirectly through an intensive inflammatory process leading to bacterial and leukocyte trafficking into the CNS. Direct invasion and translocation of bacteria across these barriers have been reported as well. Finally, induction of inflammatory cytokines and other immune mediators by *S. suis* leads to exacerbated inflammation and is mainly responsible for the clinical signs of disease. Several *S. suis* virulence factors are involved in these last steps of the pathogenesis, including suilysin, PG, LTA, and several surface-anchored proteins. *S. suis* has been isolated from other animal species, including birds, rabbits, mice, dogs, horses, cattle, fallow deer, and wild boars, complicating the global epidemiology of *S. suis*. It has been suggested that some of these animal species might act as reservoirs. *Source:* Segura et al. (2017). Reproduced with permission of Elsevier.

time, more rapid disease progression, and a higher rate of mortality have been also described (Feng et al. 2010; Gottschalk et al. 2010) and may be due, in part, to enhanced induction of inflammation.

Clinical signs and lesions

Even when *S. suis* pig carrier rate is very high, the incidence of the disease varies from period to period and is usually less than 5% (Clifton-Hadley et al. 1986). In the absence of treatment, mortality rates can reach 20% (Cloutier et al. 2003). In most cases, affected animals are generally between 5 and 10 weeks of age, but atypical cases in pigs up to 32 weeks of age and a few hours old have also been described (Cloutier et al. 2003; Lapointe et al. 2002; MacInnes and Desrosiers 1999). The earliest sign is usually a rise in rectal temperature to as high as 108.5 °F (42.5 °C). This may occur initially without any other obvious signs. It is accompanied by a detectable bacteremia or pronounced septicemia that, if untreated, may persist for up to 3 weeks. During this period there are usually a fluctuating fever and variable degrees of poor appetite, depression, and shifting lameness (Clifton-Hadley et al. 1984; MacInnes and Desrosiers 1999).

In peracute cases, pigs may be found dead with no premonitory signs. A proportion of affected pigs typically develop nervous disease as a consequence of meningitis. Early nervous signs include incoordination and adoption of unusual stances, which soon progress to inability to stand, paddling, opisthotonus, convulsions, and nystagmus. The eyes are often staring, with reddening of mucous membranes. Less remarkable clinical signs include malaise and anorexia owing to septicemia and pneumonia as well as lameness caused by arthritis. Less common clinical manifestations of *S. suis* are vegetative valvular endocarditis, rhinitis, abortion (usually due to high temperature during the fever syndrome), and vaginitis (Sanford and Tilker 1982). In North America, *S. suis* is the infectious agent most frequently isolated from cases of vegetative valvular endocarditis in pigs. Affected pigs may die suddenly or show various levels of dyspnea, cyanosis, and wasting. Polyserositis similar to Glässer's disease can sometimes be observed.

Reports from the United Kingdom describe septicemia, meningitis, and polyarthritis, but rarely pneumonia (Heath et al. 1996; MacLennan et al. 1996). In the Netherlands, *S. suis* type 2 is associated with pneumonia in 42% of the cases, followed by meningitis, endocarditis, and polyserositis (Vecht et al. 1985). In North America, early reports indicated that *S. suis* was predominantly isolated from cases of pneumonia (Hogg et al. 1996; Reams et al. 1994; Sanford and Tilker 1982). *S. suis* isolates belonging to serotypes other than 2 have been recovered from cases of bronchopneumonia in Denmark (Perch et al. 1983), the Netherlands (Vecht et al. 1985), Belgium (Hommez et al. 1986), Finland (Sihvonen et al. 1988), Australia (Gogolewski et al. 1990), Canada (Higgins and Gottschalk 1990), and the United States (Reams et al. 1994). In France, *S. suis* was not mainly associated with lung lesions at slaughter (Fablet et al. 2012). The role of *S. suis* as a primary agent of pulmonary lesions, in the absence of other pathogens, is still controversial (Staats et al. 1997). However, *S. suis* is a common pulmonary isolate in porcine respiratory disease complex where it is one of several opportunists contributing to secondary bronchopneumonia (Chapter 21). Clinical manifestations related to meningitis, arthritis, and serositis were induced by intravenous application of a serotype 9 strain in specific-pathogen-free (SPF) piglets (Beineke et al. 2008). In general, there are no differences in lesions observed in infections with strains of different serotypes (Reams et al. 1994).

Significant microscopic lesions are usually limited to the brain, heart, joints, and serosal membranes (Reams et al. 1994). The predominant lesions are neutrophilic meningitis and choroiditis, with hyperemic meningeal blood vessels and fibrinopurulent or suppurative epicarditis (Reams et al. 1994, 1996; Sanford and Tilker 1982). Evidence of encephalitis, edema, and congestion of the brain may be present (Staats et al. 1997). The choroid plexus may have disruption of the plexus brush border, and fibrin and inflammatory cell exudates may be present in the ventricles (Staats et al. 1997). Using immunohistochemistry, bacteria were observed in the cytoplasm of neutrophils and macrophages localized in meningeal lesions (Zheng et al. 2009). Interstitial pneumonia is also observed and is considered a lesion secondary to septicemia (Reams et al. 1994). There is only one report of fibrinous pleuritis and bronchopneumonia in SPF piglets experimentally infected with *S. suis* serotype 2 (Berthelot-Hérault et al. 2001). Microscopic lesions are generally the same for all serotypes (Reams et al. 1994). An exception is in rare cases of fibrinohemorrhagic pneumonia with alveolar septal necrosis where it is suggested that certain strains of *S. suis* may cause vascular lesions (Reams et al. 1995). Less common lesions of hemorrhagic and necrotizing myocarditis, fibrinosuppurative polyserositis, and subacute meningoencephalitis and meningoencephalomyelitis have also been reported by Sanford (1987a,b).

Diagnosis

Diseased pigs

Presumptive diagnosis of *S. suis* infections is generally based on clinical signs, age of animals, and macroscopic lesions, although it is sometimes difficult to differentiate from *Haemophilus parasuis* infections. Confirmation is achieved by the isolation of the infectious agent and observation of typical microscopic lesions in tissues.

Collection of more than one alpha-hemolytic colony from different tissues of the same animal or from different animals in the same herd is recommended, because multiple serotypes and strains of *S. suis* can be involved in a single outbreak, especially under the presence of concomitant diseases such as the porcine reproductive and respiratory syndrome virus (PRRSV) (Higgins and Gottschalk 1990; Reams et al. 1994). Because strains causing disease in herds may change over time (Amass et al. 1997), ongoing surveillance by periodic culture of cerebrospinal fluid (CSF) from pigs with meningitis is recommended. This is especially important to upgrade autogenous vaccines when used as a method of control. Strains considered for inclusion in autogenous vaccines should be isolated from systemic sites such as meninges, spleen, liver, and joints and not from lungs, nasal cavities, or tonsils.

Direct detection of *S. suis* from infected tissues has also been studied (Boye et al. 2000), although its application is limited due to poor differentiation of serotypes. A multiplex nested PCR to detect and differentiate *H. parasuis*, *S. suis*, and *Mycoplasma hyorhinis* in formalin-fixed, paraffin-embedded tissues from pigs with polyserositis has been described (Kang et al. 2012). Detection of some *S. suis* serotypes by PCR (or even the presence of *mrp/ef/sly* positive strains) has also been reported (Wisselink et al. 2002). However, these methods are not used in routine diagnosis in veterinary medicine, although they have been used in humans (Gottschalk et al. 2010; Nguyen et al. 2015). It is important to mention that PCR for direct detection of serotypes 2 and 1 strains will also detect serotypes 1/2 and 14 strains, respectively. Finally, oral fluid samples were recently tested for detection of *S. suis* (Cheong et al. 2017). However, since *S. suis* is normally present in saliva (Dekker et al. 2013), the use of such a sample does not have any practical advantage.

After isolation, biochemical identification of *S. suis* isolates is possible with a minimum of tests when serotyping is available (Higgins and Gottschalk 1990). Devriese et al. (1991) suggested the use of only two tests on pig isolates:amylase positive and Voges–Proskauer (acetoin) negative. However, this simplified identification schema can only be used for isolates recovered from diseased or dead pigs and from sites other than the upper respiratory tract. In addition *S. suis*-like isolates can also be misidentified as *S. suis* using these tests (Okura et al. 2016). More recently evaluation of matrix-assisted laser desorption/ionization time-of-flight mass spectrophotometry (MALDI-TOF MS), as alternative tool for *S. suis* identification, has produced good results (Matajira et al. 2017; Pérez-Sancho et al. 2015).

Serotyping is still an important part of the routine diagnostic procedure. It can be carried out by different techniques, but many laboratories have adopted the coagglutination technique. Some isolates cross-react with more than one typing antiserum, and some strains are autoagglutinating, keeping the percentage of untypable strains around 20% (Gottschalk and Lacouture, 2015). During the last years, PCR tests have been developed that would allow different laboratories to perform complete serotyping without the need of different antisera (Okura et al. 2014). However, as serotypes 2 and 1/2 as well as serotypes 1 and 14 cannot be differentiated by PCR, specific antisera are still needed to differentiate these serotypes. Recently, *in silico* serotype determination from whole genome sequencing short-read data was shown to be useful for complete serotyping with clear differentiation of these serotypes (Athey et al. 2016). It was shown that strains of serotype pairs 1 and 14 and 2 and 1/2 can be differentiated by a missense mutation in the *cpsK* gene (Athey et al. 2016). Multiplex *S. suis* serotyping assay that simultaneously detects 33 serotypes using the Luminex xTAG universal array technology has also been developed (Bai et al. 2015).

Genetic tools may be useful in distinguishing isolates of *S. suis*, in determining the origin of infection in a given herd, in monitoring the kinetics of an outbreak, or in selecting strain(s) for inclusion in a vaccine. Restriction fragment length polymorphisms, random amplified polymorphic DNA, ribotyping, pulsed-field gel electrophoresis, and multiple-locus variable number tandem repeat analysis have been used (Martinez et al. 2002; Tian et al. 2004). More recently, 876 genes were defined as the minimum core genome (MCG) of the *S. suis* species. Different single nucleotide polymorphisms (SNPs) were located in the MCG genes and were referred to as MCG SNPs that can be used to classify and compare isolates within different MCG. This typing system facilitates the application of genome data to the surveillance of *S. suis* strains in a given region. The MCG groups may also be used to define *S. suis* subpopulations with the potential to cause severe clinical infections and large–scale outbreaks (Zheng et al. 2014).

Genomic fingerprinting allows the identification of isolates involved in outbreaks within a herd (Cloutier et al. 2003). Atypically, several distinct strains of *S. suis* serotype 2 may be isolated from systemic sites in the same or different animals (Marois et al. 2007). In herds affected with serotypes other than 2, such as serotype 1/2, clinical manifestations of the disease are more likely to be the result of inherent herd factors than the virulence of a specific isolate (Martinez et al. 2002). The great genetic heterogeneity of *S. suis* strains, the isolation of different strains within the same herd, and the predominance or not of particular strains in clinical disease are evidence that infection by *S. suis* is a dynamic process and reinforce the idea that its epidemiology is very complex (Vela et al. 2003). Isolates of *S. suis* serotype 2 from different geographical origins may be genotypically and

phenotypically different (Rehm et al. 2007). However, some strains share genotypic and phenotypic characteristics. For example, the use of MLST has shown that most serotype 2 strains involved in swine diseases from Eurasia are ST1, MRP$^+$, EF$^+$, and SLY$^+$, whereas those from North America are ST25 or ST28, MRP^v, EF$^-$, and SLY$^-$.

The advent of whole genome sequencing has contributed to the identification of further diversity within the *S. suis* species, as evidenced by more than 1000 published genomes of various serotypes and STs, yet a vast majority are incomplete annotations with only a few being circularized closed genome sequences. Nevertheless, genome comparisons between different strains and serotypes have identified major variations in gene content (Segura et al. 2017). Extensive genomic comparisons involving a sample of >300 strains of different serotypes and genetic backgrounds, although of limited geographic diversity (United Kingdom and Vietnam only), identified genetic differences between systemic, respiratory, and carriage *S. suis* isolates and a generalized tendency that disease-causing isolates have significantly smaller genomes than nonclinical isolates (Weinert et al. 2015). However, it is apparent that systemic isolates of these more virulent strains with reduced genomes are also carried in the nasopharynx niche (Weinert et al. 2015).

Surveillance in clinically healthy pigs

Detection of *S. suis* from tonsils or nasal cavities has no practical utility in the diagnosis of *S. suis* disease. *S. suis* is a normal inhabitant of the upper respiratory tract and is present in almost all herds, and mixtures of avirulent and virulent strains of different serotypes may reside in the same pig or herd (MacInnes et al. 2008). These sites are highly contaminated, and traditional bacterial isolation presents a low sensitivity (Gottschalk et al. 1999). The presence of a specific *S. suis* serotype in high numbers in nasal cavities and/or tonsils may reflect active transmission of the infection rather than a carrier state (Cloutier et al. 2003; Marois et al. 2007). The prevalence of a specific serotype may also be underestimated in nasal swabs or tonsils due to the lack of sensitivity of the isolation method. Selective isolation using immunomagnetic beads coated with serotype 2-specific antibodies or use of PCR significantly increases the detection rate from tonsils when compared with the standard isolation technique (Cloutier et al. 2003; Gottschalk et al. 1999; Marois et al. 2007). However, and as mentioned above, the PCR for serotype 2 and 1 strains based on detection of the CPS gene will also detect serotype 1/2 and 14 strains, respectively (Marois et al. 2004; Wisselink et al. 2002). PCR tests for direct detection of *ef* or *mrp* positive strains from tonsils have also been described (Swildens et al. 2005; Wisselink et al. 1999); however, this technique can only be used where virulent strains are positive for these factors. In addition, since some serotypes can also harbor one of these genes, a positive PCR does not definitively mean that virulent strains positive for both factors are present. Since many *S. suis*-like strains are also normal inhabitants of the upper respiratory tract, untypable isolates recovered from tonsils or nasal cavities should be confirmed as *S. suis* by genetic methods (Okwumabua et al. 2003). Biochemical identification alone, either traditional or by the use of rapid multitests, may be misleading (Okura et al. 2016). Up to 50% of isolates recovered from tonsils of healthy pigs and biochemically identified as being *S. suis* may be negative using a species-specific PCR (unpublished observations). On the other hand, many *S. suis* isolates, mainly serotypes 9–34 as well as untypable strains, may give atypical biochemical profiles that will clearly underestimate the prevalence of real *S. suis* (Gottschalk et al. 1991; Okura et al. 2016).

Serologic tests for the detection of antibodies against *S. suis* have been evaluated (del Campo Sepúlveda et al. 1996; Kataoka et al. 1996). Recently, an ELISA test has been used to measure antibodies against *S. suis* in different tests (Wallgren et al. 2016). However, these tests are generally not useful since many cross-reactions may be detected with different strains of *S. suis* or other streptococci. In addition, *S. suis* does not induce high antibody titers, even after an experimental infection (Calzas et al. 2015). A herd/strain-specific ELISA test using either whole bacteria or a protein extract of the predominant virulent *S. suis* strain from the herd may allow the evaluation of maternal antibody levels to determine the best time for vaccination and to monitor antibody levels after either natural infection or vaccination (Cloutier et al. 2003; Lapointe et al. 2002). Practically, this approach has little utility as a routine test owing to the marked diversity of strains infecting herds and the impracticality of developing herd/strain-specific serology tests. A whole-cell ELISA test has also been reported (but not validated) to measure exposure to *S. suis* in humans (Smith et al. 2008).

Treatment

The choice of the best antibacterial agent against *S. suis* infections should be based on susceptibility of the organism, the type of infection, and the mode of administration. Determination of minimal inhibitory concentrations (MICs) in isolates from Europe showed that emergence of resistance among *S. suis* derived from swine clinical cases appeared to be limited. Resistance to ampicillin, ceftiofur, enrofloxacin, florfenicol, penicillin, and trimethoprim/sulfamethoxazole was low, whereas that to tetracycline was constantly very high (El Garch et al. 2016; van Hout et al. 2016). However, strains isolated from tonsils of healthy animals or from the environment of slaughterhouses are usually multiresistant (Soares et al. 2015; Zhang et al. 2015). In North America, a large

number of isolates were shown to be moderately susceptible to penicillin, but the sensitivity rate to amoxicillin and ampicillin was around 90% (Dee and Corey 1993). Even if MIC values for penicillin may gradually increase with time, pigs infected with strains showing higher MICs may still respond well to treatment with this antibiotic (Callens et al. 2013; Varela et al. 2013). Serotype–specific patterns of susceptibility to antimicrobials have been described and may differ between regions (Marie et al. 2002; Vela et al. 2005).

MacInnes and Desrosiers (1999) suggested that ampicillin, ceftiofur, gentamicin, tiamulin, and a combination of trimethoprim and a sulfonamide are the most useful antibacterial products for parenteral treatment. However, the choice of antimicrobials used for the treatment of diseased animals should preferably be based on knowledge of the local pattern of resistance (Dee and Corey 1993). Early recognition of nervous signs including holding back of ears, squinting, and dog-sitting followed by immediate parenteral treatment with an appropriate antibiotic with or without an anti-inflammatory agent maximizes pig survival (Amass et al. 1997). During an outbreak, pigs should be monitored 2–3 times daily, and new cases treated. In segregated early weaned pigs with acute *S. suis* meningitis, excellent results were obtained with injection of penicillin and dexamethasone (Varela et al. 2013). In outbreaks where response to parenteral treatment of acute cases is poor, it is advisable to treat all the pigs in a pen when one is affected or found dead (MacInnes and Desrosiers 1999). Treatment can also be administrated via the drinking water or in medicated feed. However, treatment needs to be started very quickly and be continued for at least 5 days (Denicourt and Le Coz 2000). Amoxicillin is frequently used since it rapidly achieves high plasma levels and diffuses well into the extracellular space (Denicourt and Le Coz 2000). In other studies, use of ampicillin and penicillin G did not significantly reduce disease in animals exposed to a coinfection with *S. suis* and PRRSV (Halbur et al. 2000; Schmitt et al. 2001). They found that treatment with ceftiofur was the only regimen that significantly reduced mortality, severity of gross lung lesions, and recovery of *S. suis* from tissues at necropsy. Another study reported that the pharmacokinetics of ceftiofur hydrochloride in pigs coinfected with PRRSV and *S. suis* was significantly different compared with that of clinically healthy pigs, indicating that the health status of an affected animal may influence the availability of this antimicrobial (Day et al. 2015).

Prevention

Reduction of predisposing factors

Streptococcus suis emerged as an important pathogen with intensification of the swine industry. In addition to virulence of involved strains, other factors impact development of disease including immune status of the herd, mixing of infected and naïve uninfected pigs, concurrent infections and immunosuppression, quality of the environment, and other management factors. Control of these factors helps prevent disease in herds harboring virulent strains.

Overcrowding, poor ventilation, excessive temperature fluctuations, and mixing of pigs with an age spread of more than 2 weeks seem to be the most important stress factors involved in the development of *S. suis* infection in susceptible pigs (Dee and Corey 1993). Management practices such as all-in/all-out pig flow can help reduce the incidence of the disease. Dividing large buildings into smaller rooms can help minimize temperature fluctuations and the age spread between pigs. Cleaning each room between groups of pigs reduces buildup of microorganisms and improves health status, average daily gain, and feed conversion (Dee and Corey 1993).

Infection with some viruses is known to render pigs more susceptible to *S. suis* disease or potentiate lesions in pigs. Control of such viruses helps minimize the impact of *S. suis*. Acute infections with virulent North American PRRSV significantly increase susceptibility to *S. suis* disease (Thanawongnuwech et al. 2000). Likewise, piglets infected with PRRSV acquired *in utero* are more susceptible to infection and disease following challenge by *S. suis* serotype 2 (Feng et al. 2001). Concurrent infection with pseudorabies (Aujeszky's) and influenza virus may enhance clinical disease caused by *S. suis* (Iglesias et al. 1992; Lin et al. 2015).

Antimicrobial preventive medication

A wide range of antibiotics are used in pig husbandry for targeted prophylactic and metaphylactic use (Seitz et al. 2016). Strategies for prophylactic antimicrobial medication for *S. suis* should reflect consideration of bioavailability, route of administration (feed or water), competition (feed and water availability), and serum concentration needed to kill *S. suis* (Amass et al. 1997). Penicillin and amoxicillin are frequently used in most countries where metaphylactic use is still allowed (Seitz et al. 2016). Byra et al. (2011) reported that potassium penicillin G administered in drinking water is effective in reducing mortality associated with *S. suis* infection.

Immunization

As the complexity of *S. suis* epidemiology in swine increases (multiple serotypes, multiple strains within serotypes with high phenotypical diversity), field reports describing difficulty in disease control and management, especially "vaccine failure", are common. In fact, *S. suis* is a clear example of a bacterial disease extremely difficult to be controlled through vaccination. For a complete and recent review, see Segura (2015).

Vaccines used in the field to prevent *S. suis* disease are either autogenous or (a very few) commercial bacterins, and results have been inconsistent (Halbur et al. 2000; Reams et al. 1996; Segura 2015). Possible reasons for failure of autogenous vaccines include degradation of protective antigens caused by heat or formalin processing, inadequate bacterial antigen concentrations, the adjuvant included in the formulation, low production of antibodies, and/or production of antibodies to antigens not associated with protection (del Campo Sepúlveda et al. 1996; Segura 2015). Field studies also reported failure of a commercial serotype 2 bacterin to protect against nursery mortality (reviewed by Segura [2015]). In a few cases, good protection against challenge with serotype 2 could be obtained with bacterins (Baums et al. 2009). Wisselink et al. (2001) showed that a bacterin with a water-in-oil emulsion adjuvant produced better results than with an aluminum hydroxide-based adjuvant. It is clear that protection (if any) is serotype dependent and commercial vaccines should not be used without clear information about the serotype/strain involved in the clinical cases. Even within the same serotype, protection obtained with a commercial bacterin may be difficult to predict due to high phenotypic variation within strains of the same serotype, based on available data for serotype 2 (Segura 2015). Efficacy of autogenous *S. suis* bacterins is uncertain as there is little published data. It is difficult to assess observations made in the field, because there are many uncontrolled factors in commercial herds that can influence the results. Certainly, any attempt to assess the efficacy of an autogenous *S. suis* vaccine in the field must include equal numbers of non-vaccinated controls (Segura 2015).

The nature of antibodies that are needed to obtain protection is unclear. Antigenicity of CPS and the need for anti-capsular antibodies in protection are still controversial. Pigs experimentally or naturally infected with *S. suis* type 2 only produced low levels of antibodies against the CPS (Calzas et al. 2015). Wisselink et al. (2002) showed that antibodies against the CPS and other bacterial components are essential for full protection against homologous challenge. Indeed, a recent study showed very good protection using a CPS-glycoconjugate vaccine based on purified CPS of *S. suis* serotype 2 conjugated to a carrier protein (Goyette-Desjardins et al. 2016). Since the structure and antigenicity of the CPS is the same for all strains within a serotype, this vaccine would be protective against any serotype 2 strain. However, a previous study showed that the serotype-specific protection obtained with a bacterin was due to the presence of opsonic antibodies directed to antigens different from the CPS (Baums et al. 2009).

Most vaccination-challenge studies have been carried out with piglets. Because *S. suis* disease is most often at 6–10 weeks of age and the first of 2 doses of bacterin need be given at approximately 3–4 weeks of age, interference by maternal antibodies must be considered. Lapointe et al. (2002) found better response to vaccination in 2–4-week-old pigs with lower levels of maternal antibodies to the serotype 1/2 bacterin strain as compared with cohorts with higher maternal titers.

Vaccination of sows and gilts has also been sometimes described as effective (Swildens et al. 2007). Sow vaccination is less costly and labor intensive, thus representing an economical alternative to piglet vaccination. Yet available results indicate that sow vaccination with bacterins as a means to protect their piglets is a matter of controversy. Vaccinated sows with a formalin-killed *S. suis* serotype 2 bacterin five and three weeks before parturition responded poorly or not at all to vaccination and resulted in low maternal immunity transferred to the litters (Blouin et al. 1994). In a field trial, vaccination of sows with a commercial serotype 2 bacterin did not consistently reduce nursery mortality due to *S. suis* (Torremorrell et al. 1997). Similarly, administration of a *S. suis* serotype 14 bacterin to sows four and one week pre-farrowing failed to confer protection against mortality and only partially protected against morbidity in their progeny after homologous challenge (Amass et al. 2000). In contrast, a field study with a *S. suis* serotype 2 autogenous bacterin showed that opsonizing antibodies were increased in the serum and colostrum of sows vaccinated five and three weeks pre-farrowing, specific antibodies were detected in their litters, and pigs were protected up to 6 weeks of age (Baums et al. 2010). A recent study showed that 5-week-old piglets from vaccinated sows were protected against an experimental infection with virulent strains of *S. suis* (Hsueh et al. 2017). These data suggest that protective passive maternal immunity for *S. suis* serotype 2 can be achieved by bacterin vaccination of sows. However, without subsequent active vaccination of the piglets to lengthen protection, this strategy might lead to highly susceptible growers (Baums et al. 2010). As in the case of piglet vaccination, scientific studies (with control groups) that include production and evaluation of antibodies in vaccinated sows, duration of maternal antibodies, and functional evaluation of such antibodies must still be done to confirm the usefulness of sow vaccination with bacterins (Segura 2015).

In herds infected with multiple strains or serotypes of *S. suis*, multivalent vaccines or vaccines that provide a strong degree of cross-immunity are needed to provide adequate control of infection. Bacterins do not seem to fulfill this requisite (Segura 2015). Subunit vaccines based on proteins conserved among serotypes may be more useful in providing practicable heterologous

protection. Although a large amount of information regarding the use of subunit candidates has been published in recent years, data are still experimental, and no commercial vaccine is yet available (Segura 2015). With a few exceptions, proposed *S. suis* candidates concern serotype 2 only, and strictly homologous protection was evaluated. Only one protein candidate, surface antigen one (Sao), has been shown to induce cross-serotype protection (Hsueh et al. 2017). Confusing data using different animal models, different strains, and vaccine formulated with adjuvants inducing deleterious side effect have been published (Segura 2015). More scientific studies confirmed by different research groups must be performed in order to identify good vaccine candidates (Segura 2015).

Of these protein vaccine candidates, MRP, EF, and SLY have been frequently proposed as protective (Wisselink et al. 2001). However, consensus of studies is that high levels of antibodies against these proteins do not provide protection and their use as subunit vaccines remains controversial (Segura 2015). In addition, since these proteins are not widely present among virulent serotype 2 strains, their usefulness as cross-protective subunit vaccines is limited, unless combined with other more universal immunogenic proteins (Segura 2015).

Based on the observation that convalescent animals are protected against reinfection, low doses of virulent *S. suis* were administered as a live vaccine and were shown to induce good protection against challenge, although the low dose virulent vaccine induced some pathology (Schmitt et al. 2001). Many studies have shown that infection of mice with live avirulent *S. suis* mutants confers homologous and, in some cases, heterologous protection (Gottschalk and Segura 2000; Segura 2015). Only a few live bacterial candidates have been tested in pigs with mixed results (Segura 2015). Side effects such as hyperthermia, extra connective tissue reactions, lameness, convulsions, and others have been reported with some of the experimental live vaccines when used in pigs (Segura 2015). Further attenuation would thus be necessary for routine use in pigs. The challenge in creating a live vaccine is to obtain a fully attenuated strain that induces protective immunity and is also safe. In addition, since *S. suis* is also a zoonotic agent, safety of a live vaccine is a major public health concern. The possibility that an attenuated strain in pigs is not completely attenuated in humans cannot be completely excluded. The risks of introducing a live vaccine strain into a commercial herd have not been well established and require further studies (Segura 2015).

Because virulent systemic strains of *S. suis* rarely colonize the upper respiratory tract of sows and gilts and few piglets are colonized with these strains by weaning, induction of nasal colonization in young pigs with the herd's systemic strain was suggested as a means of disease prevention (Oliveira et al. 2001). Results showed that inoculation of 5-day-old piglets with the herd's systemic strain of *S. suis* tended to be more effective in reducing the morbidity and mortality than the colonization of piglets by nose-to-nose contact with inoculated sows (Oliveira et al. 2001). However, once again, the use of a virulent strain with an important zoonotic potential should be carefully evaluated.

Eradication

Attempts to eradicate *S. suis* infection have focused only on serotype 2. Medicated early weaning (MEW) is ineffective since *S. suis* is a very early colonizer. Cesarean section can be used to derive pigs free of *S. suis* from infected dams. According to Clifton-Hadley et al. (1986), only depopulation and restocking with "clean" pigs will ensure eradication of the infection, and in most herds this is cannot be justified economically. The problem is in determining whether a pig or herd is "clean." There is no diagnostic test able to detect with high confidence the presence of virulent strains in carrier pigs. The definition of a "clean" herd would then need to be a herd with a history free of endemic disease due to *S. suis*. Still, the presence of carrier animals harboring virulent strains cannot be ruled out. In the presence of predisposing factors (see above), these strains may induce clinical disease. Even if accomplished, strict biosecurity measures are needed that include eliminating rodents, and perhaps flies, in order to prevent reinfection (Amass et al. 1997). Mills (1996) described procedures used to establish a purebred minimal-disease herd from gilts that were carriers of a virulent strain of *S. suis* type 2. Amass et al. (1996) did not recommend such an approach, but instead recommend optimization of management and environment of pigs coupled with strategic medication of clinically ill animals for control and prevention of mortality caused by *S. suis*. It has been suggested that *S. suis* may be purportedly eliminated from tonsils of sows through vaccination with a bacterin combined with medication, resulting in progeny free of pathogenic *S. suis* (Swildens et al. 2007). However, this approach has not been successful in the field (unpublished data). Byra et al. (2011) showed that potassium penicillin G administered in drinking water was effective in reducing mortality associated with *S. suis* infection as well as tonsillar carriage of *S. suis*.

Given the cost of eliminating *S. suis*, the risk of failure, the difficulty in maintaining a free herd, and the lack of tools to monitor herd status, it would appear reasonable to direct resources toward control measures rather than eradication.

Infections caused by beta-hemolytic streptococci

Streptococcus porcinus

The name *Streptococcus porcinus* was proposed in 1984 (Collins et al. 1984) to represent streptococci of serological groups E, P, U, and V that formed a single DNA–DNA homology group. *S. porcinus* has a unique phenotypic profile in addition to serologic differences that can be used to help identify the species.

Streptococcus porcinus can be isolated from tonsils, pharynx, and nasal cavities of clinically healthy pigs. In fact, it is one of the most common bacterial species recovered from tonsils at slaughterhouses (O'Sullivan et al. 2011). It is also occasionally found in the vaginal mucus of sows and in the semen and prepuce of boars. It is considered to be more of a secondary invader than a primary pathogen in conditions such as pneumonia, enteritis, encephalitis, and arthritis (Wessman 1986). *S. porcinus* group E has been associated in the United States with a contagious entity in growing pigs known as streptococcal lymphadenitis, jowl abscesses, or cervical abscesses. Transmission is by contact, drinking water, or ingestion of food contaminated by abscess discharge or infected feces. The organisms enter through the mucosa of the pharyngeal or tonsillar surfaces and are carried to the lymph nodes primarily of the head and neck region where abscesses are formed (Wessman 1986). Losses due to this disease in the United States were important in the 1960s, but the incidence and importance has since dramatically declined. The disease is not recognized as an important economic entity in other countries, where the bacterium represents only a few percent of the microorganisms isolated from abscesses in swine (Wessman 1986). A report of an outbreak from Spain mentioned that 80% of 50 feeder pigs had mandibular and retropharyngeal purulent lymphadenitis (Real et al. 1992). Antibiotic treatment is not usually successful in abscessed swine or in elimination of carriers. Resistance to tetracycline has been reported (Lämmler and Bahr 1996). Vaccination is possible but has not been widely used since the condition is not widespread.

Streptococcus porcinus groups P, U, and V were isolated by Hommez et al. (1991) from pig lungs, genital organs, and brains. However, no histological lesions could be associated with their presence. *S. porcinus* groups P and V were associated with abortions in pigs (Lämmler and Bahr 1996; Plagemann 1988). Katsumi et al. (1998) reported that from a total of 170 beta-hemolytic streptococci isolated from lesions in slaughtered pigs, 22.4% were identified as *S. porcinus*. Of those, 3.0% belonged to group E, 3.0% to group P, and 8.2% to group U, and 8.2% were ungroupable.

Finally, many strains of *S. porcinus* were supposedly recovered from the human female genitourinary tract and might be considered an emerging human pathogen (Pereira et al. 2013). However, it was later reported that these strains belong to a new species, *Streptococcus pseudoporcinus* (Bekal et al. 2006). Since *S. pseudoporcinus* can also be isolated from dairy cows, subspecies denominations have been proposed:*S. pseudoporcinus* subsp. *hominis* subsp. nov. for the human isolates and *S. pseudoporcinus* subsp. *lactis* subsp. nov. for the dairy isolates (Shewmaker et al. 2012). More recently, a confirmed *S. porcinus* was recovered from a wound in an abattoir worker (Shewmaker et al. 2012).

Streptococcus dysgalactiae

Vieira et al. (1998), based on multilocus enzyme electrophoresis typing and genomic DNA relatedness, proposed that alpha- and nonhemolytic streptococci of Lancefield group C are designated as S. dysgalactiae subsp. *dysgalactiae*, while beta-hemolytic streptococci belonging to Lancefield groups C, G, or L are designated as S. dysgalactiae subsp. *equisimilis*. In swine, members of the S. dysgalactiae subsp. *equisimilis* species are all beta-hemolytic streptococci. Although members of the normal flora, they are considered the most important beta-hemolytic streptococci involved in lesions in pigs (Hommez et al. 1991). S. dysgalactiae subsp. *equisimilis* can be reliably identified using MALDI-TOF MS (Matajira et al. 2017).

Streptococcus dysgalactiae subsp. *equisimilis* is common in nasal and throat secretions, tonsils, and vaginal and preputial secretions. In fact, vaginal secretions and milk from post-parturient sows are the most likely sources of infection for the piglets (Woods and Ross 1977). Streptococci enter the bloodstream via skin wounds, the navel, and tonsils. A bacteremia or septicemia occurs, and the organisms settle in one or more tissues, giving rise most commonly to arthritis, endocarditis, or meningitis. Infection is usually first seen in pigs between 1 and 3 weeks of age. Joint swelling and lameness are the most obvious and persistent clinical signs. Elevated temperatures, lassitude, roughened hair coat, and inappetence may also be noted. Early lesions consist of periarticular edema, swollen hyperemic synovial membranes, and turbid synovial fluid. Necrosis of articular cartilage may be observed 15–30 days after onset and may become more severe. Fibrosis and multifocal abscessation of periarticular tissues and hypertrophy of synovial villi also occur. Hill et al. (1996) reported that in lame pigs up to 12 weeks of age, the most common causative agent was S. dysgalactiae subsp. *equisimilis* and most of the pigs culled for arthritis were under 6 weeks of age (Hill et al. 1996). Hommez et al. (1991) mentioned that S. dysgalactiae

subsp. *equisimilis* is frequently isolated from pigs with septicemia, arthritis, or valvular endocarditis. Katsumi et al. (1998) reported that during a 7-year period, 77.6% of beta-hemolytic streptococci isolated from slaughtered pigs in Japan belonged to the S. dysgalactiae species. More recently, severe disseminated suppurative meningoencephalomyelitis due to S. dysgalactiae subsp. *equisimilis* has been described (Kasuya et al. 2014). It has also been isolated from several tuberculosis-like lesions in condemned pigs at the slaughterhouse in Spain (Cardoso-Toset et al. 2015).

Beta-hemolytic streptococci are sensitive to beta-lactam antibiotics. High MIC values to tetracyclines, danofloxacin, spectinomycin, tiamulin, and clindamycin have also been reported (Moreno et al. 2016). Long-acting antibacterial agents may be beneficial, and treatment should be given before the inflammatory process is well advanced. Insufficient consumption of colostrum or milk or inadequate levels of antibodies, especially in gilts, may predispose to disease (Windsor 1978). Since baby pigs are virtually assured of being exposed to S. dysgalactiae, effective preventive measures should be followed. Adequate intake of colostrum may ensure that the piglets receive protective antibodies (Zoric et al. 2004). Traumatic injuries to the feet and legs should be minimized by reducing the abrasiveness of the floor surface in the nursing area (Zoric et al. 2009). There are no recent reports about vaccination against groups C or L streptococci. Autogenous bacterins have been used, and a reduction in incidence of arthritis has been reported when sows were vaccinated before farrowing (Woods and Ross 1977).

Other streptococci

Streptococcus equi subsp. *zooepidemicus* (*Streptococcus zooepidemicus*) is classified in Lancefield's group C and causes respiratory disease in a variety of mammals. In Europe and the United States, *S. zooepidemicus* is the primary cause of equine respiratory tract infections in foals and infertility in mares. However in China, *S. zooepidemicus* is the mainly reported in swine. In 1975, an outbreak of *S. zooepidemicus* in swine occurred in western China, resulting in substantial economic losses (Feng and Hu 1977). From the 1990s to the present, sporadic cases and regional epidemics are still impacting the pig industry in China (Mao et al. 2008). A combined vaccine with porcine circovirus type 2 and *S. zooepidemicus* was developed in that country (Lin et al. 2014). *Streptococcus epidemicus* has also been isolated from several tuberculosis-like lesions in condemned pigs at the slaughterhouse in Spain (Cardoso-Toset et al. 2015).

Bacterial streptococcal strains were isolated from the lungs and kidney of two pigs with lesions associated with pneumonia and septicemia, respectively. The two isolates were recovered from animals on different farms located in difference provinces of Spain and in different years. The isolates were classified as a new species, *Streptococcus plurextorum* sp. nov. (Vela et al. 2009). Another new streptococcal species, *Streptococcus porci* sp. nov. has been associated with pneumonia and pericarditis (Vela et al. 2010). So far, there are no data about the habitat and/or the virulence properties of these two species.

Swine Dysentery and Brachyspiral Colitis

David J. Hampson and Eric R. Burrough

Overview

This chapter reviews a group of diseases of swine resulting from infection with anaerobic intestinal spirochetes of the genus *Brachyspira*. These include swine dysentery (SD), a severe mucohemorrhagic colitis (dysentery) caused by infection with strongly hemolytic *Brachyspira* species, as well as milder forms of brachyspiral colitis caused by weakly hemolytic *Brachyspira* species. Among the latter is a specific disease called porcine intestinal spirochetosis or porcine colonic spirochetosis (PIS/PCS) resulting from infection with *Brachyspira pilosicoli*.

Summary of recent developments

Emergence of new species of *Brachyspira* and of atypical strains of *Brachyspira hyodysenteriae* has confounded diagnosis of SD and interpretation, particularly when *B. hyodysenteriae* is detected in herds without apparent SD. Besides *B. hyodysenteriae*, the classical agent of SD, two other strongly beta-hemolytic species (*Brachyspira hampsonii* and *Brachyspira suanatina)* are also agents of SD in some parts of the world. Additionally, isolates of *B. hyodysenteriae* are increasingly cultured from herds without apparent SD. Some of these isolates exhibit typical strong hemolysis on blood agar, while others are atypically weakly hemolytic. Lack of apparent SD in these herds suggests the existence of weakly virulent or avirulent strains of *B. hyodysenteriae*. Alternatively, herd-specific cofactors such as alteration of colonic microbiota by diet or other cofactors needed for expression of SD by virulent *B. hyodysenteriae* may be lacking. This means that a definitive diagnosis of SD requires the confirmation of a strongly beta-hemolytic *Brachyspira* spp. in the colonic mucosa or feces of pigs with typical dysentery and/or lesions. It also means that the detection of *B. hyodysenteriae* in herds without apparent SD does not definitively prove that these strains have the potential to cause SD in these herds. Encouragingly, an expanding array of molecular diagnostic techniques is becoming available to support disease diagnosis and investigation.

Of particular concern is the worldwide emergence of pathogenic *Brachyspira* species and strains with reduced susceptibility to commonly used antimicrobials. Efforts to identify alternatives to antimicrobials to help control these infections are ongoing.

Overview of *brachyspira* species

The genus *Brachyspira* contains nine officially recognized and several unofficial species. These gram-negative anaerobic bacteria are genetically distinct from other spirochetes and have adapted to occupy specialized niches in the large intestines of various birds and mammals. Seven *Brachyspira* species colonize swine: the three most common pathogenic species are *B. hyodysenteriae* and *B. hampsonii*, both agents of SD, and *B. pilosicoli*, the cause of PIS (or PCS). Of the other potentially pathogenic species, *B. suanatina* is an agent of SD that has only been reported in Scandinavia (Mushtaq et al. 2015), and some strains of *Brachyspira murdochii* and *Brachyspira intermedia* may occasionally cause colitis in swine. The final species colonizing swine is *Brachyspira innocens*, a nonpathogenic commensal. Relationships between the recognized species, based on their 16S rRNA gene sequences, are shown in Figure 62.1.

All the *Brachyspira* species resemble short slender snakes with several loose coils (Figure 62.2). Those that colonize swine are 5–11 μm in length and 0.2–0.4 μm in width. *Brachyspira* have two sets of periplasmic flagella that wind around the cell body beneath the outer envelope, with each set anchored at opposite ends of the spirochete cell. These flagella confer a corkscrew-like motility that helps them to penetrate and move through the viscous digesta and mucus overlying the colonic epithelium.

Brachyspira spp. DNA has a low guanine and cytosine ratio, from 24.6 to 28%. Genome sizes are from

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

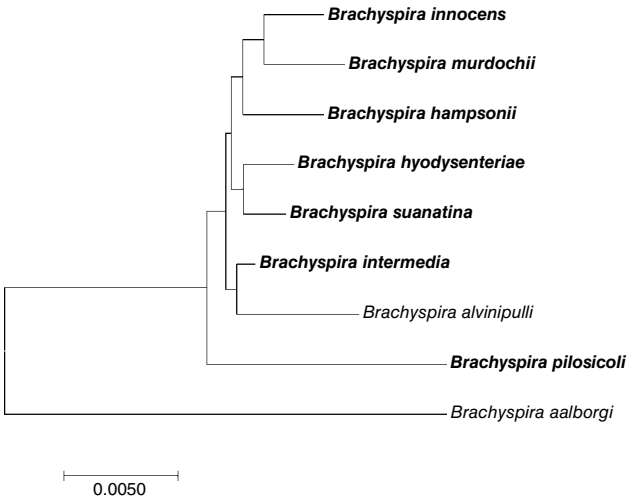

Figure 62.1 Relationships between the nine officially named *Brachyspira* species based on the 16S rRNA gene sequences of the type strains. The seven species that are known to colonize pigs are marked in bold. *Source:* Courtesy of Drs. David Hampson and Tom La.

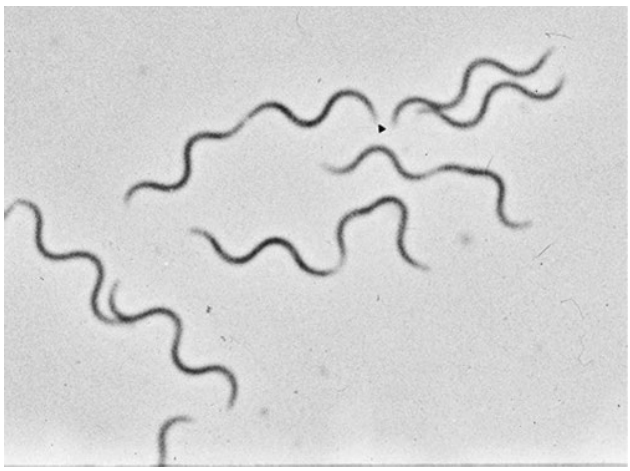

Figure 62.2 Cells of *Brachyspira hyodysenteriae* as viewed under a phase-contrast microscope.

approximately 2.5 to 3.2 million base pairs (Mbp), each with >2300 protein coding sequences. Most species share close similarities in their 16S rRNA gene sequences, implying that separation of species occurred relatively recently. *B. hyodysenteriae* strains contain a approximately 36 kb plasmid (Bellgard et al. 2009; Black et al. 2015), a 3.2 kb plasmid is present in *B. intermedia* strain PWS/A^T (Håfström et al. 2011), and a putative plasmid sequence and a bacteriophage sequence occur in *B. suanatina* strain AN4859/03 (Mushtaq et al. 2015). *B. hyodysenteriae* contains a prophage-like gene transfer agent (GTA) that randomly packages approximately 7.5 kb fragments of host DNA and transfers it to other *B. hyodysenteriae* strains (Humphrey et al. 1997; Matson et al. 2005). Other *Brachyspira* species harbor similar GTA sequences (Motro et al. 2009; Stanton et al. 2003), although it is not known whether they are functional. The GTAs could contribute to the extensive gene rearrangements that occur within and between *Brachyspira* species (Mappley et al. 2012; Zuerner et al. 2004).

The *Brachyspira* species are anaerobic but can tolerate brief oxygen exposure. They grow slowly *in vitro* and can easily be overgrown by other anaerobic members of the enteric microbiota unless selective isolation medium is used. Agar should be made selective with the addition of 400 µg/mL spectinomycin and 25 µg/mL each of colistin and vancomycin to make CVS medium (Jenkinson and Wingar 1981). The more selective BJ medium (Kunkle and Kinyon 1988) containing lower concentrations of the three antimicrobials, but with 25 µg/mL spiramycin and 12.5 µg/mL rifampin added, can also be used for agents of SD, but is not recommended for *B. pilosicoli* as it may inhibit growth. Typically *Brachyspira* form a low flat film of growth after 3–5 days at 98.6–108 °F (37–42 °C), without forming colonies. A zone of beta-hemolysis surrounds growth on plates containing 5% defibrinated ovine or bovine blood. Hemolysis is strong for *B. hyodysenteriae, B. hampsonii*, and *B. suanatina* and weak for the other *Brachyspira* species. Atypical weakly hemolytic isolates of *B. hyodysenteriae* do occur. Strongly hemolytic isolates typically display a characteristic enhanced hemolysis, or ring phenomenon, around defects or slits in the agar (Figure 62.3).

Useful features that may help to distinguish between *Brachyspira* species include their strength of beta-hemolysis, their ability to produce indole, and their enzymatic profile in the commercial API-ZYM kit (Fellström et al. 1997). Some comparative features of the porcine spirochetes are presented in Table 62.1. None can be completely relied upon for identification as strains with atypical phenotypes occasionally are found (Thomson

Figure 62.3 Blood agar plate showing zones of weak beta-hemolysis (left) and strong beta-hemolysis with ring phenomenon (right). *Source:* Courtesy of Joann Kinyon.

Table 62.1 Differentiation of seven *Brachyspira* species that colonize swine using strength of hemolysis on Trypticase soy blood agar, biochemical reactions, and utilization of sugars.

Species	Hemolysis	Indole	Hippurate	API-ZYM[a]
B. hyodysenteriae	Strong[b]	+[c]	–	1
B. hampsonii	Strong	–	–	3
B. suanatina	Strong	+[d]	–	5
B. intermedia	Weak	+	–	1
B. innocens	Weak	–	–	2
B. murdochii	Weak	–	–	3
B. pilosicoli	Weak	–[c]	+[e]	4

[a] Reactions in the commercial API-ZYM test:

1) Alpha-glucosidase positive; alpha-galactosidase negative.
2) Alpha-glucosidase positive or negative; alpha-galactosidase positive.
3) Alpha-glucosidase negative; alpha-galactosidase negative.
4) Variable reactions, including positive reactions for both enzymes; beta-glucosidase negative.
5) Alpha-galactosidase negative; beta-glucosidase positive.

[b] Weakly hemolytic strains of *B. hyodysenteriae* have been recorded.
[c] Indole-negative strains of *B. hyodysenteriae* and indole-positive strains of *B. pilosicoli* have been recorded.
[d] Weakly positive indole.
[e] Hippurate-negative strains of *B. pilosicoli* have been recorded.
+ positive reaction; – negative reaction.

et al. 2001). For example, atypical strains of *B. hyodysenteriae* have been described that are indole negative (Fellström et al. 1999), while others may be weakly hemolytic (La et al. 2016a; Mahu et al. 2016).

Swine dysentery

Relevance

SD was first recognized in the 1920s, but the spirochetal etiology was not determined until the early 1970s (Glock and Harris 1972; Taylor and Alexander 1971). The causal agent was originally named *Treponema hyodysenteriae* (Harris et al. 1972), but this species and the weakly beta-hemolytic *Treponema innocens* (Kinyon and Harris 1979) were later transferred to the genus *Serpula* and then to *Serpulina* (Stanton 1992) and are now classified in the genus *Brachyspira* (Ochiai et al. 1997). It is now known that *B. hyodysenteriae* is not the sole etiologic agent of SD. Strongly beta-hemolytic *B. hampsonii* and *B. suanatina* can also induce SD in susceptible pigs. SD is therefore redefined as a disease of pigs with characteristic mucohemorrhagic diarrhea (dysentery) and colitis from which any strongly beta-hemolytic *Brachyspira* spp. is recovered by culture of tissues or feces (Burrough 2017).

In infected herds SD causes considerable financial loss due to mortality, slow growth rates, poor feed conversion, and costs of treatment. Costs also arise from the need to implement preventative measures in herds that do not have SD and from the disruption to the supply and movement of pigs when the disease is introduced into seedstock herds. The disease can also represent a welfare issue unless it is controlled.

Etiology

Of the three known agents of SD, *B. hyodysenteriae* remains the most commonly recognized and reported species worldwide and is also the best characterized. *B. hyodysenteriae* is a discrete species within the genus *Brachyspira*, and analysis of the population structure using multilocus enzyme electrophoresis (MLEE), multilocus sequence typing (MLST), and multiple-locus variable number tandem repeat analysis (MLVA) has shown that the species is diverse, contains numerous genetically distinct strains, and is a nonrecombinant clonal species (Hidalgo et al. 2010a; La et al. 2009b; Lee et al. 1993a; Mirajkar and Gebhart 2014; Osorio et al. 2012; Råsbäck et al. 2007b; Rugna et al. 2015). A recent MLST investigation of *B. hampsonii* revealed a similar population structure (Mirajkar et al. 2015), with the species being divided into three "clades," now known as genomovars (Mirajkar et al. 2016). The existence of numerous distinct strains of *B. hyodysenteriae* can also be demonstrated using techniques such as pulsed-field gel electrophoresis (PFGE) (Atyeo et al. 1999a) and/or random amplified polymorphic DNA analysis (Hidalgo et al. 2010b). Before the advent of molecular methodology, *B. hyodysenteriae* isolates were differentiated into serogroups and serovars, defined on the basis of the antigenic properties of lipooligosaccharides (LOS) extracted from their cell envelopes (Hampson et al. 1997). It is now rare for serotyping to be undertaken, and commercial antisera are not available.

Molecular analysis of isolates has shown that new variants of *B. hyodysenteriae* may emerge on farms (Atyeo et al. 1999a; Hidalgo et al. 2010b). Other than random mutational and recombination events, GTAs may contribute to this strain "microevolution" through transduction of new sequences from other *Brachyspira* species or strains. Newly emerged strains could have altered phenotypic properties, including altered antimicrobial susceptibility, colonization potential, or virulence. Many virulence factors are identified for *B. hyodysenteriae*.

The hemolytic activity of *Brachyspira* spp. is likely an essential virulence factor. The strength of hemolysis has been suggested as a sensitive indicator of potential to induce SD in pigs (Burrough et al. 2012). Three genes (*tlyA*, *tlyB*, and *tlyC*) encoding putative hemolysins of *B. hyodysenteriae* were originally identified based on their ability to induce a hemolytic phenotype in *Escherichia coli* (ter Huurne et al. 1994). The *tly* genes may be regulatory elements rather than encoding hemolysins;

nevertheless, inactivation of *tlyA* has been shown to reduce both the hemolytic activity and the virulence of *B. hyodysenteriae* (Hyatt et al. 1994). Another gene (*hlyA*) encodes an 8.93 kDa acyl carrier protein with hemolytic activity (Hsu et al. 2001). Four other genes predicted to be involved in the hemolytic phenotype include those encoding hemolysin III, hemolysin activation protein, hemolysin III channel protein, and hemolysin (Black et al. 2015; La et al. 2016a). Atypical weakly hemolytic isolates of *B. hyodysenteriae* have been recovered from herds where SD did not appear to be clinically present, although strongly hemolytic isolates also have been recovered from other herds without disease (Hampson et al. 1992, 2016; La et al. 2016a; Lysons et al. 1982; Mahu et al. 2016; Thomson et al. 2001). These weakly hemolytic isolates may be of reduced virulence or be fully avirulent, but to date their potential to cause disease has not been fully explored under standard experimental conditions.

Brachyspira hyodysenteriae has many genes involved in motility and chemotaxis (Bellgard et al. 2009) and exhibits both chemotaxis and viscotaxis toward mucin (Milner and Sellwood 1994; Naresh and Hampson 2010). This affinity for mucin allows *B. hyodysenteriae* to associate with the gut mucosa (Kennedy et al. 1988). Disruptions introduced to *B. hyodysenteriae* flagellar genes (*flaA* and *flaB*) have resulted in reduced motility and colonization ability (Kennedy et al. 1997; Rosey et al. 1996). Colonization of the colonic mucosa may also be enhanced by the NADH oxidase activity of *B. hyodysenteriae* by protecting from oxygen toxicity. Consistent with this, strains with an inactivated NADH oxidase (*nox*) gene show a reduced ability to colonize swine and cause disease (Stanton et al. 1999).

The *B. hyodysenteriae* 36 kb plasmid has also been associated with virulence (La et al. 2011). Application of a DNA microarray to compare the gene content of strains reported to have differences in virulence identified a block of six genes on the plasmid that appeared to be correlated with virulence (La et al. 2014). The function of these genes is unclear, but they may enhance colonization capacity and hence increase the likelihood that a particular strain will colonize to levels where it can induce disease (La et al. 2014). In an analysis of 332 genes encoding predicted virulence factors in *B. hyodysenteriae* isolates from German herds, the only differences between isolates from herds without disease compared with those with disease were in the block of six plasmid genes and in genes encoding some outer membrane proteins, genes associated with iron metabolism, and those associated with hemolysis in the case of weakly hemolytic isolates (La et al. 2016a).

A number of outer membrane proteins and lipoproteins of *B. hyodysenteriae* have been described (Hampson et al. 2006). A 39 kDa variable surface protein (Bhp39) encoded by linked gene copies may be involved in immune avoidance due to differential gene expression (McCaman et al. 2003; Witchell et al. 2006). LOS, a semi-rough form of lipopolysaccharide found in the outer envelope of *B. hyodysenteriae* (Halter and Joens 1988), may produce localized toxic effects that disrupt the colonic epithelial barrier (Greer and Wannemuehler 1989; Nibbelink et al. 1997; Nuessen et al. 1983).

Compared with *B. hyodysenteriae*, much less is known about potential virulence determinants in *B. hampsonii* and *B. suanatina*, but future comparative analysis of the three species may reveal both common and novel virulence mechanisms.

Public health

None of the agents of SD are known to infect human beings.

Epidemiology

The incidence of SD varies in different countries and regions and changes with time. SD caused by *B. hyodysenteriae* remains a relatively common and important endemic problem in many countries. An overall decline in SD incidence occurred in the United States in the 1990s following establishment of new high health status herds in nontraditional swine-rearing states, and with introduction of larger units, multisite production and early weaning systems, but a recent reemergence of disease has occurred both in the United States and in Canada (Burrough 2017). Routine medication with carbadox may also have suppressed the disease, as the incidence has increased again in areas of the world where carbadox has been withdrawn from use (Hampson et al. 2015).

P280/1, the first recorded strain of what is now known as *B. hampsonii* (genomovar 3), was isolated in the 1980s from a pig in the United Kingdom (Atyeo et al. 1999b). Around 2007, *B. hampsonii* strains of genomovars 1 and 2 appeared and rapidly became widespread in pigs in the United States and Canada (Chander et al. 2012; Rubin et al. 2013b). More recently *B. hampsonii* genomovar 1 was isolated from pigs in Belgium and Germany (Mahu et al. 2014; Rohde et al. 2014), while a survey of pig herds in Australia failed to identify either *B. hampsonii* or *B. suanatina* (La et al. 2016b). To date *B. suanatina* has only been isolated in Sweden and Denmark and was first identified in the early 2000s (Råsbäck et al. 2007a).

Agents of SD naturally infect pigs (including feral pigs) and some species of birds (rheas, chickens, ducks, and geese). On infected farms, different agents of SD have been isolated from mice, rats, dogs, and waterfowl. Waterfowl appear to be a significant reservoir and potential means of introduction and spread for *B. hampsonii*, as this agent has been recovered from migratory waterfowl samples in North America and Europe

(Martínez-Lobo et al. 2013; Rubin et al. 2013a), and an avian-origin isolate of *B. hampsonii* induced SD when experimentally inoculated into pigs (Aller-Morán et al. 2016a). Similarly, *B. suanatina* has been recovered from waterfowl in Sweden and Denmark, and an avian-origin isolate induced clinical signs of SD following experimental inoculation in pigs (Råsbäck et al. 2007a).

On endemically infected swine farms, transmission mainly occurs by ingestion of feces containing spirochetes. This is especially likely in single-site, farrow-to-finish herds with continuous flow and poor biosecurity. Agents of SD may be spread by contact with clothing or footwear of animal caretakers that are contaminated with pig feces. Transmission between pens may occur in housing systems where there are open channels between pens. Lagoon water containing effluent can be a source of infection (Glock et al. 1975) and should not be recycled. Feral pigs, other animals including rats and mice, and waterfowl that access farms or their water supplies are potential reservoirs that may transmit infection (Joens and Kinyon 1982; Phillips et al. 2009).

New outbreaks of SD typically occur following introduction of asymptomatic carrier pigs that are not quarantined and/or treated prophylactically. Outbreaks also occur in herds following transmission via rodents or birds from adjacent infected farms, by introduction through contaminated feed or animal trucks, or by visitors who have had contact with infected pigs. When investigating risk factors for SD, Robertson et al. (1992) found that allowing visitors onto farms and the presence of rodents were both associated with disease. In contrast, heightened biosecurity, such as the provision of boots and protective clothing for visitors, the presence of security fencing, on-site feed mixing, and obtaining replacement breeders from a consistent source, were protective. *B. hyodysenteriae* is shed in the feces for variable periods of time, and recovered asymptomatic pigs may transmit infection to susceptible pigs for at least 70 days (Songer and Harris 1978).

Brachyspira hyodysenteriae is relatively resistant in moist feces. It survives in feces diluted in water for 48 days at temperatures from 32 to 50 °F (0–10 °C), for 7 days at 77 °F (25 °C), and less than 24 hours at 98.6 °F (37 °C) (Chia and Taylor 1978). In another study it survived for 10 days in soil at 50 °F (10 °C), for 78 days in soil in the presence of 10% pig feces, and for 112 days in pure pig feces (Boye et al. 2001). Drying of dysenteric feces rapidly kills *B. hyodysenteriae* (Chia and Taylor 1978). Phenolics and sodium hypochlorite are the most effective disinfectants.

Pathogenesis

The pathogenesis of SD is incompletely understood and has been recently reviewed (Burrough 2017). Individual animal susceptibility to development of SD varies and is, in part, due to differences in the colonic microbiota. Gnotobiotic pigs are variably colonized by *B. hyodysenteriae* but do not develop SD, while gnotobiotes inoculated with intestinal scrapings or content from pigs with dysentery readily develop disease (Meyer et al. 1974a,b). These findings suggest that infection with other microorganisms along with an agent of SD is required for disease expression. Anaerobes such as *Bacteroides vulgatus* and *Fusobacterium necrophorum* were shown to successfully fulfill this requirement (Harris et al. 1978).

Following ingestion, *B. hyodysenteriae* survives the acidic environment of the stomach and eventually reaches the large intestine where they colonize and produce disease. Experimentally, an inoculum of 10^5–10^{10} colony-forming units (cfu) may produce SD (Kinyon et al. 1977). Proliferation and colonic mucosal colonization are aided by the ability of *B. hyodysenteriae* to utilize available substrate, penetrate and move through viscous mucus down a chemotactic gradient into the crypts, and avoid potential oxygen toxicity at the surface of the colonic mucosa. Clinical signs and lesions start to develop as bacterial cell numbers reach $10^6/cm^2$ of mucosa (Hughes et al. 1977; Whipp et al. 1979). Spirochetes typically appear in the feces 1–4 days before onset of SD (Costa et al. 2014; Kinyon et al. 1977; Rubin et al. 2013b), concurrent with a shift in colonic bacteria from predominantly gram-positive to mainly gram-negative species (Robinson et al. 1984); however, preclinical shedding of up to 8 days has been reported (Wilberts et al. 2014a).

Brachyspira hyodysenteriae strains vary in their virulence (Achacha et al. 1996), but the basis is poorly understood. The presence of spirochetes close to epithelial cells in the lumen and crypts of the cecum and colon stimulates an outpouring of mucus (Wilcock and Olander 1979a,b). They attach to epithelial cells in the crypt, but the significance of this is unclear since attachment to animal cell cultures does not cause cellular damage or invasion (Bowden et al. 1989; Knoop et al. 1979).

The mechanisms of tissue destruction in SD are not fully understood. There is a loss of sulfated mucins in the colonic mucosa of pigs with acute SD relative to controls, and the mucus layer becomes disorganized and lacks the striations apparent in age-matched control pigs (Quintana-Hayashi et al. 2015; Wilberts et al. 2014a). Additionally, mucin production increases dramatically in pigs with SD due to the *de novo* production of mucin 5AC and increased production of mucin 2 (Quintana-Hayashi et al. 2015). Increased mucus affords increased binding sites for spirochetes, and alteration of the barrier structure may allow improved access to the underlying epithelium. The hemolysin(s) and LOS may then cause local damage, resulting in epithelial sloughing. Subsequent mucosal and submucosal invasion by secondary bacteria and the protozoan *Balantidium coli* may contribute to lesion formation.

Diarrhea appears to result from failure of epithelial transport of sodium and chloride ions from lumen to blood resulting in colonic malabsorption, and not from the activity of prostaglandins released from the inflamed mucosa or spirochetal enterotoxins, or from direct tissue damage induced by spirochetal cell components (Argenzio et al. 1980; Schmall et al. 1983; Whipp et al. 1978). Occasional peracute deaths may arise from endotoxin release.

Under experimental conditions diet has been shown to have a major influence on SD expression. Colonization by *B. hyodysenteriae* can be inhibited by feeding diets that are either highly digestible (Pluske et al. 1996) or rich in inulin (Hansen et al. 2010, 2011; Thomsen et al. 2007), while disease expression is exacerbated in pigs fed diets with increased insoluble fiber (Wilberts et al. 2014b). Diet-related protective mechanisms likely include causing changes in the physicochemical environment of the large intestine, changes in the colonic microbiota with increases in species that directly inhibit spirochetes (Klose et al. 2010; Leser et al. 2000; Mølbak et al. 2007), or a reduction in other anaerobic bacteria that facilitate *B. hyodysenteriae* colonization and augment inflammation and lesion formation (Joens et al. 1981; Whipp et al. 1979).

Clinical signs

SD occurs mainly in grower and finisher pigs and less frequently in weaner pigs. It may begin a few weeks after animals are moved from the nursery, coinciding with a dietary change and removal of antimicrobials used to control respiratory and enteric diseases. Older suckling piglets from gilts that have not been exposed to *B. hyodysenteriae* and piglets in newly infected herds are occasionally affected.

The first evidence of SD is usually soft, yellow to gray feces. Partial anorexia and increased rectal temperature of 104–105 °F (40–40.5 °C) may occur; however, a febrile response is not a consistent feature or predictive of spirochete shedding (Jacobson et al. 2007). A few hours to days after onset of clinical disease, large amounts of mucus and often flecks of blood are found in the feces. This progresses to watery feces containing blood, mucus, and shreds of white mucofibrinous exudate (dysentery) with concurrent staining of the perineum. Most pigs recover over several weeks, but their growth rate remains depressed. Prolonged diarrhea leads to dehydration, and the animals become weak and emaciated.

The incubation period for SD is variable, ranging from 4 days to 3 months, but disease usually occurs within 10–14 days in naturally exposed pigs. Disease usually spreads gradually, with new animals becoming affected daily. The course varies between individual animals. Occasional pigs are peracutely affected and die within a few hours to days.

In outbreaks of SD, morbidity in weaner pigs may approach 90%, and mortality may be 30% if effective treatment is delayed. Experimentally, mortality in untreated pigs may exceed 50% (Kinyon et al. 1977). In chronically affected herds, particularly if they are being medicated, the disease may not be clinically evident.

In experimentally induced SD, the occurrence and severity of disease is dependent upon the degree of stress on the pig, the quantity of infectious inoculum, the growth phase of the culture (with active log-phase inoculum being most infectious), the diet, the group size, and pig weight (Jacobson et al. 2004).

On endemically infected swine farms, clinical signs often recur cyclically at 3- to 4-week intervals in individual pigs and in large groups. Reappearance may occur after removal of antimicrobials from the water or feed or from various stressors, including moving to new pens, mixing with different animals, weighing, a change in feed, overcrowding, and/or extreme changes in ambient temperature.

Lesions

Lesions are limited to all or part of the cecum through the descending colon with spiral colon being most consistently affected in acute SD (Wilberts et al. 2014a). Distribution of lesions tends to be more diffuse in the later stages of the disease.

Typical lesions in acute SD include hyperemia and edema of the large intestinal wall, mesentery, and mesenteric lymph nodes. The large intestinal mucosa is usually edematous with loss of the typical rugose appearance and is covered by mucus, fibrin, and flecks of blood (Figure 62.4). Contents are soft to watery and contain exudate.

As disease progresses, large intestinal mural edema decreases and mucosal lesions become more severe. Exudation of fibrin increases, forming thick pseudomembranes composed of fibrin, mucus, and blood. As lesions become chronic, mucosal exudates contain less mucus and blood and are typically composed of a thin layer of fibrinonecrotic exudate resembling lesions of enteric salmonellosis (see Chapter 59). Lesions can also be observed in the colons of clinically healthy pigs as segmental reddened areas of the mucosa usually covered with mucus, but with normal contents.

