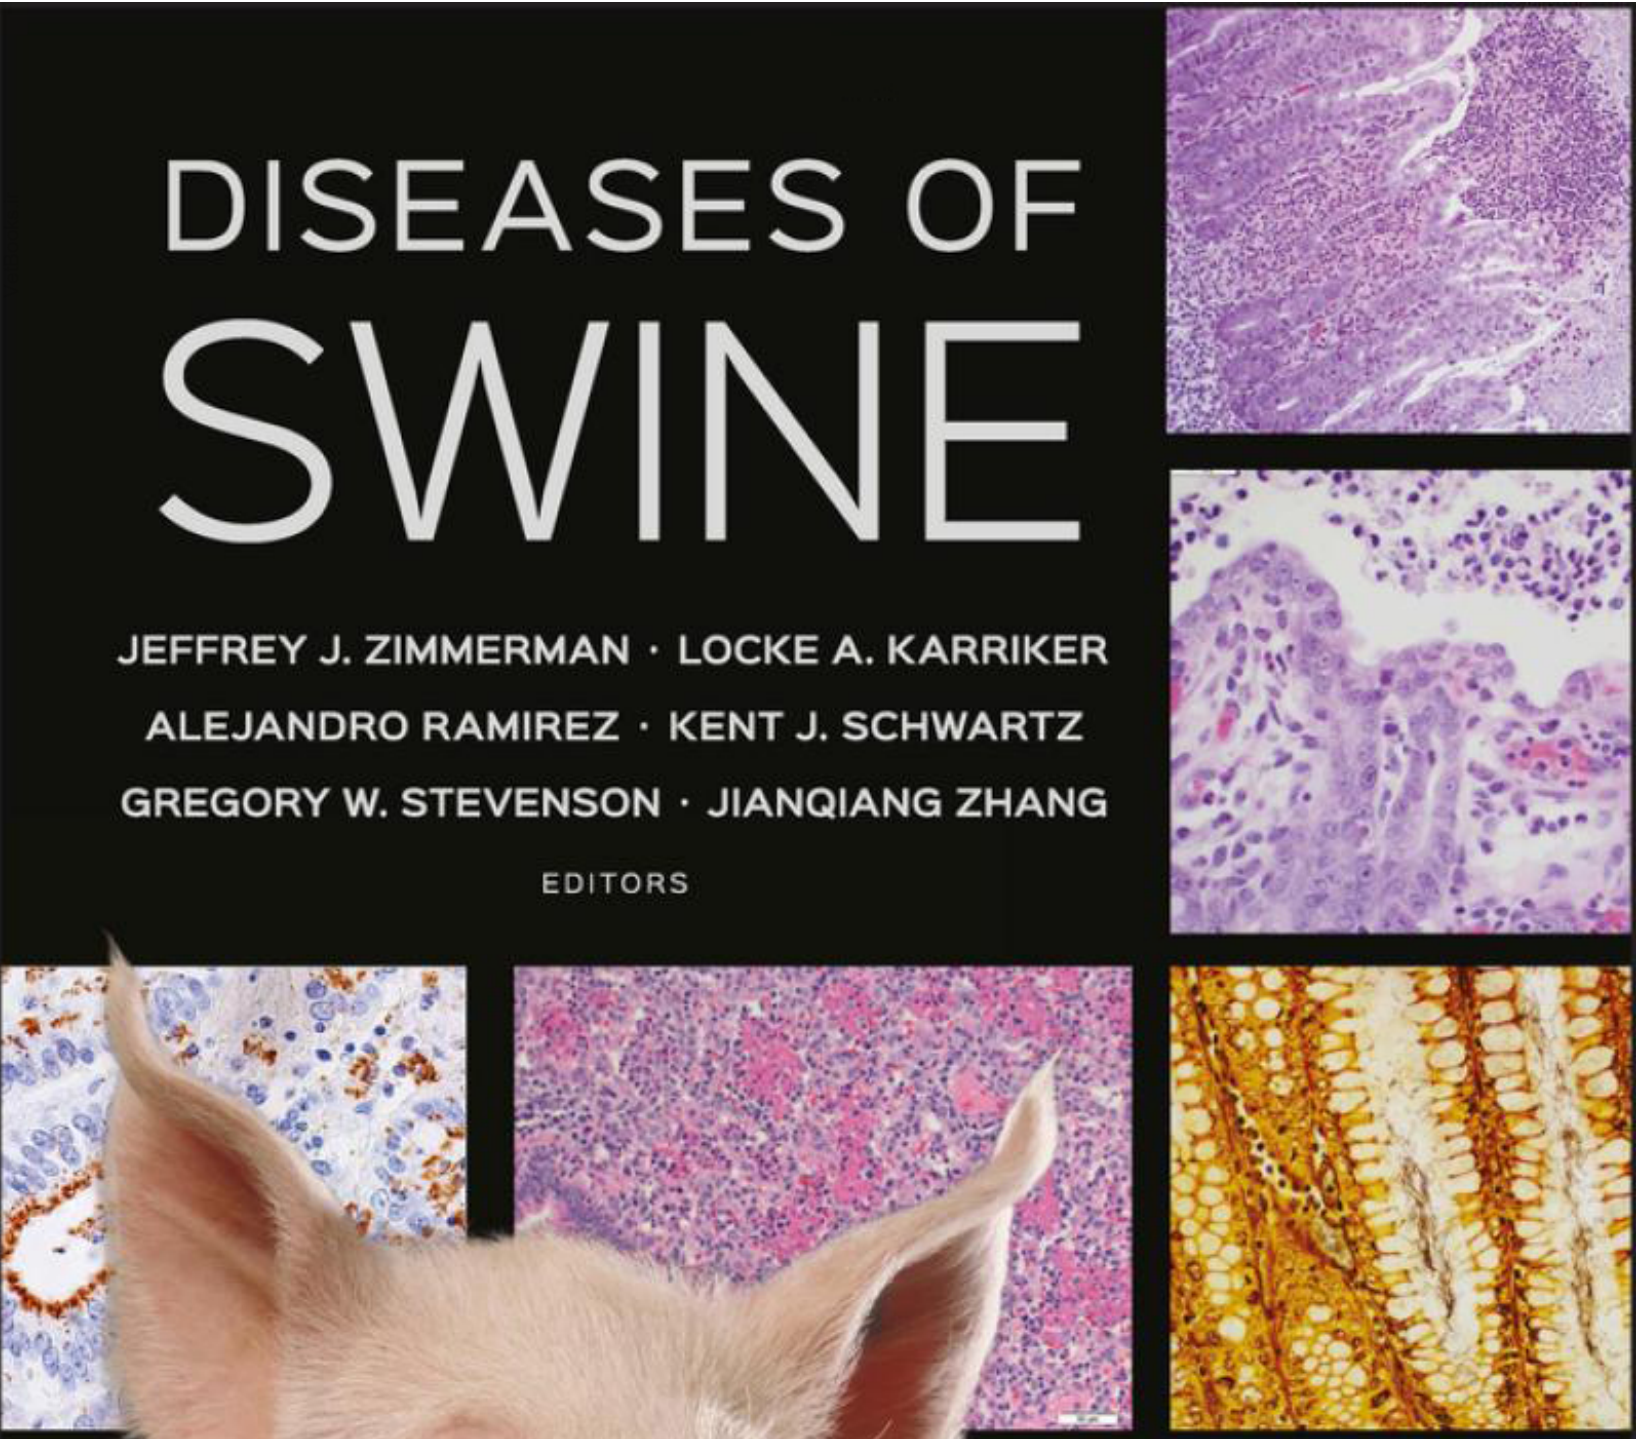
DISEASES OF SWINE

JEFFREY J. ZIMMERMAN · LOCKE A. KARRIKER
ALEJANDRO RAMIREZ · KENT J. SCHWARTZ
GREGORY W. STEVENSON · JIANQIANG ZHANG
EDITORS



11th
ELEVENTH EDITION

AMERICAN ASSOCIATION OF SWINE VETERINARIANS

WILEY Blackwell

Diseases of Swine

Diseases of Swine

Edited By

Jeffrey J. Zimmerman
Locke A. Karriker
Alejandro Ramirez
Kent J. Schwartz
Gregory W. Stevenson
Jianqiang Zhang

Eleventh Edition

WILEY Blackwell

This edition first published 2019

Edition History
Iowa State Press (1e, 1958; 2e, 1964; 3e, 1970; 4e, 1975; 5e, 1981, 6e, 1986; 7e, 1992; 8e, 1999). Blackwell Publishing (9e, 2006). John Wiley and Sons, Inc. (10e, 2012).

Registered Office
John Wiley & Sons, Inc., 111 River Street, Hoboken, NJ 07030, USA

Editorial Office
111 River Street, Hoboken, NJ 07030, USA

Wiley also publishes its books in a variety of electronic formats and by print-on-demand. Some content that appears in standard print versions of this book may not be available in other formats.

Library of Congress Cataloging-in-Publication Data

Names: Zimmerman, Jeffrey J., editor.
Title: Diseases of swine / edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, Jianqiang Zhang.
Description: 11th edition. | Hoboken, NJ : Wiley-Blackwell, 2019. | Includes bibliographical references and index. |
Identifiers: LCCN 2018042674 (print) | LCCN 2018043009 (ebook) | ISBN 9781119350903 (Adobe PDF) | ISBN 9781119350897 (ePub) | ISBN 9781119350859 (hardcover)
Subjects: LCSH: Swine–Diseases. | MESH: Swine Diseases
Classification: LCC SF971 (ebook) | LCC SF971 .D57 2019 (print) | NLM SF 971 | DDC 636.4/0896–dc23
LC record available at https://lccn.loc.gov/2018042674

Contents

Contributors *xi*
Editors' Note *xxi*
Acknowledgments *xxii*

Section I Veterinary Practice *1*

1 Herd Evaluation *3*
Records, benchmarks, four circles approach, diagnostic approaches, prioritizing interventions, reporting, blood sample collection, oral fluid collection.

2 Behavior and Welfare *17*
Definitions of welfare, normal vs. abnormal behaviors, maternal behaviors, minimizing welfare impact of invasive procedures, feeding and drinking behaviors, human interactions, behavior responses due to disease, recognizing pain, vices, objective measures of pain.

3 Genetics and Health *42*
Genetic influences on mortality, disease resistance, immune response and sow productive lifetime, with a summary of recent genetic advances.

4 Effect of Environment on Health *50*
Evaluation of the environment, recommended air temperatures, minimum ventilation rates, space recommendations, water requirements, feeder space recommendations. Investigation of death due to ventilation failure. Impact of noise levels and stray voltage.

5 Differential Diagnosis of Diseases *59*
Diarrhea, vomiting, rectal prolapses, respiratory distress, anemia, sneezing, skin, neurologic, lameness, reproductive, congenital, zoonotic, vesicular lesions, urinary tract.

6 Diagnostic Tests, Test Performance, and Considerations for Interpretation *75*
How diagnostic tests are performed, advantages, and disadvantages. PCR testing considerations including quantitative interpretation. Appropriate uses of genetic sequencing. Descriptions of metagenomics technology.

7 Optimizing Sample Selection, Collection, and Submission to Optimize Diagnostic Value *98*
Developing the diagnostic plan, diagnostic sample selection, pig necropsy, necropsy safety, knife sharpening.

8 Collecting Evidence and Establishing Causality *112*
Sources of variation in test results, sensitivity and specificity, testing in series or parallel, selecting test cutoff values, selecting appropriate sample size, screening and confirmatory tests. Evidence-based medicine, establishing baselines, evaluating interventions.

9 Disease Control, Prevention, and Elimination *123*
Routes of transmission, ecology of disease, pathogen cycles, biological risk management, principles of biosecurity, biocontainment, bioexclusion.

10 **Drug Pharmacology, Therapy, and Prophylaxis** *158*
Antimicrobial drug classes, considerations for treatment, residue avoidance, establishing treatment regimens, limiting the development of resistance, parasiticides, impact of drug treatment on immunity, bacteriophages, probiotics, hormones, anti-inflammatory drugs.

11 **Anesthesia and Surgical Procedures in Swine** *171*
Injectable anesthetic agents, sedation, catheterization techniques, epidural injection, anesthetic drug combinations, reversal agents and pain management. Surgical procedures including castration, correction of prolapses, cystostomy procedures, cesarean section, fracture repair, tusk removal, abdominal and musculoskeletal procedures.

12 **Preharvest Food Safety, Zoonotic Diseases, and the Human Health Interface** *197*
Physical, chemical, and biologic hazards, drug residues, MRSA, feed safety, certification programs.

13 **Special Considerations for Show and Pet Pigs** *211*
Dynamics of the show pig industry, biosecurity, zoonotic implications, vaccination protocols, behavior and training, ethics, teeth trimming, hoof trimming, obesity, and parasites.

Section II Body Systems *221*

14 **Cardiovascular and Hematopoietic Systems** *223*
Anatomy, pathophysiology, mulberry heart disease, anemia, shock, clinical pathology.

15 **Digestive System** *234*
Interactions of flora, nutrition, immune system, anatomy, pathophysiology, gastric ulcers, hemorrhagic bowel syndrome, prolapses, hernias.

16 **Immune System** *264*
Innate and adaptive immunity. Cellular, humoral, mucosal and passive immune mechanisms. Stress, nutrition, immunosuppression, vaccination. Lactogenic immunity.

17 **Integumentary System: Skin, Hoof, and Claw** *292*
Pathophysiology of skin, infectious conditions, vesicles, ear necrosis, porcine dermatopathy and nephropathy syndrome. Pathophysiology of coronary band, foot and claw. Traumatic and nutritional contributors to foot and claw lesions.

18 **Mammary System** *313*
Structure and development, physiology of lactation, physiology of maternal immunity, pathophysiology of lactation dysfunction, mastitis, dysgalactia, risk factors.

19 **Nervous and Locomotor System** *339*
Pathophysiology of nervous system, muscle, bone, joint, and eye. Congenital abnormalities, splayleg, congenital tremor, myopathy, porcine stress syndrome, arthritis, metabolic bone disease, rickets, osteochondrosis.

20 **Diseases of the Reproductive System** *373*
Control of estrus, pregnancy, and parturition. Pregnancy diagnosis, dystocia, prolapse, discharge, male reproductive function, semen quality. Laboratory investigation of abortion and reproductive failure.

21 **Respiratory System** *393*
Anatomy, structure, function, pathophysiology.

22 **Urinary System** *408*
Anatomy, structure, function, pathophysiology.

Section III Viral Diseases *425*

23 Overview of Viruses *427*
General characteristics of viruses, virus taxonomy, detection, characterization of viruses.

24 Adenoviruses *438*

25 African Swine Fever Virus *443*

26 Anelloviruses *453*
Torque teno sus viruses.

27 Astroviruses *457*

28 Bunyaviruses *461*
Akabane virus, Lumbo virus, Oya virus, Tahyna virus.

29 Caliciviruses *464*
Porcine noroviruses, porcine sapoviruses, St-Valérien virus, vesicular exanthema of swine virus.

30 Circoviruses *473*

31 Coronaviruses *488*
Hemagglutinating encephalomyelitis virus, porcine deltacoronavirus, porcine epidemic diarrhea virus, porcine respiratory coronavirus, porcine torovirus, transmissible gastroenteritis virus.

32 Filoviruses *524*
Reston ebolavirus, Zaire ebolavirus.

33 Flaviviruses *530*
Japanese encephalitis virus, Murray Valley encephalitis virus, West Nile virus, other flaviviruses.

34 Hepatitis E Virus *544*

35 Herpesviruses *548*
Malignant catarrhal fever (ovine herpesvirus 2), porcine cytomegalovirus, porcine lymphotropic herpesviruses, pseudorabies (Aujeszky's disease) virus.

36 Influenza Viruses *576*

37 Paramyxoviruses *594*
Menangle virus, Nipah virus, porcine parainfluenza virus 1, porcine rubulavirus (blue eye paramyxovirus).

38 Parvoviruses *611*

39 Pestiviruses *622*
Atypical porcine pestivirus, border disease virus, bovine viral diarrhea virus, Bungowannah virus, classical swine fever virus.

40 Picornaviruses *641*
Encephalomyocarditis virus, foot-and-mouth disease virus, porcine enteroviruses, porcine kobuvirus, porcine picornavirus Japan, porcine sapelovirus, porcine teschovirus, Seneca Valley virus, swine pasivirus, swine vesicular disease virus.

41 **Porcine Reproductive and Respiratory Syndrome Viruses (Porcine Arteriviruses)** *685*

42 **Swinepox Virus** *709*

43 **Reoviruses (Rotaviruses and Reoviruses)** *715*

44 **Retroviruses** *728*

45 **Rhabdoviruses** *733*
Rabies virus, vesicular stomatitis viruses.

46 **Togaviruses** *740*
Eastern equine encephalitis virus, Getah virus, Sagiyama virus, Ross River virus.

Section IV Bacterial Diseases *743*

47 **Overview of Bacteria** *745*
Characteristics of genera, disease mechanisms, table of bacterial diseases. Issues in the development of bacterial disease (normal flora, biofilms, dysbacteriosis).

48 **Actinobacillosis** *749*
Actinobacillus pleuropneumoniae – pleuropneumonia; *Actinobacillus suis* – septicemia, pleuropneumonia; *Actinobacillus equuli* – septicemia.

49 **Bordetellosis** *767*
Bordetella bronchiseptica – nonprogressive atrophic rhinitis, bronchopneumonia.

50 **Brucellosis** *778*
Brucella suis – infertility, abortion, perinatal mortality.

51 **Clostridial Diseases** *792*
Clostridium perfringens type C – necrohemorrhagic enteritis; *Clostridium perfringens* type A – enteritis; *Clostridium difficile* – necrotizing colitis; *Clostridium septicum, perfringens* type A, *novyi, chauvoei – cellulitis* and gas gangrene; *Clostridium tetani* – tetanus; *Clostridium botulinum* – botulism.

52 **Colibacillosis** *807*
Neonatal *E. coli* diarrhea, post weaning *E. coli* diarrhea and edema disease, *E. coli* causing fatal shock, systemic *E. coli* infections, coliform mastitis, nonspecific urinary tract infection.

53 **Erysipelas** *835*
Erysipelothrix rhusiopathiae – septicemia, arthritis, endocarditis; *Erysipelothrix tonsillarum* – arthritis, endocarditis.

54 **Glässer's Disease** *844*
Haemophilus parasuis – fibrinous polyserositis and arthritis.

55 **Leptospirosis** *854*
Leptospira spp. – abortion and stillbirths.

56 **Mycoplasmosis** *863*
Mycoplasma hyopneumoniae – enzootic pneumonia; *Mycoplasma hyorhinis* – polyserositis, arthritis; *Mycoplasma hyosynoviae* – arthritis; *Mycoplasma suis (Eperythrozoon suis)* – anemia.

57 Pasteurellosis *884*
Pasteurella multocida – progressive atrophic rhinitis, pneumonia, septicemia.

58 Proliferative Enteropathy *898*
Lawsonia intracellularis – acute proliferative hemorrhagic enteropathy (PHE), chronic porcine proliferative enteropathy (PPE).

59 Salmonellosis *912*
Salmonella typhimurium, *typhimurium* I 1,4,[5],12:i:-variant, *heidelberg, typhisuis* – enterocolitis; *Salmonella choleraesuis* var. *kunzendorf* – septicemia, enterocolitis; *Salmonella dublin, enteriditis* – meningitis.

60 Staphylococcosis *926*
Staphylococcus hyicus – exudative epidermitis; *Staphylococcus aureus* – skin infections, mastitis, others.

61 Streptococcosis *934*
Streptococcus suis – septicemia, meningitis, others; *Streptococcus porcinus* – cervical lymphadenitis; *Streptococcus dysgalactiae* subsp. equisimilis – septicemia, arthritis, others. Other streptococci – various conditions. *Enterococcus durans* and *hirae* – diarrhea.

62 Swine Dysentery and Brachyspiral Colitis *951*
Brachyspira hyodysenteriae, hampsonii, suanatina – swine dysentery; *Brachyspira pilosicoli* – intestinal (colonic) spirochetosis; *Brachyspira intermedia, murdochii* – brachyspiral (mild) colitis.

63 Tuberculosis *971*
Mycobacterium avium subsps. *avium* and *hominissuis*, *M. bovis, M. caprae, M. tuberculosis* – localized alimentary lymphadenitis, rare disseminated tuberculosis.

64 Miscellaneous Bacterial Infections *981*
Actinobaculum suis (Eubacterium suis) – cystitis, pyelonephritis; *Actinomyces hyovaginalis* – abortion, lung abscesses; *Bacillus anthracis* – anthrax; *Burkholderia pseudomallei* – melioidosis; *Campylobacter* spp. – enterocolitis; *Chlamydia* – enteritis, pneumonia, abortion, etc.; *Enterococci* – neonatal diarrhea; *Klebsiella pneumoniae* – septicemia; *Listeria monocytogenes* – septicemia, encephalitis, abortion; *Rhodococcus equi* – granulomatous lymphadenitis; *Treponema pedis* – ear necrosis, other skin lesions; *Trueperella abortisuis* – *abortion; Trueperella pyogenes* – pyogenic sepsis; *Yersinia* spp. – enterocolitis.

Section V Parasitic Diseases *1003*

65 External Parasites *1005*
Mange *(Sarcoptes, Demodex)*, lice, fleas, mosquitoes, flies (myiasis), ticks.

66 Coccidia and Other Protozoa *1015*
Coccidia *(Cystoisospora, Eimeria)*, *Toxoplasma*, *Sarcocystis*, *Cryptosporidium*, *Giardia*, microsporidia *(Entercytozoon, Encephalitozoon)*, *Balantidium coli, Entamoeba.*

67 Internal Parasites: Helminths *1028*
Nematodes – *Gongylonema, Hyostrongylus, Strongyloides, Ascaris, Trichinella, Trichuris, Oesophagostomum, Metastrongylus, Paragonimus, Stephanurus*, and others; Cestodes – *Echinococcus, Taenia*, and others; parasiticides.

Section VI Noninfectious Diseases *1041*

68 Nutrient Deficiencies and Excesses *1043*
Investigation of nutrient deficiencies or excesses, critical control points, inclusion rates, feed analysis, common nutrient concerns including amino acids, vitamins, and minerals.

69 Mycotoxins in Grains and Feeds *1055*
Aflatoxin, ochratoxin, citrinin, trichothecenes (T2 toxin, DON), zearalenone, fumonisins.

70 Toxic Minerals, Chemicals, Plants, and Gases *1072*
Minerals, feed additives, pesticides, toxic plants, nitrite, effects of water quality, toxic gases, ventilation failure.

Index *1088*

Editors' Note

Dr. Howard Dunne and Iowa State University Press released the first edition of *Diseases of Swine* in 1958. Our goal for the 11th edition is to provide swine health specialists the knowledge needed for effective responses to pig diseases on farms and at local, regional, and global levels. In this we have endeavored to follow the standards of excellence initially established by Dr. Dunne.

As a sojourner of a slower time, Dr. Dunne could not have foreseen either the extent or the accelerated pace at which innovations in engineering, genetics, management, molecular biology, and nutrition have revolutionized pig production. Biologically, economically, and ecologically, the successful application of new technologies to pig production has produced unprecedented advances that benefit society and provide healthful, wholesome pork products to the consumer.

Successes in disease control and pig health assurance are to be celebrated but tempered with the reality that control (much less elimination) of both emerging and historic swine health adversaries has faltered. Endemic viral and bacterial pathogens remain a pernicious burden on pig health. More sobering, the interconnectivity and interdependence of the contemporary world have accelerated the speed and inevitability with which emergent pathogens are dispersed to distant locations. Despite the considerable efforts of the animal health community, African swine fever virus, classical swine fever virus, foot-and-mouth disease virus, porcine circoviruses, porcine coronaviruses, porcine reproductive and respiratory syndrome viruses, and other major pathogens circulate widely in many parts of the world and threaten those that remain free.

Ideally, recognition of our shared vulnerabilities should spur the search for more effective solutions to animal and public health disease threats: there is much to be learned and applied. Thus, we respectfully dedicate this edition of *Diseases of Swine* to our readership as a tool in their search for solutions to swine and public health challenges.

Jeffrey J. Zimmerman

Acknowledgments

With our deepest appreciation, we thank Ella Akin, Cassandra Fitzgerald, Victoria Monahan, and Kristin J. Skoland for their excellent work on behalf of the 11th edition of *Diseases of Swine*. Without their dedication and herculean efforts, the outcome would have been in doubt.

Section I

Veterinary Practice

1

Herd Evaluation

Alejandro Ramirez and Locke A. Karriker

Introduction

With changes in the structure of the swine industry, there have also been changes in the roles of swine veterinarians. Swine veterinarians today focus more on preventive medicine and improving overall herd health rather than responding after disease occurs, the latter common in traditional "fire engine" practices of 20+ years ago. Swine veterinarians now have a proactive role in anticipating problems and preventing disease with a concurrent responsibility to provide care to each pig. This is a challenge as resources (money, labor, and time) are always limited. Consequently, swine veterinarians are highly motivated to be innovative. The use of modern technology, applied research, epidemiologic principles, biostatistics, and improved diagnostic methods guides them through the diagnosis as well as the prioritization and allocation of resources to improve the health and welfare of pigs. The successful veterinarian is not only the one that solves a problem but also creates opportunities and promotes the financial success of their clients.

Before starting any evaluation of a farm, it is important to understand the objectives and goals of each individual involved in the farm operation. This is critical as ultimately the success of any intervention requires actions by the client or those working for the client. Better understanding of the client's goals and constraints will ensure that recommendations on herd health are made in that context. The context often requires swine veterinarians to innovate because recommendations will often vary between clients and may change for a particular client over time. For example, a client may be focused on improving average daily gain for a period but may transition to reducing cost of gain as their facts, business inputs, or understanding changes. The most important question for an owner or manager who is requesting veterinary services to answer is: "What is my goal?"

Investigation of health or production issues is best approached by site visits – that is, inspection of pigs in their environment. As seen in the following discussion, there are many factors that contribute to compromised health and well-being of pigs. Many of the assumptions made by clients or swine veterinarians can only be validated by a well-designed, systematic on-farm site visit.

Preparing for a site visit

History and records

If possible, history and record evaluation should occur prior to any herd evaluation or investigation. Looking at the operation's medical records and past diagnostic laboratory reports helps provide a picture of previous areas of concern and guidance on the expected health status of the herd. It is important to see the actual past reports rather than rely on client's interpretation of results, particularly when serving a new client or as a second opinion. Experience dictates that even with the best intentions, managers and owners are more likely to recall some results while downplaying or neglecting to mention others based on their particular biases.

Production records, usually computerized, are common in modern swine operations. The value of computerized records lies in the ability to instantly query the data and summarize it in meaningful ways. Morris (1982) is reported to be one of the first to suggest the concept of "performance-related diagnosis." This capability to evaluate herd performance and then determine the need for interventions has created a dilemma in regard to the term "subclinical" (Polson et al. 1998). The true definition of subclinical implies not measurable, but today's modern records allow for measuring slight differences in productivity (clinical manifestation),

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

which without records would have gone unnoticed (subclinical). All information gathered on a farm, including records, should be evaluated objectively from a perspective of "trust yet verify." Inaccurate or misinterpreted information and records will often lead to misdiagnosis and inappropriate recommendations.

Benchmarks

Benchmarking is a unique tool that allows operations to identify areas of concern or areas where improvements can be made. Many studies have reported different benchmarks to use as targets (see review by Polson et al. 1998). Others have suggested that the best production benchmarks are those set by the herd's own records (Lloyd et al. 1987). Over time, productivity and processes change such that older benchmarks may no longer be relevant. Depending on the objectives and changing constraints of a specific operation, a particular benchmark may not have the utility or impact that it did under previous conditions. As benchmark information has becomes more available in the age of the Internet, it is increasingly important to determine the characteristics of the operations from which these benchmarks were derived. Experienced swine veterinarians are able to decipher the intricate methods of data reporting and have insight for which circumstances certain parameters are achievable. For those just starting to learn about swine production medicine, it is best to use benchmarks as means to understand the appropriate magnitudes of different parameters rather than using them as specific goals per se.

From the veterinary and diagnostic perspectives, it is better then to focus on understanding the relationship of different production parameters rather than memorizing specific values. A good example of this conceptual thinking can be seen in Figure 1.1. This figure helps show the interrelationship of several different parameters and their impact on a breeding herd's wean pig output. Basically, throughput (i.e. pigs weaned) is determined by multiplying capacity (female inventory or facility space) by efficiency (how many pigs are produced per female inventory or facility space). The advantage of understanding this productivity tree is that all factors influencing throughput can be evaluated at the same time and interventions can be implemented in different areas of the tree. Extending this example to the evaluation of number of pigs weaned, issues like preweaning mortality are obvious, while others such as female removal and replacement rates or lactation length may not initially come to mind. In the case of a producer with a target of >28-day weaning age, the number of litters weaned/female/year will automatically be impacted (fewer) by the system design.

Reporting structure

Reporting structure refers to the organization of workers, management, and owners as it occurs in larger production systems. It also refers to whom a veterinarian is to report findings and recommendations. It is important for swine veterinarians to ask and understand the proper reporting structure for any new client. This is true for operations of all sizes. For the small or family farm, it is important to know what information the owner wants to share with workers. In a larger corporate setting (corporate ownership or part of a producer cooperative),

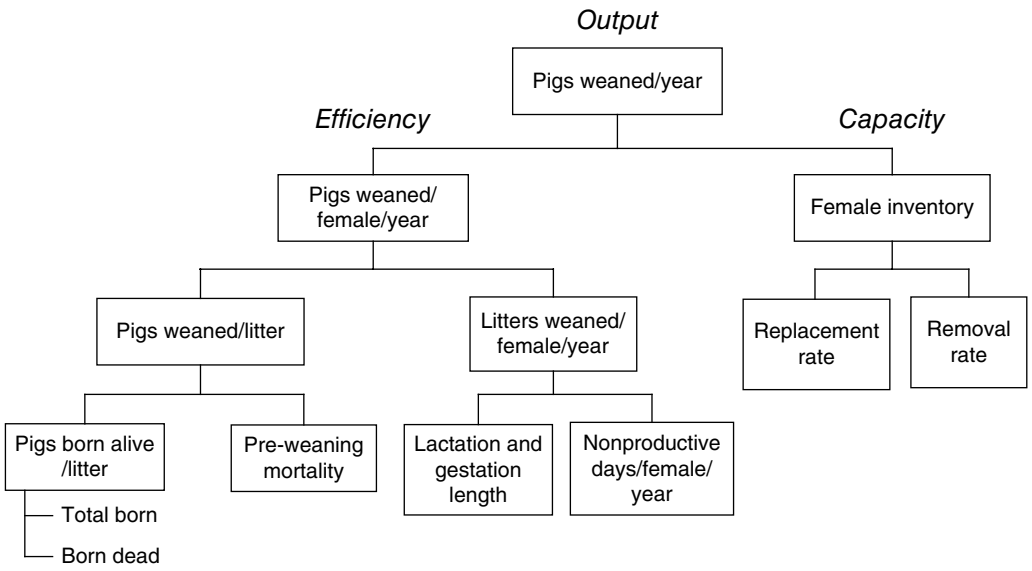

Figure 1.1 Weaned pig output productivity tree for investigating variables that impact the number of pigs weaned per year.
Source: Adapted from Gary Dial.

it is even more important to understand how decisions are made, who makes decisions, and who should get veterinary reports. Understanding reporting structures is critical in ensuring that the veterinarian and managing team are working together and a single consistent message is being delivered to workers. Providing information to the wrong person may actually hinder progress, as many times those closer to the pigs and daily processes may not be fully aware of all considerations influencing a business decision.

Frequently in the United States, the owner of the pigs is different than the caretaker. The caretaker may be focused on minimizing his/her labor efforts, while the owner may be more focused on the cost of a particular treatment or prevention option. The veterinarian is focused on food safety, maximizing pig health and welfare, operational sustainability, and owner profitability. Ultimately, the owner decides what is to be implemented.

Biosecurity

Biosecurity has been a major topic of concern for the swine industry from many years. This topic is covered in greater detail in Chapter 9.

Protocols to prevent disease transmission into the farm, within the farm, or to neighboring farms are now commonplace. Swine veterinarians and personnel need to proactively follow proper biosecurity protocols to ensure the safety and security of our food supply. The key point when performing a herd examination is for the veterinarian to be fully aware, and fully comply, with all biosecurity guidelines for the operation. To do this, the veterinarian has to be proactive and always ask for biosecurity requirements *before* visiting the site. Being informed ahead of time will help ensure that the veterinarian is prepared and able to meet the required downtime and follow proper biosecurity protocols once on-site.

Site visit

Introduction to the four circles

One of the most important concepts of a proper herd evaluation is to be consistent! It is critical to ensure that herd examinations are performed in a consistent manner so as to be thorough and efficient and to minimize the opportunity for missing something important. Checklist may be helpful for specific routine evaluations, but often not practical for a complete and thorough investigation. Checklist approaches limit the problem-solving ability of the veterinarian and are especially poor approaches to new problems. There are too many areas of interest as well as too many differences in facility type and design to make a single valid checklist across all farms.

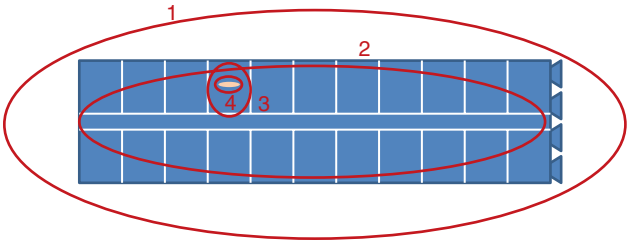

Figure 1.2 Diagram showing the concept of the four-circle approach to herd evaluation. (1) Complete circle evaluation of the "outside" of the building/site. (2) Complete circle evaluation of the "inside" of the building. (3) Complete circle evaluation of individual "pens." (4) Complete circle evaluation of individual "animals."

Farm-specific checklists or checklists for particular aspects of an operation can, however, be useful.

One systematic approach involves the concept of the four circles (Figure 1.2). The overall objective is to be systematic in the evaluation of an operation to make sure that all relevant information is evaluated when looking after pigs' health and welfare. Each successive circle becomes more focused, culminating in the evaluation of individual pigs. The most important question the veterinarian must be able to answer after going through the four-circle process is: "Is there currently a disease or welfare issue or is one imminent?"

Circle 1: evaluation of outside of the building/site

The first circle involves walking around the outside of buildings to assess the overall site. This first circle is especially important when visiting a new site. Evaluation of the outside of a building has value both clinically for the pigs and practically with respect to informing the veterinarian about the caretakers' attention to maintenance and facility management.

As one walks around the site, biosecurity risks for the operation will be better understood. Are there any other hog sites in close proximity? Is the health status of these other operations known? How close are public roads from hog buildings? What appears to be the traffic pattern for this particular site (feed delivery, removal of dead carcasses, employee parking)? How well maintained is the site? If the site is not well maintained, could it be due to lack of attention to details, insufficient staffing, or tight budgets? Either of these reasons would suggest that the veterinarian's recommendations should be tailored to accommodate these realities. For example, a manager who is very attentive to detail is more likely to follow a complex or detailed treatment protocol.

Circle 2: evaluation of inside of the building

The second circle involves walking through the inside of the building. In this case the objective is to get a better

feel for the overall environment of the pigs covering all regions of the building. One must walk from one end of the building all the way though the other side. If one takes too long to walk from one end to the other, it becomes more difficult to identify ventilation differences as one starts to become adapted to the new environment.

Stocking density is also evaluated at this time. It is important to note differences in stocking densities between pens as well as between barns. Lower stocking densities may indicate high mortalities in a particular pen or barn. Recommended stocking densities are listed in Table 1.1. Pig sizes are also assessed using the guidelines in Table 1.2 on expected pig weights based on age.

The general health of all pigs in the barn is evaluated at this time. Is there coughing, sneezing, or signs of diarrhea? The magnitude of the problem should be quantified. This is easily done by estimating the number of affected pigs in a pen as well as the total number of pigs in the pen. For example, if there are approximately 5 pigs coughing in every pen and there are around 25 pigs per pen, then it would suggest that approximately 20% of the pigs are affected. On the other hand, if it is found that only 1 or 2 pigs are affected in every other pen, then it would suggest the prevalence to be approximately 2–4% of the barn. The quantification of prevalence does not have to be exact, as usually we are more concerned on the size of the magnitude of the problem (60 vs. 10%) rather than knowing the exact prevalence of the clinical sign (8 vs. 12%). Determining general prevalence has three main goals: It allows for the correct perspective on the extent of the problems (i.e. is there currently a disease or welfare issue or is one imminent?). It helps to differentiate herd problems from individual pig issues, thus helping to determine the correct level of treatment (i.e. whole herd treatment or individual pig treatments). Finally, it provides a baseline for determining the effect of any intervention. This is especially important as although coughing may still be present after 5 days of treatment, the change in prevalence from 25 to 4% is a good indicator of improvement, suggesting that further intervention may not be warranted.

Table 1.1 Recommended space per pig by phase of production.

	Indoor		
	Solid	**Slatted**	**Outdoor**
Phase		**Area per pig in m^2 (ft^2)**	
Gilts	1.86 (20)	1.49 (16)	2.32 (25)
Sows	2.2 (24)	1.86 (20)	2.32 (25)
Farrow pen	8 (88)	NA	NA
Farrow crate	4.4 (48)	4.4 (48)	NA
Boars	NA	1.86 (20)	NA
Nursing	NA	2.0 (22)	NA
Nursery 20 kg	0.37 (4)	0.28 (3)	0.74 (8)
Nursery 40 kg	0.37 (4)	0.40 (4.4)	0.74 (8)
Grower 60 kg	0.56 (6)	0.53 (5.8)	1.86 (20)
Finisher 80 kg	0.74 (8)	0.67 (7.2)	1.86 (20)
Finisher 110 kg	0.75 (8)	0.75 (8)	1.86 (20)

Source: Dewey and Straw (2006). Adapted from English et al. (1982), Baxter (1984a,b,c), Patience and Thacker (1989a,b), and Gonyou and Stricklin (1998).
NA, not applicable.

Circle 3: evaluation of individual pens

The third circle is performed by doing an evaluation of individual pens. Based on the second circle, pens identified in the evaluation of the room are selected for further evaluation of the extent of the problem. Veterinarians must get in the pens with pigs. One cannot make a full assessment of the problem by simply walking the alleyway of the barn as many pig issues will be missed. This is the point in time that feeders and waterers are also checked for proper function (Table 1.3). Also see Chapter 4 for the effect of the environment on swine health.

The overall behavior/attitude within the pen is evaluated, identifying individual pig concerns as well as pen concerns. Differences in sizes of pigs in a pen are again noted at this time (Table 1.2). It is very important to always ask if any type of size sorting (regrouping by size) has occurred as well as knowing the expected age difference for the barn. This is a good time to look closely for evidence of diarrhea. Many times the diarrhea is first noted by the fecal character that may be present on the floor or walls of the facility, and extra observational time is needed to identify the individual pigs that may be affected.

There are no specific recommendations on how many individual pens need to be evaluated. A key point is to make sure several pens from different parts of the building are evaluated to have a true representation of the potential herd issues recognized by the second circle evaluation. Individual pig issues of concern, especially those related to welfare (severe, chronic, or moribund individuals), should also be identified at this time.

Circle 4: evaluation of individual pigs

The fourth and final circle involves a complete evaluation of individual pigs. Pigs are evaluated from head to tail. Anomalies are noted as well as suspected chronicity of issue. Rectal temperatures are taken at this time as a measure of presence of infectious disease processes and

Table 1.2 Weights and daily gain by age and relative growth rate.

	Slow				Moderate				Ideal			
Age	Weight		Daily gain in the previous 20 days		Weight		Daily gain in the previous 20 days		Weight		Daily gain in the previous 20 days

stage of infection (e.g. fever tends to suggest an acute infection). Table 1.4 provides a summary of the expected normal temperature, respiratory, and heart rates of pigs based on size. A key point to remember is that as the environmental temperature increases, so will the average respiratory rates and body temperatures for healthy pigs.

For breeding herd examinations, the body condition of females should be evaluated periodically (Table 1.5). When making recommendations for feed or feeding changes, the stage in the reproductive cycle must be considered. Females entering the farrowing house should be in their best body condition (target body condition score [BCS] of 3), while gilts exiting the farrowing house (end of lactation) will have lower BCS. Feed changes are best executed by making small changes (0.5–1.0 kg) in the daily feed allotments.

This is also a good time to identify individual pigs requiring treatment as well as acutely infected animals that would be useful for diagnostic sample collection. Animals appropriate for euthanasia, necropsy, and tissue collection are also identified at this time. When selecting pigs for diagnostic tissue sample collection

Table 1.4 Temperature, respiration, and heart rate of pigs of different ages.

	Rectal temperature (range ± 0.30 °C, 0.5 °F)			
Age of pig	°C	°F	Respiratory rate (breaths/min)	Heart rate (beats/min)
Newborn	39.0	102.2	50–60	200–250
1 hour	36.8	98.3		
12 hours	38.0	100.4		
24 hours	38.6	101.5		
Unweaned piglet	39.2	102.6		
Weaned piglet (20–40 lb) (9–18 kg)	39.3	102.7	25–40	90–100
Growing pig (60–100 lb) (27–45 kg)	39.0	102.3	30–40	80–90
Finishing pig (100–200 lb) (45–90 kg)	38.8	101.8	25–35	75–85
Sow in gestation	38.7	101.7	13–18	70–80

Table 1.5 Sow body condition scoring.

Body condition score (BCS)	Condition	Back fat mm (in.)	Description	Comments
BCS 1	Excessively thin	<10 (<0.39)	Ribs, hips, and backbone are easily visible and palpable	Sow is in poor condition and needs large amounts of muscle and fat gain to maintain productivity. Needs a significant increase in feed
BCS 2	Moderately thin	10–15 (0.39–0.58)	Ribs, hips, and backbone can be palpated with slight pressure	A moderate increase in feed is required
BCS 3	Ideal condition	15–22 (0.59–0.89)	Ribs, hips, and backbone can be palpated with firm pressure, but cannot be observed visually	Monitor feeding to maintain this body condition
BCS 4	Moderately fat	23–29 (0.90–1.13)	Ribs, hips, and backbone cannot be palpated	May be appropriate to cut back slightly on feeding
BCS 5	Excessively fat	≥30 (≥1.14)	Ribs, hips, and backbone cannot be palpated	Sow has excessive amounts of fat tissue. Reduce feeding to bring her back to a BCS 3

Source: Adapted from Ken Stalder.

(also see Chapter 7), there are several important points to consider:

1) An animal's life will be sacrificed for the good of the herd, and due consideration should be placed into selecting the appropriate pigs.
2) Animals must be selected that truly represent the major clinical signs of concern in the herd.
3) Animals should be in the early stages of the disease process. The selection of acute cases will increase the probability that the primary causative agent and compatible lesion are identified.
4) An animal that has received no antimicrobials or therapy is usually preferred.

The number of animals selected for necropsy and tissue sample collection depends on the objective. As a general rule, animals that are found dead are necropsied first. Mortalities are necropsied until a pattern of disease process is apparent, which suggests the primary herd disease issue rather than unrelated individual animal afflictions. Based on necropsy findings and clinical evaluation, representative live animals are euthanized for fresh tissue sample collection. The number of animals euthanized depends on the individual case presentation and necropsy findings in the euthanized pig. When considering multifactorial etiologies, it is important to remember that not all animals in the herd will have all pathogens present at any one time point. This suggests that in a large herd, it may be necessary to euthanize sufficient animals to completely represent the full range of clinical and pathological findings and to identify the multiple interacting disease agents. In other cases where there may be only one primary pathogen of concern, 1 or 2 euthanized pigs may be sufficient to answer the diagnostic question. The goal is to sacrifice the least number of animals yet maximize the diagnostic value for the benefit of the rest of the herd, thereby benefiting the current group as well as future groups. Live animal (antemortem) sampling is commonly done. For some pathogens (e.g. influenza A virus via nasal swabs or oral fluids), simply finding the agent in the herd is all that may be necessary. In other cases, finding a common endemic potential pathogen of interest (e.g. porcine circovirus type 2) must be in association with compatible lesions to support the role of such agent in the current clinical presentation.

Summary of four circles

The concept of the four circles is to obtain a systematic and complete picture of the clinical status of the site. It provides a systematic view that is important in deciding what interventions need to be implemented to mitigate the effects of the current disease. It starts with a big-picture overview and then narrows the focus to individual pigs. It helps separate unrelated individual pig afflictions from whole herd disease problems, both of which need to be addressed, but priorities and recommendations will be different depending on context and the client's goals and objectives. The role of the veterinarian is to help guide the client to maximize the impact of any intervention. Information obtained from this systematic approach will also help differentiate what issues are primarily due to pathogens and which ones are being confounded or even caused by management practices or management failures. It will help veterinarians formulate a more complete assessment of the prognosis and expected outcomes of the current health situation. Once mastered, the process can be quick and very efficient.

Asking Questions

The process of data collection should not be restricted to the veterinarian's observations. It is very helpful to ask others working on the farm or within the operation for their perspectives. This should be done not only from upper management individuals (i.e. managers or owners) but also from the workers themselves. Often, the managers make many assumptions as to what they believe is being done on the farm, but the actual workers have a different perspective. This may be due to lack of training, poor communication of protocols, or inadvertent deviations in protocols of which participants are unaware. This is why it is useful to ask the same questions to different people in the same production system for confirmation and to assess consistency. Questions should be formulated as open ended rather than seeking a simple yes or no answer. It is also helpful to have employees demonstrate how to perform a task ("show me how") rather than providing an explanation ("tell me how"). This ensures that the actual process and technique are observed and allow evaluation of significantly more details than are apparent in a verbal description. This has been especially useful in troubleshooting intensive, high impact procedures such as heat detection and artificial insemination.

As a site visit is performed, it is also important to examine storage and utility areas and investigate refrigerators or medicine cabinets. This process should help support and validate the different worker's answers to questions regarding processes and protocols. For example, an operation that claims routine vaccination of sows pre-farrowing and yet has no vaccine on-site may need further evaluation and discussion to ascertain vaccine management and handling procedures. A second example may be a protocol describing a temperature to store semen but no thermometer in the semen storage unit.

On-site records

Production sites should have treatment and mortality records on-site. The minimum requirement for treatment records include date, animal ID, product name, dose, route, person administering, and product withdrawal time. Mortality records are helpful in determining the total number of pigs in the original lot, number of mortalities, and the chronology of mortalities to date. Caretakers should be instructed to record euthanized animals in a different manner. A good practice is to also record a presumed "death reason" and educate clients on how to properly evaluate mortalities and record such. However, research has shown that there are significant differences between recorded and actual death reasons (Lower et al. 2007). To facilitate this process, the focus should be on the actual observations that can be accurately made by caretakers. For example, it is difficult for a caretaker to diagnose *Escherichia coli*-associated diarrhea as cause of death. Instead, the mortality should be recorded as due to diarrhea. There should also be a second code to identify whether the animal died on its own or was euthanized. Practical and more valid mortality records can be collected by simply narrowing down the options provided, focusing on general clinical signs rather than a specific disease etiology, and training all individuals on how to properly categorize mortalities.

Records for farrowing, nursery, and finishing sites may include daily water consumption and daily high and low barn temperatures. This information is easy to collect in today's modern facilities and can be helpful (especially the water) in predicting a possible respiratory outbreak (Brumm 2006). The high and low barn temperature recording is helpful in identifying possible concerns with the ventilation system. It is best to utilize an independent high–low thermometer to record temperature fluctuations rather than using the barn's electronic control system in order to validate the proper function of the controller. Finally, these records can be used to confirm each group of pigs is being checked at least daily.

For breeding herds there are many other records that are kept on-site. These records can vary in form and content from hand notes to an actual computer on-site. Log sheets are very helpful in ensuring jobs are routinely done. For example, a simple semen log can track the date, time, current temperature of the semen storage unit, and initials of the individual who rotated the semen (e.g. manually resuspended semen in extender by gently rocking the semen bags/bottles back and forth). The advantage of having this type of manual record is that it ensures this important job is done routinely and having individuals write down their initials facilitates accountability. It is a reality that in operations with multiple workers, duties are sometimes not performed because a worker believes that someone else was doing the job.

Computer records can be accessed either through daily/weekly reports provided to the farm or through direct access to a computer. The number and variety of reports that are available from computerized sow record systems precludes discussion here. It is important for the swine veterinarian to understand and objectively evaluate different herd performance parameters. The greatest advantage of computerized record systems is their ability to summarize relevant data in many different ways and, as previously mentioned, compare to relevant internal or external benchmarks to help identify those performance parameters in need of improvement.

When looking at reports, it is important to remember that data is usually summarized based on time or by cohort. In a time-based report, data is simply attributed to a particular time period. For example, January breeding and farrowing number summarizes data for all the

sows that were bred in January as well as the sows that farrowed in January, which are two distinct groups of animals. This information is helpful in monitoring the overall herd's performance, but it is not helpful in evaluating cause and effect within a particular group. To better evaluate a particular group, a cohort-based report must be used. In this case all parameters reported are specific to a common group of animals so the breeding and farrowing data pertain to the same group of animals although accumulated at different dates. This cohort-based report is very useful in evaluating the effects of different interventions.

The most important part of any data collection is the desire to take action when an abnormality is detected. When a veterinarian requests data to be collected by workers or caretakers, effective communication should outline the importance of the data, how it will be used, at what threshold they are expected to take action, and the consequences of failing to act. For example, simply recording the daily temperature of the semen storage unit has no value unless action is taken when temperature is outside of the desired range.

Diagnosis

Once a site's evaluation has been performed (four circles) and data has been collected, it is then necessary to interpret all the findings in the context of the veterinarian's clinical observations. The Greek word "diagnosis" literally means "through thinking" (Morley 1991). The process of arriving at a diagnosis can vary among individuals and clinical presentations. What is important is to be systematic, once again, to ensure that decisions are focused and objective. Figure 1.3 summarizes the field investigation and case management process. The following brief summaries are a few examples of different approaches/aspects that can be considered.

Soap

One of the traditional means for summarizing data in the medical profession is to utilize a process in which subjective observations, objective data, an assessment, and the resulting plan (SOAP) are all specified. Four senses (sight, hear, smell, and touch) are generally used when gathering data. Subjective data is focused on identifying issues reported by the owner, manager, or other workers as well as any other qualitative observations. The objective section is focused on quantitative data. The assessment is an evaluation or interpretation of both subjective and objective data. Finally, a plan of action is provided in response to the assessment. Using this SOAP approach allows for a complete and thorough thought process to occur before any diagnosis is made. It is a systematic way to ensure completeness. Consistency is king!

Grouping observations

Many times it is helpful to group observations based on commonalities. It is especially helpful to categorize based on organ system relationships. Grouping observations helps apply Occam's razor (the simplest explanations are more probable). In other words, it is more likely that pulmonary edema, ascites, and respiratory dyspnea in a pig are caused by circulatory system failure rather than the pig having three completely different pathogens, each independently causing one of the clinical findings noted. After grouping observations, a possible differential list can then be compiled.

Damnit

This approach focuses on coming up with a complete differential list to ensure all possibilities, so as to avoid too narrow a focus on infectious diseases. The following list helps identify the terms associated with each letter of the acronym:

D = Degenerative
A = Anomaly
M = Metabolic
N = Nutritional or neoplasia
I = Inflammatory, infectious, or immune mediated
T = Trauma or toxicity

One of the disadvantages of this particular acronym is that it does not help prioritize the list. It also encourages veterinarians, especially those in their early career, to generate a very long list of possible, yet not probable, differentials.

Five production inputs model

One other approach in thinking of differential diagnosis and risk factor list is to think more holistically and ensure that all aspects of production are considered. The five production inputs model of integrating cause and risk factors includes consideration of nutrition, environment, disease, genetics, and management. This model is very useful as it helps ensure multifactorial causes contributing to the clinical issue of concern. The nutritional aspect of veterinary medicine has become more important in recent years as feed prices have dramatically increased. High feed prices have promoted the use of alternative feedstuffs including the use of dry distillers grains (DDGs). The effects of these changes in diets and variability in quality of ingredients on the health of pigs have not been fully investigated. Environment also plays a key role in the health and welfare of pigs as is mentioned throughout this book but especially

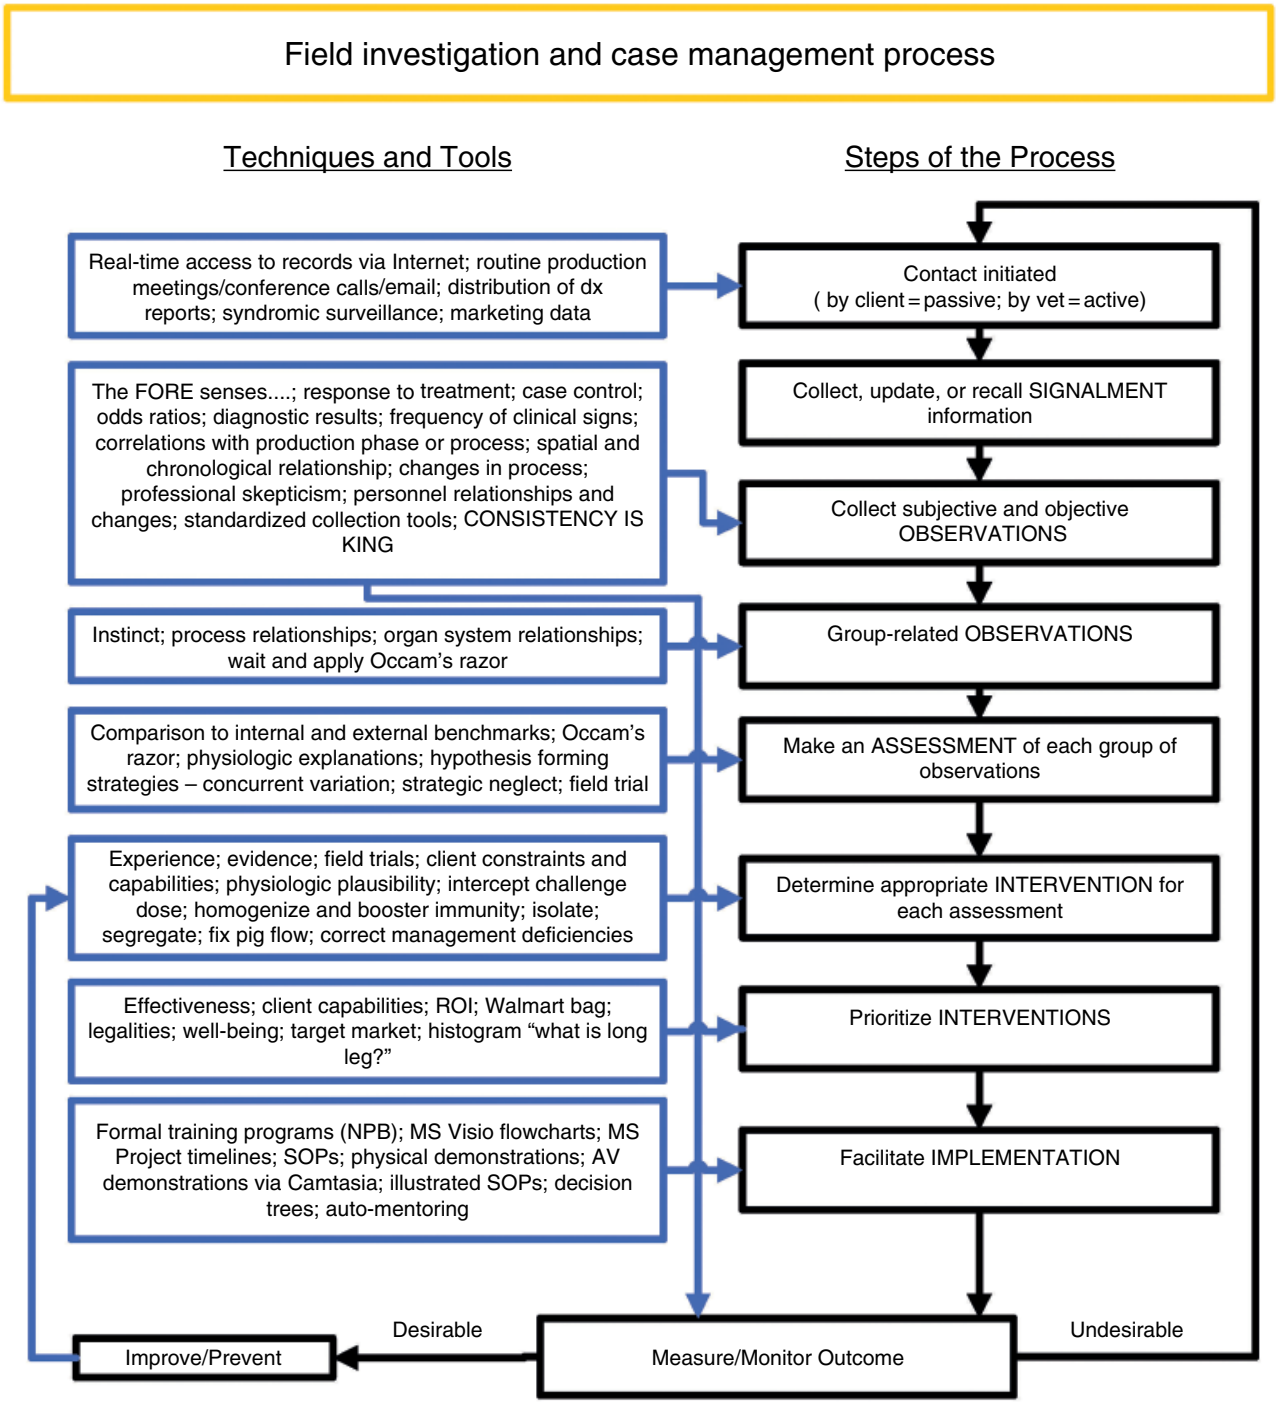

Figure 1.3 Chart depicting the flow of the field investigation and case management process. *Source:* Locke A. Karriker.

in Chapters 2 (behavior and welfare) and 4 (effect of the environment on swine health). The disease component is typically the first focus of veterinarians and is the focus of many chapters in this book. Genetics (Chapter 3) is an input that many times can be confusing as genotype and phenotype expressions are very complex especially when focused on clinical significance. Finally, management, especially all the people involved, is a very integral part of livestock production and can have a tremendous influence on the health, welfare, and success of raising animals. With the urbanization of the world and increasingly fewer people with an agricultural background, training workers on basic husbandry practices is becoming an integral part of any successful operation. New entry-level workers generally have very limited, if any, experience and knowledge on how to raise pigs.

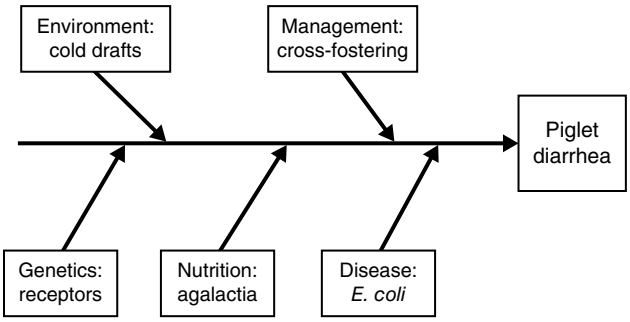

Figure 1.4 Fishbone diagram for piglet diarrhea incorporating the five production inputs model. *Source:* Kent Schwartz.

The five production inputs model works to integrate the interactions of different factors that may be working together at the same time and are influencing the health of a pig. The diagram in Figure 1.4 demonstrates the interaction of possible contributing factors associated with a simple example case of piglet diarrhea.

Determining interventions and prioritization

After observations are made and a list of differentials has been created, the next step is to identify appropriate interventions and prioritize their implementation. This step of the process becomes easier with experience. Personal experiences, client constraints and capabilities, ease, likelihood of success, and impact of intervention all play an important role in helping guide prioritization. It is important to always keep in mind the client's goals and objectives.

From the pigs' point of view, the priorities for survival and health are (fresh) air, (clean) water, (wholesome) food, and appropriate vaccination or treatment as needed. A producer's expectation and a veterinarian's training sometimes place therapeutic intervention as first priority. Vaccines will not be successful unless the pig is placed in an environment that allows the vaccine to work to its full potential. From the pig's perspective, the last area of need is vaccination or treatment as compared to having good quality air as the top priority, with access to good quality feed and water of similar priority.

Many times a diagnostic workup may be necessary to rule different differentials either in or out. Necropsies have been mentioned above, and sample collecting (blood, oral fluids, etc.) will be discussed at the end of this chapter. Chapter 5 will cover some lists for differential diagnosis. Further general information on diagnostics and their interpretation are covered in Chapters 6–8.

Usually priority is given to interventions that will have the greatest impact on the greatest number of animals. Because resources (time and money) are always limited, priorities need to be evaluated based on their cost and benefit as well as overall welfare of pigs and sustainability of operations. The benefit does not always have to be financial. Priorities that require substantial investment in resources usually will require a justification on the expected return.

Reporting

Once interventions have been identified and prioritized, it is critical to provide this information to the client in a concise and clear manner. A farm report or client letter is a very helpful tool in making sure the correct information is being communicated. Written reports and instructions will minimize miscommunications. Reports should be concise and should include a prioritized list (bullet points) with only two or three top interventions. Personal experience suggests that providing too many recommendations allows for the client to lose focus. They may select only recommendations that are desired or easiest to implement. The client may feel as though the veterinarian's recommendations are being followed but in reality have a false sense of security and may be neglecting the most important recommendations. The report should be short (preferable up to 1 page long and definitely no more than 2 pages), which helps ensure the client will actually read it. Very long reports are conducive for a quick skimming by the client, and thus many important points can be missed. Certainly there are times when a comprehensive report is needed, but for routine investigations, simpler is better. Client letters need to be provided back to the client in a timely manner (usually within a few days) in order to maximize implementation of recommendations. Integrated or complex production systems also require knowledge and understanding of the farm or company reporting structure. Veterinarians must understand and follow the proper reporting structure in order to meet client's expectations. The structure serves as means for the central entity and decision-maker(s) to have an understanding on the issues of the entire system. Following proper reporting structures ensures everyone is working together as a team.

Client reports are no substitutes for medical records. Veterinarians should keep detailed records on clinical observations and diagnosis. These complete medical records will serve as an excellent reference for future visits and have legal implications, including the justification for the use of any antibiotic per label or in an extra-label manner.

Monitoring outcomes

It is important for the client to be able to measure outcomes that can help determine the effectiveness of the intervention plans (Figure 1.3). Veterinarians must demonstrate the value they bring in order to be viewed as an asset rather than just a liability (expense).

Sample collection

Blood sampling

Blood sampling is one of the most common sample collecting techniques practiced today. There are several different techniques used in blood sample collecting in swine. Blood sample collecting requires a good understanding of pig's anatomy as all major blood vessels are non-visible, and thus a blind stick is performed. Mastery is achieved though practice. Much of this blood sampling information has been summarized from Dewey and Straw (2006).

Pig restraint

It is important to properly restrain pigs for safe sample collecting both from the perspective of the pig and from that of the person. The size of the pig and the comfort level of the restrainer will dictate the desired method. Figures 1.5 and 1.6 depict two approaches commonly used for restraint. In both cases, the person doing the restraining is just as important as the person collecting the blood sample. Pigs need to be immobilized and held in the correct position to facilitate access to the target veins. In the standing pig, it should have all four feet squarely placed on the ground. Its neck should not be stretched too much; otherwise access to the veins will be much more difficult.

Anterior vena cava

The pig's right jugular groove is identified, and the needle is inserted just cranial to the thoracic inlet. The needle is inserted aiming to the top of the opposite shoulder. This is approximately at a 30° angle from the median and 90° angle from the neckline (line from thoracic inlet to the head). Figure 1.7 depicts the approximate location of major veins. The pig's right side is used for sample collection as the right vagus nerve provides less innervation to the heart and diaphragm than the left vagus nerve. Vagus nerve puncture can cause the pig to start showing signs of dyspnea, cyanosis, and convulsions (Dewey and Straw 2006).

Jugular vein

To reach the jugular vein, the procedure is similar to that of the anterior vena cava with the needle being inserted about 5 cm cranially from the thoracic inlet (Figure 1.5). The right side of the pig is still preferred. The jugular vein is located more superficial than the anterior vena cava but cannot be visualized as in many other species. The process still requires a blind stick.

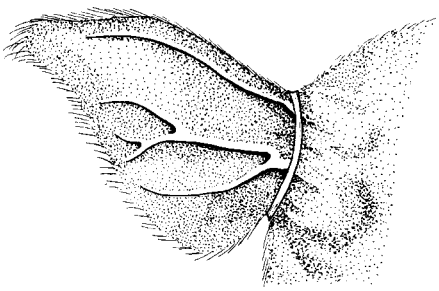

Figure 1.8 Ear veins of a pig raised by a rubber band placed on the base of the ear. *Source:* Dewey and Straw (2006). Reproduced with permission of John Wiley and Sons.

Ear veins

Ear veins can be raised by using a slight tourniquet (usually a rubber band around the ear or pressure with one's thumb) as seen in Figure 1.8. Slight slapping of the back of the ear with one's back of the fingers can help stimulate the raising of the veins. Veins in pigs with colored ears are more difficult to visualize. Venipuncture is done starting at the most distal point (toward the ear tip) of the largest vein so if a hematoma is formed, a more cranial point can still be used for sample collection. A butterfly catheter and syringe should be used. For PCR testing a simple prick of an ear vein with the tip of a 20 g needle can provide enough blood for collection with a Dacron swab.

Miscellaneous Methods

Tail bleeding (Muirhead 1981), femoral vein (Brown et al. 1978), cephalic vein (Sankari 1983; Tumbleson et al. 1968), cardiac puncture (Calvert et al. 1977), and orbital venus sinus bleeding (Huhn et al. 1969) have all been described.

Oral fluid collection

Oral fluid collection for veterinary testing is becoming a more common practice in swine medicine. Oral fluid is a mixture of saliva and oral mucosal transudates. Oral fluids can contain both organisms and antibodies of interest (Prickett et al. 2008).

The process of oral fluid collection is simple and practical. Its use and diagnostic value is described in Chapters 7 and 8.

Sample needs to be identified as an oral fluid sample when submitting for testing as special testing protocols need to be used by the diagnostic laboratory. The variety of PCR and antibody assays validated for oral fluids continue to increase.

Acknowledgments

A special thank you goes to Dr. Anna Forseth for her input in improving this chapter.

Behavior and Welfare

Anna K. Johnson, Jessica D. Colpoys, Lily N. Edwards-Callaway, Michelle Calvo-Lorenzo, John J. McGlone, Suzanne T. Millman, Christina E. Phillips, Matthew J. Ritter, Mhairi A. Sutherland, Anita L. Tucker, and Sherrie R. Webb

Defining animal welfare and animal cruelty

Animal welfare

Understanding, maintaining, and promoting animal welfare are an integral component of all livestock production systems. Animal welfare is also a topic that in the past several decades has garnered significant attention from the public as the desire to know where and how food is raised intensifies. Over time, many animal welfare definitions have emerged within and between producers, researchers, veterinarians, consumers, packers, and retailers. However, all of them usually include some combination of the following areas of focus: biological function (immune function, growth, etc.), affective states (fear, pain, hunger, etc.), and living in an animal's natural environment (Duncan and Fraser 1997; Fraser et al. 1997).

Disagreements sometimes arise in what constitutes good animal welfare because stakeholders place different levels of importance on biological function, affective states, and natural living based on their personal values. Initially Tannenbaum (1991) and later Fraser (1995) have argued that there exists an "inextricable connection" between animal welfare and values, thus determining that animal welfare cannot be only assessed as a technical issue but must additionally include ethical consideration.

Some focus on the biological functioning of animals as a key welfare indicator, which includes parameters such as reproductive success, immune function, disease presence, and injury (Barnett et al. 1991; Broom 1986, 1991; Mormède 1990; Warnier and Zayan 1985). Assessing affective states such as fear, distress, and pain but also positive states such as pleasure is used in part to measure and understand an animal's welfare state. Duncan and Fraser (1997) has argued that using the term "welfare" in and of itself requires the inclusion of subjective feelings per its definition; if something impacts an animal's welfare, it must impact how an animal feels. The public usually voices concern regarding the inclusion of an animal's ability to act naturally as a significant impact to its welfare state. Although expressing natural behavior is important, some have argued that it actually may decrease overall animal welfare status to express all natural behaviors as some represent states of distress or fear, such as distress calls or behavioral responses to extreme temperatures (Hughes and Duncan 1988).

In 1965 the Brambell Commission was formed to determine what components are essential to ensuring animal welfare in livestock species (Brambell Commission 1965), and this was a poignant event in the realm of livestock species animal welfare. Based on a review of the scientific literature available at the time, the commission proposed several conditions deemed necessary to ensure livestock welfare. In 1979, the Farm Animal Welfare Council revised the Brambell Commission recommendations and created the "five freedoms." The "five freedoms" serve as the basis for many of the livestock welfare educational, assessment, and third-party auditing programs and regulations globally. The five freedoms include the critical aspects of biological functioning (health and nutrition), nature-based measures (expression of normal behavior), and affective states (fear and distress) as discussed previously.

These freedoms are:

1) Freedom from hunger and thirst by ready access to freshwater and a diet to maintain full health and vigor.
2) Freedom from discomfort by providing an appropriate environment including shelter and a comfortable resting area.
3) Freedom from pain, injury, and disease by prevention or rapid diagnosis and treatment.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

4) Freedom to express normal behavior by providing sufficient space, proper facilities, and company of the animal's own kind.
5) Freedom from fear and distress by ensuring conditions and treatment, which avoid mental suffering.

A widely recognized animal welfare definition developed by Broom (1986) notes that the welfare of an individual animal is based on "its state as regards its attempts to cope with its environment." More recently, the World Organization for Animal Health (OIE) has defined animal welfare as "How an animal is coping with the conditions in which it lives" and provides examples that contribute to good animal welfare that include a combination of biological function, affective state, and concepts of natural living (OIE 2010). The OIE is recognized by the World Trade Organization as the international standard setting body for animal health and welfare; therefore, this definition is often referenced in international animal welfare discussions, including those regarding international trade. As retailers and food chains become more focused on animal welfare within their supply chain, many companies have been adopting the "five freedoms" as part of their animal welfare policies for suppliers.

Public, legal, and technical definitions of animal welfare

Over time, three types of animal welfare definitions have been identified: public, legal, and technical (Gonyou 1993). Public definitions of animal welfare reflect society's view of animals and are constructed from the public's previous knowledge of and experience with animals, which can be highly variable. The public definition is constantly changing as societal views evolve. Legal definitions, crafted by legislators, must satisfy and be accepted by the general public as well as be clear and concise for interpretation by the judicial system. Technical definitions of animal welfare are based on measures of welfare and influence how scientific data is interpreted. Different sectors of the population have emphasized one type of measure over another when interpreting animal welfare. Producers and large-animal veterinarians tend to focus on the biological function of the animal, whereas consumers tend to focus on what they perceive to be natural living. There is a fundamental need for a multidisciplinary approach to measuring animal welfare that includes evaluation of biological function (immune function, growth, etc.), affective states (fear, pain, hunger, etc.), and living in an animal's natural environment (Fraser et al. 1997).

Defining animal cruelty

Animal cruelty can be classified as animal abuse or animal neglect. Animal abuse is an intentional act by an individual to purposely inflict physical harm or injury to an animal (USLegal 2010) whereas animal neglect is a failure to act by the animal caretaker. Simple neglect, or failure to provide basic sustenance needs, could potentially be committed due to a lack of knowledge or ability of the owner and can be corrected through education and training. In the swine industry, animal abuse and neglect are defined as acts outside of normally accepted production practices that intentionally cause pain and suffering including but not limited to malicious hitting or beating an animal; applying electric prods to sensitive areas of the animal; driving pigs off high ledges, platforms, or steps while moving, loading, or unloading; dragging of conscious animals by any part of their body; purposeful dropping or throwing animals; causing physical damage to the snout or tusks of a boar as a means to reduce aggression (excludes nose ringing and tusk trimming); and purposeful failure to provide food, water, or minimal care that results in serious harm or death (NPB 2017).

While there are currently no federal laws in the United States that govern livestock care on farm, there are animal cruelty laws in all 50 states. The language, enforcement, and penalties of these laws vary state to state, and it is important for all veterinarians and livestock producers to be familiar with these state laws. They should be familiar with how livestock are defined and classified within the state, what acts constitute abuse, what penalties are associated with violations, and any mandatory reporting requirements that may exist specifically for veterinarians.

Due to the implications of animal cruelty on the health and welfare of animals and people, the American Veterinary Medical Association and the American Animal Hospital Association have policy statements that support veterinarians reporting cases of animal cruelty to the appropriate authorities when education of the caretaker is inappropriate or has failed, even if animal cruelty reporting is not legally mandated in a state (AAHA 2009; AVMA 2009). Anyone involved in animal care should be aware that accurate recordkeeping and documentation of these cases are essential. All of the major audit tools that have been created to monitor animal welfare within the livestock supply chain include some measure of animal abuse and neglect. The North American Meat Institute Animal Handling Audit (NAMI 2013) and the National Pork Board Common Swine Industry Audit (NPB 2017) include observation of animal abuse or neglect as an immediate audit failure. Additionally, pig farms are expected to have a zero-tolerance policy for animal abuse and neglect. All caretakers should be trained on the policy, understand how to report abuse and neglect, and understand the disciplinary steps that are associated with abuse and neglect (NPB 2017).

Comparisons between the domesticated and wild pig

When a veterinarian is assessing animal welfare, they will seek to determine if it is exhibiting normal behaviors. It is necessary to have a concept of what behaviors a feral or wild pig may choose to engage in and how this may be relevant to the domesticated pig. Comparisons between a variety of species when domesticated and wild indicate that the behavioral repertoire of a species remains relatively static during domestication, whereas the quantity of or threshold at which individual behaviors are performed may change (Price 1997). For example, the domesticated pig may perform the same behaviors as its wild ancestor but may not perform those behaviors as frequently, or more frequently. Stolba and Woodgush (1989) observed adult pig behavior in a semi-natural environment and found that although raised in confinement, adult pigs exhibited many behaviors performed by the European wild boar such as rooting, grazing, and nesting. Because domesticated pigs raised in confinement do have similar behavioral needs to their wild counterparts, the environments in which pigs are raised should be designed with the opportunity to express positive behaviors that they are highly motivated to perform.

Deviations in behavior for domesticated pigs compared with their wild/feral counterparts may indicate impaired animal welfare. For example, the presence of stereotypies (behavior(s) performed repeatedly without an obvious function) can be indicative of impaired welfare. Pig stereotypical behaviors include bar biting, sham chewing, and belly nosing. It has been hypothesized that these behaviors develop when a pig is unable to perform highly motivated behaviors, such as foraging, nest building, or suckling (Fraser 1975). However, not all behavioral deviations result in impaired welfare; anti-predator behavior, for example, is a useful behavioral sequence to have in a wild/feral setting for survival but is less important in a controlled and protected housing environment.

Scientific approaches to animal welfare

Biological function: production, health, and animal welfare

Stress can be defined as the nonspecific response of the body to any demand (Selye 1973). In commercial swine production, stressors, defined as stress-producing factors (Selye 1973), can include handling by humans, novel environments (Gray 1979), disease prevalence, high or low temperature, and aggressive pig temperament (Black et al. 2001). While the stress response is essential for animal survival and biological function, it can antagonize swine production goals such as feed efficiency, growth, carcass quality, and welfare.

Stress can occur during both positive and negative situations. Moberg (2000) defines eustress as a nonthreatening stress response and distress as a stress response with deleterious effect on the individual's welfare. Stress is often closely related to pig welfare and hence is often measured. The short-acting stress response, also referred to as the "fight or flight" response (Cannon 1929), is controlled by the sympathetic–adrenal medullary system and is typically measured through epinephrine and norepinephrine. The longer-acting, sustained stress response is controlled by the hypothalamic–pituitary–adrenal axis and is typically measured through adrenocorticotropic hormone (ACTH) and cortisol. Other measures that are commonly used to evaluate the pigs' stress response include endorphin, lactate and glucose concentrations in the blood, heart rate, respiration rate, electroencephalography, and behavior.

Responses to stress influence key metabolic, immunological, and reproductive processes governing disease resistance and production performance. Therefore, health and production performance are also used as animal welfare indicators. Stress can have negative consequences on swine performance as it results in catabolism of body tissues through lipolysis, proteolysis, and glycogenolysis (Weissman 1990). Additionally, behavioral stress responses of decreased feed intake and altered activity level also alter swine performance (Elsasser et al. 2000). In breeding animals, physiological stress responses also influence the hypothalamic–pituitary–ovarian axis. The effects of psychological stressors on performance have been well established in numerous experiments by Hemsworth et al. (1986, 1987, 1996). Unpleasant handling, in comparison with sympathetic handling, resulted in pigs that were more fearful and had chronically elevated corticosteroid levels, slower growth rates, lower pregnancy rates in gilts, and delayed reproductive development in young boars.

Stressful environmental conditions can increase the susceptibility of pigs to infectious diseases through alteration of the immune system (Kelley 1980). Sustained high levels of corticosteroid hormones in the blood can reduce proliferation of lymphocytes and decrease antibody production, impairing the ability of the pig to resist infection. Immune challenge techniques provide another potential set of measures that have been used to assess animal welfare. Morrow-Tesch et al. (1994) demonstrated that social status of pigs had an impact on lymphocyte proliferation in response to a pokeweed mitogen. The pigs that were both dominant and subordinate had lower proliferation than the intermediate pigs in the social hierarchy.

Although production parameters have been considered as appropriate measures of animal welfare (Curtis 1987) and poor productivity can be a useful indicator of a welfare problem, high levels of productivity alone are not always indicative of a high standard of welfare. It is a paradigm that a physically healthy animal is "faring well" but a healthy pig with high productivity could be mentally compromised.

Affective states of animals

Affective states, also referred to as emotional or psychological states, are an integral component of an animal's overall welfare. Although some areas of the scientific community find it hard to accept that animals can experience emotions, neuroscience has indicated that brain structures and neurotransmitters in humans and animals have similar functions and structures (Butler and Hodos 2005; Jerison 1997; Panksepp et al. 2002). Thus, pigs are considered sentient.

The "triune brain," a concept described by MacLean (1990), provides a simple illustration of the adaptations between reptilian, mammalian, and human brain regions. The centermost brain region, shared by all groups, is the limbic brain region. The limbic system is at the top of the spinal cord deep within the cortex and includes structures such as the amygdala, hippocampus, and parts of the diencephalon. It is the emotional center of the brain for both humans and animals (Panksepp 1998). Emotional circuits controlling anger and fear have been mapped in the limbic system (Panksepp 1990; Siegel 2005).

Emotions motivate an animal's behavior. When studying how certain management and production systems impact animal affective states, researchers, veterinarians, and producers usually focus on the negative emotions. For example, scientists have tried to mitigate weaning stress by studying different weaning methods (Colson et al. 2012). Additionally, caretakers try to ameliorate practices that cause stress and fear in pigs such as mixing, transport, and handling. Frustration is another emotion that is studied and often manifests itself in the expression of abnormal behaviors. For example, pigs are highly motivated to perform certain behaviors such as rooting, and when they are prevented from doing so, they may begin to develop oral stereotypies.

Modern animal welfare studies are shifting toward evaluating positive in addition to negative affective states. In a study evaluating pig behavior in anticipation of a reward, Reimert et al. (2013) identified play, playbark vocalizations, and tail movements to be indicators of positive affective states. Lay et al. (1999) assessed both behaviors expressing positive (play) and negative (aggression and stereotypies) affective states in pigs housed in hoop structures as compared with an environmentally controlled slatted floor building. They observed a lower incidence of abnormal behaviors and a higher incidence of play behaviors in the pigs housed in the outdoor hoop structures.

Animal affective states are not only characterized by changes in behavior but also by changes in certain physiological parameters such as activation of the hypothalamic–pituitary–adrenal axis and the sympathetic–adrenal medullary system (i.e. a "stress response"). These changes occur to prepare the animal for the stressor with which they are confronted. It is important to note that many of the physiological changes associated with a stress response are found in response to both negative and positive stressors, and therefore caution needs to be taken when interpreting physiological parameters (Dawkins 1998). Ethologists have designed a variety of experiments that can be used to determine how animals feel about various housing conditions and management systems. Preference tests can also be used to measure an animal's motivation for resources or environments with the underlying assumption that animals approach what they find positive and avoid what they find aversive. When given a choice between different circumstances, pigs can express their relative preference on matters such as diet, floor type, thermal environment, and degree of social contact. Refer to Elmore (2010) for studies detailing how provision of various resources can impact sow motivation and behavior.

Welfare monitoring and assessment

Monitoring and assessing animal welfare provide the producer with benchmarks. These benchmarks can then be used for decision-making regarding best management practices and provide a way for producers to demonstrate that their pigs are receiving care. On-farm measures of animal welfare typically fall into two categories: resource-based or animal-based measures.

Resource-based measures are also called input-, management-, or design-based measures. Examples include space allowance, stocking density, feed and water quantity and quality, frequency of inspections, and stockperson training and other caretaker characteristics such as attitudes, knowledge, and competency. The disadvantage of resource-based measures is that they are indirect indicators of animal welfare and therefore do not provide a true evaluation of how the animal is coping with its environment (Barnett and Hemsworth 2009). However, the advantage of resourced-based measures is that they can identify potential causes of poor animal welfare prior to the welfare of an animal being negatively impacted. Therefore, resource-based measures can be considered "lead" indicators because corrective and preventative actions can be taken for the pigs being evaluated (Manning et al. 2007).

Animal-based measures are also called output- or outcome-based measures. Examples include mortality,

morbidity, culling rates, lameness, injuries, body condition, stereotypic behaviors, aggressive behaviors, and fear behaviors. The advantages to using animal-based measures are that they serve as a direct indicator of animal welfare and they allow for variation in system design and management (Blockhuis et al. 2003). The disadvantage of these measures is that they tend to "lag" indicators, meaning that any existing welfare issues have already occurred for the pigs being evaluated and changes can only be made for future production cycles (Manning et al. 2007).

A robust animal welfare assessment program should include both animal-based measures to identify and fully understand the actual welfare of the animal and resource-based measures to identify potential causes of poor welfare. An animal's welfare state is dynamic and can be influenced by subtle changes in its health or the environment. Therefore, monitoring animal welfare must be an ongoing process.

Several science-based programs have been developed to assess on-farm swine welfare through a combination of first-, second-, and third-party evaluations. Through live observation, the observer evaluates the animals, caretakers, facilities, and records. The objective for first- and second-party evaluations is to benchmark performance and educate on good production practices. The objective of third-party evaluations is independent verification of compliance with a set standard of care. The value of these on-farm evaluations to an animal's welfare, regardless of the observer's relationship with the farm, is found in the feedback of strengths and opportunities for improvement. The producer can use this information to make informed decisions about production practices and procedures and ultimately protect and promote good animal welfare.

Recent technology advancements have introduced the concept of remote video auditing as a tool for animal welfare assessment and monitoring. Video auditing technology can help achieve good biosecurity because new people or materials are not entering the farm to conduct an audit. The technology also provides opportunity for continuous monitoring and spontaneous audits. However, remote video auditing may be difficult to implement on farm due to some facility designs. Video auditing protocols require further development to assure animal- and resource-based measures can be properly evaluated. Wearable video technology may hold merit to resolve this limitation.

Maternal behaviors

Pre-farrowing behaviors of the Sow

Gilts and sows exhibit a specific pattern of behaviors prior to farrowing (Widowski and Curtis 1989, 1990). In non-confined sows (i.e. outdoor arks, indoor huts, or pens), nest building occurs during the last 24 hours' pre-parturition and is most intense 6–12 hours before farrowing (Jensen 1986). During the same time period, sows housed in farrowing stalls have an increased number of posture changes, indicating restlessness, and nest-building behavior is redirected at pen fixtures with the absence of suitable material (Haskell and Hutson 1996).

Preweaning mortality, overlay, and trauma

Preweaning mortality is a welfare and economic problem in all swine housing systems. Piglet survival is due to a variety of complex interactions involving the sow, the piglet, and the environment (Edwards 2002). The causes of piglet mortality, including crushing, starvation, disease, and savaging, can be affected by nutrition, experience, age, health, and injury status (Barnett et al. 2001). Crushing of the piglet by the sow is the predominant cause of preweaning mortality, accounting for 70–80% of total deaths (English and Morrison 1984). Historically, crushing has been viewed as involuntary, mainly caused by the physical environment (Andersen et al. 2005). Recently, it has been hypothesized that differences in maternal behavior play a role in the variation of piglet mortality (Johnson et al. 2007). Crushing can be viewed as a sow's failure to protect her offspring. Among sows, there is a large variation in piglet mortality, even within one farrowing environment. Andersen et al. (2005) found that sows that did not crush any of their piglets ("non-crushers") showed a more protective mothering style than those that crushed several piglets ("crushers"). Non-crushers performed more nest-building activity, responded sooner to piglet distress calls, initiated nose contacts sooner after distress calls, and nosed more piglets during a posture change. These studies suggest it may be possible to decrease preweaning mortality by focusing on maternal behavior.

Housing design heavily influences preweaning mortality. For sows housed in farrowing stalls, most crushing is reported when the sow lies down, and almost none when she rolls over (Weary et al. 1996). The design of the stall can reduce these types of crushing events. In loose farrowing systems, piglets are crushed when the sow lies down and when she rolls over (Damn et al. 2005).

Considering the reciprocal relationship between sow and litter, newborn piglets are dependent on the sow for nutrition, but at the same time, the sow is the greatest threat to piglet welfare due to the possibility of crushing (Grandinson et al. 2003; Lay et al. 1999). Malnourished or starved piglets are more vulnerable to crushing for two possible reasons. First, persistent suckling attempts force them to stay close to the sow for long periods of time (Alonso-Spilsbury et al. 2007), and second, they have poor mobility due to decreased milk intake, and

they are often too weak to respond in a timely fashion to move out of the way of a sow changing postures (Marchant et al. 2001).

Savaging

Aggression directed to newborn piglets by a sow (referred to as savaging) can be defined as an attack using the jaws that results in serious or fatal bite wounds (Chen et al. 2008). Although the cause is poorly understood, the incidence of savaging has been reported to range from 5 to 12% (Harris and Gonyou 2003; Knap and Merks 1987; van der Steen et al. 1988). The cause of savaging in sows is poorly understood. Sows do not exhibit clear behavioral cues, indicating that they will savage in advance, although it has been found that sows that savage had a greater frequency of posture changes beginning before parturition and through the expulsion phase (Chen et al. 2008). Pain and fear are hypothesized to predispose gilts to savaging (Pomeroy 1960). Other possible suggestions for causation include the inability of sows to isolate themselves and perform nesting behavior, climatic stress, and human interference during parturition (Luescher et al. 1989). Savaging almost always occurs during farrowing or directly afterward (Chen et al. 2008) and has been found to be more common in primiparous sows (Harris and Gonyou 2003). Spicer et al. (1985) found that sows who savage often direct their aggression to only the firstborn piglet and are more likely to have been mated at a low body weight.

Harris and Gonyou (2003) suggested that the savaging of piglets born outside of working hours could be reduced by keeping farrowing rooms continuously lit. If savaging occurs and a caretaker is on hand, there are a few steps that can be taken in order to calm the sow: massage the udder, inject a tranquilizer (English and Morrison 1984), and remove the piglets from the sow until farrowing is complete. However, Chen et al. (2008) point out that sedation cannot prevent the behavior before it is administered or guarantee no return of the behavior after recovery from sedation.

Invasive procedures

How can we recognize pain in swine?

Pain is defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." The IASP adds, "The inability to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment." This is an important point, especially when discussing animal pain as they use auditory, physiological, and physical signs to communicate pain rather than verbal language. Pain is a complex phenomenon, and it involves multiple nerve cells, types of nerve chemicals, and different nerve cell receptors to which the nerve chemicals bind in order to propagate a pain signal to the spinal cord and brain (Coetzee et al. 2008). Not only is pain complex from the standpoint of transmission, processing, and control, but it is also complex in that there are different types of pain that have been identified based on cause or pathophysiology, the most important of which are acute and chronic pain. Because of the complexity of pain, it is understandable that pain management and pain control are complicated and difficult.

Acute pain is a protective mechanism that makes one notice an injury, move away from the danger that caused the injury, and then take care of the injury; thus, it is generally short-lived. Pain associated with more severe trauma, like surgery, begins as acute pain but can become chronic with prolonged inflammation. Chronic pain is a persistent kind of pain that may or may not be associated with injury, but is generally associated with inflammation, changes to nerve cells, and hyperexcitability of the nerve cells in the spinal cord and brain (Gudin 2004). This hyperexcitability phenomenon, or "wind-up," is a physiologic increase in sensitization of excitable nerve cells. Because the brain and spinal cord are wound up to detect pain, they are hypersensitive to future painful stimuli; thus, normally mild pain becomes intense pain after repeated physical insults. Prolonged inflammation caused by damaged tissue helps perpetuate the wind-up phenomenon and plays a large role in chronic pain. In addition, the changes in the spinal cord and brain associated with wind-up make pain resistant to treatment with analgesics (Coetzee et al. 2008). Preventing the wind-up phenomenon is an important human presurgery consideration; studies have shown that if analgesic or anti-inflammatory drugs are given to a patient prior to surgery, less analgesic or anti-inflammatory drugs are needed to control pain after surgery. Pigs are commonly teeth clipped, tail docked, and castrated without analgesia or anesthesia on commercial pig farms in the United States (FDA 2010). Scientific information describing effective pain management for these procedures is limited.

Tail docking

In North America, the majority of pigs are tail docked (Marchant-Forde et al. 2009) to prevent tail biting (refer to tail biting in the "ORAL AND LOCOMOTOR BEHAVIORS" section). Tail docking in pigs is usually performed within the first week of life and can be performed with teeth clippers, cutting pliers, scissors, scalpel blade, and gas or electrical cautery iron. The length of

the tail stump varies depending on the producers' standard operating procedures, although generally the remaining stump needs to be at least 2 cm (1 in.) long so that the tail stump covers the vulva in females.

Tail docking using side cutting pliers caused an increase in cortisol concentrations compared with non-docked controls up to 60 minutes after docking (Sutherland et al. 2008, 2011). The behavioral response to tail docking can include tail jamming (clamping of tail stump between the hind limbs without side-to-side movement) (Torrey et al. 2009), tail wagging (Noonan et al. 1994), and posterior scooting (Sutherland et al. 2008). Furthermore, tail-docked piglets produced more grunts (Noonan et al. 1994) and peak vocal frequencies during the procedure (Marchant-Forde et al. 2009; Torrey et al. 2009) compared with control piglets.

There is relatively little research comparing various methods of tail docking or methods of pain relief for tail docking in pigs. Tail docking using a heated cautery iron did not affect ACTH, cortisol, or lactate concentrations in young pigs (Prunier et al. 2005; Sutherland et al. 2008), and cortisol concentrations were lower in pigs tail docked using a cautery iron 60 minutes after docking compared with pigs tail docked using side cutting pliers (Sutherland et al. 2008). In contrast, Marchant-Forde and others (2009) found that docking using cautery iron had a tendency to increase the number of squeals during docking compared with docking using cutting pliers. Administering local anesthetic prior to tail docking or inducing general anesthesia using carbon dioxide gas reduced the percentage of stress vocalizations performed by pigs during tail docking (Herskin et al. 2016; Sutherland et al. 2011). In addition, pigs administered a nonsteroidal anti-inflammatory drug (NSAID) 30 minutes prior to tail docking were less likely to spend time isolated from other pigs than docked pigs given a placebo (Tenbergen et al. 2014). However, administering anesthetic locally or topically to the wound, inducing general anesthesia using carbon dioxide gas, or administering an NSAID did not reduce the cortisol response to tail docking in pigs (Sutherland et al. 2011; Tenbergen et al. 2014). Tail docking is routinely conducted to help prevent tail biting in pigs, and currently there is no alternative to tail docking except to not tail dock. However, strategies can be put in place to help prevent tail biting behavior such as providing enrichment in pens (refer to tail biting in the "ORAL AND LOCOMOTOR BEHAVIORS" section).

Teeth clipping

Born precocious, pigs have their deciduous canines and third incisors fully erupted at birth. These eight sharp "milk" or "needle" teeth function as weapons during sibling rivalries for preferred teats during the first 2–3 days after birth (Fraser and Thompson 1991). As the incidence of facial injuries and udder wounds is higher when needle teeth are left intact, some or all of the teeth may be clipped or ground within a day of birth (Fraser 1975).

When clipping is carried out, different techniques may be used with regard to the portion of the tooth being removed and the instruments used to do so (electric grinder vs. side cutting pliers). To prevent exposure of the vascularized and innervated pulp chamber to infection, it is preferable to remove only the tip of the tooth as opposed to the entire tooth (Heinritzi et al. 1994). Maintaining the appropriate equipment and utilizing good technique also help prevent sharp fragmentation or shattering of the tooth, two conditions that can lead to tongue and gingival lacerations and possible mouth infections (Brown et al. 1996; Meunier-Salaün et al. 2002). As a litter will establish a consistent teat order within 72 hours of birth, removal of the needle teeth beyond this time period is unnecessary and may in fact increase the chances of infection.

Teeth clipping of young pigs did not affect ACTH, cortisol, or lactate concentrations (Prunier et al. 2005); however, β-endorphin concentrations were greater in pigs after teeth grinding compared with clipping (Marchant-Forde et al. 2009). The behavioral response to teeth clipping or grinding includes increased grunting, escape attempts, and squeals (Marchant-Forde et al. 2009; Noonan et al. 1994).

No research has identified a chemical intervention to reduce or eliminate the behavioral or physiological reactions associated with teeth clipping in piglets. As the procedure is commonly performed within a day of birth when piglets are still immature, giving any pain medication that impedes piglet motor skills could increase the risk of crushing when in the presence of the sow. The extra costs and time associated with administering drugs to individual piglets are also considered to be unreasonable for most producers. This once routine procedure has become less practiced by producers in North America as the labor costs and possible risk of oral injury and infection associated with clipping are weighed against the often superficial and limited injuries resulting from piglet fighting.

Castration

Surgical castration of male piglets is a common management practice carried out on commercial swine farms to reduce the performance of aggressive and sexual behaviors and to prevent the development of boar taint. Boar taint is used to describe the unpleasant smell and flavor that can occur in pork from intact mature male pigs. Castration is usually performed surgically by making one or two incisions on either side of the scrotum using a scalpel and then removing the testes. The spermatic

cords are severed by cutting or pulling. Pigs are usually castrated within the first week of life. Reduced suckling behavior was observed in pigs in the 6 hour period following castration (McGlone et al. 1993); therefore, it may be preferable not to castrate pigs within the first 24 hours of life so as not to affect colostrum intake or establishment of teat order.

Pigs surgically castrated without pain relief have increased cortisol (Carroll et al. 2006; Prunier et al. 2005), ACTH and lactate concentrations (Prunier et al. 2005), mean arterial blood pressure (Haga and Ranheim 2005), heart rate (Haga and Ranheim 2005; White et al. 1995), and respiration rates (Axiak et al. 2007) compared with non-castrated control animals. Behavioral changes include reduced nursing, walking, and lying and increased pain-related behaviors (Carroll et al. 2006; Hay et al. 2003; McGlone and Hellman 1988; Moya et al. 2007; Taylor et al. 2001). Castration has also been shown to increase the duration and percentage of stress vocalizations (Puppe et al. 2005) and performance of defense behaviors (Leidig et al. 2009) in pigs.

Orally administered aspirin and butorphanol have been reported ineffective at reducing the behavioral response to surgical castration in pigs (McGlone et al. 1993). However, administering an NSAID (meloxicam) prior to castration reduced postsurgical pain-related behaviors (Hansson et al. 2011). General anesthetics including an injectable anesthetic consisting of xylazine, ketamine hydrochloride, and glyceryl guaiacolate administered intravenously (McGlone et al. 1993); ketamine, climazolam, and azaperone administered intramuscularly or intranasally (Axiak et al. 2007); and gaseous anesthetics including isoflurane (Hodgson 2006, 2007; Walker et al. 2004), sevoflurane (Hodgson 2007), carbon dioxide gas (Gerritzen et al. 2008; Sutherland et al. 2012; Van Beirendonck et al. 2011), and nitrous oxide (Rault and Lay 2011) have been used to reduce the pain caused by castration in pigs with varying levels of success. McGlone et al. (1993) observed an increase in mortality in piglets anesthetized using a general anesthetic and piglets that survived showed suppressed nursing behavior. The sedentary effects of an injectable or inhaled anesthetic (i.e. ketamine, climazolam, and azaperone; isoflurane) can last from 2 to 50 minutes (Axiak et al. 2007; Hodgson 2006, 2007; Walker et al. 2004). A prolonged recovery period from anesthesia could increase the risk of crushing of the piglet by the sow and reduce feeding opportunities. Pigs given local anesthetic prior to surgical castration had reduced mean arterial blood pressure (Haga and Ranheim 2005), slower heart rate (White et al. 1995), and behavioral changes (Kluivers-Poodt et al. 2012; McGlone and Hellman 1988; White et al. 1995) compared with pigs surgically castrated without pain relief. Administration of local anesthetic subcutaneously into the scrotal sac (Haga and Ranheim 2005; White et al. 1995) or intratesticularly (Haga and Ranheim 2005; Leidig et al. 2009) has been shown to reduce the behavioral and physiological response to castration in piglets. Furthermore, Haga and Ranheim (2005) demonstrated that injecting local anesthetic intratesticularly or intrafunicularly equally reduced indications of nociception. Ranheim et al. (2005) recommended injecting local anesthetic into the testes as the local anesthetic is then rapidly transported up the spermatic cords and the animal receives the benefit of analgesia at two anatomical sites, but only one injection is required. Ranheim et al. (2005) demonstrated that the highest concentration of local anesthetic is available in the testicular tissues 3 minutes after injection into the testes. Pigs given local anesthetic 2, 3, or 5 minutes prior to castration showed a reduction in frequency, duration, or number of vocalizations as compared with piglets castrated without any pain relief (Leidig et al. 2009; White et al. 1995). Local anesthetic administered to the testes at least 3 minutes prior to surgical castration appears to provide the most effective pain relief. However, topical administration of a short- or long-acting anesthetic to the castration wound was not effective in reducing the pain associated with surgical castration in pigs (Sutherland et al. 2010).

Alternatives to castration include slaughtering pigs before they reach sexual maturity, using immunocastration techniques, sperm sexing for selection of female offspring, and genetic selection for pigs with low levels of boar taint (Rault et al. 2011). Slaughtering pigs before they reach sexual maturity means harvesting pigs at a lower body weight. However, at a body weight of 80–90 kg (176–198 lbs), 5% of carcasses still exhibit boar taint (Bonneau 1998). Furthermore, the average weight of pigs at slaughter is increasing, and light carcasses are less profitable for commercial swine processors (EFSA 2004). Immunocastration involves immunizing boars against gonadotropin-releasing hormone (GnRH), which uses the boars' own immune system to suppress GnRH, consequently shutting down the stimulus to the testes, resulting in a temporary inhibition of testicular function (Thun et al. 2006). Currently, alternatives such as sperm sexing are still in the experimental stages and are not ready for implementation on farms (EFSA 2004; von Borell et al. 2009).

Tusk trimming

Boars with tusks pose a potential risk to both human handlers and other pigs. Current codes of practice for Western Australia recommend that trimming be carried out in situations where injury is likely to occur, and legislation within Canada prohibits the transportation of tusked boars in the presence of other animals (Health of Animals Act 1990). Current research by

Paetkau and Whiting (2008), however, suggests that injuries are not reduced with tusk trimming, either for boars in transit or when being held in lairage. Though aggression is common among newly mixed boars, neither the length of time assembled in pens, stocking density, size of boar, nor the presence of tusks was found to be influential in the skin injuries sustained in fighting.

Removal of the distal end of boar tusks is often carried out twice per year or prior to transport using one of two methods: clipping (using hoof trimmers or bolt cutters) or sawing (with hacksaw or orthopedic/embryotomy wire). Although more restraint is required, sawing is the preferred method as it provides more precision and less chance of pulp exposure or fracturing. Based on research by Bovey et al. (2008), the length of pulp chamber extending into the tusk beyond the gingiva varies greatly and is not related to boar age. Recommendations for the length at which tusks should be trimmed are approximately 1.5 cm (0.59 in.), as this was found to be slightly beyond the longest extending pulp chamber within their sample group.

Immunohistochemical and histological evaluation of commercial boar tusks by Bovey et al. (2008) indicates that the pulp chamber of boar tusks frequently extends into the tusk beyond the gum line and is innervated in both vascularized and non-vascularized areas. Such innervation suggests the possibility of pain; however, more research is required to determine the type of innervation present (autonomic or sensory). Exposure of the pulp cavity to bacterial infection was also a common condition associated with trimming too close to the gingiva and can progress into gingivitis and pulpitis, two conditions presumed to be painful. Little work has been scientifically conducted to understand the pain associated with tusk trimming. Housing or transporting boars singly reduces the need to trim tusks.

Pain management in the neonatal piglet during routine management: grading the quality of evidence and strength of recommendations

In 2014 global pain experts were invited by the National Pork Board to review the current published work on pain management in the neonatal piglet and were charged to provide recommendations related to pain mitigation. The Dzikamunhenga et al. (2014) systematic review's aim was to synthesize the existing primary scientific literature regarding the effectiveness of pain management interventions used for routine procedures on piglets. The review question was, "In piglets under twenty-eight days old, undergoing castration, tail docking, teeth clipping, and/or methods of identification that involve cutting of the ear tissue, what is the effect of pain mitigation compared with no pain mitigation on behavioral and non-behavioral outcomes that indicate procedural pain and post-procedural pain?" A review protocol was designed a priori. Data sources used were AGRICOLA (EBSCO), CAB Abstracts (Thomson Reuters), PubMed, Web of Science (Thomson Reuters), BIOSIS Previews (Thomson Reuters), and ProQuest Dissertations and Theses Full Text. No restrictions on year of publication or language were placed on the search. Eligible studies assessed an intervention designed to mitigate the pain of the procedures of interest and included a comparison group that did not receive an intervention. Eligible non-English studies were translated using a translation service. Two reviewers independently screened titles and abstracts for relevance using predefined questions. Data were extracted from relevant articles onto predefined forms. From the 2203 retrieved citations, forty publications containing 52 studies met the eligibility criteria. In 40 studies, piglets underwent castration only. In seven studies, piglets underwent tail docking only. In one study, piglets underwent teeth clipping only, and in one study piglets underwent ear notching only. Three studies used multiple procedures. Thirty-two trial arms assessed general anesthesia protocols, 30 trial arms assessed local anesthetic protocols, and 28 trial arms assessed NSAID protocols. Forty-one trial arms were controls where piglets received either placebo or no treatment. Forty-five outcomes were extracted from the studies; however only the results from studies that assessed cortisol (six studies), β-endorphins (one study), vocalizations (nine studies), and pain-related behaviors (nine studies) are reported. Other outcomes were reported in only one or two studies. The authors concluded that confident decision-making would likely be difficult based on this body of work because lack of comprehensive reporting precludes calculation of the magnitude of pain mitigation for most outcomes. In a companion paper, O'Connor et al.'s (2014) objectives were to develop recommendations for pain mitigation in 1- to 28-day-old piglets undergoing castration. Recommendation development followed a defined multistep process that included an evidence summary and estimates of the efficacies of interventions. Recommendations were developed for three interventions: CO_2/O_2 general anesthesia, NSAIDs, and lidocaine for use during castration. The ability to make strong recommendations was limited by low-quality evidence and strong uncertainty about variation in stakeholder values and preferences. The panel strongly recommended against the use of a CO_2/O_2 general anesthesia mixture, weakly recommended for the use of NSAIDs, and weakly recommended against the use of lidocaine for pain mitigation during castration of 1- to 28-day-old piglets.

Feeding and drinking behaviors

Dental development in the pig

The beginning of initial food mastication is highly dependent on the level of cheek teeth development (Langenbach and Van Eijden 2001), and this is one physical feature often overlooked in the ontogeny of the pig. Having a diphyodont dentition, pigs have all deciduous teeth replaced by their permanent counterparts by approximately 2 years of age (Tonge and McCance 1973). Their deciduous dentition numbers 28 ($2 \times$ incisors $^{3\ \text{upper}}/_{3\ \text{lower}}$, canines $^{1}/_{1}$, premolars $^{3}/_{3}$, molars $^{0}/_{0}$) with their permanent set increasing to 44 ($2 \times i^{3}/_{3}$, $c^{1}/_{1}$, $p^{4}/_{4}$, $m^{3}/_{3}$), the most comprehensive for any eutherian mammal (Tonge and McCance 1973). The majority of teeth used for masticating feed (i.e. the deciduous premolars) erupt between the first and fifth week of life (Tucker and Widowski 2009) and influence preweaning feeding behavior in an age-dependent fashion. Initial premolar eruption often induces bleeding and localized inflammation of the surrounding gingiva and is associated with lower feed-oriented behavior prior to 18 days of age (Tucker et al. 2010). By 21 days of age, piglets engage in more feeding behavior as premolars continue to erupt and occlude (make contact in opposing jaws). Increased levels of occlusion result in more efficient feeding (Huang et al. 1994). At weaning, piglets having both their p^{3} and p_{4} erupted (i.e. the two premolars required for initial occlusion) and have higher weight gains in the following 3 weeks (Tucker et al. 2010). In addition to eruption, growth of the masticatory muscles and learning of the motor patterns involved with chewing are also essential for feeding development. Factors influential to the timing of premolar eruption include piglet birth weight and average daily gain (ADG) in the first 2 weeks of life (Tucker and Widowski 2009).

Development of feeding and drinking behaviors

The development of independent ingestive behaviors (i.e. feeding and drinking) follows different trajectories and is controlled by different motivational systems in the young pig (Widowski et al. 2008b). Drinking has been defined as voluntary oral ingestion of liquids (Hurnik et al. 1995) and refers to the total consumption of water, which includes water that is often contained in feed (Fraser and Broom 1997). The discovery and consumption of water after birth can be facilitated by supplying bowl versus nipple or press lever drinkers and is significantly more effective if auditory bubbling cues are present. Drinking behavior can develop within several hours of birth when piglets require supplemental nutrition or hydration, particularly in response to high environmental temperatures (Fujii et al. 1990; Phillips et al. 2001). Between birth and 4 weeks, water intake increases as a function of age, but consumption per kg body weight remains constant at about 50–65 mL/kg (Phillips and Fraser 1990).

Immediately after weaning, piglets often increase their time at the drinker, possibly to alleviate feelings of hunger (by increasing gastric fill) that develop in response to low feed intakes or to relieve gastrointestinal discomfort associated with a sudden shift in feed composition and form (i.e. from a high fat and lactose-rich liquid diet to a high protein and starch solid diet). As feeding becomes established after weaning and consistent meal patterns develop, drinking becomes prandial, and most water is consumed around meal times.

The transition from suckling to independent feeding requires development in both the piglet's peripheral features (i.e. eruption of teeth, gastrointestinal maturation) and central features (i.e. shifting of motivational systems; Huang et al. 1994). The time course of this development often varies greatly between individuals and litters but is always gradual in nature. Abrupt artificial weaning in modern intensive systems therefore presents one of the most difficult periods to manage as piglets experience nutritional, emotional, and environmental challenges simultaneously. Exploration and social facilitation help piglets during the earlier stages of feeding development, with nutritional benefits becoming increasingly important as maternal inputs decline (Appleby et al. 1992; Delumeau and Meunier-Salaün 1995; Morgan et al. 2001). Overall physical maturity is the best indicator for when piglets develop independent feeding, with larger, more robust individuals ingesting more feed at earlier ages relative to their smaller, less mature littermates (Appleby et al. 1991).

Providing creep diets prior to weaning can familiarize piglets with solid feed and entice earlier consumption, particularly if those diets are complex or offered in gruel form (Fraser et al. 1994; Toplis et al. 1999). Another creep feed attribute that improves feed intake following weaning is pellet diameter. van den Brand et al. (2014) found that piglets prefer larger versus small pellet diameter (12 mm vs. 2 mm) in the preweaning period, and this led to increased feed intake and body weight gain after weaning.

Ingestion of creep feed can help prepare the gastrointestinal system for the post weaning diet by stimulating the production of certain digestive enzymes (de Passillé et al. 1989), a necessary step in the complex digestive transition accompanying weaning. Because there is significant variation in feeding, both within and across litters, with the majority of piglets not consuming significant quantities until after 19 days of age (Fraser et al. 1994), the effectiveness of using creep feeding as a management practice in preparation for weaning needs to be carefully considered with weaning age in mind.

Troubleshooting to enhance feeding and drinking behaviors

Farm animals form a social hierarchy or rank order that can affect accessibility to key resources within their pen (Bouissou 1965). In competitive situations, higher ranked animals might have more access to feed and water. If the producer considers the placement of drinkers within a pen and/or the ratio of drinkers to pigs, then lower ranking animals might have more success in obtaining water. Likewise, by increasing feeder space and feeding times (e.g. by using multiple trickle feeders for group-housed sows), aggression surrounding this limiting resource will be reduced.

Oral and locomotor behaviors

Tail biting

Tail biting behavior occurs when one pig takes the tail of another pig into its mouth and causes damage to the appendage (Schrøder-Petersen and Simonsen 2001). The behavior is often described as beginning with non-damaging exploratory behavior by one pig, termed "tail-in-mouth" behavior, which leaves no visible trauma but which then escalates to a damaging stage and the development of lesions (Fraser and Broom 1997; Schrøder-Petersen and Simonsen 2001). Once damage occurs, other pigs may quickly join in performing tail biting behavior, which can result in pen-wide or even barn-wide outbreaks (Fraser 1987). In addition to causing pain and distress, tail biting is associated with reduced feed intake and weight gain (Sutherland et al. 2009; Wallenbeck and Keeling 2013). The behavior can also lead to infection, spinal abscess, disease transmission, carcass damage, and, in some cases, cannibalism and death (Kritas and Morrison 2007; Schrøder-Petersen and Simonsen 2001).

Recommended as an animal-based measure for on-farm welfare audits (Goossens et al. 2008), the frequency of tail biting is a serious welfare and production issue. Although tail docking may reduce tail biting, it does not eliminate it, with upward of 2% of tail-docked pigs exhibiting signs of having been tail bitten by the time they arrive at the packing plant (Moinard et al. 2003; Smulders et al. 2008).

While there appears to be no single factor that results in tail biting (Goossens et al. 2008; Schrøder-Petersen and Simonsen 2001), numerous management, environmental, and individual factors have been implicated (D'Eath et al. 2014; Sutherland et al. 2009; Wallenbeck and Keeling 2013). For example, a barren growing environment has been shown to result in an increased percentage of pigs with a bitten tail (Bolhuis et al. 2005; Moinard et al. 2003). There is increasing evidence that crowded environments lead to tail biting (Moinard et al. 2003; Randolph et al. 1981), although it may be space allowance in the post weaning period that is most critical (Bovey et al. 2010; Smulders et al. 2008). Therefore, adequate space allowance in the nursery and grower barns can help reduce the behavior, as can the installation of chains or other chew toys, or the provision of straw (Day et al. 2008; Zonderland et al. 2008). These enrichments may work to draw the pigs' oral attention away from one another.

Tail dock length may also play a role in tail biting; however, the ideal length is still undetermined. Recently Bovey et al. (2010) found that a longer (4.5 cm [1.8 in.]) docked tail led to more tail biting than a shorter (1.2 cm [0.5 in.]) docked tail. It has been proposed that longer tails are more easily damaged, as pigs are able to bite them with their check teeth (Paoli et al. 2016).

Not all pigs tail bite, and it appears that some pigs may be predisposed to performing injurious oral behaviors, while others are predisposed to receiving it (Brunberg et al. 2013). Pigs with a predisposition to tail bite may be lighter at weaning (Beattie et al. 2005), be more active, and perform more nosing behavior (Keeling et al. 2004) compared with other pigs. There also appears to be a genetic component to tail biting, with the behavior correlated with lean tissue growth and backfat thickness (Breuer et al. 2003). In addition, there appear to be "neutral" pigs that have a genetic and behavioral profile that contributes to them being resistant to performing or receiving pig-directed abnormal behaviors (Brunberg et al. 2013).

Recent studies have also indicated physiological differences associated with the tail biting behavioral phenotype. Both tail biter pigs and bitten pigs were found to have lower peripheral serotonin levels compared with neutral pigs (Ursinus et al. 2014). Differences between neurotransmitters in the brain regions of pigs that tail bite and those that are bitten have also been identified. Those pigs that tail bite show higher serotonin metabolism in the prefrontal cortex, while bitten pigs show changes in both dopamine and serotonin metabolism in their limbic cortex and striatum (Valros et al. 2015).

Regardless of the cause of the behavior, the removal of both the tail biter and tail bitten pigs is an important management strategy to both reduce the probability of social facilitation of tail biting and stem any increased harm to the pigs being injured.

Belly nosing

Belly nosing was first described over 30 years ago as the distinctive, rhythmic up-and-down movement of one piglet rubbing the belly of another with its snout (Fraser 1978). This behavior, when performed persistently, can result in skin lesions on the belly and flank of the receiver

and may ultimately lead to ulceration (Straw and Bartlett 2001). Although most piglets perform some belly nosing, not all do, and there is a wide variation in the amount of belly nosing individual piglets perform.

Although belly nosing is most often associated with weaning at an early age (Fraser 1978; Worobec et al. 1999), the motivation behind the behavior is yet undetermined. It has been suggested that this behavior is the result of discomfort and stress in newly weaned piglets (Dybkjær 1992). However, since the motor patterns performed during belly nosing appear similar to those used in suckling, many researchers have hypothesized that belly nosing is redirected suckling behavior (Fraser 1978; Metz and Gonyou 1990; Widowski et al. 2008a). Other factors associated with higher frequencies of belly nosing include the presence of certain forms of enrichment (Funbar) (Bulens et al. 2015), rearing entire male pigs (Tallet et al. 2013), and rearing pigs in artificial rearing systems (Rzezniczek et al. 2015).

There appears to be a link between age and weight-for-age (Gardner et al. 2001; Torrey and Widowski 2006), but it is unclear whether there is an optimum age or weight at which to wean piglets. There also appears to be some genetic component to belly nosing, with Landrace pigs performing the behavior more than Duroc pigs (Bench and Gonyou 2007; Breuer et al. 2003). Provision of environmental enrichment (EE) (Oostindjer et al. 2011; Rodarte et al. 2004; Waran and Broom 1993), suckling devices (Rau 2002; Widowski et al. 2005), alternative drinkers (Torrey and Widowski 2004), and rearing pigs in loose housing systems during lactation (Oostindjer et al. 2011) have been successful in reducing, but not eliminating, the behavior.

Lameness

Swine lameness on farm can result in negative affective states (i.e. pain) to individual animals (Jensen et al. 2012). Veterinarians and caretakers can use on-farm scoring methods to determine lameness level within their herd. The implemented scoring system needs to be quick and affordable yet accurate. Two subjective scoring systems, the numerical rating scale and visual analogue scale, have been applied to characterize lameness in animals (Quinn et al. 2007). The numerical rating scale uses 4–6 ordinal categories to score lameness (1 being a sound animal and 6 being an animal that is unable to rise). Alternatively, the visual analogue system utilizes an observer's perception of lameness. An observer is asked to place a mark on a 100 mm (4 in.) line between two endpoints of normal and "could not be more lame" for an individual's level of lameness (Quinn et al. 2007).

There has been interest in testing other lameness tools. Tools include the embedded microcomputer-based force plate system (Sun et al. 2011), the GAITFour pressure mat gait analysis walkway system (Karriker et al. 2013; Mohling et al. 2014a; Pairis-Garcia et al. 2015a), nociceptive threshold tests (Mohling et al. 2014b; Tapper et al. 2013), classification lameness tress (Abell et al. 2014), and behavior (Pairis-Garcia et al. 2015b; Parsons et al. 2015, 2016).

When considering behavior in more detail, Stienezen (1996) observed sows prior to farrowing and through lactation for overgrown hooves. The authors reported no behavioral (percentage standing, dog sitting, or lying) differences between normal sows and sows with overgrown hooves in the 6 hours leading up to the first piglet being born but found some differences when observing the sows immediately before, during, and after their morning feed. Phenotypically normal (control) sows spent more time feeding and more time standing than sows with overgrown hooves. There were also some differences in the number of rear leg slips and rising attempts between control and overgrown hoof sows. In addition, sows with overgrown hooves tended to produce smaller-sized litters compared with control sows. In another study, Leonard et al. (1997) found that time spent feeding and standing decreased and weight shifts and slipping increased in sows with overgrown rear hooves. These results indicate that sows with overgrown rear hooves exhibited discomfort and thus decreased the amount of weight-bearing time spent on the overgrown hooves.

Pairis-Garcia et al. (2015a) noted that caretakers and veterinarians can use husbandry and management tools to provide supportive care for pigs experiencing lameness. Supportive care may include providing additional bedding or a rubber mat to create a more comfortable area for lying and resting (Elmore et al. 2010; Pluym et al. 2013). Campler et al. (2016) provided a practical case study for the use of mats in the farrowing/lactation house. This case study covered the cost, implementation, and longevity of mats. The authors concluded that (1) perforated rubber mats may provide an easy and inexpensive way to improve sow comfort in the farrowing stall; (2) mat size, cleanliness, cost, durability, and management are important factors to consider; and (3) rubber mats need to be placed properly under the sow and fastened properly to ensure maximum sow benefit.

Another approach for on-farm pain management is pharmacological techniques such as analgesics. NSAIDs are common analgesic medications used in livestock as they are easy to administer, long lasting, and cost effective. The pharmacokinetic profile of meloxicam (Pairis-Garcia et al. 2014) and flunixin (Pairis-Garcia et al. 2013) in mature sows has been determined. Paris-Garcia et al. suggested that meloxicam and flunixin meglumine are effective pharmaceutical interventions for alleviating pain associated with a chemically induced synovitis lameness model. Although analgesic drugs may be a key

tool to manage negative pain affective states associated with lameness at the time of writing, meloxicam and flunixin meglumine are not approved pain management treatments in swine in the United States.

Human and animal interactions

The role of the caretaker and the interaction of people and pigs

There is a prevalent and long-held belief that the caretaker has a more important influence on pig welfare than the choice of production system (Brambell 1965). This is likely because humans play a number of important roles for the pig. Humans act indirectly through their responsibility for the design of the environment and development of husbandry and management regimens. Caretakers also act directly by providing the day-to-day care of the animals. The human caretaker is the critical factor in the success or failure of a housing system and can impact pig welfare (Hemsworth et al. 1989, 1993, 1994). There are three important factors that will determine whether or not an individual will be a successful caretaker: (1) the caretaker's knowledge and expertise; (2) the caretaker's personality, attitude, and beliefs (Broom and Johnson 1993); and (3) the caretaker's situational variables (personnel details; Spoolder and Waiblinger 2009), all of which may be interrelated.

Fear of humans

Animals are "neophobic," that is, they are fearful of novel or unfamiliar things (Rushen 1996), and excessive fear is of concern to animal producers. Fear is defined as the general susceptibility of an individual to react to potentially threatening situations (Boissy et al. 2007), and fearfulness has been posited as a personality trait in a variety of animal species (Gosling 2001). Fearful animals are likely to grow more slowly and less efficiently than nonfearful animals and to have reduced reproductive output (Hemsworth et al. 1987, 1989, 1993).

Human exposure is one of the most frightening events that farm animals are likely to experience (Boissy 1995). In swine production, humans may have little interaction with pigs other than situations that might be perceived as negative by the pig. These situations can include medically treating (Weimer 2012), castration, tail docking, restraining, and sorting (Waiblinger et al. 2006). With little opportunity to habituate, it is suggested that even domesticated animals may often perceive humans as predators (Suarez and Gallup 1982). However, previous positive experiences with humans such as gentle tactile interaction, talking, and food provision may decrease pigs' fear of humans (Brajon et al. 2015; Muns et al. 2015; Tallet et al. 2014). Additionally, genetic selection (Colpoys et al. 2014), pig sex (Colpoys et al. 2015; Reimert et al. 2014), and housing system (Reimert et al. 2014) have been shown to alter pig–human interactions.

Fatigued pigs

Transport losses due to injury, fatigue, or death represent significant animal welfare, regulatory, and economic concerns and are estimated to cost the US swine industry $46M annually (Ritter et al. 2009a). These dead and nonambulatory pigs are most commonly observed during unloading at the packing plant, but these losses can occur at any stage of the marketing process from loading at the farm to stunning at the plant. Transport losses at US packing plants include:

- Dead on arrival (DOA): A pig that died during transportation.
- Dead in yard (DIY) or dead in pen (DIP): A pig that died after unloading at the plant.
- Nonambulatory pig: A pig unable to move or keep up with the rest of the group at the plant.

There are two types of nonambulatory pigs observed under US commercial conditions: Fatigued pigs are pigs without obvious injury, trauma, or disease that refuse to walk at any stage of the marketing process from loading at the farm to stunning at the plant. Meanwhile, injured pigs have a compromised ability to move due to structural unsoundness or due to an injury sustained during the marketing process (Ritter et al. 2009a).

Incidence of dead and nonambulatory pigs at packing plants

According to national statistics reported by the Food Safety and Inspection Service (FSIS), the percentage of dead market swine at USDA-inspected packing plants has averaged 0.20% over the last 25 years (Ritter et al. 2017). Although national statistics are not available for nonambulatory pigs at the plant, a recent summary of 23 US commercial field trials involving 6.6 million pigs reported the following rates for transport losses at the plant: 0.25% for dead pigs and 0.44% for nonambulatory pigs. It is important to note that the vast majority of nonambulatory pigs in these studies were classified as fatigued (Ritter et al. 2009a).

The fatigued pig syndrome

Ivers et al. (2002) evaluated acute stress signs and metabolic parameters in 35 normal and 35 fatigued pigs during unloading at the packing plant. Fatigued pigs showed more clinical signs of acute stress including open-mouth breathing (44 vs. 0%, respectively), skin discoloration (77 vs. 0%, respectively), muscle tremors (83 vs. 3%,

respectively), and abnormal vocalizations (30 vs. 0%, respectively). Furthermore, fatigued pigs had higher stress hormone concentrations (cortisol, epinephrine, norepinephrine), higher creatine kinase values, and blood parameters consistent with metabolic acidosis. Controlled studies have demonstrated that the vast majority of fatigued pigs will metabolically recover if the stressors are removed and pigs are allowed to rest for 2–3 hours (Ritter et al. 2009a).

Porcine stress syndromes

It is interesting to note the striking similarities between the symptoms and metabolic characteristics of fatigued pigs to those of pigs with porcine stress syndrome (PSS) (see Chapter 3), which is caused by a C to T mutation at nucleotide 1843 of the RYR1 gene and is referred to as HAL-1843. Therefore, a commercial survey involving 2109 pigs was conducted at four Midwestern US packing plants to determine the impact of the HAL-1843 mutation on the incidence of dead and fatigued pigs at US packing plants. This study demonstrated that 98% of the normal pigs, 95% of the dead pigs, and 98% of the fatigued pigs evaluated were free of the HAL-1843 mutation (Ritter et al. 2008), suggesting that the HAL-1843 mutation has minimal effects on dead and fatigued pigs at the packing plant.

It is possible that other genes or mutations may be responsible for the fatigued pig syndrome. Recently, Nonneman et al. (2012) reported that a mutation in the dystrophin gene (DMD) was associated with death in pigs during routine handling and transportation. Additional research is necessary to understand if this new stress syndrome contributes to the fatigue pig syndrome.

Predisposing factors for transport losses

Transport losses are a multifactorial problem consisting of people (handling tools and handling intensity), pig (genetics, diet, ractopamine, gut fill, live weight, health status, and previous handling experiences), facility design (pen size, pre-sorting strategies, aisle width, distance moved, and loading ramp angle), transportation (trailer design, mixing of unfamiliar pigs, loading density, and length of journey), packing plant (waiting time at the plant, unloading procedures, distance moved, facility design, and lairage time), and environmental factors (season, temperature, relative humidity, and trailer settings for bedding, boarding, and misting), which have been reviewed by Ritter et al. (2012), Johnson et al. (2013), and Zurbrigg et al. (2017). A review by Ritter et al. (2012) concluded that transport losses are impacted by (1) the HAL-1843 mutation, (2) aggressive handling, (3) group size during handling, (4) facility design, (5) crowding pigs during transport, and (6) extreme hot and cold weather conditions.

Management strategies to reduce transport losses

Preslaughter stressors have additive effects on the stress responses (rectal temperature, blood lactate, and blood pH values) of market weight pigs (Ritter et al. 2009b). Therefore, removing or spacing out the stressors to allow the pig to return to homeostasis during the marketing process can improve the pig's well-being and can potentially reduce the risk of transport losses at the plant. Management strategies to reduce transport losses under US commercial conditions include better preparing pigs for transport, improving facility design, minimizing stress during handling, and optimizing transport conditions (reviewed by Ritter et al. 2012).

Aggression

The domestic pig is largely a social animal. In the wild or feral state, pigs are found either in a matriarchal group of one to five adult females and two or more ages of offspring from successive pregnancies (Barrett 1978). When males reach puberty, they leave the herd and travel either alone or in small groups (ex. 2 boars). Females and young males are clearly social, while adult males are often (but not always) solitary. As piglets from different mothers in a herd are born, they interact with other piglets with minimal aggression. They may play fight or have small skirmishes, but among prepubertal pigs, there are infrequent injuries from fighting. Boars do fight and can injure each other in the wild; however, injury is uncommon. And sows, generally, are dominant to boars most of the time. When sows are in estrus, they will allow boars into the group for mating.

When pigs moved from outdoor pastures (where litters were socialized from birth) to indoors, litters were often kept apart from birth through weaning. We have known for decades that aggression is common on commercial farms (Signoret 1962). This aggression is a function of the production system in that unfamiliar pigs are abruptly introduced without a preweaning socialization period.

For growing pigs, mixing-induced aggression can occur when young pigs are mixed after birth to equalize litter size, after weaning, during transport, and at the packing plant. Sows are mixed when returning from farrowing to the breeding herd – and if they were previously housed individually or in small groups, they will fight. Post mixing aggression establishes a social hierarchy. This fighting is stressful but is reduced over time. McGlone (1986) showed that aggressive interactions

last for 19 hours after mixing pigs. He further reported that access to feed (or not) did not change the amount of fighting observed. Water access is more closely related to social stress. Aggressive behavior and the development of a dominance hierarchy will occur regardless of resources (feed, water, space, etc.). However, chronic or sporadic aggression may be due to limited resources. For example, even with established dominance hierarchies, growing pigs and sows that are limit fed (less than ad libitum) will show aggression. These challenges to the dominance order will occur, for example, when feed is given in limited amounts (Graves et al. 1978). Hunger makes pigs more aggressive, even if it is a few hours between meals (Kelley et al. 1980). Pigs may fight over limited resources such as feed, water, breeding mates, and/or nesting sites (Barnett et al. 1994; Csermely and Wood-Gush 1987; Edwards et al. 1994; Séguin et al. 2006). Interestingly, the social hierarchy is established without the need for all pigs to fight with each other. Mendl and Erhard (1997) mixed 4 pigs from 1 established group with 4 pigs from another group 11 times and in no single case did all 16 possible unacquainted pairs fight before stability was reached. There is a mechanism by which domestic pigs are able to assess their relative fighting ability or relative place in the hierarchy based upon information gained from their own interactions and probably from interactions of other pairs. Preexposure that permits a mixture of visual (e.g. physical size), auditory (e.g. frequency or duration of vocalizations), and olfactory (McGlone 1985) cues could reduce fighting post mixing (Durrell et al. 2003).

Persistent aggression can decrease welfare as indicated by increased stress hormone concentrations (Otten et al. 1999), increased heart rates (Marchant et al. 1995), increased injuries, and restricted access to resources (O'Connell et al. 2003) in animals that are aggressive or ones that are being attacked. Aggression can also increase costs by slowing growth and decreasing productivity (Mendl et al. 1992). During an aggressive act, a pig focuses its bites on its opponent's head and ears (Kelley 1980). When one pig submits to another pig in close quarters, it tries to protect its head and ears (McGlone and Curtis 1985). McGlone and Curtis (1985) also first reported the strong relationship between duration of aggression and the presence of wounds. Wound scores can be used in practice to determine the relative amount of aggression in groups of pigs.

A number of options have been explored to manage and reduce aggression in pigs. Pen shape has been reported to affect aggression in the short term. For example, pigs often use corners to "hide" (McGlone and Curtis 1985), and circular pens resulted in higher levels of aggression than square or rectangular pens. A solid barrier within the pen reduces the total number of aggressive interactions over a 12 hour post mixing period in sows (Edwards et al. 1993) and has longer-term benefits in sows. Barnett et al. (1993) compared adult pigs at mixing when placed into small rectangular pens (1.4 m^2/pig [15.07 ft^2]) for aggressive interactions and the consequent retaliations. The authors reported during the period of 15–90 minutes after grouping lower aggressive interactions, but the presence of stalls had no effects at this time. On the day following grouping, lying alone and standing were reduced, and concurrent lying and use of stalls (when present) were increased. In dynamic systems for sows, where subgroups are mixed into a larger resident group, dividing the pen into distinct lying bays, with one assigned to each subgroup on introduction, may have long-term advantages in reducing aggression by giving each subgroup its own "territory" (Bünger and Kallweit 1999).

Aggression can also be managed by adjusting group size. There are two hypotheses with regard to optimum group size: (1) that the number of fights will increase with the number of hierarchy positions to settle (Anderson et al. 2000; Schmolke et al. 2003) and (2) that pigs become less aggressive and may shift to a low aggressive social strategy in large social groups that may in turn provide potential benefits for the welfare of pigs under commercial production situations (Samarakone and Gonyou 2009). For a review on the impact of large groups on productivity, see Turner et al. (2003). However, to date, the optimum group size, parity balance within a group, body weight allocation, and space allowance remain relatively undecided in the United States. Probably very large groups of pigs (e.g. 1000 pigs in a large pen or building) never allow all pigs to establish a dominance order, so a small amount of fighting might be observed, or alternatively, pigs learn to not initiate aggressive interactions due to the large number of individuals in the group.

Chemical and nutritional interventions can be utilized to reduce aggression. Gonyou et al. (1988) compared levels of aggression when injected with amperozide (1.0 mg/kg IM), azaperone (2.2 mg/kg IM), or saline (0.1 mL/kg IM) immediately prior to mixing. Both drugs reduced total fighting. Amperozide resulted in fewer fights involving two pigs than azaperone or saline. Injuries to the ears and total injuries were less severe in amperozide-treated pigs than in pigs on the other treatments. Amperozide-treated pigs spent less time eating on day 1 than saline- or azaperone-treated pigs but compensated on day 2 such that total eating time in 2 days did not differ. Both drugs reduced agonistic behavior but had no effect on performance. Similar effects have been found using anti-aggression (amperozide) (Barnett et al. 1993, 1996) and sedative (azaperone) (Luescher et al. 1990) drugs. With both of these, aggression appears to be

reduced, while the effects of the drug last, but once the effects have worn off, aggression rebounds to that seen with untreated animals.

Pigs have a well-developed sense of smell. Removal of the olfactory bulb significantly reduced pig aggression (Meese and Baldwin 1975), and pigs can tell one another apart by olfaction alone (Meese et al. 1975). McGlone (1985) and McGlone et al. (1987) found evidence that biological fluids change pig behavior including aggression. They proposed several pheromones that increase or decrease pig aggressive or submissive behaviors. In addition, they proposed that male odors might reduce aggression of prepubertal pigs.

McGlone and Morrow (1988) compared prepubertal crossbred pigs to determine the minimum dose of androstenone (5α-androst-16-en-3-one) that would reduce the level of agonistic behavior among dyads of newly regrouped pigs. The authors concluded that a single application of as little as 0.5 μg/pig androstenone reduced aggressive behavior among prepubertal pigs and, therefore, may be a way of reducing fighting among newly regrouped prepubertal pigs.

Boar presence can also impact aggression. Grandin and Bruning (1993) compared barrows and gilts at the packing plant with or without a mature boar in their lairage pens (via a pheromone effect similar to that reported by McGlone and Morrow [1988]). The authors reported that boar presence reduced both the incidence and the intensity of fighting. Docking et al. (2001) found that aggressive interactions, skin damage, and flight distance for sows were all reduced by at least 28% over a 28 hour post mixing period by boar presence. However, Séguin et al. (2006) found that mixing sows in the presence of a boar following the breeding period was minimally effective at reducing fighting and scratches compared with controls and that sows showed a greater stress response in the presence of a boar.

Morrow-Tesch and McGlone (1990) identified skin secretions from sows that piglets could recognize. Pageat (1998) isolated maternal skin secretions (a mixture of fatty acids) that could be maternal–neonatal pheromones. McGlone and Anderson (2002) later showed that application of these putative maternal–neonatal pheromones reduced aggression and stimulated post weaning weight gain in pigs. Recently, Plush et al. (2016) showed that this maternal–neonatal pheromone slightly reduced aggression among group-housed adult sows; however, skin lesions were not reduced by this putative pheromone compared with a control group.

Early social experience may also play a role as a longer-term solution to reduce aggression at mixing (Pitts et al. 2000). Mixing piglets prior to weaning has been shown to benefit social skills in the longer term. Socialized piglets are able to form stable dominance hierarchies during future encounters with unfamiliar pigs quicker than piglets mixed after weaning (D'Eath 2005). Early socialization also increases consistency of behavior during social encounters (D'Eath 2004). However, the amount of aggression at mixing can still be reduced later in life by practicing repeated mixing, premixing, or preexposure with and to other pigs. With repeated mixing, pigs that are remixed three or four times post weaning subsequently show reduced aggression when mixed at 5 months of age, compared with pigs mixed just once or twice (Durrell et al. 2003; van Putten and Buré 1997). Lastly, and with largely untested potential, is the practice of preexposing pigs prior to mixing. Kennedy and Broom (1996) placed groups of five gilts in a small pen within a large pen and let the resident sows have olfactory, auditory, visual, and limited physical contact with them for 5 days before mixing. Once mixed, aggression was reduced by 60% over the course of the mixing day and the following 2-week period compared with gilts that were mixed into the resident group without preexposure. Jensen and Yngvesson (1998) have also reported this preexposure effect on aggression in nursery pigs and a reduction in interaction nosing phase.

EE for the pig may also be considered to redirect aggression onto "another" item rather than a pig within that pen (Jensen and Pedersen 2010). Elmore (2010) proposed that EE be defined as biologically relevant (i.e. have meaning for the animal in terms of its natural biology). Additions or modifications to the environment that allow coping with stressors (Moberg 2000) by promoting species-specific (i.e. "natural") coping behavior may be linked to the experience of positive affective states in animals (Boissy et al. 2007). Schaefer et al. (1990) compared EE on aggressive behavior in newly weaned pigs. Six-week-old gilts were divided into two treatment groups, and each pen either had a car tire suspended on a chain or no device. Pigs offered the tire and chain device displayed a lower frequency of total aggressive acts. Most notable was the reduced frequency of head-to-head knocks. In a further experiment, the authors compared approximately 28-day-old barrows and gilts that were assigned nothing, a pacifier (sugar–mineral block suspended in a metal basket), or a teeter-totter (metal bar with rubber belts on the ends). Pigs offered a play device committed fewer total aggressive acts (compared with the control pigs). The authors concluded that enriching their environment with play objects could modify aggression frequency in intensively raised pigs.

In a review of literature, Johnson and McGlone (2011) showed that aggressive and submissive behaviors were lowly (but significantly) correlated. Aggression of sows toward piglets (a maladaptive behavior) is highly correlated (Knap and Merks 1987). Aggression may also be

managed through selection of pigs that display low levels of aggression; although still in its infancy for application, selection of pigs based on levels of aggression is being considered (Erhard et al. 1997). Turner et al. (2000) rediscovered the correlation between wounding and aggressive behavior (McGlone and Curtis 1985) and showed that part of this relationship is genetically determined. Post mixing aggressiveness of pigs was assessed to have a heritability of 0.22. The response to selection, when all selection pressure was placed on the lesion score (LS) trait, was a 25% reduction in LS per generation. Further work by Turner et al. (2000) used a Bayesian approach to estimate the heritability of three traits associated with aggressiveness in pigs during the 24 hour post mixing: duration of reciprocal aggression and whether in receipt of or delivery of nonreciprocal aggression (NRA). The authors concluded that based on the estimated genetic parameters, the selection of breeding values for reduced LS (especially LS for the central region of the body) is expected to reduce reciprocal aggression and the delivery of NRA, but will not change the receipt of NRA directly. In pigs (and other species), selection for increased ADG can cause an increase in aggressiveness (ADG and aggressiveness are correlated phenotypically; Vargas 1987). However, selecting groups of pigs for increased ADG and reduced aggression can improve ADG (Camerlink et al. 2013). One strategy to improve the welfare of pigs is to include behavioral measures such as aggression in selection programs (Rodenburg and Turner 2012). We know that feral pigs are more aggressive than most domestic pigs. Therefore, we do understand that behaviors can be selected that work better in a commercial setting. Consumers and retailers may prefer pork from pigs that do not show damaging behaviors toward each other. We should expect genetic improvement in animal welfare in the future, including selection for less stressful and damaging behaviors.