Microscopic lesions are limited to the cecum, colon, and rectum. In the acute phase of disease, spirochetes are most numerous in the lumen and within superficial crypts (Figure 62.5), but may also be observed attached to luminal epithelium within disrupted epithelial and goblet cells, and in the superficial lamina propria, often in higher numbers surrounding blood vessels. The mucosa and submucosa are thickened due to vascular congestion, serofibrinous effusion, and infiltrating

Figure 62.4 Spiral colon from a pig 10 days after intragastric inoculation with *Brachyspira hampsonii*. There is serosal hyperemia and mesocolonic edema. A segment has been opened to reveal mucosal thickening, hemorrhage, and watery contents containing mucus, fibrin, and blood. *Source:* Courtesy of Dr. Eric Burrough.

leukocytes, predominantly neutrophils. Erosion of luminal epithelium results from loss of cohesion, necrosis, and shedding of enterocytes. Superficial lamina propria subjacent to erosions may have neutrophilic cuffing of blood vessels, hemorrhages, and invasion by luminal bacteria and protozoa. Expulsion of mucus from goblet cells fills colonic crypts 3 days after onset of clinical disease, and hyperplasia of goblet cells occurs after 5 days (Jacobson et al. 2007).

Later changes include accumulation of fibrin, mucus, and cellular debris in mucosal crypts and on the luminal surface of the large intestine. Superficial necrosis of the mucosa may be extensive, but deep ulceration is not typical. Numbers of neutrophils, lymphocytes, and plasma cells increase in the lamina propria. Chronic mucosal lesions usually include less hyperemia and edema, more extensive superficial necrosis, and extensive superficial mucosal fibrinonecrotic exudate.

Diagnosis

A presumptive diagnosis of SD can be made by the demonstration of large numbers of typical serpentine spirochetes using nonspecific stains or dark-field microscopy in fecal or mucosal smears or in tissue sections from pigs with typical dysentery and/or lesions. A definitive diagnosis of SD requires the demonstration of a strongly beta-hemolytic *Brachyspira* spp. in the colonic mucosa or feces of pigs with typical dysentery and/or lesions (Burrough 2017). Traditionally confirmation of strongly beta-hemolytic *Brachyspira* spp. has been done by selective anaerobic culture and analysis of phenotypic properties of the isolated organisms. In the United Kingdom an indirect fluorescent antibody test has been used to detect *B. hyodysenteriae* in smears (Hunter and Saunders 1977), although false-positive reactions can occur. Monoclonal antibodies (MAbs) should improve specificity (Lee and Hampson 1996), but when one was bound to magnetic beads to extract *B. hyodysenteriae* from feces, this did not increase the detection sensitivity (Corona-Barrera et al. 2004b). *B. hyodysenteriae* and *B. hampsonii* can be rapidly identified and localized within lesions in histologic sections or detected in feces or mucosal smears using oligonucleotide probes for fluorescent *in situ* hybridization (FISH) (Boye et al. 1998; Burrough et al. 2013; Wilberts et al. 2015). PCR can also be used for rapid direct detection in feces or mucosal smears. However, culture remains a more sensitive assay and is preferred since it allows for assessment of hemolysis.

Samples for testing are best collected from several acutely affected untreated animals, as they have large numbers (10^8–10^9/g) of *Brachyspira* in their colonic mucosa and feces. Colon and feces are ideal samples. Oral fluids are a complementary sample type allowing pen-level detection of agents of SD, particularly when pigs have active disease (Warneke et al. 2013). Samples should be kept moist and refrigerated during transit. Asymptomatic pigs are not optimal as they may only periodically shed the organism at detectable levels (>10^3 cells/mL contents) in their feces. However, *B. hyodysenteriae* has been identified in pigs from apparently healthy herds (Hampson et al. 2016; La et al. 2016b) if sufficient numbers of samples are tested. If disease is mild or subclinical, large numbers of samples should be tested. Pooling batches of five rectal swabs for testing increases the rate of detection, since the slight reduction in sensitivity by dilution is more than offset by the advantage of testing five times the number of animals (Fellström et al. 2001).

Optimal culture media and conditions are as described earlier. On blood agar, agents of SD produce zones of strong beta-hemolysis around a film of growth in which colonies are hard to distinguish. Spirochetes can be observed in resuspended samples using phase-contrast or dark-field microscopy. Plates without hemolysis should be re-incubated and regularly checked for up to 10 days. False-negative results can occur due to inappropriate handling or storage of samples, such as exposure to extreme temperatures, drying, or transport delays. Mixed spirochete species can be present on a plate, so individual isolates must be cloned to purity before phenotypic characterization (Table 62.1) or other means of speciation.

PCR amplification of specific sequences is widely used for speciation. The most common targets used for identifying *B. hyodysenteriae* are portions of the *nox* gene (Atyeo et al. 1999b), the 23S rRNA gene (Leser et al. 1997), or the *tlyA* gene (Fellström et al. 2001). Recently, however, it has been reported that some avian strains of *B. hampsonii* may cross-react in these *B. hyodysenteriae* PCRs and PCRs for other *Brachyspira* species (Aller-Morán et al. 2016b). *B. hampsonii* is usually identified using a *nox*-based PCR (Rubin et al. 2013b), while PCRs based on the *tlyA* and *rpoC* genes were recently described for *B. hampsonii* and *B. suanatina*, respectively (La et al. 2016b). Modifications to the basic PCRs have included a commonly used duplex reaction for identifying *B. hyodysenteriae* and *B. pilosicoli* (La et al. 2003), several multiplexed real-time PCRs for *Brachyspira* species (Song and Hampson 2009; Willems and Reiner 2010), and recently a high resolution melting assay for *B. hampsonii* (Scherrer et al. 2016). Other PCR-based methodology that allows identification of a range of *Brachyspira* species involves amplification of portions of specific genes (usually *nox* or 16S rRNA), followed either by sequencing and phylogenetic analysis of the products against know sequences (Atyeo et al. 1999b) or by restriction enzyme digestion of the products to give species-specific banding patterns after gel electrophoresis (RFLP analysis). Targets for the latter include the genes for 16S rRNA (Stanton et al. 1997), 23S rRNA (Barcellos et al. 2000), and the *nox* gene (Rohde et al. 2002; Rohde and Habighorst-Blome 2012).

PCR is usually conducted on growth from the primary isolation plate, although various PCR tests have been described for direct detection of pathogenic spirochetes in clinical samples. Isolation followed by PCR can take 3–5 days, but this method has the advantage that the isolates are available for phenotypic evaluation, antimicrobial sensitivity testing, and/or strain typing.

As an alternative to PCR, isolates in primary culture can be subjected to MALDI-TOF MS, another rapid methodology for *Brachyspira* speciation that can discriminate all known agents of SD (Calderaro et al. 2013; Warneke et al. 2014).

Although serologic tests have been developed for identifying herds with SD (La and Hampson 2001), very few laboratories use them. Generally, these tests have not been based on species-specific antigens, and so they have had low specificity and/or sensitivity. An enzyme-linked immunosorbent assay (ELISA) using LOS as plate-coating antigen has proved helpful for identifying infected herds, but not for detecting individual pigs with SD (Joens et al. 1982). LOS-based ELISA systems require knowledge of the serotypes of organisms present in the herds to be tested so that the appropriate LOS can be used as plate-coating antigen. Serological ELISAs using recombinant *B. hyodysenteriae* surface proteins Bhlp29.7 and H114 as plate-coating antigen have been described (Hampson et al. 2016; La et al. 2009a; Song et al. 2015). The ELISA using H114 correctly detected apparently healthy herds that subsequently were confirmed to contain pigs colonized with *B. hyodysenteriae* (Hampson et al. 2016). Besides serum, ELISAs run on meat juices collected at slaughter may be useful for detecting herds infected with *B. hyodysenteriae* (Song et al. 2012).

The range of diagnostic tests available for *Brachyspira* detection has expanded considerably in recent years. Newer molecular assays that improve the specificity of an etiologic diagnosis lack the sensitivity of selective anaerobic culture. Diagnostic approaches for SD should be sufficiently broad to detect all potentially pathogenic spirochetes and also have sufficient sensitivity to detect small numbers of spirochetes typically shed from asymptomatic carriers. Selective anaerobic culture, which has the capacity to detect all known agents of SD and provides a hemolytic phenotype, should continue to be an integral part of *Brachyspira* detection, diagnosis, and surveillance for SD.

A number of enteric diseases may be confused with SD, and SD often occurs concurrently with other enteric infections (Møller et al. 1998). Proliferative enteropathy (PE) caused by *Lawsonia intracellularis* (Chapter 58) may clinically resemble SD, but SD does not affect the small intestine. Salmonellosis (Chapter 59) can have similar clinical signs and lesions; however, with salmonellosis, there may be hemorrhage or necrosis in parenchymatous organs and lymph nodes and mucosal lesions in the small intestine. Deep ulcerative enteric lesions also are much more typical of salmonellosis. Trichuriasis (Chapter 67) may usually be differentiated from SD on the basis of the presence of numerous *Trichuris suis* in the large intestine; however, prepatent trichuriasis can mimic SD and requires microscopic examination of the large intestine and/or culture to differentiate. Gastric ulcers and other hemorrhagic conditions may result in blood in the feces, but this tends to be "tarry" due to digestion of the blood, and the mucosa of the large intestines lacks lesions. PIS/PCS represents the most difficult differential diagnosis, as it can closely resemble mild cases of SD.

Immunity

Changes occur in antibody levels and in cell-mediated reactivity in pigs with SD, but their importance is unclear. Serum IgG levels to *B. hyodysenteriae* correlate with duration of clinical signs, while IgA levels in the colon reflect recent exposure (Rees et al. 1989b). Neither is strongly correlated with protection from SD (Joens et al. 1982; Rees et al. 1989b).

Pigs recovered from SD may be protected against subsequent challenge with *B. hyodysenteriae* for up to 17 weeks (Joens et al. 1979; Olson 1974), although some animals (7–43%) remain susceptible (Jenkins 1978; Joens et al. 1979; Rees et al. 1989a) and approximately 10% may only become protected after two bouts of disease (Rees et al. 1989a). Immunity is partially serotype specific and directed against LOS antigens (Joens et al. 1983).

Complement components in conjunction with immune serum may be involved in clearance of *B. hyodysenteriae* from the colon (Joens et al. 1985). Cell-mediated immunity also may be involved in protection as inhibition of peripheral blood leukocyte migration, a delayed hypersensitivity response, and a T-cell proliferative response to *B. hyodysenteriae* antigens are found in convalescent pigs (Jenkins et al. 1982). CD8αα cell proliferation has been recorded in pigs recovered from SD (Waters et al. 2000a). By comparing circulating leukocytes and lymphocyte subpopulations in pigs, Jonasson et al. (2004) deduced that γδ T cells and CD8+ cells may be associated with susceptibility to infection, while monocytes and CD4+ CD8+ T cells appear to be the major responding lymphocytes. Increased numbers of neutrophils, γδ T cells, and specific antibodies have been found during the recovery phase (Jonasson et al. 2006).

Following experimental infection or vaccination with a bacterin vaccine, there is some protection against serotypes of *B. hyodysenteriae* other than those to which the animals have been exposed (Kennedy et al. 1992; Parizek et al. 1985). It is not known whether infection with one *Brachyspira* species confers any protection against infection with another species.

Prevention and control

Methods to treat pigs or control outbreaks

Only a few effective antimicrobials remain available for treatment of SD, and resistance to important drugs such as the pleuromutilins is increasing. These drugs should only be used for specific therapy of clinical disease and for eradication programs. It is important to use either agar or broth dilution methods to determine the minimum inhibitory concentration (MIC) of the antimicrobials. For comparative studies, broth dilution testing may be conducted using VetMIC Brachy panels (National Veterinary Institute, Uppsala, Sweden), incorporating the *B. hyodysenteriae* type strain B78^T as a control (Karlsson et al. 2003).

Severely affected animals may require intramuscular antimicrobials for at least 3 days; however, in most cases water medication for 5–7 days is effective. If this is not possible, then in-feed medication for 7–10 days can be used, although affected animals may have a low feed intake. Pigs should have free access to drinking water. Oral glucose–electrolyte solutions can be given to severely affected pigs. Treatment of acute SD may be followed by in-feed medication at reduced levels for 2–4 weeks to prevent reinfection.

The drugs most commonly used to treat SD are the pleuromutilins tiamulin and valnemulin, as well as tylosin and lincomycin. Their dosage rates and potential side effects are listed in Table 62.2. Based on pharmacokinetic properties and *in vitro* susceptibility data, pleuromutilins appear to be the most suitable antimicrobials. In pigs experimentally infected with susceptible isolates of either *B. hyodysenteriae* or *B. hampsonii*, water medication with tiamulin resolved clinical disease within 24 hours and eliminated viable spirochete shedding within 72 hours (Wilberts et al. 2014c). Unfortunately, decreased susceptibility to tiamulin among *B. hyodysenteriae* isolates has been reported in several countries, and a recent investigation of Italian isolates of *B. hyodysenteriae* suggests transnational spread of resistant strains throughout Europe (Rugna et al. 2015). Tiamulin usage selects for clones of *B. hyodysenteriae* with decreased tiamulin susceptibility (Karlsson et al. 2004). To reduce the risk of emerging resistance to pleuromutilins, other drugs should be used if MIC determinations or herd records indicate their efficacy. Resistance to both tylosin and lincomycin frequently occurs in *Brachyspira* species (Hommez et al. 1998; Karlsson et al. 2003). Macrolide and lincosamide resistance may be caused by point mutations in the 23S rRNA gene and/or ribosomal protein genes, with tylosin resistance developing within 2 weeks *in vitro* (Hillen et al. 2014; Karlsson et al. 1999). Multidrug-resistant strains of *B. hyodysenteriae* are also increasing (Duinhof et al. 2008; Šperling et al. 2011).

Tylvalosin is a modification of an older drug (acetylisovaleryltylosin) that may also be useful for treatment and control of SD when used through the water and followed by in-feed medication. Other antimicrobials including bacitracin, spiramycin, gentamicin, dimetridazole, ronidazole, virginiamycin, olaquindox, and carbadox have been used for treatment and prevention of SD. Unfortunately, resistance to several of these has been reported, and the availability of others is now greatly reduced internationally. Many of these drugs have low MICs against *B. hyodysenteriae*, but their pharmacokinetic properties result in low concentrations in the gastrointestinal tract that makes them only suitable as a prophylactic (de Graaf et al. 1988). Both carbadox and

Table 62.2 Dosage level, duration of administration, and side effects for four drugs commonly used for the treatment of swine dysentery.

Drug	Dosage and duration	Side effects
Tiamulin	10 mg/kg bw; im for 1–3 days 8 mg/kg bw; po for 5–7 days in drinking water In-feed medication with 100–180 ppm for 10–14 days, followed by 30–40 ppm for 2–4 weeks	Rare: erythema. Local reactions at the injection site. Lethal side effects may occur in combination with ionophores
Valnemulin	In-feed medication 3–4 mg/kg bw for 1–4 weeks	Adverse effects including lethargy, depression, erythema, edema, pyrexia, ataxia, anorexia, and deaths have been reported. Lethal side effects may occur in combination with ionophores
Tylosin	10 mg/kg bw; im twice daily for 3 days followed by appropriate in-feed or water medication 5–10 mg/kg bw; po in drinking water for 5–7 days Followed by in-feed medication with 100 g/ton feed for 3 weeks, followed by in-feed medication 40 g/ton feed	Diarrhea, pruritus, erythema, rectal edema, and prolapse have been reported
Lincomycin	8 mg/kg bw; po in drinking water for at least 5 days but not to exceed 10 days In-feed medication 100 g/ton feed for 3 weeks or until signs of disease disappear, followed by 40 g/ton	Rare

Note: The information in this table is an abbreviated summary of product labeling. For information regarding withdrawal times (which vary extensively between countries), review national regulations and product labels.
bw, body weight; im, intramuscular; po, per os (oral).

metronidazole may induce expression of the *B. hyodysenteriae* GTA, which in turn may increase transfer of resistance genes between strains (Stanton et al. 2008). Ionophore growth promoters such as salinomycin and monensin may prevent losses; however, toxicity may occur if they are used with pleuromutilins or drugs that interfere with hepatic metabolism. Various other additives and ingredients have been examined for *in vitro* efficacy against *Brachyspira* spp. (Kutasi et al. 2016: Vande Maele et al. 2016), but few *in vivo* studies have been reported.

All-in/all-out management with cleaning and disinfection between batches reduces the risk of reinfection of medicated pigs and limits spread of infection. Ideally affected batches of pigs should be moved to clean buildings after medication to break the infection cycle. Careful disposal of infected bedding, the use of boot scrubbers and disinfectant footbaths, cleaning and disinfection of equipment used in infected areas, and changing of protective clothing are all vital measures. As outbreaks of SD are often associated with stressful conditions such as pig handling, crowding, transportation, severe weather conditions, or dietary changes, it is important to minimize these as much as possible in herds at risk. Attention should also be paid to the form and composition of the diet as SD expression is heavily influenced by dietary factors.

Mice and rats can serve as potential reservoirs of agents of SD in pig herds, so implementation of effective rodent control is essential. Unfortunately, it is virtually impossible to prevent mechanical transmission of infectious material via birds, waterfowl, and other potential wildlife vectors in outdoor facilities.

Bacterin vaccines for *B. hyodysenteriae* are available commercially in some countries and may provide a degree of protection (Diego et al. 1995). Unfortunately, they tend to be LOS serogroup specific, which then requires the use of autogenous or multivalent preparations. They are relatively difficult and costly to produce on a large scale because of the fastidious growth requirements of *B. hyodysenteriae*. One publication reported that immunization with a *B. hyodysenteriae* bacterin actually exacerbated dysentery (Olson et al. 1994). A proteinase-digested bacterin may offer better protection than conventional bacterins (Waters et al. 2000b).

Apparently naturally avirulent or low virulence strains of *B. hyodysenteriae* have been used experimentally as vaccines (Hudson et al. 1976), sometimes in combination with bacterins (Lysons et al. 1986). Modified live strains have been produced by inducing mutations in genes affecting motility (Rosey et al. 1996), hemolysis (Hyatt et al. 1994), and protection from oxygen toxicity (Stanton et al. 1999); however, such strains may have a reduced ability to colonize pigs, and they have produced only limited protection.

Although the use of a recombinant *B. hyodysenteriae* 38 kDa flagellar protein as a vaccine failed to prevent colonization in experimentally infected pigs (Gabe et al. 1995), recombinant Bhlp29.7 outer membrane lipoprotein did provide a 50% reduction in incidence of disease (La et al. 2004). A combination of four other recombinant

surface proteins identified using a "reverse vaccinology" strategy gave similar levels of protection under experimental conditions (Song et al. 2009), demonstrating the general validity of this approach. The emergence of *B. hampsonii* and *B. suanatina* further complicates the vaccination issue for SD as commercial vaccines would likely need to protect against at least two of these agents depending on the geographic market.

Methods to prevent introduction or avoid outbreaks of SD

Closed herds or those in closed pyramids should remain free of SD if they are geographically isolated and use precautions to prevent contamination. Introduction of new stock is the greatest risk, so a reliable history of the source herd is essential. Purchased animals should be quarantined for at least 3 weeks and treated to eliminate agents of SD. Infectious materials also may be carried into a herd by fomites such as workers' boots, farm implements, feed or animal trucks, and wild birds or animals; thus measures must be implemented to prevent these.

Methods to eliminate agents of SD from herds

The cost for eliminating SD may be recouped in 6–12 months through improved production and reduced drug usage (Windsor and Simmons 1981; Wood and Lysons 1988). Depending on the herd structure, production system, and economic considerations, SD eradication can be accomplished in several ways. These include intensive medication of all pigs for a short period, use of medicated early weaning and multisite production, or an ongoing program of emptying and disinfection of each herd unit in a cycle and introducing medicated animals to cleaned and disinfected units. Considerable effort is needed to plan and organize the eradication and to achieve the full understanding and cooperation of all personnel involved. Generally, eradication becomes more difficult as herd size increases and as the company operation becomes larger and more complex. Wood and Lysons (1988) suggested that the chances of an eradication program succeeding were around 80–90% in carefully selected herds. A combination of total depopulation, cleanup, disinfection, and repopulation with SD-free stock is sometimes the only method available to eliminate *B. hyodysenteriae*; however, it is generally the most expensive method and should only be considered if financially feasible (Polson et al. 1992; Wood and Lysons 1988). Projected cost and probability of success should influence the choice of method.

Attempts to eliminate SD without total depopulation should only be undertaken if an effective antimicrobial agent against agents of SD isolated from the unit is available. It is also important to establish a source of replacement breeding stock that is free from SD or to isolate and medicate all replacement stock before allowing them to enter the herd.

General guidelines for an SD eradication program include the following. Diagnosis should be confirmed by laboratory testing, and several strongly beta-hemolytic isolates should be tested for their MIC to available antibiotics. Isolates also should be typed by methods such as *nox* gene sequencing to determine if more than one strain is present. Herds with a continuous production system should try to change to batch production before the eradication. The program should be performed during a warm season when environmental survival of agents of SD is diminished. The number of animals in the herd should be reduced, and ideally all weaner, grower, and finisher pigs should be removed. Stock replacement should cease during the program. A rodent and insect control program should be implemented, and measures taken to stop wild birds from entering buildings and to protect water supplies from contamination with waterfowl feces. Dogs and cats should not be allowed within the herd area. Environmental contamination of all areas where pigs are housed, as well as the watering and feeding equipment, should be removed by high-pressure washing with hot water and disinfection. A disinfection program using glutaraldehyde and calcium hydroxide has been described and was effective in eliminating *B. hampsonii* from a commercial farrow-to-wean system (Burrough and Sexton 2013). Slats should be lifted, and slurry tanks emptied, cleaned, and disinfected. In outdoor production units, shelters should be cleaned, disinfected, and relocated to fresh sites. Remaining organic material should be burned, and the ground plowed and reseeded or left empty for several months. Sows, gilts, and boars should be medicated via drinking water or feed for at least 14 days and then moved into cleaned and disinfected buildings that have been empty for at least 2 weeks. Piglets born during the medication period should be weaned, treated parenterally with the same antimicrobial, and finished off-site. Piglets born after the sows have finished their medication can be weaned and reared on-site.

Brachyspiral colitis

Relevance

Brachyspiral colitis is an umbrella term used to describe diarrhea and colitis in pigs infected with one or more pathogenic *Brachyspira* spp. and reflects an increased understanding of the diversity of species within this genus and the role that different species and strains may play in inducing inflammation in the large intestine (Hampson 2014). This term is most applicable when discussing weakly beta-hemolytic *Brachyspira* spp., and

practitioners should approach these agents with the understanding that pathogenicity is often dependent upon a combination of host, microbial, and dietary factors.

The best characterized disease in pigs associated with weakly beta-hemolytic *Brachyspira* spp. is PIS/PCS. Taylor et al. (1980) first described PIS/PCS in a study in which pigs that were orally challenged with the weakly beta-hemolytic intestinal spirochete strain P43/6/78^{T} developed mucoid diarrhea containing flecks of blood and had lesions of colitis. This strain is now the type strain of the species *B. pilosicoli* and has previously been referred to as *Anguillina coli* (Lee et al. 1993b); *Serpulina coli* (Duhamel et al. 1993), a group IV weakly hemolytic intestinal spirochete (Fellström and Gunnarsson 1995); and *Serpulina pilosicoli* (Trott et al. 1996a). Pigs with PIS/PCS exhibit variable loss of condition, which leads to increased time to reach market weight and disrupts efficient production flow (Duhamel 1998).

Occasionally other weakly hemolytic *Brachyspira* species have been implicated in causing colitis and chronic diarrhea in pigs. Some strains of *B. intermedia* have been suspected to have pathogenic potential in pigs: this is not altogether surprising given that *B. intermedia* is a recognized enteric pathogen in adult poultry (Hampson and McLaren 1999). *B. murdochii* is the species most frequently reported to be associated with lesions of mild colitis in pigs (Komarek et al. 2009; Weissenböck et al. 2005), and experimental infection of pigs with a *B. murdochii* strain confirmed that it was mildly pathogenic (Jensen et al. 2010). Infections or colonization with one or more of the nonpathogenic or mildly pathogenic *Brachyspira* species is quite common in domestic pigs (Osorio et al. 2013): arguably their greatest significance is that these spirochetes may complicate diagnosis of SD and/or PIS/PCS – both of which are much more economically important diseases and require implementation of rigorous control measures. Accordingly, the remainder of this section is dedicated to PIS/PCS.

Etiology of PIS/PCS

Studies using MLEE, MLST, and MLVA have demonstrated that *B. pilosicoli* forms a distinct species, that strains show extensive diversity, and that the population is recombinant (Lee and Hampson 1994; Neo et al. 2013a,b; Trott et al. 1998). PFGE also has been commonly used for typing strains of *B. pilosicoli* (Atyeo et al. 1996; Fossi et al. 2003). Extensive genomic rearrangements between strains have been observed, and strains vary in the size of their genomes (Mappley et al. 2012; Zuerner et al. 2004).

The *B. pilosicoli* strain 95/1000 has a approximately 2.59 Mbp circular chromosome, genes for a GTA, and an integrated prophage, but does not possess plasmids (Wanchanthuek et al. 2010). The *B. pilosicoli* outer envelope contains LOS, and this is serologically heterogeneous among different strains (Lee and Hampson 1999). *B. pilosicoli* lacks the *rfbBADC* gene cluster found on the *B. hyodysenteriae* plasmid, and hence the species are predicted to have a different LOS structure. A number of outer membrane proteins and lipoproteins of *B. pilosicoli* have been described (Trott et al. 2001). More work is needed to define their potential role in disease, including whether they may be involved in attachment and/or in generating protective immunity.

Brachyspira pilosicoli is cultured under the same anaerobic conditions as *B. hyodysenteriae*. After 3–5 days on Trypticase soy blood agar, *B. pilosicoli* forms a thin spreading surface haze surrounded by a zone of weak beta-hemolysis. Slicing the agar prior to inoculation can improve the recovery of *B. pilosicoli*, but a zone of enhanced hemolysis is not usually seen. Once isolated, the spirochete grows readily in various anaerobic liquid media, as described for *B. hyodysenteriae*.

Public health

Brachyspira pilosicoli colonizes human beings who are usually either immunocompromised or live in developing communities where hygiene is poor and fecal contamination of water supplies may occur (Margawani et al. 2004). Infection may be associated with chronic diarrhea and/or failure to thrive. Strains of *B. pilosicoli* from humans can cause disease when inoculated into pigs and chickens (Duhamel et al. 1995; Muniappa et al. 1997; Trott et al. 1995, 1996b). The potential for transmission of *B. pilosicoli* from animals to humans exists, although the risk of healthy pig industry workers developing disease from contact with pigs is slight.

Epidemiology

PIS/PCS has been reported in most pig-producing countries. Increased recognition of the condition has resulted from improved diagnostic methods, the withdrawal of routine antimicrobial growth promoters, and the fact that other major intestinal diseases are now better controlled in many countries.

Investigations in different regions have found that a variable but often high proportion of farms having pigs with persistent diarrhea problems are infected with *B. pilosicoli*, whereas little or no infection occurs in farms without diarrhea.

A wide range of species may be naturally infected with *B. pilosicoli*, and typical clinical signs and lesions have been recorded in all of them (Duhamel 2001). Isolates from pigs, dogs, birds, and humans can be closely related genetically (Lee and Hampson 1994; Trott et al. 1998).

Transmission occurs by the fecal–oral route, and infection may be introduced into naïve herds by carrier pigs.

B. pilosicoli can persist in the environment, and the disease can recur between batches of pigs if the premises are not adequately cleaned and disinfected. Feral animals and birds may be a source of infection. On one pig farm *B. pilosicoli* was detected in chickens, effluent pond water, and wild ducks on the effluent pond (Oxberry and Hampson 2003). An isolate from the pond belonged to the same genetic type as one from a pig, a finding consistent with a previous observation, suggesting that feral water birds may contaminate water supplies and so represent a potential source of *B. pilosicoli* infection for pigs (Oxberry et al. 1998). Rodents appear unlikely to serve as an important long-term biologic reservoir of *B. pilosicoli*.

The on-farm epidemiology of *B. pilosicoli* can be highly variable (Oxberry and Hampson 2003). Sometimes the incidence is low and largely confined to one age group, while in other herds it may be widespread and associated with numerous different strains. The presence of multiple *B. pilosicoli* strains within certain farms might explain why PIS/PCS commonly recurs in convalescent animals or in those treated with antimicrobials. In such cases reinfection may be with a different strain, possibly having different antigenic determinants, antimicrobial susceptibilities, or potential to colonize and cause disease.

In Finland, most farms had their own distinct genotypes of *B. pilosicoli*, while it was rare to find the same type on different farms (Fossi et al. 2003). The within-farm genotypes appeared fairly stable, as the same genotypes were found on three farms that were reexamined after 3 years.

Brachyspira pilosicoli is shed in the feces, and this may be intermittent and continue over weeks in some pigs. It is relatively resistant in the environment, surviving in lake water at 39 °F (4 °C) for 66 days (Oxberry et al. 1998) and remaining viable at 50 °F (10 °C) for 119 days in soil and for 210 days in soil with 10% pig feces and in feces (Boye et al. 2001). Although it is susceptible to many common disinfectants, the efficacy of some of them is reduced by the presence of organic matter (Corona-Barrera et al. 2004a).

Pathogenesis

Cells of *B. pilosicoli* are motile, and strains vary in their attraction to mucin (Naresh and Hampson 2010). Once in the large intestine, the spirochete is able to penetrate the mucus overlying the colonic mucosa. In the initial stage of infection, *B. pilosicoli* cells adhere in large numbers to the luminal surface of cecal and colonic epithelial cells. Attachment occurs to mature apical enterocytes between crypt units, but not to immature cells deeper in the crypts (Trott et al. 1996b).

Despite the availability of genome sequences, few *B. pilosicoli* virulence factors have been identified. Cellular attachment by *B. pilosicoli* strains has been achieved *in vitro* using intestinal epithelial cell lines, but putative adhesins or host cell receptors have not been identified (Muniappa et al. 1998; Naresh et al. 2009). Colonized monolayers demonstrated a time-dependent series of changes including accumulation of actin at the cell junctions, a loss of tight junction integrity, and evidence of apoptosis – although the mechanisms causing these changes were not identified. Interestingly, addition of the stress hormone norepinephrine to *in vitro* cultures enhances *B. pilosicoli* growth, attraction to mucin, and attachment to Caco-2 cells (Naresh and Hampson 2011). This may cause pigs to become more susceptible to infection with *B. pilosicoli* (and potentially other pathogenic *Brachyspira* spp.) during periods of stress.

As with SD, *B. pilosicoli* colonization and/or disease expression can be influenced by diet. An analysis of risk factors on farms revealed that reduced prevalence results from using home-mixed and/or non-pelleted diets (Stege et al. 2001). Adding carboxymethylcellulose to an experimental pig diet increased the viscosity of the intestinal contents and enhanced colonization with *B. pilosicoli* (Hopwood et al. 2002). High levels of soluble non-starch polysaccharide ("soluble fiber") in grains like barley and rye also may increase viscosity and therefore enhance *B. pilosicoli* colonization. Consistent with this, pigs fed diets based on cooked white rice (highly digestible and low in soluble fiber) have shown reduced colonization with *B. pilosicoli* compared with pigs fed conventional diets (Hampson et al. 2000; Lindecrona et al. 2004). Feeding a pelleted diet rather than meal increased the risk of colonization, but fermented liquid feed or lactic acid had no influence on colonization (Lindecrona et al. 2004).

Clinical signs

PIS/PCS most commonly occurs soon after weaning or in recently mixed growers placed on a new diet, but it can occur in finishers and occasionally in pregnant sows and recently introduced breeding stock. PIS/PCS may affect groups of pigs in a unit or be present in pigs of mixed ages. Various manifestations may be seen in weaners, growers, and finishers on the same farm. Not all infected animals develop diarrhea; however, subclinical infections still may depress growth rates.

The first clinical signs are hollowing of the flanks and the passage of loose, sometimes sticky feces. Fecal consistency changes to that of wet cement or porridge and may glisten. These may be the only signs in finishers, but weaners and growers usually develop watery to mucoid diarrhea that is green or brown and occasionally contains thick tags of mucus and sometimes flecks of blood. Diarrhea is usually self-limiting and lasts 2–14 days, although some animals may relapse.

Affected pigs appear unthrifty, have fecal staining of the perineum, have a tucked-up appearance, and sometimes are febrile but usually continue to eat. Pigs that develop loose feces may show significant loss of condition, decreased feed conversion, and delays in reaching market weight (Thomson et al. 1997, 1998).

Brachyspira pilosicoli may be shed in the feces within 2–7 days of experimental inoculation, although the incubation period may extend to 20 days. Between 17 and 100% of pigs may become infected, with 17–67% developing diarrhea and 8–100% having colitis (Duhamel 2001). Mortality is rare in the field.

Pigs with PIS/PCS may have concurrent sickness that exacerbates disease, particularly intestinal diseases such as SD, salmonellosis, PE, or infection with porcine circovirus type 2 (PCV2) (Duhamel et al. 1995; Girard et al. 1995; Møller et al. 1998; Stege et al. 2000; Thomson et al. 1998, 2001).

Lesions

Gross lesions of PIS/PCS are limited to the cecum and colon and may be subtle, particularly in the early stages. Soon after the onset of clinical signs, the cecum and colon may be flaccid and fluid filled with an edematous serosal surface and enlarged mesenteric and colonic lymph nodes. The large intestinal contents are usually abundant, watery, green or yellow, and frothy (Figure 62.6). There may be mild mucosal congestion and hyperemia with variable catarrhal exudate and/or multifocal erosion or necrosis. In later stages, the mucosa is thickened, and petechiae or ecchymoses may be observed on the surface. Hemorrhages, erosions, or necrotic foci may occur, and there may be small tags of adherent fibrin, necrotic material, and digesta that appear as conical scales on the mucosa.

Figure 62.6 Cecum and spiral colon from a pig 21 days after intragastric inoculation with *Brachyspira pilosicoli*. Note abundant mucoid to watery contents in the cecum (top) and colon (center). *Source:* Courtesy of Dr. Gerald E. Duhamel.

Microscopic lesions are generally confined to the mucosa and submucosa but may extend into the muscularis. The mucosa is usually thickened, edematous, and occasionally hyperemic and characterized by dilated, elongated crypts filled with mucus, cellular debris, and degenerate inflammatory cells. The presence of *B. pilosicoli* within crypts and the lamina propria may be associated with neutrophilic exocytosis (crypt abscesses) and a mixed infiltrate of neutrophils and lymphocytes in the lamina propria. In chronic infections, the lamina propria is usually infiltrated with large numbers of monocytes, lymphocytes, and plasma cells (Duhamel 2001). The crypt cell mitotic rate can be increased, and immature, cuboidal, or squamous epithelium may be present on the surface of the mucosa between crypt units. Columnar epithelium lining the surface of the colon may be covered by a fringe of spirochetes attached end-on to form a characteristic "false brush border" (Girard et al. 1995; Taylor et al. 1980) (Figure 62.7). Although this attachment is pathognomonic for PIS/PCS, it is not always found (Thomson et al. 1997). Occasionally *Balantidium coli* may be seen on the surface of the affected colon (Taylor et al. 1980; Trott et al. 1996b).

Brachyspira pilosicoli cells may be observed inside dilated colonic crypts (Trott et al. 1996b), invading through tight junctions between colonic enterocytes, within goblet cells (Thomson et al. 1997), and within the lamina propria (Duhamel 2001). Invasion has been observed both concurrent with and independent of attachment of spirochetes to the epithelium. In humans, *B. pilosicoli* has been isolated from the bloodstream of individuals with severe clinical disease or impaired immunity, and evidence of systemic spread has been

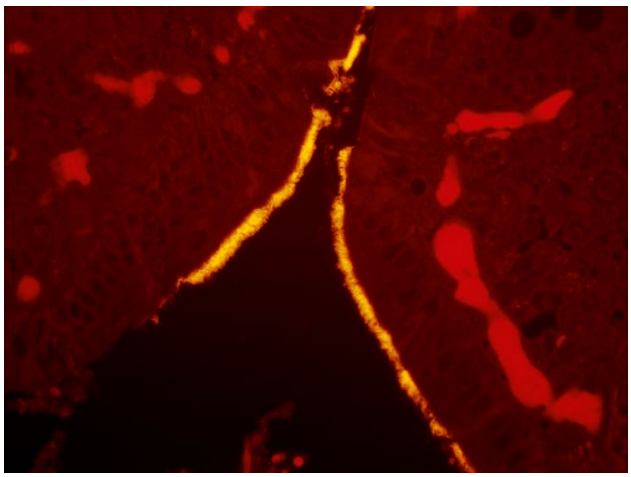

Figure 62.7 Fluorescent *in situ* hybridization using a probe specific for *Brachyspira* spp. on a section of colon from a pig with PIS/PCS. Note the dense fringe of fluorescent spirochetes attached by one cell end to the surface of the colonic epithelium to form a "false brush border". *Source:* Courtesy of Dr. Eric Burrough.

observed in experimentally infected chickens (Mappley et al. 2013; Trott et al. 1997). Systemic spread or spirochetemia has not been recorded in pigs, but they cannot be excluded.

Epithelial damage followed by local invasion and subsequent colitis combine to cause an increase in the water content of the cecal and colonic contents, together with excess mucus production. Erosion of the epithelium leads to replacement by immature cells and reduction of the surface area of the colon for absorption of water, electrolytes, and volatile fatty acids. This then leads to decreased feed conversion efficiency and diminished weight gain (Duhamel 1998; Thomson et al. 1997).

Diagnosis

A definitive diagnosis of PIS/PCS requires the confirmation of *B. pilosicoli* in pigs with typical clinical disease and lesions. *B. pilosicoli* can be confirmed in tissue sections using immunohistochemistry with specific antibodies or FISH with specific oligonucleotide probes (Boye et al. 1998; Jensen et al. 2000) where it is observed attached to the surface of colonic enterocytes (Figure 62.8), within dilated intestinal crypts, and occasionally within the lamina propria. *B. pilosicoli* can also be confirmed by culture or PCR of affected colonic mucosa or feces.

However, clinically normal pigs may shed *B. pilosicoli*, and confirmation in feces does not alone confirm PIS/PCS. The significance of positive fecal culture of *B. pilosicoli* needs to be interpreted in the context of a complete diagnostic investigation (Thomson et al. 1998). Fecal samples for culture and/or PCR should be obtained from a cross section of affected pigs and, when possible, correlated with lesions.

CVS medium is preferred for isolating *B. pilosicoli* as BJ medium may inhibit *B. pilosicoli* growth and is not recommended (Duhamel and Joens 1994; Trott et al. 1996c). Pure cultures of spirochetes can be differentiated by MALDI-TOF MS or by using the biochemical tests outlined in Table 62.1, specifically strength of beta-hemolysis, hippurate hydrolysis, and lack of beta-glucosidase activity (Fellström and Gunnarsson 1995; Trott et al. 1996c).

Reported PCR tests for *B. pilosicoli* target the genes for 16S rRNA (Fellström et al. 1997), 23S rRNA (Leser et al. 1997), or the *nox* gene (Atyeo et al. 1999b). Duplex and multiplex PCRs, sometimes also detecting other enteric pathogens, and real-time PCR assays that allow spirochete quantitation also have been described (see section on SD).

As with *B. hyodysenteriae*, RFLP analysis can be used to identify *B. pilosicoli* isolates. Indirect fluorescent antibody tests using MAbs raised against specific outer membrane proteins of *B. pilosicoli* have potential for diagnostic use on feces (Lee and Hampson 1995), but a MAb-based immunomagnetic separation of *B. pilosicoli* from feces did not improve the sensitivity of detection compared with culture/PCR (Corona-Barrera et al. 2004b).

Clinical signs of PIS/PCS can be very similar to those of PE (Chapter 58), with which it may occur. Salmonellosis (Chapter 59), post weaning colibacillosis (Chapter 52), SD and yersiniosis (Chapter 64), PCV2 enteritis (Chapter 30), trichuriasis (Chapter 67), and "nonspecific colitis," a diet-responsive colitis (Chapter 15; Smith and Nelson 1987), all should be considered in the differential diagnosis of porcine colitis.

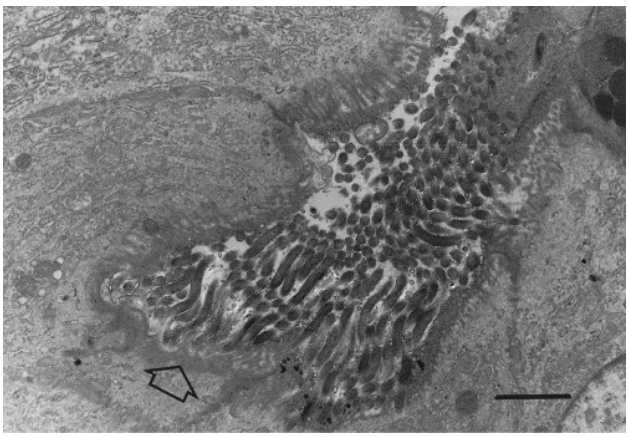

Figure 62.8 Transmission electron photomicrograph of the colonic epithelium from a pig with PIS/PCS. Note the large numbers of spirochetes attached by one cell end to the apical membrane of enterocytes causing effacement of the microvilli and disruption of terminal web microfilaments (arrow). Bar = 2 µm. *Source:* Courtesy of Drs. Darren Trott and David Hampson.

Immunity

The host immune mechanisms directed against *B. pilosicoli* are poorly understood. Agglutinating serum antibodies have been recorded in pigs recovered from experimental infection (Taylor et al. 1980), while no significant antibody levels against whole cell preparations of *B. pilosicoli* were found after 18 days in experimentally infected pigs with mild colitis (Hampson et al. 2000). In other experiments, pigs developed low levels of serum IgG against *B. pilosicoli* whole cell extracts and membrane preparations 2–7 weeks after challenge (Zhang et al. 1999; Zhang and Duhamel 2002). Little is known about protective immunity in PIS/PCS. The existence of long-term colonization suggests that the spirochete may be able to evade immune mechanisms. Cross-protection is unlikely as *B. pilosicoli* strains show considerable variability in their LOS (Lee and Hampson 1999). Nothing is known about maternal immunity, although natural infection has not been recorded in unweaned piglets.

Prevention and control

Methods to treat pigs or control outbreaks

Treatment and control of PIS/PCS are largely modeled on procedures developed for SD, although modifications can be made because of the milder economic impact of PIS/PCS. Antimicrobial therapy can be used to reduce *B. pilosicoli* infection and maintain productivity while improving welfare. It may also be required to prevent sudden increases in morbidity due to recent introduction of naïve pigs, change of diet, or other stressors. Affected pigs should be treated by water or feed medication at similar levels and durations as recommended for SD. Parenteral treatment may be necessary for severely ill pigs. Although information on the *in vitro* antimicrobial susceptibility of *B. pilosicoli* is limited, a number of antimicrobials that are effective against *B. hyodysenteriae*, including tiamulin, valnemulin, carbadox, dimetridazole, and to a lesser extent lincomycin, have been shown to have low MIC values when tested against porcine *B. pilosicoli* isolates (Fossi et al. 2000; Hommez et al. 1998; Kinyon et al. 2002; Trott et al. 1996c). Fewer isolates have been found to be susceptible to tylosin, and resistance to several antimicrobials, including tiamulin, has been recorded (Pringle et al. 2012). Olaquindox may be a useful prophylactic as it has MIC values <1.0 μg/mL against *B. pilosicoli*, and the spirochete could not be isolated from herds previously receiving 100 ppm olaquindox in-feed (Fellström et al. 1996).

Management strategies that limit access of pigs to contaminated environments can reduce the impact of PIS/PCS. Replacing continuous-flow systems with all-in/all-out systems reduces the risk of infection (Stege et al. 2001). Modification to the diet composition and/or physical form or adding zinc oxide in the feed at 3 kg/ton may be helpful (Love 1996).

Methods to avoid outbreaks of PIS/PCS

It can be difficult to avoid the introduction of *B. pilosicoli* into herds because of the presence of reservoir hosts such as wild birds, although similar strategies to those for SD can be followed. Unfortunately, no effective vaccines are available for *B. pilosicoli*. An autogenous bacterin induced systemic antibody titers, but the pigs still became colonized and developed diarrhea after challenge (Hampson et al. 2000).

Methods to eliminate *B. pilosicoli* from herds

The methods described for the elimination of SD also may be effective for PIS/PCS, but the economic impact generally does not warrant such costly procedures. Fossi et al. (2001) reported eradicating *B. pilosicoli* from a 60-sow herd by tiamulin treatment followed by relocation of the breeding herd, thorough cleaning and disinfection of the premises, and then returning the adult animals to the original location. This protocol would be more difficult to follow in larger herds, and the existence of reservoir hosts presents an ongoing threat of reintroduction.

Tuberculosis

Suelee Robbe-Austerman and Charles O. Thoen

Relevance

Tuberculosis (TB) continues to cause significant economic losses to swine producers throughout the world. TB due to *Mycobacterium tuberculosis* (human), *Mycobacterium bovis* (cattle), *Mycobacterium caprae* (goat), and other members of the closely related *Mycobacterium tuberculosis* complex (MTBC) has not been a concern in commercial swine production in developed countries for many years. However tuberculous lesions continue to be reported in the cervical and mesenteric lymph nodes of swine during meat inspection, primarily due to the ubiquitous *Mycobacterium avium* complex (MAC) of organisms. Gross and microscopic lesions are similar for all tubercular mycobacteria in swine and cannot be used to distinguish between them. While TB caused by MTBC is rarely found in commercial swine production in developed countries, feral swine and wild boar are widely identified as reservoirs and spillover hosts in various countries throughout the world including Argentina, France, Portugal, New Zealand, Spain, South Korea, South Africa, and the United States (Molokai, Hawaii) (Pesciaroli et al. 2014). In regions where MTBC are endemic in feral swine, these organisms must be considered along with MAC as causes of TB in domestic swine (Bailey et al. 2013). In countries without control programs for various members of the MTBC, endemic TB in humans, cattle, goats, or others can pose a serious risk for swine. Understanding the causative agent when investigating cases or an outbreak of TB in swine is critical, as prevention and control approaches to disease caused by MTBC or MAC organisms are significantly different.

Regardless of the causative agent, the processing of tuberculous swine carcasses is costly and results in significant economic losses. Regulations of the meat and poultry inspection program of the USDA require that unaffected portions of swine carcasses with tuberculous lesions in more than one primary site, such as cervical and mesenteric lymph nodes, be cooked at 170 °F (76.7 °C) for 30 minutes before being approved for human food (*Code of Federal Regulations*, Title 9, Sec. 311.2). The value of a cooked carcass is only about 20–25% of the value of a carcass not cooked. In processing plants where cooking facilities are not available (most high-volume modern plants), the carcass is condemned, and there is no salvage value.

There has been no direct campaign in the United States to eradicate TB in swine. However the percentage of swine with suspect tuberculous lesions at slaughter peaked in 1922 and has progressively reduced since (Table 63.1). In the United States, two major factors have reduced the number of tuberculous lesions at slaughter. The first was the campaign to eradicate bovine tuberculosis (bTB), which was started in 1917, and had successfully eradicated bTB in most areas of the United States by 1960 (Olmstead and Rhode 2004). The second major factor was the modernization of swine production. The introduction of farrowing barns and nursery facilities, which limited piglet exposure to potentially contaminated dirt and organic bedding, parallels the continued reduction of condemnation rates from the 1960s to current times. Despite the dramatic reduction in condemnation rates throughout the years, sporadic outbreaks can cause significant economic hardship to individual swine operations.

Etiology

In humans and cattle, the term tuberculosis is exclusively limited to disease caused by MTBC organisms. However, in birds and swine, TB can also be caused by MAC and occasionally other *Mycobacterium* species. The *Mycobacterium* genus contains a large number of species, 177 currently named (Euzeby 1997). The vast majority of these species are soil- and water-dwelling organisms that may act as opportunistic pathogens

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

Table 63.1 Prevalence of tuberculosis in swine in the United States as determined by inspection in abattoirs under federal supervision.

Year	Number slaughtered	Percent tuberculosis[a]	Percent condemned[b]
1912	34,966,378	4.69	0.12
1917	40,210,847	9.89	0.19

under certain conditions; among these is *Mycobacterium avium* subsp. *hominissuis* (MAH), a member of the MAC. For these environmental exposure is the main mode of infection; transmission from animal to animal is generally not considered significant. Only a very few mycobacteria are specialized host-adapted pathogens where animal-to-animal transmission is the primary mode of infection for immunocompetent individuals. These include all members of the MTBC, *M. avium* subspecies *avium* (MAA) in birds, *M. avium* subspecies *paratuberculosis* (MAP) in ruminants, and *Mycobacterium leprae* in humans. There are exceptions, but documenting these has been difficult due to the slow-growing nature of mycobacteria and the difficultly in accurate subspecies characterization and genotyping. Only recently has it been possible with the advent of whole genome sequencing (WGS) and careful epidemiological investigation to document human-to-human transmission of an environmental mycobacteria, *Mycobacterium abscessus* (Bryant et al. 2016).

A review of slaughter surveillance records at the US National Veterinary Services Laboratories (NVSL) over the last 8 years (2009–2016) indicates that of the 289 swine granulomas submitted, 123 were diagnosed by histology as mycobacteriosis compatible and of the ones that were cultured, 70 (97%) were identified as MAC and 2(3%) were identified as *Mycobacterium intermedium*. This is consistent to what historically has been reported in the United States (Thoen et al. 1975).

Prior to the recent routine characterization of isolates by molecular methods, *M. avium* and closely related isolates were identified by a combination of phenotypic characteristics and biochemical tests and then, if needed, further characterized by serovars. These methods were cumbersome and time consuming. Today identification is routinely completed to the species and subspecies level using rapid and accurate methods that include hybridization probes, high performance liquid chromatography (HPLC), matrix-assisted laser desorption/ionization time-of-flight mass spectrophotometry (MALDI-TOF MS), and polymerase chain reaction (PCR) (Lin et al. 2015; Turenne et al. 2007). The characterization of DNA has replaced serology for subspecies identification, and attempts to compare the two approaches indicate poor correlation between genotypes and serovars (Frothingham and Wilson 1993). Many molecular methods

have been used to identify mycobacterial subspecies and to genotype MAC including multiplex PCR targeting insertion elements, PCR targeting large sequence polymorphisms, and partial sequencing of *rpoB* and *hsp65 genes* (Higgins et al. 2011; Semret et al. 2006; Shin et al. 2010; Turenne et al. 2006). Higher resolution genotyping methods include restriction fragment length polymorphism (RFLP), variable number tandem repeats (VNTR), and multispacer sequence typing (MST) (Cayrou et al. 2010; Komijn et al. 1999; Thibault et al. 2007). WGS has become the gold standard genotyping method, far surpassing the resolution of previous technologies since the introduction of benchtop next-generation sequencing instruments in 2011 (Köser et al. 2012).

The primary reasons for subspecies characterization and genotyping of MAC isolates recovered from swine are to help determine the source of infection, to link cases or outbreaks to a common strain, or to understand the evolutionary history of MAC. Based on comparison of sequences of 10 genes in 56 strains of genetically diverse MAC, it was proposed that MAA, *Mycobacterium avium* subsp. *sylvaticum* (MAS), and MAP each represent a recently evolved clone of genetically similar host-adapted pathogens and that they evolved from the genetically diverse group of MAH organisms that are distributed in a wide variety of environmental habitats (Turenne et al. 2008). Since then, WGS data strongly supports and extends these findings. Figure 63.1 shows an unrooted phylogenetic tree based on whole genome sequences of 104 publically available MAC isolates representing genetic and geographic diversity of the four subspecies within MAC. Branch lengths represent the genetic distance and variation of each of the subspecies. It is clear that isolates belonging to each of MAA, MAS, and MAP form tiny clusters of highly related organisms on the tree. When considered in light of the host species and geographic origin of each isolate, this strongly suggests that MAA, MAS, and MAP are specialized pathogens that have recently evolved and that are fairly constrained to their host species. In contrast all of the remaining unnamed scattered branches on the tree represent a genetically diverse group of isolates classified as MAH. This suggests that MAH is a very large genetically diverse group of organisms without host species or geographic constraints on any of the MAH branches. Isolates from pigs, humans, ruminants, and birds with broad geographic dispersion are found throughout the branches. This is not surprising since MAH are known to be widely distributed in the environment (Falkinham III 2016; Kirschner et al. 1992; Turennne et al. 2007). Most data suggests that MAS is a phenotypic variant of MAA (Turenne et al. 2007); consequently further discussions in this chapter will include both as MAA. In summary, current data suggest that MAA and MAP are specialized pathogens in birds and ruminants, respectively,

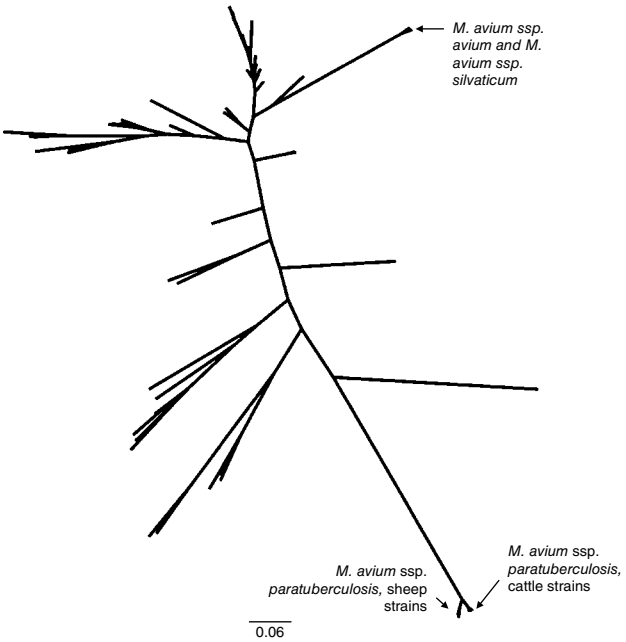

Figure 63.1 Phylogenetic tree of 104 geographically diverse *Mycobacterium avium* complex (MAC) isolates using kSNP. *Mycobacterium avium* ssp. *avium* (MAA), *M. avium* ssp. *silvaticum* (MAS), and *M. avium* ssp. *paratuberculosis* (MAP) are identified on the tree. All other branches are classified as *M. avium* ssp. *hominissuis* (MAH). These data support the current evidence that MAH is an environmental organism with a great deal of genetic diversity. On the other hand, MAP and MAA appear to be genetically bottlenecked, a pattern seen in other obligate pathogens with clear evidence of animal-to-animal transmission.

and are not widespread in the environment. In contrast, the etiological agent primarily responsible for swine TB, MAH, is ubiquitous in the environment, and outbreaks or increases in prevalence of swine TB are likely due to greater exposure to environments and/or environmental conditions where MAH thrive.

Public health

The MAC, especially MAH, cause disseminated disease or pneumonia in AIDS patients, less frequently in organ transplantees, and in other immunocompromised individuals (Abad and Razonable 2016). The incidence of MAC in humans has declined and is directly correlated with effective HIV treatment (Collins et al. 2016). While sporadic infections do occur and can be very serious, MAC are commonly identified as contaminants or incidental findings in the culture laboratory, and consequently MAC diagnosis may be overestimated (Sultani et al. 2016). Risk factors for infection in humans include immune compromise, chronic pulmonary disease, and advanced age. Chlorination of water delivery systems provides a preferential environment for proliferation of

MAC and other nontuberculous mycobacteria in biofilms (Falkinham III 2016). To date there is no data that implicates exposure to infected swine or consumption of pork as an increased risk for human infection.

Epidemiology

The epidemiology of TB in swine is dependent on the distribution of the offending mycobacterial species. Because MTBC and MAA are primarily host-adapted animal pathogens, the prevalence and geographic distribution of swine TB caused by these organisms directly correlate with the geographic distribution, prevalence, and infection rate of the mycobacterial animal host species. Unlike host-adapted tubercular mycobacteria, MAH is an ubiquitous environmental organism that is distributed throughout the world, infecting and establishing disease opportunistically when swine and other animals are susceptible either by an overwhelming dose or by a suppressed immune system.

The primary sources of information on the prevalence and geographic distribution of TB in pigs are the data obtained from meat inspection records. In the United States during 1922, 16.38% of all swine slaughtered under federal supervision had tuberculous lesions, and in 0.2% the disease was so extensive that the entire carcass was condemned (Table 63.1). Since 1922 there has been a gradual decline. The prevalence by 2008 and 2016 had decreased to 0.0178 and 0.0068%, respectively, with only 0.0018 and 0.0005% having evidence of generalized TB. The eradication of *M. bovis* is not likely the only or even primary cause of the reduction in tuberculous lesions found at slaughter. *M. bovis* has not been detected in domestic pigs during slaughter surveillance in the United States for at least 27 years (data is not available for prior years), yet the prevalence of TB in swine has continued to decrease during the same time period. This significant reduction in MAC-associated TB directly correlates with the modernization of swine production where pigs in environmentally controlled housing have limited exposure to soil, standing water, and organic bedding. Indeed, numerous reports have shown that when production systems include sawdust, wood shavings, straw, and/or peat, the incidence of TB caused by MAC increases (Álvarez et al. 2011; Matlova et al. 2004, 2005).

Sporadic outbreaks of MAC-associated TB have been reported on farms that have not been associated with organic bedding or feeding peat; however, published data describing these outbreaks is limited. One extensive cross-sectional study in Okinawa, Japan, was not able to identify specific risk factors associated with size, density, location of farm, or all-in/all-out practices (Hibiya et al. 2010). This highlights the challenges faced by veterinarians when investigating these outbreaks. Identifying risk factors or pinpointing likely sources can be difficult with retrospective studies or investigations because of the chronic nature of TB and the lack of clinical disease. The time from exposure to detection at slaughter may be several weeks or even months.

Sources of infection

Mycobacterium tuberculosis Complex (MTBC)

Pigs are highly susceptible to *M. bovis and M. tuberculosis* (Francis 1958), as well as other MTBC. *M. bovis* is not a frequent cause of TB in swine in localities where the disease in cattle is controlled by a campaign of eradication. Where *M. bovis* is endemic in cattle, the infection may be transmitted to swine by the feeding of unpasteurized milk and dairy by-products. Oral fluids and feces of tuberculous cattle or wildlife may contain viable *M. bovis*, which provides an obvious hazard where swine and cattle are maintained in a common pen or field. The practice of feeding swine the offal from abattoirs or uncooked garbage is unwise, because such material may contain tuberculous material from beef carcasses. Fichandler and Osborne (1966) described an epidemic of TB in a herd of swine in Connecticut that was fed improperly cooked offal from tuberculous cattle. Other MTBC organisms also infect swine. *M. caprae*, which is closely related to *M. bovis* and distributed throughout Europe and Asia, readily infects swine (Sabrina et al. 2011). *Mycobacterium microti*, endemic in wild rodents in the United Kingdom and Europe, has rarely been identified in swine at slaughter (Taylor et al. 2006).

Mycobacterium avium subsp. *avium* (MAA)

Experimental evidence suggests that MAA and MAH are similarly pathogenic to swine (Agdestein et al. 2012). Avian TB caused by MAA in commercial poultry was historically considered a significant source of swine TB. Due to the change in production systems of both poultry and swine, MAA incidence in poultry is lower, and exposure of infected poultry and litter to swine is less likely (González et al. 2002). Wild birds have an estimated MAA prevalence of 0.3–1.7% (Friend 1999) and are also a risk factor for MAA in swine (Alfredsen and Skjerve 1993). Currently MAA is an infrequent isolate recovered from swine slaughter surveillance cases in the United States. When MAA is confirmed as the cause of swine TB, control of potential domestic and/or wild bird tissue and/or fecal sources is indicated since it is a host-adapted pathogen and long-term establishment in the environment would not be expected.

Mycobacterium avium subsp. *hominissuis* (MAH)

The vast majority of isolates recovered from swine slaughter surveillance cases in the United States are MAH, suggesting that environmental sources rather

than birds are most common. However the role of birds in MAH epidemiology is poorly understood. Birds can be infected with MAH, and the prevalence of infection is unknown. It is also unknown whether direct transmission of MAH from birds to pigs occurs with any significance. Further confounding the potential association of MAH between birds and pigs is the impact of avian feces and debris, as this material may enhance the proliferation of MAH in the environment.

Because MAH is ubiquitous and likely exists within the vast majority of swine facilities with little to no TB prevalence, the cause of MAH outbreaks is likely due to the quantity (dose), timing of exposure, or both. Organic beddings such as wood shavings and peat are well-documented risk factors for TB in swine, and there is good evidence they provide an ideal environment for mycobacterial proliferation (Pakarinen et al. 2007). The distribution of environmental mycobacteria is far from random. They are more prevalent in environments that are damp, warm, low in pH, low in dissolved oxygen, high in soluble zinc, high in humic acid, and high in fulvic acid (Kirschner et al. 1992). Generally MAH proliferates in areas where there is active biodegradation of organic matter rather than in sterile soils. Biofilm production by MAH is also well documented (Johansen et al. 2009). This characteristic protects the organism from desiccation, disinfectants, and mechanical removal from pipes, tanks, and other colonized surfaces. Survival and proliferation in potable water systems is typical of MAH and is enhanced by the use of chorine and other water disinfectant treatments due to the removal of competing organisms (Falkinham III 2016). While swine TB caused by MAH due to contaminated drinking water has not been confirmed in the literature, it should be considered as a possibility in outbreaks in modern swine facilities.

Age of MAH exposure appears to impact the severity of lesions at slaughter. Piglets experimentally infected as early as 4 weeks of age can have significant lesions at slaughter. In one of the larger experimental infection studies, pigs infected at 8 weeks of age (slaughtered 17 weeks post infection) had the most severe lesions at slaughter followed by pigs at infected at 4 weeks of age and slaughtered 18.5 weeks later. Pigs infected later in life, 12, 16, and 20 weeks of age, and slaughtered 12, 10.5, and 6 weeks later, respectively, had fewer lesions (Acland and Whitlock 1986).

The data supporting significant pig-to-pig transmission of MAH is somewhat controversial. In natural outbreaks where higher resolution genotyping such as RFLP was conducted, the diversity in genotypes within outbreaks did not support clonal transmission of a single genotype (Matlova et al. 2004). Furthermore multiple strains of MAH can readily be found within individual pigs, suggesting environmental exposure (Wellenberg et al. 2010). Finally the highly diverse pattern of MAH displayed in the WGS phylogenetic tree (Figure 63.1) does not support clustering associated with long-term pig-to-pig transmission. Findings have been mixed in experimental transmission studies. Acland and Whitlock (1986) reported limited transmission evidenced by few microscopic lesions and no gross lesions between contacts and experimentally infected pigs. However, in other studies, contact pigs housed with orally inoculated pigs developed gross as well as microscopic lesions (Ray et al. 1972; Thoen et al. 1976b), confirming significant lateral transmission under the conditions of the experiments. There is good evidence that pigs infected with MAH shed the organism in their feces (Agdestein et al. 2014), thus augmenting environmental contamination. In Norway maintaining sows and slaughter pigs in the same pen was a risk factor for tuberculous lesions at slaughter (Alfredsen and Skjerve 1993), suggesting a role for lateral transmission from chronically infected sows. It is unknown whether the amount of MAH shed by infected pigs is high enough to reach a clinically significant threshold without environmental replication and whether the amount shed is sufficient to increase the amount already present through environmental replication to a threshold dose needed for disease. The current data, although far from settled, suggests that pigs play a limited role in the transmission of MAH.

Other mycobacteria infecting swine

Various species of mycobacteria other than MAC and MTBC have been isolated from swine and other animals. Swine appear to acquire mycobacteria that are representative of what is contained within their environment. For example, in South Texas, 98 feral pigs were examined and cultured; no MTBC were found, but 65/98 were culture positive for non-MTBC mycobacteria, and of the 15 identified, none were MAA, one was MAH, and 14 were miscellaneous other environmental mycobacteria (Campbell et al. 2011; Higgins et al. 2011). It is common to culture mycobacteria from morphologically normal lymph nodes of pigs; consequently isolating mycobacteria without supportive microscopic lesions of TB may or may not be significant. Finally there are several reports of culture of MAP from pig tissue, although it does not appear to be common and is most often the result of being co-located with cattle (Miranda et al. 2011).

Pathogenesis

The development of disease in swine depends on the ability of the tubercle bacillus to multiply within tissues of the host and to induce a host response. Although acid-fast bacilli initially encounter granulocytes and humoral components, activated mononuclear macrophages are

considered to be more important in protection of the host against mycobacteria (Olsen et al. 2010).

The capacity of MAC to produce progressive disease may be related to certain complex lipids present in the cell wall, such as the glycopeptidolipids (previously referred to as C-mycosides) localized in the exterior portion of the cell envelope (Rastogi and Barrow 1994). However, it appears that the effect of these components alone or together on phagolysosome fusion cannot fully account for virulence. Available information suggests that a combination of toxic lipids and factors released by virulent tubercle bacilli may cause disruption of the phagosome, interfere with phagolysosome formation, alter the release of hydrolytic enzymes from the attached lysosomes, and/or inactivate the lysosomal enzymes released into the cytoplasmic vacuole (Thoen et al. 2006). Some MAC strains are susceptible to bactericidal mechanisms of macrophages; however, the importance of reactive nitrogen intermediates and oxygen radicals in macrophages of animals exposed to virulent tubercle bacilli remains to be elucidated (Thoen et al. 2009). A detailed review of TB granuloma formation and its importance in the disease process has recently been published (Ramakrishnan 2012). Granulomas begin to appear after the adaptive immune system is stimulated, typically 2–3 weeks post inoculation. This is consistent with other work showing sensitized lymphocytes and detectable mycobacterial antibodies starting at 14–28 days post exposure to *M. avium* or *M. bovis* (Muscoplat et al. 1975; Thoen et al. 1979).

Clinical signs

TB in swine is usually subclinical; consequently, swine producers usually become aware of it when contacted by the slaughter plant with news of unusually high condemnation rates. Generally, tuberculous lesions are limited to small foci in a few lymph nodes associated with the digestive tract. Nonspecific clinical signs are sometimes observed in pigs with generalized TB, but they are not sufficient to suggest TB. Abortions and wasting due to MAH have been reported in rare cases of generalized disease (Eisenberg et al. 2012; Wellenberg et al. 2010).