Influence of disease on behavior

As a result of behavioral changes, ill pigs are frequently subjects of investigation and bullying by their pen mates. Consequently, diseased and injured individuals comprise vulnerable populations within the swine operation, presenting unique behavioral and welfare needs (Millman 2007). Behaviors such as decreased feeding and drinking, decreased exploration, increased sleep, heat seeking, and lethargy are often the first clinical signs of disease that are observed by caretakers and veterinarians. These "sickness behaviors" are displayed by a wide range of vertebrate species in response to bacterial, viral, and protozoan pathogens and appear to be an evolved behavioral strategy that complements the innate immune system (Hart 1988). Sickness behaviors result when proinflammatory cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor cross the blood–brain barrier or are produced by glial cells in the central nervous system (CNS) (Dantzer and Kelley 2007). These cytokines act as neurotransmitters, producing characteristic changes in physiology (e.g. fever) and behavior (e.g. anorexia).

Sickness behavior is organized as a motivational state and as such competes with other motivational states such as escape or vigilance for expression (Aubert 1999). Individual pig behavioral responses to particular pathogens will differ according to the pig's previous experiences and perception of its current environment. Understanding of the motivational factors that influence expression of sickness behavior can inform observation protocol and detection of ill individuals within a herd. Pigs infected with porcine reproductive and respiratory syndrome virus (PRRSV) spend more time lying relative to their uninfected pen mates (Escobar et al. 2007; Sutherland et al. 2007). Furthermore, PRRSV-infected pigs display lying postures that confer heat conservation (lying ventrally, lying in contact with other pigs) when housed in neutral thermal environments (24 °C), but not when housed at warmer (32 °C) temperatures (Sutherland et al. 2007). Although intake of water (Swinkels et al. 1994) and feed (Escobar et al. 2007) decrease during illness, affected pigs do not consistently reduce the amount of time spent at the feeder, perhaps due to social facilitation. In the absence of attentive observation, this behavior may provide the illusion of a healthy appetite and negatively impact detection of ill individuals in the pen.

Husbandry, handling, and housing of diseased pigs have important implications for animal welfare and pathogen transmission. Moving an ill or injured pig into a hospital can provide benefits in terms of minimizing the risk of bullying by healthy pen mates, reduced competition for resources, and ease of monitoring and medical intervention. However, social stress associated with mixing of unfamiliar pigs' results has been shown to increase shedding and transmission of *Salmonella typhimurium* (Calloway et al. 2006) and should be avoided when feasible. Furthermore, activation of the peripheral immune system has been shown to negatively impact spatial cognitive processing in piglets (Dilger and Johnson 2010), which could affect how compromised pigs respond to handling, and to navigate and find resources in novel environments. Hence, hospital pens need to be closely monitored to ensure ill and injured pigs are responding to treatment and for decision-making about humane endpoints when euthanasia is warranted (Millman 2015).

Euthanasia

Timely euthanasia is required for severely injured, non-ambulatory, and emaciated pigs and for compromised pigs that are in pain or that have little possibility of recovery. A standardized euthanasia protocol can improve overall well-being of the herd and reduce the economic costs of providing continued care for compromised pigs (Morrow et al. 2006). Euthanasia of low birth weight piglets (<0.9 kg [2 lb]), for example, may be recommended because they have higher mortality preweaning and in the nursery (Smith et al. 2007) and have higher likelihood of being of poor quality at weaning, in the nursery, and into the finishing period (Fix et al. 2010). Additionally, an euthanasia protocol for pigs entering the nursery that are identified as weak, lame, and suffering from prolapse or from two or more concurrent conditions (e.g. injury, damaged digits, hernia) has been shown to significantly improve herd welfare scores (Morrow et al. 2006). For pigs of all sizes, euthanasia should be carried out in a manner that minimizes pain, anxiety, and distress while rendering the animal rapidly insensible. The euthanasia process should result in rapid loss of consciousness, followed by cardiac or respiratory arrest and subsequent loss of brain function. Loss of consciousness should precede loss of muscle movement (AVMA 2013). Many euthanasia techniques are effective at rendering the animal insensible and causing death in one step, whereas two-step methods effectively stun the animal but require a secondary step such as exsanguination to achieve death.

There are three primary means of achieving death: chemical depression of the CNS, hypoxia, and physical disruption of brain activity (AVMA 2013). Direct depression of the CNS by anesthetic overdose initiates unconsciousness by induction into a deep state of anesthesia followed by cardiac and respiratory failure. Hypoxia limits oxygen delivery to the brain, ultimately shutting down vital centers for cardiac and respiratory function. Physical disruption of the brain, whether by concussion, depolarization by electrocution, or direct injury, targets the cerebral cortex and brain stem to damage critical pathways and regions of the brain essential for life. The prefrontal cortex and brain stem along with their connections in the thalamus are the brain regions associated with consciousness and arousal (Seth et al. 2005). If signs of sensibility are present subsequent to performing the euthanasia procedure, and it is safely possible, corrective action should be immediate. In order to ensure that death occurs without the perception of pain, signs of insensibility in the animal should be monitored throughout the process until death is confirmed.

Observations of brain stem and spinal or nociceptive reflexes, similar to those used to determine effective stunning prior to slaughter or depth of anesthesia during surgery, are the most practical measures for determining insensibility during euthanasia of animals on farms (Erasmus et al. 2010). Key brain stem reflexes include the corneal, palpebral, and pupillary light reflexes; when insensible, the animal does not exhibit a blink response when either the eyelid or the cornea is touched and the pupil remains fixed and dilated in the presence of light (Gregory 2008). Any natural blinking without stimulus indicates that the animal is sensible (Grandin 2010). However, ocular reflexes are not reliable indicators of anesthetic depth in pigs (Smith and Swindle 2008), and weak corneal reflexes can be observed during unconsciousness following damage to the cerebral cortex when the brain stem remains intact (e.g. head-only electrical stunning; Grandin 2010). Therefore, spinal or nociceptive reflexes, such as the pedal reflex, response to nose prick, or anal reflex, are important for assessing insensibility (Kaiser et al. 2006). Absence of withdrawal responses to painful stimuli indicates that the animal no longer perceives pain.

In addition to the sensory reflexes, several behavioral observations are important for assessing effectiveness of the euthanasia technique. These include the absence of rhythmic breathing, absence of vocalizations, and loss of muscle tone (Gregory 2008). The return of rhythmic breathing is one of the earliest signs of return to consciousness (Anil 1991). Vocalizations are a sign of pain or distress and should not be present at any time during the euthanasia process (Warriss et al. 1994), though unconscious pigs may exhibit involuntary noises and movements. Loss of posture and muscle tone occurs with the onset of unconsciousness, and a limp jaw or tongue is a reliable indicator of insensibility in pigs. Clonic muscle spasms, characterized by kicking or paddling movements, and tonic spasms, characterized by rigid extension of the limbs, are associated with some euthanasia techniques. These are involuntary muscle spasms and should not be confused with voluntary movements or deliberate escape attempts (Grandin 2010).

Veterinarians should work with the caretaker to design a euthanasia protocol using the most up-to-date guidelines. Human safety, costs, the technical skill required, and personnel preferences should also be taken into account. The recommended methods of euthanasia currently include veterinary-administered anesthetic overdose, carbon dioxide, gunshot, penetrating and non-penetrating captive bolt, and electrocution (NPB 2016). Manually applied blunt force trauma for small pigs (<5.44 kg [12 lb]) is accepted (NPB 2016), but due to limitations of the method and aesthetics, active pursuit of alternatives is recommended (AVMA 2013, NPB 2016).

Carbon dioxide induces unconsciousness and anesthesia by altering the pH of cerebrospinal fluid and ultimately causes death by respiratory arrest (NPB 2016).

Specifically designed equipment is necessary to ensure pain and distress is minimized during the CO_2 euthanasia procedure, including an airtight container, with non-slip flooring, and gas regulator. Compressed gas in cylinders is the recommended source of CO_2. Other sources of CO_2, such as dry ice, fire extinguishers, or chemical reactions, are unacceptable (NPB 2016). Stocking density in the container should allow all pigs to lie down without being required to lie on top of another pig. Solitary pigs may display more distress behaviors than those euthanized in groups (Fiedler et al. 2016); however, practical considerations such as the size of the pigs relative to container and discrepancy in condition of the pigs may make euthanasia of a solitary pig preferable. Though important to consider stocking density as well as other factors such as ill health that impacts the respiratory system (e.g. swine respiratory disease), these factors have minimal impact on the efficacy of CO_2 euthanasia (Sadler et al. 2014a,b).

Although CO_2 is effective for causing death, this method is controversial (Mota-Rojas et al. 2012); loss of consciousness is not immediate (Chevillon et al. 2004), and vocalizations, signs of breathlessness, and active avoidance are sometimes observed during the inhalation phase (Raj and Gregory 1996; Rault et al. 2015). Although other gases such as nitrous oxide and argon have been successfully utilized in trials (Fiedler et al. 2016; Rault et al. 2015), there are practical considerations that make these alternatives prohibitive to implement, including attainability and difficulty in maintaining an efficacious gas concentration.

Gunshot, penetrating captive bolt, non-penetrating captive bolt, and blunt force trauma should inflict sufficient physical damage to both the cerebral cortex and the brain stem to cause immediate and irreversible brain damage leading to death. For all methods, restraint allowing proper application is necessary. A gunshot to the head can be effective for pigs (AVMA 2013; NPB 2016). The trajectory of the bullet should follow the angle of the spine ideally passing through the brain and lodging in the brain stem (Woods et al. 2010). An alternative shot location is behind the ear, aiming toward the opposite eye (NPB 2016). It is imperative that the gun and load be sufficient to be effective with one shot. Neck and heart shots are not acceptable.

Captive bolt guns rely on concussion and destruction of brain tissue to render the animal immediately insensible. Sufficient transfer of energy from the gun to the head is required, and effectiveness depends on both the diameter and velocity of the bolt (Gregory 2007). Penetrating captive bolts can either stun or kill the pig. With the proper configuration, including gun design and charge, a penetrating captive bolt can be successful as a single step. Non-penetrating captive bolt guns do not cause sufficient brain damage to effectively stun or kill larger pigs and are only approved for pigs up to 31.57 kg (70 lb; NPB 2016). Similar to penetrating captive bolt, successful application of this procedure is depended on gun and charge configuration. For suckling piglets, physical methods of euthanasia may be the most practical for the caretaker. A non-penetrating captive bolt can be effective without a secondary step for suckling piglets, but the shape of the percussive bolt head and depth of depression of the bolt head into the cranium may be important. Widowski et al. (2008b) found that some piglets showed signs of return of sensibility and had a variable time to cardiac arrest when a round-headed percussive bolt was used for neonatal piglets. When the bolt head was modified to a conical shape, which resulted in a greater depth of depression, the method proved highly effective (Casey-Trott et al. 2013, 2014). Clonic convulsions (kicking and paddling) should be expected following application of blunt trauma and percussive bolt; brain stem reflexes as well as behavioral indicators should be checked to ensure insensibility.

Electrocution is another physical method of euthanasia. Only commercially available electric stunners should be used. It is important to note that both head-to-heart and head-only methods are acceptable. However, head-only electrocution causes loss of consciousness but not cardiac arrest; therefore, it is reversible and must be followed by a secondary step within 15 seconds (Anil 1991; Blackmore and Newhook 1981). Tonic and clonic neuromuscular spasms should be present in the head-only method (McKinstry and Anil 2004), but these are not seen in association with head-to-heart electrocution, which also causes cardiac fibrillation (Gregory 2008; Wotton and Gregory 1986). Electric methods should only be used on pigs over 3 days of age.

Genetics and Health

Caitlyn E. Bruns and Kenneth J. Stalder

Survival is a major economically relevant trait in the swine industry (Bergsma et al. 2008; Hermesch et al. 2014). Decreasing mortality at all production phases would increase profitability for the operation. Preweaning, nursery, and finisher livability has been trending downward over the last 6 years (Stalder 2016). Sow mortality has been increasing from 8 to 9% between 2010 and 2015 (Porth 2016). Given the mortality levels, there is opportunity for improvement. Genetic selection methods along with best management practices can be utilized to improve mortality throughout the swine industry.

Preweaning mortality

Preweaning mortality has increased by almost 1% per year for the last 6 years increasing to 17.4% in 2015 (Stalder 2016). The reason for this is not clear but may be attributed to the increase in litter size. Number weaned remained relatively flat not following the trend for increasing total born (Stalder 2016). Larger litters tend to have lower individual pig birth weights (Omtvedt et al. 1966; Roehe 1999). Lower pig birth weights observed in larger litters could result in higher preweaning mortality.

Genetic correlation estimates between total born and preweaning survival are varied. Nielsen et al. (2013) reported genetic correlations (SE) between total born and piglet mortality (including stillborns) to be 0.28 (0.06) and 0.22 (0.07) for Landrace and Yorkshire breeds, respectively. The genetic correlations reported by Putz et al. (2015) between total born and mortality to day 30 were not significantly different from 0. Additionally, Su et al. (2007) reported genetic correlations (SE) of −0.28 (0.12), −0.26 (0.12), and −0.43 (0.20) between total born and survival rate at birth, survival rate from birth to 5 days' post farrowing, and survival rate from 5 days' post farrowing to weaning for Landrace, respectively. The genetic correlation estimates for Yorkshire were −0.38 (0.16), −0.07 (0.23), and −0.527 (0.44) for total born and the survival traits (Su et al. 2007). The genetic correlations (SE) between the direct genetic effects of total born and proportion alive at birth and weaning were estimated to be 0.03 (0.01) and −0.26 (0.11) for Landrace, respectively, while the estimates for Yorkshire were not significantly different from 0 (Lund et al. 2002). The variation in genetic correlation estimates between studies suggests that the relationship between total born and preweaning survival may be highly dependent on the population. Differences in selection pressure over time may explain the varying relationship.

Selection for litter size and pig quality can be accomplished simultaneously. Using an alternative definition of litter size (e.g. number of pigs alive 5 days' post farrowing) can take advantage of desirable correlations with total born and preweaning mortality (Nielsen et al. 2013; Putz et al. 2015; Su et al. 2007). Genetic correlation estimates between total born and live pigs at 5 days ranged from 0.34 to 0.85, while the genetic correlation estimates between preweaning mortality and live pigs at 5 days ranged from −0.35 and −0.57 (Nielsen et al. 2013; Putz et al. 2015; Su et al. 2007).

Survival heritability estimates are low. Reported heritabilities for preweaning mortality ranged between 0.03 and 0.13 (Grandinson et al. 2002; Hellbrügge et al. 2008; Holl and Long 2006; Nielsen et al. 2013; Putz et al. 2015; Su et al. 2007). Selection for birth weight may be preferable when compared to preweaning survival. The heritability for the maternal genetic component of birth weight is greater than the heritability for survival. Reported heritability estimates for birth weight range from 0.04 to 0.10 for the direct genetic effect and from 0.15 to 0.26 for the maternal genetic effect (Grandinson et al. 2002; Holl and Long 2006; Hellbrügge et al. 2008; Putz et al. 2015). Since the birth weight maternal genetic effect has a higher heritability compared to preweaning survival, genetic progress can be made more rapidly in birth weight.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Selection for increased birth weight could indirectly improve preweaning survival. Putz et al. (2015) found the genetic correlation (SE) between pig birth weight and preweaning mortality to be –0.13 (0.11) and –0.14 (0.09) for Landrace and Yorkshire, respectively. These genetic correlations are not significantly different from 0, but the traits were not modeled with a maternal genetic effect. Hellbrügge et al. (2008) reported the genetic correlation (SE) between birth weight and survival rate to be 0.21 (0.16), but, again, the maternal genetic effect was not included in the model.

Based on the heritability estimates for both the direct and maternal genetic components, the maternal effect explains more variation in birth weight compared to the direct effect. It is important to understand the model used for birth weight when comparing genetic parameter estimates. Holl and Long (2006) estimated the genetic correlation (SE not reported) between the birth weight direct effect and the preweaning mortality direct effect to be –0.34, and the genetic correlation between the maternal effects was –0.16. The genetic correlation (SE) between the maternal genetic effects for birth weight and mortality was 0.18 (0.20) (Grandinson et al. 2002). These estimates are in opposite directions and suggest that genetic parameters are population specific and should be evaluated within a population before making decisions to include birth weight in a selection program. Knol et al. (2002) speculated that improving pig survival might not be possible by selecting on birth weight alone given the low genetic correlation estimates reported at that time. With greater estimates being reported in more recent years and the availability of more sophisticated tools like genomic selection, this may be worth reconsidering.

Birth weight is associated with improved performance throughout the pig's life. Pigs with greater birth weights were heavier at off-test and had greater growth rate (Fix et al. 2010a; Holl and Long 2006; Rehfeldt et al. 2008); however, heavier pigs at birth had lower loin depth and intramuscular fat percentage (Holl and Long 2006; Rehfeldt et al. 2008). Fix et al. (2010a) reported a quadratic relationship between birth weight and loin muscle area. Holl and Long (2006) found that pigs with greater birth weights had lower backfat at off-test, but Rehfeldt et al. (2008) and Fix et al. (2010a) reported no significant differences in backfat level for pigs with different birth weights. Fix et al. (2010b) observed a positive relationship between pig birth weight and survival to weaning, through the nursery, and through the finisher. Pigs with greater birth weights were higher quality at weaning and had a greater probability of being full value pigs at marketing when compared with pigs with lower birth weights (Fix et al. 2010b). In a study by Magnabosco et al. (2015), pigs in the lowest birth weight class (410–990 g) had the greatest preweaning, nursery, and finisher mortality compared with pigs in larger birth weight classes. According to Magnabosco et al. (2016), sows that weighed less than 1000 g at birth produced 4.5 fewer total pigs born over parities compared to sows that were heavier at birth. Additionally, the sows with the lowest weight at birth had the shortest productive life compared with heavier pigs (Magnabosco et al. 2016).

Nursery–finish mortality

Combined nursery and finisher mortality or mortality throughout a wean-to-finish system has increased by over 0.4% per year from 2010 to 2015 (Stalder 2016). In 2015, the average nursery, conventional finisher, and wean-to-finish mortality rates were 3.5, 4.5, and 6.7%, respectively (Stalder 2016). The combined nursery and finisher death loss is less than half of the preweaning mortality, suggesting that there is a larger opportunity to improve survival in the farrowing house compared with growing pig survival; however, the economic impact of finishing mortality may be greater depending on when the pig dies. Improving morbidity may provide another means to increase commercial swine producer profitability. Henryon et al. (2001) reported that time to treatment for growing pigs was heritable 0.10 for any disease, which was lower than heritability estimates (0.12–0.19) for time to treatment in individual disease categories. Heritability estimates for performance traits may be improved by accounting for challenge events that occurred during the finishing phase. Zumbach et al. (2008) reported a heritability estimate (SE) for carcass weight when not accounting for heat stress of 0.17 (0.01) and reported heritability (SE) estimates of 0.28 (0.01) and 0.14 (0.01) when grouping the pigs under heat stress and non-heat stress, respectively.

Disease resistance

Pigs that do not respond well to health challenges perform more poorly throughout the grow-finish phase and reduce producer economic efficiency. Additionally, improving disease resistance can improve consumer perception of the pig industry in general (Kanis et al. 2005). There is a genetic component to disease resistance; but oftentimes, this component is underestimated when field data has been used to conduct research. It is hard to guarantee that disease exposure probability was both consistent and sufficient for all pigs in a study; furthermore, clinical diagnoses are not always completely correct (Bishop and Woolliams 2010). Given that heterosis can greatly impact pig survival (Fahmy and Bernard 1972), it is important to understand what population was used to estimate genetic parameters and effects on disease resistance. Most commercial market hogs are

crossbred animals, while nucleus herds are composed of purebred animals. Survival rates are not the same among purebred and crossbred pigs (Fahmy and Bernard 1972), making selection for improved survivability at the commercial level difficult.

When considering incorporating a disease resistance component into a genetic program, it is important to understand the genetic parameters for the specific system in which the pigs will be raised. Many disease resistance studies that have been conducted have only included one line or one environment, meaning the results may not be applicable to other lines or environmental conditions. It is important to consider whether the study was conducted in a research or commercial setting (Guy et al. 2012). Additionally, understanding the selection program's goal is important. Improving disease tolerance may be more desirable than improving disease resistance. Hosts carrying a pathogen load may not experience any negative effects. Selecting for improved health and maintaining productivity when in a challenged environment may be accomplished with an emphasis on disease resistance and disease tolerance (Guy et al. 2012).

Lundeheim (1979) examined the genetic parameters associated with respiratory diseases (pneumonia, pleuritis, and rhinitis) in growing pigs. The heritability estimates ranged from 0.12 to 0.16, while genetic correlation estimates between the predisposition to a respiratory disease and growth and carcass measurements were low and not significantly different from 0 (Lundeheim 1979). The same study reported a negative phenotypic relationship between growth rate and lung lesions, enteric disease, locomotion disorders, and "failure to thrive." This suggests that an animal's health status affects its growth performance. Kadowaki et al. (2012) estimated the heritability for mycoplasma pneumonia score to be 0.07, which is slightly lower than the estimate from Lundeheim (1979); however the genetic correlation estimates between mycoplasma pneumonia score and growth and backfat were low and not significantly different from 0, which is in agreement with previous findings (Lundeheim 1979). Additionally, Kadowaki et al. (2012) demonstrated that pigs could be selected for improved mycoplasma pneumonia score while still increasing growth rate and maintaining backfat.

Immune response

Evaluating and selecting for immune response may be a way to improve the overall pig robustness in different health challenges. Pigs with more desirable immune response levels may perform better in health challenged environments regardless of the pathogens present. Clapperton et al. (2009) examined heritability for different biomarkers (acute-phase proteins and peripheral mononuclear leukocyte subsets) and their relationship with production traits. Heritabilities were estimated separately for pigs in a specific-pathogen-free (SPF) environment and non-SPF environment. The magnitude of the heritabilities was moderate for most biomarkers; however the heritability estimates were different when analyzing SPF versus non-SPF pigs (Clapperton et al. 2009). Alpha-acid glycoprotein was the only biomarker evaluated that was negatively correlated with growth rate in both SPF and non-SPF pigs. Additional negative genetic correlations existed between growth rate and monocytes in SPF pigs and growth rate and CD11R1 in non-SPF pigs. Henryon et al. (2006) estimated the heritabilities for IgG and haptoglobin serum concentration to be moderate, 0.16 and 0.14, respectively. The same study reported extremely high heritabilities for swine leukocyte antigen expression ranging from 0.46 to 1.23. Other studies have similarly reported moderate heritabilities for immune response measurements (Edfors-Lilja et al. 1994; Mallard et al. 1992).

Magnusson et al. (1998) reported that nursery-age pigs selected for high immune response had greater clinical arthritis scores in a challenged environment when compared with pigs selected for low immune response; however, there was no difference in weight gain in a challenged environment between the pigs selected for high and low immune response, and pigs selected for high immune response had higher weight gain in a non-challenged environment. This does not suggest a positive impact on growth performance when selecting for more desirable immune response.

Genetic advancements

Traditional selection for disease resistance and survivability is difficult due to challenges with measuring the traits in a nucleus herd. Nucleus herds have a higher health status when compared with commercial herds; therefore, nucleus animals are not exposed to as many pathogens. The approach to selecting for improved survivability has been to develop a pedigreed commercial herd with different pedigree ties to the nucleus herd. However, there are still challenges with this as well since the disease load is not constant or consistent over time. Disease resistance phenotypes are difficult to measure long term in order to incorporate them into a routine genetic analysis.

A single nucleotide polymorphism (SNP) is a location on the genome where variation exists between animals. These locations of variation can be used to estimate the difference in genetic potential between pigs. A PorcineSNP60 BeadChip with 60,000 SNPs can be utilized to incorporate genomic selection to estimate breeding values in swine genetic evaluations (Ramos et al. 2009). Genomic selection involves combining the estimated allele effects for each SNP analyzed with phenotypes to

calculate the expected breeding value for each pig (Meuwissen et al. 2001). Genomic selection has the most impact on traits that are difficult to measure, sex limited, or measured later in life (Goddard and Hayes 2007). Guo et al. (2015) examined the improvement in reliability when including genomic information when estimating breeding values for mortality up to day 5 post farrowing and were unable to show a significant improvement compared to traditional best linear unbiased prediction (BLUP) selection.

An alternative may be to focus on marker-assisted selection (MAS) to estimate the effect for one quantitative trait loci (QTL) and select to reduce the undesirable allele frequency (Knap 2005). Several markers have been previously identified to impact economically relevant traits like number born alive (estrogen receptor gene [ESR]), growth rate and feed intake (melanocortin-4 receptor [MC4R]), and meat quality (protein kinase adenosine monophosphate-activated gamma(3)-subunit [PRKAG3]) (Kim et al. 2000; Rothschild et al. 2007; Stalder et al. 2005). Porcine stress syndrome has been drastically reduced by incorporating a genetic marker into swine breeding programs (Stalder et al. 1997). The completion of the pig genome sequencing (Archibald et al. 2010) aided in the analysis of potential candidate genes.

Knowing the genome sequence can aid in studies exploring the allelic effects for genes expected to impact animal health. Boddicker et al. (2012) isolated a region on chromosome 4 that could reduce the impact of PRRS in a swine population. The marker was reported to explain 15.7% of the genetic variation in viral load and 11.2% of the genetic variation in weight gain in the populations evaluated. Edfors-Lilja et al. (1998) reported multiple QTLs that were associated with improved leukocyte counts and IgG levels for pigs immunized with an *Escherichia coli* vaccine. Reiner et al. (2002) showed that QTLs can affect the temperature and neurological symptoms when pigs were challenged intranasally with pseudorabies virus. Additionally, genes in the swine leukocyte antigen complex have been shown to influence antigen presentation and immune response (Lunney et al. 2009; Mallard et al. 1989). Utilizing markers found in these studies could aid in improving the pigs' response to disease challenges.

One thing that needs to be considered when determining the effectiveness for any QTL is the population that was studied as well as the pathogen strain used. The QTL effects can differ between swine populations and pathogen strains and may not be beneficial in all selection programs. A more recent approach to disease resistance is gene editing. Gene editing involves replacing a section of the genome with a synthesized sequence. Whitworth et al. (2015) validated the ability to edit the pig genome *in vitro* using clustered regularly interspaced short palindromic repeat (CRISPR) technology. Using the CRISPR technology, Whitworth et al. (2016) demonstrated that pigs edited with a mutation in exon 7 of CD163 displayed no response when infected with PRRS virus. Further investigations examining the long-term effects of the mutation need to be conducted. This may be the biggest discovery to improve PRRS disease resistance found to date. Given that PRRS has the greatest economic impact for any single disease in the swine industry, incorporating the edited gene into the population would likely increase swine industry profitability remarkably.

Sow productive lifetime

Most, if not all, economically important pork production traits including longevity are influenced by genetics and/or breeding system. Genetic effects can impact longevity through other important traits. Rydhmer et al. (1994) and Bidanel et al. (1996) have shown that genetics can impact age, weight, and backfat at puberty, which is associated with sow productive lifetime. Additionally, crossbreeding or heterosis impacts sow productive lifetime (Serenius et al. 2008). Živković et al. (1986) reported that crossbred sows averaged 5.3 litters, while purebred sows averaged 4.4 litters at culling, a significant difference of 0.9 litters per sow or 12%. They also noted that 55.2% of culling in purebred sows occurred in the first three parities. During the first three parities, only 40.4% of the overall culling occurred in the crossbred sows. Jorgensen (2000) reported that mean age and number of litters at removal were lower in purebred Yorkshire sows when compared with crossbred sows. Specifically, the purebred sows had greater culling for locomotion problems and reproductive failure. The difference in sow productive lifetime or parity at culling is particularly important for operations producing replacement gilts using an internal multiplication program. If the internal multiplication program involves purebreds or pure lines, producers must be aware of the expected differential lifetime or number of parities produced in order to maintain adequate replacement parent female and replacement pure line female populations.

Longevity may be influenced by the breed makeup of crossbred breeding females. Hall et al. (2002) noted that sows that were one-quarter Meishan had significantly greater mean productive lifetime days (778 days) when compared with sows that were one-eighth Duroc or one-quarter Duroc 674 and 639 days, respectively. This resulted in a greater mean parity at culling for the one-quarter Meishan sows (4.54) compared with the one-eighth Duroc (3.79) or the one-quarter Duroc sows (3.67) and a greater lifetime number of pigs born alive of 55.0 compared with 42.7 and 42.3, respectively.

Heritability estimates for longevity or sow productive lifetime indicate that selection should be an effective method to improve this trait. However, those experienced at genetic improvement for any trait, but particularly those that are more lowly heritable like fitness and reproduction, recognize that improvement through selection alone will be slow. Sow longevity or sow productive lifetime falls into this type of category. Stayability is a measure that some researchers use to describe longevity. Simply, stayability is the ability of a sow to produce an additional litter after producing the previous litter. Reported longevity or productive lifetime heritability estimates range from 0.05 to 0.25 in swine depending on the trait evaluated (Engblom et al. 2009; Gou et al. 2001; Mészáros et al. 2010; Serenius and Stalder 2004; Serenius et al. 2006; Tholen et al. 1996).

In addition to the direct genetic influence on sow productive lifetime, the genetic relationship between economically important production traits like growth rate, backfat, and feet and leg soundness and sow productive lifetime can impact the phenotypic longevity results observed at the herd level. The relationships or correlations can differ depending on the population evaluated. Length of productive life and lifetime number of pigs born alive were positively associated in Finnish Large White and negatively associated in Finnish Landrace (Serenius and Stalder 2004; Serenius et al. 2008).

Improving sow productive lifetime involves choosing the correct genetic lines. Johnson (2000) reported that results from the National Pork Board's Maternal Line Project demonstrated that traits contributing to longevity and attrition are heritable. The same report noted line differences for percentage of sows producing four litters, live pigs per sow life, and average sow life. Goodwin (2002) extended the analysis for the same maternal line study and found similar differences through the sixth parity. This seems to indicate that the producer's breeding stock source could impact their ability to retain sows in the breeding herd for longer periods of time or parities ultimately producing more piglets per sow lifetime.

Feet and leg soundness or lameness is usually the second largest identifiable reason for sows leaving the breeding herds, particularly the early parities 1, 2, and 3 (Douglas and MacKinnon 1993). Studies have identified a few factors that are significantly associated with improved sow productive lifetime, either positively or negatively, across several studies. Weak pasterns have a positive influence on longevity (Grindflek and Sehested 1996; Serenius et al. 2001), while buck-kneed front legs, swaying hindquarters, and upright pasterns on rear feet were associated unfavorably with longevity (Jorgensen 1996). Numerous studies have shown that feet and leg conformation scores are moderately heritable traits (Bereskin 1979; de Koning 1996; Huang et al. 1995; Lundeheim 1987; Rothschild and Christian 1988a; Serenius et al. 2001) and some of these conformation traits have even been associated with sow longevity (Fernández de Sevilla et al. 2008, 2009; Serenius and Stalder 2004; Tarrés et al. 2006; Tiranti and Morrison 2006). Heritability estimates from these studies for various leg soundness scores range from 0.01 to 0.47, with many values above 0.15.

Rothschild and Christian (1988a) demonstrated that selection for improved front leg structure was quite successful in only five generations. This seems to suggest that lines with poor leg soundness scores, poor structure, or having a substantial number of feet and leg problems could be improved through proper selection. In a related paper, Rothschild and Christian (1988b) indicated that leg weakness problems are antagonistically correlated with backfat. This seems to indicate that some selection for feet and leg soundness is necessary to maintain adequate structure especially if there is a strong selection against backfat. Selection against backfat has been employed by most seedstock suppliers for several years and may help explain some of the feet and leg problems that many commercial producers see in the females in the breeding herd.

Lopez-Serrano et al. (2000) reported unfavorable genetic correlations between stayability from first to second litter and daily gain (–0.28 in Large White, –0.06 in Landrace) and stayability and backfat (0.22 in Large White, 0.24 in Landrace), while a favorable genetic correlation was found between stayability and leg score (0.08 in Large White, 0.19 in Landrace). Similarly, Brandt et al. (1999) and Jorgensen (2000) determined that leg quality had a significant influence on the productive life of sows. In further analyses, Jorgensen (2000) reported that "standing under position" also was negatively associated with sow longevity. Knauer et al. (2011) reported moderate genetic correlations (0.09–0.49) between stayability and sow structure visual scores and a negative genetic correlation (–0.14) between locomotion scores and stayability. Genomic regions with effects on a sow's body composition (e.g. body length, body depth, body width) and the structure (e.g. pasture posture) were identified by Fan et al. (2009). With further investigation into candidate genes, Fan et al. (2011) located specific markers with effects on sow body composition and structure.

Most research results that have been published to date where feet and leg soundness traits have been evaluated were conducted where sows were housed in gestation stalls. It is not clear if the same traits, additional traits, or a completely different set of feet and leg traits would influence productive lifetime if sows were housed in group loose sow housing facilities.

Recent advances in molecular biology may prove useful in improving sow productive lifetime. Mote et al.

(2009) reported that several genes including carnitine O-palmitoyltransferase I (CPT1A) and C–C chemokine receptor 7 (CCR7) were associated with improved survival or sow productive lifetime. That same study identified genes associated with reproductive performance including insulin-like growth factor binding protein (IGFBP1) and angiotensin I converting enzyme (ACE). Two genes were associated with both sow longevity and improved reproductive performance including CPT1A.

Onteru et al. (2011a) conducted a genome-wide association to determine genetic regions with influence on reproduction traits across multiple parities. Regions explaining a significant portion of genetic variation were found for total born, born alive, stillborns, mummies, and gestation length with different regions accounting for variation in litter size traits at different parities. With further investigation, Onteru et al. (2011b) found several gene regions with an effect on sow lifetime production (total number born, born alive, removal parity, and nonproductive days). These results suggest that genotyping information can be used to select for the components of sow longevity. In the future, swine breeders may be able to improve sow longevity using both traditional selection methods and advanced molecular tools to ultimately improve performance observed at the commercial level.

It is important to note that sow reproductive trait heritability estimates can vary when sows experience different health challenges. Additionally, the genetic correlation for the same trait when animals are exposed to different health conditions is not 1, suggesting that selection for increased performance in one condition is not directly correlated with improved performance in another condition. Lewis et al. (2009) reported different heritabilities for litter size and number of matings until conception when using data from a herd during a PRRS outbreak compared with using data from the same herd in a normal health status. Given that a sow's ability to stay in a commercial herd is dependent on her reproductive performance, this suggests that a sow's ability to tolerate a disease may impact her longevity in the breeding herd.

Because genetic line differences exist and the heritability for longevity traits is of sufficient magnitude that selection would be successful in improving sow productive lifetime, pork producers should have opportunities to choose lines that have improved sow longevity. At the same time, genetic suppliers can continue to improve this trait through selection. Many commercial producers have employed internal gilt multiplication systems. Genetic improvement of sow longevity must occur using purchased semen from their genetic supplier.

Effect of Environment on Health

Michael C. Brumm

From the pig's point of view, the environment it lives in includes temperature, humidity, space, feed and water access, and air quality when housed in confinement facilities. Rather than document the impact of these variables on health, this chapter will discuss the known requirements that allow the healthy pig to grow and perform to its genetic potential.

Temperature

The pig is a homeothermic animal with a deep body temperature of 39 °C (Baxter 1984), meaning it has a constant core body temperature and will adapt behaviors to maintain this temperature. These behaviors are not only postural changes (huddling as an example when cold) but also changes in basal metabolism accomplished through a change in feed intake (more or less metabolic heat production) when forced to live in an environment warmer or colder than the thermal-neutral temperature zone.

At a constant body weight, heat production by growing pigs and lactating females has increased over the years as the rate of lean deposition and milk production has improved in response to improvements in nutrition, health, genetics, housing, etc. For growing pigs, this increase has amounted to about a 10–15% watt (W) increase at the same body weight increase every 10 years (Figure 4.1) (Brown-Brandl et al. 2004). Similar increases have been noted for early weaned pigs (Harmon et al. 1997). In lactation, the large increase in milk production to support larger litters has also resulted in a large increase in metabolic heat output (Pedersen 2002). This increase in metabolic heat production supports the conclusion that today's pigs are more sensitive to air temperature (especially warm or hot temperatures) than previous generations (Renaudeau et al. 2011).

At the same time, pigs have consistently demonstrated a preference for diurnal variation in temperatures (warmer during the days and cooler during nights). While this demonstrated variation is often 5–7 °C (Bench and Gonyou 2006; Morrison et al. 1987), fluctuations of ±4 °C during the first week after weaning have been demonstrated to increase post weaning scours (LeDividich 1981). Similarly, intermittent drafts of 0.99 m/s for 6 weeks after weaning resulted in increased respiratory distress (coughing, sneezing, and more pneumonic lesions; Scheepens et al. 1991). Brumm and Shelton (1988) and Johnston et al. (2013) have demonstrated no negative impact on pig health or pig performance when a reduced nocturnal temperature regimen is begun 1 week after weaning. This regimen often results in air temperatures in the early morning hours that are 4–5 °C lower than daytime (0700–1900 hours) temperatures.

Extended periods of heat stress have been demonstrated to impact intestinal integrity (Pearce et al. 2015), and heat stress *in utero* impacts postnatal body composition and growth potential (Johnson et al. 2015). Heat stress also impacts intestinal barrier function (Pearce et al. 2012), suggesting a negative impact on health.

Table 4.1 lists the recommended controller set points for facilities with mechanical ventilation. Generally this set point is considered to be at the lower end of the thermal-neutral zone. If temperatures in a production facility are lower than this, some type of supplemental heat is usually activated to maintain thermal-neutral conditions in the pig zone. As temperatures warm above this set point, devices such as fans, misters, or evaporative pads are activated to both remove heat and activate evaporative cooling mechanisms to assist the pig in dealing with the warmer conditions.

The low end of the thermo-neutral zone is normally considered the lower critical temperature (LCT), which is defined as the lowest air temperature that a given animal can maintain under homeothermic conditions without increasing metabolism to maintain body temperature (Hillman 2009). The suggested set points in

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

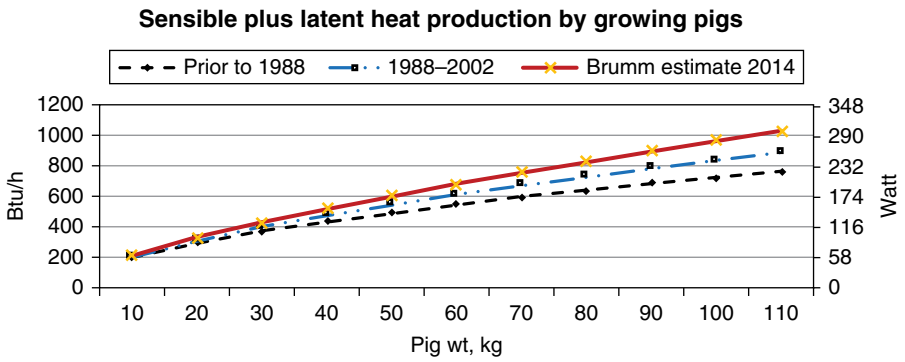

Figure 4.1 Total (sensible plus latent) heat production by growing pigs. *Source:* Adapted from Brown-Brandl et al. (2004).

Table 4.1 Recommended ventilation controller set points for fully slatted facilities.

Pig class or wt	Set point (°C)
Weaning (5–8 kg)	30
25 kg	22
50 kg	19
100 kg+	16
Individually housed gestating females	20
Group-housed gestating females	17
Lactating females week 3	20

Table 4.1 are generally within 1–2 °C of LCT for pigs housed in groups in fully slatted facilities without bedding, hovers, or other facility modifications that allow the pig to modify its LCT. When housed at temperatures in the pig zone at or slightly above the LCT, metabolic heat release to the environment is approximately 2/3 as sensible heat (air temperature) and 1/3 as latent heat (moisture). As temperatures rise, the pig must release a higher percentage of its metabolic heat as latent heat since the difference between skin surface temperature and air temperature lowers, which results in less heat dissipation via convection and conduction modes.

The exact LCT for any given pig or group of pigs will depend upon its feed intake and body size (DeShazer and Yen 2009). Pigs of any given size that consume more feed will have a lower LCT as compared with pigs consuming less feed. As a consequence, when feed intake is reduced during an illness, the general recommendation is to increase air temperature in the pig zone to compensate. The upper end of the thermoneutral zone is normally considered the upper critical temperature (UCT) or the evaporative critical temperature (Hillman 2009). The UCT can be defined as the temperature at which pigs begin to pant or perform other behaviors in order to dissipate heat to the environment in order to maintain body temperature. In general, the goal of swine housing is to provide conditions that result in the least regulatory effort by the growing or adult animal (Hillman 2009).

Humidity

The desired humidity level in swine production facilities is 60–80%. Humidity fluctuates in a diurnal pattern in production facilities, most often being the lowest in morning hours and highest in the midafternoon due to pig activities increasing the amount of moisture that is evaporated from flooring surfaces. During hot weather, high humidity levels are associated with a high total enthalpy in the environment. Because of this high enthalpy, options for using evaporative cooling such as wetting of the pigs or evaporative pads in mechanically ventilated facilities are limited. As a consequence, pig performance is decreased as the pig modifies its behavior by reducing feed intake and activity to decrease total heat production.

The minimum ventilation rates in Table 4.2 are designed to maintain humidity levels at 60–80% in cold weather in full and partially slatted production facilities. Ventilation rates higher than the minimum are generally in response to the need to remove excess heat from a facility as a result of pig growth and/or warming outside temperatures.

Causes of death in ventilation failures

With a majority of the North American pig population housed in facilities with mechanical ventilation, ventilation failures due to equipment malfunction or electrical outages occasionally occur. In many instances these failures are accompanied by pig deaths.

Table 4.2 Recommended ventilation rates for swine production facilities.

Pig class	Weight (kg)	Cold weather minimum (m^3/h)	Mild weather rate (m^3/h)	Hot weather rate (m^3/h)
Weaned pigs	5–15	3.4	17.0	51.0
Growing pigs	15–34	5.1	25.5	76.5
Finishing pigs	34–68	11.9	40.8	130.0
Finishing pigs	68–135	17.0	59.5	200.0
Gestating females		20.4	68.0	425.0
Sow and litter		34.0	85.0	1100.0

Source: Adapted from MWPS (1990)

While it is common for producers and their advisors to talk about "suffocation" as a cause of death, the primary cause of death for all ages other than newly weaned piglets is hyperthermia (Robert et al. 2003; Zulovich and Bundy 1990), not lethal levels of carbon dioxide or other gases. Zulovich and Bundy (1990) demonstrated that at typical stocking densities of North American production facilities, death from hyperthermia can occur as rapidly as 30 minutes after a ventilation failure. In this simulation, only a minimal amount of air infiltration was necessary to keep predicted carbon dioxide and oxygen at reasonable levels. For all conditions simulated, relative humidity in the facility reach 100% within 2 hours of the simulated failure. In many situations where pig death occurs due to ventilation failure, smaller pigs (runts and sick pigs) often survive because their metabolic heat output is lower due to lower levels of feed intake. They do not reach critical core body temperatures before many of the fastest-growing (i.e. highest metabolic heat output) pigs have died and barn temperatures have begun to decline.

Christison and Heidenreich (1968) recorded rectal temperatures of 44.4 °C 5 minutes prior to death when a 25 kg pig was exposed to a 38 °C temperature for 5.25 hours. On-farm rectal temperatures of 41.1 °C have been recorded 4–5 hours after death associated with a ventilation failure event (MC Brumm, personal communication). Robert et al. (2003) conducted a series of experiments in a commercial nursery with 6.8 and 22.7 kg pigs in which the ventilation system was turned off and the rate of change in temperature and carbon dioxide concentration were recorded. For 6.8 kg pigs, they determined that air temperature would never reach a critical level to result in hyperthermia but carbon dioxide levels would become critical within 150 minutes. In the same facility with 22.7 kg pigs and no mechanical ventilation operating, the critical time before temperatures approached levels creating hyperthermia would be about 60 minutes, while the critical time for carbon dioxide levels was 95 minutes.

Pen space

The growing pig's spatial requirement in m^2/pig is well understood for both full and partially slatted facilities (Flohr et al. 2016; Gonyou et al. 2006). When space is defined by the allometric equation $m^2/pig = K * BW(kg)^{0.667}$ where K is a constant and BW is body weight, the generally recognized constant is 0.0336 (Gonyou et al. 2006a). Many welfare codes define the space requirement using a constant (K) of 0.035. In general, as space per pig is restricted, feed intake and daily gain decline with a less predictable response in feed conversion. Table 4.3 details the relationship between pig weight, pen space, and "K." The predicted impact on daily gain versus adequate space (K = 0.0336) is presented in Table 4.4.

There is limited data on the impact of space allocation on pig health. Turner et al. (2000) suggested that pigs in deep straw-bedded facilities given less space had a lower humoral response to an antigen challenge. In contrast, Oh et al. (2010) reported no impact of increasing pig numbers in a fixed dimension weaned pig pen on serum IgA and IgC. Hyun et al. (1998) have suggested that environmental stressors (temperature, space, and social regrouping) have an additive impact on performance.

Feeder space

A common limit to pig performance as sale weights increase is feeder access. Producers and equipment suppliers often size feeders based on the number of "holes" the feeder offers without regard to the issues surrounding the quality of the eating space or "hole."

The width of the feeding space is defined by the shoulder width of the pig. Petherick (1983) defined shoulder width in relation to pig body weight as width (mm) = $64.0 \times (\text{body weight, kg})^{0.33}$.

Table 4.3 Relationship between pig weight, pen space, and "K."

	"K"				
Pig wt (kg)	0.025 m^2/pig	0.028	0.031	0.0336	0.035
20	0.18	0.21	0.23	0.25	0.26
40	0.29	0.33	0.36	0.39	0.41
60	0.38	0.43	0.48	0.52	0.54
80	0.46	0.52	0.58	0.62	0.65
100	0.54	0.60	0.67	0.73	0.76
120	0.61	0.68	0.76	0.82	0.85
140	0.68	0.76	0.84	0.91	0.95

Source: Adapted from Petherick (1983).

Table 4.4 Estimated impact on daily gain when space per pig is restricted in fully slatted facilities.

Wt (kg)	Space/pig (m^2/pig) at $K = 0.0336$	K when space/pig is 0.66 m^2/pig	ADG versus $>K = 0.0335$ from 25 kg to stated wt
20	0.25	0.089	
40	0.39	0.056	No impact
60	0.52	0.043	No impact
80	0.62	0.035	No impact
100	0.73	0.0305	97.5%
120	0.82	0.0270	94.6%
140	0.91	0.0245	92.6%

To allow for pig movement at the feeder, feeder spaces should be sized based on 1.1 times the shoulder width. Table 4.5 lists the estimated shoulder width in relation to pig weight and the estimated width of feeder spaces based on these shoulder width dimensions. This table supports the recommendation that feeders for today's production facilities should have a minimum feeder "hole" width of 35.0 cm as slaughter weights in the United States continue to increase (Figure 4.2; NASS, USDA, 2018 and Figure 4.3).

Gonyou and Lou (1998) using pigs with weights up to 95 kg concluded that the best compromise for feeder depth (distance from the front lip of the feeder pan to the feed delivery point) for grow-finish pigs was 20–30 cm. They concluded that the ideal feeder depth for 95 kg pigs was 32 cm. This suggests that a majority of the feeders installed in production facilities in the United States and Canada today, which have depths of 20–25 cm, are limiting to pig performance as sale weights increase.

The problem with increasing feeder depth is that of smaller pigs at time of placement stepping into the feeder to access feed and then tracking feed out of the feed pan. However this has not been an issue with "wean-finish" feeders where pigs are grown from 5.5 kg to slaughter weight on the same feeder. In this author's experience, as sale weights increase, feeders must have at least 25.4 cm of depth from the front lip to the feed delivery device or agitator plate with 28–30.5 cm preferred for dry feeders. If the distance is less than this, pigs end up pushing against the feeder with the crown of their forehead and/or have difficulty accessing the feed agitator plate.

The table also highlights a common feeder problem with swine nursery units. Many nurseries now house pigs until 25 kg or heavier. The vast majority of feeders sold in North America for placement in swine nurseries still have feeder "holes" that are 15.25 cm × 15.25 cm. Based on shoulder dimensions, these feeders most likely limit feed intake or at the minimum limit pig access to feed by limiting the number of usable spaces that pigs can eat from unless the spaces/holes are 20.3 cm wide.

Similar sizing issues arise when drinking water is furnished in trough or cup/bowl drinkers. Pigs grow in three dimensions (length, width, and height), so the need to account for increases in head dimensions for these devices as slaughter weights increase is also a reality.

Table 4.5 Shoulder width of growing pigs in relation to pig weight and estimated feeder "hole" widths necessary to accommodate this dimension.

Pig wt (kg)	Shoulder width (cm)	1.1 × shoulder width (cm)
18.2	16.8	18.3
27.3	19.1	21.1
90.9	28.4	31.2
100.0	29.2	32.3
109.1	30.2	33.0
118.2	31.0	34.0
127.3	31.8	34.8
136.4	32.5	35.6
145.5	33.0	36.3

Figure 4.3 Twelve "hole" 2.13 m long double-sided feeder with marked pig (estimated to weigh almost 136 kg) destined for removal and sale immediately after the picture was taken from a pen of 125 finishing pigs.

Water

At birth, water accounts for 82% of the pig's empty body weight. By the time the pig weighs 240 pounds, water comprises only 51% of the empty body weight (Shields et al. 1989). In addition to body tissue and metabolic functions, water is used for (1) the adjustment of body temperature, (2) the maintenance of mineral homeostasis, (3) the excretion of the end products of metabolism (particularly urea), (4) the achievement of satiety (gut fill), and (5) satisfaction of behavioral needs (Brooks et al. 1989). Major sources of water for physiological needs, including growth, reproduction, and lactation, are

water from feedstuffs, water from metabolic processes, and drinking water. As a practical matter, drinking water is the major water source (Thacker 2001) Table 4.6.

Symptoms of water deprivation in swine include reduced feed intake, crowding around drinker devices, dehydration, increased heart rates, increased body temperatures, increased respiration, and death (Thacker 2001).

Water consumption for growing pigs has a distinct periodicity with a peak at the beginning and at the end of the feeding period when nose-operated drinkers are used. Water consumption between feeding periods peaked two hours after the morning feeding and one hour after the afternoon feeding (Olsson and Andersson 1985). Weaned pigs housed under conditions of constant light showed a diurnal pattern for water intake with higher consumption recorded from 0830 to 1700 hours as compared with the 1700 to 0830 hours time period (Brooks et al. 1984). Grow-finish pigs using nipple drinkers showed a large peak from 1500 to 2100 hours and a smaller peak between 500 and 1100 hours (Korthals 1998). The number of pigs in a group (pen) apparently influences water usage. In one study water usage was higher when pigs were housed in groups of 60 versus 20. Total drinking time per pig decreased when group size increased, even though the number of pigs per drinker was the same for both group sizes (Turner et al. 1999).

While there is very good evidence that a majority of water consumption is associated with eating activities in research settings, there is limited data on patterns of water usage in commercial facilities. Brumm (2006) documented drinking water disappearance patterns in production facilities in Minnesota and Nebraska. These facilities varied in the number of pigs per pen, the type of feeder and drinker, the type of ventilation, relative pig health, etc. The similarities between the winter and summer patterns at the sites suggests that two patterns of water usage exist, depending on the temperature in the facility (i.e. time of the year). In thermal-neutral conditions (generally air temperatures in the pig zone <26 °C), grow-finish pigs begin drinking water around 6 am, with a peak in drinking water disappearance in early afternoon and a gradual decline for the remainder of the day. This pattern is in agreement with published literature.

However, when pigs are growing in warm to hot conditions (air temperatures in the pen exceeding 26 °C for 1 or more hours per day), they alter their pattern of drinking water usage. Pigs begin drinking earlier in the day, with a morning peak from 0800 to 0900 hours. There is a decline in drinking water use midday with a second peak in drinking water use from 1700 to 2300 hours. followed by the decline into the night hours.

It is interesting to note that pigs shift to this pattern of drinking water use on the first day of air temperatures in the pig zone (>26 °C or so) and maintain the pattern for 3–5 days, even if these subsequent days have temperatures considered to be thermal neutral. This adaptation is often maintained for several days in anticipation that the heat stress event will be longer than a single day. This suggests that a shift in eating and drinking behavior is one of the first adaptations of the growing pig to heat stress. In the future, it may be possible to use this shift in drinking water usage as a predictor of a performance reduction due to heat stress in grow-finish pigs.

Figure 4.4 shows the typical daily water disappearance curve for pigs in a wean-finish facility equipped with bowl drinkers and offered corn–soybean meal-based diets ad libitum. Based on producer and veterinarian

Table 4.6 Recommended water flow rates from drinking devices.

Pig class	Flow (mL/min)
Nursery pigs	250–500
Grow-finish pigs	750–1000
Breeding animals	1000

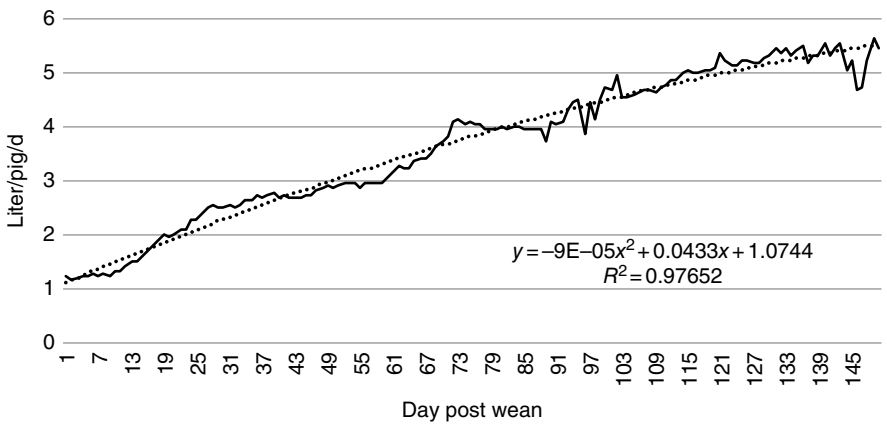

Figure 4.4 Typical drinking water usage for growing pigs. Data based on eight wean-finish groups of pigs from weaning (piglets 17–21 days of age) to day 150 post weaning.

observations, when daily water usage drops for 3 continuous days or drops more than 30% from day to day, this may indicate that a potential health challenge is occurring in the production facility (Brumm 2006).

Water–feed ratios (kg/kg) for liquid feeding systems typically range from 2.5 : 1 to 3.5 : 1 (English et al. 1988). Water–feed ratios ranging from 1.78 : 1 to 2.79 : 1 for pigs weighing from 18 to 114 kg and fed dry feed ad libitum have been reported (Brumm et al. 2000). The lowest reported water–feed ratios were with wet/dry feeders and bowl drinkers, whereas gate-mounted nipple drinkers had the highest ratios. With similar performance, this suggests that the major cause of differences in water–feed ratios between the various drinking devices is due to differences in water wastage, not differences in the amount consumed.

Water–feed ratios decrease as pigs grow. Recent on-farm data (MC Brumm, unpublished data) supports the conclusion that water–feed ratios decline as pigs grow, with a ratio as low as 1.5 : 1 common in facilities that use wet/dry feeders or stainless steel bowl drinkers in late finishing and offered corn–soybean meal-based mash diets ad libitum. Assuming similar water–feed ratios for both barrows and gilts, it follows that barrows drink more water than gilts since barrows eat more feed per day than gilts in mid to late finishing (NRC 2012). Pigs fed meal diets drink more water than pigs fed pelleted diets (Laitat et al. 1999), reflecting similar water–feed ratios and differences in feed conversion efficiency.

General recommendations exist for the number of pigs per drinking device (Midwest Plan Service 1983), but research to support these recommendations is limited. Researchers using 3- to 4-week-old weaned pigs reported a slight reduction in average daily gain and an increase in weight variation within pens of 16 pigs given access to 1 versus 2 nipple drinkers for 5 weeks' post weaning (Brumm and Shelton 1986). Generally, for groups larger than 10 pigs in a nursery and 15–20 pigs in a grow-finish facility, a minimum of 2 delivery devices is recommended (Brumm and Reese 1992).

Grow-finish pigs spent from 3 to 16 minutes per day at nipple drinkers when flow ranged from 1100 down to 100 mL/min (Nienaber and Hahn 1984). This suggests that pigs will exert some extra effort in order to obtain water. But it is not clear at what point having to wait for drinker access or exert extra effort impairs performance.

Lactating sows need considerable amounts of water, both for milk production and to remove the metabolic end products associated with this production (Thacker 2001). Water consumption (measured as disappearance) averaged 18 L/day with a range of 12–40 L/day (Lightfoot 1978). It is expected that as milk output by lactating sows increases due to advances in genetics, nutrition, and housing, this average value will increase, even as improvements in wastage are noted due to newer types of drinking devices.

Noise

The general noise level measured in mechanically ventilated pig buildings was 73 dB with naturally ventilated buildings averaging 10 dB lower levels (Talling et al. 1998). This noise level tends to be monotonous and continuous (Schaffer et al. 2001). Levels averaged 98 dB during transport (Talling et al. 1998). Loud fan noise (85 dB) has been shown to interfere with sow and nursing piglet communication, leading to disrupted nursings (Algers and Jensen 1985).

Kanitz et al. (2005) demonstrated that repeated exposure to 2 hours of 90 dB noise caused considerable alterations to the hypothalamic–pituitary–adrenal axis. They suggested that this alteration would have a substantial impact on the general vulnerability of the pig with respect to health, welfare, and productivity.

Stray voltage

Stray voltage is defined as the voltage between any two animal contact points. Most often these exist as neutral-to-earth voltages (Gustafson and Morgan 2004). These frequently occur in swine housing situations where there are large amounts of metal gating to provide a path for the electric current such as gestation stalls or farrowing crates or where there is metal flooring such as farrowing crates or weaned pig pens. Field reports indicate that when stray voltage is present, there is often a reluctance of pigs to drink from drinkers, a reduction in appetite, restlessness, increases in aggressive encounters, impaired growth, and a variety of health disorders (Robert et al. 1994a).

Current flow through gestating females was always higher on wet versus dry floors (Robert et al. 1994b). However, under controlled conditions, it has been difficult to demonstrate negative impacts on lactating female or growing pig performance or health (Robert et al. 1992, 1996).

Differential Diagnosis of Diseases

Alejandro Ramirez

Introduction

The objective of this chapter is to provide a list of differentials to consider under various different clinical presentations. They are organized by system affected. Due to the international scope of this book, these lists are designed to be inclusive rather than exclusive as prevalence is relative to geographic location. The World Organization for Animal Health (OIE) continually updates its list of diseases requiring international reporting (www.oie.int) because of their impact in animal and public health worldwide, including trade concerns. The World Animal Health Information Database (http://www.oie.int/wahis_2/public/wahid.php/Wahidhome/Home) provides a Web portal for monitoring outbreaks, disease distribution maps, and detailed country diseases for all OIE-listed diseases.

It is envisioned that readers will refer to this section to remind themselves of possible differentials. It is helpful to be open about all possible causes rather than just focus on the common causes especially when dealing with challenging cases and to ensure that new causes to a particular system or region are not missed. Many times clinical disease outbreaks in large populations are multifactorial, and thus focusing on single causes can misguide practitioners. A quick review of the respective body system chapter (Section 2 Chapters 14–22) can help guide the prioritization of the list. Individual causes can then be better researched (etiology, clinical signs, diagnosis, and prevention) in their respective chapters, which are identified in most of the tables.

It is important to remember that because these lists are inclusive rather than exclusive, there are many causes listed for which commercially available diagnostic tests are not available. Chapter 6 reviews many of the different diagnostic tests available including important information on test performance and considerations in interpreting results. Collecting evidence and establishing causality is a critical step for proper diagnosis (see Chapter 8).

Digestive system

Chapter 15 covers valuable information regarding the digestive system including useful tables summarizing the mechanisms of diarrhea (Table 15.1), diagnosis of some common gastrointestinal conditions (Table 15.2), and pathology and diagnostic confirmation of common conditions (Table 15.3).

The approximate age at which certain causes of diarrhea and vomiting are more common is shown in Tables 5.1 and 5.2 respectively. The approximate age is given solely as guidance to help emphasize certain causes based on age of pigs and does not imply the cause to be restricted only to that age group. Table 5.3 provides a general list of possible causes of rectal prolapses including a brief explanation.

Respiratory system

An overview of the respiratory system is provided in Chapter 21. Tables 5.4 and 5.5 summarize differential diagnosis lists for major respiratory clinical presentations.

Integumentary system

The integumentary system is reviewed in Chapter 17. Table 5.6 helps summarize the approximate age when specific skin diseases are more common. Tables 5.7 and 17.1 help narrow down the differential diagnosis of skin diseases based on location and clinical presentation of the lesions.

Hemopoietic system

The cardiovascular and hemopoietic systems are reviewed in Chapter 14. Anemia is a common clinical presentation related to the hemopoietic system. Possible causes of anemia are listed in Tables 5.8 and 14.7.

Table 5.3 Causes of rectal prolapses in pigs (also see Chapter 15).

Cause	Comments
Diarrhea	Abnormally acid stool in the rectum causes irritation, tenesmus, and prolapse. Refer to the section on diarrhea for differentiation between causes of diarrhea
Cough	Increased abdominal pressure generated during coughing (especially chronic prolonged bouts) causes displacement of the rectum. Refer to the section on cough for differentiation between causes of cough
Piling	Environmental temperatures too low. Abdominal pressure on the pig at the bottom of the pile produces prolapse
Zearalenone	Estrogens cause swelling of the perineal area, tenesmus, and prolapse
Floor design	Excessively sloped floors for crated sows cause increased pressure on pelvic structures as pregnancy progresses
Antibiotics	Rectal prolapse has been reported in pigs in the first few weeks after lincomycin or tylosin has been added to the feed. Prolapses cease later as pigs apparently become accustomed to the antibiotic
Inherited predisposition	Sporadic reports in the literature of herd outbreaks that occurred in the offspring of certain boars
Postpartum	Complex etiology surrounding farrowing
Prepartum	Constipation and pressure of heavily gravid uterus
Any condition that is associated with tenesmus	Urethritis, vaginitis, rectal or urethral injury post breeding, urethral calculi. Excess salt in the diet

Nervous and locomotor system

Chapter 19 reviews both the nervous and locomotor systems. It is important to note that many times diseases affecting either of these systems have similar general clinical presentations. Table 5.9 lists some causes of neurologic signs. It is important to use the right descriptive terms when describing clinical signs (see Table 19.5) to ensure proper differential diagnosis. Table 19.8 tries to further differentiate clinical presentations. Lameness conditions are summarized in Table 5.10.

Reproductive system

The reproductive system is summarized in Chapter 20. Possible causes of reproductive losses in pigs are summarized in Tables 5.11 and 20.7. Although not directly related to reproductive performance, but rather related to pregnancy, common congenital anomalies are listed in Table 5.12.

Zoonotic

An overview of preharvest food safety and zoonotic diseases is included in Chapter 12. Pig diseases with zoonotic potential are summarized in Table 5.13.

Acknowledgments

The following individuals are acknowledged for their valuable input and guidance provided: Robert Desrosiers, Phil Gauger, Eric Neumann, Kent Schwartz, Ernest Stanford, and Locke Karriker.

Defect	Prevalence (%)	Etiology	Diagnosis
Microencephaly	0.07	Heat stress midpregnancy	History of heat stress
		Unknown (most cases)	An agent affecting development in early or midpregnancy
Microphthalmia		Vitamin A deficiency	Multiple defects in affected litters; heavy neonatal mortality; history; diet analysis; serum and liver vitamin A analysis
		Hog cholera (HC) infection	HC infection in herd; virus isolation; fluorescent antibody test; serology; congenital tremor AI present in herd
		Heritable	Mode of inheritance uncertain; dominant gene (?)
		Unknown	An agent affecting embryos at 12–16 days of development
Neural tube defects (anencephaly, encephalocele, hydrocephalus, spina bifida)	0.04	Unknown	An agent affecting embryos at 12–16 days of development
		Vitamin A deficiency (hydrocephalus)	Multiple defects in affected litters; heavy neonatal mortality; history; diet analysis; serum and liver vitamin A analysis
Congenital tremor	0.20	HC virus (type AI)	HC infection in herd; virus isolation; fluorescent antibody test; serology; affects piglets of all breeds and both sexes; hypomyelinogenesis; cerebellar hypoplasia; neurochemical analysis of myelin lipids of spinal cord; small cross-sectional area of the spinal cord
		Type All (unidentified virus)	Hypomyelinogenesis of spinal cord; analysis of myelin lipids of spinal cord; small cross-sectional area of the spinal cord
		Type AIII	Monogenic sex-linked gene mutation in Landrace affecting only males and associated with defect in myelin sheath
		Type IV	Autosomal recessive gene in Saddleback affecting both sexes
		Pseudorabies (PR) virus	PR infection in herd; virus isolation; serology
		Neguvon (metrifonate, trichlorfon)	History of dosing sows in midpregnancy; hypoplasia of cerebrum and cerebellum; Purkinje cell loss; changes in neurotransmitters
	0.10	Tobacco stalks, jimsonweed, poison hemlock, wild black cherry	History of exposure to plants in early to midpregnancy
		Vitamin A deficiency	Multiple defects in affected litters; heavy neonatal mortality; history; diet analysis; serum and liver vitamin A analysis
Arthrogryposis		HC attenuated vaccine virus	History of vaccination during early pregnancy
		HC infection	HC infection in herd; virus isolation; fluorescent antibody test; serology; congenital tremor type AI in herd
		Paramyxovirus infection	Menangle virus infection during pregnancy
		Heritable	Recessive gene (?); autosomal recessive in Yorkshire pigs
		Unknown (most cases)	An agent affecting development in early or midpregnancy

Table 5.12 (Continued)

Defect	Prevalence (%)	Etiology	Diagnosis
Micromelia	0.10	Unknown	Possibly caused by limb vascular defects in early pregnancy
Cleft palate/harelip	0.07	Heritable	Possibly a recessive gene; cleft palate in Poland China pigs probably genetic
		Unknown (most cases)	An agent affecting development in early or midpregnancy
Deformed tail	0.08	Possibly heritable	Mode of inheritance uncertain; occasionally urogenital defect associated
		Unknown	Often associated with motor defects in hind limbs; vertebral defects
Myofibrillar hypoplasia	1.05	Heritable	Most common in Landrace, less in Large White; probably polygenic mode of inheritance; incidence modified by maternal stress, slippery floor, birth weight, or maternal nutrition
		Fusarium toxin	Higher mortalities than other forms; feed analysis
Inguinal hernia	0.40	Heritable	Mode of inheritance uncertain; incidence modified by environment
Umbilical hernia	1.00	Unknown	Possibly polygenic mode of inheritance
Anal atresia	0.40	Heritable	Possibly polygenic inheritance or an autosomal recessive or autosomal dominant form of transmission
Hypotrichosis		Heritable in some breeds	Mode of inheritance uncertain
		Iodine deficiency	Stillbirths and high neonatal mortality; enlarged thyroids; skin edematous; feed analysis
Epitheliogenesis imperfecta	0.05	Heritable	Possibly autosomal recessive gene; hydronephrosis associated
Dermatosis vegetans		Heritable	Autosomal recessive; associated with fatal giant cell pneumonia
Pityriasis rosea		Probably heritable	Mode of inheritance uncertain; affects young pigs, especially Landrace; benign and self-limiting
Von Willebrand's disease		Heritable	Recessive gene in Poland China pigs; excess bleeding from minor wounds; decrease in factor VIII and platelet retention time
Navel bleeding	0.14–1.2	Unknown	Cord is edematous; familial linkage
Cardiac defects	0.03	Unknown	Most cases recognized at 4–8 weeks; mostly males
Cryptorchidism	0.39	Probably heritable	Polygenic transmission; left testicle most commonly involved
Female genital hypoplasias, duplications	0.68	Probably a heritable component	Mode of inheritance uncertain; genital tract incomplete or duplicated
	0.06		
Male pseudohermaphroditism	0.2–0.6	Heritable	Mode of transmission uncertain; testicles in abdomen together with female tubular tract
True hermaphroditism		Heritable	Mode of inheritance uncertain; testicular and ovarian tissues usually with female tubular tract

Diagnostic Tests, Test Performance, and Considerations for Interpretation

Jane Christopher-Hennings, Gene A. Erickson, Richard A. Hesse, Eric A. Nelson, Stephanie Rossow, Joy Scaria, and Durda Slavic

Introduction

Diagnostic testing is used to determine the cause of disease and for surveillance of pathogens that may cause disease. There are many agents that cause disease including viruses, bacteria, protozoa, other parasites, and toxins. However, just detecting the presence of these agents or exposure to them does not necessarily indicate that they are the etiologic agent of the particular clinical disease at hand. Therefore, an accurate diagnosis of each specific case is based on the total picture including the herd history, clinical signs, gross and microscopic pathology (histopathology), and results of diagnostic tests. In addition, some organisms may only cause disease at specific thresholds. Since no single test is 100% sensitive (the test correctly identifies 100% of all infected pigs, indicating there are no "false-negative" results) or 100% specific (the test correctly identifies 100% of all noninfected pigs, indicating there are no "false-positive" results), an incorrect diagnosis could result if only one test is used and the stage and current context of the disease is not taken into consideration. To determine whether a specific test is identifying the cause of disease, multiple tests or repeated testing over time may be required, and when results of diagnostic testing are received, evaluations of the outcomes in the context of history, clinical signs, and pathology (if available) are critical (Figure 6.1).