Lesions

As seen in abattoirs in developed countries, tuberculous lesions in swine are usually limited to lymph nodes of the cervical and mesenteric regions. The lesions vary in appearance from small, yellowish white, caseous foci, a few millimeters in diameter to diffuse enlargement of the entire node (Figure 63.2). The disease may be localized in one group of nodes or may involve a number of lymph nodes along the digestive tract. The frequent occurrence of MAC in lesions limited to the cervical lymph nodes in naturally infected swine indicates that infection usually occurs by ingestion. In a study of lesion distribution in 81 pigs with tuberculous lesions at slaughter, 25 (31%) had lesions in lymph nodes in 1 of 3 sites (head, mesenteric, or inguinal), 53 (65%) in 2 of these sites, and 3 (4%) in all 3 sites (Matlova et al. 2005).

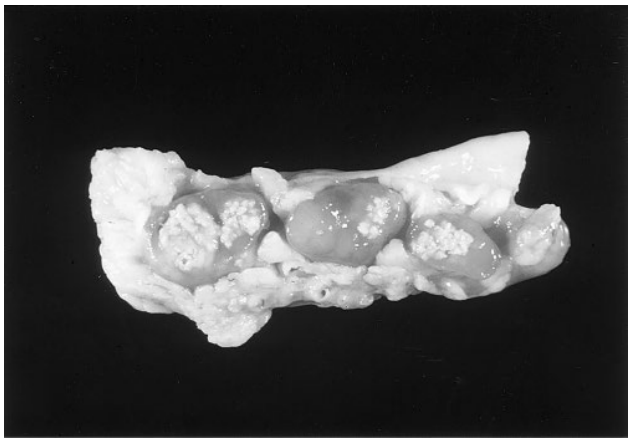

Figure 63.2 Tuberculous lesions in a mesenteric lymph node of a pig at slaughter.

Disseminated disease is relatively uncommon in swine, but is more likely with *M. bovis* (MTBC) than with MAH or MAA (MAC) (Francis 1958) and can still be observed in countries where MTBC or MAA are endemic in their host species. Feldman (1938) in an abattoir study of naturally occurring TB in swine showed that 30% of *M. bovis* cases were disseminated compared with only 0.0003% of *M. avium* cases. Distribution of gross lesions in disseminated disease is similar for both *M. bovis* and MAH or MAA. Lymph nodes of the head, neck, and mesentery are the most commonly affected, followed by liver, spleen, lung, other lymph nodes, bones, and notably the uterus and mammary glands. Infected mammary glands are the source of organisms that are shed in bovine milk of tuberculous cows and must be considered a possible source, in addition to fecal shedding, of transmission from chronically MTBC- or MAC-infected sows.

While gross differences between tuberculous lesions caused by MAC and MTBC are not specific enough to allow definitive differentiation, some features are generally more characteristic of each. MTBC typically cause discrete well-formed encapsulated tubercles, while MAC form focal, predominantly histiocytic infiltrates with occasional necrosis that blend at the margins with surrounding tissue architecture. In an infection with MAC, the lymph nodes may be enlarged and firm with no discrete purulent foci, or there may be one or more foci of caseous necrosis with indistinct borders. Mineralization is seldom demonstrable, except in very chronic lesions.

The cut surface of the lesion has a homogeneous or slightly nodular appearance with a few caseous foci. Relatively large areas of caseation may be present and occasionally will involve the entire lymph node. Although there may be diffuse fibrosis, there is typically little encapsulation of necrotic foci. As a result, the focal lesions due to MAC are not easily enucleated. In contrast, focal lesions due to MTBC tend to be discrete, caseous, mineralized, and well encapsulated and are relatively easy to separate from the surrounding tissue. These distinctions are by no means absolute, and there are many variations in the gross appearance of tuberculous lesions in lymph nodes of swine.

Microscopic lesions in MAC infections in lymph nodes and in other tissues include multifocal-to-coalescing infiltration by epithelioid and multinucleate Langhans and foreign body-type macrophages. There may be some necrosis and mineralization, especially in advanced lesions, but mineralization is not usually prominent. Fibrosis is variably observed, but encapsulation of lesions is uncommon. Acid-fast stains reveal very few organisms in the cytoplasm of macrophages. Similar changes are observed in sows and slaughter pigs (Thoen et al. 1976a). Lesions in MTBC infection have similar distribution and character, but tend toward earlier and more caseous necrosis, more distinct granuloma formation rimmed by epithelioid macrophages, fewer multinucleate cells, more mineralization, and fibrous encapsulation of granulomas (Figure 63.3; Karlson and Thoen 1971). However, consistent histopathological differentiation between lesions caused by MTBC and MAC is not possible. Furthermore, coinfections of MAC and MTBC have been reported (Barandiaran et al. 2015).

Of note is *Rhodococcus equi* that can cause granulomas in submaxillary lymph nodes of slaughter-age swine that are grossly indistinguishable from MAC or MTBC. Komijn et al. (2007) found that of granulomas detected predominantly in submaxillary lymph nodes of 0.75% of slaughter pigs in the Netherlands, *R. equi* and not MAC could be cultured from 45%. *R. equi*, like MAC, can also be routinely cultured from lymph nodes without lesions. An abattoir study from Poland reported that 26.6% of 395 submandibular lymph nodes without lesions were culture positive for *R. equi* (Witkowski et al. 2016).

Diagnosis

Antemortem testing

A clinical diagnosis of TB in swine is usually not possible since most cases will be asymptomatic or present with only nonspecific malaise. Animals with disseminated disease may have granulomas on the liver and other organs that can be visualized with ultrasound. There are several options for antemortem diagnostics available, either focused on the humoral (serology) or cell-mediated immune response.

Within the last few decades, several ELISAs for MAC in swine have been evaluated, and some have recently been commercialized (although not sold in the United States) for use in serum and in meat juice. Examples include PrioCHECK™ *M. avium* Antibody ELISA Kit (Thermo Fisher Scientific, Inc., Waltham, MA) and ID Screen™ *Mycobacterium avium* (IDvet, Grabels, France). A lateral flow assay has also been evaluated for MTBC in the wild boar (Boadella et al. 2011). The available data estimating the sensitivity and specificity of these assays are limited, but they appear to perform similarly in pigs as they do in other species known to have a fairly strong humoral response to mycobacterial infections. Specificities range from 92 to 95% with sensitivities from

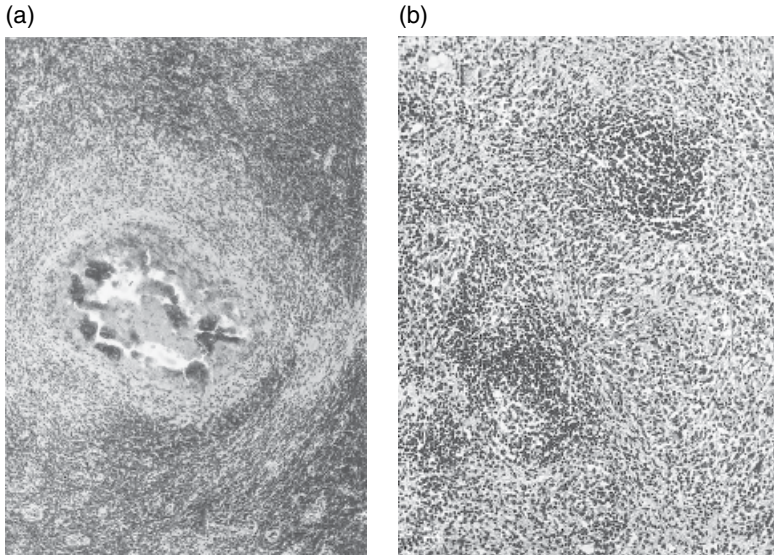

Figure 63.3 Tuberculous changes in cervical lymph nodes in swine. (a) Mammalian tubercle bacillus infection. Peripheral fibrosis, necrosis, and calcification are typical of lesions due to bovine or human types of tubercle bacilli (H&E ×40). (b) *Mycobacterium avium* infection. Diffuse cellular infiltration with little necrosis (H&E ×95).

50 to 70%, sufficient for use on a herd or population basis but problematic in low prevalence populations and insufficient for use in individuals (Wisselink et al. 2010).

Classical assays exploiting the cell-mediated immune system have also been evaluated including the intradermal (skin) test and the gamma interferon ELISA, but in most places only the skin test is readily available (Faldyna et al. 2012; Stepanova et al. 2011). There is very little recent work published on the skin test, but the test has been used for many years. Because it is a required test for export to several countries, most agriculture ministries make purified protein derivatives (PPDs) from the various *Mycobacterium* species important in that country/region available for testing, along with instructions for use and interpretation. For the United States, PPDs are available from NVSL, Ames, IA. In pigs, 0.1 mL is injected intradermally in the skin on the back of the ear, and the test is read 48 hours later. A positive test is indicated by focal swelling and redness and occasionally even hemorrhage and/or ulceration. The skin test is recommended for use on a herd, not individual, basis as false-positive and false-negative tests may occur (Payeur and Songer 1992).

Post mortem testing

Gross lesions of granulomatous lymphadenitis or disseminated granulomas are sufficient for TB to be included as a possible cause, but are not sufficiently specific for a definitive diagnosis. *R. equi* and other bacteria can cause granulomatous lymphadenitis grossly and microscopically indistinguishable from TB, and *Trueperella pyogenes* is a common cause of disseminated encapsulated abscesses in swine that can easily be confused with generalized TB. Characteristic gross and microscopic lesions with demonstration of acid-fast organisms allow a strong presumptive diagnosis of TB. An unequivocal diagnosis requires confirmation of the *Mycobacterium* spp. in tissues with lesions by culture and identification or by direct PCR (Miller et al. 1999).

Sampling for an outbreak investigation

WGS of isolated MAC gives veterinarians unprecedented resolution to identify and recognize potential sources of an outbreak; consequently it is worth discussing how to properly sample animals and the environment for mycobacterial culture. First, it is important to characterize the outbreak occurring in the animals, so tissues with lesions from at least 3–5 animals should be cultured. Sampling and combining multiple lesions into one pooled culture for each animal will help to economically identify coinfections of different strains within the animal. The pens should be investigated for areas of decomposing; damp organic matter and samples of 25 g each should be collected and frozen or refrigerated and shipped on ice to a testing laboratory within 4 days. If feed is a suspected source, 25 g samples of feed from multiple areas of the lot should be collected. Finally two 1 L samples of each water source should be collected, as well as sampling any area of chronic moisture where biofilms may have formed. This may include areas in the pens with evident algae/mold or areas with algae/mold in a water-holding tank, water line, or other component of the water delivery system. Sampling the biofilm is critical. Where there is algae/mold, a clean brush can be used to scrub the area in order to loosen the scale and algae, then collect that material and either freeze or refrigerate, and ship within 4 days. Submit all samples to a laboratory specializing in mycobacterial culture.

Prevention and control

The known epidemiology of the detected *Mycobacterium* spp. will direct efforts at prevention and control. For host-adapted *Mycobacterium* spp. (MTBC and MAA), implementation or increasing stringency of biosecurity measures aimed at preventing contact with the host (including bird-proofing buildings, feed, and water sources), host feces (bedding, contaminated lagoon surface water, etc.), or their by-products used as feed ingredients (meat and bone meal, fat, etc.) should successfully control the disease. For TB caused by environmental mycobacteria such as MAH, the solutions can be much more challenging. Wood shavings, sawdust, and peat should be avoided for use as bedding. While straw is reported to be associated with tuberculous lesions, it is not mentioned in the literature as often, so it may be a superior choice if bedding material is required. Standing water that supports the decomposition of organic matter creating "swampy areas" should be cleaned up or fenced off. Water delivery systems should be evaluated for evident biofilms, and the biofilms removed, followed by disinfection (see below). Timing of exposure matters, and for market hogs, the older the pigs are past 8 weeks when significantly exposed, the less likely and severe the lesions. Therefore, reducing risk factors for younger pigs is more impactful than for older pigs in minimizing carcass condemnations at slaughter. In most outbreaks, attention to these factors eliminates or greatly reduces slaughter condemnations. However, in some confined herds with few apparent risk factors, it may be difficult to consistently reduce condemnations. In these herds it may be useful to skin-test sows and cull positives, suggesting that recontamination of the environment by chronically infected sows may sometimes be significant in initiating new infections/outbreaks.

Appropriate tuberculocidal disinfectants should be employed. All organic matter should be physically removed, and appropriate contact times as indicated on the product labels should be followed. The most useful products for premises use are phenol based, such as One-Stroke Environ™, Tek-Trol™, and Pheno-Tek II™. These products tend to maintain effectiveness in the presence of limited organic matter. Biofilm production by MAH can provide robust protection against most disinfectants, so mechanical removal of any evident biofilm is critical prior to disinfection. Even with the best disinfectants, only a reduction in numbers of bacteria will be achieved. Consequently disinfecting without fundamentally changing the environment to prevent the regrowth of MAH is bound to fail.

The swine industries in developed countries have achieved great success in controlling and preventing TB. With the more recent realization that sporadic outbreaks of carcass condemnations are the result of MAH, an environmental mycobacterium, unique challenges to control are evident. Gaps in knowledge certainly exist, and understanding risk factors associated with changes in productions systems as the industry evolves will require sound epidemiology and applied research. This research will be best employed by a partnership between veterinarians and producers who encounter and identify prevalence changes and researchers capable of identifying species and strains of tubercular mycobacteria. As consumer preferences continue to impact types of production systems, environmental risks may change, and veterinarians and producers may need to balance carcass condemnation rates with evolving housing and husbandry practices.

Actinobaculum (Eubacterium) suis

Relevance, etiology, and public health

Actinobaculum suis causes cystitis and pyelonephritis in individual or small groups of sows and is carried by boars. It is not a public health concern. *A. suis* was earlier classified as *Corynebacterium suis*, *Actinomyces suis*, and *Eubacterium suis* (Lawson et al. 1997; Soltys and Spratling 1957; Yassin et al. 2015).

A. suis is a gram-positive pleomorphic rod, 2–3 µm long and 0.3–0.5 µm wide, and it occurs as "Chinese letters" and palisades in smears of infected tissues. It is nonmotile, does not form spores, and grows on blood agar under anaerobic conditions. Colonies are 2–3 mm and nonhemolytic after 2 days; then they flatten and develop a characteristic dry, gray, opaque surface with a crenated edge attaining a size of 4–5 mm in 5–6 days. Growth is enhanced by the addition of urea to media with a final concentration of 1.2% (w/v). The organism produces urease.

Epidemiology and pathogenesis

A. suis-associated urinary tract disease in sows has been reported in North and South America, Europe, Asia, and Australia. The pig is the main host of *A. suis* and most male pigs, aged 6 months or more, harbor *A. suis* in the preputial diverticulum. The organism may be found on the floors of pens occupied by male pigs, and uninfected males are readily infected when they are housed with carriers (Jones and Dagnall 1984). It is rarely isolated from the vagina of healthy females. Carr and Walton (1990) isolated *A. suis* from footwear of handlers working with boars.

Urinary tract infection is by the ascending route. Larsen et al. (1986) demonstrated that some strains of *A. suis* are heavily fimbriated and adhere to glycoconjugate receptors on epithelial cells of the porcine bladder. Infection of the ureters and kidneys follows infection of the bladder.

Most cases occur in females 1–3 weeks after mating with an infected boar. Water restriction and the presence of crystalluria may predispose to infection (Wendt and Sobestiansky 1995). Cases may also occur at other times of the reproductive cycle, by recent infection of the urinary tract or by recrudescence of previously existing disease.

Clinical signs, lesions, and diagnosis

Clinical signs may develop 2–3 weeks after service by an infected boar or may be delayed until farrowing. Affected sows or gilts may die suddenly or be found ill, depressed, or thirsty with hunched backs. Hematuria is the main sign in the acute phase; later affected animals are uremic, pass bloodstained, purulent urine with or without a vulval discharge, and exhibit weight loss. Clinically affected sows frequently die from renal failure. Mild cases may occur in which inappetence and vulval discharge are the only obvious signs.

Lesions are limited to the urinary tract where there is ascending inflammation terminating in pyelonephritis. The mucosa of the urethra, bladder, and ureters is inflamed, coated with catarrhal or fibrinopurulent exudate; hemorrhagic; or necrotic. Affected kidneys often have irregular yellow areas of degeneration in the parenchyma that are visible on the surface. The renal pelvis may be dilated and contain mucoid fluid in which flakes of necrotic debris and altered blood are present. The medullary pyramids may contain dark foci of necrosis. The ureters can be dilated and filled with reddish purulent urine.

Diagnosis is based on clinical signs and bacterial culture of urine or urinary tract. The presence of hematuria 2–3 weeks after service by a boar suggests *A. suis* cystitis and pyelonephritis, rather than cystitis caused by *Escherichia coli* (Chapter 52). Postmortem examination

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

reveals aforementioned lesions. *A. suis* is easily seen in Gram-stained films, often with other bacteria, notably streptococci. Anaerobic incubation for 4 days is essential for isolation from urine or affected tissue. A selective medium for the isolation of *A. suis* has been described (Dagnall and Jones 1982). Recently Amigo et al. (2012) have described a gel-based PCR, which appeared to be far more sensitive than traditional culture. Using this assay they detected the microorganism in 8.9% (17/192) and 82.2% (37/45) sow urine and boar preputial swabs, respectively, compared with 0 and 31% (14/45) by culture.

Prevention and control

A. suis is sensitive *in vitro* to several antibiotics including penicillin and tetracyclines (Biksi et al. 2003). Antibiotics are frequently effective, but relapses occur, and early slaughter of affected animals is recommended. Prolonged treatment for 20 days with ampicillin given at 20 mg/kg has been suggested (Wendt and Sobestiansky 1995). Chronically affected animals in poor bodily condition and those that have not responded to treatment should be euthanized. Use of artificial insemination may help prevent disease.

Actinomyces hyovaginalis

Actinomyces hyovaginalis was first isolated from purulent vaginal discharge, organs of aborted fetuses, and a variety of body sites of pigs (Collins et al. 1993; Hommez et al. 1991) and later from sheep (Collins et al. 1993; Foster et al. 2012) and a goat (Schumacher et al. 2009). Two biovars, type II and III, are described based on phenotypic and biochemical differences (Storms et al. 2002). Type II strains, known as "vaginal" and thought to be vaginal flora of pigs, have been isolated in mixed culture from vaginal discharges and infrequently in pure culture from aborted pig fetuses. Type III strains, known as "general," have been cultured from a variety of porcine tissues including nasal cavity, tonsil, lung, kidney, uterus, joint, liver, and urinary bladder (Hommez et al. 1991; Storms et al. 2002). Baele et al. (2001) reported type III strains among the most common isolates from tonsils of pre- and post weaned pigs, suggesting it as a commensal, and Aalbaek et al. (2003) reported type III strains in pure or mixed culture from unique pyemic lung lesions in market pigs at slaughter, suggesting hematogenous distribution of an infection that they proposed as beginning as an inhaled opportunist in the lung.

Based on limited data, it seems that type II strains are infrequent causes of sporadic abortion and that type III strains cause disseminated pyemic lesions in a variety of organs with lung lesions being the best characterized. Due to the difficulty in isolation and identification of *A. hyovaginalis*, associated disease is likely underreported.

Actinomyces species are facultatively anaerobic, gram-positive, pleomorphic, non-acid-fast, non-sporing, non-motile, slow-growing bacteria. They are part of the skin and mucosal flora of human beings and animals. Identification of *Actinomyces* species by conventional phenotypic and biochemical methods is difficult and unreliable, due to slow growth as well as poor reproducibility and lack of discriminatory power of biochemical tests. Sequencing of the 16S ribosomal RNA (rRNA) definitively identifies these microorganisms (Hall et al. 1999).

Lesions are best characterized in aborted fetuses (Hogg et al. 2012) and in lungs (Aalbaek et al. 2003; Liljegren et al. 2003). In fetuses from a litter aborted 3 weeks prior to term, inconsistent gross lesions included minimal fibrinous exudate in the thoracic cavities and on the placental surface. Microscopic lesions were also inconsistent and included subacute necrotizing and suppurative placentitis and moderate, subacute suppurative bronchopneumonia. Gram-positive pleomorphic bacteria were observed in suppurative exudate in the placenta and lung. Gross lesions in lungs of slaughter pigs were randomly distributed irregularly round white-to-cream foci that contained coagulated necrotic material. Microscopically, foci were composed centrally by coagulated necrotic lung tissue with scattered indistinct basophilic bacteria surrounded by a

thin zone of aggregated neutrophils and then a zone of macrophages and peripherally by a zone of fibrosis.

Diagnosis of *A. hyovaginalis* requires culture and typical microscopic lesions. Culture must be anaerobic with fastidious anaerobic blood agar, and identification requires extensive biochemical testing or sequencing of the 16S rRNA gene. Culture from vaginal discharge should not be considered diagnostic for reproductive failure since *A. hyovaginalis* appears to be common vaginal flora.

Bacillus anthracis: Anthrax

Relevance, etiology, and public health

Anthrax has been recently reviewed (Mogridge et al. 2010; World Health Organization 2008). Anthrax is rare in swine. Swine, along with rats and dogs, are resistant to anthrax and often survive infection. Outbreaks in swine are usually limited with low morbidity and mortality. There are three clinical forms in swine – pharyngeal (cervical), intestinal, or septicemic – each resembling more common swine diseases that confound clinical recognition and proper diagnosis. The primary importance of anthrax and its recognition and diagnosis in swine is twofold. First, proper disposal of carcasses and decontamination of premises are essential to prevent spread of anthrax spores. Second, anthrax is zoonotic, and infected swine and their pork products are a hazard to humans.

Anthrax is caused by *Bacillus anthracis*, a large encapsulated gram-positive, aerobic, spore-forming, nonmotile rod. *B. anthracis* grows well on common laboratory media. On blood agar plates, colonies can usually be detected within 12 hours. After 24 hours at 37°C, the colonies are nonhemolytic and have a "ground-glass" appearance with irregular, wavy borders that give them the "Medusa head" characteristic. *B. anthracis* may be distinguished from other members of the genus by biochemical tests and PCR techniques.

B. anthracis exists in two forms, the multiplicative vegetative form found in tissues or the environmentally resistant spore form found in the environment. The cycle of infection involves exposure of the host to environmental spores, their uptake and germination to vegetative forms within the host, and then localized or generalized multiplication resulting in tissue damage and often death. Following death, the shedding of vegetative forms to the environment through exuding body fluids, putrefaction, or the opening of the carcass through the agency of a scavenger or human prosector results in sporulation. Spores can remain viable under appropriate environmental conditions for 50 or more years.

Human exposure occurs when animals that have died from the disease are examined postmortem without appropriate precautions or during carcass disposal. Infection through open skin wounds causes focal cellulitis and lymphadenitis in humans that is often self-limiting. More serious is inhalation of spores that leads to flu-like symptoms and progresses to often fatal sepsis and toxemia. This is more likely when infected body fluids or tissues have been exposed to air and sporulation has occurred, sporulation requiring only 4–10 hours. Ingestion of vegetative forms or *B. anthracis* in undercooked contaminated pork can lead to anorexia, bloody diarrhea, and abdominal pain that can progress to often fatal septicemia and toxemia.

Epidemiology and pathogenesis

Anthrax primarily affects herbivores, occurs worldwide, and is endemic in many warmer climates including most countries of Africa and Asia, in many countries in southern Europe, and in certain locales in North and South America (World Health Organization 2008). Where endemic, outbreaks in livestock (including swine housed outdoors) and in feral animals usually occur when rains have ended a period of drought. In confined swine outbreaks are sporadic and rare, not seasonal, and are usually point sources most likely due to contamination

of feed by large numbers of spores (Ferguson 1986). This occurs from feeding contaminated animal protein products, forages containing animals killed by anthrax or contaminated vegetation originating from an endemic area. Direct pig-to-pig transmission rarely occurs. Biting flies and mosquitoes may transmit the disease (Turell and Knudson 1987).

Exposure to *B. anthracis* in swine is usually by the ingestion of spores. Spores of *B. anthracis* are noninvasive and need to transit the mucosal epithelial lining of the gastrointestinal tract to germinate. Follicle-associated epithelium of the tonsillar crypts in the pharyngeal form and that of lymphoid patches in the intestinal form facilitate uptake of spores and delivery to the underlying lamina propria. Their germination is rapid, requiring only 10–15 minutes for conversion to vegetative forms. Two major and several more minor virulence factors are operative in evading host defenses, creating tissue damage, and resulting in death in fatal anthrax. The anionic polypeptide capsule is required for virulence and greatly reduces phagocytosis by macrophages and neutrophils. Anthrax toxin binds to and damages many cell types. It impairs phagocytosis in macrophages, reduces oxidative response in neutrophils, acts as a chemokine for neutrophils, and is cytotoxic for macrophages and other types of cells. In highly susceptible herbivores and occasionally pigs, multiplication of *B. anthracis* begins locally, extends to regional lymph nodes, and rapidly becomes systemic, leading to terminal shock and death (septicemic form). In most cases of porcine anthrax, multiplication and tissue damage is limited to the site of invasion and regional lymph nodes (i.e. the pharyngeal/cervical region or the ileum and proximal colon where lymphoid patches are most numerous).

Clinical signs and lesions

The incubation period in swine ranges from 1 to 8 days. The pharyngeal form is characterized by cervical edema, lethargy, inappetence, vomiting, and pyrexia to 107 °F (41.7 °C). Animals may recover spontaneously or die due to suffocation. Pigs with intestinal anthrax exhibit any combination of lethargy, anorexia, vomiting, ataxia, loose sometimes bloody feces, constipation, and pyrexia up to 107.4 °C (41.9 °C) (Brennan 1953; Redmond et al. 1997). Death follows in severe cases, but less severe cases are more commonly followed by recovery (Brennan 1953; Redmond et al. 1997). The septicemic form usually manifests as sudden death or as lethargy, tremor, and pyrexia followed shortly by death. Young pigs may develop septicemia more frequently than older swine (Ferguson 1986).

Necropsy of anthrax cases is discouraged to reduce environmental contamination by spores and limit human exposure. However, since anthrax may not be suspected based only on clinical presentation, the gross lesions of the disease are important. Large pigs that have died may have a bloody discharge from the nose, mouth, and/or anus (Edgington 1990), and small ones can be pale and dehydrated. In the pharyngeal form the cervical tissues have a gelatinous consistency and are separated by straw-colored, pink, or red hemorrhagic fluid. The tonsils are usually covered with fibrinous exudate and can be necrotic. The pharyngeal mucosa is frequently inflamed and swollen. Mandibular and pharyngeal lymph nodes are enlarged to several times their normal size, and the cut surfaces are hemorrhagic or yellow and necrotic. In the intestinal form there is segmental necrotizing enteritis most commonly affecting the ileum and spinal colon. Affected segments have mucosal hemorrhage and adherent fibrinonecrotic exudate, there is mural thickening, and fibrin can adhere to the serosa. The peritoneal cavity can contain copious pinkish fluid that clots when exposed to air. Mesenteric lymph nodes are typically enlarged, and hemorrhagic or necrotic and edema of the mesentery is common. In the septicemic form, there are variable amounts of serosanguinous peritoneal fluid, serosal and renal cortical petechia, splenic enlargement, and generalized lymphadenomegaly.

Diagnosis

Diagnosis of anthrax in swine is made difficult by its rare occurrence, lack of unique clinical signs, and similarity of various forms to other more common swine diseases. Cervical swelling can also be caused by necrotoxic clostridial infections (Chapter 51) and cervical lymphadenitis caused by *S. porcinus* (Chapter 61). Enteritis and/or typhlocolitis with pyrexia can also be caused by *Escherichia coli* (Chapter 52), *Salmonella* spp. (Chapter 59), *Brachyspira* spp. (Chapter 62), classical swine fever virus (Chapter 39), and African swine fever virus (Chapter 25). Sudden death caused by septicemia can also be caused by *A. suis* (Chapter 48), *E. coli* (Chapter 52), *E. rhusiopathiae* (Chapter 53), *H. parasuis* (Chapter 54), *S. choleraesuis* (Chapter 59), and *S. suis* (Chapter 61). Exudation of bloody fluid from all body orifices in the septicemic form, from the nose and mouth in the cervical form, and from the anus in the intestinal form should raise suspicion in fatal cases.

The officially recommended methods for the diagnosis of anthrax are in the Manual of Diagnostic Tests and Vaccines for Terrestrial Animals (World Organization for Animal Health (OIE) 2016). If anthrax is suspected based on clinical presentation, the recommended method of confirmation is the M'Fadyean smear, which is a microscopic examination for encapsulated bacilli in a smear of blood from a dead animal stained with polychrome methylene blue stain. Necropsy examination is not recommended due to exposure of vegetative forms

to oxygen and formation of spores. Gross lesions are as described above. Culture should not be attempted unless appropriate safety precautions are available. Personnel handling the organism should be vaccinated. *B. anthracis* is readily cultured, and typical nonhemolytic colonies can be identified by their biochemical characteristics or by PCR (Fasanella et al. 2003; Hutson et al. 1993). The organism can also be directly detected from clinical samples by PCR (Drago et al. 2002). PCR kits are commercially available.

Prevention and control

Pigs with clinical anthrax can recover completely after penicillin treatment (Ferguson 1986). Oxytetracycline is effective against *B. anthracis* and may be used parenterally (Edgington 1990). Infection may persist for up to 21 days after infection in a population (Redmond et al. 1997); this factor must be considered before animals are sent for human consumption. Immunity develops in recovered animals, and serum antibody to the toxin can be detected. Vaccines can stimulate protective immunity. Kaufmann et al. (1973) used the Sterne strain anthrax vaccine, an avirulent spore vaccine, in swine with success.

The World Health Organization (2008) provides details of control measures. Qualified medical personnel can give persons exposed to the infection prophylactic antimicrobials such as penicillin and tetracyclines, and clinical disease should be immediately treated. Vaccination can protect humans against longer-term exposure. Control of the spread of anthrax differs significantly from control of most other animal diseases because it depends on preventing access to viable spores of *B. anthracis* in soil, manures, or contaminated feeds. Prevention of environmental contamination by the long-lived spores is essential. Preferred disinfectants are 5% freshly prepared sodium hydroxide or 10% formaldehyde (Edgington 1990). Few spores are formed in the unopened carcasses of animals dead of anthrax. The orifices and any cuts in a carcass should be covered with disinfectant-soaked cotton wool to prevent sporulation and spread of infection. Carcasses, bedding, and other combustible articles should be destroyed by incineration, preferably on the spot, or by deep burial in at least 4 ft (1.25 m) of soil with the carcass covered with lime. Disinfectants should be used prior to clearing out infected premises, and then exposed surfaces as well as equipment and tools should be scrubbed or pressure washed with the disinfectant.

Burkholderia pseudomallei: Melioidosis

Relevance, etiology, and public health

Melioidosis is a chronic bacterial infection of swine by *Burkholderia pseudomallei* seen in tropical and subtropical regions. Humans can be infected. Both pigs and people may contract infection from animals by consumption of contaminated meat, from water contaminated by animal or human feces, and from other environmental sources. *B. pseudomallei* is now considered a candidate agent for bioterrorists.

B. pseudomallei, formerly known as *Pseudomonas pseudomallei*, is a short, gram-negative rod that does not form spores. It produces rough (wrinkled) or mucoid colonies on a wide variety of laboratory media at 37 °C and grows on MacConkey agar to give colorless colonies.

Melioidosis in humans can be fatal, presenting as septicemia, pneumonia, or chronic suppurative lesions of skin, lymph nodes, or bone. Mortality in humans is

20–50% with or without treatment. It is rarely transmissible from person to person and is usually acquired by the ingestion of contaminated food and water. This contamination can be purely environmental or result from contamination of water and food with infected animal feces. Ingestion of improperly cooked meat from infected animals may also result in human infection.

Epidemiology and pathogenesis

B. pseudomallei is present in water and soil in tropical and subtropical areas and may infect pigs when water supplies are contaminated or when they consume infected animal or plant matter. It has been reported from Australia (Millan et al. 2007), Malaysia (Omar et al. 1962), and the Caribbean.

Phenolic (2% Lysol), chlorine (0.1–0.5%), and oxidizing disinfectants (1% Virkon®, 3% hydrogen peroxide) and formaldehyde (4%) are effective against *B. pseudomallei*.

Clinical signs, lesions, and diagnosis

Infection is often clinically inapparent, but a raised rectal temperature of 40–42 °C (104–108 °F) may develop for up to 4 days. Unsteady gait, lameness or weakness, slight nasal discharge, and subcutaneous swellings of the limbs may be seen. Deaths may occur but are rare in adults in which abortions and uterine discharges have been recorded (Laws and Hall 1964; Millan et al. 2007; Omar et al. 1962; Rogers and Andersen 1970).

Lesions are found in slaughter pigs in which clinical signs have not been seen and in pigs that have died from the disease. They consist of large abscesses filled with creamy or caseous yellow-green pus in the lungs, liver, spleen, kidney, and mesenteric and subcutaneous lymph nodes.

Melioidosis should be suspected in tropical environments on clinical grounds when prolonged raised rectal temperatures and unsteady gait are associated with subcutaneous swellings of the limbs. More frequently, presumptive diagnosis is based on the typical creamy abscesses found at slaughter (Ketterer et al. 1986). Diagnosis is confirmed by culture. A selective medium is used for environmental samples (Peacock et al. 2005). The identity of suspect colonies can be confirmed biochemically (Hemarajata et al. 2016). A hypersensitivity test resembling a tuberculin test (the melioidin test) and serum agglutination and complement fixation tests have been used to confirm diagnosis in the live pig. Antibody has been demonstrated within 7 days of experimental infection (Najdenski et al. 2004).

Prevention and control

B. pseudomallei is resistant *in vitro* to aminoglycosides but susceptible to some cephalosporins and to amoxicillin: clavulanic acid. The disease can be prevented by use of clean or chlorinated water supplies and preventing access to contaminated soil. As the disease is of public health importance, infected carcasses should be disposed of safely. Rigorous criteria for meat inspection of slaughter pigs will help to safeguard public health.

Campylobacter spp.

Relevance and etiology

A number of *Campylobacter* species are known to be residents of the gastrointestinal tract in swine including *Campylobacter coli* (Doyle 1944), *Campylobacter jejuni* (Svedhem and Kaijser 1981), *Campylobacter sputorum* subsp. *mucosalis* (Lawson et al. 1981), *Campylobacter hyointestinalis* (Gebhart et al. 1985), *Campylobacter lari* (Young et al. 2000), and *Campylobacter lanienae* (Sasaki et al. 2003). Historically, *C. coli* was erroneously thought to cause swine dysentery (Chapter 62), and both *C. sputorum* subsp. *mucosalis* and *C. hyointestinalis* were erroneously thought to cause porcine proliferative enteropathy (Chapter 58). The primary importance of campylobacters in swine is as one of many sources for infection of humans. *C. jejuni* and *C. coli* are among the

main causes of bacterial gastroenteritis in humans in all industrialized countries (European Food Safety Authority (EFSA) and European Centre for Disease Prevention and Control (ECDC) 2015; Huang et al. 2016). Although mild diarrheal disease can be produced in neonatal pigs by inoculation with *C. coli* (Olubunmi and Taylor 1982) or *C. jejuni* (Boosinger and Power 1988; Vitovec et al. 1989), campylobacters are not known to produce any generally recognized enteric or other diseases in swine.

Campylobacters are gram-negative curved rods or short spiral organisms from 0.5 to 8 µm in length and 0.3 µm in diameter with a single polar flagellum (Penner 1988). They do not form spores, but some *C. jejuni* have a polysaccharide capsule probably involved in virulence (Bacon et al. 2001). They are microaerobic and grow most readily on media containing blood or other sources of iron. Most commercial media for isolation also incorporate selective antimicrobials such as cefoperazone and amphotericin B (Corry et al. 1995). Growth occurs readily at 37 °C, but they are often cultivated at higher temperatures of 40–42 °C. Colonies generally appear after 48 hours of incubation. *C. coli* forms sprawling watery colonies on blood agar after 48 hours, and *C. jejuni* form slightly smaller colonies 2–3 mm in diameter. They can be identified presumptively to species using biochemical tests. However identification to species level is hindered by variations in methodology and the subjective interpretation of biochemical results and isolates with atypical phenotypes (Linton et al. 1997).

Public health

C. jejuni and C. coli are among the most common causes of food-borne bacterial enteric disease in humans (EFSA and ECDC 2015; Huang et al. 2016; Silva et al. 2011). *C. jejuni*, *C. coli*, and *C. hyointestinalis* of swine origin can cause disease in humans (EFSA and ECDC 2015; Gorkiewicz et al. 2002). Typical symptoms include vomiting, diarrhea, fever and headache. The disease is normally self-limiting. Rarely serious complications may result including septicemia or autoimmune neuropathies such as Guillain–Barré and Miller-Fisher syndromes. Of recent concern is the emergence of antimicrobial resistant strains in affected humans (EFSA and ECDC 2015).

Livestock carrying *Campylobacter* pose an important risk for human infection from contamination of carcasses at slaughter, of milk, and water contaminated by livestock wastes and slurries. Poultry is the main foodborne source of human campylobacteriosis, but contact with infected swine, consumption of contaminated pork products, or consumption of water contaminated by swine effluent may lead to human infection (EFSA and ECDC 2015; Horrocks et al. 2009; Kapperud et al. 1992).

Epidemiology

Campylobacter species are found in swine worldwide. *C. coli* is most commonly found in the pig but also occurs in a wide range of hosts including cattle and poultry (Alter et al. 2005; Horrocks et al. 2009; Jensen et al. 2006; Oporto and Hurtado 2011). *C. jejuni* is less frequently isolated from swine but is present in a wide range of mammalian and avian species where it may cause enteritis (Giacomelli et al. 2015; Horrocks et al. 2009). It is also commonly carried in the tract of a wide range of birds and mammals, including food-producing animals and pets, without causing clinical signs (Keller et al. 2007; Moore et al. 2005; Petersen et al. 2001). *C. hyointestinalis* and *C. mucosalis* are also found in other mammalian species (Giacomelli et al. 2015; Oporto and Hurtado 2011).

Infection takes place by the oral route and is usually direct from one infected pig to another. Organisms are carried principally on the ileal and large intestinal mucosa and shed in the feces. As the organism can survive in feces and contaminated water, indirect transmission may occur. Birds, rodents, and insects may contaminate feed and water and introduce infection to a herd (Alter et al. 2005). Piglets become infected from maternal feces (Leblanc-Maridor et al. 2011b; Soultos and Madden 2007), through contaminated water, or by horizontal transmission between animals or via farmers, domestic animals, or other environmental sources (Alter et al. 2005; Hume et al. 2002; Quintana-Hayashi and Thakur 2012). Maternal immunity does not prevent colonization. Infected animals remain carriers for long periods and pass 10^3–10^4 organisms/g feces for months (Leblanc-Maridor et al. 2008; Weijtens et al. 1999).

Enteric disease in pigs

Enteric disease has been reproduced in naïve neonatal pigs with *C. coli* (Olubunmi and Taylor 1982) or *C. jejuni* (Babakhani et al. 1993; Bibiana et al. 2009; Boosinger and Power 1988; Vitovec et al. 1989). The neonatal pig is an established model for human *C. jejuni* enterocolitis; however, campylobacters are not known to produce any generally recognized enteric or other diseases in any age of pigs.

Similar disease and lesions are described in neonatal pigs inoculated with *C. coli* and *C. jejuni*. Piglets exhibit mucoid to watery and occasionally bloody diarrhea. Gross lesions of mucosal hyperemia, edema, multifocal hemorrhage, and occasional accumulation of mucus are observed most consistently in the cecum and colon and occasionally in the small intestine. Microscopic lesions are limited to the cecum and colon and include multifocal erosions of the luminal epithelium, sparse aggregates

of neutrophils in the lamina propria adjacent to erosions, and edema of the lamina propria and submucosa.

Confirmation of enteric campylobacteriosis in neonatal pigs would require demonstration of typical clinical signs and lesions, confirmation of *C. jejuni* or *C. coli*, and elimination of other more common causes of neonatal porcine diarrhea. These include colibacillosis (Chapter 52), clostridiosis (Chapter 51), rotaviruses (Chapter 43), coronaviruses (Chapter 31), or PRRSV (Chapter 41). *C. jejuni* or *C. coli* can be confirmed in affected large intestinal mucosa by culture (see above) or by PCR (Denis et al. 1999; Jensen et al. 2005; Leblanc-Maridor et al. 2011a).

Prevention and control

Campylobacters are susceptible to most farm disinfectants. It is possible to maintain pig units founded from primary hysterectomy-derived stock free from infection by strict isolation. Nevertheless, Kolstoe et al.(2015) underlined the difficulty of controlling campylobacters as even high levels of biosecurity in Norwegian specific-pathogen-free (SPF) herds did not seem to be sufficient to keep *Campylobacter* spp. out of 6 of the 10 herds tested. Supplementation of the diet of piglets with high levels of zinc oxide can reduce the *C. coli* load, potentially leading to a lower contamination risk for meat during slaughter (Bratz et al. 2013).

Chlamydia

Relevance, etiology, and public health

Chlamydiaceae have been detected in various avian and mammalian species including the pig in a variety of conditions including conjunctivitis, rhinitis, pneumonia, enteritis, arthritis, and various reproductive disorders. However the importance of *Chlamydiaceae* as pig pathogens remains controversial because they are frequently detected in mixed infections with other pathogens, a limited number of inoculation studies have been done in swine, and confirmatory testing has not been readily available.

The nomenclature of the *Chlamydiaceae* is confusing. In 1999, it was proposed to reassign the single genus *Chlamydia* into two genera, *Chlamydia* and *Chlamydophila*. However this proposal was never officially approved, and it was recently proposed to reunite the *Chlamydiaceae* into a single genus, *Chlamydia* (Gunn and Lofstedt 2016). Four species of *Chlamydia* are found in swine *i.e. Chlamydia suis* (previously *Chlamydia trachomatis*-like), *Chlamydia abortus (previously* ruminant *Chlamydia psittaci* serovar 1), *Chlamydia pecorum*, and *Chlamydia psittaci*. Evidence for chlamydia-induced disease in pigs is most compelling for *C. suis* as a potential cause of pneumonia and neonatal diarrhea and for *C. abortus* as a cause of early embryonic death (i.e. irregular returns to estrus).

Chlamydia are gram-negative obligate intracellular bacteria that primarily multiply in mucosal epithelial cells lining the respiratory, urogenital, and gastrointestinal tracts. Elementary bodies are the infectious extracellular forms that are environmentally resistant, inactive particles 0.2–0.3 µm (200–300 nm) in diameter. Once in contact with mucosal epithelial cells, they are internalized, reorganize into reticulate bodies, and divide by binary fission within phagocytic vesicles. Condensation of progeny reticulate bodies to elementary bodies followed by cell lysis completes the life cycle. Elementary bodies can survive for considerable lengths of time in the environment where they are resistant to drying.

Epidemiology and public health

Chlamydial infections have been reported in pigs worldwide. Seroprevalence in various countries has been reported to be as high as 40–99% in fattening pigs, sows, and boars (Schautteet and Varompay 2011). *Chlamydiaceae* have been demonstrated in various pig samples including conjunctiva, lung, intestines, aborted fetal tissues, genital tract, and semen.

Common infection sources, infection routes, possible vectors, and infection kinetics have not been extensively examined. Direct transmission from infected swine is likely the greatest risk factor, including vertical *in utero* transmission. *C. suis*, *C. abortus, C. pecorum*, and *C. psittaci* have been demonstrated in boar semen (Kauffold et al. 2006; Teankum et al. 2006) and *C. suis* in extended boar semen (Hamonic et al. 2016), suggesting the potential of venereal transmission through natural or artificial service. In addition proximity to other animals potentially infected with each chlamydial species should be considered a risk factor. These include ruminants, horses, rabbits, guinea pigs, and mice for *C. abortus*, ruminants for *C. pecorum*, and birds for *C. psittaci*. Keeping poultry and pigs on the same site has been confirmed as a risk factor for *C. psittaci* infection in pigs (Eggemann et al. 2000; Vanrompay et al. 2004). *Chlamydiaceae* survive drying and can persist in dust in an infected environment. Flies or dust may be involved in the transmission of chlamydial conjunctivitis.

Until recently, *C. suis* was thought to only infect pigs. However it has been detected in conjunctival, pharyngeal, and rectal samples from clinically normal humans (De Puysseleyr et al. 2014a, 2015). To date, human clinical disease has not been associated with *C. suis*. Of concern due to the close genetic relationship between *C. suis* and *C. trachomatis* is the potential for tetracycline-resistant strains of *C. suis* to transfer resistance to *C. trachomatis* in coinfected humans (De Puysseleyr et al. 2014b).

C. abortus is among the leading cause of abortion in small ruminants but can also cause abortion in pigs, horses, rabbits, guinea pigs, and mice. It is a well-known zoonotic agent able to induce abortion in humans. Transmission to humans from infected fetuses and placenta from aborted ruminants is well established. Transmission of *C. abortus* from pigs to humans has not yet been confirmed, but it remains a potential risk for pregnant women handling aborted porcine fetuses or placenta.

C. pecorum is not known to infect humans and poses no zoonotic risk.

C. psittaci can cause mild flu-like symptoms, fever, myalgia, diarrhea, encephalitis, and/or pneumonia in humans. Most cases of human psittacosis are zoonotic from exposure to birds or aerosolized bird dander and/or desiccated bird feces. However, a recent report of pneumonia in veterinary students exposed to *C. psittaci*-infected equine fetal membranes confirms the potential of mammalian-to-human zoonosis (Polkinghorne and Greub 2017). To date, transmission of *C. psittaci* from pigs to humans has not been reported.

Pathogenesis, clinical signs, and lesions

Elementary bodies enter by the respiratory, oral, or genital routes and multiply in epithelial cells or are taken up by macrophages and distributed to lymph nodes. Infection may be local at the portal of entry and remain inapparent or latent; may cause local disease such as pneumonia, enteritis, or disturbances of reproduction; or may become generalized and produce systemic disease. A majority of chlamydial infections in swine are likely inapparent.

Chlamydia suis

C. suis has been identified in pigs affected with conjunctivitis, rhinitis, pneumonia, enteritis, and various reproductive disorders, and it is the best characterized pathogenic chlamydial species in swine. A greater degree of genetic diversity exists among strains of *C. suis* than among other chlamydial species (Bush and Everett 2001; Everett et al. 1999), suggesting variation in virulence among strains. Oral inoculation studies in neonatal gnotobiotic pigs produced acute watery diarrhea due to replication predominantly in small intestinal apical villus enterocytes resulting in severe villous atrophy and lymphangitis (Guscetti et al. 2009; Rogers and Andersen 1996). In contrast, oral inoculation of 21-day-old colostrum-fed pigs resulted in villous atrophy in the ileum and intestinal lymphangitis, but no diarrhea (Rogers and Andersen 2000). Studies utilizing intranasal and intratracheal or aerosol inoculation with *C. suis* of neonatal gnotobiotic or 6-week-old conventional pigs produced pyrexia, dyspnea, and coughing due to necrotizing bronchointerstitial pneumonia (Rogers et al. 1996; Sachse et al. 2004). All lobes of lungs in the neonatal gnotobiotic pigs were grossly consolidated. Immunohistochemistry in the gnotobiotic pigs revealed chlamydial antigen in nasal and bronchial epithelial cells, alveolar pneumocytes, and alveolar macrophages. Deposition of *C. suis* in the conjunctival sac of neonatal gnotobiotic pigs resulted in pleocellular conjunctivitis with intraepithelial chlamydial antigen, but gross lesions of conjunctivitis were not observed (Rogers and Andersen 1999).

Chlamydia abortus

C. abortus (ruminant *C. psittaci* serovar 1) is a major cause of abortion in sheep, goats, and cattle. In the pig *C. abortus* has been primarily associated with abortion, weak neonates, and irregular returns to estrus (Camenisch et al. 2004; Eggemann et al. 2000; Hoelzle et al. 2000; Thoma et al. 1997). A single small reproductive inoculation study in swine has been reported. Four sows at 42 days of gestation were inoculated with an ovine isolate of *C. abortus* resulting in detection of *C. abortus* antigen in placenta but not in abortion (Vazquez-Cisneros et al. 1994). In another study (Camenisch et al. 2004), cervical swabs were obtained 1–3 days following irregular return to estrus from 65 sows on 24 different farms, and an additional 128 swabs from sows on 14 farms without a history of irregular returns were also collected. *C. suis* was detected in 10.8% of sows with irregular returns, but none of the sows with normal reproductive history.

Chlamydia pecorum

C. pecorum has been identified in ruminants, koalas, and pigs. In these species it has been associated with various infections such as conjunctivitis and reproductive problems. Confirmatory inoculation studies in swine are not reported.

Chlamydia psittaci

C. psittaci is the agent of psittacosis in birds. In pigs, *C. psittaci* has been isolated from the genital tract and the lung of sows without apparent disease (Busch et al. 2000; Vanrompay et al. 2004). Oral inoculation of 3-day-old gnotobiotic pigs with avian-origin *C. psittaci* resulted in minimal replication in small intestinal enterocytes, mild villous atrophy, and softening of stools, but not diarrhea (Guscetti et al. 2000).

Diagnosis

Presumptive diagnosis is difficult because clinical signs of chlamydial infection are not distinctive and may include conjunctivitis, pneumonia, neonatal enteritis, and reproductive failure. Differential diagnosis should include common causes of the observed clinical signs and gross lesions, and *Chlamydia* spp. as well as other potential causal agents should be confirmed or excluded by testing.

Most veterinary diagnostic laboratories do not routinely test for *Chlamydiaceae* in pigs. Handling chlamydias is dangerous, and severe human infections can result. Appropriate safety precautions should be observed. *Chlamydia* may be detected in smears and in histologic specimens after staining by Giemsa's method or Koster's stain.

Commercial *Chlamydia spp*. antigen ELISAs may be used to detect antigen in swabs or extracts of tissue (Guscetti et al. 2009). Most of them detect the chlamydial family-specific LPS antigen and therefore detect all chlamydial species. Immunofluorescence or immunohistochemical staining of histological sections can be also used for confirmation (Chasey et al. 1981). Commercial *Chlamydiaceae* family-specific mouse monoclonal antibodies are available.

Chlamydia can be grown in embryonated chicken eggs and in cell cultures such as McCoy, HeLa, Vero, or CaCo cells. However pig strains do not grow well on the established cell lines (Schiller et al. 2004), and the zoonotic potential of many *Chlamydia* spp. makes cultivation as a routine diagnostic method impractical.

PCR technology is currently preferred for confirmation as it allows sensitive and specific identification of the *Chlamydia* spp. present (De Puysseleyr et al. 2014b; Li et al. 2011; Pantchev et al. 2010). Current PCR tests target the *omp*A, the 16S–23S rRNA, or the *inc*A genes. Targeting the 16S–23S genes increases sensitivity as multiple copies of these genes are usually present in the organism. A microarray hybridization assay for the identification of chlamydial species has also been developed. The test proved to allow unambiguous identification of chlamydial species (Hoffmann et al. 2015; Sachse et al. 2012). Sequencing of PCR products allows comparison with sequences of reference strains and strain identification for epidemiological studies.

Chlamydial antibodies may be detected using serological assays such as the complement fixation test (CFT), the microimmunofluorescence test (MIF), or ELISAs (Mohamad et al. 2010). Two types of ELISAs have been used based either on a recombinant major outer membrane protein (OMP) or the LPS (Hoelzle et al. 2004). The presence of antibody does not confirm disease, only exposure. Moreover the available serological assays cannot determine the *Chlamydia* species involved.

Prevention and control

Regular cleaning and disinfection of premises is probably worthwhile as *Chlamydiaceae* can survive up to 30 days in feces. *Chlamydiaceae* are susceptible to a wide range of disinfectants including oxidizing, phenolic, and chlorine-based products, quaternary ammonium compounds, and some detergents.

Active infections can be treated with antimicrobials. Tetracyclines are the drug of choice. However strains of *C. suis* resistant to tetracyclines have been reported (Donati et al. 2016; Schautteet et al. 2013). Macrolides could be an alternative when such strains are involved.

No chlamydial vaccines are commercially available for the pig although an immune response has been demonstrated to *C. suis* in the genital tract of sows (De Clercq et al. 2014). The efficacy of ruminant *C. abortus* vaccines in prevention of *C. abortus*-induced reproductive failure in swine is unknown.

Enterococci

Enterococci are normal inhabitants of the intestinal flora, but some strains have the capacity to colonize the mucosal surface of the small intestine extensively. Some enterococcal species that show typical adhesion to the apical surface of the enterocytes of the small intestine of young animals have been described as associated with diarrhea in different animal species (Vancanneyt et al. 2001). Cases have been reported in piglets between 2 and 20 days of age (Cheon and Chae 1996; Drolet et al. 1990).

Taxonomic studies have shown that most of these enterococci are members of the *E. faecium* species group, mainly *E. durans*, *E. villorum/E. porcinus*, and *E. hirae* (De Graef et al. 2003; Jonach et al. 2014; Vancanneyt et al. 2001). Enteroadherent *enterococci* are involved in cases of the New Neonatal Porcine Diarrhoea Syndrome (NNPDS) reported in the Scandinavian countries (Hermann-Bank et al. 2015; Jonach et al. 2014; Larsson et al. 2014).

The pathogenesis of enteric disease associated with adherent enterococci is unclear. Adherence involves fibrillar projections (Tzipori et al. 1984), and diarrhea is not associated with enterotoxin production or substantial mucosal injury (Cheon and Chae 1996). Because of the natural resistance of enterococci to some antibacterial agents, antimicrobial susceptibility testing is advised before treatment. Sanitation between farrowings is presumed to be helpful in prevention. Due to the lack of knowledge about the clinical and epidemiological aspects of this infection, other preventive measures are difficult to recommend.

Klebsiella pneumoniae

Relevance and etiology

Since 2011 several outdoor breeding herds in the United Kingdom (mostly in East Anglia) were diagnosed with septicemia in preweaning piglets due to infection with *Klebsiella pneumoniae* subsp. *pneumoniae* (Animal and Plant Health Agency (APHA) 2015). In 2016 the disease was also reported in preweaning piglets in indoor units in several Australian states (Victoria, Queensland, and New South Wales) as well as in Quebec (Canada) and the United States. Prior to these reports of outbreaks, it was more commonly diagnosed causing sporadic disease in individual pigs such as septicemia in piglets and mastitis in sows.

K. pneumoniae subsp. *pneumoniae* belongs to the *Enterobacteriaceae* family. They are gram-negative, rod-shaped, and nonmotile bacteria. They are facultatively anaerobic, produce lysine decarboxylase (LDC) but not ornithine decarboxylase (ODC), and are generally positive in the Voges–Proskauer (VP) test. Colonies are non-hemolytic and usually mucoid.

Klebsiella pneumoniae is a commensal of the porcine digestive tract and is present in the environment in both soil and water sources. It is frequently found in sawdust, which is an ideal environment for survival and multiplication.

K. pneumoniae is a cause of various human infections including pneumonia, meningitis, urinary tract infections, and neonatal septicemia, but it is not considered a zoonotic agent.

Clinical signs, lesions, and diagnosis

Klebsiella septicemia infrequently occurs in pre-weaned 1- to 4-week-old piglets. Piglets are found dead or recumbent and cyanotic. In the UK and Australian outbreaks, the cases occurred during summer months (APHA 2015; New South Wales (NSW) Department of Primary Industries and Local Land Services 2016). Overall mortality is variable but usually low (<5%), and within-litter mortality is also variable and usually low with 1–2 piglets dying per litter. However cases with mortality as high as 100% have been reported in Australia. The duration of herd disease varies from a few weeks to as long as 12 weeks. Although *K. pneumoniae* can be associated with mastitis, sows in the same farrowing group as affected piglets are not usually affected.

Lesions are nonspecific and similar to those observed in septicemia due to other bacteria such as *Streptococcus suis* (Chapter 61), *Actinobacillus suis* (Chapter 48), *E. rhusiopathiae* (Chapter 53), or *Escherichia coli* (Chapter 52). Postmortem findings include purple discoloration of skin on the ventrum and extremities and the presence of fibrin strands in the abdominal cavity, serosal petechiae, pleural effusion, and congested lymph nodes. *K. pneumoniae* is easily isolated in abundant pure culture from various tissues using standard aerobic culture on blood agar.

Prevention and control

The reasons for the emergence of outbreaks of *K. pneumoniae* septicemia in piglets are unknown. Molecular characterization of some UK isolates has shown that all are sequence type 25 (ST25) with a unique combination of a 4.3 kb plasmid and rmpA virulence gene (Bidewell et al. 2013). Four recently characterized Quebec isolates also have the same ST25. All of the isolates have an innate resistance to beta-lactams, and most have shown *in vitro* sensitivity to other antimicrobials tested. However occasional isolates with resistance to multiple antimicrobials have been detected.

In UK outdoor units, interventions included antimicrobial treatment of remaining piglets in affected litters, introduction of creep feed prior to weaning, or treatment of neonatal piglets with a combination of antimicrobial and iron. Some of these interventions resulted in cessation or reduction in mortality. However, in the absence of untreated control groups, their efficacy cannot be assessed since the disease was sometimes self-limiting on farms without interventions.

Listeria monocytogenes

Relevance, etiology, and public health

Listeria monocytogenes is commonly carried in the tonsils and intestines of swine and is a rare cause of septicemia in piglets, nervous signs in all age groups, and abortion in sows. More importantly the organism is an uncommon cause of serious foodborne disease in humans, and its carriage by slaughter swine is of concern to the food industry.

L. monocytogenes is a gram-positive bacillus 1.2 µm by 0.5 µm and does not form spores. The organism grows at temperatures as low as minus 1 °C and up to 45 °C and can multiply in the presence of nutrients in refrigerated conditions or at room temperature. It is aerobic/aerotolerant and produces 1 mm, grayish, and opaque colonies with a narrow zone of β-hemolysis on blood agar. It is capable of growth on a number of media, and the use of chromogenic media and molecular methods (PCR) to differentiate *L. monocytogenes* from other species (*L. innocua*) is of particular importance when detection is required (Raorane-Abhay et al. 2015; Yukako et al. 2016).

L. monocytogenes is a cause of septicemia, abortion, and nervous signs in humans. Pregnant women, newborn infants, the elderly, and the immunosuppressed are most at risk. Although the organism is present in the environment, food, particularly meat products, is an important source (Beloeil et al. 2003; Boscher et al. 2012; Ristori et al. 2014). Thevenot et al. (2006) have reviewed the contamination of pork and pork products with *L. monocytogenes*. Contamination increases from farm to raw meat because of cross-contamination and multiplication of the organism (Larivière-Gauthier et al. 2014). Up to 30% of raw minced pork meat may be contaminated (Ristori et al. 2014).

Epidemiology and pathogenesis

L. monocytogenes occurs worldwide and is carried by most food animal species, and clinical disease occasionally develops. Carriage of *L. monocytogenes* is common in pigs in the intestine and tonsils. Studies in various countries suggest that about 10% of slaughter pigs are carriers. Carriage rate seems to increase when liquid feed or silage is fed. Exposure in pigs is principally by ingestion. Shedding is in the feces and in the products of

abortion. The organism can be detected in manure for at least 55 days (Grewal et al. 2007) and is susceptible to most approved disinfectants. *L. monocytogenes* is destroyed by pasteurization, but food recontamination can occur after heating.

The organism has two modes of entry. In nervous disease it may travel up nerves to the brain by retrograde movement, and in bacteremia/septicemia, it enters through the tonsil or gut. Invasion of privileged sites such as the brain, joints, and uterus follows bacteremia/septicemia. Clinical signs are caused by the invasion, intracellular multiplication, and production of listeriolysin. Neonatal and pregnant animals are most likely to be clinically affected.

Clinical signs, lesions, and diagnosis

Subclinical infection is common; clinical listeriosis is uncommon. Septicemia in suckling piglets is often evidenced by sudden death or pyrexia, lethargy, and hyperemia or purple discoloration of skin on extremities. Nervous disease is characterized by tremors, lateral nystagmus, lateral recumbency, and paddling. Abortion, stillbirths, and the birth of weak piglets may all occur in affected sows.

Lesions in piglets may include hepatomegaly ± splenomegaly with large numbers of small foci of necrosis, moist lungs that fail to collapse, variable hydrothorax, and enlarged moist lymph nodes (Lopez and Bildfell 1989). Consistent microscopic lesions include multifocal hepatic and splenic necrosis with large numbers of intralesional small rod-shaped bacteria and fibrin thrombi in microvasculature. In pigs with nervous disease, gross lesions are often not observed; microscopic lesions include suppurative meningitis, perivascular cuffing, and microabscess formation in the brain. In reproductive failure, hepatic and splenic necrosis as described in neonates is sometimes observed in stillborn and weak-born pigs.

Clinical signs and lesions are not specific to listeriosis in any of its various forms. Other causes of each clinical syndrome must be included in differentials. Of particular concern is pseudorabies virus that can cause rapid death of neonates and produce multifocal hepatic and splenic necrosis similar to listeriosis. Confirmation of listeriosis requires typical clinical signs and lesions as well as detection of *L. monocytogenes*. The organism is present in clinical specimens in high numbers and produces typical hemolytic colonies on blood agar. For contaminated specimens, tonsillar material, cecal contents, feces, environmental samples, and foods, enrichment in the cold at 4 °C overnight in a simple enrichment medium or one supplemented with antimicrobials followed by subculture onto a chromogenic selective medium gives good results.

PCR using primers based on the *prs and prfA* gene sequences have been used for qualitative detection and confirmation and *prf*A for quantitative demonstration of the organism using real-time PCR (Yukako et al. 2016).

Prevention and control

The organism is sensitive to a number of antimicrobials including penicillins and aminoglycosides, and affected pigs may recover if treated early in the course of disease. Paralyzed pigs should be humanely euthanized. Composting of manures at more than 55 °C or use of aerobic composting can reduce numbers of *Listeria* in wastes (Grewal et al. 2007).

Rhodococcus equi

Relevance, etiology, and public health

Rhodococcus equi causes granulomatous lymphadenitis affecting the lymph nodes of the head and neck of the pig. The lesions can be confused at slaughter with those of tuberculosis (Chapter 63), and it is important for this reason rather than as a cause of clinical disease. *R. equi* is also a cause of infection and mortality in immunocompromised humans. Swine are not known to be a risk factor for human infection.

R. equi (Goodfellow 1987) was previously named *Corynebacterium equi*. This gram-positive coccobacillus is non-sporulating, but possesses a capsule. The cell wall contains mycolic acid, and there is an abundant acidic polysaccharide capsule, which is the basis for serotyping schemes (Nakazawa et al. 1983). *R. equi* produces pinkish colonies on solid media. Colonies are slow growing, requiring 48 hours to reach a size of 2–4 mm. The typical colony is irregularly rounded, buff pink, smooth, and mucoid. *R. equi* is biochemically unreactive.

R. equi is of importance to public health as a cause of granulomatous lesions in the cervical lymph nodes of pigs. These must be distinguished from those of tuberculosis caused by the *Mycobacterium avium* complex (MAC) and other *mycobacteria* and are therefore of concern in meat inspection. *R. equi* can infect humans and is becoming more common as a cause of necrotizing pneumonia and chronic illness in immunocompromised humans, particularly in those suffering from HIV infections (Weinstock and Brown 2002). Infection results in high mortality, averaging 25%. Human isolates are similar to some pig strains. However, pig-to-human or pork-to-human transmission is not documented.

Epidemiology and pathogenesis

Little is known of the epidemiology of *R. equi* infection in swine, but *R. equi* has been reported worldwide and infects swine, cattle, deer, horses, sheep, goats, wild birds, and humans (Woolcock et al. 1979). *R. equi* infection is likely to be acquired from the environment by ingestion in swine housed on pasture or in yards contaminated with *R. equi* (Barton and Hughes 1984). The bacterium is readily isolated from the feces of such pigs. Komijn et al. (2007) examined 15,900 cervical lymph nodes for granulomatous lesions in the Netherlands and found them in 0.75% pigs. *R. equi* was isolated from 44% of these. It is present in dust and even in cobwebs of farm buildings in areas where it occurs and is relatively resistant to chemical disinfectants.

Infection of pigs is usually by the oral route. The way in which *R. equi* causes granulomatous lymphadenitis of the head and neck in swine is not clear.

Clinical signs, lesions, and diagnosis

R. equi infection in swine is normally subclinical and has rarely been associated with clinical disease. The lesions of granulomatous lymphadenitis are detected only at slaughter. Affected submandibular and cervical nodes are enlarged and contain multiple yellow-tan foci that are often in a subcapsular location. Caseation and calcification of these foci sometimes occurs.

Diagnosis is postmortem. Gross and microscopic lesions are as described. Microbiologic identification of *R. equi* and elimination of mycobacterial infection are necessary to confirm diagnosis. Selective media (Makrai et al. 2005; Woolcock et al. 1979) improve the results of culture as the creamy or pink domed colonies of *R. equi* require 48 hours to reach a size of 2–4 mm. A quantitative PCR targeting the chromosomal gene choE and the virulence plasmid gene vapA can also be used (Rodríguez-Lázaro et al. 2006).

Prevention and control

R. equi-induced disease is not sufficiently important to necessitate antemortem diagnosis and treatment in swine or dedicated preventive measures.

Treponema pedis: Cutaneous Spirochetosis

Relevance, etiology, and public health

Treponema pedis, a spirochete previously isolated from digital dermatitis in cattle (Evans et al. 2009), has now been isolated from ear necrosis, decubital shoulder ulcers, and other chronic skin lesions in pigs (Karlsson et al. 2014; Pringle et al. 2009; Svartström et al. 2013). Other bacteria such as *Staphylococcus hyicus* and streptococci have been isolated from lesions of ear necrosis in the past, and *T. pedis* is likely not the sole or initiating agent. The syndrome of ear necrosis in swine has not yet been reproduced experimentally. *T. pedis* has no known public health significance.

T. pedis is characterized by its morphology, cultural characteristics, 16S rRNA gene sequences and flaB2 gene sequences. It is approximately 0.25 µm in diameter and 4–6 µm in length with a 3 : 6 : 3 flagellar pattern, does not form spores, is anaerobic, and produces esterases, lipases, and trypsin-like proteases. Cultivation is in strictly anaerobic conditions at 37 °C on fastidious anaerobe agar (FAA) with 10% added horse blood. Colonies become obvious in 4–5 days.

Epidemiology and pathogenesis

Chronic skin lesions including ear necrosis, decubital shoulder ulcers, and spirochetal granuloma have been reported in pigs from most parts of the world. Pigs appear to be the only species affected by these manifestations, but *T. pedis* is also found in digital dermatitis in cattle and sheep. Transmission in pigs may be through skin and ear biting as Pringle et al. (2009) found the organism in the gingiva of affected pigs. Persistence in the swine environment is not known, but infection persists in cattle slurry for some days.

The infection appears to be localized in the skin in infected lesions, possibly caused by biting or abrasion in the first instance. The production of esterases, lipases, and proteases may aid the development of the lesion. Initial infection and penetration into the tissue may be limited by the anaerobic nature of the organism.

Clinical signs, lesions, and diagnosis

Ear necrosis (see also Chapter 17) is a condition in which small inflamed areas on the margins of the ears develop after weaning, spread, intensify, and ultimately cause loss of the ear in severe cases. The lesions begin as small areas of damage on the edge of the ear and near its junction with the head, become scabby, extend, and become necrotic (Pringle et al. 2009). They can lead to loss of the entire pinna. On resolution, they heal, leaving a scar. Similar lesions may occur on the flanks and upper parts of the hind limb, and Svartström et al. (2013) describe a shoulder ulcer from which they have obtained the organism. Morbidity is usually low, and affected pigs do not perform significantly differently from unaffected controls (Busch et al. 2010). An extensive literature associates this condition and its severity with behavioral changes attributed to housing and management (Smulders et al. 2008).

The lesion is a chronic ulcerative and pustular dermatitis. A thick crust of fibrin exudate and inflammatory cells covers its edges with vasculitis with or without thrombosis in the underlying blood vessels. Bacteria can be demonstrated in the superficial layers, and spirochetes can be seen in silver-stained sections deeper in the tissue. Healed lesions may be seen as scars on older animals.

Ear necrosis and localized necrotic lesions elsewhere on the body are suggestive of infection by *T. pedis*, but *S. hyicus* (Chapter 61) may be present in some lesions. Pig pox lesions must be ruled out (Chapter 30) but are typically localized and rarely lose their scabs. Bite wounds are much more difficult to differentiate, and behavior must be watched to confirm the relevant importance of simple biting in the present condition. The progressive nature of the gross lesions suggests spirochetal involvement, and the organisms can be demonstrated in the inflamed tissue. A preliminary identification can be made microscopically in tissue sections utilizing silver stains.

Isolation is by inoculation of fastidious agar broth enriched with fetal calf (25%) and rabbit (10%) serum with added rifampicin and enrofloxacin in anaerobic conditions. Growth can be purified by the inoculation of 0.22 µm pore size Millipore filters on FAA followed by streaking to produce the pinpoint grayish slightly hemolytic colonies (Pringle et al. 2009). The organisms can be also be detected by using a PCR for treponemes (Pringle et al. 2009).

Prevention and control

Treatment of individual pigs is possible using parenteral antimicrobials but is rarely carried out, as the condition does not warrant it. Topical lincomycin–spectinomycin combinations have been used in cattle to treat *T. pedis*. Local skin disinfection may also be of value. Improvement of environmental conditions and particularly the provision of manipulable materials may improve the environmental/social reasons for flank and ear biting. Formaldehyde and glutaraldehyde can reduce infection in the environment.

Trueperella abortisuis

Trueperella abortisuis, previously *Arcanobacterium abortisuis*, was first isolated from the placenta and tissues of an 87-day-gestation aborted litter of pigs having lesions and intralesional bacteria in Japan (Azuma et al. 2009; Murakami et al. 2011; Yassin et al. 2011). Additional isolates have been obtained from placenta after abortion, such as vaginal discharges, rectal swabs from piglets, and boar sperm (Hijazin et al. 2012b; Metzner et al. 2013; Ulbegi-Mohyla et al. 2011). Although this organism caused a single case of sporadic abortion, its significance as a reproductive pathogen of swine is unknown.

T. abortisuis is a gram-positive, short diphtheroid-shaped organism. It grows under microaerobic or anaerobic conditions and produces a narrow zone of complete hemolysis on sheep blood agar. Colonies demonstrate CAMP-like activity with alpha-hemolytic *Staphylococcus aureus*. It is most easily identified by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) (Hijazin et al. 2012a; Ulbegi-Mohyla et al. 2011) or by amplification and sequencing of 16S rRNA gene sequence and gene *sodA* encoding superoxide dismutase (Metzner et al. 2013).

T. abortisuis is usually isolated in mixed culture with other bacterial species, making the importance of this novel species unclear. In the index case, 87-day-gestation fetuses were aborted with gross lesions of subcutaneous edema, congested lung, and increased fluids in the body cavities typical of *in utero* autolysis. Microscopic lesions were consistent among three fetuses and included suppurative bronchopneumonia and necrosuppurative placentitis, each with large numbers of intralesional gram-positive filamentous and/or rod-shaped bacteria. Primary antisera produced using cultured *T. abortisuis* was used to confirm the intralesional bacterial identity by immunohistochemistry.

Diagnosis of *T. abortisuis* abortion requires demonstration of lesions in fetuses and/or placenta with morphologically consistent intralesional bacteria and culture of *T. abortisuis*. Demonstration of *T. abortisuis* in vaginal discharges or in placenta absent other lesions should not be considered confirmatory given the potential confounder of fecal contamination.

Trueperella pyogenes

Relevance, etiology, and public health

Trueperella pyogenes (formerly *Arcanobacterium pyogenes, Actinomyces pyogenes*, and *Corynebacterium pyogenes*) is a common cause of suppurative lesions in pigs and ruminants throughout the world. Clinical disease can result from the destruction of tissues. As a consequence of *T. pyogenes* infection, carcasses at slaughter may contain unsightly abscesses filled with creamy pus, resulting in economic losses from trimming or condemnation. Rare cases of human infection with *T. pyogenes* have been reported (Levy et al. 2009; Plamondon et al. 2007). Patients often had a history of close contact with domestic animals.

T. pyogenes is a small, non-sporing, gram-positive pleomorphic rod. Growth is enhanced by the addition of serum or blood. *T. pyogenes* is aerobic or facultatively anaerobic and grows best at 37 °C. Colonies are small, taking 48 hours to achieve a diameter of 1 mm. They form narrow zones of complete hemolysis after 24 hours on blood agar. *T. pyogenes* is proteolytic; glucose is fermented, but fermentation of other carbohydrate reactions is variable. Identification is presently most easily carried out using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) (Hijazin et al. 2012).

Epidemiology and pathogenesis

Infections with *T. pyogenes* are found worldwide in ruminants, pigs, and horses (Ribeiro et al. 2015). It is part of the skin and mucosal flora of the host species and can be isolated in discharges from the upper respiratory tract, udder, vulva, and feces in infected animals. Transmission

may be direct or indirect via infected fomites. The organism can survive freezing and drying when protected in organic matter such as discharge. *T. pyogenes* is susceptible to a range of disinfectants.

Infection is opportunistic resulting from the invasion of skin or mucous membranes by resident *T. pyogenes* (Jarosz et al. 2014). Adhesion to tissues is aided by neuraminidases, fimbriae, and collagen binding protein (CBPA), and tissue damage results from production of the pyolysin (Billington et al. 1997; Jost and Billington 2005). The organism can multiply locally on surfaces such as inflamed bronchiolar epithelium, in the vaginal and uterine mucosa, and in the urinary tract. It causes ascending or hematogenous infections in the mammary gland and spreads by bacteremia to colonize existing minor lesions in joints, lungs, vertebral bodies, and parenchymatous organs. Their location and extent cause the clinical signs.

Clinical signs, lesions, and diagnosis

The clinical signs are quite variable, since *T. pyogenes* is responsible for a range of pathological lesions. Randomly distributed pulmonary abscesses occur due to septic emboli from *T. pyogenes*-infected skin lesions including ear or tail necrosis. Endocarditis, bronchopneumonia, and adhesive peritonitis may be fatal and be associated with fever. Suppurative osteomyelitis generally affects the vertebral bodies, leading to pathological fractures, vertebral collapse, and compression of the spinal cord. Lameness results from polyarthritis or from cellulitis and periarthritis. Purulent secretion from the teat is seen in mastitis, and abscesses are prominent in involuted glands. Creamy discharge may be seen on the vulva in endometritis, and the urine may be flecked with pus in cystitis and pyelonephritis. Subcutaneous or intramuscular abscesses are often clinically inapparent and are discovered only at postmortem or slaughter. Mortality occurs when damage to an organ becomes life threatening as in pyelonephritis in sows. Frequently abscesses do not cause clinical signs other than loss of condition.

T. pyogenes causes creamy, greenish mucoid pus on inflamed mucous surfaces and appears as flecks of pus in the urine in cases of cystitis and as ropes of pus in the kidney pelvis and ureters in pyelonephritis and in the uterus in metritis. The most noticeable and pathognomonic lesions are abscesses, which may arise in almost every tissue in the body. Such abscesses vary from a few millimeters to several centimeters in size, usually have a thick fibrous capsule, and contain yellow-green pus of variable consistency. They may be in joints, over cracked ribs, in contaminated injection sites, and in parenchymatous organs. Mastitis may be confined to one gland or may involve several glands.

T. pyogenes infection is the major cause of purulent abscessation and purulent discharges of all types in pigs, and its presence should be strongly suspected in such cases. Other pyogenic bacteria such as staphylococci (Chapter 60) may also cause abscessation, endocarditis, mastitis, endometritis, and pyelonephritis, whereas *E. coli* (Chapter 52) and *Actinobaculum suis* (see above) must also be considered. Confirmation of *T. pyogenes* requires the demonstration of the organism in typical lesions by laboratory culture or by real-time qPCR (Aghamiri et al. 2014). Pinhead beta-hemolytic colonies on blood agar are suggestive of *T. pyogenes*, and identification can be confirmed using standard bacteriological procedures or more easily by MALDI-TOF MS (Hijazin et al. 2012).

Prevention and control

T. pyogenes is sensitive to a wide range of antimicrobial agents including penicillin, tetracycline, and erythromycin. Some strains have been shown to be resistant to sulfonamides and trimethoprim. Antimicrobial treatments only are poorly effective due to difficulty achieving therapeutic levels in abscesses. Abscesses may be removed surgically where they can be identified in affected individuals.

Effective vaccines are not available. Prevention requires management to reduce or prevent conditions that predispose to the development of *T. pyogenes* infections. The implementation of needle-free injection systems in market hog production has been reported to increase the occurrence of injection site abscesses in pork carcasses (Gerlach et al. 2012).

Yersinia spp.

Relevance, etiology, and public health

The primary importance of *Yersinia enterocolitica* and, to a lesser extent, *Yersinia pseudotuberculosis* in swine is as a source for foodborne infection of humans that handle or consume contaminated pork products. Swine are the primary carrier of *Y. enterocolitica* and source for human yersiniosis. Most infections by *Y. enterocolitica* and *Y. pseudotuberculosis* in swine are asymptomatic, and their importance in enteric disease in commercial swine production is relatively minor. Of additional significance in swine, antibody to *Y. enterocolitica* serotype O:9 cross-reacts in serological tests for *Brucella* spp., causing false-positive serologic tests for swine brucellosis.

Yersinia belongs to the *Enterobacteriaceae. S*pecies isolated from pigs include *Y. pseudotuberculosis, Y. pseudotuberculosis* subsp. *pestis* (the plague bacillus), *Y. enterocolitica, Y. intermedia, Y. frederiksenii*, and *Y. kristensenii*. *Y. enterocolitica* and *Y. pseudotuberculosis* are most important in swine. Yersinias are gram-negative, non-sporulating coccobacilli or short rods. Capsules, attachment antigens, and enterotoxins have been described. Individual species can be divided into biotypes and serotypes and possess plasmids and virulence factors. *Y. enterocolitica* and *Y. pseudotuberculosis* grow at temperatures between 4 and 37°C and can therefore multiply in refrigerated products. They are aerobic or facultatively anaerobic. They grow on routine media upon which they appear as small 1–2 mm colonies within 24–48 hours.

Yersiniosis has been the third to fourth most frequent zoonosis in the European Union (EU) from 2004 to 2011 (Laukkanen-Ninios et al. 2014). Most cases are foodborne, associated with the preparation or consumption of undercooked pork. The relative prevalence as a foodborne illness is much lower in the United States where it ranked eighth in 2011 (Scallon et al. 2011) and is over-represented as a regional and seasonal disease associated with the preparation or consumption of chitterlings or "chitlins," a dish prepared from swine intestines (Drummond et al. 2012). The vast majority of human yersiniosis is caused by *Y. enterocolitica*, with *Y. pseudotuberculosis* accounting for less than 1%. Approximately 75% of human yersiniosis is attributed to the preparation or consumption of contaminated raw or undercooked pork (Laukkanen-Ninios et al. 2014; Van Damme et al. 2015). Predictably, the same serotypes and genotypes predominate in swine and human infections (Fredricksson-Ahomaa et al. 2007; Laukkanen-Ninios et al. 2014).

Most human yersiniosis manifests as self-limiting enterocolitis in children 5 years of age or younger that exhibit pyrexia, vomiting, and severe often bloody diarrhea. Adults may experience similar signs, but more commonly acute ileitis and purulent mesenteric lymphadenitis result in acute abdominal pain along with vomiting and diarrhea mimicking acute appendicitis (Bancerz-Kisiel and Szweda 2015; Drummond et al. 2012).

Epidemiology, clinical signs, and lesions

Y. enterocolitica can be isolated from a wide variety of mammals and birds, with the pig being the primary reservoir (Bancerz-Kisiel and Szweda 2015; Drummond et al. 2012). It can also be detected in the environment, including ponds and lakes (Greenwood et al. 1990). In contrast, *Y. pseudotuberculosis* is most commonly found in rodents and uncommonly in pigs. *Y. enterocolitica* is reported in swine worldwide. Limited prevalence data exists, but studies have indicated that 32–53% of US farms (Bhaduri et al. 2005; Wesley et al. 2008), 48–80% of Canadian farms (Farzan et al. 2010; Pilon et al. 2000), 69% of English farms (Ortiz Martínez et al. 2010), 25–50% of German farms (Gürtler et al. 2005; von Altrock et al. 2006; Wehebrink et al. 2008), 80–100% of Belgian, Italian, and Spanish farms (Martínez et al. 2011), and 36–80% of pigs on Finnish farms (Asplund et al. 1990; Laukkanen et al. 2009) are infected. Factors known to increase risk for farm infection are purchase of swine from outside sources, feeding of animal protein products, and use of surface or shallow-well water sources (Virtanen et al. 2014; Wesley et al. 2008). Factors that increase carriage rate on farms include solid unbedded flooring (Vilar et al. 2013), antibiotic-free rearing (Funk et al. 2013), and continuous-flow management practices.

Y. enterocolitica infects swine orally, persists in tonsils for long periods of time, and is shed in feces as soon as 5 days and for up to 10 weeks following initial infection (Fukushima et al. 1983, 1984; Nielsen et al. 1996). Grower and finishing pigs are most often infected with rates of infection much lower in breeding animals and piglets.

Enteropathogenic *Y. enterocolitica* and *Y. pseudotuberculosis* do not generally cause clinical disease in pigs on commercial swine farms (Laukkanen-Ninios et al. 2014). Watery diarrhea containing bits of fibrin and enterocolitis

have been reproduced in colostrum-deprived neonatal pigs by inoculation with *Y. enterocolitica* (Robins-Browne et al. 1985; Schiemann 1988; Shu et al. 1997), confirming potential pathogenicity in swine and serving as a model of human yersiniosis. However, *Y. enterocolitica* infection in neonates in a commercial setting is uncommon, and associated diarrheal disease is not generally recognized. Inoculation of 11- to 24-week-old pigs with *Y. enterocolitica* resulted in colonization and fecal shedding, but no clinical disease was observed (Fukushima et al. 1984). Similarly, colonization by *Y. enterocolitica* in a commercial setting is most common in 2- to 5-month-old pigs, but clinical disease is not generally observed (Fukushima et al. 1983; Nesbakken et al. 2006; Vilar et al. 2013; Virtanen et al. 2012). Neef and Lysons (1994) orally inoculated 10-week-old pigs with *Y. pseudotuberculosis* and produced watery diarrhea in 25% and gross and/or microscopic lesions of enterocolitis in 50%. This suggests the potential for clinically significant disease in a commercial setting and is consistent with the findings of Thomson et al. (1998) where *Y. pseudotuberculosis* was the sole isolate from pigs on 4 of 85 farms where enterocolitis and diarrheal disease were confirmed in 15–50 kg (33–110 lb) pigs. However, this report is atypical, and pigs shedding *Y. pseudotuberculosis* on commercial pig farms are generally without clinical disease.

Lesions reported in *Y. enterocolitica*-inoculated neonatal colostrum-deprived pigs and in *Y. pseudotuberculosis*-inoculated conventional pigs are the same. Grossly, lesions were confined to the ileum, cecum, and colon where there were scattered erosions in the mucosa. Microscopic lesions were unique and observed consistently in the ileum, cecum, and colon and inconsistently in the jejunum. Multifocal microabscesses that contained matted colonies of bacteria were observed in the lamina propria that later expanded and resulted in multifocal necrosis and erosion of the superficial mucosa. Additionally, randomly scattered septic microabscesses were observed in the liver of neonatal pigs in only one study (Shu et al. 1997).

Diagnosis, prevention, and control

Diagnosis of porcine enteric yersiniosis requires clinical signs of diarrhea, typical microscopic lesions, and confirmation of infection by culture or PCR. Positive culture in diarrheic pigs is insufficient since subclinical shedding of *Yersinia* species is relatively common and there are a large number of other causes of diarrhea in swine. Gross lesions of erosive ileitis are nonspecific since they are also observed in cases of enteric salmonellosis (Chapter 59) that is a much common disease in commercial swine.

Y. enterocolitica and *Y. pseudotuberculosis* can readily be isolated at 37°°C on blood and MacConkey agar from tissues with lesions. Most isolation methods for *Yersinia* use cold enrichment techniques in which tissues or samples under investigation are enriched at 4°°C, followed by subculture onto a selective medium. Food microbiologists use a range of methods including various selective media and immunomagnetic enrichment (Arrausi-Subiza et al. 2014; Rasmussen et al. 1995; Van Damme et al. 2015).

Absent clinical disease, Yersinia infections in swine are rarely treated, prevented, or otherwise controlled. Isolates are often sensitive to oxytetracycline, neomycin, sulfonamides, and spectinomycin. Presently there are insufficient data on how to reduce the prevalence of *Yersinia* spp. on infected farms. Control of foodborne disease is best accomplished in the slaughter plant to reduce fecal contamination of carcasses and in home with appropriate sanitation during food preparation and cooking pork and pork products to appropriate core temperatures (Laukkanen-Ninios et al. 2014).

Parasitic Diseases

65

External Parasites

Matthew T. Brewer and John H. Greve

The importance of external parasites to pork production varies greatly among geographic regions because of differences in climate and husbandry systems. Free-roaming pastured swine are exposed to more attacks by arthropods than confined swine. Confinement rearing of swine results in a large number of host animals in close association, thereby allowing for the buildup of large populations of ectoparasites. Flies, fleas, lice, mites, and ticks are all external parasites that can produce a range of clinical signs in swine, with rubbing and skin lesions being the most common. In addition, external parasites can be vectors of microbial pathogens. More difficult to appreciate are economic losses due to reduced growth rate, reduced feed efficiency, and loss of carcass value at slaughter. Indeed, skin blemishes from insect bites present at slaughter may lead to unnecessary trimming or even condemnation. In addition, products improperly used to treat ectoparasitism may produce residues in the tissues, causing contamination of the pork. Some external parasites are vectors of microbial pathogens. Addressing ectoparasite infestation involves a combination of husbandry practices along with treatment of pigs and the environment.

Sarcoptic mange

The most important ectoparasite of swine worldwide is scabies (sarcoptic mange, sarcoptosis). Herds infested with scabies suffer reduced growth rates, reduced feed efficiency, and decreased fertility in breeding sows (Kessler et al. 2003). The real economic importance tends to be underestimated, because pork producers may not recognize the presence of scabies in their herds when it occurs. Two clinical forms of scabies are recognized: a chronic hyperkeratotic form most commonly seen in sows and a pruritic hypersensitive form most commonly seen in growing pigs. Scabies historically has a high prevalence in swine herds (40–90% in some locales), with prevalence within infested herds varying from about 20 to 95%. Estimates of herd prevalence are difficult because mites burrow and low numbers of mites may not be detected by skin scraping and modern production systems and seedstock suppliers have been successful in elimination of scabies.

Etiology and life cycle

Scabies is caused by a burrowing arachnid mite that is thought to be a single species with host-adapted variants; therefore scabies of pigs is caused by *Sarcoptes scabiei* var. suis. The mite of swine scabies is host specific; hence sources of mites are other swine as reservoir hosts other than swine have not been implicated.

The mite has a globular body approximately 0.5 mm in length, barely visible to the naked eye and more easily seen when viewed against a dark background. When observed with low-power magnification, the mite has four pairs of short, stumpy legs, some of which bear a long, unjointed pedicle that terminates in a sucker-like pulvillus. These pedicles occur on legs I and II in the female mite and legs I, II, and IV in the male. The legs that do not have pedicles bear long bristles. The third and fourth pair of legs does not extend beyond the body margin. A distinguishing feature of *Sarcoptes* is that the anus is terminal, at the very posterior margin of the organism (Figure 65.1).

Sarcoptes scabiei are permanent parasites of the skin. After mating on the surface, the females make tunnels into the upper two-thirds of the epidermis, laying a string of 40–50 eggs behind them as they progress forward. Burrowing is by extra-oral digestion of the stratum corneum, stratum granulosum, and stratum spinosum. Burrows do not typically extend deeper than the stratum spinosum. In about 30 days the females die in the burrows. The larvae hatch in 3–5 days and molt into nymphs, and the nymphs molt into adults, all within the burrows. The adults reach the surface by means of side

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Figure 65.1 *Sarcoptes scabiei*, adult. Note that the third and fourth pairs of legs do not protrude beyond the body margin and the terminal anus, which is at the very posterior of the margin of the mite.

tunnels, and mating occurs in surface pockets, starting the cycle over. The time from egg to fertilized female takes 10–25 days, all of which is spent on the host pig.

Epidemiology

The main reservoir of scabies mites in a herd is sows, which transmit the mites by physical contact. Boars are less involved with the herd's daily activities because of the increasing use of artificial insemination, but they can serve as another source of infestation. The usual infestation in sows and boars is characterized by hyperkeratotic lesions on the inner (scaphal) surface of the ears. A few adult swine also may have mites and hyperkeratotic lesions elsewhere. Susceptible pigs become infested while suckling infested sows or huddling with infested pigs. Transmission from pig to pig is fairly slow. The mite stage responsible for transmission is considered to be newly fertilized females, which are on the skin surface instead of in the tunnels. Swine management practices that facilitate the spread of mites are group housing of sows, continuous-flow systems for growing pigs, and larger group sizes of growing pigs. The prevalence and severity of scabies tends to increase during cool months and decrease during warm months (Davies et al. 1991).

Environmental contamination is not very important in transmission of scabies mites; however pigs may become infested when placed in pens immediately after infested pigs have been removed (Smith 1986). Although mites have been kept alive for 3 weeks under optimum laboratory conditions, under field conditions, survival off of the host is poor, usually no more than 3 days. Viability is reduced by desiccation, sunlight, heat, and extreme cold.

Within a group of pigs, there seems to be a smaller population of pigs that harbor large numbers of mites but do not develop a severe form of hypersensitive mange. The larger population of pigs harbor few mites but develop a marked hypersensitivity reaction (Davies et al. 1996a, b). In the latter population the number of mites declines over time as the level of hypersensitivity increases (Cargill and Dobson 1979; Davis and Moon 1990). Continuing exposure over time from pen mates maintains the allergic reaction and clinical signs in the hypersensitive pigs.

Clinical signs and pathogenesis

Pruritus is the most consistent clinical sign of scabies. Generalized pruritus occurs from 2 to 11 weeks after infestation. The onset of pruritus and the intensity of rubbing will depend on the number of mites in the initial exposure and the level of ongoing exposure. After infestation, pigs develop encrusted lesions that are rich in mites, especially in the inner (scaphal) surface of the ears. These plaque-like lesions may coalesce to cover up to 70% of the surface of the pinnae, but they will regress with time. The development of pruritus may result in connective tissue proliferation and hyperkeratinization, leading to alopecia and/or abrasions, especially over the flanks.

Sarcoptes mites secrete histiocytic enzymes that dissolve live skin cells that are subsequently ingested by the parasite. These enzymes, along with mite feces and eggs, are capable of inducing hypersensitivity reactions. Focal erythematous skin papules associated with hypersensitivity occur in most animals as encrustations subside. The papules occur primarily on the rump, flank, and abdomen. Histologically, papules contain large numbers of eosinophils, mast cells, and lymphocytes. At this stage, few mites can be demonstrated on skin scrapings. Desensitization has not been demonstrated experimentally, but field evidence suggests that it occurs.

Hyperkeratotic mange, which is the prevalent form in mature swine, may occur also in growing pigs that fail to develop the typical hypersensitivity response. The lesions are characterized by thick scabs and scurf that are loosely attached to the subjacent skin and by the presence of numerous mites. These lesions occur most frequently in the ears, but they may also spread over the back, neck, and other parts of the body. The lesions are often accompanied by a thick, ceruminous, and odiferous exudate.

Diagnosis

Scabies has potential to be present in many herds unless some special measures to eradicate the mites have been followed. Many seedstock suppliers and production systems have eliminated mange, but reintroductions occur.

Scabies should be suspected when growing pigs with small red papules on the body are rubbing. Rubbing can be evaluated by observing a group of pigs for 15 minutes. It has been suggested that if more than 1 rubbing event per 10 pigs occur within this time frame, scabies may be present (Pointon et al. 1995). Finding the mites by means of skin scrapings confirms the diagnosis, but oftentimes the mites are difficult to find due to burrowing in skin. The majority of pigs in an infested herd may be subclinical and may not manifest pruritus (Kessler et al. 2003). Only a small percentage of growing pigs will harbor significant populations of mites. The ear is more likely to be positive than other skin sites (Bogatko 1974).

The best method to find the mites is to examine the inner surface of the ears of the breeding stock for encrustations. About 1–2 cm^2 of the lesion should be removed by means of a knife blade or chisel for examination for mites. The encrustations can be broken up onto a sheet of black paper and allowed to sit for a few minutes. When the crusts are carefully moved aside, mites may be seen with a magnifying glass against the dark background. Alternatively, the exudate should be minced finely with a scalpel blade, and the resulting material can be immobilized in a drop of immersion oil and examined microscopically. A more sensitive technique is to macerate the scabs in 10% potassium or sodium hydroxide. Low heat may be used to accelerate the maceration. The chitinous exoskeleton of the mites is impervious to hydroxide, so the exoskeletons can be found under low magnification. A third technique is to place the ear scrapings in a petri dish and incubate under low heat overnight. Mites will emerge in great numbers or adhere to the bottom of the dish (Sheahan and Hatch 1975).

Examination of carcasses at necropsy or slaughter provides information on the scabies status of herds. Skin lesions are scored, and categories defined according to the severity of the dermatitis. Minor spots must be disregarded, because they may be caused by reactions to bedding or insect bites. However, the grading of dermatitis about the shoulders, underline, and rump is of interest in evaluating scabies (Cargill et al. 1997).

Several enzyme-linked immunosorbent assays (ELISAs) have been used to detect antibodies to *S. scabiei* in serum (Bornstein and Wallgren 1997; Bornstein et al. 2000; Deckert et al. 2000; Zalunardo et al. 2000). Individual sensitivity varies from 29 to 64%, but as a herd test sensitivity approaches 95%. Specificity in individual pigs varies from 78 to 97% (Smets and Vercruysse 2000). Specific antibodies are not detectable until 5–7 weeks after infestation or approximately 3–4 weeks following the onset of clinical scabies (Bornstein and Zakrisson 1993). Detectable antibodies may persist for 9–12 months (Smets and Vercruysse 2000). Although antibodies can persist several months in sows following treatment, the half-life of antibody levels appears to be less than 2 months (Bornstein and Wallgren 1997). ELISA may have some use in evaluating the efficacy of eradication programs (Cargill et al. 2004).

Differential diagnosis from other skin diseases is important. Conditions that can be confused with scabies include parakeratosis, exudative epidermitis, deficiencies of niacin and biotin, swinepox, dermatomycosis, sunburn, photosensitization, and insect bites. Occasionally, in scabies-free herds, ear scrapings may reveal mites and/or mite eggs that can be attributed to pseudoparasites living in old bedding.

Treatment

Scabies may go unnoticed because farmers may consider rubbing by pigs to be a normal activity, but the recognition of the presence of scabies is essential to instituting the proper control measures. Several strategies have been reported to reduce the economic effects of mange. Treatment and control of mange is an option on some farms, whereas elimination is often a preferred option.

Successful treatment of scabies is dependent upon the correct use of acaricides. The large majority of registered products will keep scabies under control, and some even eradicate it, provided the correct dosage and treatment schedules are used. Oil mixtures are more effective than aqueous ones because oil helps to soften the hard scab surrounding the mites. Today oil mixtures continue to be used occasionally either by themselves or in conjunction with modern acaricides.

Older remedies (e.g. crankcase oil, diesel fuel, and lime sulfur) are very limited in efficacy and not recommended. Likewise, the chlorinated hydrocarbons (lindane, toxaphene) or organophosphates (malathion, trichlorfon, diazinon) were once used as acaricides in swine, but because of their toxicity, dwindling efficacy, or persistent tissue levels, they are no longer recommended.

More modern acaricides (see Table 65.1) are safer, have higher efficacies, and are easier to administer. If the active ingredient is not ovicidal, it must be readministered in 10 days in order to kill the emerging larvae. Instructions on dilutions, withholding periods, and other precautions by the manufacturer must be followed carefully. The availability of certain products depends on the legislation of a particular country. Effective modern acaricides include phosmet, used as a pour-on; amitraz, used as a spray; and the avermectins (ivermectin, doramectin, and moxidectin), which are given as injection. It is recommended that when using phosmet, a small amount of the product be placed in the inner aspect of each ear. The avermectins are broad-spectrum antiparasiticides effective against most internal parasites as well as lice and sarcoptic mange mites. Current products have varying levels of persistence. They are more efficient because of their systemic action and ease of administration.

Table 65.1 Products labeled for chemical treatment of external parasites of swine.

Chemical	Form	Parasites affected	Directions for use
Amitraz	Liquid concentrate	Mites	Spray pigs and surroundings, repeat in 7 days
Coumaphos	Liquid or solid concentrate	Lice, flies, ticks, mites, myiasis maggots	Spray premises and pigs
Dichlorvos	Liquid concentrate	Flies	Spray premises
Deltamethrin	Liquid concentrate	Lice, ticks, flies	Spray premises
Doramectin	Injectable solution	Lice, mites, larval flies	200 µg/kg body weight
Ivermectin	Injectable solution	Lice, mites	200 µg/kg body weight
Piperonyl butoxide	Liquid concentrate	Lice, fleas, flies, ticks	Spray premises
Permethrin	Liquid concentrate	Lice, ticks, mites, maggots, flies	Spray premises and pigs
Phosmet	Liquid concentrate	Lice, mites, ticks	Topical application or treatment of back rubbers. Do not apply to sick or suckling pigs
Tetrachlorvinphos	Feed concentrate	Fly maggots in manure	Add to feed according to label directions

Important: Always follow label directions, especially with insecticides that are toxic to humans and animals.

Control

Ongoing control of scabies involves identification of those animals that have chronic scabies so that they can receive regular treatment to prevent transmission to the young pigs. Therefore, control programs often focus on the breeding herd. Mercier et al. (2002) showed that a single dose of ivermectin (300 µg/kg body weight) given to sows 8 days before farrowing was very effective in preventing transmission of the mites to the piglets. Any sows with extensive hyperkeratotic lesions should be culled, and the rest of the sows should be treated before farrowing. The boars should be treated every 3–6 months to prevent transmission of mites during breeding. Pigs born to mite-free sows and housed in clean pens will remain free of mites unless they are exposed to infested pigs. If mange is present in both the breeding and growing pigs, the whole herd should be treated. However, successful elimination of mange from a two-site system can be achieved by treating animals at the breeding herd combined with hygiene and biosecurity measures at the growing facilities. All animals introduced into the herd must be treated before coming into the herd. Contaminated bedding should be removed, and the environment sprayed with an acaricide. Humans who handle infested pigs can act as mechanical vectors for the mites (Mock 1997), so it is important that workers with one herd must change clothes and shower before moving into another herd.

Elimination

The establishment and maintenance of mange-free herds and populations is facilitated by three important facts. First, piglets are born free of mites and become infested through contact with infested sows or older growing pigs. Second, the mites are highly host specific and survive poorly away from the pig host. Third, modern acaricides are very effective.

Mange-free herds can be established with Cesarean-derived pigs, by depopulation and repopulation from mange-free stock, by segregated rearing of treated pigs, and by eradication using avermectins and other products. Biosecurity measures that focus on careful scrutiny of minimal number of sources of incoming stock are usually adequate to prevent introduction of the parasite. In a number of countries, major breeding stock suppliers maintain mange-free herds, and large populations of pigs in integrated production systems have been kept free of the parasite for many years. This should be the goal of most farms.

Eradication of sarcoptic mange is possible with a variety of programs developed around the use of effective acaricides, provided the processes and procedures are properly executed. Documented successes and failures of eradication plans usually relate to the diligence of animal caretakers in following treatment and biosecurity protocols. Eradication programs involve several key points. If the whole herd is to be treated, all marketable pigs can be sold before each treatment to reduce the cost, and the withholding period for the chemical must be observed. All pigs are treated twice at the recommended interval for the acaricide used. If only the sow herd is to be treated, two options are available. All sows and boars can be treated at the recommended interval, or individual sows can be treated pre-farrowing and moved to clean pens or crates. If the latter approach is taken, boars should be treated every 3 months, and the progeny of treated sows must be isolated from the progeny of

untreated sows. Eradication is made easier in growing pigs by changing from a continuous-flow management system to an all-in/all-out system, such as age-segregated-rearing or multisite production. However, changing the management system must be combined with effective pre-farrowing treatment of sows. All of these approaches can be effective and are justified economically.

Economic importance

The effects of sarcoptic mange on production have been reviewed previously (Davies 1995). Deaths are unlikely, unless concurrent disease is present. The most significant effect of sarcoptic mange is reduced growth rate (4.5–12%) and feed efficiency in growing pigs. Other economic effects include downgrading and trimming of carcasses at slaughter, as well as damage to pens and fixtures caused by rubbing pigs. Field studies indicate that good control of scabies may increase lactation, reduce pig mortality due to overlying, and increase weaning weights (Hewitt and Heard 1982).

An interrelationship among immunity, inadequate nutrition, poor management, and hyperkeratotic scabies has been noted. Hyperkeratotic mange is considered to be a disease of poor management and of poorly fed pigs. Diets low in protein and iron are associated with reduced hypersensitivity and a greater proportion of animals with hyperkeratotic mange (Sheahan 1974). The overall clinical picture is substantially influenced by the effectiveness of treatments and herd management practices.

Demodectic mange

Demodectic mange (demodicosis, follicular mange) is relatively unimportant in swine, although it is quite common in the subclinical form as *Demodex* mites are thought to be normal skin flora in mammals. The causative agent is the mite *Demodex phylloides*, an elongate mite that resembles the head of an alligator. The mite spends its entire life inside hair follicles, alongside the hair shafts. To adapt to its narrow living space, the mite has stumpy legs and a fusiform shape. It is assumed that the life cycle of *D. phylloides* resembles that of other demodicid mites. Females live in the hair follicles and oviposit there. A series of larval and nymphal stages ensue, all in the same hair follicles. The next generation of adults matures in about 2 weeks, and the life span of the adult is 1–2 months. The rate of cycling slows down as the pig ages, so that eventually a small population composed almost entirely of adults is in the follicles. Neighboring follicles are colonized by mites crawling out of one follicle and into another.

Transmission of the mites probably occurs by direct contact with neonates while nursing or huddling. The mites can survive for several days in moist environments and up to 21 days under experimental conditions in pieces of skin kept cool and moist (Nutting 1976). However the mites can survive only 1 or 2 days if removed from the hosts' skin and are killed by desiccation in as little as 1 hour at 20 °C on the skin surface.

The sites on the body that are most commonly affected are the snout, eyelids, jowls, underside of the neck, mammary area, and inside surface of the thighs (Walton 1967). Early lesions are red pinpoint foci, but older lesions are hyperkeratotic and nodular. The nodules are distended hair follicles that contain mites, hyperkeratotic debris, and inflammatory cells. When incised, the nodules express a thick, white caseous material laden with mites. Such lesions may be confused with swinepox.

Diagnosis

The diagnosis of demodicosis is made by finding numerous mites in deep skin scrapings. Plucked hair may also reveal mites. Because the mites are present in nearly all swine, identification of a few mites does not necessarily prompt a diagnosis of demodicosis. A correlation between the presence of the mites, indications of an actively growing population of mites (i.e. large number of immature stages in the follicles), and visible lesions must be seen to justify the diagnosis of clinical demodicosis.

Treatment

There are no reports of successful treatment of swine demodicosis with any acaricide. Ivermectin and amitraz are successful in canine demodicosis. In dogs, there is a genetic predisposition to clinical demodicosis. While not proven in swine, it may be prudent to cull severely infected pigs.

Pediculosis (louse infestation)

The pig louse, *Haematopinus suis*, is among the largest of all lice and can be observed with the naked eye. *H. suis* has a worldwide distribution, is the only louse infesting swine, and is an anoplurid (sucking) louse. Accordingly, the head is long and narrow and contains stylets used for piercing skin and feeding on blood of the host. The thorax and abdomen are gray brown with black ornamentation. Females are about 6 mm in length, and the males are lightly smaller.

Haematopinus suis is strictly host specific, and their introduction does not involve rodents, birds, or any other pests. The entire life cycle takes place on the pig.

Adult females lay 3–4 nits (eggs) each day for up to about 25 days. Each nit is 1–2 mm in length and is cemented to a hair shaft. Nymphs hatch in 12–20 days. There are three nymphal instars, all of which suck blood. The third instar molts into an adult 23–30 days after the nit was laid. Lice are obligate parasites and cannot survive for more than 2–3 days off of the host. Lice are found on all parts of the body, but tend to be focused on the neck, jowls, flanks, and inner surface of the legs. They also seek shelter inside the ears where they may be found in clusters. The spread of lice is by direct contact.

The economic importance of lice has not been critically evaluated to the same extent as that for scabies. However it is known that severe pediculosis results in anemia in young pigs and may affect growth rates and feed efficiency. One estimate of reduced growth rate was 50 g/day, although others failed to demonstrate this effect. Lice have been considered to be vectors of swinepox and hides from pediculotic swine may be unsuitable for high-grade leather manufacturers.

Diagnosis

Lice should always be considered in the differential diagnosis of pruritus in pigs. Infestation can be confirmed by identifying lice and/or nits. Nits will be cemented to the proximal (lower) part of the hair shafts, which helps differentiate them from blow fly eggs, which are more diffuse in distribution. Nits are pearl white when first laid and are 1.5–2 mm in length. Adults have six legs and long sucking mouthparts (Figure 65.2).

Treatment and control

The treatment and control of pediculosis is aided by the fact that all stages of the parasite occur on the pig. Therapeutic agents may be administered to the swine in the form of sprays, pour-ons, or dusts (see Table 65.1).

Figure 65.2 *Haematopinus suis*, adult. Note the elongate mouthparts and claws adapted for grasping hair.

Control can be assisted by sprinkling insecticide granules in the bedding. Pour-ons and dusts have the advantage that they can be used in cold weather when spraying may not be indicated. If the active ingredient is not ovicidal, treatment should be repeated in 10 days.

Control and eradication strategies mentioned for scabies also are effective for pediculosis. This includes multiple treatment of sows prior to farrowing, segregation of clean and untreated animals, and treatment of newly introduced animals.

Fleas

Fleas (Siphonaptera) show a low level of host specificity; each species of flea may parasitize a range of host species of mammals or birds. Fleas may parasitize phylogenetically related species, or they may parasitize species that are related to one another by common habitat. All fleas have the same basic structure. They are wingless and are laterally flattened. The hind legs are enlarged and suited for jumping. The four fleas most often associated with swine are *Pulex irritans* (the human flea), *Echidnophaga gallinacea* (the sticktight flea), *Tunga penetrans* (the sand flea or jigger, not to be confused with chigger), and *Ctenocephalides felis* (the cat flea).

The life cycles are similar for all fleas. Adult fleas feed only on blood from the host and are the only stage found on the host. After mating the female oviposits eggs that drop off the host into the environment. The larvae that hatch in 2–16 days are hairy, wormlike creatures that feed on detritus and on the adult flea's blood-laden feces. Flea larvae require high humidity and warm temperature, allowing them to mature in 1–2 weeks. When ready to pupate, the larvae spin a cocoon, to which is stuck small particles from the environment, thus camouflaging the finished cocoon. Depending on environmental conditions, the cycle may be completed in 18 days or protracted to more than 1 year. Adult fleas depend on visual and thermal cues to locate hosts. They orient themselves toward a light source and are stimulated to jump when the light source is temporarily interrupted. Therefore, the shadow of a passing host stimulates the parasites' activity. Fleas can survive for many months awaiting the arrival of a host. How long these fleas can lie in wait depends on environmental conditions, but with optimum humidity and temperature, individuals may live for several weeks or longer off of the host. Environment is a major factor in survival of the flea population in the absence of the host.

Diagnosis

The diagnosis of flea infestation is often difficult unless the adult fleas can be found on the host. The eggs, larvae, and pupae are in the environment, not on the host, and

therefore are especially difficult to find. Adults, however, remain on the host but are somewhat elusive to observation, particularly in breeds of swine that have thicker hair coats. The adults of most flea species are found roaming on the host's skin, and bite lesions occur where fleas have fed. Bite lesions can occur anywhere, but they are most prevalent on the underline and inside surfaces of the legs. Flea bites are not particularly distinguishable from those of other insects. Allergic dermatitis (flea-bite dermatitis) similar to that seen in dogs has been described also in swine, and this may resemble scabies (Nesbitt and Schmitz 1978). Because fleas are not strictly host specific, humans in the same environment also may be attacked. Noticing attack by fleas on human observers may be the first indication of flea infestation.

A special case is *T. penetrans*, the sand flea, or jigger. This flea is found in Africa, the Caribbean, and tropical South America. The female of this tiny flea (1 mm) burrows into the dermis of the host and remains at that site for life. In the process of becoming ovigerous, she swells up to the size of a pea, causing a severe inflammation and ulceration. Humans may also be affected. Sites affected are the feet, snout, underline, and scrotum. Eggs are released through the ulcerated surface, and the immature stages develop in the environment. An unusual case involved the mammary gland, where the fleas obstructed the ducts and caused agalactia (Verhulst 1976).

Treatment and control

Treatment of fleas on the swine is readily accomplished by any of several products also used for other ectoparasites (see Table 65.1). However flea stages in the bedding are much more difficult to eradicate. Environmental control may be attained by the removal and burning of litter, dirt, and manure. Spraying of the environment with chlorpyrifos, pirimiphos, or malathion may be effective, but animal exposure and withholding periods must be considered.

Mosquitoes

While usually thought of as pests of humans, mosquitoes also attack swine and other livestock. Mosquito bites cause irritation and discomfort; the economic losses caused by these attacks have not been well documented, but in some cases it may be clinically important. Reports of mosquitoes attacking swine in large numbers exist (Becker and Gross 1987; Dobson 1973). Attacks by mosquitoes may be significant even in well-managed confinement operations.

All species of mosquitoes require some type of water to complete their cycle. Eggs are typically laid in water, and the larval and pupal stages occur there. In some cases, eggs are laid in areas that will eventually fill with water (egg holes in trees). The type of water suitable for oviposition varies according to each species. It may be salty, brackish, or fresh; stagnant or flowing; sunlit or dark; open or impounded in secluded niches; etc. Species of *Aedes* lay eggs in depressions (wheel ruts, hoof prints, tires) that are dry at the moment but will trap water during the next rain. Control measures involve treating or removing the offending water source. Because different genera utilize different aquatic environments, one method will not be effective against all species. Insecticides must be applied where the mosquitoes are and when the mosquitoes are present. Screened-in enclosures may provide relief but may be impractical. Effective mosquito control involves treatment of large regions, because mosquitoes can fly in from adjacent untreated areas.

In some localities, mosquitoes may transmit microbial pathogens to swine. The transmission of Japanese encephalitis virus, especially in rice-growing areas, was reported by Wada and Smith (1988). Also, mechanical transmission of porcine reproductive and respiratory syndrome virus (PRRSV) was documented (Otake et al. 2003). The virus survived in the mosquito's gut for up to 6 hours, but did not survive on the exoskeleton. Mosquitoes can also transmit *Mycoplasma suis* between pigs (Prullage et al. 1993).

Flies

Flies are important in swine production for several reasons. First, houseflies tend to be used as a measure of general sanitation. Second, some flies bite swine, leading to discomfort and disease (Figure 65.3). Further, some flies cause myiasis, which leads to significant disease including death. Flies express a moderate level of host specificity; therefore flies will also be pests of other livestock, wildlife, and humans.

Housefly

The most common fly in swine operations is the housefly, *Musca domestica*. It lays broods of eggs that develop into maggots in almost any moist organic matter (feces, carrion, garbage, rotting feed). The maggots crawl out of their larval environment and become thickened and darkened in color as they pupate in dry ground. Adult flies emerge from pupal cases and crawl to the surface in about 2 weeks, but that time is temperature dependent.

Musca domestica is nonbiting, but its crawling over an animal's skin is bothersome, and behaviors associated with fly avoidance may lead to decreased rate of gain. Experimentally, houseflies may act as mechanical vectors

Figure 65.3 Fly-bite dermatitis observed at slaughter after scalding.

for *Salmonella, Escherichia coli*, hog cholera, hemolytic streptococci, nematode eggs, and others. Flies may play a relatively small role in the ongoing transmission of such pests on a particular farm; the clinical relationship among flies and these pathogens is not well described. Dissemination of microbial pathogens occurs via the fly's exoskeleton (hairs, legs, proboscis), regurgitated from the fly's crop while dapping its proboscis on food, or in the fly's feces.

Removal of egg-laying sites has primal importance in housefly control. This is augmented by applying residual insecticide sprays and fogs to building surfaces where flies rest (floors, ceilings, partitions, etc.). Manure should be removed at least weekly and spread thinly on the ground to interrupt the life cycle. Electric light traps have not been found to be particularly useful for control.

Stable fly

The second most common fly in swine operations is the stable fly, *Stomoxys calcitrans*. This fly is a pesky biter. Although preferring sunlit areas, it will enter buildings. The adult flies strongly resemble houseflies, but can be distinguished by a long, pointed proboscis. The stable fly can vector hog cholera and *M. suis*. Stable flies deposit eggs in moist decaying vegetable matter such as stacks of straw, damp feed, or lawn clippings. The maggots crawl out of the larval brood site and burrow into the neighboring ground; adults emerge in about 2 weeks. The presence of stable flies is associated with annoyance and thus subtly reduces feed conversion. Control of stable flies is the same as for houseflies.

Tabanids

Tabanids (horseflies, breeze flies, deer flies, etc.) are large, robust flies with fierce biting mouthparts. Female tabanids require a blood meal for egg maturation, while the males feed on nectar and sap. Females lay egg masses on foliage that hangs over water. Hatched larvae drop into the water and feed on aquatic insects. Pupation occurs in dry ground, and adults emerge in 1–3 weeks. Tabanid bites are painful; the mandibles lacerate blood vessels, and blood trickles from bite sites for several minutes. These sites can attract muscid flies. Tabanids are capable of transmitting hog cholera and perhaps other pathogens that occur in the host's circulating blood. Control of tabanids is problematic, as insecticides and repellents work poorly. Screening of buildings or removal of swine to locations more remote from the fly's breeding site may be considered.

Gnats

Simuliids (buffalo gnats, black flies, turkey gnats) are small, stout-bodied, humpbacked biting flies that occur throughout the world. They breed only in running water, and the next generation of adults emerges from those streams in swarms. Most simuliids are ornithophilic, but many feed on a wide variety of mammals. Only the female bites. Black flies may attack in huge swarms and have been known to kill livestock. The exact mechanism leading to death (anemia, toxin, etc.) has not yet been resolved. Left undisturbed, females feed to repletion in about 4–5 minutes. Similar to tabanids, control is difficult. In areas with black fly problems, livestock may have to remain indoors until after sunset.

Myiasis

Screwworm flies cause primary myiasis. *Cochliomyia hominivorax* in South America (it has been eradicated from North America, although it has been recently reintroduced in the Florida Keys) and *Chrysomya bezziana* in Africa and southern Asia are the major causes. These flies oviposit on fresh wounds (fresh umbilical cords, surgical incisions, tabanid bites, nail scratches, fight wounds, etc.), and the larvae (known as screwworms) penetrate into living tissue. The excessive excavation caused by the larvae may be fatal. Ovipositing females attack any species of mammal. They lay 150–500 eggs at the edge of the wound, and the larvae spend 3–6 days in the wound. The larvae crawl out of the host and pupate in the ground, reaching adulthood in 3 days to several weeks. Clearing the environment of snags that may cause wounds, immediate attention to newly farrowed pigs, and similar husbandry methods to reduce oviposition sites are important. Repellent wound dressing may be applied before oviposition has occurred. If wounds are

already infested, pressurized larvicidal aerosols may be used if the larvae are still superficial. Eradication programs entail the release of irradiated sterile males. Screwworms mate only a single time, and mating with the irradiated males leads to nonviable offspring.

Blow flies (*Phaenicia*, *Calliphora*, *Phormia*, etc.) cause nonspecific myiasis in a wide range of host species. These differ from screwworm myiasis in that oviposition occurs in dead or decaying flesh. Some species of blow fly oviposit into wounds that are only slightly foul, whereas others are not attracted until the wound becomes very putrid, and still others are not attracted until the animal dies. Thus there is a succession of different blow flies during the development of the wound. This type of myiasis is much more common than the screwworm type, but it is less dangerous to the affected host, because the maggots keep within the bounds of necrotic tissue and do not wander deeper. As such, larvae from flies causing secondary myiasis have been called "surgical maggots" since they have been used to debride wounds.

Ticks

Domestic swine are susceptible to infestation by ticks but do not commonly come into contact with them. Certainly swine raised in modern confinement units are protected from most contact with ticks. Two kinds of ticks infest swine, ixodid (hard) ticks and argasid (soft) ticks. Ixodid ticks have a hardened scutum covering the entire dorsum of males and a small part of the anterior dorsum of females. Argasid ticks lack this shield altogether and resemble small moving pancakes as the mouthparts are not visible from above. Species of tick are adapted to particular geographic ranges and climatic ranges, so one should seek local assistance in identifying species of interest. In the United States ixodids occurring on swine are species of *Dermacentor*, *Ixodes*, and *Amblyomma*, and argasids are *Ornithodoros* and *Otobius*.

The life cycle of ixodids includes egg, larva ("seed tick"), nymph, and adult. Some ticks are so-called one-host ticks whereby all stages occur on the same individual. For other ticks, each stage requires a new host, and these organisms are aptly named "three-host ticks." Two-host ticks are relatively rare. Ixodid ticks position themselves on vegetation and extend their legs as they wait for a passing host, a technique known as "questing." A single large mass of eggs is laid by the ixodid female after it drops off of a host. In argasids, a small clutch of eggs is laid after each blood meal, and the adults are in the host's lair, not on the host. Argasids seek a host several times in their lives (plural-host ticks).

The main economic importance of ticks is their ability to transmit pathogens, such as protozoa, rickettsiae, and viruses. The recovery of African swine fever virus from *Ornithodoros moubata* nearly a year after experimental infection (Grieg 1972) speaks to the tick's importance as a vector and to the role ticks can play in transmitting agents from wild swine to domestic hosts.

The diagnosis of tick infestation is based upon the known geographic distribution of ticks and the access of pigs to these areas. Hard ticks are readily seen by visual inspection. Although they may occur on any portion of the host, ticks are more commonly attached to the ears, neck, and flanks. Soft ticks seldom occur on the body – they are found in the environment when not feeding. Spinose ear ticks, *Otobius megnini*, are an exception, as they are found in the ear canal.

If only a few ticks are present, they can be removed manually, and the pigs must be removed from the offending pasture. Many products are effective acaricides.

Coccidia and Other Protozoa

David S. Lindsay, Jitender P. Dubey, and Mónica Santín-Durán

Coccidia (*Cystoisospora suis* and *Eimeria* spp.)

Coccidia are obligatory intracellular protozoan parasites. The number of valid species of intestinal coccidia (*Eimeria* and *Cystoisospora*) that infect swine is unknown because most are known only from the sporulated oocyst stage. Neonatal coccidiosis caused by *Cystoisospora suis* (synonym *Isospora suis*) is the most important protozoal disease of swine. Although the causative agent, *C. suis*, was described from pigs in 1934 (Biester and Murray 1934), it was not until the middle 1970s that clinical coccidiosis was recognized as a disease problem in nursing pigs (Sangster et al. 1976). In 1978, it was demonstrated that *C. suis* was the cause of piglet coccidiosis in natural cases and coccidiosis was experimentally reproduced in nursing pigs (Stuart et al. 1978). Neonatal piglet coccidiosis has a cosmopolitan distribution and is found anywhere pigs are raised in confinement.

Life cycle of *c. suis*

Coccidial life cycles are divided into three phases: sporogony, excystation, and endogenous development (Figure 66.1). Each coccidial phase is unique for each species, and knowledge of life cycle phases is important in diagnosis, treatment, prevention, and control of coccidiosis.

Sporogony is the process by which the oocyst (environmentally resistant stage) develops from the unsporulated noninfectious stage passed in the feces to the infective stage (Figure 66.2). Proper temperature and moisture must be present for sporulation to take place. The oocysts of *C. suis* sporulate rapidly at temperatures between 20 and 37 °C (Lindsay et al. 1982). The supplemental heat of between 32 and 35 °C provided by producers for newborn piglets favors rapid development (within 12 hours) of *C. suis* oocysts in the farrowing crate. Oocysts are most sensitive to killing when in the unsporulated state and during sporulation. Once the oocysts are sporulated, they are resistant to most disinfectants. When fully sporulated, the oocysts of *C. suis* and all other *Cystoisospora* species contain two sporocysts, each with four sporozoites.

Excystation is the phase of the life cycle that occurs immediately after the infectious oocysts are ingested. Passage through the stomach alters the oocyst wall and allows bile salts and digestive enzymes to activate the sporozoites. The activated sporozoites leave the sporocyst and oocyst and are freed into the intestinal lumen. The sporozoites then penetrate enterocytes and begin the endogenous phase of parasite multiplication.

The endogenous stages of the life cycle of *C. suis* occur in cytoplasm of enterocytes throughout the small intestine, with most stages being present in the jejunum and ileum. Occasionally, in heavy infections, parasites can be found in the cecum and colon as well. Coccidial stages are usually located on the distal portions of the villi and are in a parasitophorous vacuole below the host cell nucleus (Lindsay et al. 1980). In severe clinical or experimental cases, stages may also be located in crypt enterocytes. There are two distinct types of asexual stages in the endogenous life cycle of *C. suis*. Sexual stages consist of microgamonts, which produce microgametes, and uninucleate macrogamonts. The microgametes fertilize the macrogamonts, and an oocyst is formed. These sexual stages also may be seen 4 days post infection (PI), whereas oocysts are first seen in the feces 5 days PI (rarely 4 days).

Immunity to *Cystoisospora suis*

Pigs that have been infected with *C. suis* and recover are resistant to challenge infection. These challenged pigs excrete no or very few oocysts (in contrast to initial infection) and do not develop clinical signs. Administration of corticosteroids (methylprednisolone

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

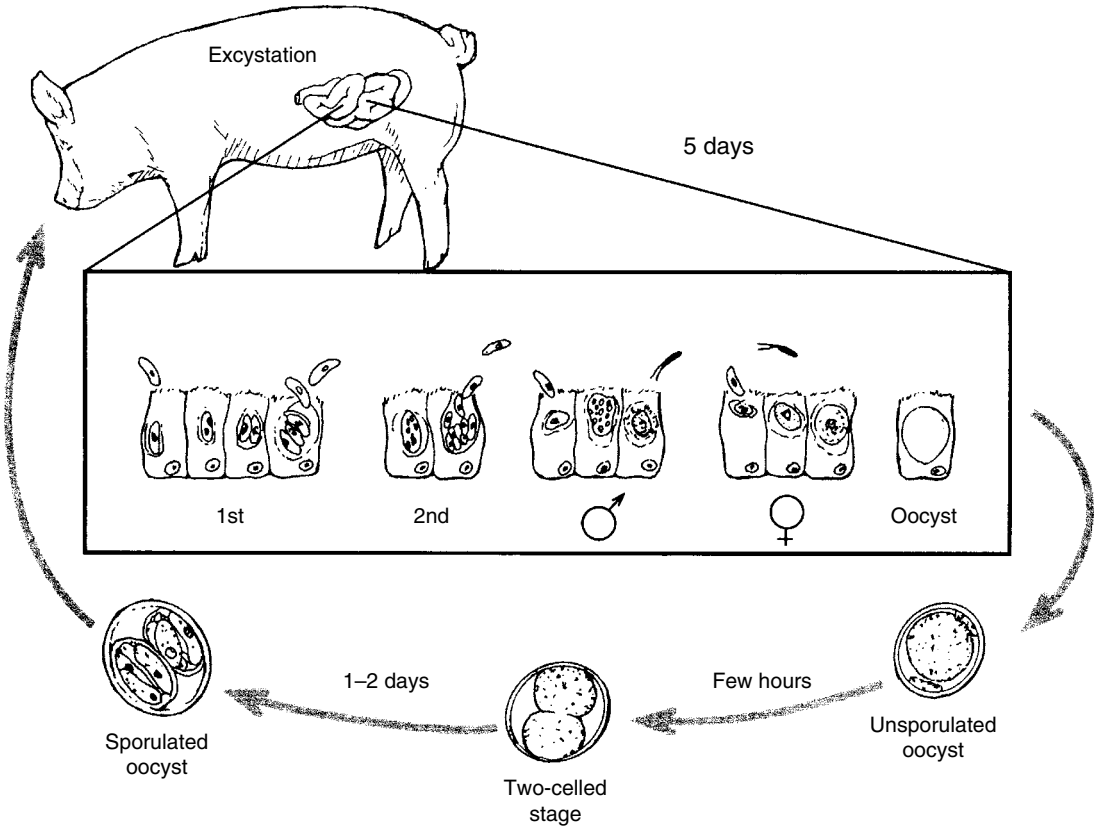

Figure 66.1 Life cycle of *Cystoisospora suis*.

acetate) does not cause these previously exposed pigs to reexcrete oocysts, suggesting good immunity has developed.

Experimental inoculation of sows with 1×10^5 *C. suis* oocysts 14 days before farrowing resulted in partial protection of piglets against clinical disease after experimental infection with 1×10^3 *C. suis* oocysts at 3 days of age (Schwarz et al. 2014). Protective substances were present in both colostrum and milk and highly correlated with IgA, IgM, and IgG antibody titers in the piglets during the first 2 weeks of life.

Pigs have age-related differences in susceptibility to experimental infection and disease (Koudela and Kucerova 1999). Pigs that are 1–2 days old develop much more severe disease than pigs inoculated with an identical number of oocysts at 2 or 4 weeks of age.

Clinical signs of *Cystoisospora suis*

Signs of disease occur in formerly healthy nursing pigs between 7 and 11 days of age (Stuart et al. 1978). Yellowish to grayish diarrhea is the major clinical sign. The feces are initially loose or pasty and become more fluid as the infection progresses. Piglets become covered with the liquid feces, causing them to stay damp and have a rancid odor of sour milk. The piglets usually continue to nurse, develop a rough hair coat, become dehydrated, and have depressed weight gains (Lindsay et al. 1985). Litters within the farrowing house vary in the degree to which they demonstrate clinical signs, and not all piglets within a litter are equally affected. Morbidity is usually high, but mortalities are usually moderate. Concurrent bacterial, viral, or other parasitic infections may lead to extreme mortalities and complicate diagnosis.

Occasionally *C. suis* oocysts are present in the feces of recently weaned pigs, some of which may have diarrhea. Diarrhea caused by *C. suis* can occur in 5- to 6-week-old pigs. Diarrhea begins 4–7 days after the piglets are weaned. It is likely associated with the stress of weaning and exposure or reexposure to environmental oocysts. Morbidity is high, but mortalities are rare. As with neonatal piglets, other causes of diarrhea besides *C. suis* need to be ruled out. *C. suis* infections do not cause disease in finishing pigs or in breeding stock.

Pathologic changes with *Cystoisospora suis*

The degree of disease is dependent on the number of sporulated *C. suis* oocysts that a piglet ingests (Stuart et al. 1980). Necropsy examination may demonstrate gross lesions of neonatal coccidiosis characterized by a fibrinonecrotic membrane in the jejunum and ileum, but this is seen

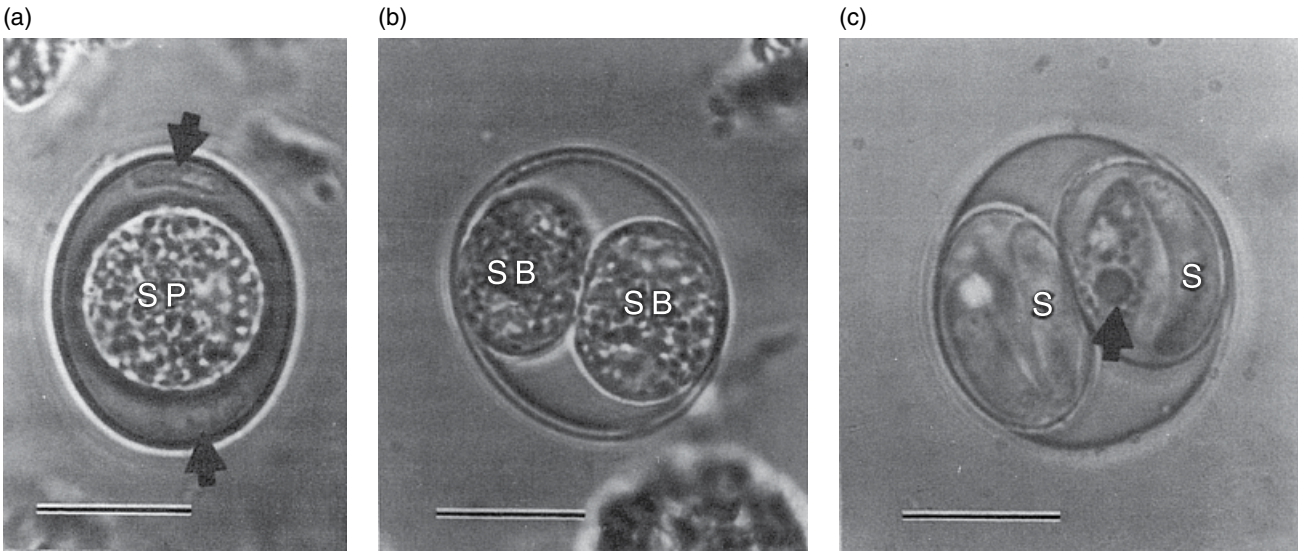

Figure 66.2 Oocysts of *Cystoisospora suis* in fecal flotation. Bar = 10 µm. (a) Freshly excreted unsporulated oocyst. Note the hazy bodies (arrows) and the sporont (SP). (b) Oocysts several hours after excretion. Note that two sporoblasts (SB) are present. (c) Sporulated oocyst approximately 1 day after excretion. Note the sporozoites (S) and residual body (arrow) in the sporocysts. *Source:* Adapted from Lindsay et al. (1982).

only in severely infected piglets. Hemorrhage is not seen even in extreme cases of natural infections or in experimental infections where large numbers of oocysts are given.

Microscopic lesions consist of villous atrophy, villous fusion, crypt hyperplasia, and necrotic enteritis (Stuart et al. 1980). The enterocytes at the tips of the villi may be destroyed, exposing the underlying lamina propria, or they may be replaced by flattened immature enterocytes. The functional ability for absorption is diminished in this altered epithelium, resulting in fluid loss and diarrhea. Lesions develop about 4 days PI and are associated with the presence of the asexual stages. In most natural cases few parasites are present in the sections, and most of these parasites are asexual stages. In severe cases piglets may succumb to coccidiosis before the sexual stages are produced.

Diagnosis of *Cystoisospora suis*

Diarrhea in nursing pigs 7–14 days of age that does not respond to antibiotic treatment is suggestive of neonatal *C. suis* infection. Other agents such as enteropathogenic *Escherichia coli*, TGE virus, rotavirus, *Clostridium perfringens* type C, and *Strongyloides ransomi* should be considered in the differential diagnosis.

Diagnosis of *C. suis* can be achieved by finding *C. suis* oocysts in the feces of clinically affected piglets (Figure 66.2a and b). This is the quickest method available for diagnosis. Fecal smears or fecal flotations should be made from several litters within the farrowing house that have been showing clinical signs for 2–3 days, because diarrhea starts about a day before oocysts are passed and peak oocyst production occurs about 2–3 days after clinical signs develop. Piglets excrete oocysts in several phases and may be negative during these phases. Pasty fecal samples are likely to contain more oocysts than liquid samples. The oocysts of *C. suis* have characteristic structures called "hazy bodies" between the oocyst wall and the sporont (Figure 66.2a). These are diagnostic for *C. suis* because none of the oocysts of the swine *Eimeria* species have this structure (Lindsay et al. 1982). Additionally, some of the oocysts may be in the two-celled sporoblast stage (Figure 66.2b), which is also diagnostic for *C. suis*. Fecal fat may make identification of oocysts in flotation preparations difficult. A solution of saturated sodium chloride and glucose (500 g of glucose in 1000 mL saturated sodium chloride solution) has been recommended as an alternative flotation medium (Henriksen and Christensen 1992).

Demonstration of developmental stages (Figure 66.3a–d) in mucosal smears can be used in the diagnosis of *C. suis* infection (Lindsay et al. 1983). The intestinal mucosa should be scraped with a scalpel or coverslip using just enough pressure to dislodge villi, and the scrapings should be prepared as a smear on a glass microscope slide. The smears are then stained with any of a number of routine blood stains.