This chapter describes common tests used for the diagnosis of swine diseases or surveillance of swine pathogens and is intended to help determine the appropriate test and interpretation of results for swine diseases. The tests are described in alphabetical order along with their diagnostic strengths and weaknesses (Table 6.1).

Agar-gel immunodiffusion

Agar-gel immunodiffusion (AGID) is a serological test for measuring the presence of antibodies to a specific antigen. It can be used to detect host exposure to a pathogen or to serotype field isolates. It has been routinely used for influenza A virus (IAV) serological testing and to serotype *Haemophilus parasuis* field isolates (Del Río et al. 2003). Although AGID continues to be used in some laboratories for *H. parasuis* typing due to the ease of use and low cost, the method has largely been replaced by indirect hemagglutination inhibition (IHA) and enzyme-linked immunosorbent assay (ELISA) due to their greater specificity and sensitivity.

The test is performed in petri plates coated with agar and a seven-well pattern (center well surrounded by six equally spaced test wells). Test antigen is used to fill the center well, and positive control serum is placed in alternating test wells around the center well. Sera to be tested are placed in the remaining wells, and the test is incubated for 1–2 days. Test plates are examined with a bright indirect light source to visualize the specific lines of identity (white precipitate) between the antigen well and positive control serum wells after diffusion of the antibody and antigen from their respective wells. A positive result is recorded when a test serum produces a line of identity in the agar between the serum and reference positive control serum. Test specificity is determined by the quality of the antigen used.

Bacterial culture and antimicrobial susceptibility testing (AST)

For detection of the majority of bacterial diseases, bacterial culture is the most common, but not necessarily the most rapid diagnostic method. It is routinely used by veterinary diagnostic laboratories to grow bacteria from clinical samples, providing evidence of their viability, in contrast to molecular diagnostic methods where detection

[c] For detection of *Leptospira* sp. antibodies only.

of nucleic acid does not discern between viable or nonviable organisms. Subsequently, bacterial growth is used for bacterial identification and subtyping (if applicable) to establish its significance. Not all bacterial isolates are associated with specific disease conditions, since some bacteria may be present in samples either as contaminants or commensals. Once the significance of bacterial isolates is established, their antimicrobial susceptibility pattern is determined to guide antimicrobial treatment decisions. Furthermore, isolates can also be saved for any future research or for vaccine production, making them a valuable source for retrospective studies and for disease prevention.

Before submitting samples for culture, it is important for clinicians to know how diagnostic laboratories process samples. There are a variety of artificial media, temperatures, and growth conditions that can be used to obtain bacterial growth from clinical samples (Markey et al. 2013). The conditions used primarily depend on sample type, animal age, and clinical history. Therefore, it is very important that the referring veterinarian provides this information at the time of sample submission to help guide sample setup and interpretation of results (Table 6.2). It is also beneficial to describe on the submission form any lesions observed and to specify if a particular bacterial disease is suspected. The next step is to select the appropriate bacterial test(s) if this option is available. Some laboratories offer a variety of bacterial cultures (e.g. aerobic, anaerobic, *Clostridium difficile*, *Mycoplasma*, *Brachyspira*, etc.) to help veterinarians make the selection at the time of sample submission. In general, a request for aerobic bacterial culture will ensure isolation of most porcine bacterial pathogens. They usually grow well aerobically on medium containing blood, and their growth is

Table 6.2 Guidelines for interpretation and troubleshooting of positive and negative bacterial culture results.

Pathogen	Analyte	Test	Outcome	Interpretation	Additional testing
Bacteria	Tissue Body fluids[a]	Culture in liquid or solid media	Positive	Bacterial agent is isolated from the sample	Identify agent to the species/subspecies/ pathotype level
	Blood Urine Feces		Negative	Bacterial agent is not isolated from the sample: • Antimicrobial treatment prior to sample collection • Inappropriate sample collection, submission, and processing • Commensal flora overgrowth • Other fast-growing pathogen overgrowth • Nonbacterial etiology	Submit samples for PCR or request IHC/PCR on histological sections/scrolls

[a] Cerebrospinal, thoracic, peritoneal, synovial.

improved in the presence of 5–10% CO_2. More fastidious aerobic pathogens (e.g. *H. parasuis* and *Actinobacillus pleuropneumoniae* biotype I) require additional nutritional supplements including nicotinamide adenine dinucleotide (NAD), whereas anaerobic bacteria (e.g. *Actinobaculum suis* and *Clostridium* spp.) must be grown in oxygen-free conditions, and therefore anaerobic culture must be requested. In some cases, enrichment methods are recommended for isolation of *Salmonella* and *C. difficile*. There are also a few swine bacterial pathogens that are very difficult to almost impossible to grow routinely. For example, *Mycoplasma hyopneumoniae* requires a specific medium, is extremely fastidious to grow, and can take up to 4 weeks to reach measurable levels (Thacker 2004). Similarly, *Lawsonia intracellularis* can only be grown in tissue cell culture that is not routinely available in veterinary diagnostic laboratories (Vannucci et al. 2012). Alternative methods such as polymerase chain reaction (PCR) or ELISA are available for detection of slow-growing or fastidious pathogens. More information about growth requirements and methods for culturing various porcine bacterial pathogens can be found in their specific chapters in this book.

When individual bacterial colonies (i.e. pure bacterial growth) are obtained, then bacterial identification and AST can be performed. Previously, the most common method of bacterial identification was based on specific growth characteristics, colony morphology, Gram staining, and a variety of biochemical tests using automated or manual identification systems. This relatively lengthy procedure took approximately 24–48 hours before bacterial identification was achieved. Although this approach is still in use in most diagnostic laboratories, it is being rapidly replaced by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). In contrast to biochemical procedures, this is a very efficient and sensitive method where a small amount of bacterial growth is directly transferred to a stainless steel target plate and mixed with matrix solution to co-crystallize the bacterial proteins. The plate can accommodate between 24 and 384 samples, and it is then transferred into the MALDI-TOF instrument where individual samples are exposed to short laser pulses, resulting in protein ionization. Ionized proteins travel through a linear flight tube and are separated based on their mass-to-charge ratio plotted against signal intensity, which is then used to create a specific bacterial protein fingerprint. This fingerprint, in most cases, is unique for a given bacterial species. It has been well documented that for species-level identification, an accurate protein fingerprint is typically in the range of 2–20 kDa. The predominant proteins in this range are ribosomal proteins, which ionize well, are abundant in cells, and vary minimally under different growth conditions. Once the bacterial protein spectra are collected, they are compared with reference spectra in the MALDI-TOF MS database to generate the bacterial identification in real time. In addition to generating bacterial identification, the software also generates a numerical score to indicate how well-generated spectra match the spectra in the database. Typically, a high score indicates that a specific genus and species identification is reached (e.g. *Actinobacillus suis*), whereas a lower score may indicate only a genus level of identification (e.g. *Actinobacillus* sp.). However, the score levels can be influenced by many factors such as the thickness of bacterial smear applied on the target plate and the method used for smear processing. Smears that are too thick will yield lower scores or occasionally result in no spectra generated. In contrast, use of an "extraction method" where bacterial proteins are purified before they are applied on the target plate will result in the highest scores. Because the "extraction method" is time consuming, it is not used routinely for MALDI-TOF MS identifications. Instead, laboratories opt to use either a "direct transfer method" or an "extended direct transfer

method." With the "extended direct transfer method," 70% formic acid (FA) is applied on smears deposited on the target to partially extract proteins before the matrix is added. In some instances, this can improve score levels over the "direct transfer method" where only matrix is used, but it also adds to time and cost of running MALDI-TOF MS. If no results are obtained, in most cases the species reference spectra are not present in the database. Since 2011, the numbers of entries into the database almost doubled, and with each manufacturer's annual database update, the number of reference spectra keeps growing. Although reference spectra of the majority of swine pathogens are in the database, there are still some gaps that need to be filled. For example, no spectra for *Actinobacillus porcitonsillarum*, a bacterial species very closely related to *A. pleuropneumoniae* biotype I, are present in the manufacturer's database. Because MALDI-TOF MS is an open platform system, this issue can easily be rectified by creation of a customized database entry within the laboratory. All customized entries, however, have to pass rigorous multiple quality checks, which start with proper bacterial identification. Isolates used for spectra creation must be well characterized, and their identity, at minimum, confirmed by either 16S rRNA or other housekeeping gene sequencing. Next, an "extraction method" must be used for protein purification. Once reference spectra are created, they should also undergo extensive manufacturer's recommended internal quality control checks before being added to the customized database. In addition, it is highly recommended to add reference spectra from a minimum of five isolates of the same bacterial species to account for their natural variability. Aside from biochemical and MALDI-TOF MS, molecular methods can also be used for bacterial identification of individual colonies. The most frequent method used is 16S rRNA gene sequencing (Janda and Abbott 2007). 16S rRNA genes are present in all bacteria and are well conserved, making them a reliable marker for bacterial identification. However, when dealing with closely related bacterial species and subspecies, occasionally other genes (i.e. *rpoB*, *sodA*, etc.) may need to be sequenced because the 16S rRNA gene sequence may not provide enough information for speciation (Angeletti et al. 2015; Shin et al. 2015). For the most accurate bacterial identification, whole genome sequencing can be used, but its cost makes it still prohibitive for routine use.

To date, numerous studies have shown that MALDI-TOF MS bacterial identification is almost as accurate (if reference spectra are in the database) as molecular identification (Bizzini et al. 2010; Carpaij et al. 2011; Randall et al. 2015). When compared with biochemical identification, MALDI-TOF MS is superior, particularly for gram-positive bacteria for which routine biochemical identification was always challenging (Cherkaoui et al. 2011; Dupont et al. 2010). The MALDI-TOF MS bacterial identification is currently limited in its ability to differentiate between very closely related species and subspecies (Randall et al. 2015). This issue is gradually diminishing with each database update, as more reference spectra are added for each problematic species and subspecies. In addition, the software is being upgraded to distinguish slight differences between species and subspecies. In the meantime, MALDI-TOF MS is replacing biochemical methods for bacterial identification. In 2016, almost half of American Association of Veterinary Laboratory Diagnosticians (AAVLD)-accredited laboratories were using MALDI-TOF MS. It is expected that this number will increase in the future since the MALDI-TOF MS provides highly reliable bacterial identification within the same day, requires minimum handling time and technical expertise, can be automated (FA and matrix deposition), and is cost effective. However, successful bacterial identification using MALDI-TOF MS still depends on growing individual bacterial colonies from clinical specimens, and AST needs to be done separately. In the future, diagnostic uses of MALDI-TOF MS may include direct detection of bacteria in clinical samples and AST (Ferreira et al. 2011; Mailhac et al. 2017; Oviano et al. 2017).

The mere isolation of bacteria from clinical samples does not automatically imply their significance. It is important to critically evaluate the isolation of specific bacterial species in association with clinical signs and lesions to assess their relevance in morbidity and mortality. This is particularly true when additional characterization is required to differentiate between virulent and non-virulent bacterial pathotypes. For example, isolation of *Escherichia coli* from the gut does not indicate its association with enteritis. Further serotyping (i.e. for presence of F4 [K88]) and/or genotyping (e.g. detection of genes for fimbriae and toxins) must be done to establish this association (Osek 2001). Furthermore, the significance of isolation can sometimes be confirmed only by the detection of toxins as in cases of *C. difficile* (Moono et al. 2016).

Despite typical clinical signs and proper sample collection and submission, bacterial pathogens may not necessarily be isolated, which may happen more frequently than anticipated (Table 6.2). Antibiotic treatment and lack of refrigeration following sample collection are two of the most frequent causes of negative culture (Oliveira 2007). Lack of bacterial isolation may also result from overgrowth by commensal flora or contaminants, particularly in respiratory and intestinal samples (Fittipaldi et al. 2003). Additionally, if field veterinarians do not specify clinical signs, lesions, and a tentative diagnosis during submission, no isolation of bacterial species with specific growth requirements will likely be achieved. If in any doubt, it is highly recommended to call the laboratory

for help with any questions related to sample collection, storage, and submission.

In summary, bacterial culture is still a widely used diagnostic method for bacterial isolation, identification, and susceptibility testing. In contrast to bacterial isolation, which has not changed in decades, bacterial identification underwent significant improvements in the last few years with the introduction of the MALDI-TOF MS. The introduction of this technology allows diagnostic laboratories to achieve bacterial identification the same day when bacterial growth is detected. This can help veterinarians with empirical treatment decisions if pathogens are isolated or help reduce antibiotic use when no bacterial pathogens are present.

After the clinical significance of bacterial species is established, then AST is recommended to help guide treatment decisions. Some clinically significant bacterial species have predictable susceptibility patterns, which do not warrant AST. For example, currently, *Trueperella pyogenes* is predictably sensitive to penicillin, and this drug can be reliably used for its treatment without AST. In general, AST should be routinely performed for bacterial species with unpredicted susceptibility patterns (e.g. *E. coli, Salmonella* spp.) and for bacteria where resistance is reported or expected (e.g. *Pseudomonas aeruginosa*). In North America, AST is performed in veterinary diagnostic laboratories following guidelines published by the Clinical and Laboratory Standards Institute (CLSI). CLSI guidelines provide recommendations for testing, including preparation of bacterial suspensions, media use, incubation conditions, and a list of antimicrobial agents per animal species that may be considered for testing to standardize test performance. They also include result interpretation guidelines, which are specific for bacterial species–antimicrobial agent combinations (CLSI 2015). Therefore, it is important to know the identity of bacterial species when interpreting AST results. However, guidelines are not available for all clinically relevant bacteria that do not have predictable susceptibility patterns. For example, guidelines are not available for slow-growing bacterial species with fastidious growth requirements such as *H. parasuis*. There are two AST methods frequently used in veterinary medicine: agar disk diffusion and broth dilution (CLSI 2015). Agar disk diffusion, also known as the Kirby–Bauer method, is a qualitative method where a suspension of pure bacterial culture is streaked onto the surface of nutrient agar and then paper disks impregnated with antimicrobials are applied on top of it. The plates are incubated overnight, and a diameter of zone of inhibition (i.e. lack of bacterial growth around disks) is measured the next day. The agar disk diffusion method is highly flexible as any drug can be easily included and/or omitted from the testing. It is cost effective, but is not suitable for testing of all pathogens because some will grow poorly or will not grow at all on the media used. It is primarily used for testing of fast-growing aerobic bacteria (e.g. *E. coli*, *Salmonella*, *P. aeruginosa*, etc.) and some fastidious aerobic bacteria (e.g. *A. pleuropneumoniae*).

In contrast to agar disk diffusion, broth dilution is a quantitative test, and the results are expressed as the minimal inhibitory concentration (MIC). Broth dilution is performed in microbroth format where an equal amount of bacterial suspension is applied to each well of a 96-well MIC plate and incubated overnight. Veterinary specific formats of MIC plates are commercially available, and they contain antimicrobials approved for use in a particular animal species in a twofold dilution range. For example, the bovine/porcine MIC plate contains penicillin in range of 0.12–8 μg/mL and tiamulin in range of 1–3 μg/mL. Therefore each well on the MIC plate contains different antimicrobial concentrations. The presence of bacterial growth indicates that a bacterium is resistant to that particular drug concentration, whereas the absence of bacterial growth indicates susceptibility. The lowest concentration of drug that will inhibit bacterial growth is called the MIC, and it is expressed in μg/mL. It is necessary to achieve that concentration at the infection site during the course of treatment to inhibit bacterial growth. As concentration of drug can vary in different body systems and fluids, it is important to have pharmacokinetic studies done in order to determine if therapeutic concentrations can be achieved at target site. Unlike the agar disk diffusion method, the MIC method is more laborious, more expensive, and less flexible because it may take a few months before any antibiotic changes to the commercial plate format can be made.

Interpretation of AST results is performed following CLSI guidelines with values expressed as susceptible (S), intermediate (I), resistant (R), or nonsusceptible (NI). MIC values (μg/mL) can also be reported if the broth dilution method is used. S implies that a particular drug used in a dosage recommended by a manufacturer will likely successfully treat infection. R, on the other hand, means that infection likely will not be treated under the same conditions and usually indicates the presence of a resistance trait. I is defined as a "buffer zone," meaning that under certain conditions, the drug can be used for a favorable clinical outcome. For example, a drug can be used for treatment of infection in a site where it can be physiologically concentrated (i.e. urine) or when a high dosage of drug can be used. The NI designation is more complex, and it is reported for bacteria where values are defined for susceptible interpretative criteria only because of lack or rare occurrence of reported resistance. When AST results do not conform within defined values, the isolates are reported as NI to the specific drugs. That does not mean automatically that they have a resistance mechanism. It is possible that within the wild bacterial population, some isolates may have susceptibility values

above the ones defined as susceptible by the current CLSI guidelines (CLSI 2015).

There are numerous antimicrobial drugs approved for use in swine, but there is no need to test all of them individually. The CLSI recommends using one representative for a specific class of related drugs. For example, tetracycline is used as a representative of the tetracycline group (tetracycline, doxycycline, minocycline). If bacteria are found susceptible to tetracycline, they are considered susceptible to other drugs within this class. However, if they are resistant, then doxycycline and minocycline need to be tested individually as they have a broader antimicrobial coverage. For the macrolide class, clindamycin is used for susceptibility testing for both clindamycin and lincomycin. As the CLSI does not endorse any commercially available drugs, only nonproprietary names are used for reporting purposes.

Overall, AST results can be used to predict the effectiveness of treatment. However, AST is an *in vitro* test performed under optimal conditions for the bacterium–antimicrobial agent interactions. Therefore, it should be used only as a general guide for drug selection, and other aspects of appropriate treatment choice(s) should be evaluated, such as pharmacodynamics and pharmacokinetics of the drug, intracellular versus extracellular location of the bacteria, and site of infection. These and other aspects of antimicrobial drug selection are beyond the scope of this chapter, and for more information, the reader is referred to the "Drug Pharmacology, Therapy, and Prophylaxis" chapter of this book.

Bioassay (swine bioassay)

A bioassay is a test performed using a live animal to determine the infectivity or potency of a particular pathogen or substance. Pigs have been used to measure the infectivity of various viruses (e.g. porcine reproductive and respiratory syndrome virus [PRRSV], porcine epidemic diarrhea virus [PEDV], porcine circovirus type 2 [PCV2], classical swine fever virus [CSFV], hepatitis E), and the conclusions are then compared to PCR results (Christopher-Hennings et al. 1995; Dee et al. 2014). The swine bioassay determines whether the detection of nucleic acid corresponds with the presence of live virus. Naïve pigs are inoculated with the infectious agent and monitored at regular intervals for the presence of viremia and/or seroconversion, which would indicate the presence of live virus in the inoculated material. Since live animals are used and need to be housed for several weeks before results can be obtained, the disadvantages of this test are cost, additional labor, and prolonged evaluation time. However, bioassays are one of the most sensitive and conclusive methods to determine whether a particular sample is infectious and could be transmitted to other swine. Swine bioassays have been utilized to determine the relative bioavailability of lead in soil (although this practice is being replaced by nonanimal assays) (Casteel et al. 1997), and mouse bioassays have been used to detect the presence of infectious *Toxoplasma gondii* in swine sausages (De Oliveira Mendonça et al. 2004).

Buffered *brucella* antigen test

There are several *Brucella* sp. tests available including the buffered acidified plate antigen (BAPA), buffered Brucella antigen test (BBAT) or card test, rapid automated presumptive (RAP), rivanol plate agglutination test (RIV), standard plate test (SPT), standard tube test (STT), complement fixation test (CFT), and the fluorescence polarization assay (FPA). Most *Brucella* sp. serology assays use the cattle antigen, *Brucella abortus*, to test swine sera for *Brucella* sp. antibodies. A positive reaction is visually discerned by agglutination of the sera with the antigen. None of these tests are specific for *Brucella suis* since there is extensive cross-reaction between the *Brucella* species, which can cause false-positive reactions (Nielsen et al. 1999). The card test is the most commonly used screening test for pigs. Serum reacting with the card test can also be tested using other assays to corroborate or refute a positive result. The FPA is commonly used as the follow-up test to sera reacting with the card test. Although the FPA is reportedly more sensitive and more specific than the current World Organization for Animal Health (OIE)-recommended BBAT, the fact that some pigs do not generate antibodies following *B. suis* infection restricts the use of these techniques for individual testing (Nielsen et al. 1999). State Board of Animal Health testing requirements vary from state to state as to what is an acceptable screening test and what follow-up test can be used for reacting sera. Some states will accept follow-up testing by state diagnostic labs, while some states insist that all follow-up testing be conducted by the National Veterinary Services Laboratory (NVSL). The NVSL result is accepted as the official final result. The best policy for *Brucella* serology testing is to know what screening test and follow-up test are required for a state or a foreign destination. State diagnostic labs will most commonly know the testing requirements for different states and countries.

Clinical pathology

Performing complete blood counts (CBCs) may indicate anemia, which could indirectly implicate an infectious agent such as *Eperythrozoon suis* (*Mycoplasma suis*). However, for direct identification, PCR tests might be used, since there are many other noninfectious causes of anemia. CBCs and clinical chemistries could also be useful in determining the presence, severity, and/or location

of inflammation, organ dysfunction, an infectious agent, or toxicant. Values of CBC or clinical chemistry parameters should be compared against normal ranges identified specifically for swine and may be dependent on age, sex, and breed (Evans 2006). Normal pig values within a specific farm are useful for comparisons.

Complement fixation

This is an immunological method used to detect antigens in infected tissues and fluids, measure antibody responses in naturally or experimentally infected pigs, and assay antigenic relationships among different strains or types of the same pathogen species (Rice 1960). For example, this test was commonly used to detect antibodies against *A. pleuropneumoniae* (Enøe et al. 2001) until a commercial ELISA test became available. Complement fixation (CF) testing is based on the ability of antigen–antibody complexes to bind to complement (plasma proteins that combine with antibody to destroy pathogens) and cause hemolysis of sheep red blood cells (sRBCs). A known concentration of sRBC and anti-sRBC antibodies is added to the assay and allowed to react with complement. In samples containing specific antibodies against the antigen of interest, antigen–antibody complexes will form and will consume the available complement prior to the addition of sRBC. Hence, a sample positive for the antibodies of interest will show minimum hemolysis. Serum samples lacking specific antibodies to the target antigen will show maximum hemolysis of sRBC.

The CF assay detects antibodies against any antigen and has been used as a regulatory test for interstate or international movement of animals. However, it is rarely used in diagnostic laboratories since it takes 2 days to complete, has extensive requirements regarding standardization of the necessary reagents, and, in most laboratories, has been replaced by ELISA testing.

Electron microscopy

Electron microscopy (EM) can be used to visualize pathogens, particularly new and emerging viruses, when diagnostic reagents are not available (Chen et al. 2014). EM can also be useful in determining the cellular pathogenesis of an agent as an aid in developing intervention strategies. The strength of EM is its ability to identify a virus family in both antemortem and postmortem sample. The weaknesses of EM include its lack of sensitivity, inability to differentiate viruses within a family, dependence on a stable and detectable virus structure in samples, and the cost of maintaining the scope and hiring trained personnel. EM has a lower limit of detection with negative stain methods of approximately 10^6 virus particles per milliliter of sample and therefore is useful for detecting viruses in enteric cases since crude fecal suspensions routinely have greater than 10^6 particles of pathogenic viruses per gram of feces. Screening for known agents by EM has largely been replaced by PCR. For example, EM cannot adequately detect and differentiate group A, B, and C rotaviruses in comparison with PCR, but it can be used as a method to corroborate the identification of virus by other techniques. Next-generation sequencing (NGS) has the potential to further reduce the value of EM in pathogen discovery.

Enzyme-linked immunosorbent assay (ELISA) (antibody ELISA and antigen ELISA)

A variety of ELISA-based tests are routinely used in herd health monitoring and disease diagnosis. ELISA technologies are particularly useful for rapid, high-volume sample analysis, and many ELISA kits are commercially available for agents associated with major disease syndromes in swine. Variations of ELISA technology can be used for the detection of antibodies against a given pathogen (antibody ELISA) or for the detection of the actual pathogen (antigen ELISA). The diagnostic sensitivity and specificity of ELISA tests are highly dependent on the selection and quality of reagents used in the assay and the intended purpose of the assay. A highly sensitive assay may be more desirable when monitoring for a reportable disease of low prevalence, and a highly specific assay may be more desirable as a confirmatory test. When used for the detection of antibodies against a particular pig pathogen, the most common ELISAs are the indirect and competitive or blocking assay. Indirect assays typically utilize a purified antigen that is coated on test wells, and unreacted well areas are subsequently coated by a protein solution to minimize nonspecific antibody attachment. Typically, a single dilution of test sera is then placed in the test wells and incubated. If antibody is present, it will bind to the test antigen. Next, an enzyme-labeled indirect or secondary antibody directed against swine antibodies is added, and when the substrate of the enzyme label is added, a color change results. The intensity of the color is measured as an optical density (OD), which is evaluated in the context of the OD of a positive and negative control. A formula is then used to obtain a sample-to-positive (S/P) ratio (the sample OD on the test well divided by the positive control OD). A "cutoff" level is designated for positive and negative results. The S/P is not generally considered a "titer" since it does not use a serial dilution of the serum to obtain a result that is immunologically meaningful, whereas a

serum titer is primarily defined as the reciprocal of the greatest dilution in a dilution sequence that produces an immunological response. For example, the titer of a serum neutralization assay (serum virus neutralization [SVN]) or hemagglutination inhibition (HI) antibody assay measures an amount of antibody in serum that neutralizes the virus or that prevents hemagglutination, respectively. In some cases, the S/P may be loosely correlated with a titer if a linear relationship can be established.

Sera may be screened for antibodies with an indirect ELISA. When unexpected positive findings are obtained, a blocking ELISA might be used to determine specificity of the findings for confirmatory purposes (Erlandson et al. 2005). A competitive or blocking ELISA is performed by coating test plates with an antigen lysate followed by blocking as for the indirect ELISA. Then, the diluted test serum is added to allow it to react with the test antigen. At the same time or after washing, a specific enzyme-labeled antibody directed against the test antigen is added, resulting in competition with the test serum antibodies. Negative serum samples result in maximum color development (lack of competition/blocking), whereas samples with specific antibodies show less color development (competition/blocking) with increasing antibody levels. This type of assay has been used for differentiation between pseudorabies virus G1- or gE-deleted vaccinated and infected pigs as well as with IAV, which uses a nucleoprotein antigen.

The greatest strengths of ELISA for antibody testing are high throughput volume, speed of testing, and sensitivity and specificity of the test. Antibody ELISAs are useful as herd screening assays; however, if ELISAs are used to determine an individual pig status, false-positive reactions have been observed in some cases and can be difficult to interpret. Repeating the test, obtaining a second serum sample for testing, or using another serological test for confirmation may be useful (O'Connor et al. 2002). However, other assays for antibody detection such as the indirect fluorescent antibody (IFA), immunoperoxidase monolayer assay (IPMA), HI, virus neutralization (VN or SVN), and CF tests may be more complex and typically require more time for antibody confirmation.

In addition to numerous applications in antibody detection, ELISA technologies can also be used for the detection of antigens. Antigen detection ELISAs may utilize various assay formats including traditional ELISA plate formats or lateral flow devices, often called immunochromatographic strips. Antigen detection ELISAs use test wells or plates coated with specific antibodies rather than antigens as would be used in an antibody detection ELISA. Lateral flow tests typically use a solid-phase membrane with test and control lines coupled with absorbent pads. The strips may be placed into a test sample, or the sample may be added to a designated area of the strip. These test formats may be used with serum or whole blood samples, tissue homogenates, or fecal samples, depending on localization of the targeted pathogen, available processing methods, and quantity of target antigen present in a given specimen. A variety of immunoenzymatic assays for swine diagnostics are available for pathogens such as IAV, classical swine fever (CSF), group A rotaviruses, and PCV2. The primary strengths of antigen detection immunoassays are that they are generally rapid, are simple to perform, and require minimal laboratory infrastructure relative to VI, PCR, or EM. Some lateral flow devices have been adapted for on-site application in field or farm settings. However, assay sensitivity may present challenges for the detection of some pathogens, and timing of sample collection may be critical. The antigen of interest must be present in adequate quantity to allow direct detection by these methods, and appropriate high-quality antisera or monoclonal antibody (mAb)-based reagents must be available for assay development.

Fluorescent antibody or indirect fluorescent antibody for antigen detection

Detection of virus-infected cells from frozen tissues of diseased animals is a classical diagnostic technique that is very rapid and specific. It is used as a presumptive test to quickly identify if a given pathogen is present, since a diagnosis is often completed in less than 6 hours of sample receipt. Another important use of fluorescent antibody (FA) is identifying viruses that may not cause a cytopathic effect (CPE) in cell culture. When monospecific antisera are used, immunological confirmation of the infectious agent and precise identification is rapidly confirmed. There are two basic FA procedures: direct and indirect. The direct FA utilizes a fluorescent-labeled primary antibody, while the IFA uses an unlabeled primary antibody followed by a labeled antispecies antibody that binds to the primary antibody. Both assay formats should use antibodies that are monospecific and do not react with other pathogens. Due to the stoichiometry/geometry of the assay systems, the indirect assay tends to be more sensitive than the direct assay. However, a properly prepared direct FA conjugate will provide brilliant fluorescence that is easily read with a fluorescent microscope. The direct staining procedure is usually shorter (about 45 minutes), whereas the indirect staining procedure takes longer (1–2 hours). Frozen section testing for specific pathogens is accomplished by mounting target tissue from a diseased animal onto a cryostat specimen holder (chuck), freezing the tissue in the cryostat, and skillfully cutting serial sections for

FA staining (usually for multiple pathogens). Once the sections have been collected on glass slides, they are fixed in acetone to keep the tissue on the slide during the staining procedure and permeabilize cells so primary antibodies can react with viral antigens in infected cells. Staining of the sections is accomplished by rehydrating the tissue, reacting with the primary antibody (with or without a fluorescent label) against the pathogen of interest, washing excess reagent from the slide, and, in the case of direct FA, mounting and adding a coverslip immediately prior to viewing with the FA microscope. If the indirect staining procedure is used, the washed section is reacted with the secondary antibody with a fluorescent label, washed, mounted, and coverslip for microscopic exam. For ease of viewing frozen section samples, counterstains like Evans blue are sometimes added to the conjugate. FA staining for pathogen detection in cell cultures is similar to the processes described above except aqueous acetone is typically used to fix the assay plates when the cells are grown on plastic. Staining of virus isolation (VI) cultures is usually done at the first appearance of CPE or at a fixed time, usually 3–5 days post inoculation to detect non-cytopathic viruses or cultures with minimal infection. FA staining for viruses is used almost daily in some diagnostic virology labs since it provides a quick, inexpensive, presumptive diagnosis. The quality of the primary antibody is critical to obtaining accurate results, so these reagents should be fully characterized for their specificity and sensitivity. False-negative results can occur if the cut tissue section does not have any infected cells. A shortage of highly trained technicians, along with newer techniques like PCR and ELISA, has decreased this testing in some diagnostic laboratories. In addition, immunohistochemistry (IHC) and *in situ* straining techniques are used in place of FA to show a correlation with histopathology and specific cell types.

Fluorescent microsphere immunoassay

Simultaneous detection of multiple targets within one sample has been developed using the fluorescent microsphere immunoassay (FMIA). These assays use multiple beads, each having a distinct dye ratio to distinguish them from each other in a flow cytometric instrument (Luminex xMAP™, Luminex Corporation, Austin, TX). Individual beads are then coated with different antibodies or recombinant proteins to capture antigen (e.g. bead is coated with a specific antibody to the target antigen) or antibodies (e.g. bead is coated with the specific antigen to the antibody) within a sample, and the instrument measures the fluorescence of a secondary fluorescently marked antibody if the target molecule binds to the bead. Beads may also be coated with nucleic acid probes, which can then bind to a complementary DNA (cDNA) target. This method may or may not use PCR as an initial step prior to detection (Mahony et al. 2007). Currently, the assay has been developed to detect swine pathogens and immune proteins (Deregt et al. 2006; Lawson et al. 2010; Okda et al. 2015). This assay may be highly relevant in the future for herd profiling and management decisions, since it simultaneously detects antibodies against multiple pathogens (Khan et al. 2006).

Hemagglutination inhibition (HI)

An inherent structural capability of some viruses to bind or agglutinate red blood cells (RBCs) is referred to as hemagglutination. This capability can be used to detect the presence of antibodies that bind to hemagglutination-associated structures or epitopes on the virus inhibiting the virus' ability to hemagglutinate RBCs (e.g. adhere to RBCs). HI activity tends to correlate well with protection – the higher the antibody titer, the greater the level of protection. HI testing is currently used most extensively for IAV serological testing, evaluation of IAV strains for autogenous vaccine formulations, and detection of antibodies to porcine parvovirus (PPV) and hemagglutinating encephalomyelitis virus. In the HI test, if specific antibodies in the test serum bind the hemagglutinating portion of the virion, hemagglutination of RBCs (which are added to the test) is blocked, resulting in a "button" of RBCs at the bottom of a microtest plate well (e.g. positive result, indicating antibodies to this antigen are present). If the RBCs do agglutinate with the virus after serum is added, this would indicate that the sera do not have antibodies, and a uniform mat of RBCs is observed at the bottom of the test well (e.g. negative result, indicating antibodies to this antigen are not present). Swine serum samples must be pretreated to remove nonspecific hemagglutinins and/or hemagglutination inhibitors. Generally, an initial serum dilution of 1 : 10 is used for the assays, and serial dilutions are then made to determine a titer, which is the highest dilution at which there is no longer sufficient antibody present to inhibit agglutination.

For influenza viruses of swine, the test is subtype specific, which means that the H1 or H3 type of the viral test antigen must be cross-reactive with the type of IAV present in swine herds. HI tests can also be developed with a farm-specific strain. Monitoring infection with a specific strain can be more informative. For North America, in 2010, a total of no less than six HI test antigens should be available for test purposes: alpha H1N1, beta H1N1, gamma H1N1, delta H1N1, novel (pandemic) H1N1, and H3N2. Fortunately, the 2001 beta H1N1 test antigen provided by the US Department of Agriculture to veterinary diagnostic laboratories cross-reacts well with sera from

swine that have been infected with either beta or gamma H1N1 viruses. Sera from pigs naturally infected by novel H1N1 can be reliably tested with gamma H1N1 or homologous test antigens. For non-vaccinated swine, HI antibody titers of 1 : 40 or higher are considered to be indicative of previous infection with H1N1 viral strains. A higher titer cutoff is used for H3N2, 1 : 80, and suspect titers of 1 : 40 in combination with other pigs having titers of 1 : 80 or higher are considered to be indicative of natural infection. However, results on acute and convalescent sera are more meaningful than a single HI result, and the timing of serum collection will affect the magnitude of the HI titer. A universal flu ELISA test detecting, but not differentiating, subtypes would be preferable for obtaining plus/minus results.

For PPV, HI titers of 1 : 256 or greater are usually considered to be indicative of natural exposure. Gilts vaccinated with a killed virus vaccine will commonly develop HI titers up to 1 : 128. It is very common to obtain titers of 1 : 2048 or 1 : 4096 for naturally infected swine. As with most diagnostic tests, developing a specific plan for whom to test and what to test will result in superior results.

Immunohistochemistry

IHC involves the detection of pathogen-associated antigens in formalin-fixed, paraffin-embedded tissues using specific antibody and an enzyme or fluorochrome label. It can be a highly sensitive and specific technique and is widely used in research and diagnostic laboratories. IHC is also of great value in retrospective studies using formalin-fixed, paraffin-embedded tissues. Excellent detailed reviews of IHC methodologies and applications in the diagnosis of swine infectious diseases are available (Ramos-Vara et al. 1999). The basic steps of most IHC procedures include tissue preparation with formalin fixation, paraffin embedding, and sectioning. Since formalin cross-links proteins, which can limit binding of antibodies to specific antigenic sites, various antigen retrieval methods are then used to unmask or uncover antigens for better recognition by antibody reagents. Common methods include enzymatic digestion or heat-induced antigen retrieval. Blocking agents may be required to reduce background staining due to endogenous enzyme activity. Next, the staining steps may involve direct or indirect procedures. Indirect staining protocols are the most common due to their greater sensitivity. A specific primary antibody is typically followed with a labeled secondary antibody. An avidin–biotin complex (ABC) method is commonly used whereby an unlabeled primary antibody is followed by a biotinylated secondary antibody, and then an avidin–biotin peroxidase reagent reacts with a substrate to produce a colored product.

A major strength of IHC is that it allows clear association of antigen detection with specific histological lesions. This is particularly useful in identifying whether a specific pathogen (e.g. PCV2) is the etiology for a given disease (e.g. post weaning multisystemic wasting syndrome [PWMS]), since some pathogens are detected more frequently than the syndrome. It may also allow for some level of antigen quantitation; however, the antigen may not be evenly distributed throughout a given tissue, and selection of appropriate specimens can be critical. IHC requires the availability of high-quality antibody reagents and highly optimized fixation and staining methods with the use of appropriate controls.

Indirect immunofluorescence (indirect immunofluorescence or indirect fluorescent antibody [IFA]) and immunoperoxidase monolayer assay (IPMA) for antibody detection

IFA and IPMA are used to detect the presence of antibodies against some infectious agents. IFA assays utilize a fluorescent-labeled secondary antibody and require a fluorescent microscope. IPMA utilizes a peroxidase-labeled secondary antibody and appropriate chromogen and can be read using a standard light microscope. The colored reaction of the IPMA is more stable than fluorescence. Three of the most common IFA assays routinely used in swine diagnostics are for PRRSV, PEDV, and PCV2 (Madson et al. 2014; Magar et al. 2000; Yoon et al. 1992). The basic procedure involves preparation of infected monolayers of permissive host cells on glass slides or 96-well cell culture plates, typically with paired wells of noninfected host cells as controls. Cell monolayers are fixed with aqueous acetone or acetone/methanol to permeabilize cell membranes and allow antibody access to internal viral proteins. Dilutions of test swine sera and control sera are incubated with the cells; then, a secondary labeled antiswine immunoglobulin G (IgG) or immunoglobulin M (IgM) antibody is added. After washing, cell monolayers are viewed under a fluorescent microscope, and antibody titers are reported as the highest serum dilution showing virus-specific fluorescence. Similar assays have been developed for porcine enteroviruses (Auerbach et al. 1994), *L. intracellularis* (Knittel et al. 1998), and other pathogens. Most IPMA procedures utilize a similar protocol except the secondary antibody is labeled with peroxidase and followed by a chromogen to provide color development (Guedes et al. 2002). Both the IFA and IPMA measure the binding of specific antibody to antigens in infected host cells, but the IPMA results can be detected without a fluorescent microscope. The IPMA has been used for detection of

PRRSV, particularly European strains, since these strains grow well in porcine alveolar macrophages (PAMs) rather than a continuous cell line, and the IPMA staining is easily observed in PAMs. One advantage of IFA and IPMA methods is that they can provide relative antibody titers by using serial dilution of samples. However, interpretation can be somewhat subjective and dependent on the experience of the technician. These assays also require replication of the indicator virus or intracellular bacterium in cell culture. When dealing with antigenically variable viruses, such as PRRSV, assay sensitivity can be affected by antigenic differences between the virus strain used in the assay and the strain infecting a given group of animals. Table 6.3 demonstrates the effect of strain variation on PRRSV IFA titer results.

Microscopic agglutination test

The microscopic agglutination test (MAT) is the reference test for serological diagnosis of leptospirosis in swine. This test is based on the reaction of specific antibodies and live *Leptospira* sp. bacterial cells. A mixture of test serum with live *Leptospira* sp. cells results in agglutination, which can be visualized using dark-field microscopy. Results are reported in titers, indicating the highest dilution that resulted in agglutination of 50% of the live *Leptospira* cells compared with the control (Chappel et al. 1992).

Laboratories that are able to maintain live *Leptospira* cultures for clinically relevant serovars affecting swine easily perform the MAT. It is a fairly sensitive test, inexpensive, and quick to perform, and the agreement between high MAT titers (>1 : 1024) and isolation of *Leptospira* from infected pigs is significant (Chappel et al. 1992). A limitation of the MAT is the subjective definition of a positive result, which varies among technicians and laboratories. Additionally, one single reading is of low diagnostic value. Different laboratories utilize different cutoff titers to define a positive sample, so two consecutive tests within a 2-week interval are recommended to detect convalescent titers indicative of infection. Considering that MAT detects both IgM and IgG, cross-reactions among serovars are commonly observed in acutely infected pigs, whereas the second test provides more specific results regarding the serovar affecting the herd (Ahmad et al. 2005).

In situ hybridization

In situ hybridization (ISH) uses either a radioisotope, fluorescent, or enzyme-linked nucleic acid (DNA or RNA) to hybridize to a specific cDNA or RNA sequence of a specific pathogen in a tissue section. This technique is distinct from IHC, which identifies protein antigens (rather than nucleic acid) in tissue sections. ISH can be used in infectious disease diagnosis since DNA or RNA probes specific

for pathogen sequences allow direct visualization of the site of pathogen replication in a tissue. It is possible to use radioactive and nonradioactive probes to simultaneously detect multiple transcripts. The most common technique used in the veterinary diagnostic laboratory utilizes digoxigenin-labeled probes. A positive hybridization signal is visualized in tissue sections after using IHC staining methods. The general method for ISH involves permeabilization of the cells with proteinase K, binding of the labeled DNA or RNA probes, antibody–phosphatase binding to the probe, and staining of the antibody with alkaline phosphatase. ISH is particularly useful for pathogenesis investigations and the precise identification of target tissues where the pathogen is replicating. The ISH procedure is very useful when the nucleic acid sequence of the pathogen is known, but no antibody-based reagents are available. The technique is extremely sensitive and has been used to study a number of pathogens including PRRSV, PCV2, and torque teno virus. Typically, ISH is more sensitive than IHC, which requires higher numbers of target molecules to produce a positive reaction. In addition, for pathogenesis studies, ISH signals may be present longer postinfection (since the RNA or DNA of the organism is still present) when antigen production is below the levels of detection. ISH is not performed in every diagnostic laboratory and has been used primarily as a research tool rather than a standard diagnostic test.

Parasite (internal) identification

Fecal flotation is used to identify specific parasitic egg morphology since adult worms are often not readily speciated. Feces are mixed with a solution (e.g. sugar solution) that has a specific gravity higher than the parasite egg. With centrifugation or passage of time, the eggs float to the surface of the solution, a microscopic coverslip can be applied, and the egg morphology is evaluated via a light microscope (Corwin 1997). This is a quick, low-cost test. To distinguish eggs from other debris, it is also important to evaluate egg size. Very small parasitic eggs such as cryptosporidia may not be identifiable via morphology, and FA or fecal ELISAs might be used. For zoonotic parasitic agents such as *Trichinella* and *Toxoplasma* sp., serological antibody ELISAs have been utilized (Gebreyes et al. 2008).

Polymerase chain reaction (PCR)

DNA and RNA extractions for detection of pathogens by polymerase chain reaction

Prior to PCR detection, the nucleic acid (RNA or DNA) of the pathogen is extracted from the specimen. Extraction is the chemical, physical, or mechanical process needed to recover, concentrate, and purify the RNA or DNA from a mixture of proteins, lipids, carbohydrates, or other materials that might be found in the clinical specimen, and it allows the PCR to proceed without interference and inhibition from these substances. There are rare circumstances where extraction may not be needed prior to PCR, but a comparison with and without extraction would need to be performed, verifying that the PCR gives the same specificity and sensitivity. There is several commercially available extraction protocols designed for specific specimens (e.g. serum, tissues, cells, whole blood) and for the specific nucleic acid that is being extracted (e.g. total RNA, viral RNA, messenger RNA, DNA, total nucleic acid) that can be performed either manually or with automation. These extractions may differ in the mechanical processes used for extraction (e.g. boiling, vortexing, sonicating, physical disruption using glass beads or enzymes) and separation processes, whereby the nucleic acids are separated from other substances with organic solvents (e.g. phenol–chloroform) or by binding to silica or magnetic beads. Since various sample types are being used for swine diagnostics such as oral fluids, semen, or blood swabs (whole blood in saline) where commercial kits may not be specifically designed for these specimens, a comparative study between these protocols needs to be performed to ensure the best sensitivity and specificity. In addition, extraction protocols are frequently improved and further refined for various specimens, so the most current, well-validated extractions need to be used. In evaluating various extraction protocols, the quality, quantity, and how well the extracted nucleic acid works in PCR need to be tested using a wide range of amounts of extracted nucleic acid in the PCR assay.

Polymerase chain reaction process

PCR is a technique that utilizes the necessary reagents and conditions to exponentially amplify DNA or RNA *in vitro*. In a diagnostic laboratory setting, PCR is mainly associated with the amplification of species-specific nucleic acid sequences from clinically relevant viruses and bacteria present in clinical samples. Amplification of nucleic acid from selected pathogens can be followed by sequencing of target segments to improve pathogen identification or define strain groups.

The basic concept of nucleic acid amplification starts with RNA or DNA extraction, followed by exponential amplification of the DNA through thermal cycling at various temperatures. The temperature variations provide for enzymatic reactions that cause conversion of the RNA to DNA (a reverse transcriptase reaction, if RNA is the starting material) followed by denaturation of the DNA, primer binding, and elongation of the copy of

DNA with the Taq polymerase enzyme. The temperature cycles are then repeated approximately 30–40 times so that theoretically, doubling of the DNA occurs (100% efficiency) during each temperature cycle, and billions of DNA copies can be obtained from one copy. Traditional detection of amplicons using gel-based methods is still used by many laboratories worldwide; however, highly sensitive and specific automated detection systems such as real-time PCR are rapidly substituting gel-based methods.

Independent of the detection system, PCR is today the gold standard for sensitive and specific detection of viral and bacterial pathogens in clinical samples. It has major advantages compared with culture for detection of bacterial pathogens previously treated with antibiotics (i.e. nonviable). In addition, it improves turnaround time from many days to a day for detection of certain fastidious viral and bacterial pathogens.

Gel-based polymerase chain reaction

Gel-based PCR uses agarose gels for detection of amplicons produced during PCR. The PCR that precedes gel-based detection utilizes a pair of species-specific primers that will anneal to the target nucleic acid and initiate the replication of target sequences by the polymerase enzyme. Once amplicons are produced, PCR products are loaded onto precasted wells in an agarose gel, and an electric current is applied to the system (electrophoresis). PCR products will migrate through the gel and will be separated by size with the smaller fragments migrating faster through the gel and identified with a lower base pair (bp) size. A known positive control is used in every PCR to assure that the amplicon obtained from clinical samples has the expected bp size for the pathogen of interest. A specific band should have the same size as the band observed for the positive control. The absence of a band is interpreted as a negative result. Amplicons are visualized on agarose gels by utilizing an intercalating fluorescent dye that binds to double-stranded nucleic acid and fluoresces under ultraviolet (UV) light. Gel-based PCR methods can be adapted to detect multiple targets (multiplex PCR). The sensitivity of this method can be considerably improved by performing a two-step amplification method known as nested PCR. In nested PCR tests, an external set of specific primers is used for the initial detection and amplification of the target sequence in the clinical sample followed by a second amplification utilizing a nested (internal) set of primers. Gel-based PCR can also be used to genotype bacterial (Oliveira and Pijoan 2004) and viral isolates (Wesley et al. 1998).

Gel-based methods are easily developed and standardized, do not require expensive equipment, and have a lower cost compared with real-time PCR. The main limitations of gel-based PCR tests are the lower sensitivity (if nested PCR is not used), the subjective interpretation due to visual inspection of bp sizes on the gel, and the time required to obtain final results, since it requires four steps: extraction of the RNA or DNA from the clinical sample, a PCR, gel electrophoresis, and visualization of the gel under UV light for detection. Another main limitation of gel-based methods is the need to open the PCR tubes after amplification for electrophoresis. The millions of amplicons that are produced during PCR can aerosolize and contaminate the laboratory, especially when nested PCR tests are used where tubes are opened more often. Nested PCR tests may cause contamination, resulting in false-positive reactions unless the laboratory has stringent requirements for prevention. These would include the use of aerosol-resistant pipette tips, dedicated rooms, instrumentation and equipment for setup rooms, and rooms where the PCR is performed, adding positive controls after samples are set up and adjusting positive control samples to be at approximately the same quantities as to what might be in clinical samples. The limited number of samples that can be performed on an agarose gel is another drawback of gel-based methods (e.g. approximately 14–28 samples can be evaluated on a single gel) compared with real-time protocols (e.g. approximately 96–384 samples can be evaluated on a single instrument).

Real-time polymerase chain reaction

Real-time PCR uses an automated system that allows for detection and quantification of PCR products as they are amplified ("real-time" detection), without the need for gel-based detection ("endpoint" detection). Production of double-stranded nucleic acid amplicons is reported as it occurs by fluorescence, which is captured, analyzed, and reported by a computer attached to the real-time thermal cycler. Most diagnostic laboratories to identify swine pathogens in clinical samples utilize two main signaling systems: double-stranded DNA intercalating dyes and labeled hydrolysis probes (Hoffmann et al. 2009).

Intercalating dyes such as SYBR Green® (Life Technologies, Carlsbad, CA) bind specifically to double-stranded nucleic acids (amplicons in positive samples), resulting in fluorescence, which is captured and reported in real time by the computer-based detection system. A melting curve analysis, which compares the temperature needed to separate the double-stranded amplicons produced in positive samples and that of the positive control, is performed at the end of the reaction to confirm the specific detection of the target sequence.

TaqMan® probes (Life Technologies, Carlsbad, CA) (a specific type of hydrolysis probe) can also be used to

report the presence of pathogen nucleic acid in clinical samples using real-time PCR. Probes are short oligonucleotides labeled with a fluorescent dye at one end and a quencher at the other end. The quencher is responsible for inhibiting light emission by the fluorescent dye in intact probes. The probe, forward, and reverse primers are specific and complementary to the nucleotide sequence of the pathogen of interest. Once the probe binds to the target DNA (if the target is present), it will be cleaved by the DNA polymerase during the amplification process, the quencher will separate from the fluorescent dye, and the fluorescence will be captured and reported by the real-time equipment, confirming the presence of the target pathogen in the sample.

Real-time PCR has several advantages compared with gel-based methods. It is usually more sensitive, since detection of positive samples is based on computerized recognition of light emission instead of visual inspection, and highly specific, considering that positives are confirmed based on melting curve analysis or by species-specific probes. Real-time assays can be quantitative, allowing the characterization of pathogen load in the sample.

Quantitative polymerase chain reaction

Quantitative PCR in swine diagnostics is typically performed through a real-time PCR assay, whereby a standard curve is derived using a known amount of serially diluted RNA or DNA. The amount of nucleic acid in the clinical samples is then extrapolated from this standard curve. Since the nucleic acid is being amplified in a PCR assay, the number of DNA copies would be a standard method of reporting. When the DNA from a sample is amplified during real-time PCR, the fluorescent intensity that occurs will cross a specific threshold at a given cycle number during the PCR thermal cycling process. This cycle threshold (Ct) will be obtained, and the Ct is inversely proportional to the amount of DNA present in the sample (e.g. a sample that has a Ct of 25 typically has a higher amount of DNA present than a sample that has a Ct of 35). Quantitative PCR results are often used as a measure of the amount of infectious pathogen present within the individual or swine population. It has also been useful in research studies to determine the efficacy of vaccines (Zuckermann et al. 2007) and virulence of various strains of PRRSV (Johnson et al. 2004). However, PCR is only measuring the amount of nucleic acid present (RNA or DNA), and there may not be any infectious (replicating) pathogen within the sample, even though the nucleic acid is detected. As one scientist stated, "we can detect and measure the amount of DNA present in King Tut, but that doesn't mean he is alive and well and running around." For example, PRRSV may be detected in serum by PCR but may not grow in cell culture in all samples or be infective in pigs (Figure 6.2).

This needs to be considered when PCR results are obtained and used to evaluate the "infectivity" of clinical samples such as environmental samples. However, in cases where there is a fresh, well-maintained sample submitted, there will most likely be some relationship between the amount of nucleic acid detected and the amount of infectious pathogen detected. When VI and PCR detected serial dilutions of PRRSV, there was approximately a 3 log higher concentration by PCR (copy/mL) than by VI (tissue culture infective dose 50 [$TCID_{50}$]/mL) (Figure 6.3).

However, the difference between infectious dose and DNA copies obtained through PCR can be variable depending on cell culture and PCR conditions used by different laboratories. The higher levels in copies/mL versus $TCID_{50}$/mL have also been observed with PCV2 (Gilpin et al. 2003). A higher copy number can be observed since the sample may have some noninfectious or replication defective virus present; there may be a greater amount of subgenomic viral nucleic acid measured since purified virus is not typically obtained from clinical samples; cell culture does measure the presence of infectivity, but it is still an "artificial" system since the virus is grown on a cell monolayer that may not be porcine derived and on a plate or flask. Therefore, VI "may not count all particles present in a preparation, even many that are in fact infectious" (Condit 2007). Factors that could affect the infectious titer in cell culture include pH, the cell culture media used in the isolation, incubation time, cell type used, viral strain, sample submission and handling, and *in vivo* antibodies, which may neutralize virus. Therefore, some caution is indicated in extrapolating results from PCR and equating them with the amount of infectious virus ($TCID_{50}$).

Multiplex polymerase chain reaction

Multiplex PCR refers to the simultaneous detection of multiple targets by PCR within a single sample. Multiple primer sets (or primer/probe sets for real-time PCR) are used to detect the multiple targets. A significant amount of optimization is needed to obtain similar sensitivities and specificities as detecting each target individually, thus somewhat limiting the number of targets that can be detected simultaneously. Multiplex PCR assays have been used in swine diagnostics to determine *Clostridium perfringens* toxin genotypes (Meer and Songer 1997), *E. coli* toxin and fimbriae types (Zhang et al. 2007), and multiple viruses or viral genotypes (e.g. PCV1 and PCV2; type 1 and type 2 PRRSV; multiple IAV subtypes) within a single sample.

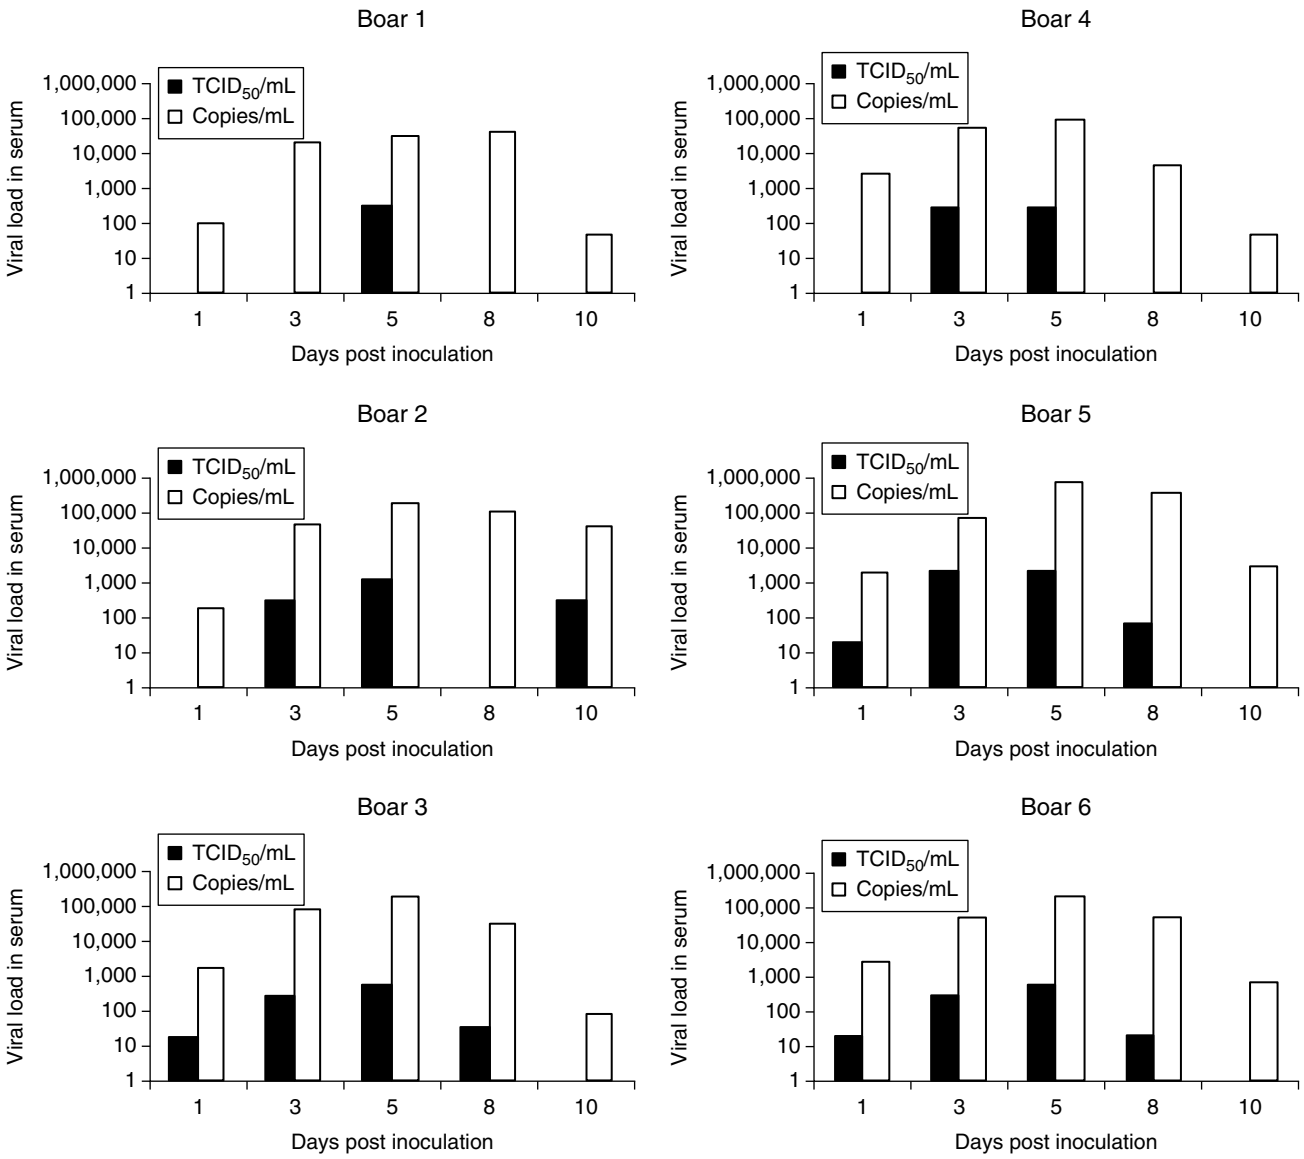

Figure 6.2 Viral load in serum, in $TCID_{50}$/mL, as determined by virus titration and in number of copies/mL as determined by quantitative real-time PCR. Values are for the first 10 days post inoculation for each PRRSV-inoculated boar. *Source:* Wasilk et al. (2004). Reproduced with permission of American Society for Microbiology.

Sequencing (nucleic acid)

Nucleic acid sequencing is a powerful tool that adds specificity and discriminatory power to veterinary molecular diagnostics. It is a rapidly evolving technology, which has undergone three generations of development. Of these, dideoxy chain termination sequencing developed by Frederick Sanger is the first-generation sequencing technology that was widely used. Sanger sequencing complements detection by PCR by further confirming the detection of the pathogen of interest and also characterizing it to the strain level, for example, fastidious bacterial pathogens (e.g. *Mycoplasma hyorhinis*, *Mycoplasma hyosynoviae*, *Brachyspira* sp.). It is also used to type bacterial and viral isolates such as *M. hyopneumoniae*, PRRSV, PCV2, and IAV DNA or cDNA (produced by PCR from RNA).

The current Sanger sequencing method adopted by most diagnostic laboratories utilizes PCR amplicons obtained from clinical samples, which are purified and sequenced. Usually, the same gene utilized for detection of a specific pathogen is also sequenced for strain typing. Amplicons produced by PCR are purified and sequenced using an automated dye-terminator method. Each of the four dideoxynucleotide chain terminators (adenine, guanine, cytosine, and thymine) is labeled with a different fluorescent dye with distinct wavelengths. The sequencing reaction functions as a regular PCR, with the incorporation of labeled dideoxynucleotides being reported to a fluorescence reader. Each fluorescence peak is recorded in a chromatogram, which reports the sequence for the amplicon of interest. The chromatogram is useful for visual inspection of the quality and purity of the sequence. It can be edited and trimmed prior to reporting of the final sequence as a text file.

DNA sequencing is mostly used as a tool to investigate and characterize the molecular epidemiology of the pathogen of interest. It provides information on strain variability and allows swine veterinarians to troubleshoot biosecurity breaches, to determine whether vaccination or treatment was successful, and to identify the emergence of new strains. Although sequencing one single gene is feasible for diagnostic laboratories and affordable for swine veterinarians, it does provide limited information, and the significance of the differences between strains should be carefully evaluated. For example, at this time, there is little information in the literature regarding the biological importance of sequence data regarding virulence and cross-protection. Interpretation of sequencing information is unique for each pathogen, and inference of virulence and protection will depend on the gene that is being sequenced. Another limitation of sequencing is that it usually requires a higher pathogen load in the sample to generate accurate data compared with detection by PCR. It is not uncommon to have samples positive for a pathogen by PCR, which can generate unreliable or no sequence data. Specific genomic regions of several swine viruses have been sequenced including those for swine influenza virus, PRRSV, PCV2, CSFV, African swine fever virus (ASFV), PPV, transmissible gastroenteritis virus (TGEV), Teschen virus, swinepox virus, vesicular stomatitis virus, vesicular exanthema virus, and FMDV. The purposes of sequencing whole genomes or portions of the viral genome are to determine genetic relatedness between various viral strains, to provide information on changes in a virus over time, to identify mutations and recombination events, to develop molecular diagnostic assays to identify conserved areas of the genome, to confirm diagnostic testing results, to determine whether a vaccine or wild-type virus is present, and to identify novel viruses.

Prior to Sanger Sequencing and second- and third-generation sequencing, typing of bacterial strains has been traditionally performed using gel-based methods (Versalovic et al. 1991). Pulsed-field gel electrophoresis (PFGE) is a genomic fingerprinting method that displays a series of bands on a gel characteristic of a specific strain. Generally, PFGE has higher resolution than single-gene Sanger sequencing. It is generally used to type new variants of a pathogen or to trace pathogen transmission patterns. For example, PFGE was used to determine the transmission dynamics of a *Salmonella typhimurium* monophasic variant in a pig production cycle (Fernandes et al. 2016).

Multilocus sequence typing (MLST) is bacterial sequence-based genotyping method that has typing resolution that is comparable with PFGE. It consists of amplifying and sequencing seven housekeeping genes that generate a species-specific sequence type (ST). MLST schemes have recently been published for several clinically relevant swine pathogens, including *H. parasuis* (Olvera et al. 2006) and *M. hyopneumoniae* (Mayor et al. 2008). Although MLST is highly discriminatory, sequencing of seven genes for each strain is laborious and expensive for routine testing. Similar to viruses, routine bacterial strain typing by sequencing should ideally be based on the direct amplification and sequencing of a single discriminatory gene from submitted clinical samples. This is the case, for example, for *M. hyopneumoniae* strain typing based on P146 gene sequencing. P146 is an adhesion-like protein that is expressed on the surface of *M. hyopneumoniae* and is highly variable among different strains. *M. hyopneumoniae* P146 sequencing is almost as discriminatory as MLST (Mayor et al. 2008). This method was used to prove aerosol transmission of *M. hyopneumoniae* and can also be used to monitor introduction of new strains into the herd (Otake et al. 2010).

Second-generation sequencing is known by different names such as massively parallel sequencing or next-generation sequencing. It is called second-generation sequencing because this was the second successful nucleic acid sequencing technology developed after the Sanger method. Unlike the Sanger method, which can typically sequence about 1000–1500 bp of an amplicon, NGS can sequence entire viral and bacterial genomes. During NGS, sample DNA is sheared at random to generate small fragments. These fragments are then clonally amplified simultaneously to generate a sequencing library. The sequence of each fragment in the library is then determined by the addition of nucleotides complementary to those in the fragments rather than through chain termination chemistry as in the Sanger method. Consequently, the entire sample is sequenced in parallel reactions, resulting in several gigabytes of data from an NGS run. Although there are several commercially available platforms used for NGS, such as Life Technologies Ion Torrent and Roche 454, sequencers developed by Illumina are the industry's leading platform. Since this method can produce gigabytes of data, several bacterial or viral samples can be multiplexed and sequenced together in one NGS run. This is achieved by adding unique fragments of DNA known as bar codes to each sample at the time of sample library preparation and sorting out the reads using bioinformatics software. To ensure the accuracy and probability of pathogen detection, enrichment of samples is often required for NGS. Depending upon the pathogen to be detected and the sample type, this can be done by PCR enrichment or enzymatic methods. For example, primers designed to amplify various segments of the pathogen could be used to selectively amplify the pathogen genome. These amplicons are then used as the input for NGS. This approach has been used to produce full genomes of PEDV from clinical samples (Fan et al. 2017). Depleting the host and environmental DNA from the samples is a common approach used for enriching samples before metagenome sequencing. This is can be achieved by the use of nucleases that selectively degrade host DNA (Feehery et al. 2013). Since NGS produces a massive amount of sequence data, which covers the entire length of sample genome, it has the highest accuracy and power of resolution when compared with any other molecular testing method available today. Because of the unprecedented resolution of NGS, it is being used in several different applications in diagnostic testing. NGS is extremely useful for identifying new variants of rapidly evolving pathogens such as PRRSV (Lu et al. 2014). The application of NGS in PRRSV genome sequencing has allowed the study of PRRSV in unprecedented detail through reconstruction of the full PRRSV genome. This approach is broadly applicable to any of the swine viruses such as influenza (Clavijo et al. 2013). Another major utility of NGS is the traceback or determination of transmission routes of a pathogen. It is particularly useful in investigating zoonotic bacterial pathogens such as *C. difficile*. Recently, NGS-based sequencing of *C. difficile* isolated from humans and swine revealed that the isolates were identical, suggesting transmission between animals and people (Knetsch et al. 2014). Since NGS is highly accurate, it can also be used to rule out pigs as a source of human infections. One such example is an NGS-based finding that a US swine herd was not the source of a human *B. suis* infection. This NGS process and analysis averted a field investigation (Quance et al. 2016). Another major evolving application of NGS is the simultaneous detection, traceback, serotyping, and antibiotic resistance profile of bacteria such as *Salmonella enterica* and *Streptococcus suis* (Athey et al. 2016). During NGS, all the genes including antibiotic resistance genes and serotype-associated genes are sequenced. When NGS was used for analyzing *S. enterica*, a high concordance (99.74%) between phenotypic and predicted antimicrobial susceptibility was detected (Zankari et al. 2013).