The presence of paired type 1 merozoites (Figure 66.3d) is diagnostic. Other asexual stages (such as binucleated type 1 meronts or type 2 meronts and merozoites) and sexual stages (microgamonts and macrogamonts) will probably be present also, but their identification is more difficult and not needed for diagnosis. Histologic diagnosis of *C. suis* in tissue sections is possible (Lindsay

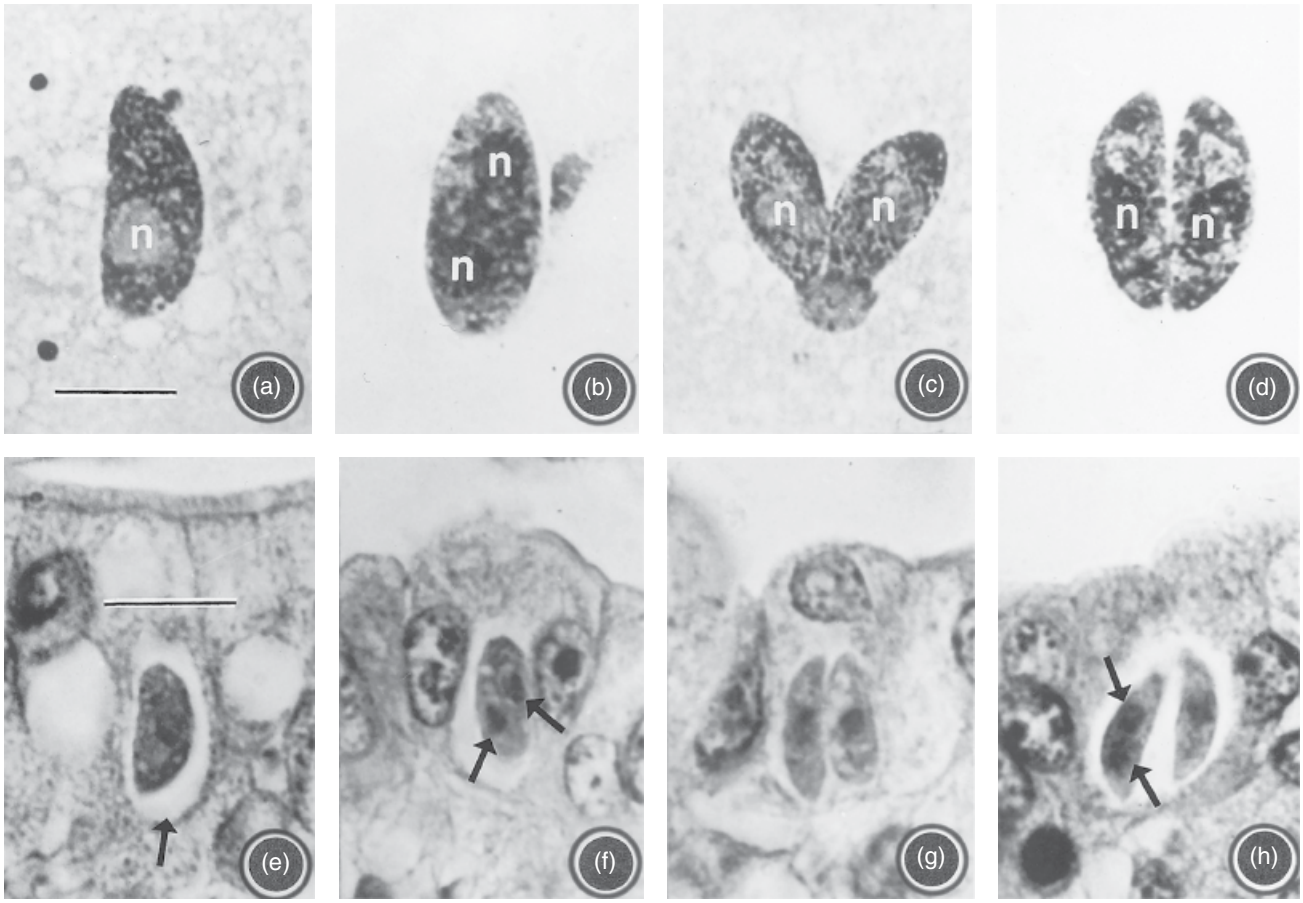

Figure 66.3 Diagnostic stages of *Cystoisospora suis* in Wright's Giemsa-stained intestinal smears (a–d: Bar = 5 µm) or hematoxylin-and eosin-stained histological sections (e–h: Bar = 10 µm). et al. 1983). As with mucosal smears, demonstration of paired type 1 merozoites is diagnostic (Figure 66.3e–h). The multinucleated type 2 meronts of *C. suis* are elongated and are often found in the same host cell. Finally, the macrogamonts of *C. suis* lack the characteristic prominent eosinophilic wall-forming bodies seen in *Eimeria* species.

Epidemiology: *Eimeria* species

Eight species of *Eimeria* occur in swine in the United States. Reports of coccidiosis in swine caused by *Eimeria* species are rare (Hill et al. 1985), but age-segregated rearing and changes in housing over the last few decades have increased the risk for outbreaks. Experimental studies have demonstrated that inoculation of large numbers of oocysts of *Eimeria debliecki*, one of the most common coccidian of swine, does not cause clinical disease (Lindsay et al. 1987). Reports of natural cases of *Eimeria spinosa*-associated disease in weaned pigs suggest that this species can cause disease under appropriate conditions in the field (Lindsay et al. 2002; Yaeger et al. 2003). Clinical coccidiosis can occur in finishing animals exposed to contaminated facilities and can occur in breeding stock that are born and reared in confinement and then exposed as breeding stock (Caudie et al. 2004; Henry and Tokach 2008).

Epidemiology: *Cystoisospora suis*

Once *C. suis* coccidiosis was recognized as a problem in nursing pigs, most veterinarians and researchers assumed that piglets were infected by ingesting *C. suis* oocysts from the sow's feces. However, studies have failed to confirm this assumption. Surveys of the swine population in the United States indicate that *Eimeria* infections are common (60–95%) in animals raised in lots or in the wild, but less than 3% of the animals sampled excrete oocysts of *C. suis* (Lindsay et al. 1984).

Another study examined the species of oocysts excreted by sows on farms with and without a history of *C. suis* infections in nursing pigs and reported that 82% of the sows on farms with a history of coccidiosis had *Eimeria* infections but no detectable *C. suis* infections, whereas sows from farms with no history of neonatal coccidiosis had an infection rate of 95% with *Eimeria* species and less than 1% with *C. suis* (Lindsay et al. 1984).

In the United States, Stuart and Lindsay (1986) examined the transmission of *C. suis* on two farms in Georgia. Daily fecal samples were collected rectally from sows 1 week prior to farrowing, the day of farrowing, and for about 1 week after farrowing. Colostrum and placentas from several sows were examined microscopically for parasites. A coccidiostat (amprolium HC1, Amprol 25% feed grade) was given to half of the sows on each farm. *Eimeria* species were the only coccidia seen in the feces of sows. None of the sows given amprolium HCl had oocysts in fecal samples at farrowing. No parasitic stages were seen in the colostrum or placentas examined. On Farm 1, 7 of 12 litters from nontreated sows and 9 of 12 litters from treated sows developed clinical coccidiosis. On Farm 2, all litters from nontreated sows and 11 of 12 litters from treated sows developed clinical coccidiosis. *C. suis* was the only species of coccidia seen in these piglets.

The results of these studies indicate that sows are not the primary source of *C. suis* infection for nursing pigs. It is still not known how *C. suis* becomes established on a farm; once it is established, it is probably transmitted through contaminated farrowing crates. The temperature (32–35 °C) and moisture in the farrowing crate favor rapid sporulation of *C. suis*.

Treatment and control

Anticoccidials

Sows do not appear to be a major source of infection for nursing pigs (Stuart and Lindsay 1986); therefore, using anticoccidial drugs in the sow's ration is of little value in controlling neonatal coccidiosis. Early studies that reported success with treating sows probably are due to improved sanitation once the producers were made aware that their pigs had coccidiosis. Studies that demonstrate anticoccidial activity of drugs in weaned or finishing pigs are of no value in predicting the ability of these drugs to control disease in nursing pigs.

Toltrazuril is an effective means of treating coccidiosis in nursing piglets. A single dose of 20 mg/kg given at 3 days of age decreases clinical signs (Skampardonis et al. 2010) and be cost effective (Scala et al. 2009). Toltrazuril's excellent activity is probably based on its ability to kill asexual and sexual stages of coccidia and because it is slowly released from tissues of treated animals.

Controlled studies conducted to date in nursing pigs have not identified other effective coccidiostats.

Sanitation

Improved attention to sanitation has been the most successful method for reducing losses due to neonatal coccidiosis in pigs (Stuart and Lindsay 1986). A good sanitation program entails thorough cleaning of the crates to remove organic debris, disinfection, and steam cleaning. In extreme cases, sealing or painting solid surfaces within farrowing crates can help break the cycle of reinfection by the hardy oocysts. Producers should limit access to farrowing crates by workers to avoid crate-to-crate contamination with oocysts carried on boots or clothing. Likewise, pets should be prevented from entering the farrowing house and spreading oocysts from crate to crate on their paws. Rodent populations should be controlled to prevent these animals from mechanically transmitting oocysts.

Facilities need to be sanitized after every farrowing. Producers should be made aware that even though clinical disease is under control, the potential for future outbreaks is still present.

Toxoplasmosis (*Toxoplasma gondii*)

Toxoplasmosis is caused by infection with *Toxoplasma gondii*, a protozoan parasite related to the coccidia. Infections are common in humans and warm-blooded animals (Dubey 2010). Postnatally, pigs or humans become infected by ingesting food and water contaminated with sporulated *T. gondii* oocysts or by consuming meat containing tissue cysts. Cats (and other felines) are the only animals that can excrete resistant oocysts in their feces and are important in the transmission of *T. gondii* to pigs and other animals (Figure 66.4). Tissue cysts are found in many edible tissues of infected pigs, and they contain bradyzoites, which are slowly multiplying stages (Figure 66.5b). Tissue cysts remain viable in pork for many years and probably the life of the pig. After ingestion, oocysts or bradyzoites can survive passage through the stomach. Once in the intestine of the host, sporozoites or bradyzoites change into a fast-multiplying stage called tachyzoites (Figure 66.5a). Tachyzoites multiply in the lamina propria of the intestine and eventually spread throughout the body. Prenatal infection may occur if the mother is infected during pregnancy. Tachyzoites from the mother's blood may cross to the fetus via the placenta. Tachyzoites cause tissue damage and eventually develop into the bradyzoite stage and form tissue cysts. Toxoplasmosis is a zoonosis, and pork is considered a source of *T. gondii* infection for humans in many countries (Dubey et al. 2005; Dubey 2009). Although the prevalence of *T. gondii* in feeder pigs in the

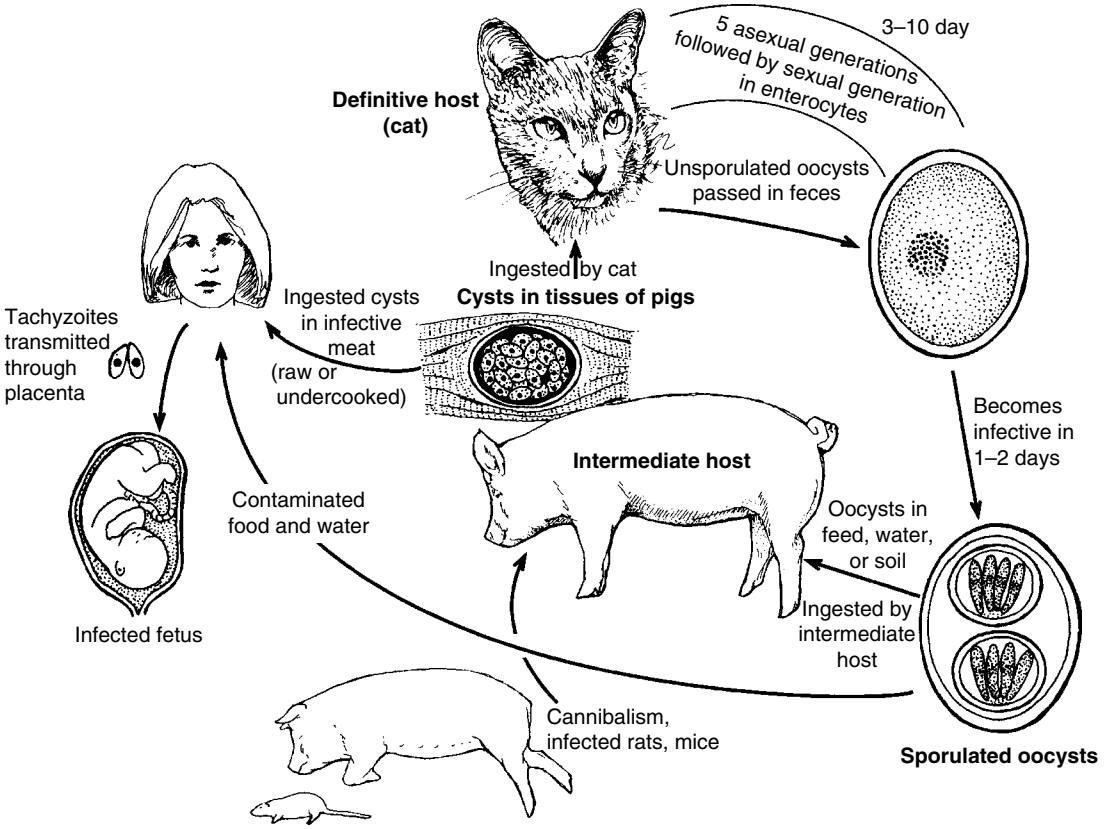

Figure 66.4 Life cycle of *Toxoplasma gondii*.

United States is declining, there are still small pig establishments with *T. gondii* infection.

Clinical signs

Infections in swine are usually subclinical (Dubey 1986). Abortions due to *T. gondii*, although uncommon, may occur in sows infected during pregnancy. Transplacentally infected pigs may be born premature, dead, or weak, or they may die soon after birth. Pigs that live may develop diarrhea, incoordination, tremors, or cough. Few reports exist on clinical disease in pigs that acquire infection postnatally, but epidemics of clinical toxoplasmosis have been observed in both young and adult pigs. Experimental studies indicate that ingestion of *T. gondii* oocysts by pigs is more likely to produce clinical disease than ingestion of tissue cysts (Dubey 1986). Severity of disease is dependent upon the number of oocysts ingested, and older pigs are less likely to develop clinical disease.

Pathologic changes

Pathologic changes are associated with necrosis of host tissue caused by the rapidly multiplying tachyzoites. Enteritis, lymphadenitis, splenitis, hepatitis, pneumonitis, and less frequently myositis and encephalitis are seen in naturally infected pigs (Dubey 1986, 2009).

Diagnosis

Several serologic tests are available for determining antibodies to *T. gondii* in pigs. The modified direct agglutination test is the most sensitive and specific for the detection of latent *T. gondii* infection in swine (Dubey et al. 1995a). Although finding *T. gondii* antibody in adult pigs only means exposure to *T. gondii*, finding antibody in a fetus indicates congenital infection because maternal antibodies are not transferred to the fetus in pigs. Histologic examination of tissues may be utilized for a presumptive diagnosis based on lesion characteristics and parasite structure (Figure 66.5a and b).

Epidemiology

The prevalence of congenital *T. gondii* infection in pigs is less than 0.01%. Prevalence of *T. gondii* antibodies in feeder pigs (younger than 6 months) is lower (<1%) than in sows (15–20%) based on large-scale surveys (Dubey et al. 1995b; Weigel et al. 1995). *T. gondii*-infected cats and infected rodents were identified as the main sources of *T. gondii* infection for pigs (Weigel et al. 1995). Cats become infected with *T. gondii* by ingesting infected animals (rodents, birds) soon after weaning. Therefore, infected juvenile cats are considered to be the main source of *T. gondii* for farm pigs.

Treatment and control

Because porcine toxoplasmosis is usually subclinical, little is known about the treatment of the disease in swine. Ponazuril (closely related to toltrazuril) is effective against acute toxoplasmosis in mice and should also be effective in swine.

Control of *T. gondii* infection in pigs is important because of public health concerns over human infections. Toxoplasmosis causes mental retardation and loss of vision in congenitally infected children. Following experimental infection, viable tissue cysts of *T. gondii* can be found in most commercial cuts of pork, and studies have shown that the tissue cysts will be viable infected pigs for at least 2.5 years (Dubey 1988). Cooking and freezing pork will inactivate tissue cysts.

Prevention of *T. gondii* infection in pigs can be achieved by practicing good husbandry. There is no vaccine. To prevent oocyst-induced infections, cats should never be allowed in buildings where pigs are housed or where feed is stored. Rodenticides should be used to control rodents and eliminate this possible source of tissue cysts. Any pigs that die should be removed promptly to prevent cannibalism. Uncooked garbage should never be fed to pigs. Feed should be kept covered to prevent cats from defecating in it.

Sarcocystis

Sarcocystis spp. are coccidian parasites that have a two-host life cycle. Three species use pigs as the intermediate host and form tissue cysts (sarcocysts) in the pig muscles. *Sarcocystis miescheriana* has a pig–dog life cycle and is the only species found in the United States. Dogs excrete infective stages (sporocysts) in their feces. The other species are *Sarcocystis suihominis*, which uses the human as the definitive host, and *Sarcocystis porcifelis*, which uses the cat as the definitive host (Dubey et al. 1989). Surveys indicate that from 3 to 18% of commercial breeding sows razed outdoors and 32% of wild swine examined in the United States have *Sarcocystis* infection (Dubey and Powell 1994). There are no reports of naturally occurring clinical disease due to *Sarcocystis* infection in swine (Dubey et al. 1989; Stentiford et al. 2016) (Figure 66.6).

Cryptosporidium

Cryptosporidium species are prevalent and ubiquitous parasites of humans and animals worldwide. These obligate intracellular protozoan parasites of vertebrates range from host-restricted species to species capable of infecting a wide range of hosts (Fayer 2010). Porcine cryptosporidiosis has been reported to occur worldwide.

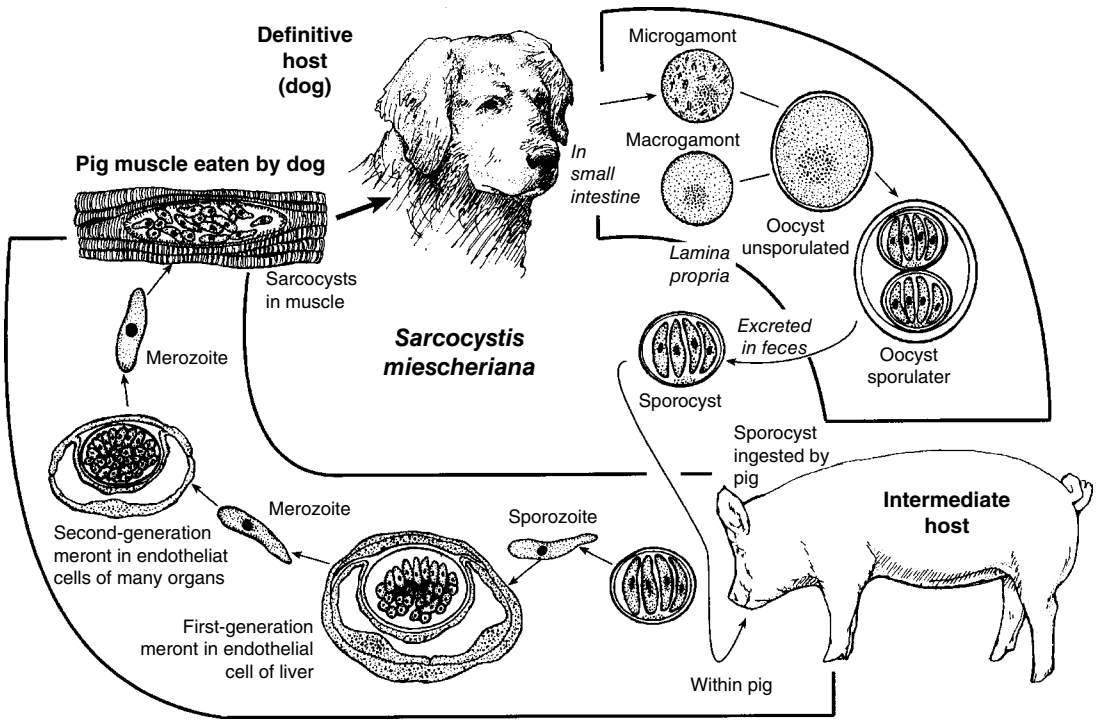

Figure 66.6 Life cycle of *Sarcocystis miescheriana*.

Although pigs have been reported to be susceptible to at least seven different species or genotypes, the most frequently found species in naturally infected pigs are host-specific species *Cryptosporidium suis* and *Cryptosporidium scrofarum*. Infections in pigs with the other species only occur occasionally.

Life cycle

Infection begins with ingestion of the oocyst stage after direct contact with feces or from contaminated food or water (Figure 66.7). Four sporozoites are released from each oocyst (diameter approximately 5 µm) in the intestinal lumen where they enter cells lining the small intestine. All endogenous stages are intracellular but extracytoplasmic, appearing to be on the luminal surface of the mucosal epithelial cells. There are two or more asexual generations, each generation producing merozoites that invade additional gut epithelial cells. Merozoites eventually give rise to male and female stages. Fertilized female stages develop into oocysts that mature internally and are infectious when passed in the feces. Generally, prepatent period ranges from 2 to 9 days with oocysts excreted for 9–15 days for *Cr. suis* infections, while prepatent period ranges from 4 to 6 days with oocysts excreted for more than 30 days for *Cr. scrofarum* infections.

Cryptosporidia: clinical signs

A wide range of clinical features has been reported for cryptosporidiosis in pigs, possibly reflecting differences among the *Cryptosporidium* isolates that cause infection in pigs (Santín and Trout 2008). Clinical signs, including inappetence, depression, vomiting, and/or diarrhea, were observed after experimental infection of piglets with oocysts derived from calves (most likely *Cryptosporidium parvum*). However, cryptosporidiosis in pigs does not always result in clinical signs. In the absence of molecular analysis, it is not possible to determine which *Cryptosporidium* species or genotypes were responsible for which infections. When the species or genotype was known, infections from *Cr. suis* or *Cr. scrofarum* were less severe than those from *Cr. parvum*. Clearly, identification of the species and genotypes is needed to establish the pathogenicity and host affinity of different *Cryptosporidium* isolates from pigs. Additionally, concomitant infection with other pathogens such as *C. suis* or viruses can influence the severity of infections. For example, incidental coinfection with rotavirus apparently resulted in severe clinical signs and the deaths of piglets experimentally infected with *Cr. suis*, whereas rotavirus-free piglets had mild signs.

Detection and diagnosis

Microscopy, fecal antigen ELISA, and PCR, with or without recovery and concentration of oocysts, have been used. However, recovery of oocysts from pig feces has been problematic with consistently lower recovery than from feces of other animals. Sucrose, cesium chloride, and other flotation media are effective in concentrating oocysts by density gradient centrifugation and reducing fecal debris.

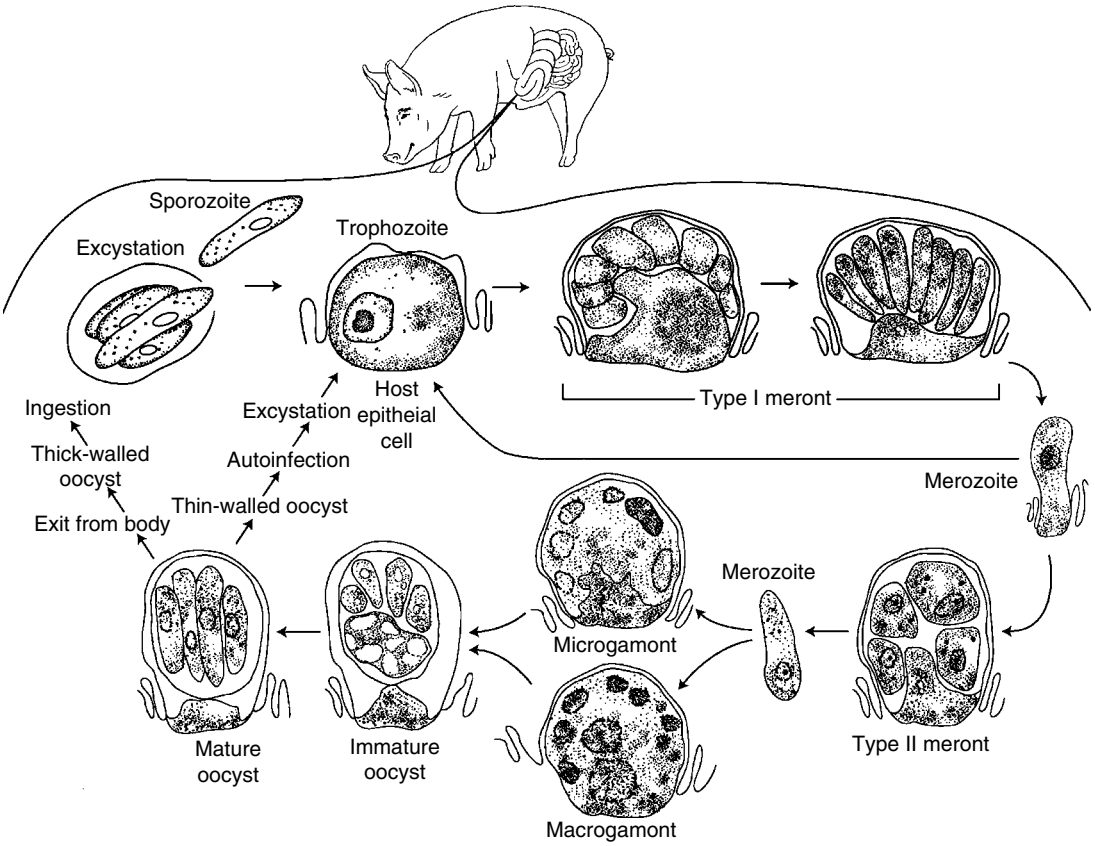

Figure 66.7 Life cycle of *Cryptosporidium*.

Because most oocysts of *Cryptosporidium* species and genotypes are nearly spherical, range in size from 4.5 to 5.5 µm in diameter, and have no distinguishing features, microscopy can be used only to determine the presence of oocysts. Definitive identification of species and genotypes requires the use of molecular techniques such as gene sequencing or PCR-RFLP. Pigs can harbor multiple species and genotypes, including *Cr. parvum*, which are infectious for humans. Therefore, molecular analysis is needed to evaluate the risk of human infection (Table 66.1).

Developing stages of *Cryptosporidium* have been reported throughout the intestinal tract, with lesions of varying degrees of villous atrophy, villous fusion, cellular infiltration of the lamina propria, and, infrequently, sloughing of epithelial cells. All species examined appear to cause similar types of damage, but lesions from *Cr. parvum* seemed most severe, reflected by the more significant clinical signs.

Epidemiology

Cryptosporidium has been found in pig of all ages. In the farm environment, pigs become infected predominantly with *Cr. suis* and *Cr. scrofarum*. Field studies have shown that *Cr. suis* and *Cr. scrofarum* differ in the age of pigs that they infect. *Cr. suis* appears to infect all age groups with lower prevalence in older pigs, while *Cr. scrofarum* appears to be specific for older pigs. Occasionally *Cr. parvum* has also been reported in natural infections. Pigs have been experimentally infected with *Cr. parvum*, *Cr. hominis*, and *Cr. meleagridis*.

Regarding zoonotic potential, *Cr.* parvum is not highly prevalent in pigs, and although sporadic cases of *Cr. suis* and *Cr. scrofarum* have been reported in humans, the risk that pigs pose as a source for human infections is apparently limited.

Treatment

Disinfection of the environment is difficult because oocysts are numerous, can remain infectious for months, and are extremely resistant to a broad range of chemicals. Heat, drying, and sunlight are most effective at inactivation oocysts. No drugs have been proven effective for treating *Cryptosporidium* in swine.

Other protozoa of minor importance or potentially transmissible to humans

Giardia

Giardia duodenalis (synonyms *G. lamblia* and *G. intestinalis*) is possibly the most common intestinal parasite of

Table 66.1 Species and genotypes of *Cryptosporidium*, *Giardia*, and *Microsporidia* found in swine and their zoonotic potential.

Species	Genotype/assemblage	Zoonotic
Cryptosporidium suis		Yes
Cryptosporidium scrofarum		Yes
Cryptosporidium parvum		Yes
Giardia duodenalis	A	Yes
Giardia duodenalis	E	No
Encephalitozoon cuniculi	III	Yes
Encephalitozoon intestinalis		Yes
Enterocytozoon bieneusi Infects many mammals including humans and pigs, 14 genotypes	D, I, O, BEB4, CALF1, CS-4, EbpA, EbpC, EbpD, Henan-III, Henan-IV, LW1, PigITS5, PigEBITS7	Yes
Enterocytozoon bieneusi Infects only pigs, 42 genotypes	CHN7-CHN10, CS-2, CS-3, CS-5-CS10, E1, EbpB, F1, HLJ-I-HLJ-IV, PigEBITS1- PigEBITS4, PigEBITS6, PigEBITS8, PigEb1-PigEb17	No
Enterocytozoon bieneusi Infects pigs and other mammals (no humans), four genotypes	CC-1, CS-1, G, H	No

humans and livestock worldwide. It is a species complex consisting of eight assemblages (A–H) that are morphologically indistinguishable, and molecular methods are used to determine assemblages. Only assemblages A and B infect humans, are zoonotic, and occur in a wide range of mammals. Other assemblages infect specific groups of animals: assemblage E infects swine and other livestock, while C and D infect dogs, F infects cats, G infects rodents, and H infects seals.

The life cycle involves two stages, the trophozoite and cyst stage. Trophozoites are flagellated, pyriform-shaped protozoa that attach to the brush border of cells lining the small intestine where they absorb nutrients and multiply by binary fission (Figure 66.8). Trophozoites encyst in the small or large intestine and pass in the feces as environmentally resistant cysts. Freshly excreted cysts are immediately infectious and can remain infectious under moist and cool conditions for weeks. Trophozoites excreted in feces do not survive outside the body. *Giardia* is transmitted by ingestion of food or water contaminated with cysts.

In the United States, no association was found between *Giardia* infections and clinical illness in pigs (Xiao et al. 1994). Likewise, on European farms, no clinical signs were associated with the presence of *Giardia* in pigs (Petersen et al. 2015).

Detection of motile trophozoites (10–20 µm long) can be seen in saline suspensions of loose or diarrheic feces. Ovoid to ellipsoid cysts (9–15 µm long) are best detected after concentration in feces using zinc sulfate flotation (specific gravity 1.18). Sucrose and sodium chloride flotation media are effective but hypertonic, distorting cysts if examination is not made quickly. Because cysts might be excreted intermittently, multiple fecal samples should be collected and examined at intervals within a week. Assemblages are determined based on genetic markers.

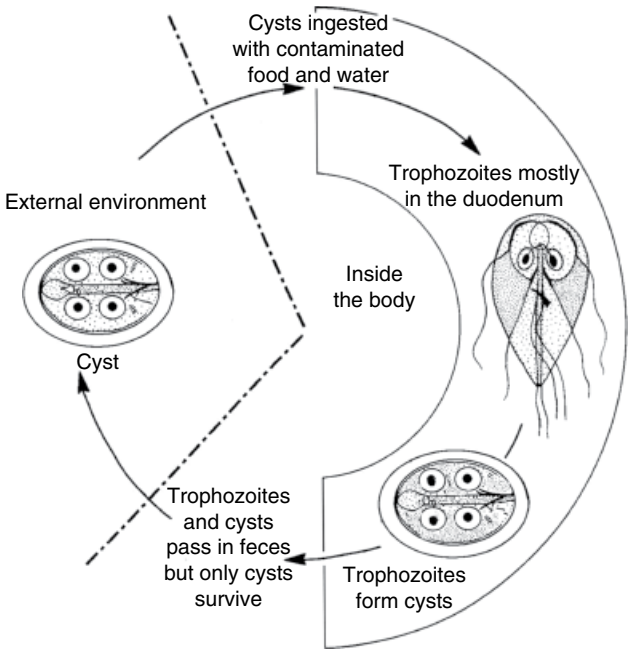

Figure 66.8 Life cycle of *Giardia*.

The role of swine and other domestic animals as sources for *G. duodenalis* in humans is unclear. *Giardia* infections have been reported in pigs in all age groups from nursing piglets to boars and sows in the United States, Canada, Europe, Australia, Africa, and Asia with the prevalence ranging between 0.1 and 20% (Armson et al. 2009). In Ohio *Giardia* was detected in 8.3% of

pre-weaned piglets, 2.6% of post weaned pigs, and 1.5% of sows (Xiao et al. 1994). Surveys worldwide indicate that most pigs infected with *Giardia* have assemblage E with few having other assemblages.

No drugs are approved for treating giardiasis in swine. However, fenbendazole and albendazole have been used to treat *Giardia* in dogs. Cysts are infectious when passed in the feces but can be rendered noninfectious by desiccation, many quaternary ammonium compounds, laundry bleach, and boiling water. After cleaning and treating contaminated spaces, thorough drying is recommended. Cysts in hog liquid manure holding tanks were found degraded, suggesting it is unlikely that distribution of liquid manure poses a serious threat for giardiasis from contamination of surface water (Guselle and Olson 1999).

Microsporidia

There are approximately 1200 named species of Microsporidia, a diverse group of obligate intracellular parasites once regarded as protozoa but now recognized as fungi. Most species infect invertebrates and fish, but at least 14 species in 10 genera have been reported to infect humans (Stentiford et al. 2016). Of these, *Enterocytozoon bieneusi* and *Encephalitozoon* spp. (*Encephalitozoon cuniculi* and *Encephalitozoon intestinalis*) are described as opportunistic pathogens in humans and have been reported in pigs, and other animals, suggesting the zoonotic potential of these parasites. *E. bieneusi* is the most frequently diagnosed species in swine and humans worldwide. It has been identified in swine in many countries, but its prevalence in pigs in the United States is not well studied. *E. bieneusi* is a complex species with multiple genotypes (Santín-Duran 2015). Surveys have demonstrated that pigs can serve as hosts for 60 *E. bieneusi* genotypes (Table 66.1). Most genotypes identified in swine are swine specific, but 14 genotypes identified in humans have also been identified in pigs. *E. cuniculi* genotype III has been reported in swine in Germany, and *E. intestinalis* in Mexico, Spain, and Slovakia; however none these two species have been reported in swine in the United States.

The life cycle stages of microsporidia are depicted using *E. bieneusi* as an example (Figure 66.9). All are intracellular, in direct contact with the host cell cytoplasm, and consist of binucleate cells, sporogonial plasmodia, uninucleate sporoblasts, and spores (Santín and Fayer 2011). Spores (1.5 × 0.5 µm) are the infective stage and are excreted in feces. Internally, spores have a polar tube with 5–6 coils, a single nucleus, and an anterior attachment complex extending to a polaroplast. After a spore is ingested, the coiled polar tube discharges, injecting the sporoplasm and nucleus into the host cell. Young proliferative stages become elongate and undergo nuclear division. Proliferative plasmodial cells contain

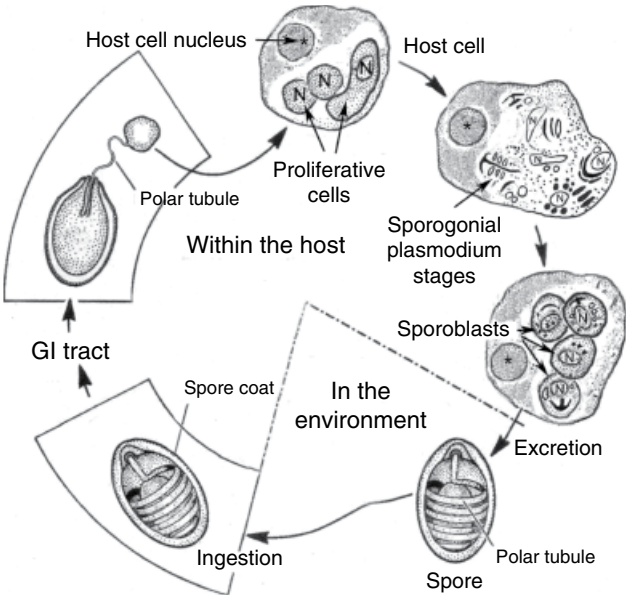

Figure 66.9 Life cycle of *Enterocytozoon bieneusi*.

multiple elongated nuclei. Later, sporogonial plasmodium develops disks, some in stacks or arcs in stages of polar tube formation. Individual nuclei with polar tube complexes segregate and mature into separate sporoblast cells that develop into mature spores. Spores released from host cells are excreted with feces into the environment where they can be ingested by the next host.

The role of microsporidia in clinical disease in swine is unclear. Disease due to microsporidia in humans occurs in immunocompromised patients. *E. bieneusi* has been detected in feces from asymptomatic pig and some pigs with diarrhea. No well-documented clinical cases have been reported. Whether certain genotypes are pathogenic whereas others are not is still unknown.

Detection of microsporidia infection is difficult because the spores are very small (1.5 × 0.5 µm). Spores can be detected by microscopic techniques used in specialized laboratories. Serological tests such as ELISA and indirect immunofluorescent antibody (IFA) microscopy can be used to detect antibodies against *E. cuniculi* and *E. intestinalis*. Specific and sensitive molecular methods are used to identify *E. bieneusi* and *E. cuniculi* genotypes. Although these tests are not routinely used in clinical diagnostic laboratories, they are widely used in research and some government public health laboratories.

Because a high prevalence of *E. bieneusi* has been reported in pigs and zoonotic genotypes detected, pigs are consider as reservoirs for potentially zoonotic microsporidia. Transmission of the spores in contaminated food and water maintains the parasites once they are introduced on a farm. Fortunately, the spores are readily killed by most common disinfectants and normal chemical

treatment of municipal water. Treatment of human patients using the anthelmintic albendazole is effective for *Encephalitozoon species* but not effective for treatment of *E. bieneusi*.

Balantidium coli

Balantidium coli is a ciliate found in pigs and in humans. Cysts that are excreted in the host's feces transmit it. The cysts are 50–70 µm in diameter and contain a macronucleus and a micronucleus. No division occurs in the cyst. Trophozoites are covered in short cilia, are up to 100 µm long, and also contain a macronucleus and a micronucleus. Trophozoites are usually found in the lumen of the large intestine.

Most infections in swine and humans are subclinical. Estimates of the prevalence in swine raised in the United States under modern production conditions are not available.

Studies conducted in the 1980s found that infection rates increased with pig age and that animals raised on pasture or dirt lots had higher infection rates than swine raised in confinement. Human infections with *B. coli* are more prevalent in areas where swine are present (Schuster and Ramirez-Avila 2008).

Entamoeba species

Amoeba in the genera *Entamoeba* has been reported in pigs in various parts of the world. The prevalence of these parasites in the US swine population is not known. Swine are not a significant reservoir for *Entamoeba histolytica*, the most pathogenic species in humans. Recent reports from Japan indicate that *E. polecki* is associated with chronic diarrhea and poor growth in young (50–70-day-old) pigs (Matsubayashi et al. 2015). This amoeba also infects humans, but little is known about the disease ecology of this parasite.

Internal Parasites

Helminths

Matthew T. Brewer and John H. Greve

Introduction

Internal parasites are common pests of swine worldwide. Controlled trials with nematode infections consistently demonstrate a reduction in average daily gain (ADG) and increase in feed to gain ratio (F/G) of infected pigs compared with their controls. In addition, internal parasites can generally compromise vigor and may act synergistically with other endemic potential pathogens. The extent of these losses depends on the quality of nutrient intake, type of housing, climate in the geographic area concerned, genetics of the swine, and veterinary costs associated with these infections. Premises heavily contaminated with thousands of infectious eggs or larvae from previous endemic infections can cause severe disease when encountered by a naïve animal. More often, subtle subclinical infections lead to insidious production losses that are substantial over time. This chapter addresses helminths, whereas ectoparasites and protozoa are addressed in Chapters 65 and 66, respectively.

Historically, schemes for parasite control incorporate sanitation, anthelmintics, and management practices aimed to reduce condemnations and production losses. While modern swine production facilities have decreased parasitism by denying pigs access to soil and/or parasite intermediate hosts, some helminths still persist due to their high fecundity and environmental stability. For example, despite the availability of efficacious anthelmintics, *Ascaris suum* remains as one of the most prevalent swine parasites throughout the world. On the other hand, pigs raised with access to soil continue to serve as hosts for a variety of internal parasites. Recent resurgence of extensive or outdoor production practices offers risk for reemergence of parasite concerns. Application of specific management practices from the last century and previous editions of this book may have merit, particularly because effective alternatives to licensed anthelmintics have not been documented.

Digestive system

The digestive system offers the most convenient entry into and exit from the host; therefore a myriad of parasites have evolved using this system as their niche. The mouth is a chaotic environment and hence is not often parasitized. However, all other levels for the digestive tract harbor helminth parasites.

Esophagus

Gongylonema pulchrum, the esophageal worm, is a spiruroid nematode occurring in tunnels burrowed into the epithelium covering the esophagus and occasionally the lingual or buccal mucosa. The tunnels are usually aligned with the longitudinal axis of the esophagus and form a sine wave appearance along their length. The males are 60 mm long, and the females about 90 mm long when removed from their tunnels. Oval-shaped eggs (55–65 × 30–35 µm) are transparent, contain a developed larva, and are passed in the host's feces. Infective L3 larvae develop when the eggs are ingested by coprophagous beetles or cockroaches, and pigs become infected when they ingest the insect intermediate host. *Gongylonema* cause minor inflammation as they glide back and forth in their tunnels. Their main importance is at slaughter, where tissue is trimmed if the lesion is discovered. Ruminants and humans are also susceptible to *G. pulchrum*, but they must ingest the intermediate host insect to become infected, so trimming of affected tissue is for appearance sake.

Stomach

Five nematode genera occur within the stomach. One, *Hyostrongylus*, is moderately common, but the other

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

four (*Ascarops*, *Physocephalus*, *Gnathostoma*, and *Simondsia*) are less common and limited geographically.

Hyostrongylus

Hyostrongylus rubidus, the red stomach worm, is a trichostrongyloid nematode occurring unattached on the mucosa of the lesser curvature of the stomach. Adults are the width of a hair and less than 10 mm in length. The eggs have typical strongyle structure (ovoid, thin shelled, transparent, 60–76 × 30–38 µm) containing the 16- to 32-cell stage when laid. These strongyle eggs resemble those of *Oesophagostomum* and *Globocephalus*; their differentiation requires careful measurement of eggs and harvest of infective ensheathed L3 larvae from incubated fecal cultures (Honer 1967). Eggs are passed in the feces and develop to infective larvae in about 7 days. The larvae migrate away from feces and onto grass where they are subsequently ingested by swine. Thus, the life cycle is direct, and hyostrongylosis is a disease of pastured swine. The ingested larvae enter gastric glands, undergo two molts, and reemerge into the gastric lumen. Some larvae may remain in the gastric glands in a state of hypobiosis, causing nodular distension of the affected glands. Hypobiotic larvae may enter the gastric lumen at a later time and mature into adult worms.

Although *H. rubidus* is reported from many areas of the world, little is known about the pathogenicity of this parasite. They suck a small amount of blood, leading to catarrhal gastritis and potential mucosal erosion. *H. rubidus* may be a factor in the pathogenesis of gastric ulceration, and these changes in the gastric mucosa can impact feed conversion and weight gains (Stewart et al. 1985).

Spiruroid stomach worms

Other stomach worms, such as *Physocephalus sexalatus*, *Ascarops strongylina*, *Gnathostoma spinigerum*, and *Simondsia paradoxa,* are spiruroid nematodes. They are stouter in appearance than *Hyostrongylus* and approximately 20 mm in length. The adults are attached by mouth to the mucosa, but this attachment causes no visible damage except for excessive mucus production. Female *Simondsia* have anterior ends that enter the gastric glands so that only their bulbous posterior is visible.

The life cycles of these four spiruroids, so far as is known, are all similar to one another. The typical spiruroid eggs (thick shelled, transparent, ovoid, contain a larva) pass in the feces where they are ingested by coprophagous beetles. The eggs (30–40 × 15–20 µm) resemble, but are slightly smaller than, eggs of *Gongylonema* (55–65 × 30–35 µm). Infective L3 larvae develop in beetles that are subsequently ingested by pastured swine.

Small intestine

Strongyloides

Strongyloides ransomi, the minute threadworm, is a rhabditoid nematode that has a cosmopolitan distribution but is more rarely present in modern indoor swine production facilities. It is particularly pathogenic in suckling pigs and has a greater importance in tropical and subtropical climates.

These minute (3–5 mm long) hairlike nematodes live embedded in the epithelium of the small intestine. Parasitic females are parthenogenetic and lay thin-shelled, transparent, embryonated eggs that are shed in feces. Rhabditiform larvae hatch in a few hours and may progress to either infective third-stage female filariform larvae (homogonic cycle) or free-living rhabditiform males and females (heterogonic cycle). The offspring of the free-living heterogonic cycle may become either rhabditiform free-living individuals or filariform infective parasitic females. Male individuals are not parasitic. Factors that determine whether individual nematodes undergo heterogonic or homogonic development are studied but poorly defined, with environmental factors such as availability of food and moisture suspected to influence which developmental pathway is taken.

Infective larvae typically infect the next host by penetration of the skin or the oral mucosa to gain access to the capillaries and carried by the bloodstream to the lungs where they are coughed up and swallowed (tracheal migration). This process results in a patent infection in 6–10 days. The most important route of infection in neonatal pigs is transcolostral (Moncol 1975). In sows, larvae accumulate in a hypobiotic state in the mammary fat until the time of parturition, whereupon the larvae become mobilized, enter mammary alveoli, and are shed in colostrum and milk. *S. ransomi* acquired by the lactogenic route produce a patent infection in 2–4 days. It is thought that piglets may also acquire larvae transplacentally; however, the lactogenic route is probably the most important. Piglets separated from their dam at birth are worm-free as opposed to nursing littermates.

Lesions are dependent on the number of infective larvae acquired and on the host's resistance. It is not uncommon to find a small number of *Strongyloides* without associated lesions. However, the adult nematodes are so small that they may be difficult to identify amid ingesta. Heavy infections in juvenile animals can lead to poor rate of gain, hemorrhagic diarrhea, and death. Immunity develops following exposure to larvae and is typically age related.

Diagnosis of patent infections is by observation of embryonated (larvated) eggs in fecal flotation procedures (Figure 67.1). However, these larvated eggs must be differentiated from other parasites such as spiruroids. This can be accomplished by culturing eggs to allow

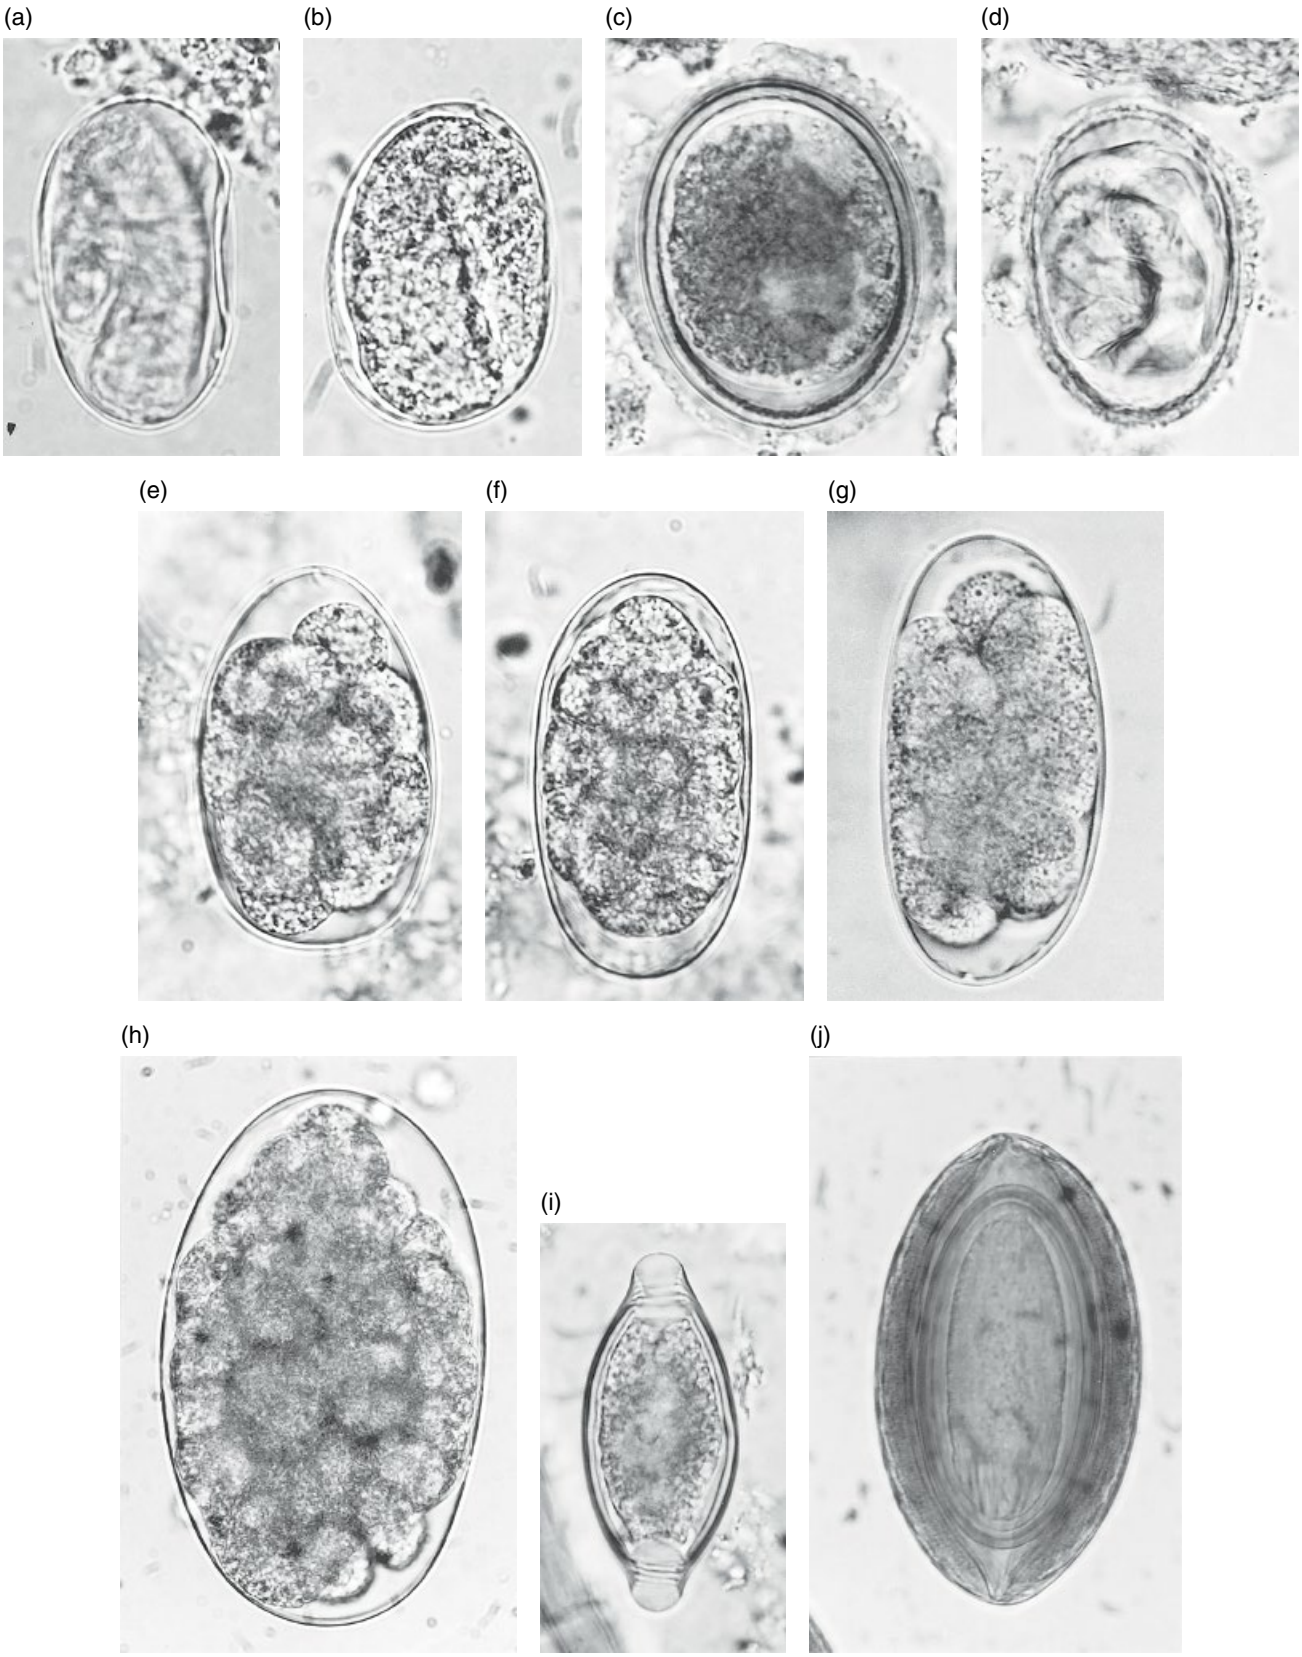

Figure 67.1 (a) *Strongyloides* egg, thick shelled, lacking one of three layers, and larvated. (b) *Ascarops* egg, larvated and similar morphologically to those of *Physocephalus* and *Gongylonema*. (c) The *Ascaris* egg has an outer proteinaceous layer, often missing. (d) *Metastrongylus* egg. (e) *Oesophagostomum* egg. (f) *Hyostrongylus* egg. (g) *Globocephalus* egg. (h) *Stephanurus dentatus* egg passed in the urine. (i) *Trichuris* egg. (j) *Macracanthorhynchus* egg. (All eggs photographed and printed at the same magnification.)

hatching and observation of rhabditiform L1 larvae. Adult *Strongyloides* may be found in mucosal scrapings, but the adults are very small (3–5 mm) and may be confused with larval stages of other nematodes. Squash preparations revealing typical eggs help address this problem as *Strongyloides* larvae do not have eggs.

Ascaris

Ascaris suum is the large roundworm and most cosmopolitan parasite of swine. *Ascaris* has persisted despite decades of pharmaceutical intervention and modern confinement systems. *A. suum* is a close relative to the human ascarid, *Ascaris lumbricoides*, and it is proposed that these two nematodes are a single species. *Ascaris* isolated from pigs is capable of infecting humans, and recent analysis of nuclear and mitochondrial genes from worms obtained from pigs suggests that human, swine, and hybrid genotypes are present (Jesudoss et al. 2017). If swine have access to soil, one can assume they are infected with *Ascaris* because of the ubiquitous nature of the nematodes and the extreme longevity of the eggs in the environment. Producers often assume that pigs are infected and administer anthelmintics, even without specific proof.

Ascaris suum adults can be easily observed at necropsy due to their large robust size (Figure 67.2): females are up to 40 cm in length, and males can be up to 25 cm. Adults live unattached in the lumen of the small intestine, swimming against peristalsis. It is proposed that *A. suum* maintains its position in the intestine by pushing up against opposing sides of the lumen. Adults mate and produce eggs that are thick and barrel shaped (50–80 × 40–60 µm). The colorless thick shell is coated with a sticky, brownish, mammillated proteinaceous layer and contains a single large cell. Females shed thousands of eggs over their lifetime of approximately 6 months. The eggs are resilient and long lived, so the environment is likely to be heavily contaminated wherever swine exist.

Life cycle

The life cycle is direct, with eggs passing in feces and developing infectivity over a period of approximately 3–4 weeks. The infective larva remains inside the protective egg, sheltered from potentially lethal environmental extremes until the egg is ingested. After ingestion, larvae hatch from the egg, penetrate the jejunal wall, and are carried by portal circulation to the liver. A few larvae may be found wandering in the mesenteric lymph nodes, peritoneal cavity, and elsewhere, but such wandering larvae probably do not complete their life cycle. Most larvae reach the liver 1–2 days postinfection and are then carried to the lungs via the blood 4–7 days postinfection. After molting and spending a few days in the lungs, larvae exit the pulmonary capillaries, breaking into the airways. Larvae are coughed up, carried to the pharynx by the mucociliary escalator, and then swallowed. Adult nematodes can be found in the small intestine 10–15 days after ingestion of infective eggs. Oviposition begins around 6–7 weeks after infection.

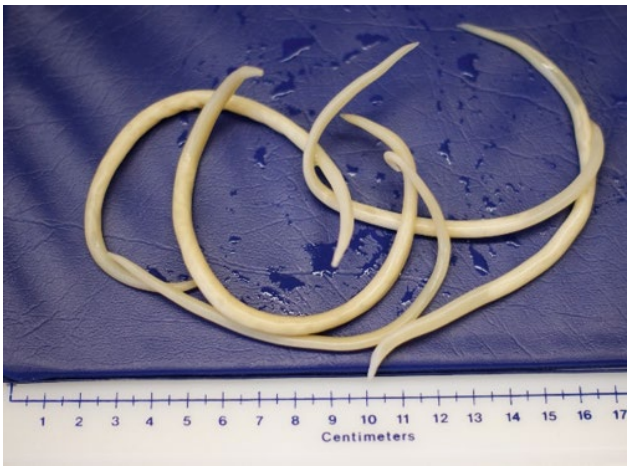

Figure 67.2 *Ascaris suum* adults removed from the intestine of a pig.

Eggs are very resistant to temperature extremes and may remain infective for years. Most chemicals have no effect on eggs, but steam may affect their viability. Because of the sticky outer layer of the egg, eggs are easily transported by boots, insects, and other means. It is thought that most piglets are exposed when they ingest eggs in manure stuck to the sows' udder.

Senescent ascarids are expelled in feces, but swine may continue to carry a small number of worms for several months. Ascarids often occur in young pigs, and by the time swine are 5–6 months old, they are often resistant to infection due to previous exposure to migrating larvae and/or by reason of age resistance. Pigs previously exposed mount an immune response, leading larvae to be trapped in foci of granulomatous inflammation. The larvae of *A. suum* are aggressive migrators and can cause visceral larva migrans in accidental hosts. The migrating larvae may cause serious verminous pneumonia or other inflammatory disease due to a prolonged migration or larval death, for example, in cattle housed in facilities previously dedicated to swine.

Pathology

Adult ascarids compete with the host for nutrients and probably interfere with nutrient absorptions as they browse on the tips of the villi, thereby causing insidious production losses. Adult ascarids swim against peristaltic waves to maintain presence and can occasionally wander up and occlude the bile duct or even approach the liver capsule. It has been hypothesized that bile duct occlusion can occur postmortem; however, ascarid occlusion of the bile duct should be considered as a potential cause of icterus in swine.

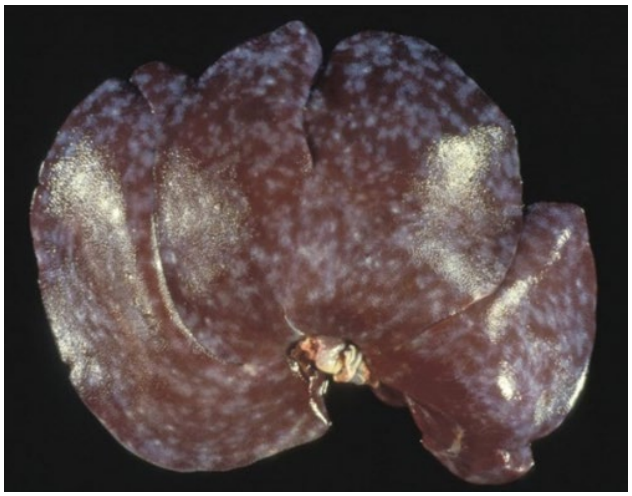

Figure 67.3 Multiple foci of fibrosis, the result of ascarid larval migrations ("milk spot liver").

In contrast to adult worms, the pathology damage associated with the migrations of larval stages of *A. suum* to the liver and lungs is substantial. Repeated waves of migrating larvae lead to an exuberant inflammation and immune response against larval antigens. In the liver, larvae migratory paths are infiltrated by eosinophils and fibrotic connective tissue that appears grossly as "milk spots." Lesions in the liver become visible 7–10 days postinfection and can expand or be variable in size if continued migrations occur. In low infestations, the "milk spots" can regress within 25 days if the liver does not experience further larval insult (Figure 67.3). Severe and ongoing infections result in diffuse liver fibrosis. Liver enzymes may be increased as a result of infection. In the lungs, larval migration is associated with petechial hemorrhages due to larvae breaking out of the capillaries and into the alveoli. Interstitial pneumonia, bronchiolitis, and alveolar edema also occur in the areas of larval migration. In mild cases, pigs are asymptomatic; however, more severely affected pigs have a characteristic expirational abdominal lift known as "thumping," sometimes with increase in cough. Most pigs become infected early in life, with immune mitigation of clinical signs. If naïve pigs are 20 kg or larger before first exposure, the pulmonary reaction may be extreme with life-threatening clinical signs similar to those of respiratory disease complex. Indeed, ascarid larval migrations may compromise the lung and exacerbate impact of other endemic viral and bacterial pathogens in the herd. The ingestion of infective eggs often occurs at low level over time, so lesions of larval migration can occur simultaneously with the presence of adults, which will continue until an immunological response develops.

Diagnosis

The diagnosis of *Ascaris* is straightforward when dealing with patent infections since the prodigious oviposition rate of the female makes eggs easy to find by standard flotation methods. At necropsy, the presence of milk spots in the liver is evidence that the animal has been infected with ascarid eggs within the past month. Early punctate lesions gradually expand in size before resolving in about 30 days. In areas where the swine kidney worm, *Stephanurus dentatus*, is present, the milk spots due to ascarid migration must be differentiated from fibrosis associated with kidney worm migration. Scars of the latter are more extensive with similar lesions occurring in other organs such as the lungs and kidney. Milk spots may also be caused by other helminths such as *Toxocara* undergoing visceral larva migrans in swine (Helwigh et al. 1999). Adult *Ascaris* are usually found in the small intestine at the time of necropsy or slaughter, but occasionally are found wandering in other portions of the gastrointestinal tract. The adults are large, often 20–30 cm in length and the diameter of a pencil with three large lips. Adults can be visible or palpable through the wall of the intestine.

When naïve pigs are exposed to egg-contaminated premises, morbidity or mortality can occur, while the infection is in the prepatent phase in which case fecal flotation is of no diagnostic value. Diagnosis is by observation of abundant milk spot lesions at necropsy. Careful examination may reveal small immature ascarids in the jejunum. Larvae migrating in lungs are difficult to observe grossly, but histopathology can offer a tentative diagnosis. Larvae can be collected by suspending snips of lung tissue in water. The motile larvae will migrate out of the lung tissue but are not strong swimmers, so they sink and can be collected with a funnel and tubing system similar to the Baermann apparatus often used to detect lungworm larvae in other domestic animal species.

Economic importance

Numerous studies have detailed economic importance of various aspects of ascarosis in swine. The results of experimental infections demonstrate some compromise of ADG and feed efficiency, even at low infection levels. *Ascaris* infection may also decrease the host response to vaccination against other pathogens. Metabolic studies show detrimental effects on nitrogen metabolism during the rapid growth phase of ascarids, about 1 month postinfection. At slaughter, there are losses due to condemnation or trimming of livers as well as condemnation carcasses due to icterus. The monetary value of these losses is enormous, though difficult to quantify. Historical estimates of losses are in the hundreds of millions of dollars in lost revenue annually (Stewart and Hale 1988). *A. suum* has continued to persist in commercial swine; a

visit to a slaughterhouse confirms the presence of these parasites on a daily basis.

Trichinella

Trichinellosis occurs in most mammals, including humans. The life cycle of this parasite is confusing as the adult nematodes live in the intestine and are seldom seen. Detection efforts focus on the larvae that live within muscle and cause disease. *Trichinella* has been found to be a diverse genus, but most cases of trichinosis are caused by *Trichinella spiralis*. Molecular characterization has revealed potential of at least eight different species in the genus with several genotypes that may achieve species status (Gottstein et al. 2009). *T. spiralis* has a global distribution, is a swine-adapted species, and is often detected in rats. *Trichinella britovi* can be found in pigs in Europe, Asia, and Africa and grouped in a single clade because they induce a thick collagen capsule during the muscle phase of infection; other species produce a capsule only detectable by electron microscopy. Examples of non-encapsulating species infecting pigs are *Trichinella pseudospiralis*, which has a cosmopolitan distribution, and *Trichinella papuae*, which can be found in Southeast Asia. Reduced incidence of *Trichinella* infections is attributed to regulation of garbage feeding to swine, public health programs, and improved detection techniques. In developed countries, trichinosis cases are now more often associated with ingestion of poorly cooked wild game meat.

Life cycle

Adult *Trichinella* are tiny (2–4 mm long) nematodes that are short lived and typically never encountered. The adults tunnel within the villi of the intestine. Within 5 days after mating, the viviparous females continuously deposit larvae in the lamina propria for duration of life, which is 2–3 weeks. The larvae enter the circulation and are distributed throughout the body until opportunity to penetrate the sarcolemma of skeletal muscle cells. After entering the myocyte, the myocyte becomes a "nurse cell" that supports the quiescent larva for months or years (Figure 67.4). Circulating larvae that do not enter myocytes eventually are arrested within granulomas. When cysts from the muscle are ingested, the larvae excyst and develop into adults within 48 hours. Examples of transmission within swine herds include tail biting, scavenging (rats, raccoons, etc.), and eating of garbage containing uncooked meat.

Pathology

The intestinal adults may be associated with enteritis although this is not typically observed clinically. Pathology and disease is associated with the larvae in the nurse cell. As the nurse cells form, there is malaise, pyrexia, and myalgia accompanied by eosinophilia.

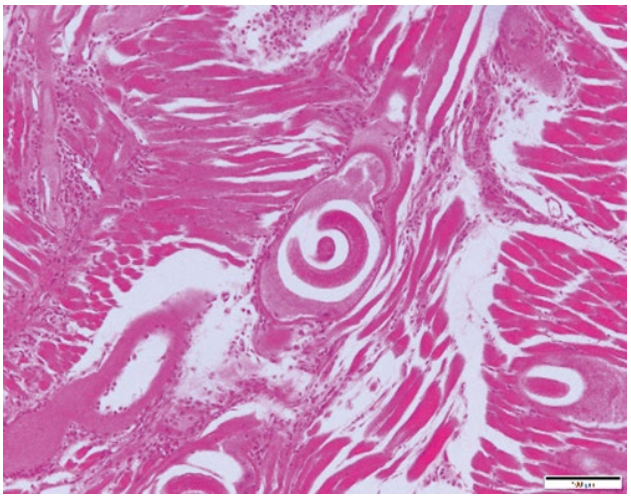

Figure 67.4 *Trichinella* larvae in a nurse cell.

Growth rates may be reduced, but the disease is often undetectable. Ten larvae per gram of body weight are thought to be a lethal infectious dose in a pig. As the nurse cell forms, the myocyte is walled off by collagen. Once the development of the nurse cell is complete, clinical signs regress, and normal growth rates resume.

Diagnosis

Traditional methods of diagnosis are aimed at finding nurse cells, which are not distributed homogeneously throughout the musculature but tend to be concentrated in particular muscle groups (diaphragm, extrinsic muscles of the eye, and muscles of posture). Both of the two main methods for detecting muscle cysts are labor intensive and produce false negatives. The first is by microscopic examination of bits of muscle compressed between glass plates, and the other is by digestion of several grams of muscle in artificial gastric juice (1% pepsin, 1% hydrochloric acid at 37 °C) and microscopy of sediment. These techniques have been largely replaced by a serum ELISA that detects pig antibodies directed at a larval secretory antigen (Murrell et al. 1986). False-negative ELISA results can occur when low populations (<5 larvae/g of muscle) of parasites are present.

Public health

Trichinella are zoonotic, infecting humans as well as other mammals. The source of *Trichinella* varies but can include pork products. Ground pork or sausage is particularly of concern because a single infected carcass may find its way into numerous sausages or can be used to dilute venison or beef sausage. In recent years, more cases of human trichinellosis in the United States have been caused by eating undercooked bear, wild game meat, or home-slaughtered pork. The incidence of swine trichinellosis in the United States has varied from 0.1 to

0.3% since the mid-twentieth century because the use of control measures (prohibition of feeding raw garbage, raising pigs in confinement, docking of tails, etc.) has practically eliminated trichinellosis in commercial pork. In the United States, there is a voluntary National Trichinae Certification Program aimed to continued efforts to eliminate trichinellosis.

Trichinella larvae cooked to a uniform temperature of 60 °C are not infective; therefore the US Department of Agriculture recommends that fresh pork be cooked to an internal temperature of 63 °C, allowing it to rest for 3 minutes between cooking and cutting. This temperature includes a safety factor that allows for variation in cooking methods (e.g. microwave ovens do not heat evenly). Freezing of fresh pork products less than 15 mm thick at −15 °C for 20 days or at −29 °C for 6 days will kill most larvae, but not isolates adapted to cold (e.g. *Trichinella nativa*, which is not a problem in commercial pork industry). Salt curing does not reliably kill larval *Trichinella*, so cured products should be cooked.

As a result of public health and veterinary food safety efforts, the number of cases of human trichinellosis in the United States has dropped from 450 cases per year in 1947 to about 12 cases per year 50 years later (Kennedy et al. 2009), and similar results have been achieved elsewhere. *Trichinella* is still present at a low level in swine as well as in wildlife in some regions, which is justification for continued vigilance.

Hookworm

Globocephalus urosubulatus is distributed throughout the world, but in North America it is limited to swine pastured in southern states. Adults attach to the jejunal mucosa by way of a large buccal capsule that lacks teeth or cutting plates. Young pigs are more likely to become anemic than older, more resistant individuals. However, clinical disease attributed to hookworms in pigs is rare. Adult *Globocephalus* are about 7 mm in length and lay strongyle-type eggs (52–56 × 25–35 µm) similar to those of *Hyostrongylus*. Infective larvae develop in the environment and infect other pigs by ingestion or skin penetration. Geographic distribution is limited to areas that do not freeze. Unlike hookworms infecting dogs and cats, *Globocephalus* is not associated with cutaneous larva migrans in humans.

Tapeworms

Although the swine gut is home to a myriad of helminth parasites, they are not typically definitive hosts for the adult stages of cestodes (tapeworms). Swine can, however, be important cestode intermediate hosts for *Taenia* and *Echinococcus* as discussed elsewhere in this chapter.

Acanthocephalans

Acanthocephala ("thornyhead") is a phylum distinct from Nematoda, characterized by parasites with protrusible proboscis. *Macracanthorhynchus hirudinaceus* is a large acanthocephalan up to 40 cm in length and has a dusty coral pink color, and the anterior end has a spiny proboscis with which it attaches to the jejunal wall. Its body may be turgid or wrinkled and flattened depending on hydration status and hence may be mistaken for an ascarid or a cestode. Ascarids lack a proboscis and do not attach, while cestodes have true segments (not mere wrinkles) and have a scolex that is not as dramatic as the proboscis of an acanthocephalan.

Eggs of *M. hirudinaceus* (70–100 × 40–65 µm) are passed in the hosts' feces and have a three-layered shell that is almond shaped, is brown, and contains a larva (acanthor). The acanthor has an ellipsoidal shape and needlelike hooks on one end. When ingested by white grubs of certain beetles (June bugs, dung beetles, etc.), an infective larva (cystacanth) develops in about 3 months, surviving metamorphosis to be present in the adult beetle. Pigs are infected by ingesting a grub or adult beetle while rooting. Once ingested, the cystacanths mature into adults in the small intestine, mate, and lay eggs after about 2–3 months. Since commercial swine are generally raised in confinement that denies pigs access to intermediate host, acanthocephalans have become rare. There are a few reports of *M. hirudinaceus* in humans in cultures that eat raw beetles. Because the life cycle is indirect, there is no danger in handling eggs or tissues of the adults.

Macracanthorhynchus hirudinaceus inserts its proboscis into the wall of the jejunum. The proboscis is large and capable of penetrating through the entire thickness of the intestinal wall, resulting in a perforation. This lesion may be encapsulated with nodular fibrous connective tissue that can be seen at necropsy, or they may rupture causing peritonitis. There are typically more nodules than adult worms, suggesting that release and reattachment may occur. Clinical disease associated with acanthocephalans is not reported often, but intestinal perforation may lead to abdominal pain, diarrhea, fever, and emaciation.

Large intestine

Two kinds of nematodes occur in the cecum and colon of pigs: nodular worms and whipworms. Both are very common, and both can lead to important clinical disease.

Whipworm

Trichuris suis, the swine whipworm, occurs in the cecum and colon. Much like ascarids, whipworms have persisted as an important parasite of pigs raised in confinement

facilities. Adult *Trichuris* are approximately 60 mm long, and about two-thirds of their length consists of a filamentous esophageal portion of the body that is stitched into the mucosa and not readily noticed. The thick posterior portion of the body protrudes from the mucosal surfaces. Intact nematodes are difficult to collect at necropsy because the delicate, long esophageal portion breaks. The eggs are thick shelled and lemon shaped (50–58 × 21–35 µm), each containing a single large cell. The egg shell is smooth and brown with a translucent plug filling an opening at the poles of each egg.

Life cycle

The life cycle of *Trichuris* is direct. Eggs pass in the feces, and once outside the body the first-stage infective larva develops within the egg in 3–4 weeks. The infective larva remains within the egg until ingested by a pig. Eggs can remain viable for several years in the environment. After ingestion, the plugs dissolve, perhaps stimulated by fimbria of intestinal bacteria. The first-stage larva penetrates the mucosa of the colon and undergoes four molts over a period of about 2 weeks. The posterior of the whipworm's body extends out into the lumen, and oviposition begins 6–7 weeks postinfection, while the worm's life span is approximately 4–5 months (Beer 1973).

Pathology

Low populations of adult *Trichuris* cause minimal lesions, although they may provide an entry point for other pathogens. Heavy infections with *Trichuris* are associated with ulceration of the mucosa, mucosal edema, and hemorrhage. Much of this tissue damage is caused by the histotrophic larvae, before adults are grossly present. Clinical signs include diarrhea, hematochezia, and rectal prolapse.

Diagnosis

The presence of adult *Trichuris* can be confirmed by demonstrating the characteristic eggs in fecal flotations; however, false negatives may occur due to sporadic egg laying by females, as well as the long (6–7 weeks) prepatent period. Adult worms can be detected at necropsy but are often overlooked due to their small size. Often, the most severe clinical signs, including dysentery, are produced by migrating larvae that may not be grossly visible for the first 3 weeks after infection. The tiny larvae and immature worms can be found in mucosal scrapings or recognized by histopathology. Whipworms can be recognized by their unusual esophageal structure of a single line of large glandular cells known as a stichosome. The uterus of a mature female contains eggs of typical morphology often visualized by histology. Commercial *Trichuris* antigen detection tests have been developed for use in other domestic animal species, but their utility has not yet been proven for *T. suis*.

Nodular Worms

Nodular worms (*Oesophagostomum* spp.) are common although less prevalent in swine raised indoors. These strongyloid nematodes inhabit the mucosal surface of the cecum and colon. Adults range from 8 to 15 mm in length, and males possess a copulatory bursa. There are several species, but their appearance and life cycle is similar. Eggs are typical strongyle eggs (70 × 40 µm) containing a morula stage.

The life cycle is direct; eggs passed in feces develop into first-stage larvae that hatch from the egg and molt twice in the environment to produce an infective third-stage larva that is ingested by swine. Infective larvae retain their last molted cuticle as a sheath, so they are moderately resistant to environmental extremes and can survive for several months or more. Ingested larvae exsheath and enter the mucosal glands of the ileum, cecum, and colon. They penetrate into the lamina propria, molt, and remain for about 2 weeks. They emerge into the intestine to become adults, and eggs begin to appear 3–6 weeks after infection.

Adults cause minimal damage to the mucosa and do not cause much in the way of clinical signs. The migration and molting of larvae in the lamina propria cause the characteristic nodule that is usually small (about 2 mm) but may be much larger, especially in animals with repeated infections. The larvae may remain within the nodules for several weeks before escaping into the lumen.

Antemortem diagnosis of nodular worms depends on finding the eggs in fecal flotations. However, this is complicated by the fact that eggs of *Hyostrongylus* and *Globocephalus* resemble them. For definitive identification, larval culture to the L3 stage is needed. At necropsy, the finding of nodules in the cecum and colon is suggestive but must be differentiated from other causes of inflammation, diverticulitis, or abscessed lymphoglandular complexes.

Respiratory system

Lungworms

Metastrongylus spp. have a worldwide distribution, with *Metastrongylus apri* being the predominant species, but mixed infections are common. The adults are slender, 40–50 mm in length, and occur in the bronchi and bronchioles, usually in the diaphragmatic lung lobes. Masses of entwined worms covered with mucus may occlude the peripheral airways. The eggs bear a thick rough coat, are colorless, contain a larva, and measure 50–60 × 35–40 µm.

The life cycle is indirect. Eggs are coughed up, swallowed, and passed in the feces. Certain earthworms, notably *Eisenia* and *Allolobophora* spp., ingest the eggs. Larvae hatch and invade the earthworm's tissues (calciferous

glands, heart, dorsal blood vessel, and crop). When swine eat the earthworm, the lungworm larvae migrate to the lungs via the lymphatic system and begin laying eggs in 4–5 weeks. Clinical signs are not pronounced, but heavy infections and infections complicated with bacterial infections cause coughing and "thumping."

Lungs with metastrongylosis have wedge-shaped areas of emphysema or atelectasis, usually at the tips and about midway along the length of the diaphragmatic lobes where major bronchi approach the lobe periphery. Often, hypertrophic bronchial muscle, hyperplastic epithelium, and nodular lymphoid hyperplasia are associated with the nematodes. Concurrent bacterial pneumonia is not uncommon.

Diagnosis of metastrongylosis is accomplished by finding the characteristic eggs on flotation, but the eggs do not float well. Postmortem diagnosis is accomplished by trimming 1 cm strips from the edge of the diaphragmatic lung lobe and squeezing to express adults from the bronchi.

Lung fluke

Paragonimus kellicotti is a trematode fluke that occurs in bronchial cysts of a wide range of hosts, including swine, in North America. *Paragonimus westermani* is a similar species occurring in Southeast Asia and a few areas of South America. *Paragonimus* are large, fleshy, brownish flukes that measure 8–12 mm long, 4–6 mm wide, and 3–4 mm thick. They are often found in pairs. The cysts are about 2–3 cm in diameter and are easily seen and palpated at necropsy. Usually there are few clinical signs because a few cysts do not compromise lung function. On the other hand, heavy infections can produce a productive cough with dyspnea and hemoptysis.

The life cycle is indirect. Miracidia hatch from the egg and penetrate the first intermediate host, a snail. Cercaria exit the snail and are consumed by the second intermediate host, which is a crayfish for *P. kellicotti* or either crayfish or crab for *P. westermani*. When eaten by a swine, the metacercariae in the crustacean excyst, penetrate the intestinal walls, burrow through the diaphragm, and enter the pulmonary parenchyma. They settle in pairs, mature, and begin oviposition in about 60 days. Pairs live in cysts that communicate with bronchi. Worms are hermaphroditic, but it is thought that they may either mate with another individual or self-fertilize. Eggs are coughed up, swallowed, and passed in feces.

At necropsy, the characteristic cysts can be found in the lungs. Adult flukes may be teased from the cysts or may be observed by histopathology. The eggs are relatively heavy but will float in a saturated sugar solution with centrifugation. The eggs are brown, vase shaped, and large (80–110 × 50–60 µm) and have a thickening at the junction of the operculum and shell. The number of eggs appearing at any one time varies because their presence in the feces depends on being coughed up and swallowed. Eggs may also be detected in smears of sputum. Some migrating excysted metacercariae wander, and adults may be found ectopically in lymph nodes, liver, peritoneum, etc.

Liver and pancreas

Aside from being the site of larval migration (e.g. *Ascaris* and *Stephanurus*), the liver and pancreas are the niches for only a few helminths.

Liver fluke

Fasciola hepatica is a cosmopolitan trematode fluke that has a broad host range that includes swine. The adult fluke is large (30 × 10 mm) and leaf shaped, with a conical anterior end. The eggs are large (130–150 × 65–90 µm), oval, yellowish brown, and operculated.

Eggs passed in the feces develop in water. A ciliated miracidium hatches and penetrates a lymnaeid snail that undergoes asexual reproduction and results in the release of hundreds of cercaria. Each cercaria encysts on vegetation to form an infective metacercaria. Metacercariae may remain infective for a long period of time but are killed quickly under dry conditions. After being ingested by the final host, the metacercaria penetrates the intestinal wall and the liver capsule and migrates in the liver parenchyma for 6 or more weeks. It eventually reaches the biliary duct system and migrates to the larger bile ducts and sometimes the gallbladder. The prepatent period is 10–12 weeks.

Migrating adolescent flukes cause necrohemorrhagic tracts in the liver parenchyma. These tracts regress once the flukes have entered the bile ducts. Adults cause bile duct hyperplasia and fibrosis, leading to the characteristic "pipestem liver" lesions that resemble the stems of clay pipes. Adult flukes and brownish exudate can be expressed if the affected bile ducts are incised. Clinical signs associated with fasciolosis are anemia and hypoproteinemia due to liver damage and hematophagia by adult flukes. Infected individuals may have weight loss or poor gains, but infections are often silent. The liver is condemned at slaughter. Ruminants and humans can also be infected. A similar fluke, *Fasciola gigantica*, infects swine in Africa and Asia.

Echinococcus (hydatid cyst disease)

Adult *Echinococcus* cestodes occur worldwide in carnivores, and their larval cysts (hydatids) occur in various herbivores and omnivores, including humans and swine. The adults are very small (3–6 mm) and typically occur

by the hundreds in the definitive host's intestine. Egg-laden proglottids are shed into the environment via feces. The eggs are identical to those of other taeniids (e.g. *Taenia*), and, when ingested by a pig, the oncosphere hatches from the egg, penetrates the intestinal wall, and enters the circulation. A large proportion becomes trapped in the liver where they nidate and develop into hydatids. Unilocular hydatid cysts (*Echinococcus granulosus*) have an external fibrous cuticle and an inner germinal membrane, while multilocular hydatids (*Echinococcus multilocularis*) have a germinal layer on both the inner and outer surfaces, which are capable of producing a more invasive lesion similar to that of a neoplasm. The germinal layers give rise to many thin-walled brood capsules, and each brood capsule contains several dozen protoscolices, often referred to as "hydatid sand," which can be visualized ultrasonographically. The end result is that numerous protoscolices are produced from each egg ingested. When ingested by a carnivore, each protoscolex develops into an adult cestode.

There are no clinical signs that imply hydatid cyst disease, and diagnosis is usually done at necropsy. Aspirates of hydatid cysts contain protoscolices that contain calcareous corpuscles and hooks. Histologically the brood capsules and protoscolices can also be identified. One challenge for diagnosis is that some hydatids developing in pigs, particularly those of *E. granulosus*, are "sterile" (e.g. contain no protoscolices), which makes for a more difficult diagnosis. Hydatid cyst disease is uncommon in the United States, but sylvatic cycles of the parasite mean that it is an ever-present threat. In areas of the world where pigs are free roaming or where offal is fed to carnivores, hydatid cyst disease is both an economic and a public health concern since humans can develop hydatids.

Urinary system

Kidney worm

Stephanurus dentatus adults occur in perirenal cysts that open by a fistula into the ureters. It is common to discover ectopic cysts in other organs such as the spleen, stomach, urinary bladder, and spinal cord. Renal parenchyma per se is seldom involved. Adult *S. dentatus* are large stout worms, measuring 20–40 × 2 mm with visible internal organs. Their eggs are typical for strongyles but can be differentiated from those of hookworms, nodular worms, and other strongyles because they are found in urine.

First-stage larvae develop in the egg, hatch, and molt twice into an infective third-stage larva. Infective larvae may survive on pasture for up to several months and can either be ingested or penetrate the skin, migrate to mesenteric lymph nodes, molt, and enter the liver via portal veins. There they migrate for several weeks, growing to a size of 5–6 cm before exiting the liver and migrating to retroperitoneal tissues where adults cluster within an inflammatory cyst that fistulates to the ureters or kidneys. The prepatent period is long (9–12 months), and adults may live for several years. Migrating larvae are aggressive and can be found in ectopic sites including the epaxial muscles and spinal column, and because early migration takes place in blood vessels, it is thought that some pigs may become infected *in utero*. Migrating larvae produce hemorrhagiconecrotic tracts wherever they go and hence produce considerable abscessation, eosinophilia, and fibrosis, including much more prominent hepatic "milk spots" than those caused by ascarids.

The infection is limited geographically to areas that do not experience severe winters, and confinement rearing has dramatically reduced the incidence of kidney worm. In systems where the problem persists, a "gilts-only" breeding system can be implemented in order to control the parasite. This measure is successful due to the long prepatent period; gilts are slaughtered prior to developing a patent infection.

Musculoskeletal system

The body musculature harbors immature stages of only a few helminths. Already mentioned above are the larvae of *Trichinella* in "nurse cells" and aberrantly migrating larvae of *S. dentatus*. In addition to these nematodes, the cysticercus of *Taenia solium* lives within muscle tissue.

Cysticercosis ("pork measles")

The larval stage (metacestode or cysticercus) of *T. solium* occurs in the skeletal muscles and myocardium of swine as a fluid-filled cyst. Prior to a complete understanding of the life cycle, this organism (stage) was named *Cysticercus cellulosae*; some authors still use this nomenclature to describe the metacestode of *T. solium*. The adult form of this cestode occurs in the intestine of humans. Although once widespread in distribution, the infection is now limited by methods of human hygiene and cooking of pork. However, human cases from endemic areas occur, and diaspora assures continued cases and public health concerns.

Taenia hydatigena, "the long-necked bladder worm," is another source of cysticercosis in swine. Unlike *T. solium*, *T. hydatigena* infects canine definitive hosts and does not develop in humans. The cysts are larger (approximately 8 cm) and found in the omentum and mesentery. The cyst bears a long armlike extension (neck) that holds the inverted protoscolex.

Life Cycle

Humans infected with adult *T. solium* shed proglottids in the feces. The egg-filled proglottids release eggs when the proglottids are desiccated or damaged as no uterine pore occurs in *Taenia*. The eggs or proglottids are ingested by swine. The oncospheres hatch from the egg, penetrate the small intestine, and are distributed throughout the body by the circulation. They become trapped in capillary beds associated with muscle tissue and develop into infective cysticerci. This condition is sometimes called "pork measles" by packers. The term measles refers to the spot that is the cysticercus. Cysticerci are subspherical, whitish, translucent, fluid-filled cysts about 1 cm in diameter. Visible through the surface is a white, 1–2 mm spot that is an inverted protoscolex that will become the scolex of the adult tapeworm when ingested. Cysts remain infective for up to 2 years, but eventually they die and undergo caseation and mineralization. Cysticerci develop in any muscle of the body but are most commonly found in the heart, psoas, masseter, tongue, and limbs. Humans can become accidental intermediate hosts and develop cysticercosis following ingestion of eggs from human feces.

Diagnosis

There are no characteristic clinical signs associated with cysticercosis. Risk factors for infection include pigs that are free roaming and have access to domestic waste and human feces. The presence of a cysticercus is revealed at necropsy or slaughter. Palpation of the tongue may reveal deeply seated cysts. Microscopy of squash preparations of cysticercus can reveal the rostellum containing hooklets; hooklets do not disintegrate despite caseation. Several ELISA assays have been developed to detect *Taenia* antigens as well as anti-*Taenia* antibodies. These assays have been applied in humans but are not regularly used for surveillance in swine herds.

Public health

Viable *T. solium* cysticerci are infective for humans, so meat inspectors search for them regularly. If inspection reveals only a few cysticerci, they may be excised and discarded. Finding several organisms requires the entire carcass be cooked at 170 °C for 30 minutes (which kills the cysts) prior to releasing for consumption; however, finding high numbers of cysticerci leads to condemnation of the entire carcass. Freezing cuts of pork is another method of killing cysticerci; the temperature and time held at that temperature depends on the size and thickness of the piece of pork. Discovery of cysticerci should prompt an investigation of how pigs are coming into contact with human waste.

Besides acting as the definitive host for *T. solium*, humans can become accidental intermediate hosts after ingesting the eggs. In humans the cysticerci have a predilection for the central nervous system; neurocysticercosis is thought to be the cause of cognitive dysfunction in humans wherever *T. solium* is endemic. Humans infected with adult *T. solium* can be treated with praziquantel. Swine intermediate hosts are not treated; elimination of the life cycle is accomplished by sanitation, treatment for infected humans, and proper disposal of human feces.

There are many other helminths reported to infect swine but are considered of lesser importance (Table 67.1).

Control of helminth parasites

Parasite control methods may be broadly categorized as preventative or therapeutic. Preventative methods focus on interrupting critical points in the parasite life cycle, whereas therapeutic approaches utilize pharmaceutical agents to remove parasites from the pig. Seldom will therapeutic approaches alone eliminate a helminth parasite from a herd.

Prevention

Those parasites requiring an intermediate host can be successfully prevented by removing pigs from contact with the intermediate host (e.g. dung beetles, earthworms, snails, etc.). Therefore, maintaining pigs on concrete will prevent infection with spiruroids, acanthocephalans, and metastrongyloids. An added benefit would also be the reduction or prevention of infection by strongyles, such as *Hyostrongylus*, *Globocephalus*, and *Trichostrongylus*, that are transmitted more efficiently under pasture conditions.

Good sanitation is a critical element for controlling parasitic infections. The major mode of transmission of internal parasites is through contaminated food, soil, or bedding with feces or urine. Since parasite eggs need moisture and warmth to develop and survive, direct sunlight or dry conditions shorten egg and larval survival. Thorough cleaning of buildings, pens, and equipment with detergent and steam is the best way to control parasite eggs and larvae. Steam penetrates cracks and crevices and kills the tiny eggs and larvae. The common disinfectants used on the farm do not kill eggs of *A. suum*.

Since parasites compete with the host for available nutrients, adequate nutrition aids in reducing the adverse effects on feed efficiency and ADG. Pigs on a good plane of nutrition are less likely to exhibit clinical parasitic disease as opposed to individuals with a negative energy balance. However, improved nutrition alone will not abrogate a serious helminth problem in a herd.

A management system in which gilts only are used as breeders has been shown to be effective in eradicating

Table 67.1 Gastrointestinal helminths of lesser importance.

	Locale	Description	Comments
Gastrodiscus aegyptiacus Gastrodiscoides hominis	Small and large intestine in Africa and southern Asia	Flaky paramphistome flukes 5 × 14 mm; operculated eggs 150 × 70 µm	Infects humans; infection acquired by ingesting metacercariae on vegetation
Fasciolopsis buski	Small intestine in southern Asia and India	Large fluke 20–75 mm long; operculated eggs 135 × 85 µm	Infects humans; cycle similar to that of *Fasciola hepatica*
Gnathostoma spp.	In nodules in gastric wall in Eurasia and Africa	20–40 mm long, spinose cuticle; eggs with one polar plug, 70 × 40 µm, brown pitted shell	Second intermediate host is small vertebrate (reptile, bird, etc.); prepatent period about 3 months
Ascarops strongylina	Mucosal surface of stomach	15–20 mm; eggs thick shelled, transparent, embryonated, ellipsoidal 30–40 × 15–20 µm	Intermediate hosts are coprophagous beetles; prepatent period 4–6 weeks
Physocephalus sexalatus	Mucosal surface of stomach	15–20 mm; eggs similar to those of *Ascarops*	Cycle similar to that of *Ascarops*
Simondsia paradoxa	Stomach mucosal glands	15–20 mm; posterior end of female bulbous and filled with eggs	Cycle similar to that of *Ascarops*
Eurytrema pancreaticum	Pancreatic ducts	Flukes 10–15 × 2 mm; eggs 40–50 × 25–35 µm; dark brown; contain miracidium	Second intermediate host is grasshopper
Clonorchis sinensis	Bile ducts	Flukes 10–25 × 4 mm; eggs 27–35 × 12–20 µm; light brown; contain miracidium	Second intermediate hosts are freshwater fishes

kidney worms. This is possible because of the lengthy prepatent period of 9 months or more. Selling breeders as soon as first litters are weaned and maintaining boars separately or replacing them with young stock will prevent contamination of the premises. Using the gilts-only breeding system was used to achieve eradication of kidney worm in less than 2 years (Stewart et al. 1964).

For some parasites, prevention is the most effective method for eliminating the organism. For example, elimination of feeding raw meat, scavenging, and cannibalism is effective in preventing the transmission of *Trichinella*. Similarly, denying pigs access to human fecal material is efficacious for halting the transmission of *T. solium*.

Treatment

Therapeutic anthelmintics present only a temporary solution unless the conditions under which the parasites were acquired are altered. No drug is effective against all stages of all parasites, and the tissue damage prior to therapy results in slower growth rates and increased nutrient requirements. A good management system will incorporate practices, such as sanitation, genetic selection, and nutrition, to prevent infections and will not use treatment as the sole method of controlling parasites. The choice of anthelmintic is dependent on the parasite species present and the relative cost of the products. Routine surveillance and strategic treatment for parasites are advisable on farms with a previous history of clinical disease. Treatment reduces the number of egg-producing parasites and keeps further premise contamination to a minimum. For pigs placed in high-risk environments, the use of prophylactic compounds pyrantel tartrate and fenbendazole fed for several weeks can control infections and reduce lesions from ascarids and nodular worms, reduce worm populations, or may enhance immunity against *A. suum* (Southern et al. 1989; Stankiewicz and Jeska 1990). Treatment of sows 10–14 days before farrowing has been shown to be effective in preventing transmission of nematodes and *Sarcoptes scabiei*.

Macrocyclic lactones

Macrocyclic lactones, such as avermectins and milbemycins, are fermentation products of the fungus *Streptomyces avermitilis* and are thought to act by preferentially binding glutamate-gated chloride ion channels, a class of ion channel that is only found in invertebrates, which leads to paralysis and death of susceptible invertebrates. Avermectins are available as injectable and pour-on formations or as feed additives and have stated slaughter withdrawals. In general, they control *A. suum* (adults and fourth-stage larvae), *H. rubidus* (adults and fourth-stage larvae), *Oesophagostomum* (adults and fourth-stage larvae), *S. ransomi* (adults), and

Metastrongylus (adults). Doramectin is labeled for *A. suum* (adults and fourth-stage larvae), *Oesophagostomum* (adults and fourth-stage larvae), *S. ransomi* (adults), *Metastrongylus* (adults), and *Stephanurus* (adults) and has variable efficacy for *Trichuris*.

Benzimidazoles

Benzimidazoles preferentially bind nematode beta-tubulin and disrupt cell division. This class of drugs is thought to have a wide margin of safety as it preferentially binds the nematode protein as opposed to mammalian tubulin. Thiabendazole is well known but less efficacious in swine than fenbendazole, which is the only benzimidazole labeled for helminths in swine in the United States, available for administration in an oral suspension or feed additive with a slaughter withdrawal. Fenbendazole products are labeled for the treatment of *A. suum*, *Metastrongylus*, *Oesophagostomum*, *Hyostrongylus*, *Stephanurus*, and *Trichuris* in the United States. It should be noted that fenbendazole is thought to be one of the few anthelmintics effective for removal of *Trichuris*.

Imidazothiazoles

Levamisole binds nematode nicotinic acetylcholine receptors, leading to paralysis and death. It has been used in water or feed. It is effective for the treatment of *Ascaris*, *Oesophagostomum*, *Metastrongylus*, *Strongyloides*, and *Stephanurus*. It has a slaughter withdrawal in the United States.

Tetrahydropyrimidines

Pyrantel tartrate is the only tetrahydropyrimidine labeled for use in swine; it also acts by binding nematode nicotinic acetylcholine receptors. It is available for incorporation into feed, most commonly used as a continuous dewormer for 30 days in starter and growing pigs as an aid in the prevention of larval migration and establishment of *A. suum* and *Oesophagostomum*. Pyrantel has a slaughter withdrawal in the United States.

Piperazine

Piperazine salts are an older generation of antiparasitic purge dewormer that causes a neuromuscular blockade by disrupting GABA neurotransmission. Piperazine is administered in feed or water and should all be consumed in an 8–12 hour period; withholding feed or water the previous night is beneficial for stimulating consumption. It is currently approved for treatment of adults of *Ascaris* and *Oesophagostomum*.

Organophosphate compounds

Dichlorvos is an organophosphate compound added to feed with good efficacy against *Ascaris, Oesophagostomum, Trichuris,* and *Hyostrongylus* with slightly lower efficacy against *Strongyloides* (Marti et al. 1978). It can be incorporated into slow-release polyvinyl chloride pellets that allows for continued effect in the cecum, producing the desired removal of whipworms.

Nutrient Deficiencies and Excesses

Steve S. Dritz, Robert D. Goodband, Joel M. DeRouchey, Mike D. Tokach, and Jason C. Woodworth

In modern swine production, the diagnosis of nutrient deficiencies or excesses is rarely a straightforward, linear process. A typical case usually starts with unremarkable or nonspecific clinical signs such as "elevated mortality," which may lead to a diagnostic investigation. The astute clinician will carefully collect a history and specific clinical description, coupled with necropsy findings, before determining the case definition. The case definition should provide the basis for a differential diagnosis that informs the collection of specific types and numbers of samples for a proper diagnostic investigation. Diagnostic investigation usually can identify disease processes involving pathogenic agents, but rarely will a specific diagnosis involving a nutritional component emerge with routine diagnostic investigation. A summary of clinical signs that may be associated with specific nutrient deficiencies (Table 68.1) and the base information in this chapter can be used to develop a list of rule-outs for further investigation from a nutritional perspective.

Pigs are a highly adaptable omnivorous species with a long domestication history of being fed many different ingredients. The majority of pigs today are fed grain and protein source-based diets with added vitamins and minerals. However, there are a wide variety of diet formulation practices due to local availability of ingredients and the capability of the pig to utilize a wide cross section of primary energy and protein sources. As with other deficiencies and toxicities in general, both the duration and dosage of specific nutrients are important determinants of effect on the animal. The transition between deficient, marginal, optimal, tolerable and toxicity is not always clearly defined (Figure 68.1).

Pigs may tolerate high dosages of a particular nutrient for short periods, but long-term feeding may have detrimental consequences. Likewise, low dosages of some nutrients can lead to either acute or chronic deficiency disease. Furthermore, pigs in some physiologic stages, such as young, old, reproducing, or disease-challenged states, may be more sensitive to deficiencies or toxicities. Few studies under modern pork production conditions are focused on quantifying clinical signs of deficiencies or toxicities, thus making early recognition of compromised pigs and the diagnosis of nutritional diseases difficult. Growth and reproductive performance are sensitive indicators of many nutrient deficiencies or excesses. Characterization of these criteria can be useful in confirming diagnosis or monitoring responses to dietary changes. Unfortunately, these indicators are closely associated with many other disease processes and so have limited use in the primary diagnosis of a nutrient deficiency or toxicity.

Most scientific studies evaluating nutrient requirements evaluate dose responses focused on optimizing growth, performance, and economic return. Seldom are these studies performed to characterize nutrient deficiencies or toxicity. Economic drivers sometimes lead to purposeful fortification of some nutrients at levels below or above the commonly acknowledged requirements to obtain maximal growth, in order to lower cost and increase profit. For example, feeding slightly below the amino acid requirement during the finishing phase will result in slightly slower growth and poorer feed efficiency but will usually result in optimized economic performance. Similarly, feeding excess feed to gestating sows has a negative impact on subsequent lactation performance and cost. Nutritional optimization is beyond the scope and not the objective of this chapter. This chapter will have a primary focus on clinical nutrient deficiencies or toxicities.

Investigation of nutrient deficiencies or excesses

Critical control points in feed production

The feed production chain in most modern swine systems is a highly integrated process that involves the procurement of ingredients, accurate weighing and mixing

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Table 68.1 Clinical signs with micronutrient deficiencies or excesses.

Clinical sign	Deficiencies	Excesses	Clinical history considerations
Anemia	Fe, B_{12}	Cu	Inadequate iron preweaning; little evidence to support inadequate dietary iron post weaning with anemia
Congenital defects	Vitamin A	—	Uncommon; requires deficiency for extended period; usually premix formulation errors
Coronary band separation	—	Se	Diet formulation or environment
Diarrhea	Niacin	Crude protein	Niacin deficiency is uncommon, but availability often is unknown; excess crude protein post weaning; other nutrients or ingredients may cause transient diarrhea when fed in excess
Fractures, lameness	Ca, P, vitamin D	Ca	No sunlight; phytase usage; formulation errors; mixing errors; equipment malfunctions
Growth plate/cartilage, kyphosis, rickets	Ca, P, vitamin D,	Vitamin A	
Hemorrhage, ecchymosis, or hematomas	Vitamin K	—	Aged premix; unstable source of menadione; heat in processing
Hair loss	I, Zn, B vitamins	Se	Goitrogens or low I (neonates); chronic high Se exposure through soils or feed
Neurologic (altered gait, ataxia, tremors, paresis)	Pantothenic acid; Ca, P, vitamin D	Vitamin A, Se, Na	Formulation errors; feedstuff origin; tetany can occur with severe deficiency Ca, P, or vitamin D; Na toxicity is due to water deprivation and will not occur when water access is adequate
Neurologic with polioencephalomalacia	Thiamin	—	Sodium metabisulfite; thermal processing; unprocessed fish meal
Skin lesions, parakeratosis	Zn, multiple vitamins	—	Low Zn; other minerals high; diet supplementation error
Sudden death	Se, vitamin E	Se, Fe	Geographic origin of feedstuff; errors; Fe sudden death potentially associated with injectable doses while there is little evidence with oral doses

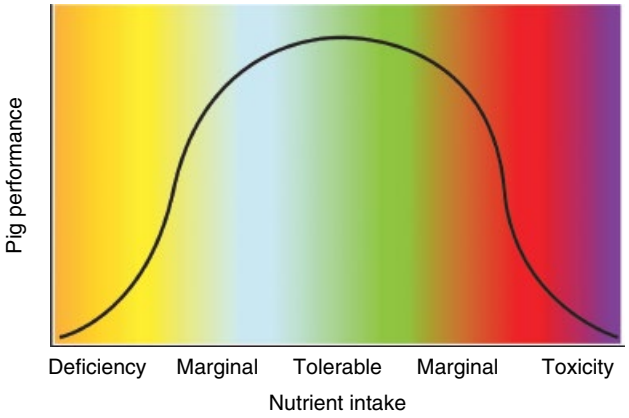

Figure 68.1 Responses to increasing nutrient fortification are on a continuum.

of ingredients, feed processing, and delivery of the correctly formulated diet to a specific group of pigs. With improved understanding of ingredient composition and current nutrient requirements of swine, gross deficiencies or excesses are less likely to be the result of failure to recognize the metabolic role of a specific nutrient and more likely a breakdown in the feed manufacturing chain. Therefore, the clinician needs to have a thorough understanding of the feed manufacturing process to help identify critical control points within the system. Critical control points in this process include:

1) Accounting for the potential variation of nutrient composition and bioavailability of feed ingredients based on their source or local conditions where they were grown. For example, variation in geographical distribution of soil selenium influences concentration in grain produced.
2) Recognition that processing of an ingredient before delivery to the feed mill can have impact on product quality. For example, an ingredient such as dried distillers grains with solubles (DDGS) can have compromised nutrient content if heat damaged in the drying process. Processing of DDGS is an example where removal of the starch results in a concentration of any mycotoxins initially present in the grain because mycotoxin activity is unaffected by the fermentation process.
3) Awareness and audits to verify that ingredient storage and handling maintains nutrient quality. For example, bins should be completely sealed or aerated to prevent moisture accumulation. Products with expiration dating, e.g. vitamin premixes, should be properly stored and used before expiration.

4) Verification processes to assure that the correct and accurate transfer of the diet formula from the nutritionist to the feed manufacturing center occurs. Errors in transcription and computer entry are not uncommon.
5) Proper calibration and periodic verification of accuracy of scales used to weigh macro- and micro-ingredients is critical. Many ingredients with low inclusion rates (less than 0.25 kg/ton [0.5 LB/ton]) are often used in many formulas. Both the scales and the augers for delivering such ingredients must be designed to handle low inclusion rates.
6) Assure that the mixer capability is adequate to properly mix the diet. Regular monitoring of feed for proper mixing and regularly conducted mixer efficiency tests is prudent.
7) Monitoring for excessive thermal processing (i.e. pelleting or extrusion) of complete diets; excess heat has been shown to inactivate some vitamins and enzymes.
8) Mitigation strategies for all-too-common errors in the delivery of the right diet to the right location. Feed bins should be easily identified, and drivers trained and reminded to be aware of the importance of making the correct delivery of diets.
9) Quality assurance on preparation and composition of the various premixes that contain supplemental vitamins and trace minerals. Vitamins and trace minerals are typically mixed into premixes, which are then added to the diet as a separate ingredient – thus another point in the manufacturing process where errors occur.

Guidelines for dietary nutrient inclusion rates

If nutritional involvement is still suspected after these critical control points are ruled out, then steps are taken to ensure that the diet formulation meets requirements for the intended stage of production. A standard reference for nutrient requirements in the United States is provided by the NRC (2012) and provides a good benchmark for supplementation practices. Such references indicate nutrient concentrations, but do not address ingredient selection. For example, NRC (2012) will not address important and common variations in diet formulation items. Examples such as a weanling pig diet that contains specialty protein sources like dried whey or fish meal or a finisher diet that may contain an excess of wheat middlings that limits growth performance are quite common. It should also be noted that the requirements suggested in NRC (2012) are suggested minimums. Suggested vitamin and mineral tolerances have also been provided in more detail by the NRC (1987, 2005). A more practical guide to typical dietary vitamin and mineral additions has been published by Flohr et al. (2016), which summarizes vitamin and mineral additions and their ranges as surveyed across a wide spectrum of swine production systems in the United States.

Role of feed analysis

Chemical analysis of ingredients and diets can be used for confirmatory diagnostic evidence. As with all diagnostic procedures, appropriate sampling technique is critical (AAFCO 2017; Gonçalves et al. 2016). In brief, sampling accuracy is improved using grain probes or other specialized sampling tools. It is important to obtain multiple samples from a free-flowing stream of ingredients or feed. These are pooled, thoroughly mixed, and then subsampled to assure that the final sample is representative. When sampling sacks, trucks, or feeders, at least 10 sampling points should be probed, pooled, and subsampled for analysis.

Feed manufacturing facilities following good manufacturing practices will retain samples of ingredients and diets. Many farms also retain feed samples from each delivery for some period of time, usually at least 1 month. Chemical analysis of final diets will have higher rates of variability compared with analysis of ingredients or premix mixtures (AAFCO 2015), but can confirm gross diet formulation or mixing errors. The testing of final diets is of less diagnostic value in those clinical cases where the quantity or quality of specific ingredients is compromised, particularly for low supplementation rate vitamins and trace minerals. Testing the premixes containing these low supplementation rate ingredients has considerable merit since they are in a more concentrated form that has better analytic accuracy.

Even if the feed or ingredients are sampled properly, there is analytical variation that impacts interpretation of the analytic results (Table 68.2). Analytic variation can be used as a guideline to interpret the expected concentration. For example, if the expected diet zinc concentration is 2000 ppm, a laboratory analysis result of 1600–2400 (±20%) is within the expected range. Note that analytic variation is in general higher for vitamins compared with other nutrients. Also, it is important to understand that analytic variation as a percentage is greater at low nutrient concentrations compared with high concentrations.

Another important point is to retain a sample in case further analysis is needed. These retained samples should be stored in a freezer to inhibit the growth of insects and molds. Also, if legal consequences are anticipated, establishing a chain of custody for the sample analyzed is important.

Testing of serum for specific nutrients is rarely definitive for diagnosis because most serum levels of nutrients are tightly regulated in a narrow range and abnormal values may not be noted until an advanced state of deficiency or toxicity is achieved. An example is calcium (and phosphorus) where mobilization of bone mineral stores will maintain normal values until an advanced stage of clinical disease. Another confounder is the paucity of recently published normal physiological ranges or

Table 68.2 Analytical variation.[a]

Item	Analytic variation (%)
Protein	±(20/*x* + 2)[b]
Fat	±10
Lysine	±20
Calcium	±(14/*x* + 6)
Phosphorus	±(3/*x* + 8)
Copper	±25
Zinc	±20
Selenium	±25
Sodium	±(7/*x* + 5)
Vitamin A	±30
Vitamin B_{12}	±45
Niacin	±25
Pantothenic acid	±25
Riboflavin	±30

[a] Adapted from AAFCO (2015). Note analytic variation only takes into account laboratory variation and does not take into account sampling variation.
[b] To obtain the expected variation, insert the expected concentration into the formula. For example, if the expected protein is 20%, the analytic variation is 3 (20/20 + 2), and if the laboratory result is between 17 and 23% and fails to indicate, the result is outside the expected range.

expected values for defining a truly deficient, healthy, or toxic status. Reference values from more recent studies where the specific nutrient was titrated are useful; however, these values are generally available only for a limited set of nutrients, age, genotype or diagnostic criteria. The selection of appropriate pigs for sampling is critical; slow-growing, unhealthy, or emaciated pigs selected for sampling may not accurately represent the primary problem because they may not have been consuming feed. Liver is usually a better sample for determining deficient or toxic nutrient status, particularly for trace minerals and fat-soluble vitamins. Despite best practices in selection and sampling, biological and sampling variation makes it challenging to confirm a herd diagnosis of suspected nutrient deficiency or toxicity from individual pig tissues or serum.

Common clinical nutrient concerns

Protein and amino acids

There are few distinguishable clinical signs of protein or amino acid deficiency other than moderate decreases in growth and performance. Because of the economic significance of amino acid requirements, there are excellent reference resources available as guidelines for amino acid fortification in swine diets (NRC 2012; PIC 2016). It is now common to supplement feed-grade crystalline lysine, methionine, threonine, tryptophan, and valine to swine diets, which adds complexity to proper diet formulation and preparation. Local conditions and availability of various by-products utilized in swine diets can vary greatly. It is important to account for availability of amino acids in these ingredients. Finally, supplementation rates for some amino acids may be quite low; feed manufacturing equipment must be sensitive enough to handle the low inclusion rates.

Excess of an individual amino acid is well tolerated when the basal diet contains adequate protein and other amino acids. An amino acid antagonism is when the addition of very high concentrations of one amino acid can interfere with absorption or utilization of another structurally similar amino acid, resulting in a dramatic decrease in feed intake (NRC 2012). Examples include decreased lysine absorption caused by high concentrations of arginine (structurally like lysine) due to competition of the amino acid transport channels through the small intestine or the interactions between the branch chain amino acids (leucine, isoleucine, and valine) where deficiencies and excesses of these amino acids are observed via decreased feed intake and growth (Baker 2005). Methionine and cysteine, if added at 2–3% of the diet, can compromise performance by decreased feed intake. Threonine appears to be the least toxic of the amino acids (Baker 2004). Importantly, imbalances and antagonisms with amino acids are rare and are not observed with typical practical diet formulations.

Excess crude protein is of little clinical significance except the period immediately after weaning (Goodband et al. 2014). High crude protein and high soybean meal-based diets have been shown to lead to an immune-mediated hypersensitivity that causes villous atrophy and reduced absorptive capacity in the small intestine (Li et al. 1991). High crude protein starter diets also can result in a large quantity of undigested nitrogen in the large intestine, which appears to be a factor in post weaning diarrhea (Heo et al. 2009). Lowering the quantity of protein in the diet decreases the ammonia concentration (Bikker et al. 2006), urea nitrogen, and volatile fatty acids in the small intestine (Nyachoti et al. 2006). It is thought that the decreased nitrogen concentrations going into the large intestine then reduce post weaning diarrhea due to reduced bacterial protein fermentation (De Lange et al. 2010). Nutrition in the post weaning transitional period has been managed by including high levels of lactose and highly digestible protein sources such as fish meal and spray-dried blood products (DeRouchey et al. 2010). However, a small amount of soybean meal in these diets has been useful to develop immune tolerance and mitigate the negative effects of delayed-type hypersensitivity

(Engle 1994; Friesen et al. 1993). The potential transmission of viral disease with animal products (Kim et al. 2008; Passick et al. 2014; Thimmasandra et al. 2015) has fostered current strategies using feed-grade amino acids, refined soy products, and reduced crude protein diets to manage the transition period around weaning

Sodium and chloride

Diets are typically supplemented with salt as a source of sodium and chloride due to relatively low cost and availability. Short-term Na and Cl deficiency in grain–vegetable protein source-based diets can cause marked reductions in feed intake and growth rate. Long-term salt deficiency will cause dehydration and mortality (NRC 2005). Chloride requirements are generally met with adequate supplementation of salt to meet the sodium requirement.

Most animal-derived products such as spray-dried blood products, fish meal, and dried whey typically have relatively high sodium content, so in some cases nutritionists will adjust the salt levels when these ingredients are used. A change in the composition of these products may lead to a deficiency, as seen in cases arising from the recent movement away from animal products in nursery diets. This change in nursery diets coupled with the relatively high requirement for sodium and chloride of the young pig has led to reevaluation and confirmation of their requirement estimates (NRC 2012; Shawk et al. 2017).

Sodium can cause toxicity when fed in excess with limited water availability (NRC 2005). The term "salt toxicity" is usually the result of limited water intake leading to increased osmolality in the brain (see Chapter 70). Rapid rehydration will lead to rapid swelling in the brain accompanied by neurologic signs and microscopic lesions (NRC 2005). Careful clinical history should focus on adequate access to water. Salt toxicity scenarios encountered include plugged water lines, large-scale facilities built with inadequate water supply lines, failure of wells or pumps during periods of high demand, or failure to open proper water valves after water medication, facility cleaning, or when restocking a room or barn.

Forms of added dietary salt can range from food-grade to rock salt. Salt available for animal diets must comply with standards as some forms of rock salt used for deicing roads may contain impurities or contaminants. Finally, water sources with high sodium or other mineral concentrations may be result in greater potential for toxicity than dietary salt and may influence water intake (NRC 2005).

Calcium, phosphorus, and vitamin D

Disorders of calcium, phosphorus, and vitamin D metabolism are among the most frequently encountered clinical nutritional disease in swine practice. Although these nutrients are involved in a wide array of metabolic functions essential for growth, the clinical signs most frequently presented are disorders of the musculoskeletal system, including fractures and pathology of the growth plates, or, less frequently, acute hypocalcemia tetany. Kyphosis in growing pigs associated with maternal vitamin D deficiency have been described (Amundson et al. 2016; Rortvedt and Crenshaw 2012). Clinical signs can also include lameness, which is clinically indistinguishable from that due to an infectious process. Due to the ability of the pig to mobilize calcium and phosphorus from bones while still maintaining growth rates, bone fractures and lameness are more sensitive clinical indicators than growth performance (Dritz et al. 2000), consistent with data indicating that calcium and phosphorus requirements are higher for bone mineralization than for growth performance (NRC 2012).

Phosphorus is the third most expensive component after energy and amino acids in swine diets, so diets are typically formulated to minimize its excess. Most phosphorus in plant-based ingredients is found in the form of phytic acid, a form low in bioavailability. As a result, swine diets are frequently supplemented with commercial phytases to improve the digestibility of phosphorus in plant-based ingredients. Because margins of safety are low with phosphorus in relationship to its requirement, anything that inactivates phytase, such as heat or prolonged storage (greater than 2–3 months), can result in phosphorus deficiency.

Calcium concentrations are low in most plant-based ingredients; however, addition of calcium to diets is relatively inexpensive. Limestone is a common supplemental source of calcium in swine diets and is also frequently used as a diluent for premixes and medications or as an additive to increase flow ability. If these supplemental sources are not accounted for, greater than expected calcium concentrations in diet can occur. Also, the calcium released by phytase is frequently not accounted for in formulations. When dietary available phosphorus is marginal, these unaccounted sources of calcium may result in a higher than expected calcium to phosphorus ratio. The increased ratio of digestible calcium to phosphorus will limit phosphorus absorption and lead to reductions in growth rate and bone mineralization (González-Vega et al. 2016). The ratio leading to clinical problems is not well defined, but an analyzed calcium to analyzed phosphorus ratio of more than 1.5 should be critically evaluated. An excess of calcium is of little consequence with adequate dietary phosphorus concentration (Létourneau-Montminy et al. 2012).

Vitamin D is important in the metabolic pathway to stimulate absorption of calcium and phosphorus from the gastrointestinal tract (Deluca 2014). There are different forms of vitamin D available for dietary additions, but vitamin D_3 (cholecalciferol) is the form most com-

monly supplemented in swine diets. Endogenous activation of vitamin D to D_3 is dependent on exposure to the ultraviolet spectrum from sunlight. Because many pigs are raised without direct exposure to sunlight, vitamin D_3 is routinely added to all swine diets, usually at levels above estimated requirements to provide a margin of safety. Dietary supplementation ranged from 5 to 10 times the suggested requirement (150–220 IU/kg; NRC 2012) in growing swine to 2 times or greater in adult swine (800 IU/kg) in a recent review of inclusion rates in the United States (Flohr et al. 2016).

Under short-term feeding conditions (less than 60 days), swine can tolerate as much as 33,000 IU D_3/kg of diet (NRC 1987). Higher doses will decrease feed intake. Feeding excess vitamin D for extended periods of time can result in calcification lesions in soft tissues and organs. For growing swine, the presumed maximum level of vitamin D_3 for long-term feeding conditions (more than 60 days) is 2200 IU D_3/kg of diet. The form of vitamin D supplemented may influence the toxicity, but there is only enough information available to set a minimum tolerance for vitamin D_3 supplementation (NRC 1987).

Special consideration for use of phytase is warranted. As phytase dosage increases, the release value of phosphorus increases at a diminishing rate, and the phosphorus release per unit of phytase varies across sources (Jones et al. 2010). Because phytase is an enzyme, it is susceptible to degradation during thermal processing; however, some forms have special coatings that provide resistance to heat degradation. The degradation has been shown to be accelerated by prolonged storage (greater than 60 days), increased ambient temperature, and the presence of other minerals and vitamins (Sulabo et al. 2011). Reduced amounts of phytate substrate found in certain ingredients, such as by-products of fermentation (e.g. DDGS) or grains that have high concentrations of endogenous phytase (e.g. wheat), can cause diminished phytase efficacy. Starter diet with high dose zinc supplements can reduce phytase efficacy and decrease calcium and phosphorus digestibility (Augspurger et al. 2004; Blavi et al. 2017). Added dietary phytase has dramatically decreased the need for inorganic phosphorus sources. As a result, feed manufacturing equipment may not be designed to handle the low inclusion rates, and errors in diet formulation can result from inappropriately sized or calibrated discharge augers for the calcium and phosphorus sources. Equipment malfunctions and failure to accurately add premixes or other micro-ingredients have also been implicated in clinical calcium and phosphorus disorder cases.

Chemical analysis of dietary phosphorus is typically consistent with laboratory variation of approximately 13% (AAFCO 2015). Calcium analysis, on the other hand, is more variable with a coefficient of variation of approximately 26% (AAFCO 2015). This variation in analytical accuracy must be kept in mind when comparing laboratory results with calculated composition. Also, this variance only accounts for laboratory analysis and does not account for sampling variance that emphasizes good sampling technique. Analysis of complete diets for vitamin D and phytase is rarely fruitful due to the large amount of analytic variability. However, in suspect cases where inclusion rates are confirmed, testing of a premix or phytase supplement is more appropriate because of the high concentrations in a premix or pure source lends itself to greater accuracy.

Bone ash is a common procedure used in a research setting as a measure of bone mineralization to determine the relative impact of dietary treatments (NRC 2012). Unfortunately, bone ash has not been useful as a diagnostic indicator. One reason for this is that bone ash cannot reliably predict the dietary mineral concentrations that the pig has been consuming nor reliably predict bone strength properties (Crenshaw 1986). Another reason is lack of standardization of the bone evaluated and analytic procedures such as whether the bones are defatted or not.

Serum calcium and phosphorus are tightly regulated by the body, so they may not be useful indicators of their physiological status until the advanced stages of a severe deficiency. For example, pigs affected with acute tetany or ataxia may have serum calcium levels from 4 to 8 µg/dL, which is diagnostic for acute hypocalcemia. Serum concentrations of 25-hydroxyvitamin D_3 offer the best indicator of vitamin D status. Extremely low or undetectable levels are diagnostically useful; however, clear diagnostically useful cutoff values are not available in swine. For example, research suggests that oral supplementation of vitamin D above that provided by the diet can influence serum 25-hydroxyvitamin D_3 across a wide range of values but without affecting bone mineralization or growth rate (Flohr et al. 2016). Urine chemistry values have been established but have not been validated across a variety of dietary exposures and are not practical in a field setting (Hagemoser et al. 2000).

Vitamin E and selenium

Acute death of rapidly growing young pigs is the classic clinical sign of mulberry heart disease, long associated with vitamin E or selenium deficiency. Cases are most commonly observed in the first few weeks after weaning (Pallarés et al. 2002). Gross lesions are those of acute heart failure, including excess fluid in pericardial and pleural cavities and multifocal to locally extensive hemorrhages on and in the myocardium. Microscopy confirms multifocal or diffuse acute myofibrillar necrosis, sometimes with mineralization. These lesions are consistent with the importance of these two nutrients in

cell membrane integrity (NRC 2012). Hepatomegaly and multifocal hepatic necrosis are less commonly observed. In the breeding herd, litter size has been shown to be improved in sows over four parities when supplemented with 0.15 or 0.3 ppm selenium compared with sows fed a basal diet without selenium supplementation that contained less than 0.1 ppm Se (Mahan and Peters 2004).

Natural vitamin E sources are more bioavailable in swine diets compared with the chemically synthesized vitamin E sources (Shelton et al. 2014). As with many other vitamins, placental vitamin E transfer does not occur, and colostrum intake is critical for providing vitamin E to the baby pig (Shelton et al. 2014). Toxicity from vitamin E has not been demonstrated in swine (NRC 1987).

Geographic location, both locally and regionally, has an influence on selenium content in grains. In the United States, grains from the Great Lakes region or east and southern coasts have lower selenium concentrations compared with those grown west of the Mississippi River (Mahan et al. 2005). Selenium-deficient regions occur globally, including large regions of China (Oropeza-Moe et al. 2015). In contrast, grains grown in the arid regions of the Dakotas, Wyoming, and the Prairie provinces of Canada have high selenium concentrations (Mahan et al. 2005; NRC 2005). This regional variation warrants attention to details of history, including exposure to soil and plants as well as sources of feedstuffs.

Selenomethionine from plant sources is more bioavailable than inorganic sodium selenite, which is typically added to swine diets (NRC 2005). The bioavailability of selenium in feed ingredients seems to vary widely depending on the ingredient and concentration in the ingredient (Henry and Amerman 1995). Bioavailability of selenium from organic yeast was greater than sodium selenite demonstrated by the increased transfer to colostrum and milk (Mahan and Peters 2004).

Selenium is the most toxic trace element added to swine diets. The maximum legal selenium addition in the United States is 0.3 ppm, and the maximum tolerable level in diets for swine is 4 ppm (NRC 2005). Decreased growth rate and feed efficiency are the most sensitive indicators of toxicity but are not specific. Clinical signs of more chronic exposures include hair loss and lameness resulting from separation of the coronary band at the hoof wall (Kim and Mahan 2001). Rapid development of paralysis resulting from bilateral spinal cord gray matter lesions has been reported with exposure to high dosages (NRC 2005). Kim and Mahan (2001) noted clinical signs of toxicity in the pigs fed either organic or inorganic selenium, but the former appeared to be better tolerated.

Although mulberry heart disease is often considered to be a result of vitamin E or selenium deficiency, in some cases the serum and tissue vitamin E and/or selenium concentrations are considered normal, and dietary concentrations are analyzed with at or above recommended levels (Pallarés et al. 2002; Shen et al. 2011). This and observations that suggest mulberry heart disease results from uncompensated stress suggest that vitamin E or selenium deficiency is not the only cause of this condition.

Supplemental vitamin E, in particular, is thought to aid in prevention of acute deaths. Appropriate physiological reference values derived from older literature may not properly reflect the status of modern production practices.

Other vitamins typically supplemented

Vitamin A

Vitamin A is an essential vitamin for growth and reproduction (NRC 2012). Because of liver storage levels, it has been difficult to create deficiency models in swine to clearly define requirements; consequently vitamin A deficiency has been difficult to accurately define. Several studies evaluating injection of vitamin A or its precursor, beta-carotene, have observed some reproductive benefit (Coffey and Britt 1993; Lindemann et al. 2008), whereas others have not (Tokach et al. 1994). Because the response is inconsistent, the wide-scale implementation of vitamin A injections in the breeding herd is not warranted.

Acute vitamin A toxicity is characterized by disturbances of nervous function (NRC 1987), whereas chronic signs of vitamin A toxicity include spontaneous fractures and bone malformation in growing pigs or osteomalacia in adults, as well as internal hemorrhage (Dittmer and Thompson 2015). Toxicity has been observed with dietary intake of approximately 10 times the estimated requirement of 20,000 IU/kg of diet for growing swine and 40,000 IU/kg of diet for breeding swine (NRC 1987). A survey across a broad section of the US swine industry indicates that supplementation rates on average ranged from 2.8 to 5.2 times recommended vitamin A requirement depending on the production stage (Flohr et al. 2016).

Although vitamin A deficiencies are rare, sporadic reports include congenital malformations such as arthrogryposis and eye defects, night blindness, or incoordination and altered gait. Diagnosis is by systematic and complete diagnostic investigation, including thorough examination of the nervous system and skeletal system. Analysis of livers from affected animals for vitamin A content can be useful to confirm deficiency.

Vitamin K

Deficiency of vitamin K results in increased clotting times and hemorrhages at multiple locations that fail to clot. Vitamin K deficiency in breeding females is most commonly reported as extended duration of newborn

pig navel cord hemorrhage. In contrast to other vitamins, few clinical signs outside of the association with decreased blood clotting time have been described. For example, in studies to establish vitamin K as an essential nutrient in the baby pig, normal growth was reported until signs of hemorrhage were observed (Schendel and Johnson 1962). Another mechanism of deficiency is intoxication with vitamin K antagonists such as warfarin, either from natural sources (sweet clover) or from rodenticides.

The normal gastrointestinal flora synthesis of vitamin K in growing pigs and adults can provide a significant amount of vitamin K to the point that pigs with access to fecal material may not require dietary supplementation (NRC 2012). However, as a precaution, vitamin K is routinely added to diets for all classes of swine. Menadione is the most commonly supplemented form of vitamin K in swine diets in the United States. Menadione pyrimidinol bisulfite (MPB) and menadione nicotinamide bisulfite (MNB) are the most commonly added forms of vitamin K. Menadione nicotinamide bisulfite has been observed to have the best stability characteristics of the vitamin K sources especially in the presence of choline or mineral mixes (Albers et al. 2002). Compared with other added vitamins, vitamin K is the least thermal-stable vitamin, and its oxidation can be as great as 50% after 30–60 days of storage in a premix; therefore it is routinely added above any suggested requirement to provide a margin of safety.

In swine, there has been little information to suggest any adverse effects from excess vitamin K or derivatives that provide vitamin K activity. A level of at least 1000 times the dietary requirement for menadione supplementation has been suggested as a minimum level to establish toxicity (NRC 1987).

Niacin (vitamin B_3, nicotinamide)

Niacin is a critical component of enzymes involved in energy metabolism. Severe niacin deficiency has been characterized by necrotic typhlocolitis, which resolved when supplemented (Dunne et al. 1949). Niacin is generally added to all swine diets because the bioavailability in feed ingredients is generally low (NRC 2012). The niacin requirement was increased from 10 ppm in the grower and 7 ppm in finisher pigs to 30 ppm in growing and finishing pigs in the latest edition of the NRC (2012). The requirement change was based on improved average daily gain and feed conversion when pigs were supplemented with niacin (Real et al. 2002). Ivers and Veum (2012) observed that 14 ppm niacin added to a diet maximized growth performance and prevented the occurrence of diarrhea, suggesting the niacin requirement may vary and be lower than 30 ppm in some situations. Tryptophan can be converted into niacin but inefficiently; hence it should not be relied upon. Few studies are available to define the niacin requirement in lactating and gestating sows; however, the NRC (2012) requirement is 10 ppm, while the average addition is 45 ppm in the United States (Flohr et al. 2016). Although data is limited, the maximum tolerable amounts of niacin in swine diets are at least 100 times the requirement (NRC 1987).

Riboflavin (vitamin B_2)

Riboflavin, like many of the other B vitamins, serves as a cofactor in energy and protein metabolism. In one of the few studies with riboflavin, an improvement in farrowing rate but not litter size was observed in sows supplemented greater than 60 mg/day compared with those supplemented 10 mg/day (Pettigrew et al. 1996). Riboflavin is deficient in typical corn–soybean meal diets (NRC 2012) and is routinely added at approximately two times the NRC (2012) requirement for all stages of production as a margin of safety (Flohr et al. 2016). High oral dosage at 10 and possibly 100 times the estimated requirement can be tolerated safely, but riboflavin does have a toxicity potential when administered parenterally (NRC 1987).

Pantothenic acid (vitamin B_5)

Toxicity with pantothenic acid, as with other water-soluble vitamins, is seldom an issue. Classic pantothenic acid deficiency signs are uncommon but described as "goose-stepping" or a gait with hyperextension of rear legs, which appears after approximately 7–10 days of feeding a purified diet devoid of pantothenic acid. Added dietary pantothenic acid is essential in diets for pigs up to approximately 15 kg body weight (Grinstead et al. 1998), but it appears that the pantothenic acid in corn and soybean meal may be sufficient to meet the requirements of 25–120 kg pigs (Groesbeck et al. 2007). When using cereal grains or ingredients other than corn and soybean meal, pantothenic acid may be less bioavailable; thus, added pantothenic acid may be needed (Southern and Baker 1981). To minimize any potential deficiency symptoms, pantothenic acid is typically added to diets fed to all classes of swine (Flohr et al. 2016).

Vitamin B_{12} (cyanocobalamin)

Anemia is one sign of vitamin B_{12} deficiency; however, there are few published papers available to establish a requirement estimate. Vitamin B_{12} is typically added to diets in all stages of production (Flohr et al. 2016). Plant products are practically devoid of vitamin B_{12}, but due to enteric microbial production, signs of deficiency are difficult to characterize (NRC 2012). No toxicity information is available in swine, but data from other species suggest that an upper safe level is at least 100 times the requirement (NRC 1987).

Other minerals typically supplemented

Copper

Copper is involved in a wide array of metabolic processes that range from hemoglobin production to a cofactor in several enzymes. Copper in a grain–soybean meal-based diet may be adequate to provide the nutrient requirement for growth performance in growing and finishing pigs (Gowanlock et al. 2013). However, copper is typically added to all swine diets with the suggested requirement ranging from 3 to 20 ppm (NRC 2012). In some countries, copper is added to diets for growth promotion at rates up to 250 ppm, particularly in nursery pigs (weaning to 22 kg).

Copper as sulfate or chloride salts and in organic forms have high bioavailability compared with other sources of copper (NRC 1998). Some have observed negative effects on growth from feeding 500 ppm copper for extended periods of time (NRC 2005) but not when feeding 250 ppm; therefore the maximum tolerable concentration has been set at 250 ppm added copper in swine diets (NRC 2005). Copper toxicity can cause hemolytic crisis similar to that described in other species, which is manifested as icterus, anemia, hemoglobinuria, and nephropathy. Feeding pigs added copper for growth promotion will lead to elevated liver concentrations.

Iodine

Iodine is an integral component of the thyroid hormones essential for metabolism (NRC 2012). Soil iodine varies by geographic location, which influences iodine content in crops and their respective feed ingredients. Iodine is a low-cost mineral, so it is typically supplemented in swine diets for all production stages (Flohr et al. 2016). Iodine deficiency results in thyroid hyperplasia ("goiter") from continued agonist effects of thyroid-stimulating hormone. Thyroid glands are grossly enlarged, and the characteristic lesion can be confirmed with histopathology. Nonspecific signs of reproductive failure, as well as piglets born with low viability, hairlessness, and grossly visible goiter, are reported with iodine deficiency.