Unlike the Sanger method, which requires prior knowledge about the target gene and a validated set of primers available for amplifying the target sequence, NGS does not require such knowledge and can sequence the entire genome. This makes it suitable for detecting unknown bacterial or viral pathogens. For example, when no known viral agent is detected by other testing methods, sample RNA could be converted into cDNA, and the entire cDNA could be sequenced using NGS. Resulting sequences are then used to search against all known viral sequences in public genomic databases to identify related viruses. This approach is called metagenome sequencing since it sequences all known and unknown genomes in the given sample. Metagenome sequencing is advantageous since it involves sequencing nucleic acids from the sample directly without the need for culturing. One example of the success of this approach is the recent discovery of a pestivirus that causes Parkinson's-like tremors and high mortality in pigs (Hause et al. 2015). Metagenomics is useful also for identifying the possibilities of the combined pathobiology behind disease complexes such as PMWS and for detecting the presence of various infectious agents in such complicated disease situations. Although PCV2 is known as the main etiologic agent behind PMWS, NGS-based metagenomics was used to establish that a novel bocalike parvovirus was also associated with PMWS (Blomstrom et al. 2010).

Although NGS is extremely accurate and powerful, it has several disadvantages. The first is the higher cost of the reagents and the sequencing infrastructure. Consequently, the cost per sample for NGS-based testing is much higher than Sanger sequencing-based methods. To be cost effective, several samples need to be

multiplexed in an NGS-based test. If a laboratory does not obtain a sufficient number of samples to multiplex, the test may need to wait for more samples to arrive, or it will need to be run at a very high cost per sample. Secondly, NGS-based tests typically require high capacity computing hardware and a dedicated bioinformatics staff to analyze the data. Because of this, adoption of NGS in veterinary diagnostic laboratories has been slow. However, the infrastructure costs are rapidly declining, making this method more user friendly.

Recently, a third-generation sequencing technology called nanopore sequencing has been commercialized by a company called Oxford Nanopore Technologies (ONT). This is called the third-generation sequencing method because it does not depend on chemistry-based reactions. An ONT sequencer is a handheld device that detects the base sequence of DNA when it passes through nanometer-sized pores in a membrane embedded in the device. Since it detects charge differences in the bases, it can produce extremely long sequences. Often it can identify the entire viral genome without the need for fragmenting samples as in the case of NGS. It is extremely portable and works by connecting to the USB port of a computer. This makes it suitable for field applications such as sequencing virus samples in the field during an outbreak (Quick et al. 2016). A major advantage of this method over NGS is that it is economical to sequence a single sample without the need for multiplexing. ONT nanopore sequencing also has very short detection times (e.g. approximately 1 hour), which is more rapid than PCR and Sanger sequencing. It has been employed to detect antibiotic resistance gene profiles in *Staphylococcus aureus* and *Mycobacterium tuberculosis* (Bradley et al. 2015). It is not yet widely available in the clinical diagnostic laboratories as this method is yet to be benchmarked against the current Sanger sequencing method. Secondly, the error rate in the sequence base calling in ONT sequencing is higher than the previous generation sequencing methods. However, this method is expected to become a common technique in clinical diagnostics. A comparison of sequencing methods is provided in Table 6.4.

Advances in nucleic acid sequencing such as second- and third-generation sequencing are making bioinformatics an integral part of clinical diagnostics. New sequencing methods generate massive amount of data. To be useful, the data need to undergo several steps of analysis. Typical steps involved are removal of error-prone reads, assembly of the sequencing reads into larger fragments called contigs, and then their comparison against a reference viral or bacterial genome. When there are no reference genomes available, reads are assembled using *de novo* assembly algorithms. Genes in the assembled genomes are then determined using a process called genome annotation. These computational steps have been an impediment in the adoption of new sequencing

Table 6.4 Comparison of nucleic acid sequencing technologies that are used (or have the potential to be used) in swine diagnostics.

Sequencing technology	Common uses	Advantages	Disadvantages
1. Amplicon sequencing by the Sanger dideoxy method	• Sequence single genes or PCR fragments amplified from viruses and bacteria (e.g. sequencing ORF5 of PRRSV to determine antigenic variability)	• Low cost • Extremely fast and well established • Data is simple to manipulate and analyze	• Requires prior knowledge about the target and standardized primers • Limited sequence information
2. Second-generation sequencing (NGS)	• Determining the whole genome sequence of viruses and bacteria • Detect emergence of new variants of bacteria and viruses • Traceback studies to identify the source of infection • Identification of unknown causes of infection	• Very high resolution • Can sequence several samples simultaneously • Can be applied to samples without a known sequence or primers available	• High cost per sample • Long turnaround time • Need for bioinformatics expertise
3. Third-generation nanopore sequencing	• Same as NGS	• Same as NGS with turnaround times faster than PCR • Very low infrastructure cost • Extremely portable	• Still evolving method. Data analysis requires a specialist lab with bioinformatics expertise • Needs to be benchmarked against standard methods • Higher error rate in sequence data compared with other methods

technologies in clinical diagnostics. However, easy-to-use bioinformatics analysis applications are being developed. Many of them are cloud-based applications that require uploading of raw sequence data and downloading the results in tabular graphical formats. Some examples for this include an application for determining the serotype of *Salmonella* (Zhang et al. 2015). Combined with declining costs of newer sequencing methods and cloud-based bioinformatics applications, NGS and nanopore sequencing methods are likely to be adopted increasingly in complex clinical cases that are not resolved by other diagnostic methods.

Toxicology/chemistry testing

Toxicities and vitamin or mineral deficiencies can be major contributors to disease syndromes, and diagnostic chemistry testing along with history, clinical signs, and postmortem findings is important in considering a diagnosis. Toxicities are more thoroughly covered in Chapter 70, and excellent references are available (Osweiler et al. 1976; Sachana and Hargreaves 2007).

Virus isolation (VI)

Since viruses are intracellular parasites, VI is used to grow and identify viruses from clinical samples within cells maintained in the laboratory. The variety of cell lines maintained by most laboratories depends on the permissiveness of various cell lines to viruses expected to be encountered. Primary and secondary cell cultures are often prepared from trypsinization of fresh tissues, including primary PAM cultures such as used for PRRSV diagnostics. Alternatively, established continuous cell lines can be used, since they are stable, easier to manage in laboratory settings, and very sensitive for many viruses. Embryonated eggs were widely used for viral diagnosis in the past but are now generally replaced by continuous cell lines. However, they are still used in some laboratories to grow certain strains of influenza A.

Received specimens are processed and inoculated onto susceptible cell cultures and monitored for CPE, which are characteristic morphological changes in a given cell type, such as lysis, syncytium formation, and inclusion body formation. CPE may be characteristic of certain virus infections but often are not definitive, so immunofluorescent staining or other methods are often used for verification. VI is a very sensitive procedure to detect certain viruses that readily replicate in cell culture. It can be highly definitive and may provide a viral isolate for further analysis such as for use in sequencing or production of autogenous vaccines. It can also be used as a test to detect new viruses where PCR is not available due to limited or no sequence information being available for PCR primer design.

Many viruses are very fastidious or may not replicate in the available cell cultures. VI requires freshly submitted samples maintained under refrigeration, and it may require an extended period of time (2 or more weeks) to obtain results. VI requires specialized equipment and skills and high-quality reagents to confirm isolation of a given virus. Additional challenges occur when dealing with specimens that have high levels of bacterial contamination.

Virus neutralization (or serum virus neutralization)

SVN assays can be used to measure the presence of neutralizing antibody to a given virus, indicating previous exposure to the virus. Classical SVN involves the binding of antibodies to virions, preventing infection of susceptible host cells. A variety of SVN assays can be applied to swine diagnostic serology. The assay can provide quantitative results, and testing of paired serum samples (acute and convalescent) can provide an indication of recent exposure. SVN can also be used as a tool in identification of an isolated virus or to determine the serotype or strain of an isolated virus, provided that appropriate monospecific antisera or mAb is available. The identification of group A rotavirus G and P types (which have importance in vaccine selection or development) is one example of this application.

SVN assays are generally highly sensitive and specific due to the very specific nature of antigen–antibody interactions. However, the assays may be too specific for useful general diagnostic applications when dealing with extremely diverse viruses, such as PRRSV, where limited cross-reactivity may be seen among different strains of the virus. Some viruses, such as PRRSV, may not induce robust levels of detectable neutralizing antibodies, or the neutralizing antibody response may be delayed until several weeks or more after initial infection, thus limiting the practical utility of VN assays in routine diagnostics.

When used for the evaluation of virus-specific neutralizing antibodies in serum samples, most SVN assays involve adding a constant amount of virus to dilutions of the serum samples to be tested, along with appropriate control sera. These mixtures are then incubated to allow any neutralizing antibodies present to bind to the virus. Susceptible host cells are then added to the serum–virus mixture, or the mixture is added to existing monolayers of host cells and incubated for 3–5 days until replicating virus induces a visible CPE in the host cells. If no neutralizing antibody is present, CPE will be apparent. If virus-specific neutralizing antibody is present in a given

serum sample, no CPE will be apparent at lower serum dilutions and an antibody titer or endpoint can be determined at a point in the dilution series where CPE becomes apparent.

Variations of the traditional CPE-based VN assays include the plaque reduction neutralization (PRN) assay. This assay is similar to the traditional approach except cell monolayers are overlaid with a soft agar prior to the 3- to 5-day incubation. Any non-neutralized infectious virions present at a given test serum dilution will infect host cells, and a "plaque" of lysed cells will develop. These plaques can then be visualized by staining cell monolayers with crystal violet, neutral red, or similar stains and by counting the clear plaques at selected dilutions of test and control sera. Endpoint titers are typically determined as the highest serum dilution, resulting in a 50–90% reduction in plaque-forming units.

Another variation is the fluorescent focus neutralization (FFN) assay that is of particular value when dealing with viruses that can infect a host cell but do not induce obvious CPE. The test is performed in a manner similar to the traditional CPE-based VN except cell monolayers are fixed with aqueous acetone or similar fixative at a selected time point after inoculation, generally 24–48 hours depending on the replication rate of the selected virus. Cells are then stained using standard FA staining techniques, and foci of infected cells in test serum and control wells are counted. Endpoint titers are determined as the highest serum dilution, resulting in a 50–90% reduction in fluorescent focus-forming units (FFUs).

Summary of diagnostics and interpretations

Diagnostic testing is used to answer several important questions: (1) Which pigs have what pathogen, and when and how did they acquire it? (2) Which pigs have maintained a negative pathogen status? (3) Which pigs have seroconverted to a planned exposure or vaccination? Each of these three categories has inherent challenges for test selection and interpretation of the test results. However, sample selection may be much more important than test selection. It is necessary to know what question(s) needs to be answered for collection of the appropriate sample(s) and to understand the basic pathogenesis of each disease and the effect of preexisting immunity so that the timing of sample collection is optimal.

Many of the frustrations and challenges with diagnostic testing interpretation occur due to living with endemic diseases. It can be difficult to assess the clinical relevance of a detected pathogen, when the ebb and flow of disease agents creates a moving target. Therefore, it is imperative to know what pathogen the pigs have, the timeline of when they became infected, the pathogen "load," and what effect it has on them to understand the results of a carefully planned sample and test selection. It is important to know what "normal" is to then determine what is "abnormal." Many times answering the question is straightforward. For example, if a client finds 30 dead, 5-week-old pigs one morning and the diagnostic lab reports a heavy pure growth of F4 (K88) or F18 *E. coli* from multiple intestines, it is known that the sudden death of 30 pigs is unexpected and a heavy pure population of a F4 (K88) or F18 *E. coli* in the intestine is not normal. Therefore, a cause and effect can be deduced. Knowing with certainty what caused the problem allows for a specific intervention and a probable return to the expected norm. Alternatively, finding 30 dead pigs over the course of 2 weeks in a group of 80 lb pigs experiencing respiratory disease may be an expected, albeit unwanted, event. The plan to understand what is causing the deaths may involve multiple submissions from younger pigs and samples from the farm or farms of origin. In this case, determining who has what, when did they get it, and how did they get it is a much more complex problem to unravel, treat, and prevent. An intrinsic bias to avoid in understanding endemic disease is diagnosis by "ego." With the myriad of agents and known or unknown interactions that result in clinical disease, determining which agents to specifically test for may lead to mistaken or inappropriate interventions, continuing morbidity and mortality, and client dissatisfaction. Negative test results can be as valuable as positive test results. Endemic disease is ever changing and should never be approached with the thought of conclusively knowing what is going on.

Determining if a group of pigs has maintained a negative disease status is usually a straightforward process and commonly involves testing for seroconversion to a disease agent along with looking for the infectious agent in pigs that have not yet seroconverted. Again, knowing when pigs will typically seroconvert from an infection, what samples to collect, and when to collect them is imperative to maintaining a negative herd status. Problems that arise with testing negative groups may involve both test sensitivity and specificity, but test specificity is the more common aggravation. Simply put, diagnostic testing is biology and not accounting. Diagnostic testing is subject to the inherent nonspecific reactions that can occur when people are involved with collecting and measuring samples produced by pigs. When judging test results that appear to be spurious, considerations for resolving the problem include determining if the pigs are in an early stage of infection or were actually vaccinated; if the lab, client, or veterinarian mixed up samples; if the correct pigs were tested; if

a new test kit or reagent at the lab was used; if there is a nonspecific reaction; and if that nonspecific reaction is reproducible with the same sample and with follow-up samples from the same animal (e.g. if you do not identify the animals tested on the submission form, you cannot answer this last question). Actions taken to resolve spurious results include asking the lab to make sure the right case was tested, retesting the original sample with the same test, testing the same sample with another test that has a different target for the agent, testing for the agent and for antibodies to the agent or vice versa, re-bleeding and recollecting samples from the group, re-bleeding and recollecting samples from the reacting animal(s), euthanizing the pig to look at tissues for evidence of an agent if you think the antemortem samples available are not adequate for determining the true status of infection, and inquiring at least three times to make sure the animals were not inadvertently vaccinated. These actions are important to investigate because people make mistakes, test wells are not always uniformly coated with antigen or antibody, pigs can produce nonspecific antibodies that react with one antigen but not another antigen to the same agent, pigs can temporarily produce nonspecific antibodies that react with multiple antigens of the same agent, pigs can permanently produce nonspecific antibodies that react with multiple antigens of the same agent, the PCR target for an agent may be inappropriate due to agent mutation, people are afraid to admit mistakes, pigs are mistakenly vaccinated, and bad test kits and reagents are produced and distributed to laboratories. The only way to avoid these problems is to never submit anything for testing. The more logical approach is to understand how problems can occur and how to resolve them. Leave a little time between testing and movement to allow for resolution, have a plan for resolving the problem, and stay calm. No one likes false positives or false negatives.

Confirming seroconversion to vaccination or live pathogen exposure is another testing event that is usually straightforward. For vaccinations, which tests to use and time-to-seroconversion are typically known and predetermined. Live pathogen exposure is not always a uniform or consistent event, but ensuring infection and an immune response is very important in preventing the introduction of pathogens into naïve populations. The inadvertent introduction of naïve animals into an infected group can greatly alter the disease dynamics affecting not only the naïve animals but also the existing population.

Optimizing Sample Selection, Collection, and Submission to Optimize Diagnostic Value

Paulo H.E. Arruda and Phil Gauger

Diagnostic question and identification of the problem

The diagnostic process requires a systematic and unbiased collection and eventual integration of history, signalment, and clinical signs that should eventually be correlated with gross pathology, histologic lesions, and molecular, bacteriology, and/or serology test results that will reliably and accurately address the veterinarian's diagnostic question. Using an evidence-based medicine approach, a final diagnosis should be supported by objective evidence generated throughout the diagnostic process. Producing diagnostic evidence is truly a partnership between producer, farm employee, veterinarian, and the diagnostic laboratory. Direct communication between the diagnostician and veterinarian is highly recommended to develop a diagnostic plan that includes appropriate animal selection, thorough and proper sample collection, and selection of relevant diagnostic assays. Selection of the most appropriate diagnostic assay(s) can be optimized by the collaborative effort between the veterinarian and the diagnostician. The level of communication is often directly correlated with the complexity of the diagnostic case to be investigated. The diagnostic information generated through this process will be the foundation for the development of strategies to prevent and treat diseases as well as to guide the improvement of management practices.

Optimizing the value of the diagnostic process fundamentally begins with an objective and unbiased collection of detailed clinical information based on thorough observations of the environment and affected animals (Chapter 1; four-cycle approach) followed by the formulation of a well-defined diagnostic question. The environmental and clinical evidence collected as well as the diagnostic question should be included on the laboratory submission form to maximize information that will allow the diagnostician to thoroughly investigate the case. A straightforward and unambiguous diagnostic question is necessary to avoid potential misunderstandings and confusion that can affect diagnostic outcomes. The diagnostic question should dictate the diagnostic plan such as selecting the most appropriate sample type, number of sample(s) necessary to answer the question, and the most suitable diagnostic test(s) (Chapter 6). Common questions include but are not limited to diagnosis of clinical disease(s) in an individual animal, diagnosis of disease(s) in a population, detection of a pathogen(s) in an individual animal, detection of current pathogen(s) in a population, detection of prior exposure in an individual animal, detection of prior exposure in a population, estimation of prevalence (within a specific subgroup or other well-defined denominator) and estimation of incidence (number of cases over time divided by the population at risk), monitoring the presence of pathogens over time, estimation of efficacy of a particular intervention, and continuous improvement tools.

Evidence collected and shared by the veterinarian should paint a "clinical picture" and guide the diagnostician through the investigation process. Inclusion of information such as geographic location of site, animal age, detailed and accurate description of clinical signs, medication and vaccination history, feed and water source, and morbidity and mortality data is highly recommended. From a chronological perspective, the collection of information at the farm level should precede the formulation of the diagnostic question(s) and hypothesis regarding the presumptive causative agent (the final diagnosis may or may not be infectious). A failure to respect this order might lead to known cognitive biases such as confirmatory or selective bias. To illustrate this, the proper collection and quality of information, number and nature of samples, and diagnostic assays selected can be significantly influenced if the hypothesis has been subjectively constructed prior to gathering evidence. This process often occurs unconsciously and tends to confirm our own purported

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

hypothesis that may potentially lead to incorrect or partially correct diagnosis.

If necropsy is performed at the farm, veterinarians should provide an accurate description of macroscopic lesions preferably using standard pathology terminology. This should include organ(s) affected, chronicity of lesions, lesion distribution, the presence and type of exudate, and overall severity. For instance, animals suffering from influenza infection might demonstrate the following morphologic diagnosis: acute, cranial ventral, multifocal and lobular, pneumonia (Khatri et al. 2010). Macroscopic lesions are often not pathognomonic; however, gross pathology will help refine the differential diagnostic list. Furthermore, complete and appropriate description of clinical signs using proper medical terminology is highly desired as this could directly impact the course of the investigation chosen by the diagnostician. For instance, "central nervous system (CNS) signs" are commonly reported by veterinarians as a descriptor for clinical signs that include CNS, lameness, paralysis, or metabolic disease. However, these descriptions are vague and nonspecific. Investigation of hind limb paralysis in swine suffering from teschovirus-associated disease will require a completely different diagnostic process when compared with swine experiencing convulsions and paddling as observed in cases of bacterial meningitis or water deprivation/sodium toxicity. Both of these scenarios are often considered CNS clinical signs despite the marked differences in clinical presentation (see Table 19.5 for CNS terminology).

Unfortunately, the importance of these initial diagnostic processes are often overlooked and underestimated despite their essential nature. Thoroughly collecting all relevant clinical information will decrease the turnaround time of results, decrease unnecessary testing, and lower the economic impact of diagnostics. Furthermore, diagnostic results should always be interpreted in the clinical context that is provided by the veterinarian on the submission form.

Identification of diagnostically representative animals (individual vs. population medicine) and proper collection of samples

Once the clinical information has been collected and the well-defined diagnostic question has been formulated, sample selection and collection should proceed. The first major aspect to consider is the fundamental differences between individual and population medicine and how this could impact the interpretation of results. From a commercial swine perspective, the majority of diagnostics are conducted using a population medicine strategy. By definition, population medicine uses the diagnostic results generated from a group of individuals to make recommendations to the remainder of the herd with the ultimate goal of improving the health of the population. While this concept has been widely utilized and provides numerous advantages, proper selection of the individuals within the population to be sampled becomes crucial. Similarly, the diagnostic question should dictate which animals and sample types to be collected. If the goal is to diagnose clinical disease, the selection of acutely affected animals is recommended. For instance, if the objective of the diagnostic investigation is to determine why pigs are actively coughing, submission of samples from acutely affected and non-medicated animals is recommended. The stage of the disease process based on an individual or a population basis must be considered to optimize sample selection. The likelihood of pathogen detection or isolation is directly influenced by the stage of the disease process (acute, subacute, or chronic) and the pathophysiology of the pathogen to be investigated. For example, pigs with subacute or chronic cough due to influenza infection might lead to negative influenza PCR results despite the presence of histologic lesions (necrotizing bronchiolitis) suggesting a previous infection with an epitheliotropic virus. In this case, resubmission of samples including oral fluids from a population can dramatically increase the chances of detecting influenza virus given that this is the objective of the diagnostic investigation. Oral fluid samples represent a population that includes different animals at various stages of the disease process. In contrast, if the objective is to determine the seroprevalence or identify evidence of previous exposure through the detection of antibodies against a specific pathogen, samples must be collected after sufficient time has allowed the induction of detectable antibodies, or often after the virus or bacteria are no longer present in the affected animals. This dynamic is often agent dependent; additionally, different types of serologic assays for the same agent can also alter the dynamic of detection.

From an individual animal standpoint, the onset and duration of clinical signs as well as likelihood of pathogen detection can be influenced by the stage of the disease process as well as animal age, host immune status, route of infection, dose, pathogen strain (virulence factors), the presence of coinfections, and management practices. Clear understanding of clinical signs, lesion distribution, and pathogen transmission rates provides an opportunity to identify individual pigs that may be at different stages of the disease process. This allows a variety of sample types to be collected from within the population. In general, fever can be used as a reasonable predictor of success for detecting infectious agents in live pigs; if the pig has a fever, the odds of detecting and isolating the agent increase. Thus, if the objective is to

detect the agent, antigen, or genetic material, finding acutely affected, febrile pigs to sample is the first step. Selection of pigs prior to antibiotic treatment is essential if bacterial isolation is desired. In contrast, if the objective is to demonstrate antibodies, selecting pigs that are beyond the febrile stage is more likely to be successful. While selection of chronically affected animals might lead to a large spectrum of macroscopic and histologic lesions, diagnostic results often do not represent the herd problem and therefore should be avoided in the context of population medicine.

The biology of the etiologic agent must also be considered in the diagnostic planning. For example, *Clostridium difficile* is found exclusively in the large bowel; therefore sections of colon (large intestine) and colon contents are essential for an accurate diagnosis of *C. difficile* clinical disease. Similarly, influenza virus does not have the capability to spread systemically in swine; therefore submission of whole blood or serum for influenza RNA detection in a clinically affected animal will not be appropriate. Furthermore, when investigating an abortion outbreak where influenza is suspected, submission of sow blood or fetuses will not help with its diagnosis; nasal swabs or oral fluids from clinically affected sows are the recommended samples for influenza virus detection.

The endemic nature of an infectious agent adds another level of complexity when investigating clinical cases. The majority of agents causing disease in swine are ubiquitous and considered part of the normal microbiota at some point in the pig life. Therefore, mere identification (detection) of the agent does not necessarily indicate clinical disease and only suggests a possible diagnosis. Knowledge regarding the pathogen biology, ecology, and distribution within the environment and host must be considered when assigning clinical relevance. Characterization of macroscopic and histologic lesions, differentiation between strains of bacteria through the presence of virulence factors, and anatomic location from which the pathogen was detected should be taken into consideration when determining causation. For example, the pig intestinal tract contains approximately 800 different bacterial species (Looft et al. 2012) including some potential pathogens such as *Clostridium* sp., *Escherichia coli*, and *Salmonella* sp.; however, these agents will only cause clinical disease under certain circumstances. If the intent is to find virulent strains of *E. coli*, samples should be taken from clinically affected pigs rather than random fecal samples. Isolates can be further characterized by genotyping to detect the presence of toxin and attachment genes to help support potential clinical significance (Moon et al. 1999). Similarly, the upper respiratory tract is colonized by a complex and diverse microbiota. For instance, simply detecting or isolating *Haemophilus parasuis* or *Streptococcus suis* by PCR or routine culture, respectively, from the nasal cavity and nasopharynx does not confirm clinical relevance or suggest that they are involved in a disease process. Thus, infection does not guarantee clinical disease. If the purpose of an investigation is to find an *H. parasuis* isolate responsible for causing polyserositis or meningitis, cultures should be attempted from fibrinous exudates, affected joints, or the brain from clinical animals rather than lung parenchyma or nasal swabs (Oliveira 2004).

Diagnostic sample selection and collection

Antemortem

Antemortem diagnostic testing has increased in popularity in the swine industry as production systems consolidated and incorporate disease monitoring and surveillance programs. These programs track changes in agent detection over time, survey a population at a single point in time, or evaluate potential exposure. Depending on the sample type and test availability, antemortem diagnostic testing can be used to detect the presence of viruses, bacteria, or an immune response indicating previous exposure. The veterinarian should use caution when interpreting antemortem test results that may indicate the presence of a pathogen or antibody that suggests only a presumptive diagnosis. Further diagnostic testing with histopathology and ancillary tests are necessary to assign potential causation (see Chapter 8).

Common antemortem diagnostic samples used for swine include serum, oral fluid, nasal swabs, and fecal or rectal swabs. Serum serves the dual purpose for detection of systemic pathogens during acute infection or presence of antibodies after sufficient time has been allowed for seroconversion. Approximately 2–5 mL of serum is desired for most diagnostic tests, and subsequent retesting if needed. Depending on the laboratory, serum can be pooled in groups of five for some PCR assays without decreasing sensitivity (Gerber et al. 2013).

The use of oral fluids for diagnostic testing has dramatically increased over the previous decade due to their ease of collection, minimal welfare implications, and broad applicability for pathogen detection. Oral fluids are most often collected as a pen-based sample and represent a population unless swine were trained for individual collection (Ramirez et al. 2012). Oral fluids are validated for PRRSV antibody tests but have more broad application for pathogen detection assays such as PCR. It is important to check availability of current tests with each diagnostic laboratory. Again, caution is urged when interpreting antemortem test results from oral fluids. Using ancillary tests that are analytically sensitive, such as PCR, will detect pathogens considered common flora

in the respiratory tract as well as residual genetic material that has contaminated the environment from a previous infection.

Oral fluids are easy to collect using cotton rope suspended in the pen at a length accessible to the size of pig (shoulder length). Use 1.3 cm rope for nursery pigs and 1.6 cm rope for grow/finish/adult swine. Allow 20–30 minutes in active pens for pigs to chew on the rope and collect the oral fluid. Extract the fluid by squeezing the rope into a plastic bag so that the sample accumulates into one corner. Transfer the sample to a plastic falcon tube (approximately 4–5 mL) or use a conical tube with a secure cap. It is best to chill or freeze the sample as quickly as possible and transport to the laboratory using ice packs. Use 1 rope for each 150 animals and space the ropes evenly throughout the barn. Avoid extraneous contamination of the rope with feed, feces, or soil as this may affect PCR tests through inhibition of the assay.

Nasal swabs are most commonly used to detect viral agents that replicate in the upper respiratory tract such as influenza A virus (IAV) with less application for other respiratory agents such as PRRSV, *Mycoplasma hyopneumoniae*, and other bacteria. Snout wipes have also been used to detect IAV but may be less sensitive for most diagnostic tests and have increased chance of cross-contamination occurring between animals during collection. Nasal swabs should have a synthetic tip with a plastic shaft; if the goal is PCR analysis, avoid gel-based transport media that are only applicable for bacterial culture. Transport media should prevent the swab from desiccation and preserve the viability of the pathogen. After proper restraint and clearing the nasal planum of debris, insert the swab deep into the nasal cavity (at least into the middle third of the nose), rotate the swab gently, and withdraw. Return the swab to the transport media provided, chill, and prepare for shipment to the laboratory.

Collection of feces or rectal/fecal swabs is often appropriate to detect most enteric viral pathogens and can be used for routine bacterial culture. Swabs should be collected on an individual basis in sufficient numbers to account for the expected prevalence of the pathogen in the population. The same type of swab can be used for either nasal or fecal collection. After collection, swabs should be placed in a transport medium, chilled, and submitted to the laboratory.

Postmortem

Swine practitioners are among the few medical professionals who routinely perform postmortem examinations (necropsies) of their patients (King and Meehan 1973; Pinto Carvalho et al. 2008). The postmortem examination is a valuable opportunity for veterinarians to understand not only the disease processes involving the individual pig under examination but also to initiate the process of identifying emerging health threats. The postmortem examination is the first step in an inquiry that goes beyond "dissection and microscopic examination of tissues" to include a vast array of assays and techniques to find disease agents or evidence of their presence (Dada and Ansari 1996). It is important to develop a routine that is consistent, thorough, logical, and systematic. The routine will vary among individuals but should be consistent for an individual.

One means of developing a systematic approach is to have necropsy kits prepared in advance, including labeled specimen containers for complete sample selection and correct grouping of samples. Specimen containers can be pre-labeled using permanent markers. Another approach is to carry packets of preprinted labels that can be placed on the containers at the time of collection. The primary purpose of using labels is to provide the checklist function to ensure complete sample collection is performed.

Collection and submission of fresh samples from affected animals is essential for pathogen detection, isolation, and identification. Sample collection should focus on salient features or macroscopic lesions and should include a section of both affected and non-affected tissue. If gross lesions are not observed, select multiple but random samples from tissues that are related to the diagnostic question. Samples should be refrigerated immediately after collection and should not exceed 5 cm × 5 cm in dimeter. If needed, fresh samples can also be frozen. If possible, samples should be placed in individual bags that are tightly sealed to avoid cross-contamination. At the very least, organs such as the brain, spinal cord, lung, heart, liver, spleen, and kidney should be bagged separately from intestines or gastrointestinal content.

When submitting samples to the diagnostic laboratory, make sure the box is appropriately labeled and in accordance with the specific requirements of that country. In general, fresh samples should be accompanied by ice packs or immersed in dry ice. Amounts of ice packs or dry ice will vary depending of the mail system to be utilized, time of year (season), shipping distance, and time to arrival.

Formalin-fixed specimens are invaluable aids for assessing pathological significance of suspected disease processes or infectious insults. Histopathology is relatively inexpensive such that multiple tissues and lesions can be examined to confirm a role of suspected agents or disease as well as suggest the presence of alternative insults that have not been considered. For some disease processes, immunohistochemistry is a very useful diagnostic test for demonstrating a causative agent within compatible lesions.

Samples for histopathology should rarely exceed 1 cm in thickness to allow proper fixation. One hundred percent formalin is the aqueous solution of dissolved formaldehyde gas available as a 37% saturated solution in water. Tissue fixation is optimized in 10% formalin. Buffered formalin concentrates are commercially available that can be diluted with water to achieve a 10% neutral buffered formalin solution. Ten percent neutral buffered formalin can be prepared by combining ingredients in the following proportions: 900 mL distilled water, 100 mL 37% formaldehyde solution, 8.0 g NaCl, 4.0 g potassium phosphate monobasic, and 6.5 g potassium phosphate dibasic. Alternatively, non-buffered 10% formalin can be substituted using a 1 : 9 ratio of 37% formaldehyde solution (100% formalin) to water.

Sample selection for histopathology should focus on salient features or lesions that include a section of affected and non-affected tissue. Five sections of lung that includes the anterior and cardiac cranioventral lung, intermediate lung, and two sections from the caudodorsal lobe of lung are recommended. Lesions are often segmentally distributed in the small intestine and colon. Select 4–6 sections of the ileum and jejunum and 2–3 sections of the spiral colon. In general, one section of the liver, kidney, spleen, and heart should be sufficient for proper evaluation. Samples to be submitted for histopathology examination should not be frozen as this process will lead to the formation of artifacts that can potentially impact histopathology examination. Frozen samples can be used for culture and PCR testing.

Pig necropsy: external examination

It is of the utmost importance to select pigs that represent the herd issue to achieve an accurate final diagnosis. If the pigs are alive and to be euthanized, it is recommended to collect serum and whole blood prior to euthanizing if these samples are desired. Approved euthanasia methods must be chosen and administered carefully to ensure the safety of the people and the welfare of the animal.

An external examination of the skin, extremities, umbilicus, joints, oral cavity, upper respiratory tract, and the perineum are appropriate prior to conducting the necropsy. Assess and record the general body condition of the pig. Physical abnormalities or gross pathology should be described and ultimately guide the sample collection process that will complement the diagnostic investigation. The carcass and extremities such as the ears and legs can be evaluated for discoloration (pale, purple, red), necrosis, edema, or the presence of vesicles; when noted, these features should be considered when formulating the differential list as well as the selection of diagnostic assays to be performed.

Evaluation of the skin should include the anatomical location, size, shape, and descriptions of the type and amount of exudate. Common descriptors include but are not limited to confluent or raised, pustular or plaques, rhomboid, ulcerated, hyperkeratotic, vesicular, necrotic, or exudative. It is also appropriate to note the presence of abnormalities in the oral cavity, ocular or nasal discharge, palpebral edema, fecal staining, swollen joints, trauma/fractures, and hernias. Diagnostic specimens should be collected prior to the examination of internal organs to avoid cross-contamination. Sections of affected skin, ears, and whole legs with affected joints should be collected to preserve the integrity of the sample. Fresh and formalin-fixed skin samples are appropriate for bacterial culture, molecular assays, and histopathology examination. Whole legs or specific joints should be submitted chilled using ice packs with no further processing to prevent contamination and preserve tissue architecture.

Pig necropsy: internal examination

Entire texts have been published regarding the proper procedure to necropsy swine and help suggest a presumptive diagnosis of swine diseases (Guillamon and Jalon 2002). The following is a general guide to follow in concert with specific recommendations from the veterinary diagnostic laboratory. Individual laboratories and diagnosticians within laboratories may have preferences that differ from the recommendations provided here. Healthy dialogue with the diagnostic pathologist is always recommended.

The necropsy can be performed with larger pigs and adult swine lying on their left side or on their back. For smaller pigs, necropsy is usually conducted with the pig lying on its back. Make the initial incision by holding the foot of the right forelimb and abducting the limb while making a cut from the angle of the right jaw through the skin and axillary musculature and along the right ribs to reflect the right forelimb. Making the cuts through the skin from the subcutaneous tissues outward reduces the dulling of the knife. A second incision similarly reflects the right hind limb. Raise the foot to abduct the hind limb and cut starting at the right flank at the juncture of the leg with the abdomen through the interior thigh musculature and hip joint capsule (severing the ligament) posteriorly through the proximal ham to just lateral to the tail. Reflect the skin past the midline ventrally and dorsally by cutting the subcutaneous connective tissue and muscles. Examine and collect fresh and fixed samples of the inguinal lymph nodes at this time.

Open the abdominal cavity, being careful not to puncture any of the digestive tract, by making an incision along the posterior margin of the ribs. Start at the sternum and continue dorsally to the vertebral column. Continue the cut to the posterior limit of the abdominal

cavity and then continue ventrally to the midline. Make sure not to touch any abdominal organs at this time as to minimize contamination.

Thoracic cavity

The rib cage is opened next by one of several methods, depending on the size of the pig and the tools available. In immature pigs, the costochondral junctions between the ribs and the sternum can usually be cut fairly easily using a knife by cutting through the cartilaginous bone at the costochondral junction. Alternatively, if a pruning shears is available, the pruners can be used to snip the ribs individually along the sternum up to the ventral limit of the thoracic inlet. If the pruner is available, the ribs can be snipped along the vertebral column beginning at the last rib and extending to the dorsal limit of the thoracic inlet and the ribs can be cut free by incising the diaphragm posteriorly and the muscles and vessels at the thoracic inlet anteriorly. Alternatively, the ribs can be reflected individually or in groups of two or three by incising the intercostal muscles lengthwise between every one, two or three ribs, and then each section of ribs can be manually reflected back over the vertebrae to expose the thoracic cavity.

The ribs can be examined at this time for evidence of bone weakness or prior fractures. Assess bone density by trimming a single rib out entirely and bending it back against the greater curve of the rib manually until it breaks. In growing pigs the break should produce a pronounced snapping noise and sensation when the rib cracks. Lack of this snap sound indicates bone weakness and may suggest a mineral or vitamin imbalance that warrants further investigation. In adults, the ribs should be very difficult to break and produce a sharp snap if it can be broken manually. While metabolic or nutritional bone disorders are rare in pigs, this assessment is simple and inexpensive and has proven sensitive with practice. The practice gained by routinely snapping ribs from normal pigs provides the basis for comparison when bone density is low.

Determine which bone is preferred by your diagnostic laboratory to evaluate bone density. Submitting an entire unfixed long bone such as the second rib for mineral analysis and a fixed section of the costochondral junction of another rib is indicated if bone density is suspected. Ribs have been reported as more sensitive than other bones to dietary changes and thus present a more diagnostically useful sample (Walker et al. 1993). Submission of serum is recommended if vitamin D_3 analysis is desired.

For smaller pigs, the opening of the carcass is conducted with the pig in dorsal recumbency. Both forelimbs are reflected laterally using the same cutting procedures as described for larger pigs. At least one of the hind limbs is reflected as described previously. Then the thoracic and peritoneal cavities are opened by first making cuts through the skin on the lateral aspects of the ventral jawline and then using this skin as the starting point for a full-length bilateral sagittal section to reflect the ventral body wall caudally, maintaining the plane of the cut above the organs being exposed.

At this point the thoracic and abdominal cavities are entirely exposed. This represents an opportunity to evaluate the presence of macroscopic lesions and/or abnormalities *in situ,* which should be noted on the submission form. Prioritization of specific anatomical areas should be based on the clinical signs noted as well as the presence of macroscopic lesions; a different order of tissue examination and collection will follow to optimize sample quality and integrity.

The next step depends on the primary clinical problem to be addressed. In most cases, the necropsy will proceed with examination and collection of tissues from the thoracic cavity. However, if neurologic disease or lameness is the primary concern, there is merit in collecting samples to investigate these problems prior to contaminating equipment and surfaces with thoracic or other tissues.

Examination and sampling (Table 7.1) of thoracic organs involve removal of the tongue, trachea, and lungs by first extending incisions bilaterally along the medial aspects of the jawbones, extending from the angle of the jaw rostral to the apex. Using blunt dissection, the tongue is lifted ventrally from the jaw and carefully dissected away, noting the tonsils of the soft palate. Excise the tonsils and place one-half in 10% formalin and retain one-half unfixed. The trachea and esophagus are further exposed by pulling the tongue ventrally along with a combination of blunt dissection and careful trimming through to the thoracic inlet. The trachea can be incised and examined grossly at this time. The lungs and heart are then lifted out of the thoracic cavity with continued careful trimming, with final cuts through the esophagus and blood vessels at the diaphragm.

The mediastinal lymph nodes are located near the thoracic inlet and proximal to the bifurcation into the lungs. These and the submandibular and tracheobronchial lymph nodes should also be examined and collected if enlarged or hemorrhagic. When lesions appear similar in different lung lobes, 1–2 samples are sufficient. However, if there are areas that differ in texture, color, or appearance, each unique lesion should be sampled (fresh and fixed sections). Fixed and fresh section/samples should always include at least one section of major airway especially when IAV or *M. hyopneumoniae* is suspected. Lung lesions in pigs are often most severe in the cranioventral lobes. Color can be a deceiving indicator of pneumonia, especially with hypostatic congestion or even modest autolysis. Lung texture is a more reliable indicator of lung disease, with firm, rubbery, congested, or non-collapsing areas of particular interest. However, if gross

Table 7.1 Porcine respiratory disorders – specimen collection.

Tissue/sample	Fresh (preferred chilled than frozen)	Fixed (10% buffered formalin)
Serum	4–5 mL	
Swabs	Caudal nasal passage, turbinate, bronchial swab	None
BAL	~10 mL	None
Nasal turbinate	2 × 2 × 2 cm	1 cm thickness
Lung	6 × 6 × 6 cm – 2–5 sections per pig with visible airways	Three pieces per pig from affected areas with different gross appearances (2 × 2 × 1 cm)
Lymph nodes	Mandibular, mediastinal, tracheobronchial, mesenteric, and superficial inguinal	Mandibular, mediastinal, tracheobronchial, mesenteric, and superficial inguinal
Tonsil	½	½
Heart	4 × 4 × 4 cm piece	2 × 2 × 1 cm including L and R ventricles and septum
Liver	4 × 4 × 4 cm piece	2 × 2 × 0.5 cm
Kidney	Half of a kidney	0.5 cm slice through center
Spleen	5 cm piece	1 cm thickness

Animal selection – three euthanized pigs with representative clinical signs, acutely affected, and untreated (if available) or three freshly dead pigs.
Sample submission – package and identify specimens from pigs individually.
BAL, Bronchoalveolar lavage.

lesions are not present, a random sample of five sections of lung is appropriate for a thorough histological evaluation of the lung.

Collecting samples for histologic examination was described previously, but in the specific case of the lung, there is an added caution to handle the tissues very gently during examination and sample collection. If too much pressure is applied to the lung prior to fixation, histologic examination is compromised due to the compression of airways and alveolar spaces.

Fresh lung samples should be of sufficient size to allow for bacterial culture in addition to other tests (PCR, virus isolation, etc.). Generally, unfixed pieces that are at least 5 cm cubes are adequate. Fixed and fresh lung samples should include pleura. If septicemia (Table 7.2) or pleuritis is present, affected areas of the lung should be sampled specifically.

The heart is examined by first cutting through the pericardium to expose the heart. Collect excess or abnormal pericardial fluid in a syringe, if present. Fibrinous exudates can be collected with swabs. Examine the surface of the heart for evidence of inflammation or hemorrhage. Incise both ventricles and the septum and examine the valves for inflammation and the muscle for hemorrhage or fibrosis. If indicated by clinical or pathological examination, collect sections of any lesions as well as septum, papillary muscle, and right and left ventricles for fixation and an unfixed piece of ventricle.

Abdominal cavity

The location of intestinal organs should be noted so as to make sure no volvulus or torsions are present. The spiral colon should be located in the pig's left side with the apex of the cecum on the pig's right side. If indicated, fibrinous exudates can be collected with swabs and urine with a syringe. Solid organs including liver, spleen, lymph nodes, and kidneys are sampled next, collecting fixed and fresh samples. In adult animals, the female reproductive tract and bladder can be examined for gross pathology as routine sample collection of these organs is not typically included. The ovaries are also evaluated grossly for abnormalities as well as matching the findings to the animal's recorded stage in the reproductive cycle. Intestinal lymph nodes (especially the mesenteric and gastrohepatic) should be examined next for size, texture, and the presence of hemorrhage.

When enteric disease is suspected (Table 7.3), longitudinal incisions of multiple sections of small and large intestine to examine mucosa should be routine. The ileum is the next section sampled. The ileum is easily located by finding the cecum and following the ligament to the ileum (Figure 7.1). Fixed samples (3–4 sections) are collected from the proximal and distal portions of the ileum, including a 15 cm section of fresh intestinal segments for bacterial culture. The jejunum and duodenum are sampled similarly, along with all areas with suspected lesions.

Fixed and fresh samples are also collected from the cecum (optional) and spiral colon (2–3 sections). When sampling the spiral colon, samples should be taken from the proximal, middle, and distal portions. A short cut into the lumen of the descending colon or rectum will help determine fecal consistency at the time of death.

Table 7.2 Porcine septicemia – specimen collection.

Tissue/sample	Fresh (preferred chilled than frozen)	Fixed (10% buffered formalin)
Serum	5 mL	None
Whole blood	3 mL in EDTA	None
Swabs	Brain, epicardium, joint (periarticular tissue including synovium), fibrin	
Cerebrum,[a] cerebellum, and brain stem	Cut brain in half longitudinally, slightly off the midline. Submit larger half fresh/chilled	Fix the smaller half in formalin
Lung	6 × 6 × 6 cm – two sections per pig with visible airways	Three pieces per pig from affected areas with different gross appearances (2 × 2 × 1 cm)
Heart	4 × 4 × 4 cm piece	2 × 2 × 1 cm including L and R ventricles and septum
Liver	4 × 4 × 4 cm piece	2 × 2 × 0.5 cm
Kidney	Half of a kidney	0.5 cm slice through center
Spleen	5 cm piece	
Lymph nodes	Mandibular, sternal, tracheobronchial, mesenteric, and superficial inguinal	Mandibular, sternal, tracheobronchial, mesenteric, and superficial inguinal
Ileum	10 cm segment	2 cm segment

Animal selection – three euthanized pigs with relevant clinical signs, acutely affected, and untreated (if available) or three freshly dead pigs.
Sample submission – package and identify specimens from pigs individually.
[a] Submission should include representative sections of the cerebrum (frontal, parietal, occipital, and temporal cortices), brainstem (midbrain, pons, and medulla), and cerebellum.

Table 7.3 Porcine diarrhea – specimen collection.

Tissue/sample	Fresh (preferred chilled than frozen)	Fixed (10% buffered formalin)
Serum	5 mL	None
Oral fluid	5 mL	None
Swab	Rectal swabs, environmental swabs	
Tonsil	½	½
Liver	4 × 4 × 4 cm piece	2 × 2 × 0.5 cm
Stomach	3 × 3 × 3 cm piece	1 cm thickness
Spleen	5 cm piece	1 cm piece
Jejunum	10 cm segment	Three sections, 2 cm long, unopened
Ileum	10 cm segment	Three sections, 2 cm long, unopened
Mesenteric lymph node	Entire lymph node	1 cm thickness
Spiral colon	Approximately ¼ to ½ of colon bagged separately from small intestine	Three sections, 2 cm long, unopened
Fluid contents from cecum or colon	In leakproof container	

Animal selection – three euthanized pigs with relevant clinical signs, acutely affected, and untreated (if available) or three freshly dead pigs.
Sample submission – package and identify specimens from pigs individually.
Note: Ideally, fix intestines within 15 minutes of death for best preservation.

Once all abdominal organs have been sampled, the stomach can be opened. This is done by cutting along the greater curvature. Presence or absence of feed is noted as well as presence or absence of ulcers or hemorrhage. In pigs, gastric ulcers are located in the non-glandular portion of the stomach, also known as the pars esophagea. The pars esophagea should be carefully examined to rule out gastric ulcers. The stomach is rarely sampled for routine diagnostic purposes.

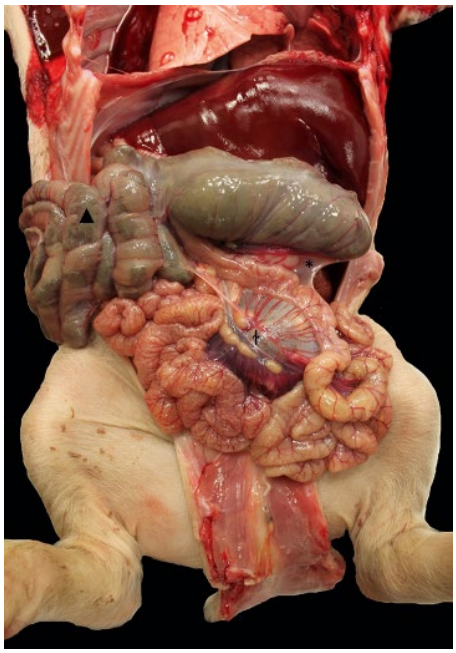

Figure 7.1 Pig necropsy. Pig lying on his back after the front and back legs have been reflected. Visualization of the gastrointestinal organs – ileum, ileocecal ligament, spiral colon, cecum, and mesenteric lymph nodes. ▲Mesocolon. *Ileocecal ligament – cecum is located in the cranial portion and ileum located ventrally. ‡Mesenteric lymph nodes.

Table 7.4 Porcine abortion – specimen collection.

A. *Optimum specimens*, chilled

1) At least three intact fetuses and placenta each from aborted litters or different parities – including the freshest fetus
Note: If there are mummified fetuses, submit nine mummies – three smallest, three medium, and three largest (freezing the fetuses is acceptable if they cannot be sent immediately to the laboratory)
2) Sow serum (5 mL) – If attempting to diagnose PRRSV, sera are best collected when sows are acutely affected (off-feed and febrile)
3) Nasal swabs or oral fluid from sows with aborted litters and/or showing respiratory signs

B. *Alternate specimens* – Note: Pooling tissues from multiple fetuses is acceptable

Tissue/sample	Fresh (preferred chilled than frozen)	Fixed (10% buffered formalin)
Heads	3	
Thoracic fluid	2 mL	
Stomach content	3 mL	
Lung	3	Three samples: 1 cm × 1 cm × 1 cm
Heart	3	Three samples: 1 cm × 1 cm × 1 cm
Liver	3	Three samples: 1 cm × 1 cm × 1 cm
Kidney	3	Three samples: 1 cm × 1 cm × 1 cm
Spleen	3	Three samples: 1 cm × 1 cm × 1 cm
Placenta	3	Three specimens: 3 cm × 3 cm
Superficial inguinal lymph nodes	3	Three samples
Mummies (intact; if available)	9 (see above)	

Collection of reproductive and abortion tissues

Porcine abortions can be primarily divided as follows: (1) sporadic abortions and (2) abortion storm outbreaks. Determination of the primary cause or pathogen leading to abortion is difficult particularly in the sporadic events, although diagnostic tests are routinely utilized to rule out an infectious etiology or an occasional noninfectious cause. The majority of abortions are considered idiopathic; this occurs when diagnostic tests fail to detect an etiologic agent and histopathology is unremarkable.

Diagnostic efforts often focus on the aborted fetuses particularly when dams are not showing clinical signs. It is recommended to submit 4–6 fetuses per litter from at least 3 affected litters (Table 7.4). When mummified fetuses are present, submission of three from each of the smallest, medium, and largest mummies is recommended. Necropsy of neonatal piglets, aborted fetuses, or mummified fetuses should be performed as described for nursery, grower, or finisher swine. Measuring the crown-rump length of the smallest to largest fetus in a litter will provide a rough estimation of gestation length. Gross pathology is often absent in aborted fetuses. However, it is important to recognize and note any lesion or abnormality that should be included in the history and signalment. Fresh and formalin-fixed lung, heart, liver, kidney, and spleen should be submitted for molecular assays, histopathology, and bacteriology to rule out the primary differentials of abortion that include PRRSV, PCV2, porcine parvovirus, leptospirosis, ascending bacterial infection, and bacterial septicemia. Placenta, when available, is an important diagnostic specimen to include in all abortion investigations. In addition, fetal thoracic fluid and stomach content are important diagnostic samples for ancillary tests and bacteriology, respectively. Although mummified fetuses are rarely useful for histopathological evaluation, fresh samples are necessary for parvovirus diagnostic assays. All samples should be chilled prior to shipment on ice packs.

It is important to focus diagnostic efforts on the dam when clinical signs are observed and systemic or localized illness is suspected. Anorexia, lethargy, fever, or respiratory signs such as coughing will help determine the appropriate sampling strategy for a diagnosis.

Collecting serum from acutely affected dams is appropriate to detect systemic agents such as PRRSV (PCR is the most appropriate diagnostic assay in this circumstance). Nasal swabs or oral fluids are appropriate when respiratory disease is observed. Submitting samples from both affected dams and fetuses is recommended when clinical signs are suggestive of maternal illness. Agents such as IAV are not systemic and will not be detected in fetal tissues; samples from affected dams are essential to achieve an accurate diagnosis. Serum and nasal swabs should be chilled as soon as possible after collection and submitted on ice packs during transit to the laboratory.

Collection of CNS tissue

In cases where neurologic signs are the primary complaint, submission of brain and spinal cord is essential (Table 7.5). Neurologic tissue is highly specialized and structurally and anatomically complex. In general terms, the brain is divided into four major regions: cerebrum, cerebellum, diencephalon, and brainstem. These anatomic locations have different functions and when affected will lead to different clinical signs. For instance, in cases of teschovirus-associated disease, animals often show loss of coordination and posterior paralysis but remain alert and responsive to environmental stimuli. As a result, the frontal cortex might have minimal diagnostic value; lesions are concentrated primarily in the spinal cord and brain stem. Proper sample selection is essential to reach an accurate diagnosis. To exemplify, when investigating cases of edema disease caused by Shiga toxin-producing *E. coli,* submission of approximately 6 sections of small intestines is crucial as the bacteria do not go systemic and are not evenly distributed in the intestine. Lesions and clinical signs are a consequence of the effects of the Shiga toxin toward endothelial cells lining blood vessels within the nervous tissue (Boyd et al. 1993). Additionally, the stage of disease process plays an important role in pathogen detection; submission of an acutely affected animal is highly advised.

Submission of brain swabs in addition to three to four formalin-fixed sections of the cerebrum and cerebellum is recommended to properly diagnose a bacterial meningitis such as *S. suis* and *H. parasuis* infection. The atlas–axis junction can be exposed in pigs lying on their back and tilting the head dorsally while incising just below the pharyngeal area. The spinal cord is exposed as the head is tilted more acutely, and a swab can be inserted directly into the foramen magnum and pushed back into the brain cavity until it stops (Figure 7.2a). The swab will stop at the junction of the cerebrum and cerebellum, a common site for recovering bacteria that cause meningitis in pigs. The first cervical vertebrae can then be cut off with the spinal cord in place for histologic examination. This can be cut using a knife through the intervertebral disk or by use of a pruner shears or a hacksaw. Submit the swab for bacteria culture and the vertebrae with spinal cord fixed in formalin.

The brain is removed by first skinning the skull in the area bounded by the eyes rostrally, the ears laterally, and the foramen magnum caudally. The calvaria is removed by making a circle of cuts through the skull from the occipital condyle to the base of the ear, from the base of the ear to the eye socket, across the skull to the other eye socket, back to the base of the other ear, and finally back to the occipital condyle. These cuts can be made using a saw or hatchet, depending on availability and preference. The calvaria is pried free, exposing the meninges and brain, which can be dissected free by cutting cranial nerve attachments. The brain can be split longitudinally, with half preserved in formalin and half submitted unfixed.

In younger pigs, the skull can be split using a necropsy knife that is thrust through the nasal cavity and extending the knife to the apex of the mandible followed by inserting the knife with blade facing distal and extending the atlas–axis junction or back of the head. Leverage is applied carefully to the knife handle to cut through the skull longitudinally, and the brain can be cut loose from the cranial nerves as previously described.

For cases in which some or all of the vertebral column is needed, remove the entire pluck and offal from the carcass and trim away the muscle from the region to be sampled. If thoracic vertebrae are needed, the ribs can be disarticulated from the spine by cutting with a knife or pruner. If only cervical or lumbar vertebrae are needed, these sections can be cut away from the thoracic vertebrae with a knife, saw, or pruner and submitted intact. Alternatively, the spinal cord can be excised *in situ* using a Barnes dehorner as a bone rongeur to scoop out the ventral portion of the vertebrae to expose the vertebral canal (Figure 7.2b–d). Spinal ganglia will be exposed using this process and should be collected. Severe lymphoplasmacytic ganglioneuritis can be observed in animals suffering from teschovirus-associated encephalomyelitis (Yamada et al. 2014). Ideally, sections of the cervical, thoracic, and lumber regions should be collected (half fresh and half formalin fixed). Alternatively, selection of spinal sections can be targeted based on clinical assessment. Spinal cord samples should be aseptically collected as pathogens such as teschovirus and sapelovirus can be endemic within feces (Arruda, et al. 2017; Buitrago et al. 2010; Cano-Gomez et al. 2013; Chen et al. 2012), making interpretation of results difficult.

Locomotor tissue: arthritis and lameness sampling

If arthritis or lameness is the primary concern, sampling joints prior to taking thoracic or abdominal tissue samples is preferred to avoid contamination of joint samples with endemic bacteria that may be present as normal microflora within other tissues. The important step for

Table 7.5 Porcine neurological disorders and septicemia – specimen collection.

Tissue/sample	Fresh (preferred chilled than frozen)	Fixed (10% buffered formalin)
Serum	8 mL	
Swabs of: 1) Meninges 2) Brain	1) Swab meninges immediately after exposed 2) Swab one cerebral hemisphere into a lateral ventricle	None
Cerebrum,[a] cerebellum, and brain stem	Cut brain in half longitudinally, slightly off the midline. Submit larger half fresh/chilled	Fix the smaller half in formalin
Spinal cord[b]	5 cm segments of the cervical, thorax, and lumbosacral regions	5 cm segments of the cervical, thorax, and lumbosacral regions
CSF	3 mL	None
Lymph nodes[c]	½ of the sternal, tracheobronchial, mandibular, superficial inguinal, and mesenteric enlarged lymph nodes	½ of the sternal, tracheobronchial, mandibular, superficial inguinal, and mesenteric enlarged lymph nodes
Lung	5 × 5 × 5 cm pieces. 3–5 pieces with macroscopic lesions	2 × 2 × 1 cm sections (2 or 3) – include gross lesion if present
Pleura or pericardium	Swabs, pericardium fluid, fibrin (if present)	1 × 1 × 1 cm
Heart	4 × 4 × 4 cm section	2 × 2 × 1 cm section
Liver	4 × 4 × 4 cm piece	2 × 2 × 0.5 cm
Kidney	Half of a kidney	0.5 cm slice, including cortex and medulla
Spleen	5 cm piece	1 cm piece
Jejunum	10 cm segment	Two sections, 2 cm in length
Ileum	10 cm segment	One section, 2 cm in length

Animal selection – three euthanized pigs with relevant clinical signs, acutely affected, and untreated (if available) or three freshly dead pigs.
Sample submission – package and identify specimens from pigs individually.
CSF, cerebrospinal fluid.
[a] Submission should include representative sections of the cerebrum (frontal, parietal, occipital, and temporal cortices), brainstem (midbrain, pons, and medulla), and cerebellum.
[b] Collection of enlarged lymph nodes should be preferred regardless of anatomical location.
[c] Aseptic collection of spinal cord is highly recommended.

obtaining optimal joint sample begins with an aseptic and systematic technique; thorough examination of all accessible joints, including the carpus, shoulder, elbow, stifle, and hock, is also highly recommended.

Obtaining clean samples from joints can be a challenge in field settings. As a result, some practitioners prefer to submit intact joints for careful and proper dissection at the diagnostic laboratory. This approach can be successful, but some bacteria that cause infectious arthritis are fastidious and less likely to be cultured a day or two after joint samples are collected. Therefore, careful dissection of joints and collection of joint fluid and tissue in the field can increase the likelihood of isolation and/or detection of the pathogen(s) involved.

Joint fluid can also be aspirated with a needle and syringe once the skin is reflected or percutaneously if the skin has been aseptically prepared (Figure 7.3a and b). The joint fluid can be submitted for culture, molecular testing, (PCR) and clinical pathology. Antemortem joint fluid collection under short-term injectable anesthesia is also a useful tool especially in populations where necropsy is not an option. More details regarding investigation of lameness in swine and collection of diagnostic material can be found in Canning and Karriker (2016). Recently, clinical pathology reference intervals have been created for commercial finisher hogs and will be an additional tool available for practitioners (Canning et al. 2016). Changes in clinical pathology parameters such as protein, pH, and total nucleated cell counts can provide practitioners with evidence of inflammatory changes within the joint. As infectious pathogens often have a temporary residence within the joint, clinical pathology will be helpful in providing context to PCR and culture results. It is important to examine multiple joints from pigs suspected of having lameness or arthritis problems. Specific joints of interest may depend on the age of the pig and clinical signs present.

Clean samples can also be obtained from joints by first reflecting the skin away from the joints to be sampled and then using a new #22 scalpel blade to trace the outline of the bones through the joint capsule. Making

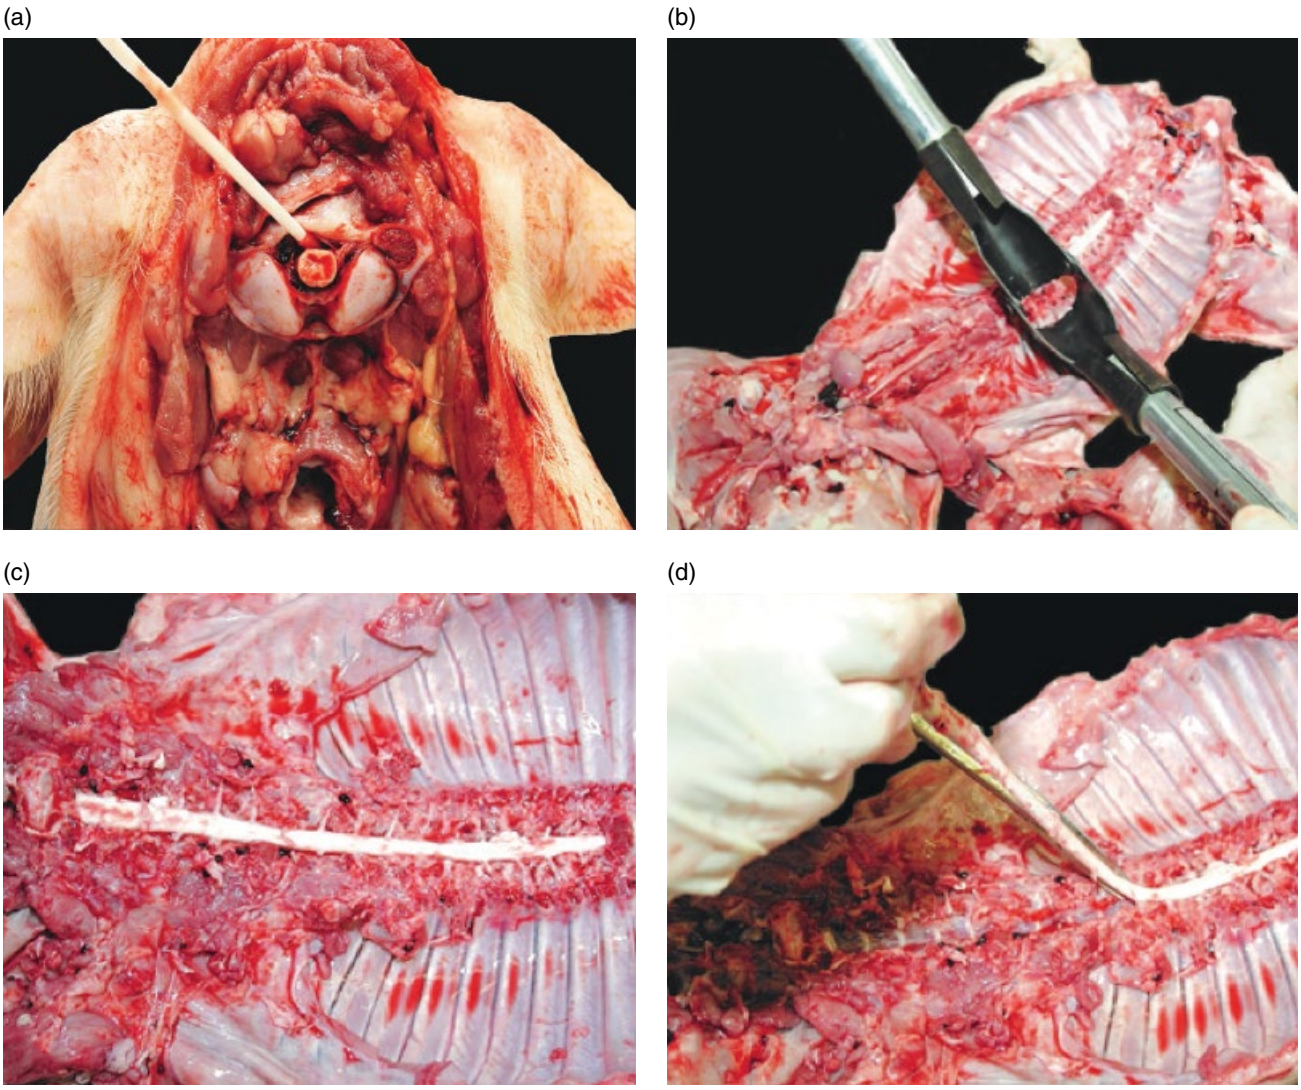

Figure 7.2 Illustration of brain swab and spinal cord collection. (a) Collection of a brain swab prior to extracting the brain tissue. Expose the atlas–axis junction and insert the swab directly into the foramen magnum. (b) Collection of spinal cord *in situ* using a Barnes dehorner. this cut is simpler on the medial aspect of the joint where less muscle is present. The clean scalpel blade is less likely to contaminate the joint than the necropsy knife. Leverage applied to the distal portion of the limb exposes the joint so that fluid and joint sample materials can be collected (Figure 7.3c and d). With practice, each joint can be opened with minimal cutting and potential for contamination. Once exposed, examine the synovial tissue, synovial fluid, and cartilage for abnormalities. Joint swabs should be collected for bacteriology and/or molecular assays (Figure 7.3c). In addition, synovial tissue should be collected for histologic examination (Figure 7.3d). Histologic examination plays an essential role in the interpretation of PCR and culture results from joint fluid. Similar to the investigation of other tissues, test results from joints should always be interpreted in a clinical context. Additionally, identification of macroscopic and histologic lesions should add confidence to the causative role of potential agent detected. For instance, isolation of *S. suis* from joint swabs of pigs with no clinical history suggestive of a bacterial sepsis nor synovial histologic lesions should be interpreted with caution.