Certain species of *Brassica*, which includes rapeseed, can increase the iodine requirement in swine diets. Older varieties of rapeseed or rapeseed meal contain glucosinolates, an anti-nutritional factor affecting thyroid metabolism; however, modern varieties of rapeseed (canola and other varieties) have been selected for low glucosinolate concentrations. Thermal processing can also mitigate the effects of these anti-nutritional compounds.

The suggested requirement for iodine is 0.14 ppm for all stages of swine (NRC 2012) with the maximum tolerable limit reported at 400 ppm (NRC 2005). One report indicates a moderate decrease in growth performance (Li et al. 2012); as dietary iodine concentration increased, the effect was greatest in grower pigs as opposed to finishing pigs. Iodine is typically included in the trace mineral premix for swine diets.

Iron

Iron is a critical component of hemoglobin and myoglobin for oxygen transport. Compared with other species, pigs are born with relatively little iron stored in the liver. This, coupled with low milk iron concentrations and lack of exposure to iron from the environment in modern production, can quickly lead to iron deficiency in suckling pigs. Supplemental iron by injection at birth or shortly thereafter has significant impacts on subsequent growth performance in the nursery phase. For example, in one study, pigs given a 200 mg injection of iron at birth were 3 kg heavier 28 days after weaning compared with those that were not treated with iron (Peters and Mahan 2008).

Iron deficiency in growing swine consuming typical diets is of little practical significance (NRC 2005). Animal products, grains, and oilseed meals typically include highly available forms of iron; hence supplementation of growing pig diets may not be necessary (Gowanlock et al. 2013). Limestone and phosphorus ingredients and other products mined from the ground also usually contain significant iron concentrations, as can water, which contributes to the total dietary iron concentration.

Dietary iron sources vary in bioavailability with sulfates the most available (NRC 1998), whereas oxides have virtually no absorption. Large excesses of other trace minerals can decrease iron absorption. Excess dietary iron in nursery pigs may facilitate the proliferation of pathogenic *Escherichia coli*. The maximum tolerable concentration of iron has been set at 3000 ppm in swine diets (NRC 2005); however, the maximum concentration tolerated is considerably lower when given either orally through water or parenterally. Also, some data suggest that pigs from sows with low vitamin E status are more susceptible to toxicity from iron injection (NRC 1987). Iron overload from parenteral injection causes acute necrosis and hemorrhage in multiple body systems, including the kidneys, muscle, liver, and stomach. While the molecular mechanisms are unknown, they appear to revolve around the breakdown of mitochondrial function (NRC 2005).

Manganese

Although typically added to swine diets, there are few reports that well characterize signs of a manganese deficiency well. Those cited report lameness, poor reproduction, and ataxia in offspring, but there is very little current data (NRC 2012). Gowanlock et al. (2013) observed that there was sufficient manganese in a corn–soybean meal–based diet to meet grower/finisher pig requirements for growth and hematological measurements. Reported requirements are considerably higher

in gestating and lactating sows (25 ppm) than growing pigs (4 ppm; NRC 2012).

Manganese is considered one of the least toxic essential elements (NRC 2005). Excess calcium, phosphorus, and iron can inhibit manganese absorption and may decrease tissue concentrations in some species. Pigs fed low iron concentrations are more sensitive to excess manganese, which may be the case with other trace minerals as well.

Zinc

Zinc is also essential for an array of metabolic processes and is a critical factor in protein metabolism. Zinc deficiency in swine is characterized by parakeratosis, especially on the legs, neck, and head. Nonspecific signs are slow growth and poor feed conversion. Due to zinc concentration variation and bioavailability in plant-based ingredients, zinc is typically added to all swine diets (Flohr et al. 2016). Requirement estimates for zinc in swine diets range from 50 to 100 ppm total zinc (NRC 2012) and sometimes at higher rates in boar diets to support spermatogenesis (Flohr et al. 2016). Since phytate reduces the bioavailability of zinc from plant sources, standard practice has been to provide concentrations more than the suggested requirement. In contrast, some reports suggest that added zinc is not needed in finishing pig diets (Gowanlock et al. 2013; Mavromichalis et al. 1999). Factors that may explain these responses in finishing pigs include mobilization of zinc from body stores (after adequate zinc concentrations have been fed in the nursery phase) and wide-scale adoption of phytase. Phytate reduces zinc bioavailability in plant-based ingredients, and inactivation of phytate with phytase improves trace mineral digestibility and reduces the need for dietary addition (Jolliff and Mahan 2012). High zinc dosages will decrease absorption of other minerals. In contrast, high calcium concentrations will decrease zinc absorption. This is especially important as some diets will contain relatively high calcium concentrations.

Supplemental zinc sulfate, zinc chloride, and organic sources are generally considered to have similar availability (100%) with zinc oxide considered to be 50–80% bioavailable (Baker and Ammerman 1995; NRC,1998). Supplementing zinc from zinc oxide at 1500–3000 ppm from weaning to approximately 12 kg is common practice in the United States and some other parts of the world to control diarrhea and improve growth performance (Flohr et al. 2016). Studies generally indicate that feeding high doses of zinc from zinc oxide is not additive with feeding growth-promoting concentrations of copper, but is additive when feeding antimicrobials (Hill et al. 2000, 2001; Shelton et al. 2011; Woodworth et al. 2005). The zinc dosage, rather than source, seems to be a more important factor for the growth-promoting response. However, serum zinc concentrations are increased when feeding highly bioavailable sources, which may potentiate toxicity (Hahn and Baker 1993). Feeding high zinc doses from zinc oxide reduces phytase efficacy and calcium and phosphorus digestibility (Augspurger et al. 2004; Blavi et al. 2017).

The maximum tolerable zinc concentration in swine diets has been set at 1000 ppm because toxicity signs have been noted when feeding 2000 ppm for long durations (NRC 2005). In one study, gilts were fed 0, 50, 500, or 5000 ppm zinc from zinc oxide from weaning through two parities. Sows fed 5000 ppm zinc weaned fewer pigs had greater rates of osteochondrosis and low liver concentrations of copper compared with sows fed the other concentrations (Hill et al. 1983). As a result, the maximum tolerable zinc level was left at 1000 ppm. The reasoning is that other sources of zinc used in diets may be more bioavailable and may be less tolerated. Despite this, feeding zinc from zinc oxide at 2000–3000 ppm for the first few weeks after weaning (up to approximately 12 kg) is common in the United States and other parts of the world. These high dose feeding regimens will lead to elevated liver zinc concentrations.

Added vitamins for specific situations

Biotin (vitamin B_7)

Biotin deficiency is commonly associated with hoof lesions, and the requirement for maintaining hoof integrity is between 0.05 and 0.1 ppm (Kopinski and Leibholz 1989). However, reports of improvements in reproductive performance and decreases in hoof lesions have not been consistent with biotin supplementation (NRC 2012). Nonetheless, biotin is commonly added to gestation, lactation, and boar diets. Because there are few reports consistently suggesting a biotin requirement for growing–finishing pigs (NRC 2012), it is infrequently added to diets for growing pigs (Flohr et al. 2016). Bioavailability appears to be low in plant-based ingredients (Kopinski et al. 1989). Data indicate that swine can safely tolerate dietary levels of 4–10 times the nutritional requirements and the maximum tolerable level of biotin may be much higher (NRC 1987).

Choline

Choline is an important source of labile methyl groups (NRC 2012). In most animals, the liver can produce sufficient amounts of choline needed for growth, but synthesis can be insufficient if diets are deficient in methyl groups. Betaine, pyridoxine, and methionine may spare choline as they also serve as methyl donors.

Choline is routinely added in gestation and lactation diets, but not routinely used in nursery and growing or finishing diets (Flohr et al. 2016). Data indicates that the pig has a high tolerance for choline with little evidence for toxicity (NRC 1987). An important consideration for

choline chloride addition to vitamin premixes is that it enhances the degradation of other vitamins and phytases in premixes or diets.

Folacin (vitamin B_9)

Folacin, supplemented as folic acid, is involved in metabolism of single carbon compounds such as methyl groups that have a wide range of metabolic functions. Although not all data agrees, folic acid supplementation has improved reproductive performance in several studies (Matte and Lauridsen 2013; NRC 2012). Folic acid supplementation is typically low cost; hence it is routinely added to all gestation and lactation diets (Flohr et al. 2016; NRC 2012). Deficiency signs in growing pigs have only been demonstrated using purified diets and inhibitors. There is little data to suggest any adverse effects for administration of high dosages relative to the requirement (NRC 1987).

Pyridoxine (vitamin B_6)

Pyridoxine is critical for nervous system function and tryptophan metabolism (NRC 2012). The requirement estimate for pyridoxine in the nursery pig is 7 ppm and is based on data indicating improved growth performance of weanling pigs (Matte et al. 2005; Woodworth et al. 2000; Zhang et al. 2009). Also, data suggests that pyridoxine may play a role in reproductive performance (NRC 2012). In a survey of US production systems, pyridoxine was added by approximately half the respondents in diets for the breeding herd and nursery pigs but by none in finishing pig diets (Flohr et al. 2016). Little information is available to determine maximum tolerable levels in swine (NRC 1987).

Thiamin (vitamin B_1, thiamine)

Thiamin is not routinely added to swine diets because typical feed ingredients provide ample amounts to meet requirements and there is no benefit to supplementation (Woodworth et al. 2000). However, thiamin is one of the most heat-labile vitamins and can also be inactivated in by-product ingredients such as unprocessed fish meal that contain thiaminase or sulfur-containing compounds (NRC 2012). Another notable exception is in diets containing sodium metabisulfite, which is used to reduce the effect of vomitoxin (Frobose et al. 2017). Metabisulfite has been shown to inactivate thiamin; hence when adding sodium metabisulfate to swine diets for vomitoxin mitigation, added thiamin may be necessary. Pigs affected with clinical neurologic signs and polioencephalomalacia lesions were responsive to thiamin injections after fed pelleted diets with a commercial feed additive containing sodium metabisulfite (Hough et al. 2015).

Mycotoxins in Grains and Feeds

Steve M. Ensley and Scott L. Radke

Introduction

Mycotoxins are secondary metabolites of mold or fungal growth in grains or forages. They affect many body systems with a wide variety of signs, lesions, and impaired productivity. The annual cost of aflatoxin (AF), vomitoxin, and fumonisin to US agriculture has been estimated at $1.66 billion (CAST 2003a). Economic impact may vary between years, but it is estimated that approximately 25% of the world's crops are affected by mycotoxins annually (Dohlman 2003). Wu and Munkvold (2008) estimated that if all US swine feeds had 20% inclusion rate of distillers dried grains with solubles (DDGS), losses of $147 million annually could occur from weight gain reduction due to fumonisins alone.

Most swine mycotoxin problems involve feed grains (e.g. corn, wheat, milo, cottonseed, barley, and other cereals). Fungal growth requires readily available carbohydrate (grains), moisture, oxygen, and appropriate temperatures, often 12–25 °C (Wilson and Abramson 1992). Plant or fungal stressors (drought, high ambient temperatures, insect damage, mechanical harvest damage, and reduced plant vigor) predispose crops to toxigenic fungal infection with subsequent mycotoxin production (CAST 2003a).

Simple visual examination, spore counts, or culture of either grain or feed will not predict safety for animals. Physical appearance of grain is not an accurate indicator for presence of mycotoxins as toxigenic fungi can occur in grains without production of mycotoxins, and there is little correlation between spore counts or degree of fungal growth and presence or concentration of mycotoxins. Conversely, absence of molds does not assure absence of mycotoxins, since high temperature and pressure during milling/pelleting may kill molds but the heat-tolerant mycotoxin persists (CAST 2003a). This explains how mycotoxins can be concentrated in some distillers byproducts, sometimes up to 3× the concentration present in the corn used for fermentation. Control of mycotoxins and reduction of effects in animals depend primarily on environmental and climate factors, crop management, storage conditions, and appropriate use of mycotoxin binders in the diet. This chapter will emphasize the six high-risk mycotoxins for swine: aflatoxin B_1 (AFB_1), ochratoxin A (OTA), deoxynivalenol (DON), ergot, fumonisin B_1 (FB_1), and zearalenone (ZEA).

Mycotoxin formation

Fungi infect and grow in growing crops. Mycotoxins may be elaborated by fungi during the growing season (field formed) or after harvest and in storage (storage formed). Conditions that favor fungal growth and mycotoxin formation are summarized in Table 69.1.

Field fungi (e.g. *Fusarium* spp.) require high equilibrium relative humidity (>70%) or grain moisture (>22%) for growth and potential toxin production. They cause death of ovules, shriveling of seeds, and weakening or death of embryos, but they grow poorly in storage after harvest; therefore toxin production may not occur in stored dry grain even if remoistened (Christensen and Kaufmann 1965).

Storage fungi, which include most *Aspergillus* spp. and *Penicillium* spp., may produce mycotoxins even when grain moisture is 12–18% and temperatures are 10–50 °C. However, *Aspergillus flavus*, considered a storage fungus, often produces AF in crops prior to harvest.

Certain geographic regions are at high risk for specific mycotoxins (Pier 1981), but regional predilection is altered by local growth conditions (e.g. drought, insect damage, early frost), transport or blending of grains, and improper storage.

Environment and management influence mycotoxin production and animal exposure to mycotoxins. Mycotoxins are higher in damaged or broken grain (e.g. screenings or milled grain). Screenings fed on-farm or locally at harvest increase mycotoxin exposure. Grain

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Table 69.1 Sources and conditions for selected mycotoxins important to swine.

Mycotoxin produced	Fungal source	Grains most affected	Optimal conditions	Agronomic influences
Aflatoxins B1, B2, G1, and G1; AFB_1 most toxic	*Aspergillus flavus* *Aspergillus parasiticus*	Corn, peanuts, cottonseed, milo	24–35 °C ERH 80–85% EMC 17%	Drought; insect damage; day–night temperature >21 °C; may produce toxin in storage
Deoxynivalenol	*Fusarium graminearum*	Corn, wheat, barley, other cereal grains	26–28 °C ERH 88% EMC 22%	Alternating warm and cool growing season; humid conditions; less likely increase in storage
Ergot alkaloids (ergotamine, ergovaline, others)	*Claviceps purpurea*	Rye, wheat, triticale, oats, barley	Moderate to cool when seed forms. Moist humid weather	Warm, humid conditions; wind and insects favor spread of infection
Fumonisin; toxins B_1 and B_2 most toxic; B_1 most prevalent	*Fusarium verticillioides*	Corn. Other commodities not reported	Likely <25 °C EMC > 20%	Dry, hot growing conditions, followed by moist autumn
Ochratoxin; ochratoxin A (OTA) is toxic fraction. Citrinin toxin	*Aspergillus ochraceus* *Penicillium viridicatum* *Penicillium citrinum*	Corn, wheat, barley, rye	12–25 °C; may produce toxin down to 4 °C. ERH 85% EMC 19–22%	Lower temperatures favor increased toxin yield; endemic in some parts of Europe; rare in the United States
T-2 toxin	*Fusarium sporotrichioides* *Fusarium poae*	Corn, barley, milo, wheat,	8–15 °C EMC 22–26%	Alternating cool and warm conditions; overwintered crops
Zearalenone	*Fusarium graminearum*	Corn, wheat	7–21 °C EMC 24%	Alternating high and low temperatures during maturation

ERH, equilibrium relative humidity; EMC, equilibrium moisture concentration.

above optimum moisture continues to respire in storage, producing water; alternating warm and cool temperatures during fall and spring may promote moisture migration and condensation during storage, reaching free moisture levels supportive of mold growth and toxin production. Feed in warm, humid conditions such as a nursery may mold and produce mycotoxins within a few days. For more extensive discussion and documentation of mycotoxin formation and sources beyond the scope of this chapter, see CAST (2003a). In addition, reputable federal, state, or commodity websites maintain information about crop risk from molds and mycotoxins. Computer models for estimating the probability of mycotoxin production based on rainfall, temperature, and insect damage have been developed to assist in predicting mycotoxin risk in crops (Dowd 2004; Prandini et al. 2009).

Intoxication by mycotoxins

Mycotoxicosis results from consumption of contaminated grain or feed by a susceptible animal. Dosage is usually expressed as parts per million (ppm) or parts per billion (ppb) in the diet. To convert from ppm in the diet to dose as mg/kg BW, use the following equation: %BW eaten × ppm (feed) = mg/kg BW where percentage is expressed as a ratio (e.g. 3% = 0.03).

Dietary deficiencies of protein, trace minerals, and vitamins may predispose to mycotoxicosis, and drugs that alter foreign-compound metabolism or detoxification could change metabolic response to mycotoxins (Coppock and Christian 2007).

Combinations of mycotoxins may be additive or synergistic in their effects. Mycotoxins that occur most frequently together are AFB_1 with FB_1 and DON with ZEA (CAST 2003b). Documented synergistic combinations are AFB_1 with FB_1, DON with FB_1, and experimentally AFB_1 with DON (Chaytor et al. 2011; Harvey et al. 1995a, 1996; Robertson et al. 2011).

Some mycotoxins are reported to alter immune function under certain conditions, enhancing development of infectious diseases (Bondy and Pestka 2000; Panangala et al. 1986; Pier 1981). Aflatoxins, trichothecenes, and OTA have been reported immunosuppressive in swine but with inconsistent conclusions. See individual mycotoxins for details. Immunosuppression is expressed indirectly; hence mycotoxin-facilitated infections are difficult to recognize or confirm and may sometimes be diagnosed incorrectly.

Clinical mycotoxicoses

Clinical response of swine to mycotoxins may be acute, subacute, or chronic and is both dose and time dependent. Response is usually subacute or chronic, and the presenting signs may be subtle or vague or expressed as alterations in feed intake, growth, feed efficiency, reproduction, or immunosuppression. Nevertheless, knowing the range of effects for specific mycotoxins is important in differential diagnosis and evaluation of clinical prognosis. Common mycotoxins affecting swine are summarized in Table 69.2 and discussed below.

Table 69.2 Characteristics of common mycotoxicoses in swine.

Toxin	Commodities	Clinical effects	Lesions, diagnosis, residues
Aflatoxins: B_1, B_2, G_1, G_2	Corn, cottonseed, wheat, peanuts, sorghum/milo	Reduced protein synthesis; hepatotoxicosis, cholangiohepatitis, hemorrhage, coagulopathy; chronic slow growth, poor feed conversion, reduced milk production, immune system dysfunction; classified a carcinogen	Hepatic necrosis, increased serum bile acids, bile duct hyperplasia; aflatoxin in feed; aflatoxin M_1 in liver or urine; return to normal 1–2 weeks post-exposure
Ochratoxin Citrinin	Corn, wheat, peanuts Wheat, rye, oats, barley	Nephrotoxicosis with polyuria and polydipsia. Gastric ulcers; anorexia and weight loss; reduced immunocompetence – for both ochratoxin and citrinin	Gastric ulcers and renal tubular damage or fibrosis; ochratoxin metabolites in kidney; high protein excretion in urine; residues may persist for weeks
Trichothecenes, macrocyclic (e.g. T-2 toxin; diacetoxyscirpenol) Relatively rare in North America	Corn, barley, wheat, rye sorghum	Hematopoietic suppression, anemia, leukopenia, hemorrhage, diarrhea, dermal irritation, or necrosis; reduced immunocompetence; self-limiting due to feed refusal	Test mycotoxin in feed; oral ulcers; lymphoid depletion; residues brief – 1–3 days; not common at clinical levels in North America
Deoxynivalenol (DON, vomitoxin)	Corn, wheat, barley, sorghum; common trichothecene worldwide	Feed refusal, vomiting, diarrhea, depression; variable effects on immunocompetence; rare reports of reduced litter size of stillbirths	DON concentration >0.5 ppm in feed – mild effect; clinical results 1–8 ppm; residues rapidly excreted (1–3 days); glucomannan binders variable effects on some aspects of toxicosis
Zearalenone	Corn, wheat, barley, sorghum	Estrogenic. Prepubertal gilts: vulvovaginitis, vaginal and rectal prolapses; signs of estrus. Mature sows: variable – nymphomania or anestrus; pseudopregnancy, retained corpora lutea – responsive to injection of PGF2α	Enlarged uteri/vulva (gilts), retained corpora lutea (sows); vaginal cornification; zearalenone >1 ppm in feed; excreted in urine, less in milk after 1–5 days
Fumonisins	Corn	Acute, fatal pulmonary edema (high dosages); hepatotoxicosis with icterus and liver necrosis (subacute exposure); some reports of chronic pulmonary effects; classified a carcinogen	Histologic lesions of massive pulmonary interlobular edema; liver apoptosis and bile retention; residues brief, mainly liver/kidney; serum increases in AST, GGT, bilirubin, and cholesterol are characteristic
Ergot alkaloids (ergotamine, ergocristine, ergonovine, ergocornine, ergovaline)	Cereal grains (barley, rye, triticale, wheat, oats) and grasses	Acute high doses: peripheral vascular necrosis with peripheral gangrene (feet, tail, ears); in late pregnancy causes reduced prolactin release with agalactia and piglet starvation	Ergot bodies should be <0.3% in feed; ergot alkaloids in urine 1–2 days post-exposure; ergot alkaloids recommended <100 ppb in feed; residues rapidly excreted; residues typically not a problem

Mycotoxin testing in grains and feed

A variety of diagnostic tests are available for the detection of mycotoxins in grains and feeds, which include bright green-yellow fluorescence, high-pressure liquid chromatography (HPLC), enzyme-linked immunosorbent assay (ELISA), and liquid chromatography with mass spectrometry in tandem (LC/MS/MS). Fluorescence is typically utilized as a mycotoxin screening method at grain elevators. Although rapid, it is not a reliable test for mycotoxins other than AF and is suggestive of the presence of AF but not definitive. ELISA kits are now used for initial detection and quantification of suspect grains and feeds (CAST 2003b). LC/MS/MS is highly specific and can be used to identify and quantify multiple mycotoxins that may contaminate grains and feed at the same time (Di Muvunga et al. 2009).

Grain and feed samples should be representative of what is being or will be consumed by animals; however, due to the potential of mycotoxicosis resulting in chronic complications, suspect grains or feed may no longer be available at the time of clinical signs. A prudent practice is to save a representative sample from each batch of diet mixed for at least a month after feed is consumed or until swine are marketed. Samples of feeds or grain should be representative and taken after feed is well mixed by passing a cup through a moving auger stream at frequent intervals, mixing samples thoroughly, and saving a 2–4.5 kg (5–10 LB) sample for analysis (Davis et al. 1980). High-moisture samples should be either dried to 12% moisture or stored frozen. Long-term storage is recommended in paper bags permanently marked with the date and source of the feed or grain, and samples should be held in a dry, clean location.

Aflatoxins

Formation and Metabolism

Aspergillus flavus, *Aspergillus parasiticus*, and *Aspergillus nomius* produce AF (AFB_1, B_2, G_1, and G_2) before harvest and in storage. Aflatoxins B_1 and B_2 are more likely produced by *A. flavus* in corn and cottonseed, while *A. parasiticus* usually produces all four fractions in peanuts (Coppock and Christian 2007). AFB_1 is the most abundant and toxic fraction from natural contamination. Conditions supporting AF formation often occur in the southeastern United States (Bennett and Klich 2003) or during drought and insect infestation elsewhere. Aflatoxins are not destroyed during ethanol production and can be concentrated three- to fourfold in the distillers grains by-product (Rustemeyer et al. 2010). Contaminated corn sold to ethanol plants may increase mycotoxicosis risk, and because variation in mycotoxin occurrence in DDGS is expected, consistent sampling and testing is prudent.

Aflatoxin B_1 is metabolized by liver microsomal mixed-function oxidases to seven metabolites (Coppock and Christian 2007). The major toxic metabolite is an 8,9-epoxide that binds covalently to DNA, RNA, and proteins. The DNA N^7 adduct is resistant to repair and likely responsible for causing clinical signs, lesions, and hepatic cancer. Impaired protein synthesis and inability to mobilize fats cause early lesions of hepatic fatty change and necrosis, as well as reduced growth. Protein-deficient diets enhance AF effects on depression of weight gain (Coffey et al. 1989).

Toxicity

Aflatoxin effects in swine depend on dose, diet, exposure time, and age. The single acute oral dose LD_{50} for swine is 0.62 mg/kg body weight (BW) (equivalent to approximately 20 ppm in diet for 1 day); dietary levels of 2–4 ppm for extended time can cause fatal toxicosis; rations containing 260 and 280 ppb for several weeks cause reduced growth (Allcroft 1969; Marin et al. 2002). A diet containing 2.5 ppm AFB_1 fed to 17.5 kg barrows for 35 days decreased BW, rate of gain, and feed consumption (Harvey et al. 1995a,b), serum gamma-glutamyl transferase (GGT) and total iron concentration (TIC) increased, and blood urea nitrogen (BUN) and total iron-binding capacity (TIBC) decreased. Relative liver weight increased, and liver was pale, rubbery, and resistant to cutting. Microscopic lesions included hepatic necrosis and degeneration accompanied by bile duct proliferation.

Prolonged dietary AF affects productivity and immune function (Cook et al. 1989; Dilkin et al. 2003; Harvey et al. 1988, 1989b; Marin et al. 2002; Rustemeyer et al. 2010). Liver lesions are caused by dietary concentrations of 140 ppb for 12 weeks in 18–64 kg swine, and 690 ppb produced mild liver lesions in 64–91 kg finishing hogs (Allcroft 1969). AFB_1 fed at 280 ppb to weanling pigs for 28 days caused significantly decreased weight gain, but no effect on total erythrocyte count, differential leukocyte count, total globulin, albumins, or total protein concentration in serum. Rustemeyer et al. (2010) fed 0, 250, and 500 ppb to barrows for 7, 28, or 70 days. The 500 ppb AFB_1 diet depressed feed intake and average daily gain but 250 ppb did not. Serum aspartate aminotransferase (AST) was higher in AF groups, but BUN was lower than controls. Lower BUN may be from reduced protein turnover and/or reduced liver function. Both 250 and 500 ppb produced adverse effects on some measures of performance and health. Taken together, most studies suggest that a threshold for moderate effects on performance of swine is slightly above 200 ppb.

Clinical effects

Acute-to-subacute aflatoxicosis causes depression and anorexia, anemia, ascites, icterus, hemorrhagic diarrhea, and sometimes coagulopathy from hypoprothrombinemia (Coppock and Christian 2007; Osweiler et al. 1985). Hepatocellular enzymes are elevated, including AST, ALT, alkaline phosphatase (ALP), and GGT. Other serum clinical chemistry changes are decreased TIBC, total protein, albumin, cholesterol, BUN, and glucose (Harvey et al. 1989b). Total bilirubin, icterus index, sulfobromophthalein clearance, prothrombin time, and partial thromboplastin time are elevated (Panangala et al. 1986).

Lesions

Lesions of aflatoxicosis include pale tan or clay-colored liver with centrilobular hemorrhages, fatty change, subserosal petechial to ecchymotic hemorrhages, and intestinal and colonic hemorrhages. With time, the liver becomes yellow, and fibrosis develops with a firm parenchyma, accentuated lobular pattern, and generalized icterus. Microscopic alterations useful for diagnostic purposes include hepatocyte vacuolization, necrosis, and lipidosis, which are all predominant around the central veins. As disease progresses to subacute or chronic, hepatomegalocytosis, multiple nuclei, interlobular fibrosis, and biliary hyperplasia appear (Cook et al. 1989; Harvey et al. 1988, 1989a).

Reproductive effects

Abortion is not expected. Sows fed AF have maintained normal reproduction through four successive gestations at dietary concentrations of 500 and 700 ppb. Piglets nursing these sows had reduced growth from AF excretion in milk (Armbrecht et al. 1972; McKnight et al. 1983). Mocchegiani et al. (1998) observed reduced piglet birth weight where sows were fed 800 ppb AFB_1 from day 60 of gestation through 28 days post farrowing. Liu et al. (2015) observed a decrease in oocyte maturation *in vitro* following oocyte exposure to AFB_1.

Immunocompetence

Aflatoxin affects cell-mediated immunity and phagocytic cell function (Bondy and Pestka 2000). Common diseases influenced by AF under experimental conditions include swine erysipelas, swine dysentery, and salmonellosis (CAST 2003b). Immunocompetence was reduced in piglets nursing AF-exposed sows (Silvotti et al. 1997) where sows fed 800 or 400 ppb purified AFB_1 through gestation and lactation had AFB_1 and aflatoxin M_1 (AFM_1) residues in milk 5 and 25 days after parturition. Residues were approximately 1000-fold lower than that in the feed, with increases during the 25 days after parturition. Lymphoproliferative response to mitogens was reduced, and monocyte-derived macrophages failed to efficiently produce superoxide anions after oxidative burst stimulation *in vitro*. Mehrzad et al. (2014) observed that AFB_1 reduced phagocytic capacity of monocyte-derived dendritic cells as well as a reduction in these cells to induce T-cell proliferation. Ability of macrophages to phagocytose red blood cells was not compromised, but granulocytic cells had reduced chemotactic response *in vitro*. Marin et al. (2002) reported that 4-week feeding of 280 ppb AF reduced weight gain in swine while increasing leukocyte count and raising serum gamma globulin. Immune response to *Mycoplasma agalactiae* was reduced, and cytokine mRNA expression was associated with decrease of some proinflammatory factors (IL-1β and TNF-α), but increased anti-inflammatory IL-10 cytokine expression.

Residues

The AFM_1 metabolite can occur in tissues, milk, and urine of swine at relatively low concentrations and is not persistent. Dietary concentrations of 400 ppb resulted in tissue residues of 0.05 ppb or less, which rapidly disappear when AF feeding stops (Trucksess et al. 1982).

Diagnosis

Depression, hemorrhagic diarrhea, acute icterus, hemorrhages, and coagulopathy suggest acute aflatoxicosis, whereas chronic signs include slow growth, malnutrition, icterus, and persistent low-grade infections. A history of contaminated feed is important. Liver lesions, clinical chemistry changes, and chemical analysis of the ration and grain supply are important for confirmation. Effective and economical ELISA kits are used for detection and initial quantification of suspect grains. Use only USDA-GIPSA-approved test procedures; if positive by ELISA, use a confirmatory chemical analysis to verify the result (CAST 2003b). Make sure the ELISA kit used is valid for the feed analyzed. Many ELISA kits are only validated for whole shelled corn.

Therapy

Aflatoxicosis is generally not amenable to individual animal treatment as specific practical antidotes for affected animals are not available. Supportive intervention such as increased high-quality protein, selenium, and vitamins A, D, E, K, and B complex supplements have been recommended (Coffey et al. 1989; Coppock and Christian 2007). The potential of organic Se to reduce immunocompromising effects of AFB_1 by increasing antioxidant

ability and expression is reported by Hao et al. (2016). Supplemental therapy with choline and methionine has been recommended for aflatoxicosis in poultry, but has not been evaluated in swine (Cullen and Newberne 1994). Concurrent infectious diseases in animals with AF-compromised immune function can be appropriately medicated or immunized. Lincomycin and tylosin added to AF-contaminated diets neither decreased or enhanced the detrimental effects of aflatoxicosis in growing swine (Harvey et al. 1995b).

Prevention

No Food and Drug Administration (FDA) approved preventive additives for aflatoxicosis are available in the United States. Availability of preventive feed ingredients varies in other countries. One or more common anticaking agents for feed may provide effective physical binding for AF. Hydrated sodium calcium aluminosilicates (HSCAS) at 0.5% in the diet have consistently provided substantial protection against loss of gain and occurrence of lesions from dietary AF in swine (Harvey et al. 1989b; Phillips et al. 2002). Sodium or calcium bentonite also has value as an adsorbent (Schell et al. 1993). Clay- and yeast-based ingredients may have some ability to reduce the impact of mycotoxins (Weaver et al. 2013). Treatment of grain with anhydrous ammonia for 10–14 days has reduced AF concentration in grain, and swine accept ammoniated grain with growth comparable with controls. Meissonier et al. (2009) fed weanling pigs up to 1912 ppb AFB_1 for 28 days in combination with diet containing 0.2% glucomannans derived from yeasts in prevention of aflatoxicosis and found that those receiving dietary glucomannan had decreased severity of liver lesions, protected phase I metabolic enzymes, and restored ovalbumin-immunized specific lymphocyte proliferation compared with inhibition caused by AF.

Ochratoxin and citrinin

OTA and a related mycotoxin, citrinin, are fungal nephrotoxins. See Table 69.1 for sources and conditions of production. OTA is commonly found from eastern and northern Europe, Canada, and the northern United States (Juszkiewicz et al. 1992) and is also reported prevalent in Denmark, associated with the feeding of barley and oats (Carlton and Krogh 1979). Toxicosis has been documented in swine fed contaminated corn in the United States (Cook et al. 1986).

Toxicity is related to binding of OTA in specific renal organic ion transporters (Huessner et al. 2002) resulting from inhibition of phenylalanine-metabolizing enzymes, adenosine triphosphate (ATP) production, and lipid peroxidation (Marquardt and Frohlich 1992). Ochratoxin is a genotoxic carcinogen via oxidative DNA lesions coupled with DNA adducts (Pfohl-Leszkowicz and Manderville 2007). Immunosuppressive effects are a combination of suppressed lymphocyte proliferation and interference with the complement system (Bondy and Pestka 2000).

In swine, OTA at 1 mg/kg BW (0.03 ppm dietary) is lethal in 5–6 days. Concentrations of 1 ppm in the diet for 3 months cause polydipsia, polyuria, reduced growth, and lowered feed efficiency. Levels as low as 200 ppb for several weeks cause detectable renal lesions. Additional clinical signs are diarrhea, anorexia, and dehydration. Sometimes no clinical signs are noted, and the only effect observed is the appearance of pale, firm kidneys at slaughter, a not uncommon association with OTA in endemic areas of Eastern Europe, Denmark, and Sweden.

Clinical pathology changes are increases in BUN, plasma protein, packed cell volume, AST, increased urinary glucose, and proteinuria. Riley and Petska (2005) identified a correlation between histological renal damage from ochratoxin and high-level excretion of urinary proteins. Citrinin, ochratoxin, and penicillic acid are synergistic and produce nephrosis characterized by necrosis of the proximal convoluted tubules, followed by interstitial fibrosis. Liver damage with fatty change and necrosis may occur but is less severe than for other primary hepatic toxicities. Gastric glandular mucosal ulceration is a characteristic and consistent lesion in prolonged clinical cases (Carlton and Krogh 1979; Szczech et al. 1973). Boars given 20 µg OTA orally for 6 weeks had reductions in ejaculation volume, and sperm viability and motility after 24 hours storage were significantly reduced compared with controls (Biro et al. 2003). These were 250 kg boars given 20 µg, a dose of 0.08 µg/kg (ppb).

Spontaneous occurrence of dose-related clinical *Salmonella choleraesuis* infection occurred in piglets fed 1 and 3 ppm dietary ochratoxin (Stoev et al. 2000). In further studies, *Brachyspira hyodysenteriae* and *Campylobacter coli* infections were concomitant with OTA immunosuppression and delayed immunization response.

Diagnosis is confirmed by finding toxin and/or metabolites (ochratoxin alpha) in feed or fresh kidney combined with history and characteristic lesions. HPLC accompanied by tandem mass spectrometry can be used to detect OTA in renal tissue (Hou et al. 2015). The approximate half-life for OTA in swine tissue is 3–5 days, and little or no ochratoxin can be found in kidneys 30 days after ochratoxin exposure ceases (Carlton and Krogh 1979). Mildly affected animals may recover if removed promptly from the contaminated feed, but if clinical course is prolonged, recovery is slow.

Countries with known or potential ochratoxin contamination have regulations controlling the presence of OTA in food and animal feeds because of concerns for food contamination and potential carcinogenicity.

Trichothecenes

Trichothecenes include at least 148 structurally related compounds. Those of known veterinary importance are produced by *Fusarium*, especially *Fusarium graminearum* and *Fusarium sporotrichioides* (Table 69.1). This group of sesquiterpene toxins has an epoxide group responsible for most toxic effects. Those receiving most attention worldwide are T-2 toxin, diacetoxyscirpenol (DAS), and DON (vomitoxin). Even though much work has been done with the macrocyclic trichothecenes (T-2 and DAS) in swine, they rarely occur at toxic concentrations in North American grains. DON, however, is a common contaminant with potentially multiple effects (Mostrom and Raisbeck 2007).

Trichothecenes are metabolized in two phases. Phase 1 oxidation and hydrolysis is followed by conjugation with glucuronic acid. In the gut the epoxide ring is cleaved by gastrointestinal (GI) microflora (Bauer 1995). Serum, bile, urine, liver, kidney, and muscle may contain DON metabolites (mainly de-epoxy DON) (Doll et al. 2003; Goyarts et al. 2007). The glucuronide is rapidly excreted in urine and appears not to accumulate in plasma (Eriksen et al. 2003).

T-2 toxin in large dosages can cause direct skin irritation and necrosis, profound lymphoid depletion, gastroenteritis, diarrhea, shock, cardiovascular failure, and death from experimental direct dosing. Chronic administration causes hematopoietic suppression and eventual pancytopenia, and T-2 and DAS are immunosuppressants. Although T-2 and DAS are potent toxins, they occur at relatively low concentrations, and their tendency to induce feed refusal and/or vomiting in swine makes them somewhat self-limiting as toxins, except as potential causes of reduced feed consumption.

DON is a common mycotoxin of corn, barley, and wheat and is an economic issue because of feed refusal or reduced feed intake in swine (Bergsjo et al. 1993; Rotter et al. 1996; Trenholm et al. 1984). In corn, DON occurs at low levels during some harvest seasons, with prevalence as high as 50%. Contamination in other grains and in other parts of the world also occurs (CAST 2003a).

Clinical effects of DON

The effect of DON is dose related and starting at approximately 1 ppm, which can lead to a reduction in feed consumption in weaning-age swine; total feed refusal may occur at concentrations in excess of 10 ppm (Bergsjo et al. 1992; Pollman et al. 1985; Rotter et al. 1996; Young et al. 1983). DON at four dietary levels <1 ppm caused no reduction of feed intake (Accensi et al. 2006).

Studies of hematology and clinical chemistry for DON toxicosis are limited, with limited impact suspected at low or moderate dosages. Accensi et al. (2006) found that pigs accepted DON feeds containing <1 ppm and there were no changes in 9 standard hematological variables or 18 routine biochemical variables (cations, glucose, urea, creatinine, bilirubin, cholesterol, triglycerides, and plasma enzyme activity). Low concentrations caused no changes in piglet immune responses for immunoglobulin (Ig) subset concentration, lymphocyte proliferation, and cytokine production. Based on pair-fed control studies, altered clinical laboratory values appear due to differences in feed intake; thus hematologic and blood chemistry tests may be of limited value in diagnosing low-level dietary DON in swine (Accensi et al. 2006; Lun et al. 1985; Prelusky et al. 1994; Swamy et al. 2003).

There are many controlled studies of DON in swine in a dosage range of 2–8 ppm DON, a common level for naturally contaminated grains and for the variable effects on feed refusal. Generally, most experience shows that DON effects are transitory and any disturbed function is recovered shortly after DON is removed from the diet as compensatory or adaptation mechanisms are established (Rotter et al. 1994).

DON feeding studies with dietary levels from 2 to 8 ppm show linear reductions in feed intake and rate of gain, but variable results for feed efficiency (Dänicke et al. 2008; Doll et al. 2008). Signs include lethargy, restlessness, weight loss, cannibalism, and one report of increased skin temperature. Gross lesions are absent to variable but have included loss of body mass, empty GI tract, increased folding of the esophageal stomach, increased liver weights, and reduced thyroid size. The most consistent clinical laboratory changes have been decreased serum proteins, globulin, and alpha globulin with increased albumin/globulin ratio and reduced serum urea. Variable or inconsistent laboratory values have included decreased hematocrit, segmented neutrophilia, hypocalcemia, hypophosphatemia, increased serum thyroxine (T4) and changes in serum cortisol, or no consistent changes reported (Bergsjo et al. 1993; Dänicke et al. 2008; Diaz-Llano and Smith 2007; Doll et al. 2007, 2008; Rotter et al. 1994).

Laboratory evidence of immune dysfunction varies among swine studies. In general, DON appears to increase IgA concentration in blood, and nonspecific lymphocyte proliferation can be either increased or decreased (Doll et al. 2009; Frankic et al. 2008; Pinton et al. 2008; Tiemann et al. 2006). Pinton et al. (2008) fed pigs 2.2–2.5 ppm DON for 9 weeks. Results included increases in ovalbumin-specific IgA and IgG. Lymph nodes from treated pigs had reduced expression of TGF-β and IFN-γ mRNA, interpreted by the authors that DON may reduce immune response to vaccine. Doll et al. (2009) found *in vitro* changes that included the following: DON and LPS were synergistic for increased mRNA expression of TNF-α in hepatocytes,

DON stimulated a dose-dependent induction of IL-6 mRNA, supernatant concentrations of LPS-induced IL-6 were significantly decreased, and mRNA expression of the anti-inflammatory IL-10 was increased by DON. They concluded that DON has the potential to provoke and modulate immunological reactions of porcine liver cells.

Variable results from *in vitro* and *in vivo* studies are characteristic of DON response in other mammals as well. There is no clear dose–response relationship across available studies. There is need for continuing effort to refine and expand the clinical and laboratory knowledge of effects of DON in swine.

Feed refusal mechanisms

DON in swine causes conditioned taste aversion and flavoring agents did not correct that refusal (Osweiler et al. 1990). Low-level DON exposure (30 µg/kg intragastric) increases cerebrospinal fluid 5-hydroxyindoleacetic acid (5-HIAA). DON feeding sequentially elevates brain tryptophan, serotonin (5-hydroxytryptamine [5-HT]), and 5-HIAA. Hypothalamic dopamine (DA) is decreased and 5-HIAA:5-HT ratios are elevated. Brain norepinephrine levels decrease as well. Serotonin (5-HT) increases initially and then drops significantly at 8 hours (Prelusky 1993, 1996; Swamy et al. 2002, 2004). Fusaric acid (FA) is a less well-known mycotoxin that appears to interact with DON in the tryptophan–5-HIAA–serotonin relationship. It is considered an interacting or potentiating mycotoxin with DON for feed refusal and is likely an important part of feed refusal mechanisms (Swamy et al. 2002, 2004).

Diagnosis

Mycotoxin-related feed refusal presents a difficult problem to the clinician as a multitude of factors including other toxins, drugs, concurrent disease, inclement weather, and reduced water intake may contribute to feed refusal. There is no apparent detectable effect of DON on plasma levels of brain neurotransmitters at DON doses that cause vomiting in swine. Thus, sampling of peripheral blood would not predict the central serotoninergic effects associated with DON toxicosis (Prelusky 1994). Trichothecenes are rapidly metabolized, and diagnosis by analysis of tissue or blood samples is rarely practical. Variable blood and tissue values and rapid excretion of metabolites do not support diagnostic differentiation of animals fed low levels of DON (Doll et al. 2008). Fortunately, rapid metabolism and excretion reduces residue potential in edible swine tissues (Bauer 1995).

Often the DON concentration detected chemically in feed is insufficient to fully explain feed refusal. The discovery of conjugated trichothecene mycotoxins, including conjugated DON, has shown that standard chemical methods may not detect all DON present in grains, but they may be released by hydrolysis in the GI tract. Analytical laboratories are currently working to detect this portion of mycotoxins in feed sources (Berthiller et al. 2005; Zhou et al. 2007). When mycotoxins are bound to other compounds, they may become masked and potentially difficult to detect analytically.

Antiemetics that are specific serotonin (5-HT) receptor antagonists (ICS 205-930, BRL 43694 A) prevent DON-induced vomiting in swine, and anticholinergic compounds were moderately effective at high dosages acting directly at the emetic center. However, antihistaminic and antidopaminergic antiemetics were not effective against DON (Prelusky and Trenholm 1993).

Prevention

Attempts to prevent DON effects have been by feeding adsorbents or using chemical or physical means for detoxification (see Table 69.3). These have included calcium aluminosilicate, bentonite, and sodium metabisulfite. Few of these have been successful in an economic and practical way. Avantaggiato et al. (2004) developed an *in vitro* GI model for reduction in intestinal absorption of DON and nivalenol. With 2% activated carbon (charcoal), there was a reduction of absorption from 51 to 28% for DON and from 21 to 12% for nivalenol. Addition of 5% citric acid or 5% lactic acid solutions to feed has the potential to decrease trichothecene concentrations in feed (Humer et al. 2016). Addition of sodium metabisulfite to swine diets negates some of the adverse effects of DON (Dänicke et al. 2010). Sodium metabisulfite lessens the effects of DON on ADG and feed efficiency. Feeding of a polymeric glucomannan adsorbent (GMA) to starter pigs prevented some known effects of trichothecenes on brain neurochemistry and promoted increased serum Ig concentrations, but did not improve growth rate (Swamy et al. 2002). Swamy et al. (2003) also fed starter pigs diets contaminated with combinations of DON, FA, and ZEA to test the ability of GMA to control mycotoxin effects using pair-fed control group to account for effects of reduced feed intake and found that GMA prevented some toxin-related changes in metabolism; however, the growth depression was not corrected by GMA. Most of the adverse effects on laboratory values were caused by reduced feed intake. Diaz-Llano and Smith (2006) fed 5.5–5.7 ppm DON to pregnant gilts from gestation day 91 through farrowing. A comparable group fed DON was supplemented with 0.2% GMA. Those fed diets containing DON at 5.5–5.7 ppm with no GMA had reduced daily gain and a significant increase in

Table 69.3 Selected approaches to inactivate mycotoxins in swine feeds.

Mycotoxin	Agent or process	Details and comment	References
Aflatoxins	Ammoniation via anhydrous ammonia infusion or jack bean meal (urease)	Effectively destroys aflatoxins and is accepted by swine; not currently approved by FDA for use in food animals. Commercial products for aflatoxin destruction generally not available	CAST (2003c)
	Bentonite, zeolite	Effective in some studies; generally less effective than HSCAS (see below)	CAST (2003c)
	Hydrated calcium aluminosilicates (HSCAS)	Effective in improving performance (weight gain, feed efficiency) and protection against liver damage at 10 g/kg diet (range 5–20 g/kg). Available commercially as an anticaking agent (e.g. Novasil®) but not FDA approved for this use	CAST (2003c); Phillips et al. (2002)
Deoxynivalenol (DON)	HSCAS, bentonite, and zeolite	Generally ineffective for binding of trichothecenes including DON	CAST (2003c)
	Glucomannan adsorbents (GMA)	Benefits are variable for improving feed intake or rate of gain when DON is prominent. Some benefit occurred in studies where DON and/or zearalenol was associated with reduced fertility or live-born pigs or with increased serum ammonia	Avantaggiato et al. (2004); Diaz-Llano and Smith (2006, 2007); Diaz et al. (2010); Swamy et al.(2002, 2003)
	Physical decontamination	Abrasive pearling procedure removed 66% of DON with loss of only 15% of grain mass	House et al. (2003)
Ergot	Physical methods of cleaning to remove ergot bodies	Chemical binders generally have not been tried or have not been effective in feeds	CAST (2003c)
Fumonisins	Binding of fumonisins with glucose or fructose	Chemical inactivation of fumonisins has been accomplished with glucose or fructose; this method, while effective, has not yet been developed for commercial use	Fernández-Surumay et al. (2005)
Zearalenone	GMA binders	Some studies have shown benefits from GMA binders where zearalenone is present; more work is likely needed in this area	See references for DON above
	Activated charcoal or alfalfa meal	Activated charcoal in rations or high levels (≥20%) of alfalfa meal have also been effective against zearalenone	Avantaggiato et al. (2004) James and Smith (1982);
Mold growth	Prevention of mold growth	Keep storage conditions clean and moisture to recommended levels. For wet or damaged grains, organic acids (e.g. propionic acid) are available to control mold growth, but does not destroy preformed mycotoxins	CAST (2003c)

stillborn piglets; no effects on standard clinical chemistry values were observed.

Physical decontamination of DON from barley was demonstrated by use of an abrasive pearling procedure, which removed 66% of DON with loss of only 15% of the grain mass (House et al. 2003). This method could provide a practical means for reducing DON contamination to a manageable level in years of widespread crop contamination.

Xiao et al. (2013) detected increased proliferation of peripheral lymphocytes and an improvement in feed efficiency through the use of antimicrobial peptides in pigs dosed with DON. Four experiments conducted by Frobose et al. (2015) to evaluate preventatives for effects DON in swine diets found positive response to pelleting and a commercial additive containing a combination of preservatives, antioxidants, amino acids, and direct-fed microbials. Sodium metabisulfite has been reported to lessen the effects of DON in swine diets (Dänicke et al. 2005).

In 2011, the US FDA updated a nonbinding guidance statement on use of DON in animal feeds for a maximum DON of 5 ppm in grain and grain products with a maximum dietary inclusion of 20%, resulting in a 1 ppm maximum for finished feeds on an 88% dry matter basis (Table 69.4).

Table 69.4 Exposure guide to mycotoxin effects in swine.

Toxin	Category of swine	Dietary level	Clinical effect
Aflatoxins	Growing–finishing Brood sows and gilts	1) <100 ppb 2) 200–400 ppb 3) 400–800 ppb 4) 800–1200 ppb 5) >2000 ppb 6) 400–800 ppb	1) No clinical effect 2) Reduced growth and feed efficiency; possible immunosuppression; mild microscopic liver lesions 3) Microscopic liver lesions, cholangiohepatitis; elevated serum liver enzymes; immunosuppression 4) Reduced growth; decreased feed consumption, rough hair coat; icterus, hypoproteinemia 5) Acute hepatosis and coagulopathy; deaths in 3–10 days 6) No effect on conception; deliver normal piglets that grow slowly due to aflatoxin in milk
Ochratoxin and citrinin	Finishing Sows and gilts	1) 200 ppb 2) 1000 ppb 3) 4000 ppb 4) 3–9 ppm	1) Mild renal lesions seen at slaughter; reduced weight gain 2) Polydipsia; reduced growth; azotemia and glycosuria 3) Polydipsia and polyuria 4) Normal pregnancy when fed first month
Trichothecenes T-2 and DAS	Growing–finishing	1) 1 ppm 2) 3 ppm 3) 10 ppm 4) 20 ppm	1) No effect 2) Decreased feed consumption 3) Decreased feed consumption; oral/dermal irritation; immunosuppression 4) Complete feed refusal, vomiting
Deoxynivalenol (DON, vomitoxin)	Growing–finishing	1) <1 ppm 2) 2–8 ppm 3) 10 ppm	1) No clinical effect; minimal (10%) reduction in feed consumption at >0.5 ppm 2) 25–50% reduction in feed consumption; taste aversion to same diet. Limited and variable immunosuppression – humoral and cell mediated; occasional reports of stillbirths 3) Complete feed refusal
Zearalenone	Prepubertal gilts Cycling sows and gilts Pregnant sows Mature boars	1) 1–3 ppm 2) 3–10 ppm 3) >30 ppm 4) 200 ppm	1) Estrogenic; vulvovaginitis, prolapse in prepubertal gilts 2) Retained corpora lutea; anestrous; pseudopregnancy 3) Early embryonic death when fed 1–3 weeks post mating 4) No effect on fertility
Ergot	All swine Sows last trimester	1) 0.1% 2) 0.3% or >3 ppm ergot alkaloids 3) 1.0%	1) Reduced weight gain 2) Decreased feed consumption; agalactia, reduced piglet birth weight; piglet starvation 3) Gangrene of ears, tail, and feet
Fumonisins	All swine	1) 25 ppm 2) 50–75 ppm 3) 75–100 ppm 4) >100 ppm	1) Minimal changes in clinical chemistry – increased AST and AP 2) Minimal reduction in feed intake; possible mild hepatosis 3) Reduced feed intake, reduced weight gain; hepatosis with icterus and increased bilirubin and GGT 4) Acute pulmonary edema after 3–5 days consumption; survivors develop hepatosis

Zearalenone (f-2 toxin)

Sources and mechanism

Fusarium graminearum (*Fusarium roseum*) produces ZEA, an estrogenic mycotoxin in corn, milo, and wheat. *F. roseum* can produce either ZEA or DON (Diekman and Green 1992). High moisture (23–25%) is required for growth. Poorly dried ear corn and alternating high and low ambient temperatures favor ZEA production (Christensen and Kaufmann 1965). Often it is produced in the field prior to harvest with delayed harvest potentially playing a role in its production as well.

ZEA is a substituted resorcylic acid lactone that binds competitively to estrogen receptors of the uterus, mammary gland, liver, and hypothalamus. It causes hypertrophy of the uterus and cornification of vaginal epithelium. ZEA is rapidly absorbed from the intestine and is metabolized to alpha- and beta-zearalenol and then conjugated with glucuronic acid for excretion in bile and urine (Meyer et al. 2000).

Clinical signs

Response to ZEA varies with dosage and age of swine exposed. In prepubertal gilts, concentrations as low as 1–5 ppm in the ration cause vulvovaginitis, which is characterized by tumescence and edema of the vulva and vagina and precocious mammary development. Tenesmus is common, occasionally with resultant rectal prolapse (Osweiler 2000). ZEA at clinically effective dosage in sexually immature gilts causes ovarian follicle atresia and apoptotic-like changes in granule cells. Intensified cell proliferation occurs in both uterus and oviduct (Obremski et al. 2003). Prepubertal gilts fed 2 ppm for up to 90 days attained normal sexual maturity with no adverse effects on subsequent reproductive function (Green et al. 1990; Rainey et al. 1990). Doll et al. (2003) fed contaminated corn to piglets up to a diet maximum of 4.3 ppm DON and 0.6 ppm ZEA. BW gain was significantly reduced, and uterine weights compared to BW were increased by nearly 100%.

Reproductive effects of ZEA on mature cycling sows are quite different from effects seen in prepubertal gilts. As with other estrogens, ZEA is luteotropic in swine, and dietary concentrations of 3–10 ppm can induce anestrus in sows if consumed during the middle portion of the estrous cycle. Abortion is unlikely because estrogens are luteotropic in swine. Anestrus and elevated serum progesterone persist for several months long after exposure to ZEA has stopped (Edwards et al. 1987).

Fewer pigs per litter are seen in sows fed high concentrations of ZEA. The susceptible period for reduced litter size appears to be in the preimplantation stage at 7–10 days post mating (Diekman and Long 1989; Long et al. 1983). ZEA fed at 1 mg ZEA/kg BW (equivalent to approximately 30 ppm dietary ZEA) on days 7 through 10 after mating resulted in mild blastocyst degeneration by day 11 and advanced degeneration by day 13. Viability of individual embryos is apparently not maintained beyond 21 days. ZEA did not cause morphologic changes in the endometrium associated with hyperestrogenism (height of the endometrial luminal epithelium and morphology of secretory vesicles in the endometrial glandular epithelium) (Long et al. 1992). ZEA at 22.1 ppm in the ration of breeding gilts caused a decrease in number of corpora lutea, ovarian weight, and number of live embryos, but an increase in deadborn piglets (Kordic et al. 1992).

ZEA and its metabolites, alpha- and beta-zearalenol, are present in milk of exposed sows and may contribute to estrogenic effects in piglets, including enlarged external genitalia and uteri (Dacasto et al. 1995; Palyusik et al. 1980). A perinatal hyperestrogenic syndrome reported in swine herds and by experimental verification included lower conception rate, increased numbers of repeat breeders, decreased litter size, and increased numbers of stillbirths. Clinical signs in neonatal gilts were swelling of the vulva and teats and edematous infiltration of the perineal region, ventral abdomen, and umbilicus, usually accompanied by exudative crusted inflammation and necrosis of the teats. Lesions of hyperestrogenism included enlargement of the ovary and uterus, ovarian follicle maturation, glandular proliferation of the endometrium, and epithelial proliferation in the vagina (Vanyi et al. 1994). Swine diets containing 2 ppm ZEA from day 30 of gestation through weaning did not adversely affect reproduction in sows. Estrogenic effects on testes and on uterine and ovarian weights were observed in the piglets at 21 days of age, but subsequent breeding performance was not affected (Yang et al. 1995).

Preputial enlargement may occur in boars exposed to ZEA. Young boars may have reduced libido and decreased testicular size, but mature boars are unaffected by concentrations of ZEA as high as 200 ppm (Ruhr et al. 1983; Young and King 1983).

Diagnosis

ZEA toxicosis may resemble effects of estrogenic feed additives and natural estrogens such as coumestrol in mature alfalfa. Suspect rations of corn and feed should first be analyzed for the presence of ZEA and other estrogens. For a summary of ZEA effects in different classes of swine, see Table 69.4.

Treatment

Reversal of effects depends on the nature of the effect and the age and reproductive status of swine. Removal of the feed from prepubertal gilts will allow regression of signs within 3–7 days. Medical and surgical treatment of vaginal and rectal prolapse may be needed. For mature, nongravid sows with anestrus, administration of one 10 mg dose of prostaglandin F_{2a} or two 5 mg doses on successive days is useful in eliminating retained corpora lutea (B.N. Day, personal communication, 1982; Green et al. 1990).

Prevention

Dehydrated alfalfa has experimentally shown some protection from ZEA-induced enlargement of the uterus of gilts (James and Smith 1982) although the high concentrations needed (>20%) are not considered practical in swine diets. Activated charcoal or cholestyramine has been used at 2% in an *in vitro* GI model system to evaluate its binding effect on ZEA. Both activated charcoal and cholestyramine reduced absorption of ZEA from 32 to 5 and 16%, respectively (Avantaggiato et al. 2004). The dramatic reduction caused by activated charcoal could be useful for contaminated grain if feeding trials are effective.

Ergot

Ergot, the parasitic fungus *Claviceps purpurea*, infects cereal grains, especially rye, oats, and wheat. The fungus invades the plant seed and forms a sclerotium, a dark elongated body that produces ergopeptine alkaloids that cause gangrene and reproductive interference. Major toxic alkaloids have additive effects and include ergotamine, ergosine, ergocornine, ergocryptine, and ergocristine; total ergot alkaloid content commonly ranges from 0.2 to 0.6% of sclerotia weight. Tolerance levels of ergot bodies or alkaloid content vary among countries. In the United States, the allowable level of ergot in wheat and rye destined to become livestock feed is 0.3 ppm (Coufal-Majewski et al. 2016), which can be determined by analytical chemistry methods to quantify all the ergopeptines in feed.

Gangrenous ergotism is the result of a combination of vasoconstriction and endothelial damage, leading to prolonged ischemia and eventually gangrene of appendages. Because venous and lymphatic drainage remains intact, the gangrene is "dry" in nature. Signs occur over a period of days or weeks and include depression, reduced feed intake, rapid pulse and respiration, and general ill-thrift. Lameness may occur, most commonly in rear limbs, and in advanced cases necrosis and sloughing of the tail, ear tips, and hooves can occur. Signs may be exacerbated by cold weather. Reduced weight gain may be caused by as little as 0.1% ergots in the ration. Higher levels (3.0%) have been implicated in feed wastage and slow growth (Roers et al. 1974).

Ergot alkaloids from *C. purpurea* consistently cause sow agalactia, the result of stimulation of D_2 DA receptors leading to prolactin suppression in pregnant sows fed ergot sclerotia; piglets are born healthy but starve because of agalactia (Whitacre and Threlfall 1981). Pregnant gilts fed either 0.3 or 1% sclerotia during gestation had low piglet birth weights, low piglet survival, and poor piglet weight gains. Agalactia occurred in 50% of gilts fed 0.3% sclerotia in the gestation and lactation rations (Nordskog and Clark 1945). Recently Kopinski expanded on earlier work (2008), showing that *Claviceps africana* ergot sclerotia fed to sows up to 1.5% of the diet (equivalent to 7 ppm ergot alkaloids) 6–10 days prior to parturition caused agalactia and 87% of piglets died. Blood prolactin was reduced. The authors recommended no more than 0.3% ergot or 1 mg/kg dietary ergot alkaloids for multiparous sows and no more than 0.1% ergot for primiparous sows or avoid ergot completely in primiparous sows.

Differential diagnosis and treatment

Evaluation should include ZEA or other estrogenic factors, bacterial infections, and mastitis–metritis–agalactia syndrome. If the clinical signs suggest ergotism, grains should be examined for the presence of significant amounts of ergot sclerotia. Commonly, HPLC is used to analyze suspect ground or processed feeds for ergopeptines, which may be necessary to confirm the diagnosis (Coufal-Majewski et al. 2016).

Gangrenous areas should be cleaned and treated locally, and secondary infections controlled with broad-spectrum antibiotics. Removal of the feed is followed by improvement within 2 weeks for gangrenous effects. When agalactia has occurred, milk production returns 3–7 days after feed is changed. In the interim, supplemental nutrition and milk replacers may be used to save the piglets.

Fumonisins

Fusarium moniliforme and *Fusarium proliferatum* fungi are ubiquitous in white and yellow corn worldwide (Bezuidenhoudt et al. 1988; Gelderblom et al. 1988) and the source of the fumonisin mycotoxins. Swine consuming fumonisins can develop the disease generally known as porcine pulmonary edema (PPE). Fumonisins are produced when corn is stressed by moderate drought followed by persistent rainfall or high humidity late field development (P. Nelson, Personal Communication, 1989). Corn screenings are the most common source of fumonisin toxicosis (Harrison et al. 1990; Osweiler et al. 1992; Ross et al. 1991, 1992).

Fumonisins commonly present in corn are FB_1, fumonisin B_2 (FB_2), and fumonisin B_3 (FB_3). They are water-soluble, heat-stable, and alkaline-resistant aliphatic hydrocarbons with a terminal amine group and two tricarboxylic acid side chains (Steyn 1995). FB_1 and FB_2 are of approximately equal toxicity (P.F. Ross, personal communication, 1996), while FB_3 is nearly nontoxic to swine (G.D. Osweiler, unpublished data).

Mechanism of action and toxicity

Fumonisins are poorly absorbed orally (3–6% of ingested dose), and once absorbed, they are excreted readily and rapidly in bile and urine (Prelusky et al. 1994). Fumonisins inhibit the enzyme-mediated conversion of sphinganine to sphingosine, raising the sphinganine/sphingosine (SA/SO) ratio and potentially interfering with cell cycle control and cell function (Vos et al. 2007). FB_1 affects cell signaling proteins including protein kinase C (PKC), a serine/threonine kinase involved in a number of signal transduction pathways that include cytokine induction, carcinogenesis, and apoptosis (Gopee and Sharma 2004). FB_1 appears also to inhibit ceramide synthase in the sphingolipid signaling pathway on the ascending aortic impedance spectrum of pigs. This is associated with inhibition of myocardial L-type calcium channels with a decrease in cardiac contractility and mean systemic

arterial pressure, decreased heart rate, and increased pulmonary artery pressure leading to left heart failure and massive pulmonary edema and hydrothorax (Constable et al. 2003; Smith et al. 2000). Zomborszky-Kovács et al. (2002) reported that very low concentrations of FB_1 fed for 8 weeks resulted in chronic pulmonary changes of connective tissue proliferation in subpleural and interlobular connective tissue of lungs and in peribronchial and peribronchiolar areas.

More than 120 ppm dietary fumonisins for 4–10 days produce acute PPE (Colvin et al. 1993; Haschek et al. 1992; Osweiler et al. 1992). Surviving pigs develop subacute hepatic toxicosis 7–10 days later. Hepatosis results after feeding dietary levels >50 ppm for 7–10 days. Although 25 ppm or less causes no apparent clinical effects, mild microscopic hepatic lesions are documented for dietary levels as low as 23 ppm. The serum SA/SO ratio has been altered experimentally by diets containing 5 ppm fumonisins, although the clinical relevance of this change is not known (Moetlin et al. 1994; Riley et al. 1993). Fumonisins have been evaluated for their potential interactions with AF and DON. Effects of AF and fumonisins were found to be additive when fed together, except for the variables cholinesterase and ALP, which showed a synergistic response to AF and FB_1 (Harvey et al. 1995a). For a combination of FB_1 and DON, the effect on most variables was additive. However, for BW, weight gain, hepatic weight, and mean corpuscular hemoglobin concentration, the responses were interactive in a greater-than-additive manner (Harvey et al. 1996).

Clinical signs and lesions

Dietary fumonisins greater than 120 ppm are likely to cause acute interstitial pulmonary edema and hydrothorax, with attack rates up to 50% and case fatality rates of 50–90%. Initially there is lethargy, restlessness, depression, and dermal hyperemia. Mild salivation, dyspnea, open-mouth breathing, posterior weakness, recumbence, and moist rales develop rapidly, followed by cyanosis, weakness, and death. Initial signs begin after 4–7 days of continuous fumonisin consumption (Colvin and Harrison 1992; Osweiler et al. 1992). Once signs appear, death usually occurs in 2–4 hours. Survivors may develop hepatic disease. Feeding fumonisins at concentrations from 75 to 100 ppm for 1–3 weeks, without development of pulmonary edema, causes hepatic disease characterized by icterus, anorexia, ill-thrift, and weight loss (Osweiler et al. 1993).

Serum chemistry analyses include elevated concentrations of GGT, AST, ALP, lactate dehydrogenase (LDH), cholesterol, and bilirubin. Early increases in the serum enzymes and cholesterol are followed by increased GGT and serum bilirubin accompanied by clinical icterus (Colvin et al. 1993; Osweiler et al. 1992).

Based on current evidence, fumonisins are considered mild immunosuppressants in swine. One study has shown transient reduction in lymphocyte blastogenesis and delayed titer response to pseudorabies vaccine (Osweiler et al. 1993). Others have reported decreased lymphoblastogenesis (Harvey et al. 1995a, 1996). Tornyos et al. (2003) fed pigs a high FB_1 dose (100 mg/animal/day for 8 days) or low dose (1, 5, and 10 ppm) for 3–4 months and then vaccinated against Aujeszky's disease with inactivated vaccine, which had no significant effect on the humoral and cellular specific and nonspecific immune response.

Lesions of pulmonary edema and hydrothorax occur with 200–350 mL of clear, cell-free, straw-colored thoracic transudate. Lungs are heavy and wet with wide seams (3–10 mm) of interlobular edema. Bronchioles, bronchi, and trachea are relatively clear with little alveolar edema (Colvin et al. 1993; Haschek et al. 1992; Moetlin et al. 1994; Osweiler et al. 1992; Palyusik and Moran 1994). Acidophilic fibrillar material is found in alveoli and interlobular lymphatics, and hyalinized alveolar capillary thrombi may be present. Increased numbers of pulmonary intravascular macrophages (PIM) filled with osmiophilic material are reported by electron microscopy – possibly a result of phagocytosis of damaged cellular components. Pancreatic necrosis and hepatosis with disrupted hepatic architecture, increased mitotic figures in hepatocytes, apoptosis, and single-cell hepatic necrosis are seen with subacute fumonisin toxicosis (Haschek et al. 1992). Chronic exposure can include hepatic hyperplastic nodules and medial hypertrophy of small pulmonary arteries.

Abortions 1–4 days after acute spontaneous toxicosis presumably are due to fetal anoxia caused by severe pulmonary edema in the dam (Becker et al. 1995; Osweiler et al. 1992). Concentrations of 100 ppm FB_1 fed in the last 30 days of gestation caused no pulmonary edema and did not cause abortion, fetal abnormalities, or infertility in sows (G.D. Osweiler, unpublished data).

Diagnosis

Clinical signs of acute respiratory distress with high mortality and lesions of interstitial edema and hydrothorax suggest fumonisin toxicosis. A history of consumption of corn screenings or poor quality corn is typical. Serum chemistry changes and elevated serum SA/SO ratios are expected, and the acute liver enzymes usually peak at from 4 to 7 days after initial exposure, while bilirubin and GGT continue to increase for 1–2 weeks if sublethal exposure continues. Serum SA/SO ratio is the most sensitive indicator of fumonisin exposure and appears unique to the fumonisins (Moetlin et al. 1994; Riley et al. 1993). However, this assay is currently not widely available as a diagnostic test. Assay for fumonisins in feeds or corn is routine in many veterinary diagnostic and private laboratories. Chemical analyses to detect fumonisins in tissues

are not readily available, and the rapid metabolism and excretion rate of fumonisins generally precludes this mode of diagnosis (Prelusky et al. 1994).

Treatment and management

There is no antidote. The acute and massive changes of PPE do not allow for effective symptomatic and supportive therapy. Because clinical signs appear after days to weeks of exposure, oral detoxification is usually not useful. Liver damage from fumonisin toxicosis may be lessened by appropriate supportive care. Fernández-Surumay et al. (2005) demonstrated that a process binding fumonisins with glucose effectively prevents development of clinical signs, lesions, and clinical chemistry changes of fumonisins.

Analysis of corn or feeds for fumonisins can identify a source and help in estimating the risk from a specific feedstuff (Ross et al. 1991). Contaminated corn should be cleaned, and the good quality grain analyzed to demonstrate that a safe level of fumonisins has been reached.

As potential carcinogens in both humans and animals, fumonisins are often monitored or regulated (Table 69.3). Current FDA guidance for fumonisins in corn for swine is no more than 20 ppm in corn at a 50% inclusion rate for an effective feed concentration of 10 ppm on a dry matter basis (Federal Register 2001).

Prevention and management of mold and mycotoxin problems

When mycotoxicosis occurs or is suspected, corrective actions should include a change in the source of feed even when a specific mycotoxin has not been confirmed, and a thorough inspection of grain storage bins, mixing equipment, and feeders for caking, molding, or musty odors. Remove all contaminated feed, clean equipment, and sanitize storage areas with hypochlorite (laundry bleach) to reduce contaminating fungi.

Analyze representative samples of feed and feedstuffs for known mycotoxins. Visual observations of molds, spore counts, or fungal cultures alone do not confirm a diagnosis but may give some indication of the potential for mycotoxin production.

If storage conditions are adverse or grain moisture is high, use a mold inhibitor such as sodium or calcium propionate to reduce or delay mold growth; however, mold inhibitors do not destroy preformed toxins.

Dilution of contaminated grain with clean grain is commonly used to reduce mycotoxin effects, but care must be taken that wet or contaminated grain does not introduce new fungi and conditions of contamination.

Mycotoxins commonly compromise feed quality. The diagnosis and management of such present formidable challenges to the swine producer and veterinarian because diagnosis is sometimes difficult and effective therapies or prophylaxis are often lacking. Another current major diagnostic and scientific concern still unresolved is accuracy of current methods of detection and quantification of mycotoxins and closely related metabolites. This concern, articulated in a recent report, suggests that some mycotoxins can bind to other compounds and/or be completed masked, leading to inaccurate analytical results or perhaps even evade detection (Kovalsky et al. 2016). A sound, practical preventive program is a prudent part of every swine management system but requires continued vigilance to implement effectively.

Toxic Minerals, Chemicals, Plants, and Gases

Steve M. Ensley and Scott L. Radke

Although modern confinement facilities, accurately formulated rations, and improved management practices have reduced some risks of poisoning, cases of poisoning in swine still occur. The occurrence of swine toxicoses associated with the environment, feed, or management practices is frequent enough to warrant their inclusion in differential diagnostic considerations for swine health problems. The following discussion summarizes the impact of potentially toxic agents to which swine may be exposed.

Essential minerals

Most formulated swine feeds are properly fortified with trace elements; however, for various reasons, some trace minerals may deliberately be added in excess, including copper (Cu), selenium (Se), zinc (Zn), and, occasionally, iron (Fe). The existence of concentrated premixes of these minerals raises the risk of feed mixing errors, resulting in the accidental feeding of high, potentially toxic levels of these elements.

Copper

Dietary requirements of 5–6 ppm Cu have been established for swine. A dietary level of 250 ppm is generally considered the maximum tolerable level (MTL) of Cu for swine. Ration levels ranging from 300 to 500 ppm cause reduced growth and anemia. The tolerance to Cu is related positively to dietary levels of Fe and Zn. For example, animals consuming feed containing 750 ppm Cu are essentially normal if also supplemented with 750 ppm Fe and 500 ppm Zn. Copper in both organic and inorganic forms has been added to growing swine diets at concentrations as high as 134 ppm with positive effects on growth and health. Additive effects of higher levels of dietary copper and zinc in diets for nursery pigs have been demonstrated. Copper sulfate or tribasic copper chloride (TBCC) at 125 ppm and zinc oxide at 0 or 3000 ppm from day 0 to 14 and 0 or 2000 ppm from day 14 to 28 have been shown to increase average daily gain, average daily feed efficiency, and feed/gain (Shelton et al. 2011). Limited information is available when using other sources of Cu. Reduced levels of dietary Zn and Fe or high calcium (Ca) can accentuate copper toxicity (NRC 2012).

Copper toxicity in swine can cause a hemolytic crisis characterized by icterus, anemia, hemoglobinuria, and nephropathy, although not as commonly as in sheep. Diagnosis can be suspected by clinical signs and a history of feeding excess Cu. Feed refusal was observed in swine when dietary Cu in the form of TBCC was detected in excess of 4000 ppm. Liver and kidney Cu levels greater than 250 and 60 ppm, respectively, on a wet-weight basis are diagnostically supportive.

Iron

The recommended dietary levels of Fe range from 40 to 150 ppm, the highest requirements being in the youngest pigs. Many factors influence the risk of Fe toxicosis. Elemental Fe and iron oxides are relatively nontoxic, whereas iron salts are more toxic. Dietary phytate, phosphate, cobalt (Co), Zn, Cu, manganese (Mn), and disaccharides competitively depress Fe absorption. Ascorbic acid, sorbitol, fructose, and several amino acids improve Fe absorption, which is facilitated by being chelated with citric, lactic, pyruvic, and succinic acids; Fe chelated by desferrioxamine is poorly absorbed.

Pigs fed 1100 ppm Fe as a salt have shown reduced weight gains. Animals fed 5000 ppm have displayed depressed feed intake and rates of gain as well as rickets characterized by hypophosphatemia and reduced bone ash. The condition has not been prevented by providing 0.92% dietary phosphorus (P). High single doses of iron salts will cause gastroenteritis, followed by apparent recovery and then, frequently, collapse and death within

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

2 days. Diagnosis may be facilitated by consideration of history, clinical signs, and necropsy changes. Feed and serum should be analyzed for Fe. Normal serum Fe levels are approximately 100 mg/dL and will increase during toxicosis.

Injections of Fe, usually as the dextran, have caused intoxications characterized by cardiovascular shock and death within hours after administration as well as staining at injection sites and in regional lymph nodes, liver, and kidneys. Piglets originating from vitamin E-deficient mothers are reported to be more susceptible to Fe toxicosis (Arpi and Tollerz 1965). Excess Fe in the feed may also interfere with vitamin E absorption or increase the catabolism of vitamin E, potentially causing a deficiency.

There is no practical individual treatment for Fe toxicosis. Desferrioxamine (Desferal) may be used in selected cases. Dietary imbalances or injection dosages should obviously be corrected.

Selenium

The recommended dietary level of Se varies from 0.1 to 0.3 ppm. Selenium, as the selenate or selenite, is approved for addition to swine feeds at up to a legal limit of 0.3 ppm by the Food and Drug Administration (FDA) because of the narrow margin of safety. Oversupplementation of swine feeds with selenium premixes has been a sporadic problem due to mixing errors, especially when responding via additional supplementation to a diagnosis of mulberry heart disease.

Selenium levels of 5–8 ppm fed to growing swine have caused anorexia, alopecia, separation of hooves at the coronary band, and degenerative changes in the liver and kidney. Liver lesions may look remarkably like those described for vitamin E–selenium deficiency (hepatosis dietetica). A level of 10 ppm fed to breeding sows has caused decreased conception and pigs dead or weak at birth. Misformulated feeds containing from 10 to 27 ppm Se produced a paralytic disease in growing swine characterized by quadriplegic or posterior paralysis while the pigs remained mentally alert and continued to eat and drink. Focal symmetrical poliomyelomalacia was found in affected swine (Casteel et al. 1985; Harrison et al. 1983).

Several injectable products containing varying concentrations of Se are currently available for treatment or prevention of Se-responsive diseases. Death losses have approached 100% when Se overdose occurred from the mistaken use of a more concentrated product or from miscalculation of the recommended dosage. The minimum lethal dose of injectable Se is about 0.9 mg/kg body weight, with pigs that are Se deficient being the most susceptible to toxicosis (Van Vleet et al. 1974). Weakness and dyspnea progressing to irregular gasps and death occur within 24 hours of the parenteral overdose. Caution should be used when using injectable Se-containing products, particularly those used for vitamin E supplementation, as vitamin E is never a toxicity issue but Se can be.

Diagnosis of Se toxicosis in swine can be made by consideration of a history of Se supplementation, clinical signs, necropsy findings, and chemical analysis of tissues and feeds. Liver and kidney Se concentrations greater than 3 ppm (wet weight) are expected with toxicosis.

Zinc

Recommended dietary levels of Zn for swine vary from 15 to 100 ppm based on age, sex, stage of production, and other ration components. A level of 2000 ppm zinc carbonate produced growth depression, arthritis, intramuscular hemorrhage, gastritis, and enteritis. The MTL is probably less than 300 ppm, possibly because zinc salts in large concentration are unpalatable. Zinc interacts competitively for absorption with Fe, Ca, and Cu. Pigs fed 268 ppm Zn developed arthritis, bone and cartilage deformities, and internal hemorrhages. However, feeding 3000 ppm Zn as zinc oxide for 14 days has shown increased weight gains and reduction of post weaning scours without adverse signs. Toxicity of Zn depends largely on its source as the MTL for dietary Zn in swine is 1000 ppm with the exception of zinc oxide (NRC 2012). Zn sulfate and Zn methionine have not consistently demonstrated positive effects. Zn toxicosis has been observed when other highly absorbable sources of Zn, such as zinc carbonate, have been used. Diagnostic considerations should include clinical signs, history, and chemical analyses of feed and tissues. Normal kidney and liver levels of Zn are 25–75 ppm (wet weight) and may increase during toxicosis. However, excretion is quite rapid.

Nonessential minerals

Arsenic

Inorganic arsenicals, which are distinctly different from phenylarsonic feed additives discussed later, have been used in antiquated ant baits, herbicides, insecticides, and some animal medications. Pigs are relatively resistant to inorganic arsenic (As) poisoning with 100–200 mg/kg body weight of sodium arsenite being a lethal oral dose. This is equivalent to about 2000–4000 ppm in the feed. However, pigs have refused to consume 1000 ppm in the feed. Clinical signs of acute As poisoning are colic, vomiting, diarrhea, dehydration, collapse, convulsions, and death within hours to days. Prominent necropsy findings are dehydration and severe hemorrhagic gastritis and enteritis with sloughing of mucosa and edema. Diagnostic considerations should include history, clinical signs,

lesions, and chemical analyses. Kidney and liver tissue levels of 10 ppm (wet weight) are significant. Prognosis is generally poor and depends on the degree of tissue damage and dehydration.

Fluorine

Although uncommon, fluorosis may be observed in animals consuming water or forages contaminated by nearby industrial plants or eating crops raised on soils high in fluorine (F). Inhaled F does not appear to accumulate in animals (NRC 2005). A common source is consumption of minerals high in F. Feed-grade phosphates by law must contain no more than 1 part F to 100 parts P (Thompson 1980). It is recommended that swine be fed feeds containing no more than 70 ppm F during their lifetime to prevent fluorosis. Sodium fluoride has been used as an ascaricide at levels of 500 ppm but is no longer used for this purpose in swine. Other signs of acute toxicosis are diarrhea, lameness, tetany, collapse, and death.

A tentative diagnosis of chronic fluorosis may be difficult, since the lameness may appear similar to rickets, mycoplasmosis, and erysipelas. Normal bone F levels in swine are 3000–4000 ppm. Higher levels are associated with fluorosis. Normal urine F levels are 5–15 ppm; higher levels are diagnostically significant. Necropsy findings may reveal exostoses on the long bones and tooth mottling. Treatment should be aimed at reducing dietary F and feeding aluminum or calcium (Ca) mineral supplements.

Lead

Swine are quite resistant to elevated lead (Pb) exposure; consequently field cases of lead poisoning in swine are extremely rare. Experimentally, pigs fed 35.2 mg lead (as the acetate)/kg body weight for 90 days did not die from lead poisoning despite blood lead concentrations as high as 290 µg/dL (Lassen and Buck 1979). If toxicosis is suspected, a thorough diagnostic workup including blood, kidney, and liver analyses should be performed to ensure food safety. It is recommended that animals with blood lead levels exceeding 0.1 ppm not enter the food chain until levels are found to be below 0.1 ppm in two consecutive blood samples at least 30 days apart.

Mercury

Mercury (Hg) has been used in paints, batteries, paper, and fungicides, but most uses have now been restricted. All mercurial compounds are toxic, but organic forms are the most toxic to all animal species. Mercury is cumulative, and toxicity depends on form, dose, and duration. Swine have been poisoned after consuming seeds treated with organic mercurial fungicides.

Initially, signs of gastroenteritis may be evident, followed by uremia and central nervous system (CNS) disturbance, including ataxia, blindness, aimless wandering, paresis, coma, and death. Mercury toxicosis may be confused with erysipelas, cholera, or poisoning by pigweed or phenylarsonics. Clinical signs, history, necropsy findings, and chemistry should aid in the diagnosis. The kidney and liver normally contain less than 1 ppm Hg but will contain much higher levels following Hg toxicosis. Treatment is usually unrewarding.

Feed additives

Adverse effects of drug additives are rare except in cases of misuse, misformulation of rations (Lloyd 1978), or unanticipated adverse interactions with other compounds that are simultaneously administered to pigs. Details of specific drug effects have been reviewed (Adams 1996).

Phenylarsonic compounds

Phenylarsonic compounds, occasionally referred to as organic arsenicals, have at times been used as growth promotants or historically as treatments of swine dysentery or eperythrozoonosis (*Mycoplasma suis*). Arsanilic acid and roxarsone (3-nitro-4-hydroxyphenylarsonic acid) have been used in swine rations, and their sodium salts have been used in drinking water. Arsanilic acid use in complete swine rations ranges from 50 to 100 ppm (45–90 g/ton). As of 2013, arsenical compounds are no longer utilized in animal feed in the United States following withdraw of FDA approval (US FDA 2015). With no approved use for swine and current limited availability, toxicosis would not be expected unless old sources are used off-label.

Onset of clinical signs involving arsanilic acid toxicosis occurs within a few days at feed levels of 1000 ppm, 2 weeks at 400 ppm, and 3–6 weeks at 250 ppm. Clinical signs include ataxia, posterior paresis, blindness, and quadriplegia. Paralyzed animals will continue to live and grow if provided food and water. Swine that receive lower doses for extended periods are prone to develop hypermetria or "goose-stepping" and total blindness from sciatic and optic nerve damage, respectively. Swine that receive very large doses, for example, 10,000 ppm in the ration, may exhibit a gastroenteritis resembling poisoning by inorganic arsenic compounds.

Roxarsone could once be used continuously in swine rations at levels of 22.7–34.1 ppm or at 181.5 ppm for 5–6 days. Poisoning may result with feed roxarsone levels of 250 ppm or more from 3 to 10 days. Clinical signs include uncontrolled urination and defecation as well as muscle tremor and convulsive seizures, all of which are

induced by physical stimulation. Ataxia may be observed, although not as severe as the "drunken sailor" incoordination of arsanilic acid toxicosis. In advanced stages, pigs show paraparesis and paraplegia, but will continue to eat and drink.

Clinical signs and a history of accidental exposure or administration of arsenicals in feed or water may be the best basis for suspecting phenylarsonic toxicosis. Necropsy findings are generally unremarkable, but histopathologic examination of the peripheral nerves, especially the sciatic nerves, may reveal demyelination. Chemical analysis of tissues for the specific phenylarsonic compounds may not be helpful since the compounds are excreted within a few days after withdrawal; however, analysis of the kidney, liver, muscle, and feed for As may assist in the diagnosis. Elemental arsenic levels (wet weight) greater than 2 ppm in kidney and liver and 0.5 ppm in muscle are illegal and indicative of excess As intake. Further analysis of feed for the specific phenylarsonic compound will provide more diagnostic evidence. Deficiencies of B complex vitamins, especially pantothenic acid and pyridoxine, may cause a similar demyelination of peripheral nerves, as can the effects of a delayed organophosphate such as *ortho*-cresyl phosphate. Chronic phenylarsonic toxicosis may also resemble rickets. The CNS signs of phenylarsonic compound toxicosis may be confused with sodium ion toxicity, organic mercurial poisoning, and certain viral diseases. Clinical signs of toxicosis are reversible if arsenicals are promptly removed from the feed and water.

Carbadox

Carbadox (Mecadox), where available, is added to feed at 10–25 ppm as a growth promotant or at 50 ppm to control swine dysentery or bacterial enteritis. A feed level of 100 ppm has caused decreased feed consumption and growth retardation. Higher levels have caused feed refusal and emesis. Mild lesions in the glomerular zone of the adrenal cortex are reported with 50 ppm carbadox in the feed for 10 weeks, while more extensive lesions are seen at feed levels of 100–150 ppm after 5 weeks of consumption (Van der Molen 1988). When fed a ration containing from 331 to 363 ppm carbadox, recently weaned pigs refused to eat and showed poor weight gains, posterior paresis, the passing of hard, pelleted feces, and death in 7–9 days (Power et al. 1989). Swine that have ingested carbadox are required to be withheld from slaughter for a minimum period of 42 days (Lundeen 2017).

Dimetridazole

Dimetridazole, listed as an anti-histomoniasis drug used in turkey rations, was once used for treatment and prevention of swine dysentery. Dimetridazole, suspected to be a carcinogen, and other imidazole compounds are now illegal for use in swine in the United States. A level of 1,500 ppm has caused no toxicosis, but 17,000 ppm has caused diarrhea in swine. Large overdoses of dimetridazole would cause ataxia, bradycardia, dyspnea, salivation, muscle spasms, prostration, and death. Death or recovery would be rapid.

Ionophores (monensin, lasalocid, and narasin)

Narasin (trade name Skycis) is fed at levels from 15 to 30 ppm in swine to increase rate of gain and feed efficiency and as a coccidiostat in chickens when fed up to 100 ppm (Lundeen 2017). Narasin toxicosis occurs as a result of mixing errors, errant feed deliveries, and the severe negative interaction with tiamulin, an antibiotic commonly used in swine.

In 9-week-old pigs, the median oral lethal dose of narasin has been reported to be 8.9 mg/kg of body weight. Clinical signs of anorexia, dyspnea, weakness, ataxia, and recumbency have been reported in cases when approximately 90 ppm, nearly three times the recommended dose, was included in the diet (Carpenter et al. 2005). Risk of narasin toxicity exists when fed at >45 ppm or when tiamulin is concurrently administered with narasin. Pigs offered tiamulin in either feed or water at any approved therapeutic level concurrently with approved levels of narasin are at high risk to develop adverse clinical signs.

Swine poisoned from this combination of narasin and tiamulin show acute ataxia with pain due to massive necrosis of skeletal muscles leading to myoglobinuria and acute death. Histopathological lesions of ionophore toxicity exacerbated by tiamulin include myonecrosis of skeletal muscle characterized by clustered necrotic myofibers with loss of striations and hyaline degeneration and cellular infiltrates (Sturos et al. 2016). Monensin is marketed as Rumensin for use in cattle or as Coban as poultry coccidiostat. Use levels are up to 120 ppm for poultry and 44 ppm in cattle feeds; some premixes may contain up to 440 ppm. Swine may be fed monensin by mistake, but the drug is not highly toxic to them; pigs fed monensin levels ranging from 11 to 120 ppm in the feed for 112 days were not affected, nor was feed consumption or weight gain altered. Gilts fed 110–880 ppm had a transient anorexia for 14 days; thereafter, only weight gains were depressed. The LD_{50} of monensin in swine is 16.8 mg/kg. Pigs suffering from monensin toxicosis showed open-mouth breathing, frothing around the mouth, ataxia, lethargy, muscle weakness, and diarrhea. These signs were visible within 1 day of exposure and persisted for about 3 days. Myocardial and skeletal muscle necrosis was present in pigs receiving 40 mg monensin/kg.

The greatest risk of poisoning from monensin and narasin in swine appears to be with the concurrent administration of the antibiotic tiamulin that potentiates the effect of monensin (Van Vleet et al. 1987) or narasin. Studies have demonstrated that tiamulin inhibits the oxidative drug metabolism via the formation of a cytochrome P450 metabolic intermediate complex (Monshouwer et al. 1996).

Lasalocid is a polyether antibiotic marketed as Bovatec for feedlot cattle and Avatec for poultry to improve feed efficiency and weight gains. Swine fed lasalocid at 2.78 and 21 mg/kg showed no adverse effects. However, transient muscle weakness occurred at a dose of 35 mg/kg (equivalent to about 1000 ppm of lasalocid in the feed), and death occurred at 58 mg/kg when fed for 1 day. Additional ionophores used as feed additives include salinomycin marketed as Bio-Cox or Sacox and laidlomycin marketed as Cattlyst.

In the event of ionophore toxicosis, stopping all administration of tiamulin and immediate removal of suspect feed and cleaning of feed bins should be performed to prevent further intoxication. Prevention includes ensuring correct mixing of rations and cleaning of equipment at feed mills; especially mills catering to various species can aid in reducing intoxications along with vigilance for concurrent use of any ionophores, particularly narasin and tiamulin. Computerized feed dosing and batching systems have been involved in some cases involving mixing errors.

Sulfonamides

Overdoses of sulfonamide antibacterials will cause crystalluric nephroses. Pigs are not likely to be intoxicated from drinking water containing sulfonamides because of the lack of palatability, but overdosing in the feed, coupled with low water intake, may cause nephrosis and uremia. The only feed-grade sulfonamides labeled for swine in the United States are sulfathiazole and sulfamethazine. Nephrotoxic mycotoxicoses such as those caused by citrinin and ochratoxin will predispose sulfonamide toxicosis. Sulfonamide residues in pork are related to persistence of the drugs in feed and excreta and are not a toxicosis. The only feed-grade sulfonamide is sulfamethazine, labeled for use only in combination with tylosin (Lundeen 2017).

Urea and ammonium salts

Swine may be fed cattle feeds containing nonprotein nitrogen compounds such as urea and ammonium salts. Urea is relatively nontoxic for swine, a level of 2.5% causing only reduced feed intake and growth rate, elevated blood urea nitrogen (BUN), polydipsia, and polyuria. Higher levels of urea should not cause signs of acute toxicosis. Ammonia and ammonium salts are toxic for swine, however, with individual doses of 0.25–0.5 g/kg body weight causing intoxication and doses of 0.54–1.5 g/kg being lethal. Considering that growing swine consume feed equal to 5–10% of their body weights, the expected toxic and lethal levels of ammonium salts are 0.25–1% and 1.5–3%, respectively. Pigs poisoned with ammonia and ammonium salts would be expected to become depressed, have tonoclonic convulsions, and either die or recover within a few hours.

Ractopamine

Ractopamine is a beta-2 agonist used as a feed additive (4.5–9 g/ton of complete feed) during the last 6 weeks of finishing to stimulate muscle growth in swine. Beta-2 agonists have the potential for adverse effects, including tachycardia, hypotension, tremors due to overstimulation of skeletal muscle beta-2 receptors, behavioral changes of anxiety or restlessness, weakness or lethargy, and hypokalemia (Rosendale 2004).

Pesticides: insecticides

Concurrent production of both livestock and crops on the same premises may provide a unique opportunity for exposure of swine to agricultural chemicals. Among the chemicals presenting the greatest potential hazard of poisoning are the organophosphorus (OP), carbamate, and the older chlorinated hydrocarbon (CH) insecticides.

Poisoning may occur when insecticides are accidentally incorporated into swine feed. Discarded or unlabeled portions of granular insecticides can be mistaken for mineral mixes or dry feed ingredients and added to swine feeds. When farm equipment used for feed handling is also used for insecticide transportation, contamination of this equipment may result in insecticides being inadvertently mixed into animal feeds. In addition, swine may have accidental access to insecticides when they are stored or spilled on the farm premises. Improperly operating back rubbers and oilers may provide an additional source of these insecticides for livestock.

Miscalculation of insecticide concentrations in spraying, dipping, and pour-on procedures may also result in toxicosis. Re-treating animals with OP or carbamate preparations within a few days' time may result in poisoning.

Organophosphorus and carbamate insecticides

OP and carbamate insecticides are discussed together because of their similar mechanisms of action. Cholinergic nerves utilize acetylcholine as a neurotransmitter, and under normal conditions, acetylcholine released at the

synapses of parasympathetic nerves and myoneural junctions is quickly hydrolyzed by cholinesterase enzymes. When the hydrolyzing enzymes are inhibited, the continued presence of acetylcholine maintains a state of nerve stimulation and accounts for the clinical signs observed with poisoning from these insecticides.

The clinical syndrome produced by OP and carbamate insecticides is characterized by a rapidly progressing overstimulation of the parasympathetic nervous system and skeletal muscles. Earliest clinical signs of acute poisoning frequently include mild to profuse salivation, defecation, urination, emesis, stiff-legged or "sawhorse" gait, and general uneasiness. As the toxicosis progress, signs observed include profuse salivation; gastrointestinal hypermotility resulting in severe colic and vomiting (especially common in swine); abdominal cramps; diarrhea; excessive lacrimation; miosis; dyspnea; cyanosis; urinary incontinence; muscle tremors of the face, eyelids, and general body musculature; and acute death. Hyperactivity of the skeletal muscles is generally followed by muscular paralysis, as the muscles are unable to respond to continued stimulation. Swine may exhibit increased CNS stimulation but rarely, if ever, convulsive seizures. More commonly, severe CNS depression occurs. Death usually results from hypoxia caused by excessive respiratory tract secretions, bronchoconstriction, and erratic, slowed heartbeat. The onset of clinical signs of acute poisoning may appear within a few minutes in severe cases to several hours in milder ones.

Lesions associated with acute OP or carbamate toxicosis are usually nonspecific but may include excessive fluids in the respiratory tract as well as pulmonary edema.

Diagnosis is usually by history of exposure to OP or carbamate insecticides associated with clinical signs of parasympathetic stimulation, which warrants a tentative diagnosis of poisoning with these compounds. Chemical analyses of animal tissues for the presence of insecticides are usually unrewarding because of the rapid degradation of OP and carbamate insecticides, resulting in low tissue residue levels. Finding the insecticide in the stomach contents and feed or suspect material is valuable in establishing a diagnosis. Cholinesterase enzyme activity is inhibited in whole blood and brain tissue of poisoned animals. A reduction of whole blood cholinesterase activity to less than 25% of normal is indicative of excessive exposure to these insecticides, and animals dying from these insecticides will generally have less than 10% of normal brain activity. Well-chilled whole blood and brain samples along with stomach contents and the suspect feed or material should be submitted to a laboratory for chemical analysis.

Treatment of animals poisoned by OP or carbamate insecticides should be considered an emergency because of the rapid progression of respiratory distress in the clinical syndrome. Initial treatment for poisoned swine should be atropine sulfate at approximately 0.5 mg/kg body weight. One-quarter of this dose may be given intravenously for a quick response in especially severe cases. Atropine does not counteract the insecticide–enzyme bond but blocks the effects of accumulated acetylcholine at the nerve endings. Although a dramatic cessation of parasympathetic signs is generally observed within a few minutes after administration of atropine, it will not affect the skeletal muscle tremors. More atropine at approximately one-half the initial dose may be required but should be used only to control recurring parasympathetic signs. Although the use of atropine alone is generally adequate, especially if vomiting has occurred, specific cases may warrant the use of pralidoxime chloride or activated charcoal.

Oral activated charcoal is recommended for treatment of any ingested insecticide to reduce continued absorption of the insecticide from the gut. Although a useful treatment, the need for activated charcoal in swine may be reduced if vomiting has occurred. The use of the oximes (e.g. TMB-4, 2-PAM, pralidoxime chloride) in large animals, although efficacious, may be economically unfeasible. If used, pralidoxime chloride is recommended at a dose of 20 mg/kg body weight; however the oximes are of no benefit in treating carbamate toxicoses.

Dermally exposed animals should be washed with soap and water to prevent continued absorption of these compounds.

Morphine, succinylcholine, and phenothiazine tranquilizers should be avoided in treating OP poisoning.

Chlorinated hydrocarbons

CH insecticides (e.g. toxaphene, chlordane, aldrin, dieldrin, and lindane) produce toxicosis in swine by acting as diffuse but powerful stimulants of the CNS. These products have been restricted from the market for over 35 years, yet leftover products may remain in old barns or storage areas.

Clinical signs often appear 12–24 hours after exposure. Initially, animals may appear apprehensive with a period of hyperexcitability and hyperesthesia characterized by exaggerated responses to stimuli and spontaneous muscle spasms observed. The spontaneous tremors and fasciculation are usually in the facial region and involve lips, muscle, eyelids, and ears, progressing caudally to involve the heavy muscles of the shoulder, back, and hindquarters. These spasms may progress into a tonoclonic convulsive seizure. Abnormal posturing, elevation of the head, and chewing movements may be observed. Varying degrees of respiratory paralysis occur during the seizures, with periods of depression and inactivity between successive seizures. The rapidity of onset and severity of clinical signs provide a poor index of the prognosis of the episode in individual animals. Occasionally, animals will die during

seizures, while others may completely recover following several severe episodes.

Diagnosis is tentatively made by observation of clinical signs of hyperexcitability and tonoclonic convulsive seizures, along with a known exposure to CH insecticides. Demonstrating the presence of significant levels of CH insecticide in the liver, kidney, or brain tissue or in stomach contents or feed is essential for confirming diagnosis. Samples of these tissues as well as stomach contents and suspect material such as feed or spray should be submitted to a laboratory. Avoid contamination of specimens with hair or gut contents to prevent erroneous analytic results.

Treatment is symptomatic since there is no specific antidote for CH insecticides. Sedation with long-acting barbiturates to control convulsive seizures, washing off dermal residues, and administration of activated charcoal are indicated.

Animals dying from CH insecticide toxicosis are a source of contamination for feed ingredients such as tankage, meat and bone meal, and fats because of the persistence of CH insecticides and their concentration in fat deposits of the carcasses. Tissue residues of these chemicals in swine surviving an episode of insecticide exposure should be an important consideration in market animals. In some cases the time required for excretion of these residues is too long to make decontamination economically feasible.

Pyrethroids, formamidines, neonicotinoids, and phenylpyrazoles

Several synthetic pyrethroids (e.g. permethrin, fenvalerate) are commercially available for fly and external parasite control. As a class, synthetic pyrethroids are relatively nontoxic to mammals. Amitraz is a formamidine pesticide with insecticidal and acaricidal properties. It is available in the United States as Taktic for control of lice and mange on swine. The neonicotinoids were developed in the late 1970s and are used as insecticides. Imidacloprid is the most common insecticide in this class and has a wide safety margin. These insecticides act on the postsynaptic nicotinic receptors swine. Fipronil is a member of the phenylpyrazole class of pesticides. These compounds target the GABA-regulated chloride channels. These are all very safe compounds and are unlikely to produce toxicosis in swine.

Fungicides

Captan has been widely used as a seed treatment although some newer fungicides are now being employed. Field corn seed produced commercially may be treated with captan at a level of approximately 1000 ppm, but consumption of captan-treated seed corn represents little hazard of poisoning, as the acute lethal dose of captan for livestock is greater than 250 mg/kg body weight.

Organomercurials include phenyl mercuric chloride, phenyl mercuric acetate, various aliphatic compounds such as ethyl mercuric chloride, and complex aromatic derivatives like hydroxy mercuric cresol. The toxicoses associated with mercury-based seed treatments are discussed above, in the section on mercury.

Pentachlorophenol (PCP) has been employed for over 45 years as a wood preservative and fungicide. PCP- or "penta"-treated wood has found application in livestock handling and housing facilities, where wood is in contact with soil, manure, or moisture. Acute poisoning is not a major problem from PCP-treated wood, although toxicosis, including stillborn pigs, may occur when livestock have contact with surfaces that have been freshly treated with PCP preparations (Schipper 1961). A single oral dose of 80 mg/kg was not fatal to a weanling pig. If toxicosis occurs, depression, emesis, muscular weakness, accelerated respiratory rate, and posterior paralysis are clinical signs that may be observed. A problem of greater concern may be the recognition of blood and tissue PCP residues in swine that have been in contact with PCP-treated facilities. Finding from 10 to 1000 ppb PCP in whole blood is apparently unrelated to manifestations of toxicosis.

Chromated copper arsenate (CCA) is widely used as a wood preservative in consumer lumber intended for outdoor use. CCA-treated wood generally presents a negligible hazard to swine, as the metallic salts are bound in the wood fibers. However, the residual inorganic arsenic in the ashes of burned CCA wood can produce poisoning in swine. Since 2003, no wood can be treated with CCA for residential uses according to the EPA.

Herbicides

Organic and selective herbicides are commonly used for control and elimination of noxious weeds. Toxicity from consumption of treated plants or overspray is rare; most are associated with human error or accidental ingestion of concentrates or sprays.

Chlorophenoxy herbicides (e.g. 2,4-D; 2,4,5-T; MCPA, Silvex, dicamba) are selective herbicides widely used in crop production and pasture and range management. Because the toxic dose of 2,4-D and 2,4,5-T is greater than 300 mg/kg body weight for several days, the hazard of poisoning by these compounds under normal conditions of use is very low.

Amide herbicides (e.g. thioamide, allidochlor, propanil) may cause anorexia, salivation, depression, and prostration. The toxic doses are quite high, making intoxication under typical field conditions quite rare. Other classes of

herbicides (e.g. glyphosates, triazines, and benzoic acid derivatives) are relatively nontoxic.

Dipyridyl herbicides (e.g. diquat, paraquat) are plant-desiccant types of herbicide and have found widespread application in no-till farming. Accidental as well as malicious poisoning of swine with paraquat has resulted in toxicosis. An approximate lethal dose of paraquat for swine is 75 mg/kg. Acute effects involving necrosis and erosion of the oral and gastric mucosa are attributed to the carrier solvent. The more classic effects, however, occur 7–10 days after ingestion and are characterized by pulmonary congestion and edema. The pulmonary lesions progress to a severe diffuse interstitial pulmonary fibrosis. Initial clinical signs include emesis and diarrhea, and the later stages are characterized by respiratory distress. Once clinical signs suggesting pulmonary involvement develop, therapeutic measures are usually futile.

Rodenticides

Rodenticides are used to control rat and mouse populations in or around farmsteads, feed storage areas, and swine production facilities. Accidental access to these compounds constitutes the usual route of exposure, although malicious poisoning of swine with rodenticides has also occurred.

Anticoagulant rodenticides

Anticoagulant rodenticides (e.g. warfarin, diphacinone, chlorophacinone, bromadiolone, brodifacoum, pindone) compose the largest group of rodenticides available through retail outlets. Swine are quite susceptible to this class of compound, as evidenced by toxicosis occurring after a single oral dose of warfarin at 3 mg/kg body weight. Repeated oral doses of only 0.05 mg/kg per day for 7 days also produced toxicosis in swine (Osweiler 1978). These rodenticides produce lowered prothrombin levels by interfering with vitamin K utilization. The physiologic result is increased blood clotting time, which is manifested clinically as mild to severe hemorrhage. The clinical signs – including lameness, stiffness, lethargy, recumbency, anorexia, and dark tarry feces – are related directly to extravasation of blood. Observed lesions include hematoma, articular swelling, epistaxis, intermuscular hemorrhage, anemia, and melena.

Anticoagulant intoxication may have food health and safety implications due to potential of relay toxicosis and prolonged volatile residues in tissue. A study involving bromadiolone, a second-generation anticoagulant, showed that liver residues persisted for a period of weeks in cases involving controlled high dose administration (Enouri et al. 2015).

A diagnosis of anticoagulant rodenticide toxicosis should include demonstration of a defect in the clotting mechanism as evidenced by increases in clotting time, one-stage prothrombin time, or activated partial thromboplastin time. The chemical detection of the rodenticide in samples of blood, liver, or suspect baits is also warranted. Injectable vitamin K and oral vitamin K supplements are included in a successful treatment regime.

Strychnine

Strychnine, an indole alkaloid, is available commercially, often as either a green- or red-dyed pellet or grain or as a white powder. This alkaloid acts by selectively antagonizing certain types of special inhibitory neurons, thereby allowing uncontrolled and relatively diffuse reflex activity to proceed unchecked. The approximate oral lethal dose of strychnine for swine varies from 0.5 to 1 mg/kg body weight.

Clinical signs appear within 10 minutes to 2 hours after ingestion and are characterized by violent tetanic seizures that may occur spontaneously or in response to external stimuli such as touch, light, or sound. The intermittent seizures are usually separated by periods of relaxation. Death occurs from anoxia and exhaustion during the seizures, often in less than 1 hour.

Diagnosis is best confirmed by detection of the strychnine alkaloid in either the stomach contents or urine. Treatment consists of controlling seizures with long-acting barbiturates and other muscle relaxants.

Cholecalciferol

Rodenticides containing cholecalciferol (vitamin D_3) are commercially available as Agrid3, Quintox, or Ortho Rat-B-Gone. Toxic doses of these products produce vitamin D poisoning with hypercalcemia, mineralization of soft tissues, and clinical signs of depression, weakness, nausea, anorexia, polyuria, and polydipsia.

Bromethalin

Bromethalin-based rodenticides, marketed as Assault, Vengeance, or Tomcat, produce cerebral edema and signs of rear leg ataxia and/or paresis and CNS depression.

Toxic plants

Amaranthus retroflexus (redroot pigweed)

A distinct disease syndrome of swine called perirenal edema occurs during the summer and early fall months. Its onset is associated with sudden access to pastures,

barn lots, or fencerows containing moderate amounts of *Amaranthus retroflexus* (redroot pigweed). Clinical signs appear suddenly 5–10 days after access to the pigweed. Initial signs are weakness, trembling, and incoordination. The disease rapidly progresses to knuckling of the pastern joints and finally to almost complete paralysis of the rear legs. Affected pigs usually lie in sternal recumbency, and if disturbed, attempts to walk will be in a crouching gait or with the rear legs dragging. The body temperature is usually normal and the eyes are bright. Coma and death generally occur within 48 hours of the onset of clinical signs, but affected swine may live from 5 to 15 days, with progression from signs of acute nephrosis to those of chronic fibrosing nephritis. In affected herds, new cases may appear for as long as 10 days after removal from the source. Morbidity ranges from less than 5% in some herds to 50% in others, and the mortality is usually about 75–80% in those showing clinical signs.

Gross necropsy findings are dramatic and characterized as edema of the connective tissue around the kidneys. The amount of fluid in the perirenal area varies, at times occupying the greater portion of the abdominal cavity. The edematous fluid may contain considerable blood, although the kidney itself is usually of normal size and pale. Edema of the ventral body wall and perirectal areas as well as ascites and hydrothorax may be observed. Histologic lesions of affected swine are characterized by hydropic degeneration and coagulative necrosis of both proximal and distal convoluted tubules. Glomeruli may be shrunken, with dilation of Bowman's capsules. Proteinaceous casts are numerous in distal and collecting tubules.

As a consequence of severe renal disease, there are elevations in BUN, serum creatinine, and serum potassium. The electrocardiograph of affected swine is characteristic of hyperkalemic heart failure (Osweiler et al. 1969). Immediate removal of affected pigs from the source of the weeds is the only definite therapeutic recommendation that can be made at this time.

Xanthium spp. (cocklebur)

Cockleburs, including *Xanthium strumarium* and other species, are annual herbs that reproduce only from seed. They may be found throughout the world in cultivated fields, fencerows, and ditches and may heavily infest pastures as a result of being washed in from adjacent cropland.

The greatest potential for cocklebur poisoning arises when the more toxic two-leaf seedling stage or ground seeds are ingested. The unpalatable more mature plant contains less of the toxic principle, carboxyatractyloside. Within 8–24 hours after ingestion, swine develop signs of depression, nausea, weakness, ataxia, and subnormal temperature. Spasms of the cervical muscles, vomiting, and dyspnea may occur. Death occurs within several hours after the onset of signs.

Lesions typically include ascites with large fibrin strands on the surface of the liver and other viscera and congestion and centrilobular accentuation of the liver. Microscopically acute centrilobular hepatic necrosis is observed (Stuart et al. 1981).

Treatment includes mineral oil orally to delay absorption of the carboxyatractyloside. Intramuscular injection of 5–30 mg physostigmine may produce a dramatic response in some cases (Link 1975).

Solanum nigrum (black nightshade)

Even though black nightshade is easily recognized and found in woods, permanent pastures, and fencerows, actual cases of poisoning are rare. The alkaloid solanine is found principally in the leaves and green berries, but the plant is generally not palatable and is usually consumed under conditions of its abundant growth and lack of other suitable forage.

Affected animals display anorexia, constipation, depression, and incoordination. Poisoned swine may vomit. Dilation of the pupils and muscular trembling are neurologic signs observed. Animals may be seen lying on their sides and kicking with all feet, progressing then to coma and death. Necropsy may reveal some degree of gastrointestinal irritation. The toxic alkaloid is rapidly eliminated through the urine (Kingsbury 1964).

Nitrates and nitrites

As monogastric animals, swine are relatively resistant to the effects of nitrate, especially when compared with cattle. Nitrate or nitrite toxicosis occurs most commonly when these ions accumulate in either plants or water sources. Some fertilizers, such as ammonium nitrate or potassium nitrate, may also be a source of nitrate for animals. Several different plants may accumulate nitrate, depending on varying climatic and soil fertility conditions. Nitrate may accumulate in the lower stalk and perhaps leaves of corn and other plants, but not in the fruit or grain.

The nitrates from both water (see the section on water quality below) and plant sources are additive and should be evaluated together. The nitrate ion (NO_3) itself is not particularly toxic and may produce no more than gastrointestinal irritation. However, nitrite (NO_2), the reduced form of nitrate, is quite toxic. The nitrite ion oxidizes ferrous iron in hemoglobin to the ferric state, forming methemoglobin, which cannot accept and transport molecular oxygen. The result is tissue hypoxia from poorly oxygenated blood.

Pigs given single oral doses of greater than 10–20 mg nitrite-nitrogen (as potassium nitrite)/kg body weight developed clinical signs of poisoning but recovered, whereas those given doses greater than 20 mg nitrite-nitrogen/kg body weight died within 90–150 minutes after ingestion (London et al. 1967). Clinical signs became apparent when approximately 20% of the total hemoglobin was present as methemoglobin; death was associated with methemoglobin levels of approximately 80%.

Clinical signs observed with acute nitrite toxicosis include increased respiratory rate, salivation, miosis, polyuria, weakness, ataxia, and terminal anoxic convulsive seizures. The blood and tissues are a chocolate brown color from the methemoglobin. Treatment of acute nitrite toxicosis consists of intravenous injection of 10 mg methylene blue/kg body weight in a 4% solution (Link 1975).

Water quality

The availability of adequate quantities of good quality water is essential for successful swine production. Water as the cause of poor performance and vague disease conditions in swine suggests that water evaluation should be part of a thorough diagnostic investigation. A detailed history of the animals as well as the water source, careful clinical evaluation, and submission of representative animal and water specimens should be included in the investigation. Results of water tests should be evaluated in view of existing standards for livestock water quality. Some general guidelines for evaluating water quality parameters for livestock are presented in Table 70.1.

Information about the source of the water should be recorded. Ponds, wells, and regional rural water systems are the most common water sources, and each may influence the quality of the water supplied. The depth of wells may also be helpful, as deeper wells tend to have a higher mineral content, while shallower wells are more likely to have higher nitrate levels and coliform counts. Sometimes the age of the well and type of pumping device may suggest certain mechanical problems, including a cracked casing or defective sanitary seal. Estimates of the amount of water consumed using water meters may also be helpful when investigating potential water problems.

Table 70.1 Water quality guidelines for livestock.

Item	Maximum recommended limit (ppm)
Major ions	
Calcium	1000
Nitrate + nitrite	100
Nitrite alone	10
Sulfate	1000
Total dissolved solids	3000
Heavy metals and trace ions	
Aluminum	5.0
Arsenic	0.5[a]
Beryllium	0.1[b]
Boron	5.0
Cadmium	0.02
Chromium	1.0
Cobalt	1.0
Copper (swine)	5.0
Fluoride	2.0[c]
Iron	No guideline
Lead	0.1
Manganese	No guideline
Mercury	0.003
Molybdenum	0.5
Nickel	1.0
Selenium	0.05
Uranium	0.2
Vanadium	0.1
Zinc	50.0

[a] 5.0 if not added to feed.
[b] Tentative guideline.
[c] 1.0 if fluoride is present in feed.

Microbiologic standards

Microbiologic examination of water samples determines the general sanitary quality of the sample and indicates the degree of contamination of the water with waste from human and animal sources. These examinations usually do not attempt to isolate pathogenic bacteria but rather detect the presence of indicator organisms. The coliform groups of bacteria are used to assess the degree of water pollution and thus the sanitary quality of the particular sample. The differentiation of fecal coliforms as a subgroup within the general category of coliforms is increasingly available. In the United States, the EPA (1973) proposed that acceptable levels for water to be used directly by livestock should not exceed 1000 cfu/100 mL. Since animals are allowed to range freely and drink surface waters, these proposed limits are unenforceable and of doubtful value. The standard plate count, which enumerates the number of bacteria multiplying at 35 °C, is of doubtful significance in evaluating livestock water sources other than helping judge the efficiency of various water treatment processes.

Salinity

Salinity, or total dissolved solids (TDS), generally expressed in milligrams per liter, is an expression of the amount of soluble salts in a particular water sample and is one of the most important parameters used to evaluate water quality. The ions most commonly involved are calcium, magnesium, and sodium in the bicarbonate, chloride, or sulfate form. Hardness is sometimes confused with salinity, but the two are not necessarily correlative. Hardness is expressed as the sum of calcium and magnesium reported in equivalent amounts of calcium carbonate. Although hardness of water may affect the mechanical function of valves and waterers because of the formation of mineral deposits, hardness itself has a minimal impact on animal performance.

Salinity is estimated by mg of soluble salts/L. Water with less than 1000 mg/L is not a hazard; between 1000 and 5000 mg/L may cause mild temporary diarrhea or be refused at first by swine not accustomed to it (Anderson and Strothers 1978; NRC 1974; Paterson et al. 1979); between 5000 and 7000 mg/L may present a health risk for pregnant, lactating, or stressed animals; and more than 7000 mg/L should be considered unsafe for swine.

In some regions, sulfates are a major portion of the TDS in water. Veenhuizen et al. (1992) demonstrated that except for an increase in fecal moisture content, water containing up to 1800 mg of sodium and/or magnesium sulfate per liter had no effect on nursery pig performance. An epidemiologic study of water on swine farms did not find an association between sulfate concentrations and the prevalence of diarrhea, although water sulfate levels increased with the depth of the wells tested (Veenhuizen 1993). A study of water quality on 173 Iowa swine farms found a mean TDS of 343 mg/L (range 100–2500), but measured no significant effects of elevated TDS on several performance parameters (Ensley 1998). However, drinking water sulfate concentrations >1000 ppm can cause an osmotic diarrhea in pigs.

Nitrates and nitrites

Nitrates and nitrites are water soluble and thus may be leached from the soil or soil surface into groundwater. Animal wastes, nitrogen fertilizers, decaying organic matter, silage juices, and soils high in nitrogen-fixing bacteria may be sources of contamination through surface-water runoff to adjacent poorly cased, shallow, or low-lying wells or reservoirs.

The upper limit for nitrate in human drinking water is 45 mg nitrate/L (USEPA 1975), established as preventive for the methemoglobinemia of "blue baby" syndrome in human infants who receive formulas made from high-nitrate waters. There is no evidence to suggest that neonatal swine have greater susceptibility to elevated nitrates, and Emerick et al. (1965) concluded that 1-week-old pigs are no more susceptible to nitrite-induced methemoglobinemia than older growing swine. A review of water quality for livestock (NRC 1974) proposed 440 mg nitrate/L as the maximum nitrate that could safely be allowed in livestock water.

Reports of experimental production of a chronic or low-level nitrate-poisoning syndrome in livestock have been extensively reviewed (Emerick 1974; Ridder and Oehme 1974; Turner and Kienholz 1972). The bulk of the evidence indicates that sublethal or chronic effects are extremely rare and difficult to verify. London et al. (1967) fed growing pigs up to 18.3 mg nitrite-nitrogen/kg body weight for 124 days without serious effects developing. No effect on the performance of growing–finishing swine or on reproductive performance of gilts was observed when the drinking water contained 1320 ppm nitrate (Seerley et al. 1965).

Miscellaneous toxicants

Sodium ion toxicosis

Sodium ion toxicosis, also called water deprivation or salt poisoning, is a common problem in swine. The occurrence of sodium ion toxicosis is inversely related to water intake and is almost always related to water deprivation caused by inadequate or interrupted water supply and oversights in husbandry. The likelihood of toxicosis will also increase with increased dietary salt, but the condition occurs when rations contain normal levels of added salt, for example, 0.25–1%. It has also been associated with the feeding of whey and other milk by-products. Sodium ion toxicosis may occur after water deprivation of a few hours, but in most cases the time exceeds 24 hours.

The initial clinical signs are thirst, anorexia, and constipation, followed by CNS involvement. Intermittent convulsions start within 1 to several days after water deprivation and are often exacerbated by rehydration. The frequency of the characteristic tonoclonic convulsions with opisthotonos, often starting from a "dog-sitting" position, increases with time. Affected animals are afebrile and may also wander aimlessly, head-press, and appear to be blind and deaf. Moribund pigs become comatose, often lying on their sides with continuous paddling. Most affected animals die within a few days. Some pigs that appear to be unaffected may succumb later from polioencephalomalacia. Salt poisoning from eating excess salt or consuming brine usually will cause vomiting and diarrhea.

Diagnosis is best accomplished by establishing that water deprivation occurred, which may be difficult in some cases. Necropsy findings may reveal an absence of ingesta, gastritis, constipation, or very dry feces; rehydration-exacerbated

deaths may have stomach distended with water. Chemical analysis of serum and cerebrospinal fluids may confirm a hypernatremia with levels of Na above 160 mEq/L (Osweiler and Hurd 1974). However, after rehydration, normal values of 140–145 mEq/L may exist. Fresh brain tissue is required for accurate analysis of brain sodium concentration. Brain sodium levels above 1800 ppm (wet weight) are consistent with a diagnosis of sodium ion toxicosis. Histologic examination of brain tissue, especially the cerebrum, often reveals a nearly pathognomonic eosinophilic meningoencephalitis characterized by cuffing of meningeal and cerebral vessels with eosinophils. However, when pigs live several days, eosinophils may disappear or be replaced by mononuclear cells. Brains of pigs affected subacutely may have a laminar subcortical polioencephalomalacia. Analysis of feed for sodium is usually of limited value. Gradual rehydration in cases of known water interruption is critical to prevent clinical manifestations. The prognosis is poor for animals showing clinical signs.

Coal tar pitch

Coal tars are a mixture of condensable volatile products formed during the destructive distillation of bituminous coal. The phenolic portions of these products have the greatest acute toxicity. Sources of these substances for swine are "clay pigeons," lignite tar flooring slabs, tar paper, and tar used in waterproofing and sealing. Because of the rapid clinical course, sudden death is often the first sign observed. Weakness, depression, and increased respiratory rate can be observed in animals that may live for several hours or even days. Icterus and a secondary anemia may develop. Necropsy of pigs poisoned by coal tar pitch reveals a greatly enlarged friable liver. The hepatic lobules are very distinct grossly; some are darkened in color, and others are yellowish orange. Microscopically, this lesion is observed as severe centrilobular necrosis with subsequent intralobular hemorrhage. Ascites and large turgid kidneys may also be observed. There is no specific treatment for this condition. Removal of animals from the source of the coal tar is important to prevent recurrence of poisoning.

Ethylene glycol

Many permanent antifreeze/coolant mixtures for liquid-cooled engines contain approximately 95% ethylene glycol. A hazard of poisoning exists when animals have accidental access to antifreeze solutions during periods of engine maintenance or when these solutions are used in plumbing systems to prevent freezing. Swine may be poisoned by ingesting 4–5 mL ethylene glycol/kg body weight. Ethylene glycol toxicosis is exhibited in two clinical phases. Initially the glycol may enter the cerebrospinal fluid, producing a narcotic or euphoric state of intoxication. Subsequent clinical signs of acidosis and renal failure are associated with the highly toxic metabolites of the glycol and formation of calcium oxalate crystals in the kidney tubules. Renal tubular blockage with development of uremia is observed 1–3 days after ingestion.

Clinical signs generally include emesis, anorexia, dehydration, weakness, ataxia, convulsions, coma, and death. The entire course of illness may be as short as 12 hours following consumption of large quantities of ethylene glycol. Oxalate nephrosis can be demonstrated histopathologically and is characterized by finding pale yellow birefringent oxalate crystals in the tubules. Polarizing filters greatly aid in the detection of oxalate crystals in kidney sections or in impression smears of freshly incised kidney.

Once clinical signs of renal failure are evident, treatment is usually of no avail. If treated within the first 6–12 hours after ingestion, reasonable response has been achieved in ethylene glycol–poisoned dogs by using 5.5 mL/kg body weight of 20% ethyl alcohol intravenously and 98 mL/kg body weight of 5% sodium bicarbonate intravenously.

Gossypol

Cottonseed meal (CSM), a by-product of the cotton fiber and cottonseed oil industries, is an important protein supplement for livestock rations in cotton-producing regions. Its use as a protein supplement for swine, however, is limited by gossypol content, which varies with the strain of the cotton plant, its geographic location, climatic conditions, and the oil extraction procedure used. Gossypol, a polyphenolic binaphthalene, is a yellow pigment in glands of decorticated cottonseed. The toxic "free" gossypol becomes partially inactivated (bound) during the extraction and milling processes, as well as spontaneously in the prepared meal. Toxicity of gossypol depends on the species and age of the animal and on various components of the diet, particularly the protein, lysine, and iron concentrations (Eisele 1986).

Toxicosis only follows prolonged feeding (weeks to months) of CSM with a high content of free gossypol and may be manifested simply as ill-thrift or as an acute respiratory problem followed by death. The main pathologic changes are cardiomyopathy, hepatic congestion and necrosis, skeletal muscle injury, and severe edematous changes throughout the animal. A decrease in hemoglobin total serum, protein concentration, and packed cell volume is seen in pigs fed a diet containing >200 mg of free gossypol/kg (Haschek et al. 1989).

Recommendations for growing and fattening swine include feeding no more than 9% CSM in the diet, with less than 100 mg (0.01%) of free gossypol/kg, in a 15–16% protein diet. Tolerance to gossypol can be induced by adding $FeSO_4$ (400 mg/kg) at a 1 : 1 weight ratio with free

gossypol. Increasing the amount of crude protein or supplementing with lysine can also induce tolerance (Pond and Maner 1984).

Disinfectants

Cleaning compounds like the quaternary ammonium and glutaraldehyde products need to be used with care as these compounds can be in contact with animals and result in severe dermal burns. In general, intoxication with disinfectants is rare.

Ventilation failure and consequences

Confinement of swine in closed structures dependent on mechanical ventilation increases the risk of hyperthermia or impact of toxic gases. Fortunately, concentrations of ammonia and hydrogen sulfide, the two most dangerous gases associated with manure decomposition, remain below toxic levels even at relatively low ventilation rates used during cold weather. However, accidents, poor design, power failure, mechanical failure, and improper operation may result in insufficient ventilation and increase the concentration of poisonous gases to toxic levels. It is useful to be reminded of some of the terminology used when investigating ventilation failures: hyperthermia (elevated body temperature), asphyxiation (displacement of oxygen by another gas such as CO_2), intoxication (toxic effect of gases such as hydrogen sulfide, ammonia, or carbon monoxide on structure or function), and suffocation (physical obstruction of air passages).

Ammonia and hydrogen sulfide are the most important gases released by the decomposition of urine and feces; carbon dioxide and methane are also produced but seldom reach significant concentrations. A number of vapors responsible for the odors of manure decomposition are also produced, including organic acids, amines, amides, alcohols, carbonyls, skatoles, sulfides, and mercaptans. Concentrations of toxic gases are usually expressed as parts of the gas per million parts of air (ppm) by volume.

Swine deaths associated with ventilation failures are usually due to mechanical failures or power loss rather than simple accumulation of toxic gases. Losses, sometimes disastrous, may occur at any time of year in part or all of a confinement facility. Similar dynamics and death losses occur in tightly sealed insulated trucks used to transport pigs.

Hyperthermia

When ventilation fails because of storms, power outages, or mechanical failure, the dynamics of air movement, heat dissipation, and high humidity in the confined space may quickly become critical. These factors greatly suppress evaporative cooling, which often and quickly leads to fatal hyperthermia in confined swine. Death losses may approach 95% under these circumstances; frequently only the smallest pigs survive. Although there is no method to specifically confirm hyperthermia as a cause of death, a history of ventilation failure, rapid carcass decomposition, a pale "cooked" appearance to the muscles, and blood-tinged foam in the trachea are usually seen. Hyperthermia is often an overlooked contributor to deaths while in pursuit of "toxic gas" diagnosis.

Ammonia

Ammonia (NH_3) is the toxic air pollutant most frequently found in high concentrations in animal facilities, and production is especially common where excrement can decompose on a solid floor. This gas has a characteristic pungent odor that humans can detect at approximately 10 ppm or even lower. The NH_3 concentration in enclosed animal facilities usually remains below 30 ppm even with low ventilation rates; however, it may frequently reach 50 ppm or higher during long periods of normal facility operation.

Ammonia is highly soluble in water and as such will react with the moist mucous membranes of the eye and respiratory passages. Consequently, excessive tearing, shallow breathing, and clear or purulent nasal discharge are common signs of aerial NH_3 toxicosis. At concentrations usually found in practical animal environments (<100 ppm), the primary impact of this gas is as a chronic stressor that can affect the course of infectious disease as well as directly influence the growth of healthy young pigs. The rate of gain in young pigs was reduced by 12% during exposure to aerial NH_3 at 50 ppm and by 30% at 100 or 150 ppm (Drummond et al. 1980). Ammonia at 50 or 75 ppm reduced the ability of healthy young pigs to clear bacteria from their lungs (Drummond et al. 1978). At 50 or 100 ppm, aerial NH_3 exacerbated nasal turbinate lesions in young pigs infected with *Bordetella bronchiseptica* but did not add to the infection-induced reduction in growth rate (Drummond et al. 1981a). In another study, aerial NH_3 at 100 ppm reduced the rate of gain by 32%, and when ascarid infection was imposed simultaneously, the rate of gain was reduced by 61% (Drummond et al. 1981b). More extensive reviews of aerial NH_3 and its effect on animal production are provided by Curtis (1983) and the National Research Council (1979a).

Hydrogen sulfide

Hydrogen sulfide (H_2S) is a potentially lethal gas produced by anaerobic bacterial decomposition of protein and other sulfur-containing organic matter. The source of H_2S that presents the greatest hazard to swine is liquid manure holding pits. Most of the H_2S, which may be continuously produced, is retained within the liquid of the pit. However, agitation of waste slurry to suspend solids prior to being pumped out causes the rapid release of much of the H_2S that may have been retained within it. Hydrogen sulfide is heavier than air and consequently accumulates in pits, tanks, and other low areas of a facility. The concentration of H_2S usually found in closed animal facilities (less than 10 ppm) is not toxic, but the release of gas upon agitation may produce concentrations of H_2S up to 1000 ppm or higher within the facility.

Acute H_2S poisoning is directly responsible for tragic deaths of humans and swine in closed animal facilities, particularly during pit manure agitation and removal. Humans can detect the typical "rotten egg" odor of H_2S at very low concentrations (0.025 ppm) in air. Exposures to these low concentrations have little or no importance to human health, and thus the olfactory response is a useful warning signal of its presence. However, at higher concentrations (greater than 200 ppm), H_2S presents the distinct hazard of a paralyzing effect on the olfactory apparatus, thus effectively neutralizing the warning signal (NRC 1979b).

Hydrogen sulfide is an irritant gas. Its direct action on tissues induces local inflammation of the moist membranes of the eye and respiratory tract. When inhaled, the action of H_2S is more or less uniform throughout the respiratory tract, although the deeper pulmonary structures suffer the greatest damage. Inflammation of the deep lung structures may appear as pulmonary edema. If inhaled at sufficiently high concentrations, H_2S can also be readily absorbed through the lung and can produce fatal systemic intoxication (O'Donoghue 1961). At concentrations in air exceeding 500 ppm, H_2S must be considered a serious imminent threat to life; between 500 and 1000 ppm, it produces permanent effects on the nervous system via polioencephalomalacia. If spontaneous recovery does not occur and artificial respiration is not immediately provided, death results from asphyxia or from respiratory paralysis of intoxication.

Management is the most important part of preventing animal deaths from H_2S. When manure stored in a pit beneath a building is agitated, animals should either be moved out of the building or other steps taken to protect the animals during agitation. In mechanically ventilated buildings, the fans should run at full capacity; in naturally ventilated buildings, manure pits should not be agitated unless there is a brisk breeze blowing. Immediate rescue of affected swine should not be attempted for the rescuer may quickly become a victim of H_2S toxicosis.

Carbon dioxide

Carbon dioxide (CO_2) is an odorless gas present in the atmosphere at 300 ppm. It is given off by swine as an end product of energy metabolism and by improperly vented, though properly adjusted, fuel-burning heaters. It is also the gas evolved in the greatest quantity by decomposing manure. Despite all this, CO_2 concentration in closed animal facilities rarely approaches levels that endanger animal health (Curtis 1983).

Methane

Methane (CH_2), a product of microbial degradation of carbonaceous materials, is not a poisonous gas. It is biologically rather inert and produces effects on animals only by displacing oxygen in a given atmosphere, thereby producing asphyxiation. Under ordinary pressures, a concentration of 87–90% CH_2 in a given atmosphere is required before irregularities of respiration and eventually respiratory arrest due to anoxia are produced. The chief danger inherent in this material is its explosive hazard as concentrations of 5–15% by volume in air are reached (Osweiler et al. 1985). Recently, the US Midwest has experienced increased propensity for methane-containing foam to form in pits. In the last decade, changes in ration constituents have increased the occurrences of pits generating gas and methane-laden foam, resulting in accidently explosions and fires on swine farms, some of which have claimed human lives (Yan et al. 2014).

Carbon monoxide

Carbon monoxide (CO), which is produced from the inefficient combustion of carbonaceous fuel, is also potentially lethal to swine. Poisoning occurs when improperly adjusted and improperly vented space heaters, furnaces, or equipment are operated in tight, poorly ventilated buildings such as farrowing houses. Ambient background levels of CO are 0.02 ppm in fresh air, 13 ppm in city streets, and 40 ppm in areas with high vehicular traffic.

Carbon monoxide acts by competing with oxygen for binding sites on a variety of proteins, particularly hemoglobin. The affinity of hemoglobin for CO is some 250 times that for oxygen. Therefore, CO is preferentially bonded to the heme group, which forms carboxyhemoglobin, thereby reducing the oxygen-carrying capacity of heme. Cellular and tissue hypoxia occurs, but the carboxyhemoglobin will often cause blood and tissues to appear "cherry red" by gross examination.

High concentrations of CO (>250 ppm) in swine farrowing houses can produce an increased number of

stillborn piglets. Stillbirths are often accompanied by a clinical history that includes very limited inadequate ventilation due to blocked apertures of natural systems or reduction to minimal winter rates for mechanical systems; use of unvented or improperly vented LP gas-burning space heaters; a high percentage of near-term sows delivering dead piglets within a few hours of being put in an artificially heated farrowing facility; sows that appear clinically normal but that produce whole litters born dead; and negative laboratory results for the detection of infectious causes of abortion (Carson 1990). Exposure to high levels of CO can be confirmed by actually measuring the CO level in the air or by measuring the percentage of carboxyhemoglobin in the blood of the affected animals. In addition, perhaps most common diagnostic technique is to demonstrate carboxyhemoglobin concentration of greater than 2% in fetal thoracic fluid for diagnosis of CO-induced stillbirth in swine (Dominick and Carson 1983).

Anhydrous ammonia

On occasion, swine may be exposed to anhydrous ammonia (gas-NH_3) used as an agricultural fertilizer nitrogen source. This gas presents a unique risk of exposure to both animals and people because of its presence on farms and the fact that it is stored, transported, and applied under high pressure. Poisoning with gas-NH_3 is associated with gas release from broken hoses, failure of valves, and errors in operating transport or application equipment. Once released, gas-NH_3 rapidly combines with water and forms caustic ammonium hydroxide. The cornea, mouth, and respiratory tract are high in moisture and especially susceptible to the resulting strong alkali burns. Acute death from laryngospasm and accumulation of fluid in the lungs can occur within a matter of minutes. Blindness from corneal opacity and sloughing epithelium in the respiratory tract may be seen in swine surviving initial exposure. Residual respiratory damage and secondary bacterial invasion may not allow affected animals to regain full productive status.