Necropsy safety

Safety is always a concern when performing postmortem examinations on pigs. Pigs harbor microorganisms that can potentially infect humans (Tucker 2006), floor

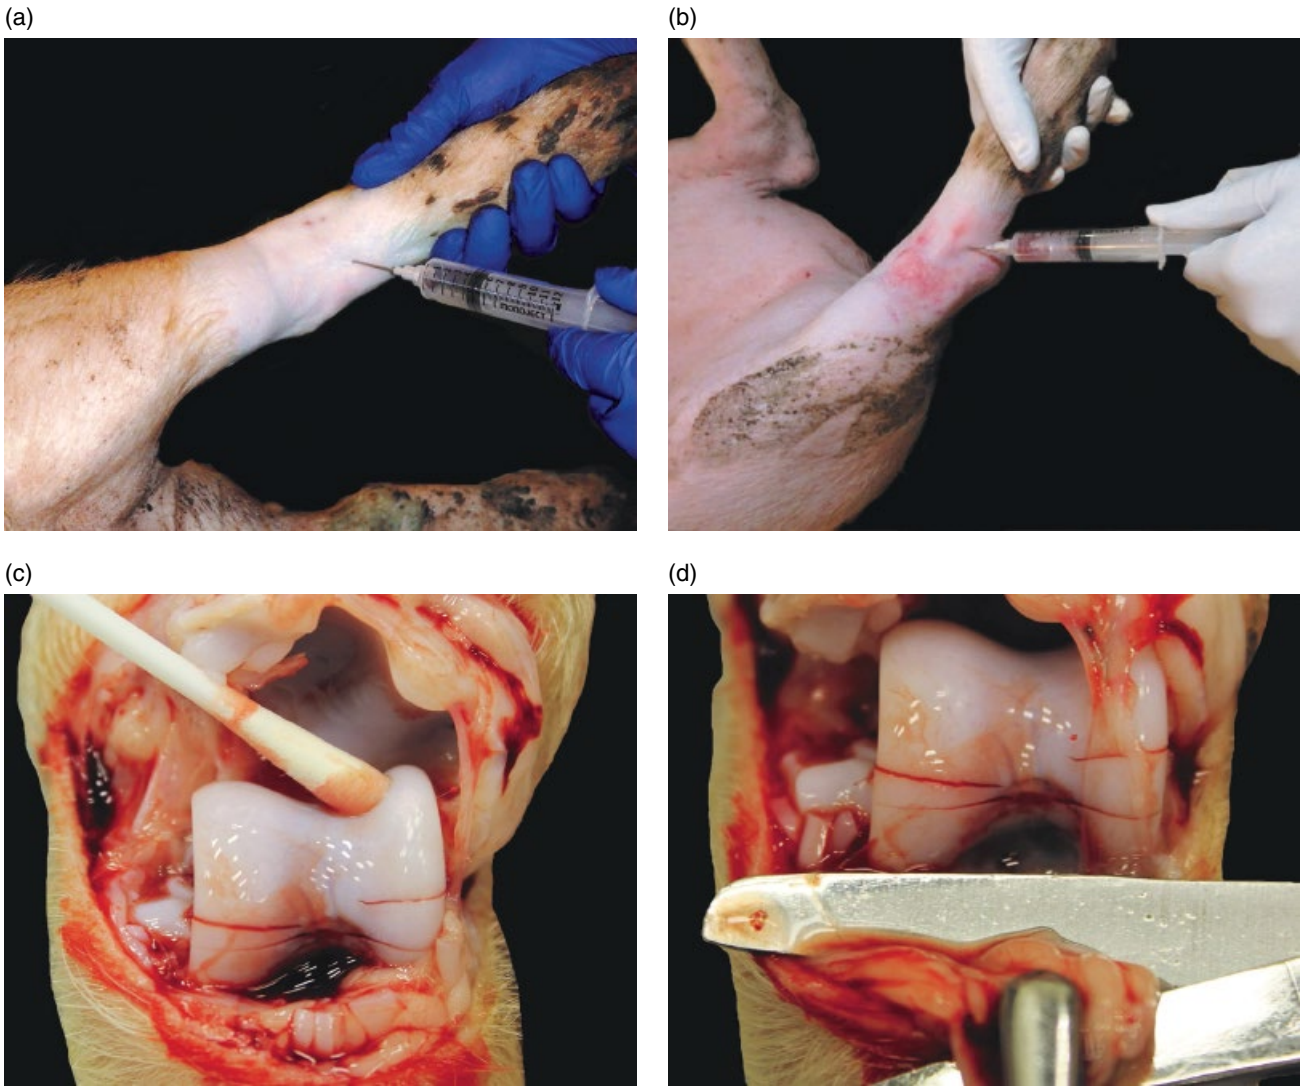

Figure 7.3 Collection of synovium fluid, joint swab, and synovium tissue. (a, b). Collection of synovial fluid prior to exposing the joint cavity. Collection can be performed from either the dorsal (a) or lateral side (b) of the joint. (c) Complete exposure of the joint cavity for macroscopic examination and swab collection. surfaces can become slippery from body fluids, and the sharp tools used in the course of the examination can cut the prosecutor as well as the pig. The environment in which field necropsies are performed is often not ideal from a safety standpoint, so care should be taken to reduce the risk of injuries when planning postmortem examinations. Personal protective equipment should be worn that is appropriate for the risk posed by the examination. At the very least, waterproof gloves should always be worn to reduce the risk of skin contamination with body tissues and fluids.

Safe knife handling is obviously important during the necropsy. Most knife injuries can be avoided by adhering to three knife safety rules: (1) always cut away from yourself, (2) use your knife only as a knife, and (3) keep your knife sharp. These three points might seem obvious, but practitioners often find themselves violating one or more of these to save time or make do with the available resources, leading to avoidable injuries. Using a postmortem knife for purposes other than a pig necropsy can damage the knife and the operator. Using a sharp knife is safer because cutting time and force are reduced, which decreases fatigue and the probability that the blade will slip on the surface being cut. There is also less opportunity for the operator's hand to slip off the knife handle (McGorry et al. 2003).

Keeping track of knives and other sharp instruments is also important and can be a challenge during an extensive necropsy. Storing the knife by inserting the blade into large muscles in the carcass when not in use during the necropsy saves time and prevents injuries.

Conclusion and final comments

In summary, the diagnostic process should start with the accurate assessment of the primary complaint and formulation of a well-defined diagnostic question. Formulating a well-defined diagnostic question is imperative to additional steps in the diagnostic process that includes sample selection, proper collection, adequate preservation, and secure submission. The investigation should be based on the unbiased and objective collection of accurate history, signalment, and clinical observations, which should be included in the submission form to be sent to a diagnostic laboratory. Following an assessment of the clinical scenario, representative animals must be selected for necropsy that includes the identification and documentation of gross pathology that may or may not be associated with the primary problem. A systematic process including the selection of the most appropriate animals, sample types, and numbers of samples is essential to achieve a final accurate diagnosis that should align with the clinical assessment. Diagnostic data generated through this process should provide the empirical foundation necessary to the implementation of strategies needed to address the issues of concern.

Collecting Evidence and Establishing Causality

Eric R. Burrough, David H. Baum, and Kent J. Schwartz

Introduction

Assigning cause (or blame) for an event is a seemingly visceral compulsion of humans. Assigning cause by providing a diagnosis is a core competency of swine veterinarians, often aided by laboratory testing, but it bears noting that establishing causation is not as simple as obtaining a test result. A single test result may suggest cause for an epidemic of new disease related to introduction of a single agent and can be relatively straightforward. However, in modern swine production, diseases are often multifactorial involving multiple infectious agents and risk factors. The expression of endemic potential pathogens as disease is often associated with noninfectious risk factors or compromised herd immunity. Disruption of herd immunity, incomplete elimination protocols, or early weaning stressors can lead to disease epidemics from previously subclinical infections such as Glasser's disease or mycoplasmosis. Management and environmental risk factors also predispose to disease expression. For example, changes in piglet processing can result in expression of inguinal abscesses and umbilical hernias, or changes in pig flow and commingling can exacerbate systemic viral or bacterial disease expression. In those cases, the identification of a specific infectious agent as cause of a specific lesion or disease can appropriately be considered as "proximate cause." Veterinarians are well trained and highly adept at identifying proximate cause(s). A broader view would be to seek and identify those risk factors that underlie or contribute to disease expression, most appropriately viewed as "ultimate cause(s)," which typically are population or herd-level diseases or risk factors. Ultimate causes are often the focus of intervention for disease control, prevention, or elimination through appropriately applied intervention or management practices. Therefore, causality in swine production is a synthesis of both proximate cause (the infectious agent or specific insult type associated with lesion or disease state) and ultimate cause (risk factors leading to disease expression). Both are important for deriving appropriate interventions for sustainable production.

Accuracy in assigning causation is a matter of confidence in the quality and interpretation of all available evidence within the context of the presenting clinical scenario. An awareness of laboratory, experiential, institutional, and personal sources of bias is prudent if accuracy and scientific confidence is desired in assigning cause. Accuracy is enhanced when a diagnosis is deduced with due consideration of all available evidence, a process that uses evidence to limit possibilities. In contrast, diagnosis by inductive reasoning is extrapolation of a diagnosis from limited evidence, such as assigning cause from a single diagnostic test or report without the context of relevant history and/or clinical signs and data. The nature of biology is that there is will always be some level of uncertainty in the data used to assign a final diagnosis. The presence of an insult type in an individual or population can be confirmed with near certainty, but mere presence is not always sufficient to assign causation. Multiple insult types and risk factors can affect the extent of disease expression. Diligence is required to not interpret association as causation. Diagnosis by exclusion or having a negative test for an insult type in an individual or population will always have a level of uncertainty as it is not possible to prove a negative.

These concepts are essential to integrate purposefully into collection of evidence and establishing causality using objective clinical skills and current scientific knowledge as a foundation for diagnostic investigation. In simple terms, and above all else, a proper diagnostic investigation must begin with one or more well-defined questions or specific objectives. All subsequent aspects of the investigation, including animal selection and sampling, the number of samples required, and the selection of particular diagnostic tests with estimates of diagnostic sensitivity and specificity, are wholly dependent upon the clinical context and specific questions raised.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Determining if the goal of diagnostic testing is for confirming diagnosis of a clinical disease or is for pathogen monitoring or surveillance is a critical decision in the process and might best be viewed dichotomously. It is like a fork in the road where the sampling approach commits to one or the other with specific efforts to increase confidence that the diagnostic question can and will be answered (Figure 8.1).

There are times when a practitioner might want to determine both causality (a disease diagnosis) and get an estimate of potential related coinfections (pathogen monitoring/surveillance); however, these situations will likely require two different sets of purposefully collected samples to accurately answer these two separate objectives. While pathogen monitoring can take many forms, pathogen surveillance requires some specific quantity of a sample type to estimate presence and prevalence of a pathogen in a population at a calculated level of confidence. Disease diagnosis generally relies on a complete and broad set of samples from typically affected animals to determine relative contribution of a pathogen or pathogens to disease expression with some level of confidence. Often,

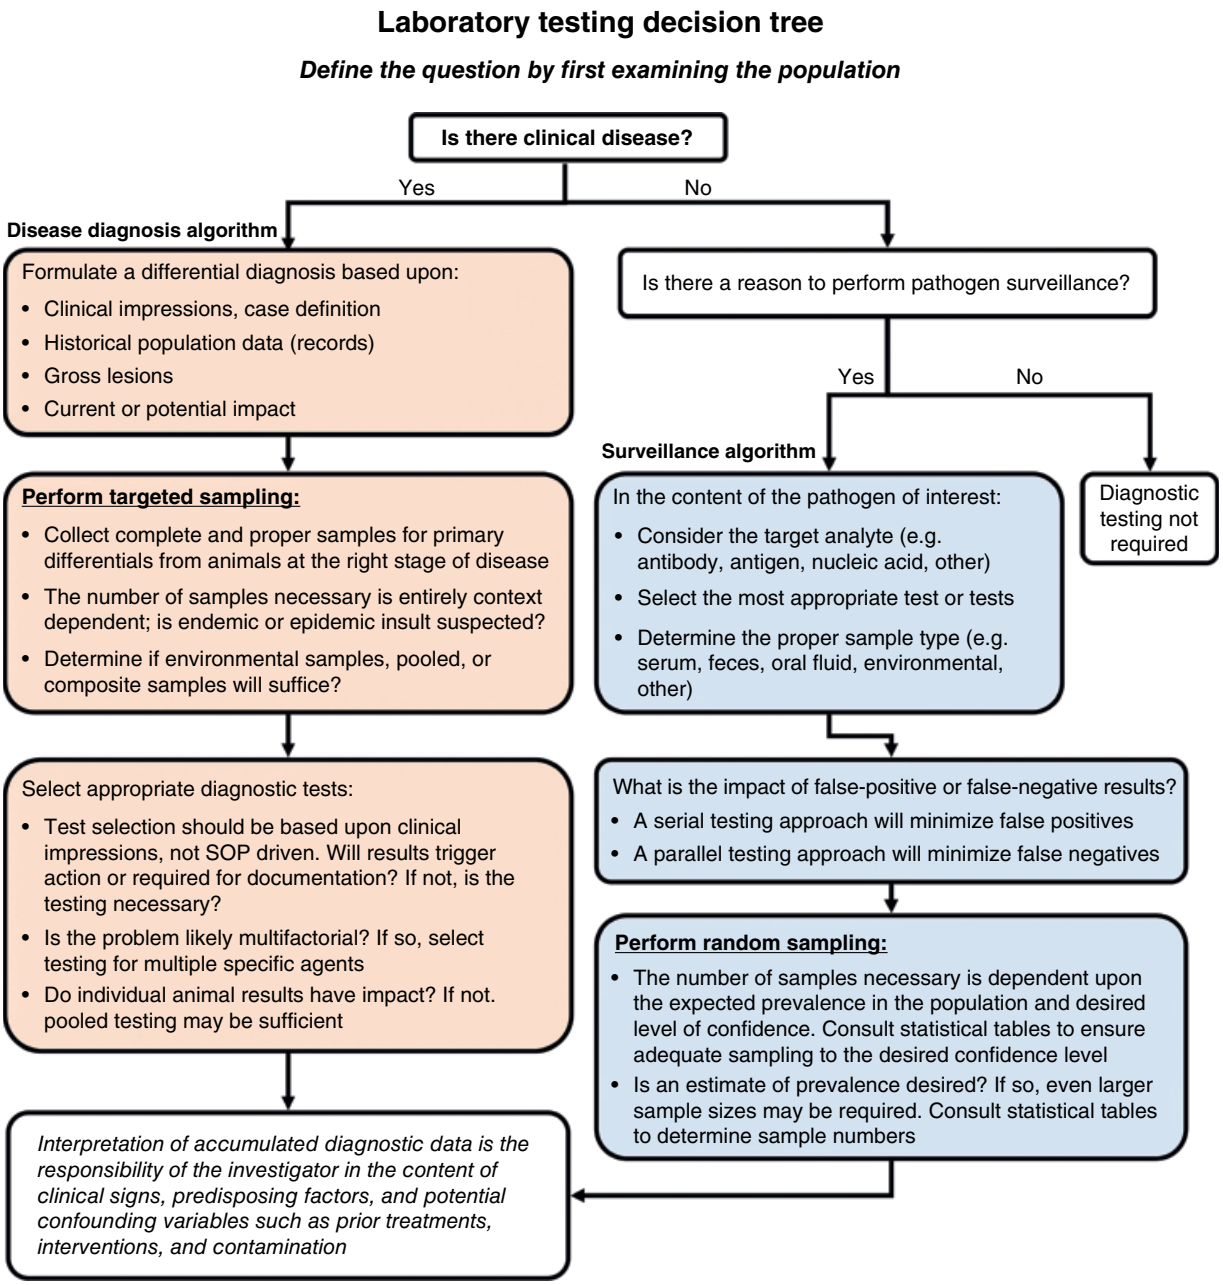

Figure 8.1 Decision tree for laboratory testing in diagnostic investigations. Proper clinical context is essential prior to diagnostic sampling and generation of data.

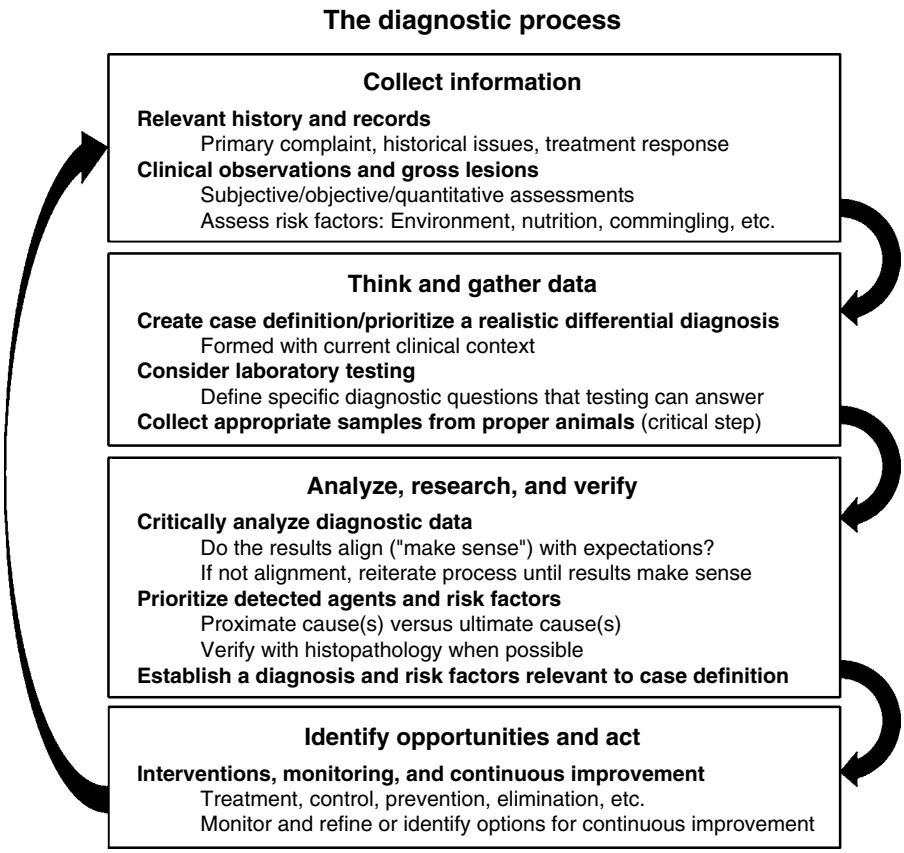

Figure 8.2 The diagnostic process as a continuum. When properly executed, the diagnostic process involves a consistent, systematic approach with continual evaluation of the validity of data generated and alignment of diagnostic results.

laboratory submissions for proper disease diagnosis are of inadequate quantity (not enough animals sampled) for confident pathogen surveillance or estimates of prevalence. Similarly, submissions for pathogen surveillance are often of insufficient depth (too few tissues per animal sampled) for confidence in etiologic or disease diagnosis. Accordingly, this chapter has two primary subsections, each outlining best practices and methods to increase confidence in the interpretation of data collected. It is assumed the reader has a solid understanding of the technical aspects of individual diagnostic assays (Chapter 6) and methods for optimal diagnostic sampling (Chapter 7).

Collecting evidence for disease diagnosis

Theory

Diagnostic process

There are three main reasons to pursue a diagnosis: (1) to accurately label an observed condition, (2) to satisfy scientific curiosity, and (3) to determine appropriate therapeutic action (Crombie 1963). The latter of these is often of greatest concern to swine practitioners and underlines the importance of accuracy in the diagnostic process to reduce errors and unnecessary treatment costs. Accordingly, a proper diagnostic investigation should be a systematic repeatable process within a scientifically validated framework to deduce the presence, etiology, epidemiology, and/or risk factors associated with a suspected disease or infection from all available evidence. The diagnostic process outlined in Figure 8.2 assures a systematic approach to collect data and to evaluate the validity of that data. The narrative and final diagnosis generated from this process should align all relevant observations, data, information, and current scientific knowledge to ultimately "make sense." If these data (observations or laboratory data) do not completely align with conclusions, there is likely some error in the data or deductive process, and this incongruency should trigger the practitioner to begin the process again.

While the swine practitioner often has a short-term goal of establishing or confirming a diagnosis in a cohort of pigs, it is important to remember that the diagnostic process is a continuum within the population, often with many intermediate diagnoses along the way. Examples of diagnosis types may include a clinical diagnosis,

differential diagnosis, morphologic diagnosis, etiologic diagnosis, and laboratory diagnosis. These intermediate diagnoses all have implications with individual constraints and limitations that must be incorporated and aligned within the context of the case as the practitioner attempts to assign a final or herd diagnosis and determine the proper course of action.

When an animal or population of animals has clinical signs of disease, a swine practitioner often uses knowledge gained from textbooks and scientific journals to formulate a prioritized differential diagnosis, typically accompanied by a strong belief as to which differentials are most likely present. While this belief may be true, it cannot be considered knowledge without proper evidence or justification. If confirmed through empirical evidence and experience, this belief becomes knowledge and serves as a framework to guide future clinical investigations. This is an example of deductive reasoning where the application of existing knowledge is used to generate new knowledge. Accordingly, it is imperative that such new knowledge be acquired and validated through a purposeful, repeatable diagnostic process. If new knowledge is acquired by luck, chance, or random events, as is often the case with inductive reasoning, it is not a justified true belief. In other words, the process of justification or acquiring evidence is equally important as the justification or conclusion itself.

For example, the knowledge gained from a positive PCR test for *Mycoplasma hyopneumoniae* derived from a lung sample selected from an animal with clinical signs and gross and microscopic lesions of enzootic pneumonia would have far greater knowledge value than would a positive test derived by chance from a random sample of lung. The former has more evidence to support association with disease than the latter. Diagnostic accuracy is enhanced because the process that selected the lesioned tissue is more likely to produce future disease confirmations than the random method and therefore creates more complete knowledge from which to base future investigations.

Sensitivity and specificity

Another key to understanding disease diagnosis by laboratory testing is that analytical sensitivity and specificity of a laboratory test are not the same as diagnostic sensitivity and specificity, though many will inadvertently confuse the two. Diagnostic specificity is reflected in the positive predictive value of an assay regardless of the analytical sensitivity and specificity (Saah and Hoover 1997). In other words, diagnostic specificity describes the likelihood that an animal with a positive test actually has disease. Similarly, diagnostic sensitivity is a reflection of the negative predictive value of an assay. The fact that an assay has high analytical sensitivity (often also referred to as limit of detection) and can detect minute quantities of an analyte in the laboratory, as is the case for nucleic acid in many PCR assays, does not automatically make it the best diagnostic assay.

Diagnostic sensitivity is, by definition, the probability that a test correctly identifies animals with the condition of interest: true positives/(true positives + false negatives). For example, a test with 80% diagnostic sensitivity for detecting infection with an agent would correctly identify an average of 80% of infected pigs in a population as test positive and would incorrectly identify 20% as noninfected because they tested negative (false negatives). Herein the original diagnostic question put forth by the practitioner again becomes important as the diagnostic sensitivity of the same assay may be different for detecting infection versus detecting disease. Consider that if a diseased animal is more likely to shed the organism of interest than subclinically infected animals, then the same assay described as 80% sensitive for detecting infection may be 98% sensitive for detecting disease. The diagnostic question matters.

Diagnostic specificity is the probability that a test correctly identifies animals without the condition of interest: true negatives/(false positives + true negatives). A test with 90% diagnostic specificity would correctly classify 90% of non-affected pigs on average as negative and would falsely classify 10% of pigs as affected (false positives). Here again the diagnostic question is important: is the practitioner interested in detection (presence or absence of a pathogen) or disease (impact on the animal or population)? Many new diagnostic assays have high analytical sensitivity and analytical specificity, which makes them highly efficient at detecting infectious agents; however, for many pathogens, particularly those that can become endemic in a population, the mere presence of the agent is not highly correlated with a diseased state.

In most field situations, high diagnostic sensitivity and specificity are both desirable although nearly impossible to obtain from a single test. In a general diagnostic context, sensitivity and specificity, once established, are inversely related (as one increases, the other decreases). Lowering the minimum detection limit of a test, such as increasing the cutoff value for a positive PCR result, may improve diagnostic sensitivity but will undoubtedly lower the diagnostic specificity of the test. Buyers of pigs and regulatory officials in importing states and countries typically want tests approaching 100% diagnostic sensitivity for detecting specific pathogens to minimize the risk of introducing new pathogens to an area. A similar line of reasoning can also be applied for tests to detect agents of public health concern (i.e. *Salmonella* spp., *Trichinella* spp., etc.) and antibiotic residues. On the other hand, owners of breeding herds prefer tests of high diagnostic specificity to maximize their chance of selling replacement animals and eliminate issues related to false-positive results. High diagnostic specificity is also

desirable for commercial producers participating in eradication programs where economic losses from false-positive results can be substantial.

Application and examples

Many common diseases can be diagnosed by clinical observations and history; however, confidence in accuracy is increased when the framework of a diagnostic investigation is customized around the context of the case. A diagnostic investigation, then, is executed in much the same fashion as a research protocol with a clear clinical (case) definition, identification of the specific population involved, clearly defined diagnostic objectives, and strategically selected tests, samples, and methods to acquire the evidence from which to identify cause, propose solutions, or monitor interventions.

Preparing diagnostic submissions

Properly executed, each step of the diagnostic process (Figure 8.2) provides at least a portion of the information necessary for confidence in accuracy and utility of identifying and implementing solutions to clinical concerns and/or monitoring outcomes for continuous improvement. The concepts embedded in the diagnostic process and testing can be applied to individual animals, to a group of animals, to successive groups in a particular flow or herd of animals, or to an entire production system. The population should always be defined with estimates of accuracy and confidence in place as part of the diagnostic process. Remember the goal of the diagnostic investigation process is to generate the evidence in a systematic fashion that will allow deduction of diagnosis of one or more insults with the greatest confidence that the conclusions are accurate.

Case definition relies on clinical skills and suppression of bias through objective observation and proper data collection. This initial case definition and sample selection forms the basis for all further diagnostic testing, interpretation, and analysis, and it cannot be stressed enough that outsourcing this critical task to field managers and livestock producers is a significant risk that may derail the entire diagnostic process from the outset. A thorough clinical examination of individual animals and tabulation of clinical signs should allow one to write one or more case definitions for the affliction of individual animals as well as multiple insults encountered in populations of pigs. Mortality is not a clinical sign or diagnosis; it is an outcome and should not be viewed as a case definition or clinical sign. Avoid the temptation to force all clinical signs into one box or assign causation to one etiology. In fact, it is preferable to not think of a specific etiology when creating the case definition(s). A case definition provides the criteria that will be used to classify, categorize, and quantify the afflictions present in the group. The use of specific clinical descriptors will allow more accurate communication of the clinical issue at hand and can be augmented by visual images or video. For example, diarrhea is a nondescript term often used to describe enteric disease and provides little information on potential proximate causes. On the other hand, descriptors such as watery, pasty, bloody, mucoid, voluminous, and projectile not only invoke a vivid mental picture but also help to narrow a differential diagnosis and direct diagnostic testing. Principles of epidemiologic investigation coupled with clinical examination should allow for localization of where lesions may be expected and direct diagnostic sampling.

Necropsy is one of the most valuable tools a practitioner has for presumptive diagnosis. Necropsy of affected or dead animals that meet the case definition can reveal lesions compatible with a particular insult type or rule out some of the differentials developed from the case definition. This is also the opportunity to collect and preserve appropriate samples for laboratory investigation (see Chapter 7). Often the greatest source of error in defining true status by testing is in the process around sample selection and preservation. No amount of effort or test sensitivity can overcome the limitations of improper sampling and preservation. As noted above, careful attention to collection of data from history, clinical signs, case definition, and gross lesions will allow prioritization of a differential diagnosis. Clinical and pathological data objectively collected can usually localize a likely source of insult into one or more body systems. Carefully consider the potential causes; do not assume a diagnosis. Differential diagnosis – which is essentially pausing to ask the question "what could this be?" – is the primary driver for selection of the most appropriate samples and tests for continuing the diagnostic investigation through laboratory testing. Samples should then be collected accordingly and completely. When there is any doubt, seize the opportunity to collect samples in a systematic, organized, thorough, and complete manner. There is no better time, and perhaps no other opportunity, to collect appropriate samples than at the initial site visit. Samples can include serum or whole blood (affected and non-affected cohorts), all relevant tissues from representative animals (both fresh and formalin fixed), oral fluids, water, feed, and/or environmental samples (see Chapter 7).

In general, tissue samples from two to three acutely affected animals that truly represent the case definition are sufficient for diagnosis of disease. However, in some situations, a cross-sectional or sequential approach to sample collection is warranted. For example, arthritis or chronic polyserositis in grower stages often has origins in the nursery phase. For an accurate herd diagnosis, it is prudent to design a cross-sectional or sequential

diagnostic investigation to better understand which agents are contributing and the sequence in which they occur. Samples from animals later in course of disease and/or mortalities can be useful to implicate sequential insults or involvement of multiple agents or insult types. As multiple diseases can be simultaneously present and have cumulative and interacting effects within a population, it is often difficult to obtain a rapid and accurate diagnosis from a single or limited number of sample submissions for diagnostic testing.

Similarly, nonrandom antemortem sampling can be useful if the clinical status of uniquely identified individual animals is known. For example, serologic titers for a particular agent such as *Leptospira*, Aujeszky's disease, or PRRSV would be expected to be positive and relatively high 2 weeks after abortion. Such nontrivial change in antibody titer between two time points (seroconversion) is useful supporting evidence for disease diagnosis. This type of targeted sampling is not random; hence fewer samples are required to establish the presence of herd infection than in random sampling approaches described for surveillance.

Selecting the best diagnostic test for a given situation requires a thorough understanding of the stage of disease in the population, treatment history of the animals sampled (including past vaccinations), and the potential pathogen(s) at hand. The array of tests, technologies, and protocols available can make selection of laboratory tests confusing; however, the selection and interpretation of laboratory tests can be another significant source of error within the diagnostic process. In general, a diagnostic test should not be performed unless the practitioner can anticipate all of the likely results of the test and can interpret the results in the context of the animal or population sampled and at least one of the potential results of the test will trigger purposeful action. Testing solely for the sake of generating data is a perilous approach that is often uninterpretable, wastes valuable resources, and muddies the diagnostic picture.

Good communication with knowledgeable diagnosticians is a necessary component of the diagnostic process to avoid pitfalls and misdiagnosis. Figure 8.3 provides examples of situations where microbial culture, serology, and molecular diagnostics may be useful in the diagnostic process for pathogen detection as well as situations where each may be of little or no value. Such assays help determine if a host is infected (e.g. a microbe is present and proliferating within the host) but may not be sufficient to differentiate between subcategories of infection, which include colonization, subclinical infection, and diseased. Thus, clinical context is essential in the selection and interpretation of diagnostic assays. The practitioner should strive to communicate specifically and effectively with the diagnostic laboratory using the telephone, digital images, video, written descriptions on submission forms, historical data, charts, records, and whatever other methods are available to improve mutual understanding of issues at hand in the population sampled and to document and archive for ongoing reference and herd history.

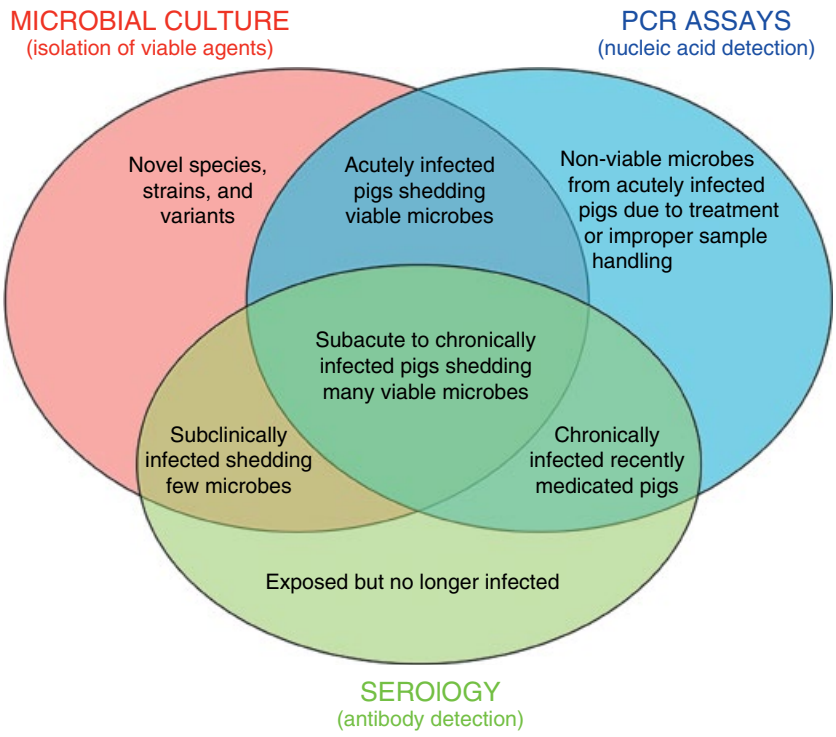

Figure 8.3 Venn diagram of different clinical scenarios related to infectious disease and the diagnostic assays expected to be effective in detecting an etiologic agent from individual pigs. Note that there is no universally "best" test and a parallel testing approach may be warranted in many situations.

The value of data accumulated over time and application of appropriate data management tools offer the possibility that disease occurrences, interventions, and outcomes can be continually analyzed with real strides toward continuous improvement and identifying best practices. However, the "big data" approach to swine disease control will only be valid if the original diagnosis and assumptions as to etiology (cause) are valid and accurate within a known and accurate context. Databases must have accurate inputs, gathered with an understanding of where the numbers come from, how they are derived, accurate denominators, specific clinical context, and the likely impact of any detected pathogen/analyte. Furthermore, databases must be continuously monitored and improved through appropriate controls and feedback loops (Nielsen 2011).

Combining multiple diagnostic tests

Methods to improve accuracy of disease diagnosis often include the application of serial or parallel testing, depending upon the diagnostic objective, as described in the following paragraphs.

Serial testing with a stepwise combination of multiple tests increases diagnostic specificity at the expense of diagnostic sensitivity (more likely to miss a few cases but with added confidence that those identified are diseased) and is useful in answering questions regarding pathogen impact and the presence of disease. One of the most common serial approaches in routine diagnostics is to first use a test with high analytical sensitivity, such as PCR, and to follow up on positive results with histopathology to confirm compatible lesions. If further confirmation is desired, immunohistochemistry or *in situ* hybridization can be applied to the affected tissue sections to demonstrate the presence of pathogen antigen or nucleic acid within lesions, respectively – the proverbial smoking gun. Requiring all tests in serial to be positive in order to classify the animal or population as diseased will greatly improve the specificity of the diagnosis.

Parallel testing, on the other hand, requiring only one test in a battery to be positive in order to classify the animal or population as affected greatly increases diagnostic sensitivity (a wider net) at the expense of diagnostic specificity (more likely to have some false positives) and is most useful in addressing pathogen surveillance questions. This loss of specificity comes as a consequence of using multiple imperfect tests, which therefore increases the chance of abnormal results in otherwise healthy and/or non-exposed pigs. The probability of at least one abnormal test result increases as the number of independent tests is increased. For example, suppose that a sow was screened by two different unrelated assays for a specific bacterial infection. If the sow was never really exposed to the agent (unknown to the veterinarian) and each test had a specificity of 95%, the probability that both tests are negative would be approximately 90% ($0.95 \times 0.95 = 0.9025$). Hence, the probability that at least one test would yield a (false) positive result is now 10%.

As diagnostic cases become more complex, and submitting practitioners more sophisticated, diagnostic laboratories can aid in refining test strategies and expectations. Diagnosticians generally appreciate the opportunity to be involved in protocol development for difficult cases, case series, field studies, or field research. Repeated submissions to gain insight on a complex problem, or cases series to better define compromises in a system or flow over time, are becoming increasingly common requests. A diagnostician's insight can be quite helpful in formulation of an action plan once the submitter's concerns, issues, objectives, and resources are known. The quality of investigation in these circumstances is often greatly enhanced with a consistent specific protocol and standardized submission. A single diagnostician providing oversight in the laboratory can also assure continuity and greater insight into the question at hand. The same is true for those requesting testing as part of a field trial or actual research trial. As stated throughout this section, communication is essential in the diagnostic process. When a laboratory result does not make sense, investigate until it does. While it may be laboratory error, the adept practitioner should be open to the possibility of something totally unexpected or even something new.

Sampling for surveillance and prevalence estimation

Theory

In veterinary diagnostic medicine, it is useful to remember the following truisms: (1) there is no perfect diagnostic test, (2) there is no perfect diagnostician, (3) it is not possible to prove a negative, and (4) time and observation are allies. Accordingly, the swine practitioner does well to use their knowledge of diagnostic medicine with due respect for that which is known, but also objective perspective of that which is unknown. "We've never heard or seen that before! How can it be true?" is the practitioner's confession of reticence to new paradigms. In this mindset, one tends to ignore or procrastinate the opportunity to hone their diagnostic framework through new observations, data, and time, which become allies to new knowledge. In the 1880s, Robert Koch proposed four straightforward postulates for proving causality related to infectious agents and disease; however, with time it was shown that not all infectious agents fit this model (viruses, co-pathogens, prions, etc.) and refinements and amendments to these postulates were required (Evans 1976). Such is the background to understanding principles of causality and in particular to

approaching methods for surveillance and monitoring in animal populations as new diagnostic tests, sample types, and advanced methodologies become available. As science and technology continue to evolve and expand, further discoveries will likely continue to test accepted models of causation and will require practitioners to be open to new interpretations. When such new developments arise, the practitioner is implored to approach and adopt new knowledge with common sense and sound reasoning.

Monitoring versus surveillance

There are significant differences between pathogen/disease monitoring and surveillance in an epidemiologic context (Christensen 2001). Both involve continuous collection of data; however, the intent of monitoring is to assess the disease status of a given population over time, while surveillance describes situations where purposeful actions will occur when the measurement reaches a certain level (Christensen 2001). In a general sense, monitoring is performed for diseases that are known or suspected to be present in a population, whereas surveillance is for those diseases or agents that are not expected to be present. Thus, the differentiating factor is if the intent is to take immediate action or not.

When submitting samples for pathogen monitoring or surveillance in a population, it is important to remember that absence of evidence should not necessarily be interpreted as evidence of absence. Put another way, it is prudent to exercise caution when interpreting a zero numerator (all samples test negative) and to always do so in the context of the denominator (number of samples from a defined population). To this end, the number of samples necessary (the denominator) to detect a pathogen or disease in at least one animal in a population at a given point in time is inversely related to the expected prevalence within the population sampled. Further, the number of samples increases dramatically as the desired confidence level for detection increases or approaches 100% and even more so if the expected prevalence is low. Accordingly, truly random sampling from a population for detection of a disease or infection of low expected prevalence requires large numbers of samples to be confident that the population is truly negative when all test results are negative. For example, even with a perfectly sensitive test at least 60 animals should be randomly sampled for a disease of 5% expected prevalence if the desired confidence level is 95%. If the assumed prevalence approaches 50% or more, then the number of samples required for detection drops to 5 or fewer with 95% confidence. Tables describing specific sample numbers necessary to detect a pathogen or disease within a population at various confidence levels and with varying disease prevalence are available elsewhere (DiGiacomo and Koepsell 1986).

Proving a population negative for a particular attribute with absolute certainty is impossible. Hence, cases where all of the individual results of a particular test are negative require thoughtful interpretation, particularly when there is little context regarding the samples themselves. A useful rule for interpreting negative results from random samples is the "rule of three," which stipulates it can be safely concluded with 95% confidence that the upper limit of prevalence of an outcome (in this case a positive test result) is at most $3/n$ where n is the number of samples with negative results (Hanley and Lippman-Hand 1983). For example, if 20 samples are collected and all samples test negative for a pathogen, it would be tempting to conclude that the population is negative for this pathogen; however, the "rule of three" provides a more conservative and appropriate interpretation such that one can confidently conclude the prevalence of the pathogen within the tested population is less than or equal to 3/20 or 15%. This conclusion still includes the possibility of a truly negative population but suggests additional testing may be required in the context of the diagnostic question. As the total number of negative samples increases, the upper limit of the prevalence estimate decreases. A derivative of this rule can also be used to quickly estimate the number of samples necessary to detect a pathogen with 95% confidence and is calculated as $3/P$ where P is the expected prevalence in decimal form. For example, if a pathogen is assumed to have a prevalence of 25% in a population, then the number of samples needed to confidently screen for the pathogen is 3/0.25 or 12. This estimate aligns well with published table values when disease prevalence is less than 50% and is a slight over estimate when disease prevalence is high.

Estimating prevalence

Understanding disease prevalence and infection rates in a large population may be desired in efforts to determine the effectiveness of prevention and control programs; however, this requires a proactive monitoring or surveillance program. Due to feasibility and financial constraints, it is often desired to estimate prevalence in a herd from observed prevalence in a sampling of the population. The precision of the estimate is dependent upon the true prevalence in the population and the sample size. Accordingly, larger sample sizes are necessary to accurately estimate prevalence (5% maximum error), and estimates derived from less than 10 samples are only applicable for conditions of very high (>90%) or very low (<10%) prevalence with an expected error rate of 15–20%. Thus, attempts to estimate population prevalence require a specific proactive random sampling approach designed with regard to the expected prevalence and population size, and attempts to estimate prevalence from cumulative data derived from routine diagnostic submissions would be tenuous at best as common sampling sizes (5–10 samples) are too small

for precise comparisons. Tables describing specific sample numbers necessary to estimate the prevalence of a pathogen or disease within a population and at various error limits are available elsewhere (DiGiacomo and Koepsell 1986).

Application and examples

The swine practitioner, having determined the desire to perform pathogen monitoring or surveillance, must ultimately decide the nature of the data they wish to generate: qualitative or quantitative.

Qualitative data and cutoff values

Qualitative results (positive, suspect, or negative) are laboratory interpretations based upon statistics generated during the assay validation process. Qualitative results are certainly helpful and can be definitive; however, the assignment of the proper test interpretation category (positive or negative) is dependent upon a predetermined, somewhat arbitrary cutoff value. Depending on the context of the diagnostic question, this can affect final test interpretation when samples have test results near the cutoff value. This is most relevant when considering results of serologic and PCR-based tests, for which cutoff values may differ between laboratories, versus results of microbial culture that are not dependent upon a specific cutoff.

Cutoff values are determined with one of three objectives: (1) to maximize the diagnostic sensitivity and diagnostic specificity of the assay, (2) to maximize only the diagnostic sensitivity, or (3) to maximize only the diagnostic specificity. The chosen cutoff value therefore determines the interpretation of each result as positive or negative, regardless of the assay platform. Ideally, the data for determining assay cutoff values come from controlled infection studies of known naïve animals. Samples collected at consistent intervals from the known-infected and negative control animals afford investigators the opportunity to understand antibody, antigen, and nucleic acid detection over time. For example, samples containing nucleic acid at the threshold of detection for a given PCR assay will be sometimes positive and sometimes negative based on the cutoff threshold (CT) of a particular test, the efficiency of extraction in the laboratory, and other sources of laboratory error. Rarely is this an issue with acute disease diagnosis (see previous section) as dogma suggests that there should be abundant pathogen nucleic acid in appropriately collected samples from animals with acute disease. However, generalizing these concepts to assign "positive or negative status" to environmental samples for surveillance is often an inappropriate interpretation. Depending upon the expected impact, test–retest strategies, confirmation testing, or resampling may be more appropriate options.

The same is true of most modern antibody assays. The cutoff used to assign "positive" or "negative" is the interpretation of continuous data generated from a spectrophotometer. Results of repeated testing of the same sample, with continuous data assays, vary around an average of their values. That is, the same sample will produce test results (which are continuous data) with different interpretations if the result is near the value defined as the cutoff for the assay.

Quantitative data and time

Quantitative data, by definition, provide a numerical value for each sample and are useful to display the variation within a sample set and among sample sets over time. This variation and associated sample set averages build an objective understanding of overall system output. The results are also independent of any subjectively defined cutoff value. This can be particularly useful with ELISA sample-to-positive (S/P) ratios, clinical pathology results, and other continuous data.

Time is your ally when considering the conceptual framework and connectivity of infection, disease, clinical recovery, and serologic response as well as relationships between time of onset and duration of infection as depicted in Figure 8.4. Exposure can lead to infection in which the offending agent replicates and is shed by the host. Clinical disease may or may not occur. The agent or its antigens or genes may be detectable by some method for some duration. Infection typically results in an immune response often measured by an antibody assay. In most cases, the agent is eventually cleared from the host and no longer directly detectable, while antibody remains for a longer period and provides options for indirect detection. Each offending agent and each individual animal will have its own timeline, usually hovering around averages but commonly with significant outliers. Variation is expected in clinical outcomes and in

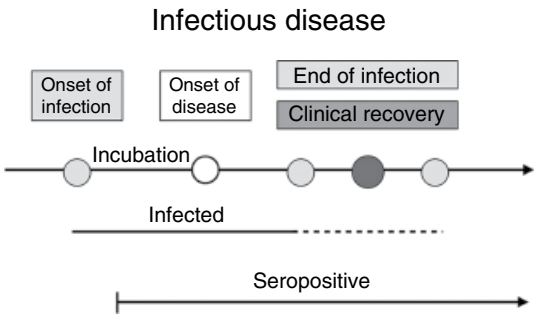

Figure 8.4 General relationships between infection, disease, recovery, and serologic response over time. Note that clinical recovery does not necessarily mark the end of infection or impact serologic status. Knowledge of these relationships helps determine appropriate diagnostic testing (direct vs. indirect methods) for specific pathogens. *Source:* Courtesy of Dr. Greg Stevenson.

magnitude and duration of various assays along the timeline. This illustrates the infrequency of black-and-white outcomes and solutions for the multifactorial nature of infectious diseases. The absence of clinical signs does not mean absence of infection.

Using diagnostic data for process improvement

A model for process improvement was proposed by Walter Shewhart and later promoted by W. Edwards Deming as the Shewhart Cycle of Plan, Do, Study, Act (Deming 1986). This cycle provides a framework for learning about a process and then working to improve the process. The Shewhart Cycle of Plan, Do, Study, Act (Deming 1986) directly applies to swine health management and the use of diagnostic data. A plan for using diagnostic data for major pathogens, particularly those for which elimination has merit, likely involves herd health stabilization, pathogen elimination, and prevention of reintroduction. At all stages of the health management process, there is a need to collect proper diagnostic data to measure success and drive future action. Without applicable and appropriate measurement tools, there will be no accurate information to analyze and study.

If health management is the objective of sampling and testing, the swine practitioner has made the decision to be engaged in disease monitoring and/or surveillance. Prior to collecting this health management data, an

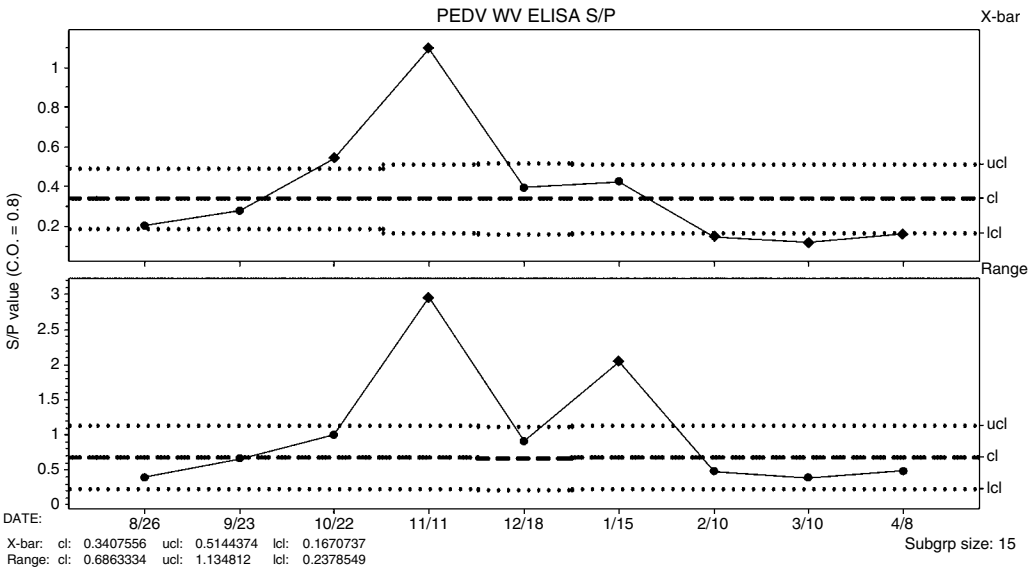

Figure 8.5 Statistical process control (SPC) chart for PEDV exposure using PEDV whole virus ELISA results (S/P) from monthly collection of 15 serum samples. Prior to collecting these samples, it was determined that data from the first three months would serve as baseline data for determining upper and lower control limits (UCL and LCL). The table contains the raw S/P data for each month, and the averages of each month's S/P values are reflected in the upper graph, while the lower graph shows the variation (range) for each month. There are signals of abnormal variation in the data from November and January, suggesting recent exposure to PEDV ahead of those sampling periods.

operational definition (adapted from Deming 1986) must be created and includes:

A specific test to be applied for a specific agent, disease process, or physiological parameter – for example, testing for antibody, antigen, or nucleic acid in animal or environmental samples to detect evidence of the agent.

A criterion or criteria for judgment (e.g. presence of evidence of an agent within an animal or population).

A decision (yes or no) if the sample did or did not meet the criterion (or criteria); thus an action is or is not required.

As laboratory data related to an operational definition are collected, a consistent and purposeful method to analyze the results should be implemented. A statistical process control (SPC) chart is one effective method for examining quantitative data over time, and an example is provided in Figure 8.5. In this example, a specific test (PEDV WV ELISA on serum collected monthly), with specific criteria for judgment (average S/P ratios with expected upper and lower limits as defined by the first 3 months of data), is used to monitor population status and screen for potential PEDV exposure events. In this case the assumption would be that averages outside the calculated upper limit are evidence of potential exposure to PEDV and would trigger additional action including diagnostics and confirmatory testing as described in the first half of this chapter. Additional information related to SPC charts and understanding variation is available elsewhere (Wheeler 2000; Wheeler and Chambers 1992). SPC charts are dependent upon not only how the data are generated but also the frequency of data collection. Assuming quality data are collected, SPC charts then require proper creation, interpretation, and use.

Disease Control, Prevention, and Elimination

Eric J. Neumann and William F. Hall

Introduction

Biosecurity, or preventing the transmission or introduction of diseases, is a cornerstone of modern veterinary service in the pig industry. Eradication of diseases from pig farms remains an important goal, though it is one rarely achieved. Fortunately, through the process of attempting to eliminate diseases, transmission of diseases and hence their frequency or occurrence (and often their severity) are reduced. This chapter describes a framework for understanding an infectious disease through knowledge of the pathogen's interaction with the host, the production setting, and its broader environmental landscape, a framework described as "disease ecology." Disease ecology is prefaced on the categorization of pathogens based on the mechanisms they rely on to perpetuate themselves between leaving one host and finding a new one. By considering pathogens in terms of their ecology, rational approaches to disease control and eradication can be developed even when complete information about a pathogen is lacking.

Disease transmission

Disease transmission includes any mechanism by which an infectious agent is spread from an infected host, animate or inanimate vector, or environmental reservoir to a susceptible host. Implicit in a transmission event is the requirement that a new host becomes infected. This situation is in contrast to an exposure event whereby an infectious agent is presented to a potential host with transmission as one possible outcome. The possibility of transmission is a function of the combined likelihood of several serially occurring events. Transmission requires that a pathogen successfully exits an infected host, escapes potential threats to its existence in the environment, breaches the defense systems of a new and susceptible host, and then reaches an anatomical site suitable for further replication or perpetuation in that host (Zimmerman 2003).

Some authors have elaborated on the need to draw distinction between modes of transmission and routes of infection (Smith 2006). Modes of transmission can be classified as horizontal (between contemporaries or animals of the same generation) or vertical (between infected animals of one generation and uninfected animals of the succeeding generation, *in utero* or through the colostrum). Within horizontal modes of transmission, further distinctions can be made to categorize transmission events that occur as a result of direct or indirect contact with an infected animal or through exposure to an airborne pathogen.

Route of infection specifies the means by which a pathogen enters the host including the alimentary, respiratory, or urogenital tracts, skin, or conjunctiva. To gain a thorough appreciation of the determinants of disease transmission, one must resist the urge to systematically classify pathogens based on their most likely, prevalent, or important pathway of travel between infected and uninfected animals. The advent of molecular-based diagnostic tests and advanced epidemiological analyses has enabled a more complete understanding of the complex interactions between host, pathogen, and the environment. An alternative approach to understanding disease transmission in the context of this new information is through a framework that attempts to explain where the pathogen hides or resides when it is not in the host animal.

An important objective for veterinarians, animal scientists, and farmers is the prevention, control, and, when possible, eradication of disease in commercial livestock. Fundamental to these objectives is knowledge of the habitat in which the pathogen can persist. "If we can combat the pathogen only when it has invaded our stock we shall never eradicate it; if it has any other habitat to hide in, we must find that habitat" (Halpin 1975).

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Ecology of disease: host–pathogen-environment

In broad terms, disease is either a physiological or psychological dysfunction and includes both cellular pathology and clinical signs; these may be a result of infection with a pathogenic agent or be associated with any number of noninfectious causes. For the sake of this chapter, disease will be taken to mean only those pathologies and clinical signs caused by infection with a pathogenic agent.

Disease may persist long after a pathogen has been cleared from the host. Disease may be classified based on temporal staging (peracute, acute, subacute, chronic, persistent/latent), severity (unapparent, mild, moderate, severe), or the organ systems that are affected. Under the right circumstances, organisms from all taxonomic kingdoms are represented among the list of potentially infectious pathogens of the pig.

An understanding of why disease occurs and how it can be controlled requires some knowledge of contributions made by the environment in which the host and pathogen reside. A more apt term that incorporates the complex interactions between host and pathogen, including environmental variables, is "disease ecology." After making its first appearance in the scientific literature nearly 60 years ago (Bejarano 1960), the term was used primarily in discussion of arthropod-borne and wildlife diseases until the 2000s. However, in recent years, use of the term has expanded into epidemiological studies of animal and human diseases as analytical techniques capable of simultaneously integrating spatial, climatological, temporal, and demographic data with traditional measures of disease occurrence have become more widely used.

Ecology is the study of the distribution and abundance of organisms and their interactions with the environment (Begon et al. 2006). Implicit in the term is a sense of balance, an imperative that an ecological system will evolve over time into a stable circumstance that reacts to external influences in such a way to maintain that stability. In the context of disease ecology, one could use as an example the relationship that evolves between *Mycoplasma hyopneumoniae* bacteria and young pigs in the environment of a conventional continuous-flow growing-finishing barn. Over time, a high prevalence of infection will be established in the pig population but with few overt clinical signs (endemicity). The prevalence of infection, its phenotypic and genotypic characteristics, systematic environmental variables (throughput, pig density, and pig husbandry and management), and the pig's own evolutionary progression (body functions, body size, social behavior, and body defense mechanisms) will remain stable. In the absence of external stimuli, there is no obvious imperative for the host, the pathogen, or the environment to change.

From a more philosophical perspective, one can even incorporate the influence of public policy (as an environmental contributor to pig disease) into the disease ecology paradigm. Law and Mol presented a compelling discussion on the "politics of boiling pigswill" in a 2008 paper that offered their reflections on the influence that the regulation of waste-food feeding to pigs had on the 2001 foot-and-mouth disease virus (FMDV) outbreak in the United Kingdom (Law and Mol 2008). They suggested that through regulation of the "mundane and material" practice of boiling pigswill, competing politico-environmental ethics were established whereby the rich were divided from the poor through separation of FMDV-free countries from those in which the disease was endemic. The authors stated, "To boil pigswill at Heddon on the Wall [the index farm] is to reproduce a distinction between a productive and a less productive agriculture. It is also a technique for making and maintaining a specific geographical distribution of that productivity." We are no longer raising pigs in the isolation of our own farms; we are subject to the effects of the political winds of the day, and this should be considered in the modern framework of disease ecology.

A specialized discipline within disease ecology has evolved to deal with the unique mode of disease transmission carried out through arthropod vectors, that being "landscape epidemiology." Like disease ecology, landscape epidemiology had its origins in the scientific literature of the 1960s but experienced resurgence in use during the 2000s. Landscape epidemiology has a spatially defined focus with the intent of measuring changes in the dynamics of host, vector, and pathogen interactions and their association with the risk of disease transmission to the host species (Reisen 2010). Geographical information systems in combination with analytical techniques accessible to a broader group of scientists have allowed those working with vector-borne diseases (specifically arthropod-borne pathogens) to describe nidalities of infection. Nidalities are pathogen specific and are fundamentally determined by the concurrent spatial overlap of landscapes that offer the requisite combination of vegetative cover, elevation, latitude, and microclimate capable of supporting populations of competent and infectious vectors, competent vertebrate reservoir species, and susceptible host species.

Japanese encephalitis virus (JEV) is a mosquito-borne Flavivirus and is the most frequent cause of arboviral-induced encephalitis of people around the world; domestic pigs are the most important reservoir for this virus. Recent work utilizing a landscape epidemiology approach has shown that the seasonal increase in the

number of human infections in Southeast Asia and Oceania is now occurring up to 2 months earlier in the year and persisting for up to two months longer than typically expected (Hsu et al. 2008). The explanation appears to be related to the local effects of climate change on ambient temperature and the increased frequency and intensity of rainfall, both of which have contributed to a change in the ecology of the mosquito vector. Similar findings have been reported for West Nile virus and Bluetongue virus (Weaver and Reisen 2010); evidence of both infections can be found sporadically in domestic pigs though their role in further transmission is unlikely (Sugiyama et al. 2009; Teehee et al. 2005). A landscape epidemiology approach enabled researchers to identify these important public health trends that have the potential for substantially impacting the pig industries in affected regions.

Measuring the occurrence of disease

There are several ways to measure disease occurrence depending on the question one is trying to answer. Important to these measures is defining the number of animals in the population that are at risk of becoming infected. Commonly used measures of disease occurrence are shown in Table 9.1. Two important distinctions should be recognized when interpreting prevalence and incidence: (1) prevalence measures the occurrence of infection at a single point in time, while incidence incorporates the frequency at which new infections occur over a defined period, and (2) prevalence assumes all individuals in the population are (or were) at risk of becoming infected some time before being diagnosed, while incidence considers only those animals susceptible to infection at the beginning of a defined time period.

Incidence measures tend to be of more use than prevalence in study of disease transmission as calculations of both incidence risk and incidence rate consider only those animals known to be free of infection at the beginning of a defined time period and relate this occurrence to the accumulation of new infections over time. Incidence measures inform one of the "force of infection" or the rate at which new cases occur over time, a particularly useful determinant in predicting the course of a disease epidemic. In calculating incidence rate, the cumulative time at risk for individuals in the population is recorded in order to precisely account for the time that has elapsed prior to an animal becoming infected.

For relatively stable populations in which the incidence rate of a disease is constant (rare for most infectious diseases in commercial pig production), the relationship between prevalence, incidence rate, and disease duration can be represented by the following formula (Dohoo 2003):

$$\text{Prevalence} = \frac{(\text{incidence rate} * \text{average duration of disease})}{(\text{incidence rate} * \text{average duration of disease}) + 1}$$

A cascade of successful events must occur in order for disease transmission to take place starting with exit of the pathogen from an infected host and ending with the pathogen finding a suitable habitat or cell to occupy in a susceptible host. Each step in this cascade has an associated probability of success, sometimes conditional or dependent on events that occurred in a previous step. The combination of these probabilities results in a determination of the likelihood that the new host becomes infected and can be expressed qualitatively (low, medium,

Table 9.1 Commonly used measures of disease occurrence.

100 pigs are monitored two times, over a 30-day period for infection with pseudorabies virus, based on seroconversion to the virus.

Measure	Formula	Day 0 Positive = 10 Negative = 90	Day 30 Positive = 25 Negative = 75	Interpretation at day 30
Prevalence risk	$\frac{\text{No. positive}}{\text{No. in population}}$	$\frac{10}{100} = 0.10$	$\frac{25}{100} = 0.25$	25% of pigs have evidence of prior infection with PRV
Incidence risk	$\frac{\text{No. becoming positive during period}}{\text{No. at risk at start of period}}$	NA (unknown time at risk)	$\frac{(25-10)}{90} = 0.17$	There is a 17% chance of a pig becoming infected with PRV during a 30-day period
Incidence rate	$\frac{\text{No. becoming positive during period}}{\text{Accumulated "time at risk"}}$	NA (unknown time at risk)	$\frac{(25-10)}{((90*15)+(75*15))} = 0.006$	6 pigs become infected with PRV per 1000 pig-days at risk[a]

NA, not applicable.

[a] Assumes all pigs became infected halfway through the period (i.e. 15 days after monitoring began).

or high likelihood) or quantitatively (10, 50, or 90% likelihood). In common terms, a pathogen might simply be described using descriptors such as "highly contagious" or "very infectious," for example, when it is perceived that transmission between pigs or farms is inevitable. Given that current laboratory techniques allow precise enumeration of the number of pathogens shed by an infected host and determination of the minimum dose required for transmission to occur, some clarification of terms related to the likelihood of successful transmission is useful. "Infectious(ness)" describes those diseases (as distinct from pathogens) that are capable of being transmitted between individuals or can be alternatively described as the inverse of those diseases having a noninfectious cause. For example, neoplasia (perhaps excepting those with suspected viral origins) is considered noninfectious, while most conventional diseases of pigs have an infectious cause (bacteria, viruses, internal and external parasites, and fungi/yeasts). "Contagious(ness)," by contrast, is a qualitative descriptor synonymous with the combined likelihood of success of all the events necessary for transmission to occur. The combination of host, pathogen, and environmental variables that would make transmission from an infected host to a susceptible host very likely to occur would also promote rapid spread between individuals; these types of diseases would be considered very contagious. By these definitions, a pig in the chronic stages of a resolving pneumonia that was initiated by infection with influenza virus two weeks previously would be considered to have an infectious disease (the pathology was initiated by influenza virus, and the lung continues to harbor transmissible secondary bacterial pathogens) but is currently in an ecological state whereby the disease is not very contagious (influenza virus is no longer present, and the secondary bacteria are unlikely to be transmitted to an otherwise healthy pig).

The number of pathogens that must be delivered to the host in order to successfully establish infection is referred to as the infectious dose. This does not represent the number of pathogens that must be delivered to the site of replication in the host, as this number would theoretically be the same for a given pathogen, regardless of the route of exposure. As all infectious pathogens (and the pig host) are subject to normal biological variation (related to virulence attributes of the pathogens and active or innate immune effectiveness for the pig), one should anticipate that there will be variation in the infectious dose associated with a given pathogen. To standardize calculation and reporting of this information, infectivity of a pathogen is generally stated as an infectious dose 50, or "ID_{50}." The ID_{50} of a pathogen represents the dose level that will result in successful infection of 50% of those hosts that were exposed (to that dose level). Using porcine reproductive and respiratory syndrome virus (PRRSV) as an example, the ID_{50} for oral, intranasal, and parenteral routes of exposure were reported to be $10^{5.3}$, $10^{4.0}$, and $10^{2.2}$ tissue culture infectious dose 50 ($TCID_{50}$, interpreted similarly to ID_{50}), respectively (Hermann et al. 2005). In this case, oral exposure required a 1263-fold higher dose as compared with parenteral exposure, reflecting the additional steps involved in the transmission pathway for PRRSV to reach its site of replication through oral exposure; presumably the same number of virus particles reached the site of replication in both instances.

Patterns of disease occurrence

Understanding the pattern of disease occurrence at a population level is an important consideration when hypothesizing the cause of a disease and how it might best be prevented, controlled, or eradicated. Critical to determining the pattern of disease occurrence is establishment of a case definition. This may be as simple as accepting a positive diagnostic test result but more often includes multiple criteria such as the presence of one or more clinical signs, the presence of a characteristic histological lesion, or perhaps even the lack of a confirmed diagnosis of a known pathogen. Once a case definition is established (recognizing the definition may need to be refined over time), one can proceed in establishing the disease's orientation in space and time. Examination of the course of disease events over time is important in establishing associations between cause and effect. This is particularly important considering the difficulty in establishing the incidence rate of the disease when pigs are raised in "open populations" characterized by the continuous movement of pigs into and out of the population over time (e.g. continuous-flow growing-finishing facilities).

From a temporal perspective, disease occurrence is often described as sporadic, endemic, or epidemic. Sporadic disease occurrence refers to episodes of disease that occur randomly over time; cases are clustered in time but with variable intervals of time between the clusters. This may occur when opportunities for contact between a pathogen and a susceptible host are infrequent or when the presence of multiple factors (or agents) necessary for disease to occur is absent. Endemic disease generally refers to a situation whereby disease occurs at a stable prevalence with a predictable and invariable incidence rate; cases occur at an expected rate. While endemic is often thought to indicate a disease of low prevalence, *M. hyopneumoniae*-induced pneumonia of growing pigs presents an obvious example of an endemic disease that can establish at a high prevalence. Seasonal fluctuations do not preclude the use of the term endemic as seasonal effects tend to be reasonably predictable. Endemic disease occurrence often suggests

long-term adaptation by the host and pathogen, usually accompanied by little or no mortality. Epidemic disease occurs when incidence rate increases to the extent that prevalence rises above an expected level. The interval between epidemics can be variable or invariable based on the specific ecology of the disease condition. Epidemics are often a result of an imbalance between host and agent due to a change in virulence, a change in the disease ecology, or introduction of a novel agent.

Epidemic curves are a useful graphical means of determining the pattern of disease occurrence; examples of sporadic, endemic, and epidemic occurrence are shown in Figure 9.1. Examination of an epidemic curve can provide insight as to the type of pathogen causing the disease and the stage of the epidemic (early, peak, or declining). More detailed discussion of epidemic curves and their interpretation are available from other sources including the previous edition of this text (Neumann 2012).

In describing epidemics, it is useful to classify animals in the population according to a simple system: susceptible, infectious, or recovered. Of course, pathogenesis varies among different infectious organisms such that other disease states may also need to be represented: incubating (infected but not yet infectious to others), latent (infected but not continuously infectious to others), recovered (but not resistant to reinfection), and others. To put these terms in perspective, Kennedy published the following description using a grass fire as an analogy for the evolution of an epidemic disease outbreak (Kennedy and Roe 1987):

> An infectious epidemic behaves very much like a grass fire. Whether an epidemic (grass fire) develops or not will depend on current conditions, the 'pressure of infection' (amount of sparks/flames), a threshold proportion of susceptibles (dry grass) in the population, and the size and density of the susceptible population. The more resistant individuals (green grass) in a population, the more the epidemic is impeded. However, if the pressure of infection (fire) is high enough, even the resistant individuals may succumb (burn). Human intervention may also affect the course of the epidemic. Susceptibles may be immunized (back-burning) and cases may be treated (sprayed). Also, the infective and susceptibles may be isolated and quarantined (fire-breaks). Eventually, an epidemic may burn itself out as the number of susceptibles falls below the threshold, or may smolder on at endemic level until conditions are again conducive to another epidemic.

There exist several motivations for the development of tools that can describe or predict the nature of disease transmission events within animal populations. One obvious reason is to facilitate exotic disease response planning, but other less obvious reasons include animal welfare (minimizing the number of animals affected by disease), economic evaluation of disease management strategies, and support for public policy around international trade of animals and animal products. Software tools utilizing either mathematically based modeling techniques or outbreak simulations have been developed to provide information on the likelihood, extent, and time course of disease epidemics.

The mathematically based tools generally utilize a state transition approach whereby all individuals are assumed to exist in one of the three states: susceptible (S), infectious (I), or recovered (R). Assumptions are made about the contagiousness of the disease and the duration for which an individual remains contagious to others, and then a series of differential equations are solved to transition individuals from one disease state to another at the predicted rates (Anderson 1982). While SIR models may seem overly simplistic, they are particularly useful in evaluating the effect of potential interventions, when attempting to identify the start of an outbreak (predicting backward in time to identify an index case or time), or predicting when the peak of an epidemic is expected to occur. For complex diseases, SIR models can be expanded to incorporate the effect of open populations (introduction of new susceptible individuals), latency, or the potential for reinfection of recovered individuals.

The pattern of disease occurrence is related to spatial factors as well as time. An important assumption underlying SIR modeling is that all individuals in the susceptible population have an equal probability of becoming infected. In recent years, spatially relevant modeling procedures have become available as an alternative to, or enhancement of, traditional transmission modeling methods (Pfeiffer 2008). By combining spatial and temporal information about animal populations, the extent and frequency of contact between individuals, and the relevant ecological factors in the environment, accurate assessments of the likelihood of disease transmission in a real-life setting are possible.

Mechanisms of disease persistence

The essence of veterinary medicine lies in control of animal diseases. Stopping transmission of pathogens between infected and susceptible hosts is a prerequisite for disease control as the economic, moral, and animal welfare implications of disease control programs that rely entirely on treatment postinfection are substantial. There exist numerous modes of transmission including aerial spread, direct contact with an infected host,

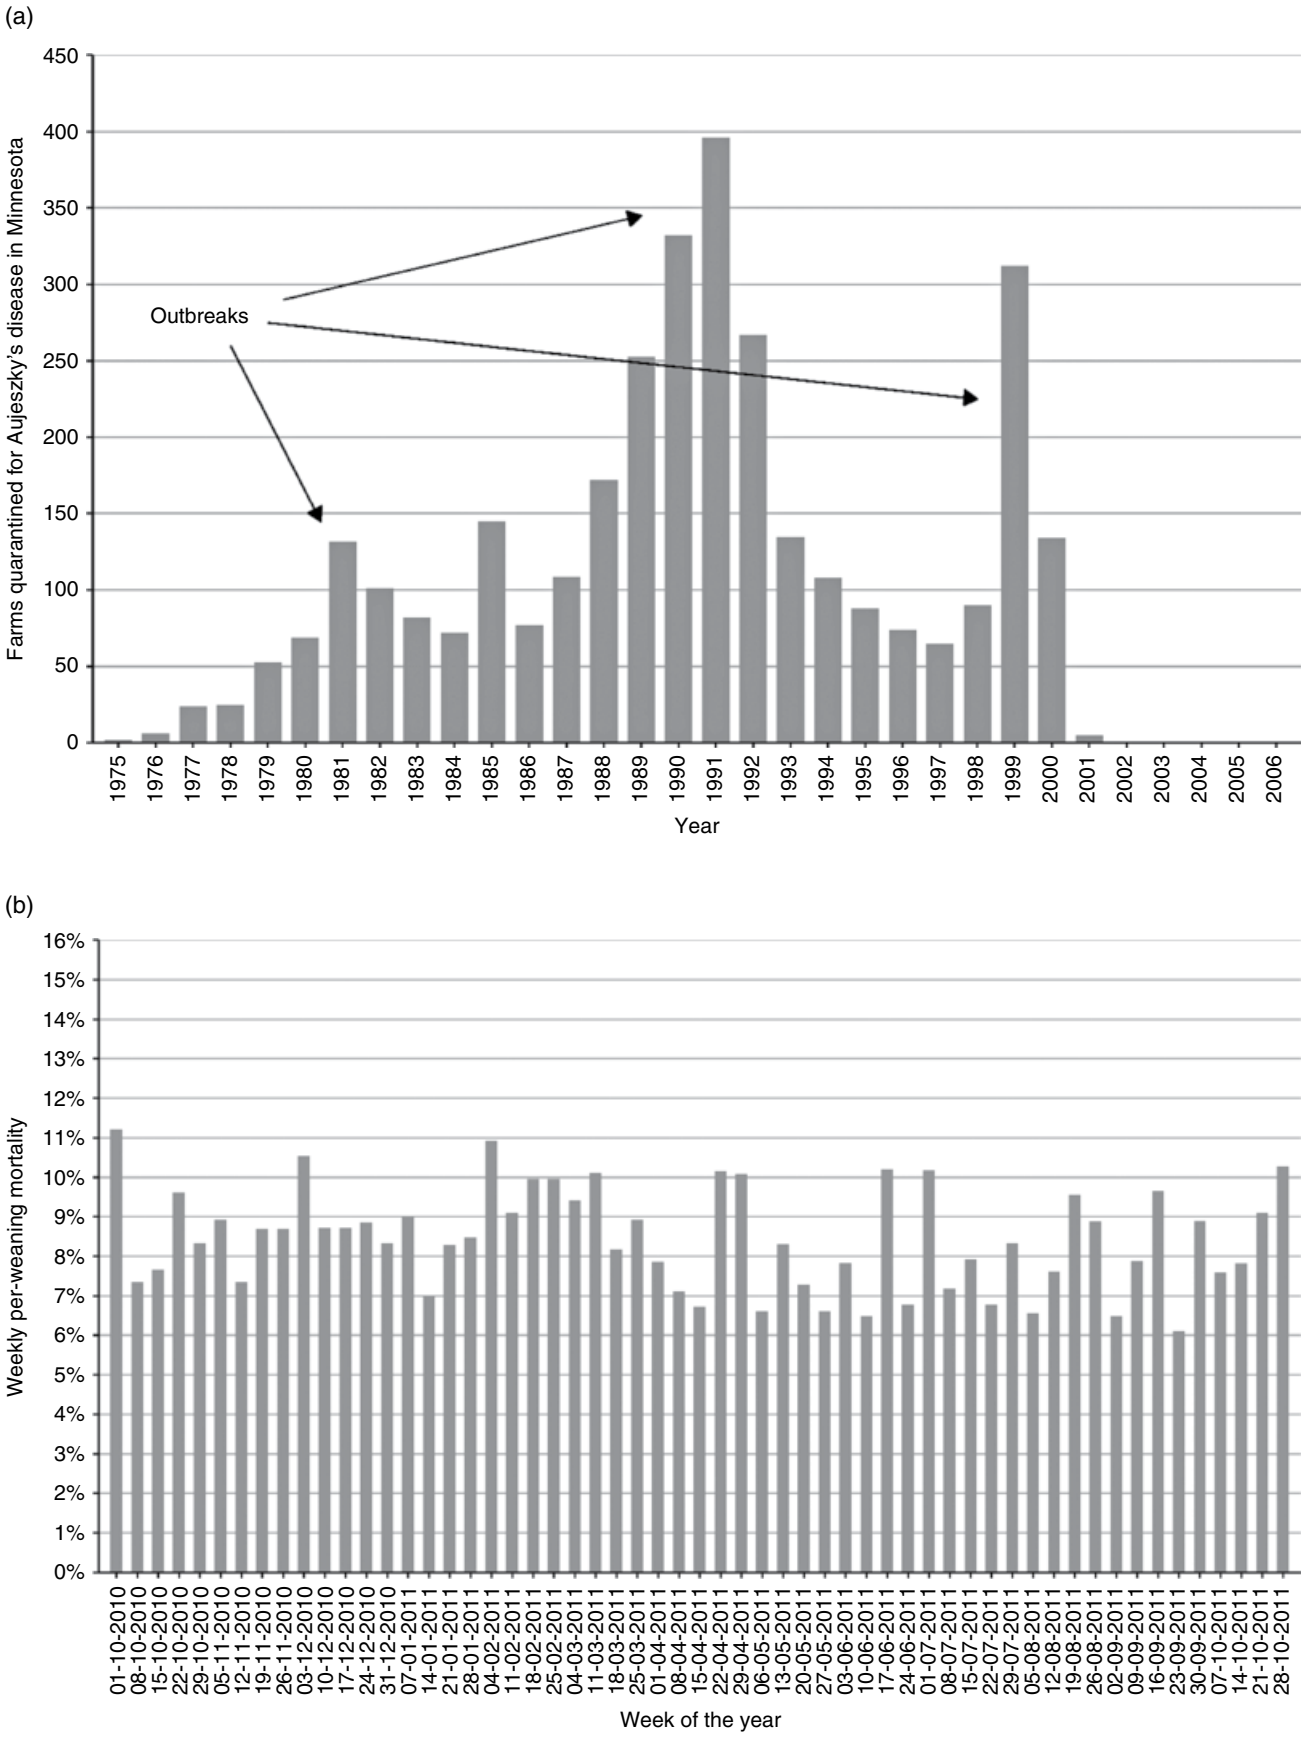

Figure 9.1 Epidemic curves representing sporadic (a; ADV outbreaks from 1975 to 2006 in Minnesota [*Source:* Anderson et al. 2008]), endemic (b; weekly preweaning mortality rate on a typical US farm [*Source:* Gillespie 2009. Reproduced with permission of Dr. Gillespie, American Association of Swine Veterinarians]), and epidemic (c; number of farms infected with classical swine fever in the Netherlands during 1997–1998 outbreak [*Source:* Elbers et al. 1999]) disease occurrences.

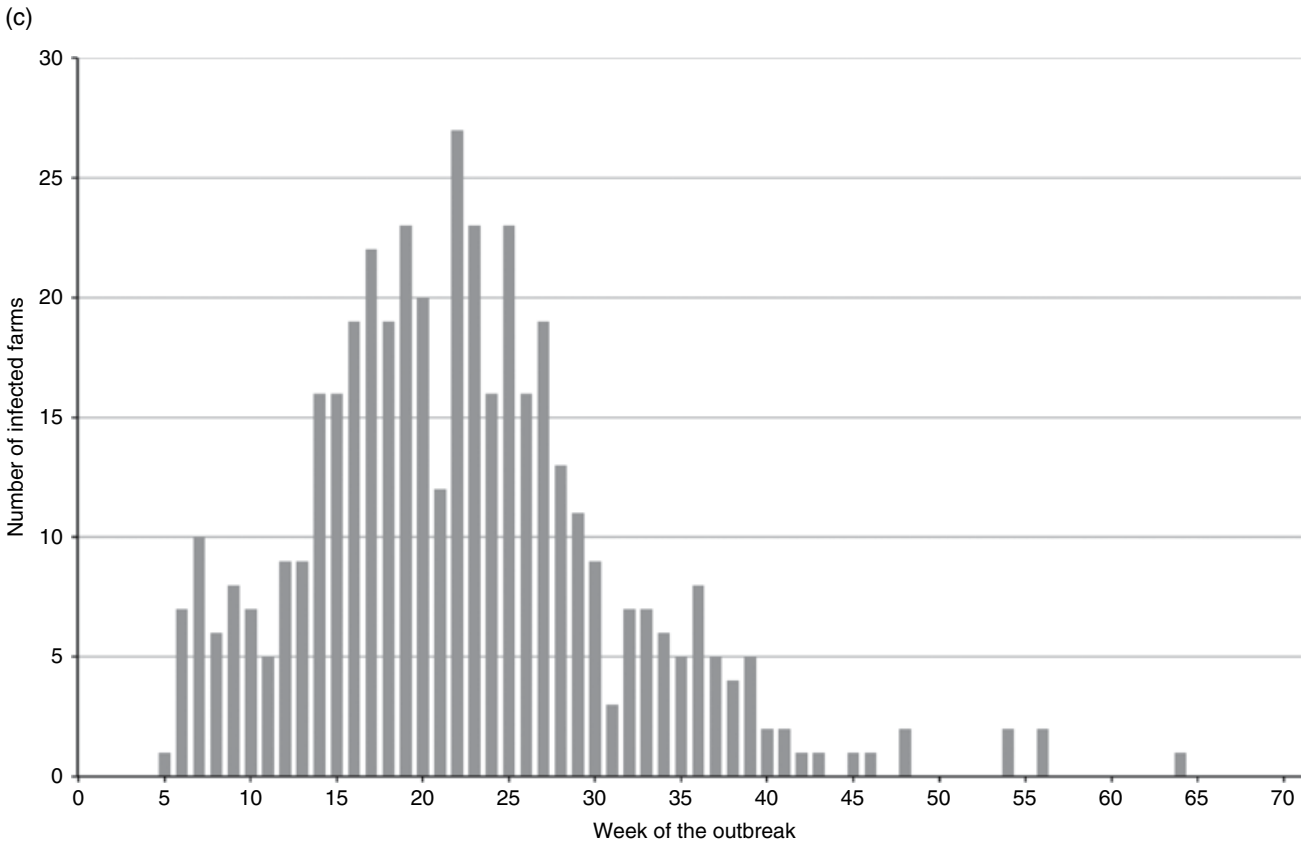

Figure 9.1 **(Cont'd)**

or indirect contact with an infected host through an animate or inanimate vector. Many pathogens take advantage of more than one of these modes in order to gain entry into the susceptible host through the alimentary tract, reproductive organs, or respiratory system, across the integument, or by inoculation (iatrogenic or wounds). Despite our best efforts, management of these modes of transmission or routes of entry does not reliably result in eradication of disease unless one also considers the mechanism by which a pathogen is able to persist in the absence of a suitable host. For a pathogen to perpetuate, a mechanism must be available for it to survive in nature. Thorough study of the mechanisms by which pathogens are able to perpetuate themselves will also have the advantage of giving insight into potential reservoirs of emerging agents. With this information, we may be better equipped to anticipate the impact of the changing ecology of traditionally important pig pathogens, as production settings are altered to meet the challenges of global food distributors, exacting consumers, and environmental mandates.

Classification of pathogens based on their mechanism for perpetuation leads to sensible guidance on the complexity of control and eradication programs that are required for their management. Through modification of early published insight on the topic of pathogen perpetuation (Matumoto 1969), five categories are proposed and described in order of the least to the most complexity required for pathogen eradication: vector-borne pathogens, short-cycle pathogens, long-cycle pathogens, resistant pathogens, and commensal pathogens.

Vector-borne pathogens

For the current discussion, pathogens that absolutely require a vector for successful transmission between infected and susceptible hosts will be considered vector-borne pathogens. Two features of this criterion should be clarified, namely, that the vector is animate and that the vector is required for transmission to occur. Inanimate vectors (e.g. boots contaminated with pig feces containing *Salmonella*) are essentially an extension of the infected pig itself and suggesting that there is any particular role the infected boot is playing in the transmission pathway is nonsensical. Also for the sake of clarification, pathogens such as African swine fever virus (ASFV) or PRRSV that are known to utilize insect vectors in their transmission but are not limited only to arthropod-borne spread will not be considered here. As an example, ASFV has three distinct transmission pathways, namely, a sylvatic cycle involving *Ornithodoros* ticks and wild suids, an *Ornithodoros* tick and domestic pig cycle, and a direct pig-to-pig transmission cycle,

suggesting that simply controlling the tick vector will not ensure eradication of the disease from a population of infected commercial pigs (Arzt et al. 2010). The essence of a vector-borne disease in the context of disease eradication is that control of the vector will ensure eradication of the disease.

At least two important infectious agents of pigs should be considered as exclusively vector-borne pathogens: JEV and vesicular stomatitis virus (VSV). Both agents are relevant to this discussion but for distinctly different reasons. Though the clinical disease due to JEV can be mild in pigs, pigs serve as an important reservoir of infection for maintaining a population of infected mosquitoes in a geographical region. Japanese encephalitis is a globally important pathogen of humans for which pigs play an important role in the disease's landscape epidemiology. Similar to JEV, VSV is also transmitted between pigs by an arthropod vector (the virus has been recovered from several different genera of mosquitoes, flies, and midges). However, the disease occurs relatively infrequently though the New Jersey serotype of VSV is particularly well adapted to pigs (Martinez et al. 2003). The significance of the disease, at least among FMDV-free countries, is that VSV produces vesicular lesions in pigs that are grossly indistinguishable from other notable vesicular diseases including those produced by FMDV, vesicular exanthema virus (VEV), and swine vesicular disease virus (SVDV). Clinical outbreaks of VSV in pigs will produce predictably significant short-term effects on international trade until other exotic pathogens are ruled out.

For these examples, introduction of the pathogen into a population of pigs, maintenance of the pathogen in the pig population, and transmission of the pathogen between pigs in the population can be absolutely controlled by preventing contact with their respective arthropod vectors. This makes their control and eradication a straightforward, though practically, very difficult process.

Short-cycle pathogens

Short-cycle pathogens include those agents whose greatest imperative is to quickly be transmitted to the next susceptible host as they generally have a very limited ability to survive outside the host. At first, one might assume this category would include all viruses as viruses are absolutely unable to replicate outside their host. However, there are at least a few notorious viruses and many bacteria that are perfectly content to bide their time (waiting, though not increasing in number) in a suitable environment until the right combination of ecological factors occurs that facilitates their entry into a new host where replication can begin again. Characteristics of short-cycle pathogens include rapid inactivation outside the host, short incubation periods, commencement of shedding shortly after infection becomes established (but without persisting for an extended time), rapid development of protective immunity, and a requirement for access to large populations of susceptible hosts in order for continuous transmission to occur.

Both bacterial and viral agents are represented in the short-cycle pathogen category with influenza A virus (IAV) in swine being an obvious member. IAV enters the respiratory tract as part of an oronasal or aerosol transmission event. Clinical signs of the disease become apparent in a matter of 3–5 days concurrent with establishment of high viral loads in lung tissue. High levels of virus are expelled in sputum or droplet nuclei over a relatively short period (less than 1 week) at which point clinical signs rapidly abate and solid immunity is conferred. Dense populations of susceptible individuals are necessary for the virus to propagate into an epidemic form. IAV epidemics are seasonally apparent in people due in some respect to the increased congregation of people indoors due to colder winter conditions. However, this seasonality is less apparent in modern pig production as large production cohorts are established in pig-dense regions on a continual rather than seasonal basis, thus meeting the requirement for access to large populations of susceptible hosts. The virus has evolved in a way that ensures an adequate size population of susceptible pigs (or a population of cohorts of pigs) remains available; IAV has the propensity to genetically drift and recombine at a rate faster than immunity from a prior infection is able to persist. Though having a different pulmonary cell tropism, porcine respiratory coronavirus follows a pattern similar to that of IAV and thus is also classified as a short-cycle pathogen.

Several enteric agents can also be considered short-cycle pathogens. Transmissible gastroenteritis virus (TGEV) and a related coronavirus, porcine epidemic diarrhea virus (PEDV), share similar features of oral exposure, rapid incubation (hours), high levels of virus shedding over a short period of time, and generation of a robust immune response (although short in duration).

Given their need for large populations of susceptible hosts, their infected host's short duration of contagiousness, and their limited ability to remain viable outside the host, control and even eradication are achievable goals for short-cycle pathogens. The fundamental element in eradication plans for these pathogens is the creation of closed populations so that a steady supply of new susceptible host is unavailable (by definition, transmission is primarily limited to direct contact); facilitating exposure of the pathogen to remaining susceptible hosts (when appropriate) in the face of an outbreak can also be utilized in order to shorten the duration of an epidemic and subsequently the risk of exposure to other susceptible populations.

Long-cycle pathogens

Long-cycle pathogens are those characterized by the ability to establish an infection in such a manner that the host remains contagious for an extended period of time. While these pathogens may share some attributes of short-cycle pathogens such as a rapid incubation phase, their hallmark feature is the ability to find an ecological niche in the host that will allow them to resist clearance by the normal immune mechanisms of the pig. Congenital and other forms of vertical transmission are also common features among long-cycle pathogens. Because of their propensity to establish a long-term contagious state in the host, these pathogens are not dependent on having access to large or dense populations of susceptible hosts; their ability to persist is largely independent of population size.

Several noteworthy viruses fall into the category of long-cycle pathogens as do a number of rather unique bacterial species. *Actinobacillus pleuropneumoniae*, *M. hyopneumoniae*, and *Mycobacterium* species (especially *Mycobacterium avium*) are respiratory bacterial pathogens characterized by their ability to induce chronic, smoldering infections in the lung. While sporadic outbreaks do occur, particularly with *A. pleuropneumoniae*, all three establish long-term residency in their own unique biological niche (pulmonary abscesses for *A. pleuropneumoniae*, the extracellular surface of the bronchial epithelium for *M. hyopneumoniae*, and lymph node or pulmonary abscesses for *M. avium*) that keeps them well isolated from the direct effects of the pig's immune system and promotes an extended period of contagiousness. Similarly, long-cycle viral pathogens exist that have a pulmonary tropism including Aujeszky's disease virus (ADV) and PRRSV. Despite both demonstrating the short-cycle attribute of rapid incubation period (and creating explosive epidemics as a result), their most significant epidemiological feature is the ability to establish a persistent infection. As a member of Herpesviridae, ADV creates a classic latent infection through invasion and residency in the trigeminal nerve where it remains ready to be reactivated to systemic sites (in preparation for an impending transmission event) when biological stress is experienced by the pig. Neurons are a site preferentially sequestered from most of the usual pathogen clearance mechanisms of the pig as most of these mechanisms are lethal to the host cell that is harboring the pathogen; with little redundancy in the nervous system, any immune response that results in the destruction of neurons is likely to have a profoundly negative effect on the host. While much of the pathogenesis related to PRRSV infection has been reported, the exact means by which it escapes clearance by the immune system remains unclear. The virus has a strong preference for long-term residency in various immune cells of monocytic lineage, and evasion mechanisms including production of quasispecies, presentation of decoy epitopes, and induced dysregulation of various cytokines and other immune messengers have been hypothesized though not fully explained (Mateu and Diaz 2007).

Long-cycle pathogens also occur in other body systems beyond the respiratory system. Various serovars of *Leptospira interrogans* occur in pigs and establish long-term infections in the kidney and urinary tract, *Mycoplasma suis* resides in the blood and hematopoietic system for extended periods, and *Brucella suis* establishes persistent infection of male reproductive tissues. The enteric system is home to several unique long-cycle pathogens. *Lawsonia intracellularis* presents in several different clinical forms but all share the unique histological feature of chronic inflammation of the small intestine caused by persistent intracellular infection of enterocytes and lamina propria cells by the bacterium. Spirochetal diseases of the colon (*Brachyspira hyodysenteriae* and *Brachyspira pilosicoli*) can create clinical signs reminiscent of the diarrhea associated with *L. intracellularis* but are generally more severe. Intracellular residency in the epithelial cells of the colon again provides refuge from the immune system as it attempts to resolve the ongoing infection. *Salmonella* species, particularly *S. choleraesuis* var *kunzendorf*, also take advantage of the intracellular niche to avoid detection by the immune system. Erysipelas is another disease caused by a bacterial pathogen that finds a location preferentially sequestered from the immune system. Often as sequelae to the acute stages of the systemic illness (producing the unique erythematous dermatitis lesions that are the hallmark of erysipelas), the bacterium will often lodge in joint fluid, synovial membrane, and surrounding tissues to cause chronic arthritis. The acute bacteremia apparently violates the integrity of the joint–blood barrier, allowing *Erysipelothrix rhusiopathiae* to enter the joint space; after resolving the acute infection, the integrity of the barrier is restored, effectively separating the bacterium from the full range of immune clearance mechanisms.

The significance of long-cycle pathogens is the difficulty for which successful eradication programs can be established (excepting, of course, through complete depopulation of herds). Similar to short-cycle pathogens, most long-cycle pathogens are not particularly well equipped to thrive outside the living host for extended periods. What they are well equipped for is thriving inside the host for extended periods. Few reliable protocols for eradication of these pathogens exist at the herd level, and even fewer at an industry level. Quality diagnostic tests become the critical arbiter for most eradication programs designed for these pathogens. ADV stands out as a uniquely eradicable long-cycle pathogen given the combination of a highly efficacious vaccine, the availability of diagnostic tests that can differentiate infected

from vaccinated animals (DIVA), and accessibility to a wide array of highly accurate, sensitive, and specific diagnostic tests for both ruling in and ruling out infection with ADV. For the foreseeable future, efforts in managing most of the long-cycle diseases will be through control plans rather than eradication efforts. However, over time and with good compliance, effective control plans can lead to pathogen elimination but with whole herd test and removal procedures often required to identify the last of the persistently infected pigs.

Resistant pathogens

Some pathogens adopt a perpetuation strategy that involves creation of a stable form resistant to environmental degradation or inactivation. Whether this strategy is a result of evolutionary selective pressure or simply in response to the failed ability to transmit between hosts at short intervals is unknown, but regardless of the reason, it has developed into a highly successful strategy by a few bacteria and viruses and also by most of the pig nematodes. The characteristic feature of resistant pathogens is simply their resistance to inactivation in the environment (many remaining infective over months to years); resistant pathogens have no reliance on access to large or dense populations of susceptible animals. An additional common, though not requisite, feature of many long-cycle pathogens is their ability to indiscriminately affect different host species.

Two important bacteria will serve as fitting examples of resistant pathogens. The first bacterium is *Bacillus anthracis*. *B. anthracis* can produce various lesions and clinical signs in pigs ranging from acute sudden death to less dramatic syndromes that induce multifocal lymphadenitis. It is a historically important disease (though rarely seen any more in modern pig industries) but remains an important zoonotic risk for abattoir workers, particularly in those plants processing grass-fed ruminants. *B. anthracis* is a large gram-positive bacillus that when shed into the environment (often as a result of the death of an acutely affected animal) is signaled through exposure to oxygen to form a capsular spore that makes the organism highly resistant to inactivation by heat, desiccation, ultraviolet light, and disinfectant chemicals. Contaminated environments (notably, burial pits established as part of cleanup efforts after large outbreaks of anthrax) can remain a hazard for susceptible hosts for years. *B. anthracis* is able to infect nearly any mammalian species. The second bacterium that will be used as an example of a long-cycle pathogen actually represents most of an entire genus of bacteria: *Clostridium* spp. *Clostridium perfringens*, given its high prevalence in many commercial pig populations, will serve as a convenient example of the genus though a similar case could also be made for *Clostridium novyi, Clostridium botulinum, Clostridium chauvoei*, or other clostridial species. *C. perfringens*, like *B. anthracis*, is a relatively non-species-specific, gram-positive bacillus, proficient at spore formation under appropriate environmental conditions. Infection of young pigs by this particular species of *Clostridium* generally results in neonatal diarrhea with high within-litter prevalence. Farrowing sows that are housed outdoors often have a higher prevalence of clostridial diarrhea in their nursing piglets compared with their peers that farrow indoors, likely due to the simple fact that routine and periodic cleaning/disinfection of indoor farrowing facilities reduces (though does not eliminate) the infectious dose of bacteria presented to the neonatal pig. Genotyping of *C. perfringens* occurs as part of diagnostic investigation on some farms in order to support appropriate choice of pre-farrowing vaccinations, but once diagnosed on a farm, the disease tends to be managed rather than any attempt being made to eliminate the organism. *C. perfringens* is commonly found in commercial bovine, sheep, and goats with no or minor genetic changes relative to those isolates recovered from pigs.

Internal parasites comprise most of the membership in the group of resistant pathogens. For most of the pig nematodes of which the reader will already be familiar, the adult form of the parasite is relatively fragile in an environment outside the host. It is the parasite's ova that present the long-cycle perpetuation opportunity for the pathogen. Life cycles vary extensively between *Ascaris, Ostertagia, Trichuris*, and other significant pig nematodes, but the parasites do share some common features: they have long and complex prepatent periods ("incubation periods" relative to bacteria and viruses), require sexual reproduction, and produce ova capable of lasting years or decades in typical pig-raising environments. These ova can successfully resist desiccation, chemical inactivation, and in some cases (*Ascaris suum*) even physical removal from the environmental surface itself. Notable microscopic parasites that share some of these same features include *Trichinella spiralis* and *Toxoplasma gondii*; while previously mentioned nematodes such as *A. suum* do periodically infect man, *T. spiralis* and *T. gondii* have the well-deserved reputation of being substantial risks to public health in some countries.

In the context of disease transmission, control, and eradication, pathogens that perpetuate through use of environmentally resistant life stages present both opportunities and challenges. The bacteria used as examples demonstrate the difficulty that would be faced in attempting to establish eradication programs as the life span of the resistant organism likely exceeds the life span of the pig and the farmer! If one chooses to raise pigs in an environment that was used by a pig in a former time, there can be reasonable surety that the resistant pathogens have remained behind. Often, only low infectious doses are required to establish infection with resistant

pathogens, and once the first successful transmission event occurs, the infected individual can effectively recontaminate the environment with a sufficient number of the agent to repeat the cycle again in a week, a month, a year, or a decade later. Similarly, the internal parasites described above can be difficult to eradicate depending on the environment in which one chooses to raise the pigs. Over time, contaminated indoor facilities can be rid of parasite ova with fastidious hygiene, persistent use of anthelmintics, and screening of new stock to avoid reintroduction of the pathogen. In an outdoor environment that has previously housed pigs, eradication is likely an unachievable goal. Conceptually, for control of resistant pathogens, all one has to do is avoid contact between the susceptible host and the agent. Practically, that is also the biggest problem. "Where once a pig has lived, the roundworm will remain."

Commensal pathogens

Commensal, derived from the Latin word c*ommensalis* (*com-* meaning together and *-mensalis* indicating a feature *of the table*), was originally cast to describe those infectious organisms habituating the alimentary tract but causing no apparent harm to their host. The term has come to more broadly indicate the co-association of any two organisms that are not either dependent or parasitic on each other. Using this definition, one is provided with an apt descriptor for a class of pathogens that seem to be found in association with otherwise healthy pigs but have the notorious reputation for periodically transforming into a virulent state with expression of fulminate clinical disease. Mechanisms involved in this periodic occurrence are poorly understood for most of the pathogens in this group, though concurrent or recent infectious conditions, the presence of an external stressor causing a disruption in homeostatic mechanisms, and diminished barrier function have been implicated as contributing factors in humans (Tlaskalova-Hogenova et al. 2004).

Multifactorial causation is another term for the requirement that specific cofactors must be present in order for a commensal pathogen to cause clinical disease. Perhaps the prototypical pig diseases in this respect are the porcine circovirus-associated diseases (PCVADs); the causative agent porcine circovirus type 2 (PCV2) only recently emerged in pigs (Firth et al. 2009). Its associated clinical expressions remain a significant challenge to reproduce experimentally despite its widespread occurrence across pig farms around the world (Madec et al. 2008). Its classical presentation as a cause of nonresponsive wasting in juvenile pigs cannot be reliably reproduced in an experimental setting even when using low-passage field virus from affected farms. Characteristic tissue lesions can be generated in this setting but only rarely to the degree of severity and prevalence common in field outbreaks. Infection in the laboratory or in a field setting results in high levels of viral shedding with subsequently high levels of transmission occurring. However, the overt clinical signs described for PCVAD only seem to occur when the virus is present in combination with other infectious and noninfectious cofactors. Vaccination of pigs infected or expected to become infected with PCV2 reliably prevents the occurrence of clinical signs of PCVAD in affected farms (Kixmoller et al. 2008; Neumann et al. 2009), and even more interestingly, anecdotal evidence is accumulating that suggests vaccination against PCV2 can improve the performance of pigs on farms with known presence of the virus but without any clinical signs of PCVAD (Agten et al. 2010; Brons et al. 2010; Luppi et al. 2010; Sidler et al. 2010).

Commensal pathogens that appear to require the presence of an external stressor in order to be induced into causing clinical disease include *Haemophilus parasuis* and *Streptococcus suis*. Vertical and horizontal transmission pathways have been described for both bacteria; indeed it is very likely that no pig farm in the world is free of either of the pathogens. While genetically distinct strains of each organism are known to occur and these strains possess different combinations of identified virulence factors, it is rare that the presence of one of these virulence factors in a given strain is enough to simply explain the occurrence of clinical disease. The anecdotal literature presents examples of farms that operate with little or no clinical disease related to either pathogen for extended periods of time until without clear explanation, a spontaneous outbreak occurs (MacInnes and Desrosiers 1999; Tokach 1993). External stimuli proposed to induce outbreaks of clinical disease for *H. parasuis* or *S. suis* include temperature changes, feed outages, and coinfection with other agents (Drum and Hoffman 1998; Oliveira and Pijoan 2004; Villani 2003). Another streptococcal bacterium, *Staphylococcus hyicus*, is a common inhabitant of the pig and its environment and, in most instances, appears to simply exist as part of the external skin flora. However, the agent is implicated as the causative agent of exudative epidermitis or "greasy pig disease." Both the anecdotal and peer-reviewed literatures report that the disease appears both sporadically and epidemically on farms often without explanation; hypothesized cofactors for expression of the disease include low herd-level parity, hygiene, and overall poor quality of farm management and pig husbandry (Clark 2002; Murray and Rademacher 2008; Schwartz 2002; Zoric et al. 2009).

Colibacillosis, presenting both as neonatal diarrhea (primarily *Escherichia coli* possessing the fimbrial antigens F4, F5, F6, and F41) and as post weaning diarrhea (*E. coli* F41 or F18), presents an interesting situation with regard to diseases that are caused by commensal

pathogens. Numerous members of *Enterobacteriaceae* are considered commensal organisms, generally categorized as such by the absence of one of these recognized fimbrial types. However, reports describing typical clinical cases of neonatal colibacillosis or post weaning diarrhea but associated with non-typical or non-typeable *E. coli* are becoming more common (Harel et al. 1991). The extent to which an *E. coli* is either "pathogenic" or "commensal," or whether a given pathovar can move between these states, has not been fully resolved. Genetic mechanisms (horizontal gene transfer [HGT]) for exchange of virulence factors between pathovars of *E. coli* that allow for rapid shifts in the severity of the infection have been described in human infections (Croxen and Finlay 2010). In pigs, virulence factors similar or identical to those described for human isolates of the bacterium have been described, and it is likely that the same genetic mechanisms for their exchange occur (Wu et al. 2007; Zhang et al. 2007). Data from field studies of pig farms have shown that at least on a population basis, numerous fimbrial types of *E. coli* are present in pigs from shortly after birth (including those presumed to be pathogenic) and that the relative contribution of each fimbrial type changes with pig age (Katouli et al. 1995). The F4 fimbrial type has been studied extensively in this regard, and a particular pathovar expressing the O149 somatic antigen has been isolated from both healthy and diarrheic pigs (Amezcua et al. 2002, 2008; Melin et al. 2004). An explanation for its apparent presence both as a commensal and as a pathogen on a single farm remains unexplained but may involve contributions from the host, the environment, and additional virulence factors that are expressed or acquired in response to these contributing factors. The extent to which these genetically based changes are random or occur as a result of selective pressure is not entirely known.

The significance of recognizing the existence of a commensal pathogen type is that one has to recognize the fact that some pathogens are extraordinarily unlikely to be eradicable. Management of commensal pathogens will rely on establishing control measures (vaccination, treatment, and husbandry) that temporarily shift the balance of power into the hands of farmers and veterinarians and away from the pathogens.

Causal inference

Formal postulates for determining disease causation had their beginnings during the mid-nineteenth century and were most famously incorporated into an essay written by Jakob Henle (1838). His postulates were subsequently revised by one of his former pupils, Robert Koch, and presented in their more commonly accepted form in 1890 (Koch 1890): the agent must be present in every case of the disease under appropriate circumstances, the agent should occur in no other disease as a fortuitous and nonpathogenic agent, and the agent must be isolated from the body in pure culture, repeatedly passed, and induce disease when reintroduced to the host. The inadequacy of these postulates in covering all the potential relationships between pathogen and host became apparent within 10 years of their publication but nonetheless remain today as a useful framework for establishing infectious disease causality. Because of limitations introduced by strict interpretation of the Henle–Koch postulates, authors have attempted to generate other lists of causal criteria that incorporate an epidemiologically sensitive perspective of the agent–host–environment relationship embodied in disease ecology. A set of criteria for determining disease causation was published by Hill (1965) that seems to have captured the essence of an epidemiological diagnosis (Table 9.2).

Reading these criteria points out the need to understand the distinction between necessary and sufficient causes of disease. Multifactorial diseases are those cre-

Table 9.2 Epidemiological criteria for assessing disease causation.

Causal criteria	Definition
Strength of association	There is a strong association between the putative factor and disease (as measured by relative risk, odds ratio, and others)
Consistency	The association should be repeatedly observed by different persons, across different places, circumstances, and times
Specificity	The occurrence of one (or a group of) causal factor(s) should lead to only one disease, and the disease should result only from that cause
Temporality	Cause must precede effect; the putative factor must precede the occurrence of the disease
Biological gradient	When exposure to the factor falls along a gradient, higher exposure should result in more severe (or frequent) disease; a dose–response effect should exist
Plausibility	The association should be plausible with respect to biological knowledge, recognizing that our knowledge is limited to facts known at the time
Coherence	The cause and effect interpretation of the association should not seriously conflict with the generally known facts about the natural history and biology of the disease
Experiment	It may be possible to generate prospective experimental evidence whereby removal of the putative factor results in less severe (or frequent) disease
Analogy	Similar known examples of cause and effect can support the existence of a causal association

Source: Hill 1965.

ated by exposure to a combination of several independent factors. A necessary cause is considered to be an exposure (to an agent or risk factor) without which the disease cannot occur. Implicit in this definition is that this exposure, when occurring in isolation, may not cause disease in all individuals. Other risk factors (or agents) may need to be present simultaneously in order for the disease to occur. When, in combination, exposure to a defined group of factors results in disease in all the individuals, this group of factors is considered to be a sufficient cause. Necessary and sufficient cause provides a flexible framework for undertaking disease outbreak investigations in which the true cause of the outbreak is unknown. A cautionary note is, however, required. When sorting through the myriad potential causal factors associated with the occurrence of a disease, it is inevitable (particularly in the early phases of an outbreak investigation) that factors will be identified that have the appearance of being causally related to the disease but in truth are not causal. These factors are termed confounding variables or "confounders." By definition, a variable is a confounder if it is associated both with the true causal exposure variable and with the occurrence of the disease; however, the confounding variable must not be caused by the disease. A simple example illustrates the concept: as facts, we know that (1) smoking is strongly associated with the occurrence of lung cancer, (2) people that smoke tend to have yellow staining on the skin of their forefingers, and (3) only people that smoke have yellow staining on their fingers. If an early researcher was investigating the cause of lung cancer and did not consider the impact of smoking on the occurrence of lung cancer, he/she might erroneously report yellow fingers as the cause of lung cancer (i.e. strong evidence of a causal relationship as described above by Hill's criteria)! Unfortunately, most real-life situations are not this clear as we may have very little prior knowledge about risk factors and their relationship to a disease outcome. In order to organize one's thought processes during disease investigation activities, path diagrams or "webs of causation" can be created to evaluate the potential role of confounding variables in the outbreak. A causal web illustrating the association of various risk factors with respiratory disease in pigs is shown in Figure 9.2 as an example. Analytical methods

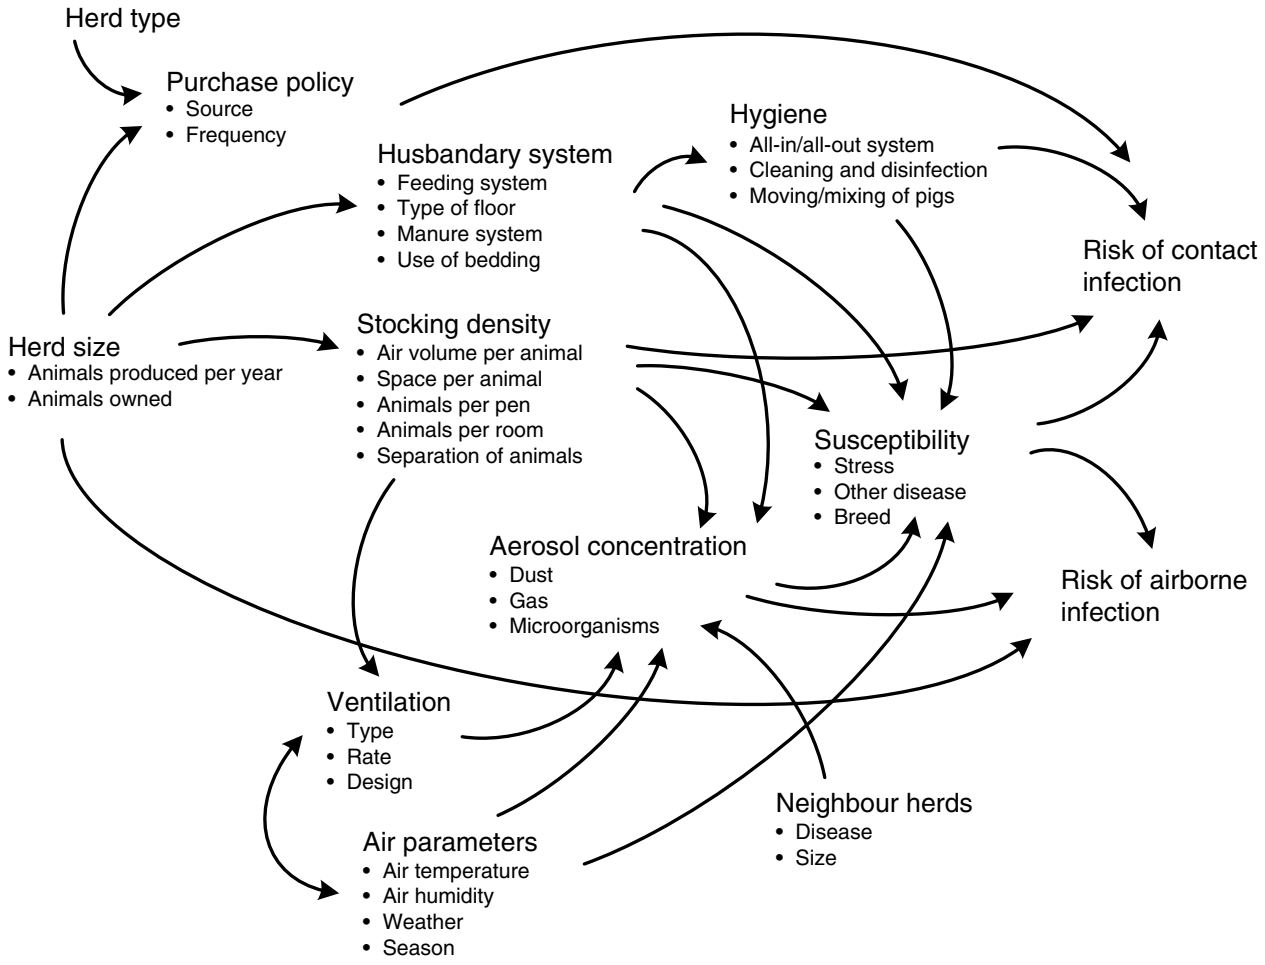

Figure 9.2 Causal pathway of risk factors associated with respiratory disease of pigs. *Source:* Stark (2000).

are available for assessing the certainty, strength, and interaction of risk factors and disease outcome when presented as causal webs (Stage et al. 2004).

Biosecurity

Biosecurity plans at their most rudimentary level attempt to manage the risk of introducing new pathogens into farms, livestock industries, or countries and to minimize the transmission of endemic diseases between farms within these levels. These goals are accomplished through segregation of uninfected from infected animals (or the pathogen itself) and thorough cleaning and disinfectant of livestock premises and facilities (Madec et al. 2010). However, when considering biosecurity, there is a greater imperative at stake than just the health of livestock species. Veterinarians and farmers have an opportunity and perhaps even an obligation to develop a more holistic approach to biosecurity that appreciates agriculture's contribution to zoonotic disease transmission, farmed animals as a source of human foodborne pathogens, and the broader impact of livestock farming on the environment.

Biosecurity is fundamentally about managing two sources of special cause variation on farms: pathogens and people. Sources of variation in the biological or financial performance of a farm can be attributed to either normal (i.e. random) variation or special cause variation. Normal variation – be it related to a pig's genetic potential for growth, the lysine content of a soybean, or the average ambient temperature in Ames, Iowa, during December – is by definition predictable given some current and historical knowledge of the biology, chemistry, or physical properties of that particular variable. By contrast, special cause variation describes those fluctuations in the value of a variable that exceed the boundaries of what we consider to be "normal"; this exceptional fluctuation may be defined as one that falls beyond plus or minus three standard deviations from the mean value, one that contributes more to the risk of a particular outcome than what would normally be expected, or any other measure one may determine is appropriate for the purpose. Systematic fluctuations due to normal variation in livestock production systems cannot be eliminated, though one strives to reduce the range of normal variation. The occurrence (and magnitude or frequency) of special cause variation in production systems, however, can absolutely be managed with the ultimate goal being to eliminate it entirely.

Biosecurity as a discipline began making an appearance in the livestock-related literature during the 1990s with several authors presenting work aimed at creating consensus around definition of the term and the scope of activities that it might encompass (England 2002; Pyburn 2001). A review of relevant literature on the subject around the same time (Amass and Clark 1999) confirmed a paucity of facts that could scientifically support the recommendations being made by veterinarians to their clients about biosecurity measures. The same author then embarked on a series of innovative studies to debunk biosecurity myths (Amass et al. 2000), establish the efficacy around commonly used disinfects and their appropriate usage (Amass 2004), and understand the role of people and inanimate objects in disease transmission (Amass et al. 2003a,b,c).

With the advent of real and perceived global worry over terrorism and the occurrence of large-scale outbreaks of animal disease, including the emergence of novel zoonotic pathogens (Table 9.3), a plethora of organizations began publication of biosecurity guidelines for use by livestock producers. One author surveyed the literature and the Internet for farmer-targeted publications on biosecurity in the United States and found 111 publicly available sources representing all the major livestock species (Moore et al. 2008). Despite a similarity in recommendations made across many of the publications, the author speculated that the sheer mass of information available likely contributed to poor biosecurity compliance due to confusion over "which guidelines do I use?" Indeed, several authors have reported poor farmworker compliance with biosecurity recommendations (Nespeca et al. 1997; Vaillancourt 2005) with at least one study suggesting that farmers could not perceive which of the biosecurity practices (that they were asked to perform) were most useful or important (Casal et al. 2007).

Biosecurity planning

Within farm (herd level)

Biological risk management (BRM) has been suggested as a term for use of management tools that help to identify infectious hazards to a farm (or veterinary practice, other livestock premises, etc.), to assess the risk presented by each hazard, and then to develop plans for managing each of the hazards (Bickett-Weddle 2005; Ramirez and Zaabel 2012). Based on traditional thinking, a farm's biosecurity plan would be considered a failure at the moment a disease was introduced to that farm. However, a more modern approach to biosecurity planning such as that embodied in BRM planning recognizes that disease risk cannot be completely eliminated, but only managed. Also, because few farms are constructed or operated in an identical manner, it would be illogical to think one biosecurity plan could meet the needs of all farms. Several risk-based methodologies have been established for development of biosecurity plans including a public–private partnership in the United States called the Secure Pork Supply (http://www.

securepork.org/index.php), an audit-based approach developed specifically for use on pig farms called the Production Animal Disease Risk Assessment Program (http://vdpambi.vdl.iastate.edu/padrap/default.aspx), and an Australian swine-specific biosecurity assurance program called the Australian Pork Industry Quality Assurance Program (http://www.apiq.com.au/) that has its basis in hazard analysis and critical control point (HACCP) methodology.

HACCP methodology is a useful tool in constructing BRM plans. It had its origin in the US National Aeronautics and Space Administration (NASA) in the 1960s. Logistical planners involved in design of systems that would support astronauts while they were in space recognized a need for systematic methods of quality assurance (QA) around food products that would accompany the astronauts. Recognizing the inadequacies of a quality system that relied on end-product testing of food (accuracy and reliability of testing, determination of which hazards should be tested, high cost, and time factors related to testing), NASA began working with process engineers at Pillsbury to develop a method that would ensure the creation of safe food products through quality monitoring of the production process rather than

the production output. The full history and development of HACCP is reported elsewhere, and the reader is encouraged to read further for more detail (Dunkelberger 1995; Sperder and Stier 2009). Process monitoring rather than end-product testing is a useful paradigm for establishing BRM plans.

HACCP methods are based on seven principles: (1) identification of potential hazards; (2) determination of critical control points (CCPs) at which a process can be established to mitigate any hazard that is introduced; (3) establishment of critical limits around each CCP; (4) creation of a process to monitor each CCP; (5) establishment of corrective actions to be taken in the event a critical limit is exceeded; (6) institution of recordkeeping procedures that can document CCP monitoring activity; and (7) verification of HACCP system performance through periodic quality testing of the end product. As described above, pathogens and people present the two most important sources of special cause variation. The fact that both are animate variables (as opposed to a kernel of corn, a concrete floor, or a mechanical fan) gives them the unique ability to respond to feedback from the farm operator, and they are thus likely to generate special cause variation. Pathogens respond to this feedback through evolutionary mechanisms such as acquiring resistance to antibacterials (Aarestrup et al. 2008), modifying their epitopic presentation to a pig's immune system (Ostrowski et al. 2002), acquiring virulence mechanisms (Villa and Carattoli 2005), or simply emerging from nature as a novel pathogen (Kirkland et al. 2007). People respond to feedback through all of the predictable behaviors that typify the human condition: avoidance of disliked tasks, poor compliance with procedures having little direct or short-term benefits to themselves, reluctance to seek clarification when requested assignments are poorly understood, and the "creative will" or tendency to modify established processes for their own best fit. Using HACCP methods as a basis for development of BRM plans, especially when they are developed in conjunction with the farmworkers expected to comply with the BRM plan, provides a platform whereby biosecurity compliance can become the norm rather than the exception. HACCP helps us to separate special cause variation from normal variation, identify the cause of the special variation, and then remediate the process.

A simple example using HAACP to manage the hazard of disease introduction (e.g. leptospirosis, toxoplasmosis, swine dysentery, others) through exposure of pigs to rodents will illustrate the process. For this example, step one or hazard identification is straightforward: lack of an effective rodent control program will increase the likelihood of contact between pigs and the disease vector. Step two is identification of appropriate CCPs; this step may be assisted through construction of process flow diagrams or causal webs as has been described above. Logical CCPs in this rodent control process might include placement and management of baiting stations and environmental management around the periphery of buildings (avoiding accumulation of materials that may be used by rodents as nesting/hiding spaces, controlling vegetation, and avoiding feed spills). Establishment and monitoring of critical limits around these CCPs are straightforward and will fulfill the third and fourth steps in HACCP. For example, the expected rate of bait usage can be estimated with assistance from a pest management company, and monitoring the usage rate of the farm can be as simple as tracking the history of bait purchase and ensuring the appropriate amount is being used each month. Establishment and monitoring critical limits around the environmental management CCP requires a bit of creative thinking but little hard work: grass and weeds should be kept mowed to a height less than 10 cm, a walking space the width of a person's outreached arms should be maintained clear of debris around the exterior of all buildings, and all feed spills should be cleaned up on a daily basis (effectively, zero tolerance). Step five or the establishment of corrective actions is again straightforward in this example but has to be considered in two phases. Phase one is giving immediate attention to the CCP that is out of control, e.g. "go mow the grass" or "go clean up the feed spill." Phase two of the corrective action is as important as phase one but is often forgotten – that being the need to remediate any product (sick pigs) that may have been negatively affected during the period, the CCP was out of compliance. In our example, it may be the case that the farm was participating in a *Leptospira*-free production scheme and that the potential exposure to rodents may require a self-imposed quarantine period, a "no-ship" period, temporary use of vaccines or medication, or undertaking targeted surveillance in order to reenter the scheme. Step six in HACCP is creation of a system of written documentation that provides evidence of all management activities related to each CCP. This can seem an onerous task to the farmer but actually provides a value-added opportunity for the willing veterinarian, as well as providing information useful when working backward in time to determine the cause of a disease outbreak or production loss. Periodically, HACCP-monitored processes require validation to ensure they are actually doing the job for which they were designed. Validation is the essence of the seventh and final step in HACCP. Returning to the rodent control example, validation steps might include an inspection of the building spaces for evidence of rodents (feces, holes in walls, bedding material), a nighttime visit to maximize the chance of visualizing rodents, rodent trapping, and serological disease testing of the pigs.

Establishing a thorough understanding of a risk-based process for developing a BRM plan is critical for both the farmer and the veterinarian. It offers an intuitive process for engaging the farmer and the staff, it provides a logical framework for organizing one's ideas about the specific biosecurity needs of a given farm, it forces one to methodically analyze effectiveness of a BRM plan, and it creates a clear understanding about the consequences of noncompliance with the plan.

The specific elements to be included in a BRM plan can vary extensively between farms and geographic regions. Resource documents are widely available from producer and veterinary organizations (Moore et al. 2008), state and national animal health departments, and international organizations such as the World Organization for Animal Health (OIE) and the Food and Agriculture Organization of the United Nations (FAO). The reader is encouraged to familiarize himself/herself with the resources available, much of which can be freely accessed via the Internet. A recent and comprehensive guide that defined a number of good practices for pig farm biosecurity was produced by FAO in 2010 (Madec et al. 2010). Given the global audience of FAO, the guide necessarily discusses the unique issues presented by several types of pig industries including village-based low-intensity pig scavenging production, small-scale but confined pig production, and large-scale intensively managed production. The guide avoids an explicit discussion of risk-based BRM plan development but instead provides a succinct discussion of the major causal pathways for disease introduction related to a failure in biosecurity; this is a fitting addition to the early planning stages of risk-based BRM plan development in modern intensive production systems.

Between farms (national level)

Biosecurity planning does not stop at the farm gate and, in many respects, is not confined to one's own sector of the agricultural industry. National-level biosecurity planning has achieved a much higher profile than even 10 years ago for reasons including real and perceived anxiety over national security, terrorism, negative responses to large-scale euthanasia campaigns associated with animal plagues, and emergence of novel human, animal, and zoonotic pathogens. These factors when combined with increasing public worry over our care of the environment, concerns about global climate change, growing sensitivity to animal use and well-being, and the recent occurrence of several unusual foodborne disease outbreaks have created a paradigm shift among national policymakers. This paradigm shift is all about harmonization.

In a key guidance document published by FAO in 2007, the following definition of biosecurity was proposed: "A strategic and integrated approach to analyzing and managing relevant risks to human, animal and plant life and health, and associated risks to the environment" (Anonymous 2007). Through the use of this definition, the authors developed arguments that supported development of harmonized national biosecurity policies that could take advantage of synergies that may exist across different economic sectors and between industries within a single economic sector. Intuitively, there would seem to be an advantage that could be gained from establishing a single authority that could manage all the biosecurity risks across primary production (animal feed and livestock), food processing (slaughter and processing), and the environment (water and air quality) as the activities involved in all these economic sectors are interdependent. This national biosecurity model was proposed by authors of the FAO report *a priori*, meaning there existed little prior evidence at the time to establish that the harmonized approach would, as a matter of fact, be an improvement over the traditional approach to biosecurity whereby primary production, food processing, and the environment are managed under separate authorities. At the same time, we do have compelling evidence that inadequacies do exist in traditional national biosecurity models, so the current momentum to shift toward a more modern approach will likely continue with some advantages and disadvantages yet to be realized.

Risk-based biosecurity planning remains important at the national level just as it did at the local farm level described above. While the seven steps in HACCP allow one to work at a relatively high level of detail for planning that is customized to the specific needs of a farm, a modification of the approach is required for use at the national level. The HACCP model places particular emphasis on hazard identification, recognition of special cause variation, and then remediation of the process or product after an out-of-control event has been detected. The modifications to HACCP that have been made in order for it to function at a national level shifts the emphasis to gaining a better understanding of the nature of a particular identified hazard: what is the probability that a recognized hazard will occur, what are the consequences if the hazard does occur, and what is the cost-to-benefit ratio of mitigation strategies that might be employed to prevent the hazard from occurring?

The OIE pioneered some of the early efforts to establish a harmonized framework for assessing risk around national biosecurity and animal health, and the framework is widely used as the basis for many types of risk analysis today (Anonymous 2010). The OIE risk analysis process includes four steps: hazard identification, risk assessment, risk management, and risk communication (Figure 9.3).

The OIE hazard identification step is identical to step one in HACCP and attempts to answer the question

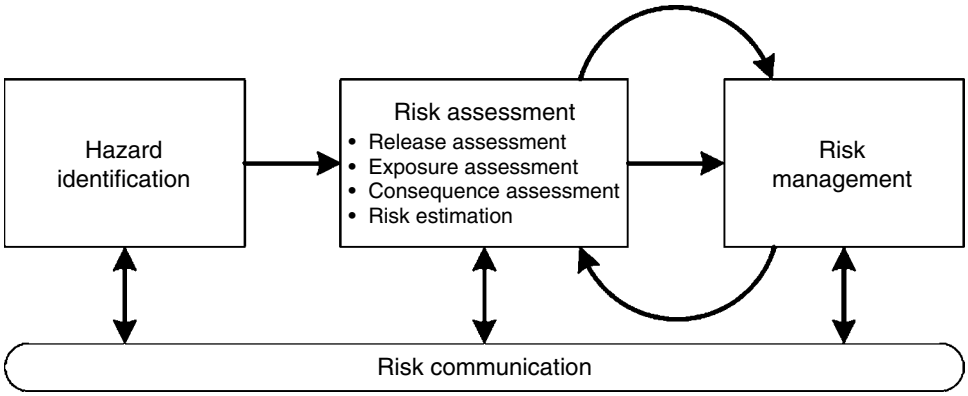

Figure 9.3 OIE risk analysis framework for development of import health standards.

"What can go wrong?" and, depending on the reason for conducting the risk analysis, may be answered simply through creation of a list of unwanted livestock pathogens or diseases, or may be more complex including identification of hazards that cross species or economic sectors. Step two of the OIE risk analysis is the actual risk assessment itself. The distinction between "risk analysis" and "risk assessment" is important. Risk analysis reflects the entire process from hazard identification through to the communication plan around the process and its outcomes. Risk assessment, however, refers specifically to the characterization of the risk associated with each identified hazard and includes an assessment of the likelihood of occurrence and the likely severity of an occurrence. In the context of a risk analysis conducted to inform policy around proposed changes to importation of a risk item (animals, animal products, semen, etc.), OIE specifies four tasks that should be completed as part of a complete risk assessment: First, a release assessment describing the biological pathways necessary for an importation event that would result in introduction of the pathogenic agent into a country should be prepared; this should include an estimate of the probability of those events occurring. Second, an exposure assessment should be conducted to described the pathways and associated probability of a domestic animal (or human, or farm) becoming exposed to an imported pathogen that was able to successfully negotiate the barriers designed to prevent its release. The third task that should be carried out is a consequence assessment that explores the consequences (production losses, welfare implications, financial impact) of a successful exposure event. This necessarily includes determination of the farm, national, and cross-sector consequences of a successful exposure. At the conclusion of these three tasks, a fourth task called the risk estimation is undertaken. The risk estimation combines the probabilities of all the events occurring, from hazard identification through the consequence assessment, to arrive at an overall estimate of the risk associated with the proposed activity; the risk estimation may be quantitative, qualitative, or descriptive depending on the quality of data inputs and the needs of the relevant stakeholders. After completion of hazard identification and risk assessment, the risk management step is initiated. Risk management, as the name implies, explores the possible mitigation strategies that will be considered to manage any residual risk that was identified during the risk estimation step. In a thorough risk analysis, the risk management proposals will be analyzed using a process similar to the process used for risk assessment and will yield three important risk estimates for comparison: the baseline likelihood of entry (the *status quo* risk that existed prior to the proposed activity being undertaken), the unrestricted likelihood of entry (the expected *post facto* risk if the proposed activity is undertaken, but no risk mitigations are implemented), and the restricted likelihood of entry (the expected *post facto* risk that remains if the proposed activity is undertaken and the recommended risk mitigations are implemented). These three estimates of risk are compared in light of what is considered an acceptable level of risk (ALOR) and may include a macroeconomic cost-to-benefit analysis as well. The fourth and final step in the OIE risk analysis framework is referred to as risk communication. Ideally, conducting risk analyses should be a participatory process (consultation with stakeholders at each step in the analysis), iterative, transparent, and public (inform stakeholders of the conclusions that were reached).

Across borders (international level)

Methodology for management of transboundary animal diseases at an international level is similar to that described for national policy on biosecurity. The additional influence presented by the current global political situation, the global economy, and international treaties and agreements to which a country is bound bears mentioning. Regulation of international biosecurity is only complicated if a country wishes to conduct trade with another country. In the absence of trade, there is no

mandate to follow any other country's recommendations or requirements. However, most countries do not have the ability (or desire) to remain independent from international trade of goods, and nearly always, some give-and-take is required in order for two countries to agree on the terms of trade.

International standard setting organizations such as the Codex Alimentarius Commission (CAC), the OIE, and the World Trade Organization (WTO) develop standards that can serve as a unifying framework, if not obligatory standard, by which countries can reach consensus around their differing trade requirements. The CAC is a body that was created in 1963 by FAO and the World Health Organization (WHO) for the purpose of establishing standards relating to foods, food production, and food safety. The OIE was established through international agreement in 1924 (in response to an outbreak of Rinderpest in Belgium in 1920); the organization is responsible for improving animal health around the world and currently has 176 member countries and territories. The WHO is an agency within the United Nations that has a role similar to that of OIE but focused primarily on public health rather than animal health; WHO was established in 1948. The WTO is responsible for the Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement). The SPS Agreement is an international treaty managed by the WTO since 1995. Under the SPS Agreement, guidelines relating to the safe importation of food, animal, and plant products are negotiated and maintained.

Rushton in 2006 presented four principal threats that could contribute to the occurrence of a transboundary biological emergency (Rushton and Upton 2006): (1) emergence or occurrence of transmissible disease from a local wildlife population, (2) disease relocation as a result of movement of migratory wildlife or birds, (3) disease introduction through legal or illegal exportation of wildlife and livestock products, and (4) emergence of a disease or difficulty related to changes in the way we raise livestock.

Other factors of unknown significance might also be added to the list of global contributors to animal, human, and zoonotic diseases. It seems the extensive interconnectivity of modern society has created numerous complex systems, defined by nonlinear flow processes that by their very nature tend to be unstable, unpredictable, and interdependent and that when they fail produce sequelae that cannot be anticipated. Who could have anticipated the chain of events that would be required to link purposeful melamine contamination of wheat gluten by a Chinese supplier to contaminated pet food in California and to melamine exposure in pigs in various regions of the United States (and the subsequent worry over human exposure through consumption of tainted pork) (Baynes et al. 2008; Burns 2007)?

Plant pests, and biosecurity plans to manage them, have their own historical narrative, but a theme that runs through the commercial agronomy sector (but with application to the commercial livestock sector) is the risk presented by monoculture of particularly desirable crop species. Given the introduction of a suitable pest, monoculture plantings create a bounty of susceptible hosts of which a pest can take advantage; the introduction of soybean rust (*Phakopsora pachyrhizi*) into the Midwestern United States (Li et al. 2008) and the epidemic infestation of pine bark beetles (*Dendroctonus* spp.) in forests and timber plantations on North America's Pacific Coast (Flint et al. 2009) are classic examples of the vast biological niches available to an appropriately positioned pest in today's modern agriculture. Do commercial pigs essentially represent a mammalian monoculture? It is a challenging task to qualify what differentiates one pig breed from another in modern commercial pig genetics, but at least at a phenotypic level, there exists a huge similarity between pigs across the world, a population ready to be exploited by a fortuitous or cunning pathogen.

The significance of the two most important sources of special cause variation, pathogens and pigs, cannot be underestimated. The role of pathogens has been described in the preceding paragraphs. However, the role of people deserves another special mention – that being the risk of intentional introduction of infectious diseases to livestock populations. Agricultural bioterrorism has been an increasingly worrisome topic for national biosecurity managers and policymakers alike. Though one author has identified the occurrence of only two intentional biological attacks on North American agriculture (purposeful iatrogenic contamination of veterinary supplies with anthrax and glanders around the time of the First World War and contamination of dead stock that were destined for processing into animal feed, with pesticides in 1997) (Ackerman and Giroux 2006), the world investment in modification of infectious agents as weapons (for people or animals) is extensive (Szinicz 2005). Indeed our ability to create life from the pool of available molecules and laboratory accessories appears to become more proficient each day (Gibson et al. 2010).

Distinguishing special cause from normal variation (or signal vs. noise) will be an important requisite skill for risk analysts, biosecurity managers, and veterinarians in the future. It presents the evidence for distinguishing risk from reality in the spectrum of livestock disease.

Diagnosing failures of biosecurity

People working at all levels in animal agriculture benefit from good biosecurity practices and therefore have a role in behaving responsibly with regard to actions that may increase the risk of diseases occurring. Whether one is part of a commercial farming enterprise, raises a few

animals or birds as hobby, or is only affiliated as a service provider such as a veterinarian, feed supplier, or livestock hauler, everyone involved in livestock or poultry production has a responsibility to develop good biosecurity habits. Animal agriculture is highly interconnected, meaning that one person's bad behavior will not only negatively affect that person's animals but is also very likely to have a negative consequence for someone else such as a neighbor or business relation.

When disease occurs, some investigation of the cause of the disease is usually undertaken. In the case of endemic pathogens or for relatively low-consequence diseases, the farmer may initiate an investigation himself/herself armed with historical knowledge of his/her own farm and its disease history. However, in those situations where a disease outbreak is caused by a new, unusual, or high-consequence pathogen, a more formal investigation to determine the cause of the outbreak is warranted and may involve a number of different people.

In an earlier edition of this book, Dial et al. (1992) presented a series of hierarchical trees that described the interrelationships between various factors that contributed to reproductive failure in swine breeding herds. These flow diagrams challenged the reader to look beyond the symptom of a reproductive failure (such as "low numbers of pigs weaned per sow per year") when investigating a problem and instead focus on identifying and resolving the points of failure that actually created the observed symptom. By analogy in a clinical setting, a veterinarian tends not to focus on examination and treatment of the erythematous dermatitis lesions on pigs that are produced as a result of infection with *Erysipelas rhusiopathiae*. Instead, the clinician should focus on risk factors for the disease itself including vaccination status, vaccine efficacy, sources of exposure to the organism, and others to ensure that in addition to providing supportive care to the infected individuals, adequate resources are put toward reducing the likelihood of occurrences of the disease in the future.

Using a similar approach, a framework for logically exploring the potential areas of biosecurity failure that might have contributed to a disease incursion is described in the sections below. Risk factors contributing to biosecurity failure have been aggregated into four themes: live animals, transportation, feed and feed ingredients, and people. While additional themes could be developed, these four provide sufficient guidance to ensure that the individuals involved in conducting most disease outbreak investigations probe deeply enough into the "symptoms" of biosecurity failure to discover their underlying root causes.

Live animals

Contact between diseased live pigs (including all the body fluids they excrete) and non-diseased pigs provides the best opportunity for successful transmission of pathogens. In modern commercial pork production, the notion of "population medicine" drives investigation, treatment, and prevention of disease. One of the tenets of production in this respect is the maintenance of closed herds, which do not permit the routine introduction of live animals not reared by that farm, versus open herds, which permit introduction of live pigs not reared by that farm. Production systems in the United States frequently operate as a series of "multisite" farms, which complicates the definition of a closed versus open farm. However, as a basis for exploring risk factors related to live animals, this provides a convenient first criterion (Figure 9.4).

Closed herd (farmer raised)

As the name implies, in a closed herd, all gilt replacements are selected from animals raised on the farm, and no additional pigs are brought onto the site for finishing. Closed herds must be further separated in order to deal with the significant differences presented by closed herds that operate in multisite production systems (which are often large, complex, and involving commingling of pigs from different sites) and more traditionally defined closed herds that operate on a single site. In the case of multisite closed herds, one can most simply manage their biosecurity risk by considering them to be a special case of an open herd; risk factors related to live animals on these herds will be discussed in the section below on open herds.

Disease management The cornerstone of managing live animal biosecurity planning is implementation of an overall disease management strategy for the farm. This will likely include standard protocols for managing the overall health of the herd such as identification and treatment of sick animals, vaccination programs, and biofeedback procedures but will also describe specific actions related to ongoing monitoring of herd health.

Whole herd disease monitoring Key to ensuring healthy internal replacement gilts on a closed herd is maintaining excellent health across the entire herd. While needs vary between farms, many veterinarians recommend the use of routine slaughter checks and review of data collected at the processing plant, review of performance records, and ongoing diagnostic testing such as routine serology and submission of tissues to a diagnostic laboratory.

Replacement gilt disease monitoring Though in many respects one can consider all pigs on a single-site farm to have the same health status, acclimatization and monitoring internally selected replacements prior to their introduction into the breeding herd are warranted. Most

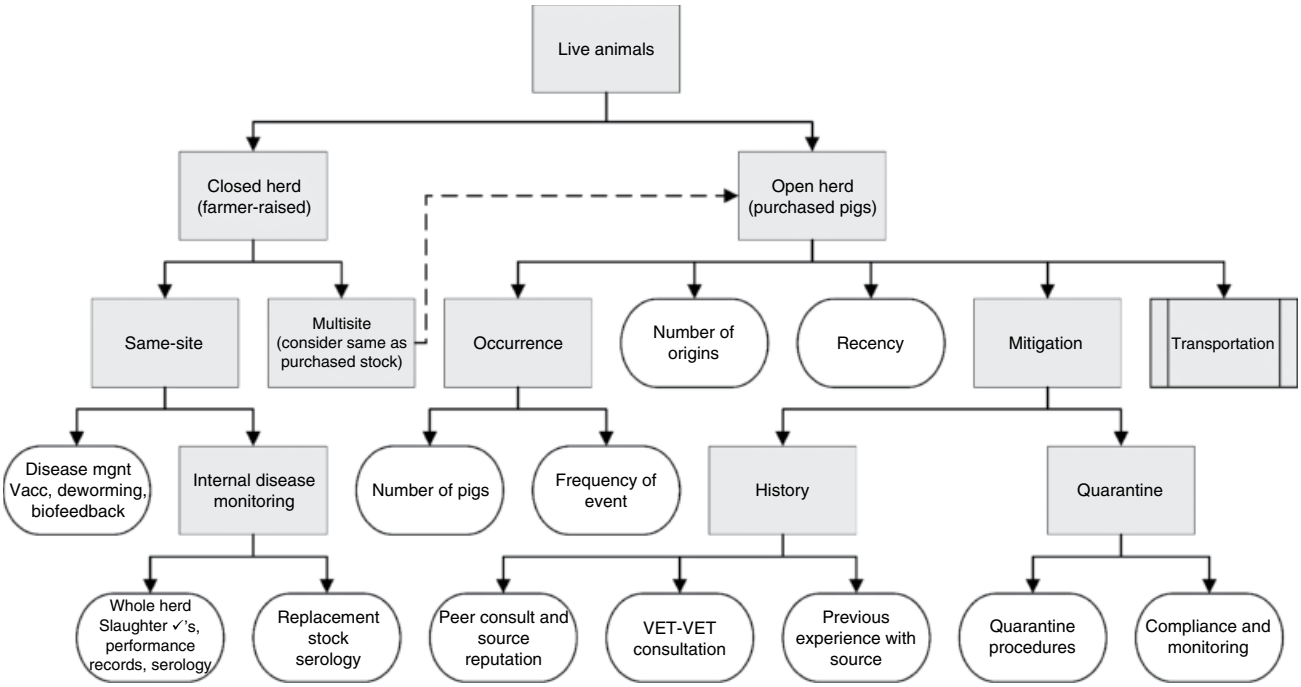

Figure 9.4 Root causes of biosecurity failure related to introduction of live animals.

typically, the focus for these animals is acclimatization to ensure they have been safely exposed to (and recovered from) reproductive pathogens that are circulating in the breeding herd. Serological monitoring can be a useful to tool to determine if these animals have had adequate controlled exposure (through biofeedback or vaccination) to agents such as porcine parvovirus and PRRSV (if present) before breeding occurs. As with all diagnostic testing procedures, attention should be given to collecting samples from a statistically valid, representative sample of animals.

Open herd (purchased pigs)

Open herds may be composed of breeding animals, growing animals, or both. In all cases, it is ideal that pigs managed as open herds are derived from a single source. In addition, for grower herds, it is ideal that these pigs be managed as a single all-in/all-out (AIAO) cohort with cleaning and disinfection (C&D) between cohort groups. When the open herd includes breeding females and the stock being introduced are replacement gilts, additional steps should be included to ensure their biosecurity risk to the existing breeding herd (which is not typically operated in an AIAO manner) is managed.

Number of origins Reducing the number of different origins from which purchased pigs are sourced is an effective means of managing the risk of disease incursion. This is true specifically in the case of significant endemic agents (such as PRRSV in the United States) that are known to exist as divergent variant strains for which immune cross-protection is unlikely or unpredictable. By limiting the number of pig sources, the likelihood of introducing new strains will decrease. The same holds true for exotic pathogens but to a lesser extent.

Recency Considering the time period between observation of a disease event and the last introduction of purchased animals can be very helpful in assessing the likelihood of the purchased animals being responsible for the disease incursion. In most cases, as the interval increases, the likelihood of the new pigs being the source of a new disease decreases.

Related to the number of origins and recency, two additional risk factors associated with the occurrence of new pig introductions should also be considered by those managing the risk or responding to a disease outbreak: number of pigs being introduced and the frequency with which new pigs are introduced.

Number and frequency of pig introductions Though their significance can be either hidden or overinterpreted when assessed using "one-size-fits-all" outbreak questionnaires, information related to both the number of pigs introduced per event and the number of introduction events per time should be examined carefully. Personal experience and review of the scientific literature are often relied in assessing this information as there is no single rule of thumb that separates a "risky" from

a "safe" introduction of pigs. Knowledge of pig management factors, housing, environment, pathogen factors (route of transmission, ID50), and host factors (immunity, age) are required to interpret the significance of number and frequency risk factors.

There are few activities that contribute risk to disease introduction that cannot be mitigated to some extent. When developing biosecurity plans related to the introduction of live animals, mitigation measures can be applied both ahead of the event (evaluation of historical information) and after arrival of the pigs (quarantine activities).

Peer consultation and source reputation, "vet-to-vet" consultation, and previous experience with source People or businesses that make a habit of knowingly supplying diseased pigs or whom fail to act responsibly when it occurs by chance are often well known by their own reputation. Veterinarians and farmers should take action prior to the purchase of pigs to establish a consensus opinion on the health status of the pigs to be purchased from a potential supplier. This can be done by each contacting individuals in their own peer groups, talking to other customers, speaking to the veterinarian that works for or is employed by the supplier, and considering one's own previous experience with the supplier.

It is important to establish whether the source herd has had any recent disease outbreaks, determine what diseases have or have not been detected or tested for in the source herd, and become familiar with the vaccines and antimicrobials used on the source farm. Determine if the source herd routinely conducts serological surveys of the herd, and if so, request recent results of the surveys.

In addition to collecting as much historical information as possible about the source herd, isolation and quarantine procedures should be formally developed for the recipient farm. Once developed, a monitoring program should be established to ensure the established isolation and quarantine program is being followed by farm staff.

Quarantine procedures Because the incubation period for different disease agents is highly variable and the incoming stock may not exhibit any disease symptoms for some time, it is essential that these animals remain in quarantine until test results and clinical observations provide reasonable assurance they are healthy. The quarantine period also allows time for any new diseases that have incurred on the source farm to be recognized and to inform customers. Quarantine also provides insurance in the rare event that the incoming pigs became infected with a pathogen while in transit. The duration of isolation will depend on the disease agents that are of the most concern but typically lasts between 30 and 60 days.

Isolation allows pigs to recover from the stress of transport to the farm and adapt to a new environment and provides a window of time for any incubating infections to become evident. When possible, isolation should be accompanied by an acclimatization program that ensures the incoming pigs have time to be effectively vaccinated against (or exposed to through controlled biofeedback) for those diseases known to be endemic on the recipient farm. Pigs should be moved through the quarantine facility as an AIAO group. When possible, a separate person and equipment should be dedicated to work in the isolation facility, or if not possible, work at the facility should be left as the last work task of the day.

Activities related to the quarantine and acclimatization program such as vaccinations should be recorded on a daily log along with any health observations including the presence of coughing, excessive sneezing, diarrhea, blood or mucus in the feces, loss of appetite, skin lesions, or lameness. It is typical that some type of serological monitoring program be undertaken as part of the program. This may involve blood sampling at entry and again prior to release from quarantine to look for the presence of disease antibodies or to confirm acclimatization procedures have provoked an immune response in the pigs. Importantly, enough time needs to be allowed for the return of laboratory results and the potential need to retest animals if necessary.

Compliance and monitoring In HACCP terms, quarantine and acclimatization can be considered a CCP, which is monitored through review of the daily activity log and serological monitoring of pigs at arrival and departure. However, given the importance of quarantine and acclimatization, farms should take the extra step to have a "third person" (someone without daily responsibility for care of pigs in the isolation facility) periodically assess the level of compliance with the procedures that have been established for the facility. This may involve reviewing the daily log of activities from several AIAO cohorts of animals that transited the facility, review of any serology results that are available, interviews with staff members charged with its daily operation, and possibly retesting of pigs that were introduced to the farm 6–12 months prior.

Transportation

Transportation, as a risk factor for biosecurity failure, is related primarily to movement of animals (live and dead), feed and ingredients, and other general supplies on or off the farm. The following sections will deal with transportation of animals and other supplies; feed will be covered in its own section.

This section on transportation will focus on processes related to the act of transportation, as distinct from the risk associated with the goods that are being transported.

In this respect, the risks associated with transportation of live or dead animals can be combined and discussed as one. These risks can be categorized into those that are associated with the driver, those associated with the truck, and those that occur as a result of transportation management or methods (Figure 9.5).

Live and dead pigs

Hygiene and behaviors of the driver Drivers contribute a very tangible risk to the transportation process because in many instances, the driver is either not involved with the rearing of pigs being hauled (and hence disconnected from any of the negative consequences of his behaviors) or is acting as an external contractor to the farm (and therefore may not be directly responsible to the farm but instead is responsible to his employer). In any event, one must accept that drivers themselves are a distinct risk factor for which training and minimum standards of performance should be developed.

While describing the exact standards for managing this risk is beyond the scope of this text, a few basic tenets are offered. Drivers should be provided with and expected to wear clean clothes or coveralls and boots during loading and unloading procedures. Related to this is a requirement to train the driver in donning and removing this gear in a manner that avoids him cross-contaminating his clothing or the inside of the driver compartment. The driver is expected to comply with all biosecurity measures that are in place on the farm, which again requires that the farmer invest in providing some basic level of training to the driver. Drivers should not enter farm buildings under any circumstance, and therefore a clear virtual or physical line of separation needs to be established at all loading and unloading areas.

Vehicles and their drivers that present a risk of transmitting diseases into a pig production unit include straight trucks, semi-tractors, semi-trailers, pickups and trailers, cars, all-terrain vehicles, motorcycles, farm tractors, livestock carts, farm equipment, etc. The degree of risk depends on how recently the vehicle has been exposed to other pigs or livestock farms and if the pigs on the farm have direct or indirect contact with the vehicle. Specific aspects of risk factors related to the vehicle are described below.

Cleaning and disinfection Proper C&D of vehicles used to transport live pigs is one of the key methods to prevent transmission of disease to a swine operation. In addition to commercial vehicles, farm vehicles hauling market pigs and cull sows need to be properly cleaned and disinfected prior to returning to the farm perimeter. When commercial truck wash facilities are not available, a dedicated cleaning area for pig transport vehicles that have been used off the farm should be established. There is extensive literature on development of C&D processes for a given farm including required equipment, use of detergents, high-pressure steam, disinfectants, and drying.

In some regions, recycled wash water is commonly used in the early stages of trailer cleanout protocols, and when this is the case, strict policies should be in place to manage the potential for cross-contamination of "cleaned" trailers. It is important to thoroughly clean and disinfect the tires, wheel arches, and underside of the vehicle as well as the transport compartment itself. Special procedures need to be developed to ensure the driver compartment is cleaned at the same time as the trailer and that the driver is trained in how to minimize contamination of the area during deliveries.

Drying and downtime Drying of all surfaces within the truck prior to moving fresh batches of animals is a critical step in the C&D process. In and of itself, drying, especially if done under heating conditions, can serve as a very effective disinfectant process for surfaces that have already been cleaned. When C&D has been properly applied, the additional risk-reducing contributions of drying or downtime are difficult to quantify. However, in reality, C&D procedures are rarely perfect, and given the enormous negative consequences of a disease incursion related to transportation, many farms willingly invest in the extra transportation capacity required to allow for drying or downtime of trailers. To improve the economics, some farms opt to build these procedures into high-consequence transport events such as the movement of replacement females but forego the risk in lower-consequence movements such as the final movement of finishing pigs to a processing facility.

As described above, in addition to driver- and vehicle-related biosecurity risks for transportation, there are also aspects of how transportation is managed that can contribute to or mitigate the risk.

Multispecies hauling In some parts of the world, the use of trucks to sequentially or simultaneously move several species of livestock is common practice. While for explicitly species-specific pathogens this practice would seem to be a reasonable way to improve the economics of haulage due to less downtime for cleaning and perhaps better vehicle usage efficiency, the problem is that one never knows what pathogens are on a truck, and therefore the potential for "the next load" of animals (of a different species) to become infected is also unknown. The practice also tends to propagate a sense that hauling livestock in contaminated vehicles is acceptable, which, when combined with the likelihood that the driver is disconnected from the rearing of these same livestock, does little to contribute to good overall biosecurity habits.

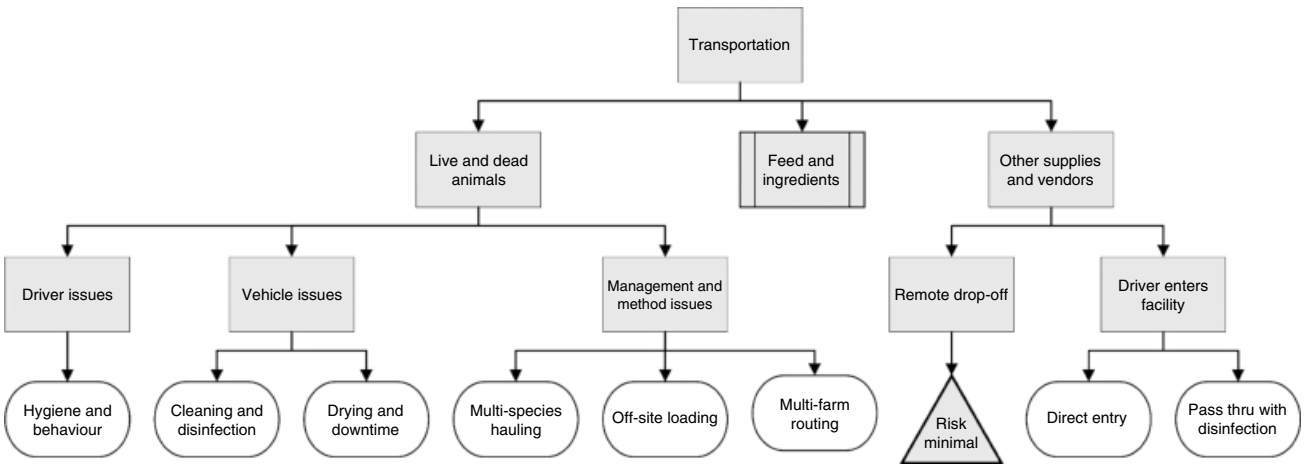

Figure 9.5 Root causes of biosecurity failure related to transportation of animals and other materials.

It goes without saying that adoption of multispecies haulage practices will lead to larger-than-expected outbreaks of high-consequence multispecies pathogens such as FMDV, when they occur.

Off-site loading Loading and unloading pigs is a common means of bringing disease onto farm. To manage this risk, the loading ramp should be sited at the perimeter of the farm whenever possible and connected to the rearing facilities by covered alleyways. However, this is an uncommon setup on most commercial farms that more often resort to attaching the loading ramp directly to the facility. When this is the case, clear procedures need to be established to avoid drivers entering the facilities, farm staff entering the transport vehicle, and pigs inadvertently returning to the facility after having entered the trailer.

In many cases, particularly when the transport event is infrequent, "off-site loading" can be implemented. While there are many variations of this practice, the basic principle is to use a dedicated farm vehicle to remove pigs from a facility, which is then driven a short distance outside the farm perimeter where a commercial transport is waiting. The two vehicles can then reverse to each other and allow pigs to be transferred directly from the farm vehicle to the commercial hauler. The hauler can then depart for its destination having never entered the farm premises, and the farm vehicle can then be cleaned and disinfected at the dedicated location on the farm premises. Obviously, an identical procedure but in reverse order can be used to move animals into the farm facility.

While on-farm composting is becoming increasingly common, many regions still rely on pickup of dead stock by commercial animal rendering companies. Under no circumstances should rendering pickup vehicles enter the farm premises. Instead, a small mortality depot station should be constructed that spans the farm perimeter. The depot should have one door on the farm side for staff to deliver dead stock and a second door on the opposite of the depot that can be accessed by the rendering hauler. In this way, cross-contamination between the parties can be easily avoided.

Multi-farm routing

In an ideal world, all pig deliveries would arrive as a single point-to-point delivery. Often however, particularly in the case of breeding stock deliveries, this is not practical. In this case, the best option for the farm is to be the designated first delivery point. Of course, not every farm can be the first delivery point, and therefore adoption of an off-site loading procedure may be the most appropriate way to manage the risk. In a multi-farm routing situation, adherence to good biosecurity practices outlined above related to the driver and vehicle is singularly important.

Other supplies and vendors

Pigs are only one of the biosecurity risks that arrive (or depart) from farms. Feed and feed ingredients represent another important potential biosecurity risk that will be covered in a later section. However, other supplies (or vendors) routinely arrive at farms and present a biosecurity risk. These supplies and vendors may carry goods that have an inherent risk (such as semen), but the risk being described here again is related to the carrier, not the goods themselves. Delivery companies bringing goods and supplies to farms often organize their routing such that dedicated drivers and vehicles are assigned to rural routes. In other words, it is highly likely that a delivery person will be making multiple stops and different farms, all within a few minutes or hours of each other. Depending on how the delivery is managed at each farm, the delivery person, or their vehicle, or both can have a high risk of carrying infectious agents from farm to farm. Fortunately, options exist to manage this risk.

Remote drop-offs

Remote drop-off points provide an excellent way to prevent vehicles and drivers from entering the farm. A drop-off point might be as simple as a locked shed at the perimeter of the farm premises, a cooperating local rural business, or a staff member's garage. While it is possible that the delivery person contaminates the area around the drop-off point, the farm staff has the advantage of knowing that contamination potentially occurred and takes measures to mitigate the risk; the farmer takes responsibility for managing the risk rather than entrusting his herd's health to the postal service! This method is only suitable for small items and may not be appropriate for perishable items such as vaccines or semen, so other options are needed, which require the delivery person to enter the farm premises. In the special case of service personnel (electricians, plumbers, engineers, etc.), these people usually must enter the farm facility itself.

Direct entry

If a driver must enter the farm premises to make a delivery, suitable procedures or physical barriers should be established to prevent the driver from entering the facility itself. While more elaborate systems are possible, the simplest rely on fencing the farm perimeter, allowing for only a single entry point through a locked gate. On the gate should be a sign that provides two phone numbers: mobile number for the farm manager and a land line for the farm office.

Service personnel should be notified well ahead of time that they will be required to follow all the biosecurity procedures required of farm staff before being allowed inside the farm facilities. Often, only certain vendors cater to the specific needs of pig farms, and they will be familiar with the need to attend to biosecurity during their visit.

Pass-through with disinfection Some farms make use of a pass-through box that allows a delivery person to place items into a small chamber accessed outside the farm (office usually) and the farm staff to retrieve the item from inside the office. Some pass-through boxes have inbuilt disinfection equipment, but more often, the pass-through box is located in a known "high-risk" location where the outer packing material can be disinfected (or destroyed), thereby managing the potential for the packing material itself to act as a physical vector for pathogens.

Feed and ingredients

Feed and ingredients present a special biosecurity risk to farms for several reasons. First, feed or ingredients typically require delivery to the farm and therefore present a transportation risk (covered above). Second, because of their high usage rate, transportation events are frequent, and even rare feed-associated risks are highly relevant because of the high quantity of the products that are used. Third, pig feed in many countries contains ingredients that are derived from pigs or other animal (or fish) species, thereby opening the possibility of direct pathogen introduction into the pig farm. This section describes the risk of biosecurity failure related to feed and feed ingredients, categorized by risk associated with delivery and risks associated with manufacturing (Figure 9.6).

Delivery issues

Multi-farm routing and other transportation issues While this issue was covered in some detail in the transportation risk section above, it is worth noting a few unique transportation issues related to feed. Feed delivery trucks are commonly on multiple farms each day (different loads) and are often scheduled on multi-farm delivery routes; this occurs much more commonly than with livestock transport vehicles. In principle, managing the transport risks for feed and ingredients is much the same as for livestock trucks, but one must be diligent in their management because the frequency of delivery is much higher than for livestock. It is rare for more than 1 week to pass without a feed delivery truck entering a farm. Ideally, trucks delivering feed should be able to unload the feed without entering the pig site. This procedure requires that all bulk bins and facilities storing bagged feed be on the inside edge of the pig site perimeter. Having the feed truck fill all bulk bins without entering the pig site is not practical on many pig farms because numerous bulk bins are located at different sites within the pig unit, some bins hold a small volume of feed, and several different diets are simultaneously used (Levis and Baker 2011). Therefore, other procedures to minimize risk of disease transmission by the feed truck and driver must be used.

Cross-contamination of compartments and loads While feed trucks come in many different configurations, nearly are constructed in such a way that multiple diets or ingredients can be kept separate during transport. With this convenience comes the potential for cross-contamination. Specific procedures for loading, unloading, and cleaning out feed trailers are well established but are beyond the scope of this text. Cross-contamination between compartments within a truck can result, for example, in feed specified and correctly manufactured as "animal protein-free" being delivered to a farm with low levels of animal protein contamination as a result of inappropriate truck cleanout procedures. A similar risk exists for contamination with noninfectious yet unspecified ingredients such as antimicrobials. Further complicating the issue of cross-contamination in trucks is that much of the manipulation of the unloading controls is done blindly by the driver as he is not able to easily visualize what is happening inside the truck until after unloading has been completed.

Manufacturing issues

Manufacturing issues that contribute to biosecurity failures may be associated with the manufacturing process, the ingredients themselves, or inadequate QA processes aimed at detecting and remediating manufacturing faults. Each of these issues will be described in turn in the following sections.

Biosecurity risks related to the feed manufacturing process may occur as a result of cross-contamination events inside the manufacturing plant or as a result of defective further processing steps that occur after feed ingredient mixing.

Cross-contamination in the facility may occur between ingredients, between finished feeds (or between finished feeds and ingredients), or by finished feed or ingredients coming into contact with non-feed contaminants.

Between ingredients All commercial feed manufacturing facilities are under managed under strict state and federal regulations aimed at controlling the use and distribution of antimicrobials, ingredients of animal origin, and potentially toxic ingredients, ingredients that are a potential risk to humans, and others. To the extent possible, manufacturers use dedicated ingredient storage bins (or disposable bags) to manage the potential for cross-contamination of these ingredients. However, for high-volume ingredients or high-throughput ingredients, bulk storage is common. This creates the possibility that a bulk storage bin is not completely emptied prior to a subsequent load (or perhaps even a different ingredient) being added. Commercial feed mills can be relied upon to have processes in place to manage these issues, but

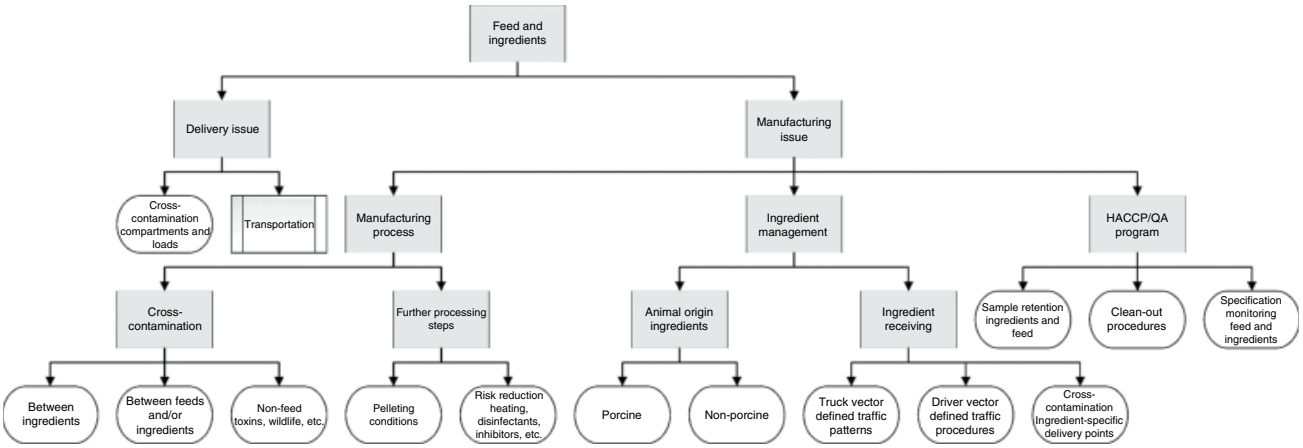

Figure 9.6 Root causes of biosecurity failure related to feed ingredients and manufacture.

on-farm feed manufacturing is exempted from many of the regulations enforced at commercial facilities. In any event, when unexpected or unexplained disease events occur on farms, one is expected to thoroughly investigate all possible points of failure including feed ingredient cross-contamination.

Between feeds and other ingredients The potential exists for cross-contamination to occur during latter stages of the feed manufacturing process, both at commercial facilities and on-farm mills. Managing the issue and investigating cause of disease outbreaks that may be related to a feed contamination event are identical to those described above for ingredients.

Non-feed toxins, wildlife, etc. Feed and ingredients are presented with an opportunity for contact with numerous non-feed contaminants. Among others, these can include fungal spores, industrial fluids from manufacturing or delivery equipment, pesticides, herbicides, rodenticides, and feces or urine from wildlife, birds, or pets. Some of these contaminants may produce no harm to animals or the public, but others can have quite significant effects. Those charged with investigation of animal disease outbreaks need to keep an open mind and seek to identify all risk factors that might have contributed to what has been expressed as an infectious disease outbreak.

For various reasons including minimizing risk associated with feed-borne animal pathogens, further processing steps are often employed as part of feed manufacturing. When animal diseases occur despite the implementation of these further processing steps, investigation of the processes should be undertaken.

Pelleting conditions Pelleting is a very common process involving application of steam, heat, and pressure that serves to improve feed digestibility, improve feed handling characteristics, and lower the concentration of infectious agents in which they exist. Importantly, the time and temperature required to sterilize feed through the pelleting process could have the simultaneous effect of substantially decreasing the nutritional value of the feed. Pelleting (when done correctly) does not sterilize feed but can substantially reduce pathogen numbers if they are present; this effect varies according to the pathogen, and therefore a uniform reduction of risk should not be anticipated for all pathogens.

Remember that poor manufacturing, delivery, or storage practices post pelleting can result in the feed becoming recontaminated, again reinforcing the need to evaluate all steps in the feed manufacturing and delivery processes to determine their contribution to a disease outbreak.

Risk reduction, heating, disinfectants, inhibitors, etc. Besides pelleting, other further processing steps may be implemented, or other ingredients may be added in an effort to minimize the risk of infectious agents being delivered to pigs through their feed. These will not be covered in detail here, but similar to pelleting, when the role of feed is being investigated as a contributing factor in a disease outbreak, efforts should be made to identify and assess all further processing steps that are being used in the manufacturing facility.

As described earlier in this section, some feed ingredients themselves present a biosecurity risk to pigs. Specifically, ingredients derived from animals are frequently included in diets as a high-quality source of amino acids or energy (as fat). Managing the risk associated with these ingredients requires special attention and is a particular area of focus for authorities that regulate manufacture of animal feeds. More generally, commercial and on-farm feed manufacturers receive frequent deliveries of ingredients (animal origin and otherwise), and if good procedures are not in place to ensure their careful receipt and storage, the potential for cross-contamination abounds.

Porcine origin In some countries, the general restriction on feeding same-species ingredients to livestock is exempted for pigs as there is no clear evidence supporting the existence of an endogenous porcine prion. For this reason, feeding of porcine blood products and some tissue extracts continues in these countries. Under perfect conditions, the likelihood of most pathogenic bacteria and viruses relevant to pigs surviving the manufacturing process for these ingredients is very low, and any that do appear to be present in extremely low concentrations are unlikely to provide an infectious dose to a pig. However, manufacturing processes are imperfect, and so occasional batches of product can be assumed to have higher than anticipated levels of contamination or have somehow become cross-contaminated with untreated raw ingredient during manufacture, storage, or transport. When these ingredients are being included in pig diets or when feed being used on a farm is being sourced from a manufacturer that uses these ingredients, they should be included in the investigation of a disease outbreak.

Uncommon in most commercial pig farming industries but common among noncommercial and backyard farmers is feeding of human food waste (e.g. swill) to their pigs. Virtually all countries with a functional national agriculture ministry or department have regulations that stipulate heat treatment of food waste before it can be fed to pigs; many countries have banned the practice altogether. Nonetheless, the practice of feeding untreated food waste (often derived from large institutions such hospitals, restaurants, schools, or prisons) appears to be relatively

common in some countries with modern commercial pig industries. When an outbreak of an unexpected disease occurs in a commercial herd and noncommercial pigs are known to be kept in the vicinity of the farm, the possibility of the noncommercial farm becoming infected through feeding of untreated waste food (and subsequently infecting the commercial farm through aerosol, indirect, or local spread) should be investigated.

Non-porcine animal origin Ingredients derived from ruminant, poultry, and fish are common in many feed manufacturing facilities, even if not being purposefully included in pig diets. Animal pathogens are promiscuous, and given an opportunity, many have the potential to cross-species and infect pigs. As all of these animal-origin ingredients have the potential to be contaminated with pathogens, they need to be included in any investigation of feed as a contributing factor to a pig disease outbreak.

Regardless of their origin, all feed ingredients have the potential to become contaminated during the receiving process. The contamination can occur as a result of truck or driver mismanagement or through cross-contamination in the receiving equipment (dumping pits, augers, etc.).

Truck vector (defined traffic patterns) It is impossible for feed transport vehicles to avoid dirty roads and possible contamination. This can be a particular problem during the winter when liquids and debris can freeze on the exterior surfaces of the truck, only to fall off once arriving at the feed mill premises. Traffic patterns should be developed for the mill premises that will minimize ingredient delivery trucks (i.e. not typically traveling to farms) coming into contact with feed delivery trucks (i.e. traveling to and from farms on a frequent basis). In addition, hygiene procedures should be developed that minimize the opportunity for debris and liquids that dislodge from the truck to fall into the receiving equipment.

Driver vector (defined driver procedures) Similar to procedures developed for truck drivers (feed or animals) making deliveries to farms, procedures should be implemented to ensure ingredient delivery truck drivers do not contaminate the ingredient they are hauling, as well as contribute to keeping their own personal cleanliness (including the driver compartment) to a high standard. Just as the trucks themselves should follow designated traffic patterns at the feed manufacturing facility, the drivers should also have dedicated footpaths that keep them separate from drivers making deliveries to livestock farms.

Cross-contamination (ingredient specific delivery points) Some ingredients due to their volume, frequency of delivery, or risk profile require dedicated receiving areas or equipment. As is the case with all other activities related to feed or ingredient manufacture, storage, or distribution, any failure in process management will lead inevitably to a cross-contamination event.

The final element to consider in assessing the contribution of feed to an animal disease outbreak is related to implementation of a QA program at the manufacturing facility. These QA programs are typically designed using HACCP principles and importantly should cover all activities that occur at the manufacturing facility as well as prescribe quality standards or specifications for their ingredient suppliers. There are at least three functional areas that should be included in a QA program: sample retention, cleanout procedures, and specification monitoring of ingredients and finished feed.

Sample retention (ingredients and feed) Regardless of whether feed is being manufactured at a commercial facility or on farm, a policy for sample retention (ingredients and finished feed) should be implemented. The specifics of a sample retention policy are beyond the scope of this text but are available from other sources. Sample retention is not a simple procedure as it requires an investment in time, space, and recordkeeping. However, the rapid rate of feed disappearance on most farms means that any feed considered to have the potential for involvement in an animal disease outbreak has typically been consumed prior to investigation of the disease. In these cases, sample retention programs are the only way to go back in time and determine the true contribution to the outbreak.

Cleanout procedures There are numerous points at which cross-contamination of feed or ingredients can occur during manufacturing, storage, or delivery. Aside from having good procedures and training in place designed to avoid the occurrence of cross-contamination, having clearly defined cleanout procedures at every stage in the process where contamination might occur is the best way to mitigate the risk.

Specification monitoring, feed, and ingredients Fundamental to HACCP-based QA programs is the need for quality specifications at all CCPs, a program to monitor the specifications through collection and analysis of data, and finally period verification processes to ensure the specifications are adequate to achieve the desired level of quality in the final product.

All feed mills should demand quality of themselves through production of safe feed manufactured to the specifications demanded by the customer, as well as demanding quality from their suppliers. Because of the regulatory environment around commercially manufactured feeds and ingredients, quality specifications are generally available. However, it is up to the customer to know what they are getting. Specifications do not necessarily equate to high quality; specifications simply state the extent to which a

product meets some standard (within a given level of tolerance) when in fact the standard may be inadequate for the desired purpose! Determine the appropriate standard for your purpose, inform your supplier, and then periodically test the supply at an independent laboratory to verify compliance with the specification.

People

People comprise the fourth and final risk factor that can contribute to a failure in biosecurity and result in an outbreak of disease. The discussion of people-related risk factors that follows first explores the risk contributed by people who have recently traveled internationally (and hence potentially been exposed to pathogens exotic to their country of residence) as compared with people that have only traveled nationally in their recent history. In this respect, we are chiefly concerned with the risk associated only with those people that may have direct or indirect contact with the pig farm of interest: risk contributed by the remainder of the general population can be ignored with a few notable exceptions, which will be described later (Figure 9.7).

People can act as either a biological vector (the person is truly infected with an agent that can also infect pigs) or a physical vector, meaning they are acting as a fomite carrying the agent on their person, clothes, gear, or perhaps their oronasal surfaces.

The risk of people acting as a vector should be considered in light of their anticipated extent of interaction with pigs on the farm. For farm visitors (including people such as vendors or delivery personnel), direct contact with pigs is not expected, and therefore they present only a minimal risk of introducing a pathogen onto the farm. This of course assumes that these individuals follow the prescribed protocols developed as part of the transportation section of a farm biosecurity plan described above.

Regardless of the above, it should be standard practice to have a designated visitor parking area away from any of the pig facilities, that visitors are wearing visibly clean clothes and footwear, and that they sign a visitor log that must include, among other items, their most recent contact with pigs.

Farm staff or other people that can be expected to have either direct or indirect contact with pigs on the farm require much more scrutiny. A number of conditions might reasonably be required of these people including such things as not being permitted to own or work with other pigs, not being allowed to live at another pig farm, not being allowed to come to work if they have influenza-like symptoms, and not being permitted to bring raw or untreated meat products onto the farm as part of their personal lunch. In addition, standard processes should be established and trained around implementation of a number of key risk-reducing practices.

Shower-in/shower-out

Many farms, particularly in the United States, require all visitors and staff to shower in to the farm at the beginning of the work day and then shower out at the end of the day. While providing an opportunity to remove and pig pathogens being carried on the person, the real benefits of shower-in/shower-out systems are that there is a clear demarcation of where "dirty" (i.e. outside the farm facility) ends and "clean" (i.e. inside the farm facility begins) begins and the process forces staff to leave their personal clothing and footwear outside the farm and only use gear that is

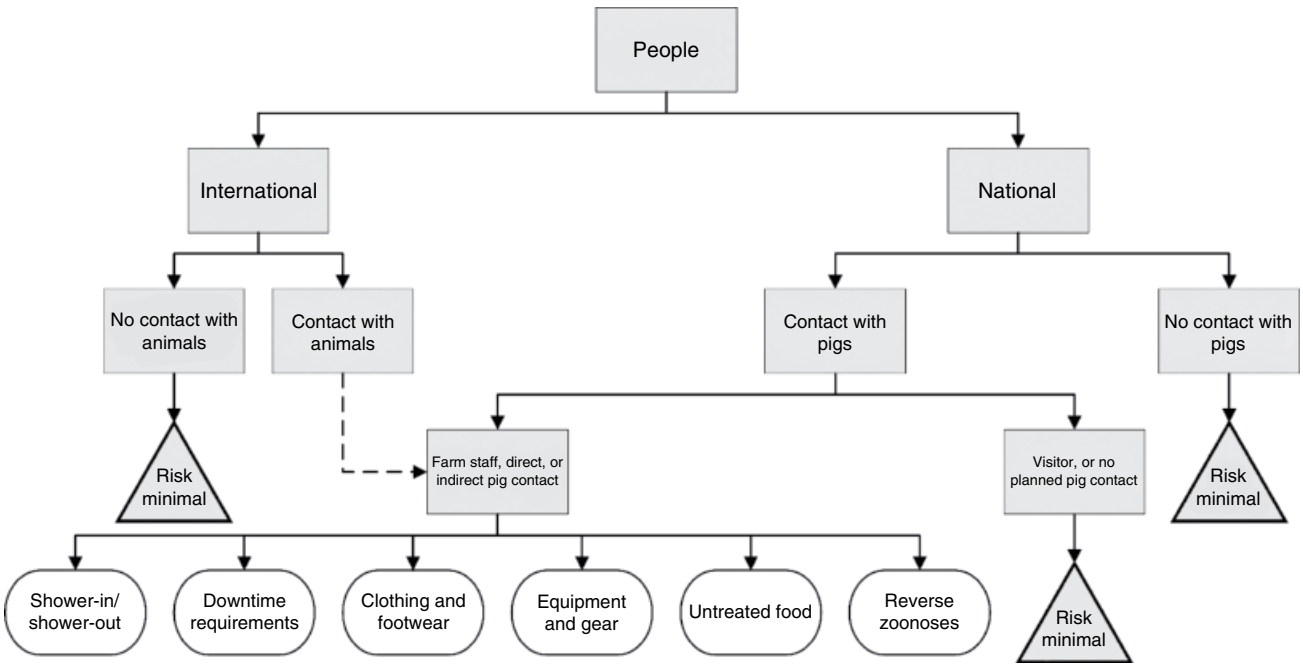

Figure 9.7 Root causes of biosecurity failure related to animal contact with people.

known to be clean while coming into contact with the pigs. The process has the side benefit of allowing staff to leave the farm in a clean state, minimizing contamination of their personal vehicle and home. Farms that implement shower-in/shower-out typically provide all the necessary clothing and footwear for all staff and provide facilities to launder everything inside the farm facility, avoiding the need to carry any farm clothing outside the facility.

Downtime requirements

The duration of time a visitor needs to be away from all pigs before allowed entry into a pig farm is quite variable, almost certainly related to the paucity of actual data on the subject. However, intuitively it makes sense to avoid contact with pigs prior to entering a farm. Some farms vary the requirement based on the consequences that might result if a disease incursion was to occur. For example, a boar stud might require 5 days of downtime, while a commercial finisher might only require an overnight downtime.

Clothing and footwear

Given the low cost of coveralls and boots, farms should not allow staff or visitors to bring their own gear onto the farm. Instead, they should keep a small inventory of gear in a range of sizes that can be made available to the occasional visitor as required. While coveralls can be easily laundered, boots typically are difficult to get completely clean. In both cases, it is simplest for the farm to provide gear rather than permit visitors to bring their own.

Equipment and gear

All equipment and consumable supplies brought into the pig operation should arrive clean and undamaged. Many farms bring supplies through a fumigation room or spray them with disinfectant at the entry point. The greatest risk that accompanies consumables is that they may have been delivered to another farm, returned to the supplier, and then redistributed by the supply company.

Specialist equipment and supplies often need to be brought onto a pig farm by service people such as electricians or plumbers. It is not unusual that these specialists have brought their gear onto other pig farms. As their services are often needed on an emergency basis, farmers typically have little choice but to allow the equipment into the farm. However, it is perfectly reasonable to inspect all equipment that is to be brought onto the farm, to clean and disinfect it as best as possible, and importantly to try to position the equipment once in the facility in locations that minimize the opportunity to come into direct contact with pigs.

Farm machinery and equipment can also be a risk for transmitting disease to a pig operation, especially if the machinery and equipment were used at or nearby other pig operations. Whenever possible, avoid borrowing equipment from other farms and when it is necessary, following procedures described above for gear used by service contractors.

Untreated food

If left untreated, all products of animal origin have the potential to harbor animal pathogens, and this includes raw meat products or any food items that come into contact with raw meat. Some farms or staff members are in the habit of preparing meals at the farm rather than preparing food at their home and then bringing to the farm for direct consumption or reheating. Given the level of international trade in meat products, it is likely that at least some raw meat products brought onto a farm were sourced internationally and therefore may be contaminated with high-consequence exotic pathogens. Rather than trying to mitigate the risk through some other means, the best policy is to avoid bringing untreated meat products into the farm facility.

Zooanthroponosis

Some pathogens are able to move between animals and humans (zoonosis). Those zoonotic agents (or diseases) that have a propensity to travel from humans to pigs are termed zooanthroponosis. Influenza, specifically the 2009 pandemic strain, is notable for this behavior. For this reason, people with influenza-like symptoms should avoid contact with pigs. More broadly, people and pigs can impact each other's health by acting as reservoirs of the infection. Encephalitis B virus is an important cause of viral encephalitis in people across much of South Asia. The virus moves between people, pigs, and mosquitoes, reminding one that livestock farming cannot be done in isolation from the rest of the general public. Farmers have a responsibility to stay engaged and aware of larger public health issues and not ignore the role of pigs for some human diseases.

Principles of evidence-based biosecurity

All the features of size, production flow, commercial imperative, geographical location, local industry density, connectedness to other farms, and physical building characteristics that describe a farm are the same features that make it impossible to develop a one-size-fits-all BRM plan suitable for use across the pig industry. As an alternative, the following ten principles are proposed as fundamental criteria that must be fulfilled when developing biosecurity plans for pig farms. Scientific evidence is available to support application of each principle that is appropriate for most farm and disease settings that will be encountered. Readers are encouraged to develop their own studies that can further our knowledge of these topics for use by an even broader cross section of the international industry. The principles are not complicated, though they can be difficult to institute effectively and with adequate levels of compliance (Figure 9.8).

Drug Pharmacology, Therapy, and Prophylaxis

Locke A. Karriker, Johann F. Coetzee, Robert M. Friendship, and Michael D. Apley

This chapter is an overview of the major considerations specific to drug therapy in swine. Major drug classes and biological agents used in swine, with a focus on antimicrobial drugs and the basic principles on which effective drug use is based, are included. Readers seeking a general review of antimicrobial therapy principles are referred to excellent reviews elsewhere (Boothe 2006). Anesthetic drug properties, tranquilizers, and anesthetic protocols are discussed in Chapter 11. A useful additional reference for anesthetic information in swine is the comprehensive bibliography by Smith (2011). A key consideration in selecting drug therapy in swine is compliance with local, state, territorial, national, and international regulations that impose limitations on use or expectations for the safety of products derived from the animals treated. Due to the international audience of this book and the highly variable regulation of drug treatment, it is incumbent on the reader to understand applicable law for their case context and apply discretion when using information from this chapter. Specific regulatory impacts on drug treatment will not be discussed further in this chapter.

Major considerations for drug therapy

Managing the effective use of drugs or biological agents for prevention and treatment of disease is an important responsibility of swine veterinarians, which involves detailed knowledge of these agents, the risks involved to both humans and animals by their use, and the applicable local, national, and international regulations. In swine, priority is placed on the production of safe meat and protection of animal welfare. Additional considerations include cost, efficacy, and ease of application. Within each of these broad categories exist several swine-specific issues that must be managed by the animal caretaker and veterinarian (Table 10.1).

All decisions to initiate drug therapy must recognize that any chemical addition to the animal has the potential to negatively impact homeostasis. Energy, enzyme pathways, and metabolic substrates must be diverted from growth and homeostasis to eliminate exogenous chemical additions including therapeutic drugs. Therefore, clear evidence that the potential benefit to the animal is greater than the negative impact on homeostasis is a prerequisite to treatment. Demonstrating a clear benefit is predicated on correct identification of existing or potential clinical compromise, most commonly infectious disease. All drug use involves a calculation that benefits of use exceed the risks involved. The goal is to minimize use of drugs in pork production while ensuring the production of healthy animals in a humane, cost-effective, safe, and environmentally sustainable manner. Changes in swine production practices continue to reduce reliance on antimicrobial drugs and improve pork safety in modern production.

Selecting appropriate drug therapy consists of several specific steps: (1) determine the treatment objective using the sum of clinical and diagnostic evidence available, (2) identify the best treatment option while considering swine-specific physiology, (3) establish the treatment regimen in light of production logistics and regulation constraints, (4) facilitate implementation and compliance, and (5) assess the outcomes and modify protocols as indicated. The most complex treatment decisions in swine are generally those where an antimicrobial is used for treatment of clinical disease. A useful organization scheme for the swine veterinarian when making a comprehensive antimicrobial selection is the "S.P.A.C.E.D." mnemonic described in Table 10.2.

Determining treatment objective

The current standard for determining a treatment objective in the context of antimicrobial therapy is a diagnosis that includes bacterial culture and identification accompanied

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Table 10.1 Considerations for drug use in swine.

Major consideration	Further considerations
Human safety	Direct drug toxicity to user, toxicity to consumer through tissue residues, contamination of environment
Animal welfare	Prevention of reduction of disease, ease of administration for animal, need for restraint
Host animal safety	Direct toxicity to pig, tissue damage, adverse drug reactions, indirect adverse effects such as disruption of microflora
Regulations	Availability of products, national regulations on use, international regulations for export, use authority, compliance with established withdrawal periods, veterinarian–client relationship
Efficacy	Assessment of efficacy, setting client expectations for efficacy, cost/benefit of treatment, effects of concurrent disease
Drug dosage and administration	Route required, ease of administration, physiochemical properties, frequency of administration
Pharmacology/ pharmacokinetics	Evidence for dose, route, duration, frequency, estimations of drug clearance rates, distribution to target tissues, mechanism of action, expected routes of elimination, mechanism of drug metabolism
Recordkeeping	Requirements for dispensing such as prescriptions or feed directives, documenting treatment, tracking disposition of treated animals, data collection to assess efficacy
Drug storage/accessibility	Physiochemical conditions impacting drug concentration or viability during storage or use, drug-specific legal requirements for storage and possession
Resistance/tolerance	Antimicrobial resistance resulting in animal or human treatment failures, increasing tolerance of the animal to drug effects

Table 10.2 Antimicrobial selection considerations (S.P.A.C.E.D.).

Spectrum	Drug efficacy against pathogen; pathogen Gram staining; pathogen metabolism (aerobic or anaerobic)
Pharmacokinetics and pharmacodynamics	Drugs' ability to reach the pathogen at the site of infection in high enough concentrations to be effective; plasma antimicrobial concentration vs. time profile; concentration dependent or time above MIC dependent or AUC above MIC dependent; volume of distribution; protein binding
Adverse reactions	Safe to use in this disease state, breed, age group, or class of animal; potential contraindications/toxicities; potential risks to the person administering the drug
Compliance	Caretaker's ability to provide the full course of treatment; legality of use in this class of animal
Environment	Site of infection characteristics; potential for resistance development
Diagnostics	Pathogen identification; actual or estimated susceptibility profile

with antimicrobial sensitivity testing of that isolate. In swine cases, this isolate should be the consequence of a complete diagnostic investigation that confirms that lesions consistent with the pathogen are present in appropriate tissues. Further, the case needs to be representative of the primary problem in the target swine population. It is often necessary to confirm culture and sensitivity data for several representative cases in a specific population as pathogens are not necessarily a homogeneous species or even genus in a swine population. Several pathogenic bacteria can coexist with nonpathogenic strains of the same genus and species in the pigs such as the case with intestinal *Escherichia coli*.

When culture and sensitivity confirmation is not available or the urgency of intervention on behalf of swine welfare requires initiating therapy before results are available, several sources of information are available to supplement empirical treatment. Practitioners have the capability with some diagnostic laboratory cooperation to maintain antimicrobial sensitivity summaries for their clients or practice region compiled from a series of diagnostic cases. Several diagnostic laboratories summarize the percentage of isolates that are susceptible to selected antimicrobials on a routine basis. These summaries are generally available online and may represent a more current and broad view of microbial susceptibilities than even randomized controlled trials using single isolates.

Treatment options and specific impacts of swine physiology

Major classes of antimicrobial drugs

A brief overview of some key aspects of the major classes of antimicrobial drugs, their antimicrobial activities, pharmacokinetic properties, toxic or other adverse effects, and major clinical applications is given in Table 10.3. Further

Table 10.3 Overview of the major classes and identities of antimicrobial drugs used in swine, their antimicrobial activities, pharmacokinetic properties, toxic and other adverse effects, and major clinical applications.

Drug class	Specific agent or example of agents	Antibacterial activity, resistance	Pharmacokinetic properties	Toxic or adverse effects	Major applications
Sulfonamides	Sulfamethazine, intermediate acting; others used	Bacteriostatic; broad-spectrum, gram-positive and gram-negative aerobes; anaerobes; acquired resistance very widespread; active intracellular bacteria, protozoa	Rapidly absorbed from intestine, well distributed in tissues	Violative kidney residues from feed use through recycling; feed contamination if feed not withdrawn 15 days before slaughter	Minor value; largely growth promotional; possible disease prevention
Sulfonamide–diaminopyrimidine combinations	Sulfamethazine/trimethoprim	Bactericidal; gram-positive and gram-negative aerobes; anaerobes; *Mycoplasma* and *Leptospira* resistant	Rapidly absorbed from intestine, well distributed in tissues; crosses uninflamed blood–brain barrier	Wide safety margin	Largely water use for acute infections (pneumonia, streptococcal meningitis); in feed and water for atrophic rhinitis
Beta-lactam	Penicillin G, potassium penicillin	Bactericidal; highly active many gram-positive aerobes; some fastidious gram-negative aerobes, for example, *Haemophilus parasuis* and *Pasteurella multocida*; anaerobes; *Leptospira*, enteric bacteria, and *Mycoplasma* resistant	Poorly absorbed from intestine, relatively poorly distributed in tissues; crosses only inflamed blood–brain barrier; procaine penicillin G has more prolonged plasma concentrations due to slower release from the injection site	Safe drug; possible anaphylaxis or procaine-induced excitement	Excellent for IM use in *erysipelas*, *streptococcal* infections including meningitis, and *Clostridial* infections; some bacterial pneumonias. Potassium pen in water
Beta-lactam	Ampicillin, amoxicillin	As penicillin G, broader activity against gram-negative aerobes, but resistance widespread	As penicillin G, but better absorbed orally and distributed through tissues	Safe drug	Similar to penicillin G; addition of beta-lactamase inhibitors (e.g. clavulanic acid) has resurrected penicillin use in other species
Beta-lactam	Third-generation cephalosporins; ceftiofur	Bactericidal; gram-negative aerobes especially, including *Escherichia coli* and *Salmonella*; gram-positive aerobes; anaerobes; *Mycoplasma* resistant	Poorly absorbed from intestine, relatively poorly distributed in tissues; crosses only inflamed blood–brain barrier	May predispose to *Clostridium difficile* colitis if used in neonatal pigs; resistance emerging in *Salmonella* may represent human health hazard	Excellent for IM use in gram-negative aerobic infections, including colibacillosis and salmonellosis, and gram-negative bacterial pneumonias
Aminoglycoside	Gentamicin, neomycin	Bactericidal; gram-negative aerobes, including enterics	Poorly absorbed from intestine, relatively poorly distributed in tissues	Nephrotoxic with prolonged parenteral use; persistent kidney residues	Gentamicin IM for neonatal *E. coli* infections; neomycin orally for *E. coli* infection
Aminocyclitol	Spectinomycin	Bactericidal; gram-negative aerobes, including enterics	Poorly absorbed from intestine, relatively poorly distributed in tissues	Safe drug in swine	Orally for *E. coli* infection
Lincosamide	Lincomycin	Bacteriostatic; gram-positive aerobes; anaerobes including *Brachyspira hyodysenteriae*; *Mycoplasma*	Well absorbed from intestine and well distributed in tissues	Safe drug in swine	Oral use for control of *Brachyspira*; oral or IM use for control of *Mycoplasma*

Macrolide	Tylosin, tulathromycin, tylvalosin, tilmicosin	Bacteriostatic; gram-positive aerobes; anaerobes; some gram-negative aerobes; *Mycoplasma*	Well absorbed from intestine and well distributed in tissues	Safe drug in swine except injected tilmicosin is fatal; others are IM irritant; may cause rectal edema; pruritis; anal protrusion	Oral use for control of proliferative enteropathy, atrophic rhinitis, and possibly leptospirosis
Pleuromutilin	Tiamulin	Bacteriostatic; gram-positive aerobes, anaerobes, some gram-negative aerobes; *Mycoplasma*; more active than tylosin	Well absorbed from intestine and well distributed in tissues	Safe drug in swine	Oral use for control of *Brachyspira*, *Mycoplasma*, chronic pneumonias, proliferative enteropathy, and leptospirosis
Tetracyclines	Oxytetracycline, chlortetracycline	Bacteriostatic; classically broad spectrum, gram positive, gram negative but acquired resistance extremely widespread; *Erysipelothrix*, *Haemophilus*, *Leptospira*, and *Pasteurella* are exceptions	Well absorbed from intestine and well distributed in tissues	Safe drugs in swine	Oral use as "feed" drugs for growth promotion and nonspecific disease prophylaxis in countries where allowed; used in feed, occasionally IM, for treatment of infections caused by bacteria listed as being susceptible
Phenicols	Florfenicol	Binds 50s ribosomal subunit; bacteriostatic may be bactericidal at high concentrations	Well absorbed orally	Florfenicol relatively safe; chloramphenicol is toxic to humans and banned in US food animals	Labeled for *Actinobacillus pleuropneumoniae, P. multocida*, *Salmonella choleraesuis*, and *Streptococcus suis* in water. Use of injectable is extra label in swine
Quinoxaline derivatives	Carbadox	Bactericidal; mechanism is unknown; primarily active against gram-positive bacteria with little efficacy against some gram negatives	Orally absorbed	It is carcinogenic and genotoxic in rodents, and, consequently, the usage of carbadox is prohibited in Europe and Canada	Carbadox is most commonly used as a feed additive to promote growth in swine; controls swine dysentery (*Serpulina hyodysenteriae*); nasal infections (*Bordetella bronchiseptica*)
Fluoroquinolones	Enrofloxacin	Bactericidal; inhibits bacterial DNA gyrase or topoisomerase IV, preventing DNA supercoiling and cell replication	Well absorbed with a high volume of distribution. Enrofloxacin is de-ethylated to form ciprofloxacin, which comprises <10% of the amount of enrofloxacin present in the plasma	The long-term effects on articular joint cartilage have not been determined in pigs above market weight. US federal law prohibits the extra-label use of fluoroquinolones in food-producing animals	Treatment and control of swine respiratory disease (SRD) associated with *A. pleuropneumoniae*, *P. multocida*, *H. parasuis*, *S. suis*, *B. bronchiseptica* and *Mycoplasma hyopneumoniae*. Control of colibacillosis in groups or pens of weaned pigs where colibacillosis associated with *E. coli*. has been diagnosed

details are available through manufacturer's package inserts and through pharmacology-focused textbooks (Giguere et al. 2015).

Antimicrobials may be classified as bactericidal or bacteriostatic based on the outcome of specific *in vitro* drug–bacteria interactions. Typically, a drug is considered bactericidal when there is a 3-log reduction in bacterial cultures over a 24 hour period. It has been suggested that bactericidal drugs are preferred for treatment of serious life-threatening infections, when host defenses are impaired, and infections of vital tissues such as meninges, endocardium, and bones, where host defenses are also not fully functional. In other cases, bacteriostatic agents may be equally useful. It should be recognized that this classification is only one of many aspects that should be considered when making appropriate antimicrobial selections.

To some extent, drug dosage can be tailored to the susceptibility of the organism, the site of infection, and the pharmacokinetic and pharmacodynamic properties of the selected antimicrobial agent. However, *in vitro* susceptibility data are laboratory derived, and the standardized conditions under which the susceptibility data are generated do not exist at the site of infection. When interpreting antimicrobial susceptibility testing, it is important to know if the laboratory is conforming to Clinical and Laboratory Standards Institute (CLSI) standards as well as applying CLSI interpretive criteria. Where CLSI approved standards and interpretive criteria exist for a combination of the animal species, pathogen, disease, and drug regimen, then more confidence may be placed in the clinical application of these results. Where there are no CLSI interpretive criteria, such as for any enteric disease in swine, much more care must be taken in interpretation.

Factors involved in tailoring a dosing regimen include, among other things, the susceptibility of the pathogen in terms of minimum inhibitory concentration (MIC), the concentration of the antimicrobial agent at the site of infection in active form (pharmacokinetic properties of the drug), and the pharmacodynamic properties of the antimicrobial agent. Some antimicrobials (aminoglycosides, fluoroquinolones) are concentration dependent (optimum action of the drug depends on concentration of the drug above MIC), whereas others (beta-lactams, lincosamides, macrolides, trimethoprim/sulfamethazine) are time dependent (optimum activity depends on how long they remain at concentrations above MIC). The complex issues involved in optimal antimicrobial therapy are beyond the scope of this chapter although it can be concluded that some dosage recommendations for drugs licensed in the past have not taken modern understanding into account and are suboptimal or inappropriate based on more recent data. Although several factors determine optimal dosage, the factor that most frequently limits dosage is toxicity. The upper level of the recommended dosage (when provided as a range) should not be exceeded, because this is often determined by toxicity. In some instances, a drug's antibacterial effects may be limiting and may determine the upper level of dosage. For example, the killing rate of beta-lactam drugs has an optimal concentration with little benefit of the plasma concentration exceeding 2–4 times the MIC, whereas the killing rate of the aminoglycosides or fluoroquinolones is proportional to drug concentration. Penicillin G is virtually nontoxic in nonallergenic patients, but its dosage is limited by marginal return in the form of antibacterial action above a certain concentration. By contrast the dosage of aminoglycosides is limited not by antibacterial effects but by its toxicity.

In terms of duration of treatment, the variables affecting length of treatment have not been adequately defined in swine. Responses of different types of infections to antimicrobial drugs vary, and clinical experience with many infections is important in assessing response to treatment. For acute infections, it will usually be clear within 2 days whether therapy is clinically effective. If no response is seen by that time, both the diagnosis and treatment should be reconsidered.

Drug selection for specific diseases

It is beyond the scope of this text to discuss all product indications, cautions, and regulations, nor is it within the scope of this text to include all possible treatment options. Readers are referred to the relevant specific disease chapter for further suggested treatments.

A few swine-specific treatment examples are noted here to guide veterinary practice and illustrate general principles. For example, parenteral tilmicosin is fatal to swine even at very low concentrations. However, oral administration is approved for *Actinobacillus pleuropneumoniae* and *Pasteurella multocida* (Backstrom et al. 1994).

Bimazubute et al. (2010) demonstrated that concentrations of oxytetracycline could be achieved in nasal secretions of swine that were greater than the MIC for *P. multocida* and *Bordetella bronchiseptica*, key pathogens in atrophic rhinitis. However, this could only be achieved with intramuscular (IM) injection at 40 mg/kg body weight. This dose level was four times the swine label recommendation. Although peak concentrations in plasma and nasal secretions both occurred 4 hours after administration, the maximum concentration of the drug in nasal secretions was 6.29 µg/mL compared with 19.4 µg/mL in plasma. Efficacious levels were not achieved with lower IM doses nor feed formulations containing oxytetracycline at 400 mg/kg of feed. In many species including pigs, enrofloxacin is metabolized to ciprofloxacin, which also has potent antimicrobial activity. Variations in the amount of enrofloxacin converted to ciprofloxacin occur with age in swine. None of the

original dose of the parent enrofloxacin was detected as ciprofloxacin in 10 kg pigs compared with 52% of the original enrofloxacin detected as ciprofloxacin in 76 kg pigs (Bimazubute et al. 2009). It is important to consider that the majority of swine in the world are marketed before they achieve maturity, and therefore most treatments are applied to juvenile animals. In most species, including pigs, age-specific variation in metabolism is recognized and must be considered. Unfortunately, swine-specific data for most drugs have not been developed.

Cornick (2010) demonstrated that fewer pigs fed tylosin or chlortetracycline shed *E. coli* O157:H7 for longer than 2 weeks compared with pigs fed no antimicrobials. Experimentally, antimicrobial-free pigs can be infected and shed for longer than 2 months. However, field studies rarely recover this organism from domestic pigs. Potentially, feed medication protocols used in commercial swine production have reduced the presence of this food safety risk. As antimicrobials are removed from swine populations worldwide, it will be necessary to monitor for unintended consequences to animal welfare or food safety.

Most pharmacokinetic parameters are studied in healthy, disease-free pigs. There are few studies evaluating how disease impacts the pharmacokinetics of drugs and the implications for modifying treatment regimens. In one study, the mean of maximum plasma tetracycline concentrations was lower and achieved significantly later postinjection in pneumonic pigs relative to healthy pigs (Pijpers et al. 1991). Pigs infected with porcine reproductive and respiratory syndrome virus (PRRSV) had decreased plasma ceftiofur concentrations relative to healthy pigs (Tantituvanont et al. 2009). Vaccination of pigs with a modified live PRRSV vaccine prevented the changes in pharmacokinetics induced by wild-type virus infection (Sparks et al. 2017).

Establishing treatment regimens considering production logistics and regulatory constraints

Routes of drug treatment

In general, individual animal treatment through injection is preferred for serious, rapidly developing infections such as acute systemic infections (septicemia, acute pneumonia, or streptococcal meningitis), but medication of an entire group is preferred when ease of administration can be considered, identifying sick individuals in population is challenging, or it is necessary to avoid the animal welfare implications or human safety concerns of handling and restraining the animals. IM injection is preferred for serious infections since it usually results in more complete absorption of drug and higher tissue concentrations than oral administration. Parenteral therapy of individual animals by IM injection is administered just behind the ear on the lateral side of the neck. This site is chosen in case the drug preparation causes local tissue damage as well as to prevent the possible additional effect of sciatic nerve damage if the ham muscles were used. Needleless injection devices are available for vaccines but are so far infrequently used for treatment due to dose limitations imposed by the design of the devices.

Oral medication is easier to apply to groups of pigs and reduces injection-related food safety problems of broken needles, abscesses, and tissue damage. Oral medication for infections outside the gastrointestinal tract generally represents a less efficient use of the total antimicrobial applied to a population. For example, the range in reported oral bioavailabilities of amoxicillin is 11–47% (Hernandez et al. 2005). Water medication is a more rapid method of treating a group of sick pigs than feed medication, with the advantages of immediate implementation and that sick pigs will continue to drink when they will not eat. However, the disadvantages are that not all drugs are water soluble, that water may be spilled or wasted, and that some drug carriers may occlude nipple watering systems. Administration of drugs by water is through an in-line proportioner containing a concentrated drug solution or by a water tank containing the appropriately dosed drug. Pigs drink about 8–10% of their body weight daily, depending on environmental temperature and palatability of the drug.

As an example, amoxicillin has been demonstrated to achieve therapeutic levels in swine (Agerso et al. 1998) via water delivery. Mean plasma concentrations fluctuated between 0.5 and 1.3 μg/mL during the treatment period and were suspected to reflect pig drinking behavior. Consumption of amoxicillin-containing water also increased as pen temperature increased during the study. Several studies have demonstrated relatively large individual animal variation (Agerso et al. 1998) relative to group plasma means. This variation in effective dose, and corresponding variation in response to therapy, must be considered when setting treatment expectations for water medication protocols. In fact, when tetracycline plasma levels were evaluated in pigs administered water medicated at labeled concentrations, plasma levels were highly varied and generally lower than 0.3 μg/mL, which suggests that therapy would have questionable value for most target pathogens (Dorr et al. 2009). Another study of tetracycline water medication in swine revealed that the oral bioavailability is very low (Mason et al. 2009).

In-feed medication has historically been the most common route of administration of anthelmintic and antimicrobial drugs. The disadvantage for treatment of acute infections is not only that sick pigs may not eat but also that existing non-medicated feed needs to be either removed or eaten. For this reason, in-feed medication is

often reserved for long-term use in the prevention, control, or treatment of chronic infections.

Principles of prophylaxis

Antimicrobial drugs are administered to swine for the prevention of diseases. The timing of prophylaxis is especially critical and may not vary significantly from the optimum for treatment except that prophylaxis implies clinical signs are not yet occurring although the animal or population may already be infected. The generally accepted principles of antimicrobial prophylaxis are as follows:

- Medication should be directed against specific pathogens or diseases.
- Prophylaxis should be used only where efficacy is established. It should be of a duration that is as short as possible consistent with efficacy.
- Dosage should be the same as that used therapeutically.
- Adverse effects itemized earlier should be minimized.
- Prophylactic use of antimicrobials should be restricted for the treatment of animals that are most likely to respond to treatment.
- Alternatives to these antimicrobial use practices need to be found and employed when possible.

One prophylactic practice in swine is that of "pulse medication," whereby a therapeutic level of a specific drug is included in the feed at therapeutic concentrations periodically for a short duration to significantly reduce clinical disease while allowing the animal to develop natural immunity because of infection by the pathogen. This approach requires sufficient diagnostic history from the population to anticipate a predictable onset of the disease on a particular farm. When applied correctly, this approach can limit total antimicrobial use while preserving animal welfare. A comparison of pulse dosing to continuous dosing in feed demonstrated improved performance and survivability in the presence of naturally occurring disease for both treatments. However, pulsing permitted sufficient natural exposure to stimulate active humoral immunity to *Mycoplasma hyopneumoniae*, while continuous treatment did not (Walter et al. 2000). The implications of this approach for the development of antimicrobial resistance are not completely understood.

In a study of ceftiofur administered as a single injection of the crystalline-free acid, pigs injected 13 and 10 days prior to challenge did not have removal rates significantly different than untreated controls after challenge with *A. pleuropneumoniae* (Crane et al. 2006). However, treatment 7, 4, and 1 days prior to challenge resulted in fewer removals than the control group. Understanding the duration of antimicrobial effect for the selected treatment is an important component of treatment success.

Multidrug therapies must be considered for their potential to create toxicities that would not occur because of either treatment independently. In swine, the most commonly described example of this is toxicity due to concurrent exposure to an ionophore (narasin, for example) and tiamulin. Radke (2017) described three cases where the toxicity was manifested as neurologic/musculoskeletal signs, ataxia, tremoring, lameness and increased vocalization, especially when forced to move. In all three cases, an error in the manufacture of feed led to the accidental administration of an ionophore concurrently with the intentional administration of tiamulin.

Regulation

The use of antimicrobial drugs in food animals is regulated by law in many countries, and veterinarians need to know and abide by the regulations. The regulations involve an approval process of drugs produced by a manufacturer only if they meet human and animal safety standards as well as being shown to be efficacious at specified dosages for particular purposes. In the United States, general limits to how antimicrobials are used exist. Extra-label use is allowed when drugs are approved for use in humans or food animals and the specific requirements of the Animal Medicinal Drug Use Clarification Act are met. However, extra-label use via feed delivery is not allowed, and there are specific drugs that are banned in food animals in the United States. None of these circumstances are swine specific and will not be discussed further here, but the swine veterinarian is cautioned to be aware of the most current regulations for their practice location.

Drug withdrawal

Most drugs must not be used near slaughter to avoid any significant residues in meat products. While generally understood for antimicrobials, it is often overlooked that most vaccines have required withdrawal times as well. The use of vaccine near market in growing animals is unlikely, but timing the vaccination of sows that might be candidates for culling requires observation of the withdrawal time. The precise period varies with the drug and the dosage. For drugs used at the labeled dosage, this will be specified on the package insert. For extra-label drug use, withdrawal information may be obtained from the manufacturer or in some cases from national or international databases such as, in the United States, the Food Animal Residue Avoidance Databank (www.usfarad.org). Veterinarians should be aware that there is robust international trade of pork products, acceptable residue limits in pork vary among countries, and the withdrawals included on the label may only be valid for the country in which the drug label was approved. Consequently, some harvest plants have extended withdrawal periods for specific

drugs to prevent residues using the limits of the destination country. It is important to accommodate the requirements of the destination market with the lowest maximum residue limit (MRL). In most cases, the harvest plant will know the potential destinations for pork products they export and will have withdrawal suggestions. Dialogue with the harvest plant is imperative to create treatment withdrawals that protect a producer's ability to market at the desired plant.

Limiting development of resistance

Numerous reports have recommended that all stakeholders concerned with the use of antimicrobials in both food animals and humans must be involved in an overarching global strategy to contain resistance (e.g. World Health Organization 2000a) and have recommended steps to enhance the prudent use of antimicrobials in animals, including the removal of growth promotion use of antibiotics if they are important in human medicine (e.g. World Health Organization 2000b). It is critical to note that resistance mechanisms are not limited to antimicrobials but have also been reported for copper and zinc (Fard et al. 2011). Further, as mentioned previously, direct evidence that even low levels of antimicrobials reduce the shedding of human pathogens by swine (Cornick 2010) must be considered in the formulation of risk mitigation regulations at the national level. At the international level, the World Organization for Animal Health continues to formulate recommendations and options for risk management relating to antimicrobial use in animals (OIE 2003; WHO 2004). Outside the EU, other countries are in the process of assessing or starting to reassess the use of antimicrobial drugs in food animals based on the importance of the drug in human medicine and the likelihood of exposure of humans to resistant bacteria or resistance genes arising from animals (e.g. Health Canada 2002; Center for Veterinary Medicine, US FDA 2004).

There are opportunities to apply innovation to reduce the amount of antimicrobials used in production. While the inclusion of antimicrobials in semen extenders does not represent a significant portion of the total use in swine, a recent study demonstrated the potential for innovation to limit antimicrobial use. In this study, Morrell and Wallgren (2011) used single layer centrifugation to separate sperm from bacteria to create semen doses free of bacterial contamination.

In recent years many countries have started to monitor resistance in both important pathogens (e.g. *Campylobacter jejuni*, *Salmonella*) as well as "indicator" commensal bacteria isolated from animals, foodstuffs, and humans. For example, in the United States, the National Antimicrobial Resistance Monitoring System (NARMS) established in 1996 is designed to document emerging resistance problems, as well as to provide data on which public health policy decisions can be made for the use of antimicrobial drugs in food animals. In Canada, the Canadian Integrated Program for Antimicrobial Resistance Surveillance (CIPARS) has taken a similar approach to NARMS. In 2010, CIPARS reported (Deckert et al. 2010) that in sentinel grower/finishers, antimicrobials considered very important to human health were not frequently used. Additionally, resistance as determined by culture and sensitivity of samples obtained on farms was characterized as low.

One emerging resistance problem that will likely receive greater attention in the future is extended-spectrum cephalosporin resistance in multidrug-resistant *E. coli* and *Salmonella* serovars (Winokur et al. 2001; Zhao et al. 2003), in which the *cmy-2* gene encoding expanded-spectrum cephalosporin resistance may be found on several different plasmids that can readily be transferred through bacterial conjugation (Carattoli et al. 2002). However, as deftly pointed out by Davies (2010), "Genes encoding for antimicrobial resistance are not foodborne pathogens."

Tracking genetic changes provides warning of adaptation and spread of the capability to transcribe cellular modifications that would make foodborne pathogens harder to combat. One example of an opportunity for swine practitioners to guide more judicious use involves the use of colistin (a cationic polypeptide antibiotic) in pig production. There is very little pharmacokinetic data to guide colistin use in swine, and it has reemerged in human medicine to treat infections caused by gram-negative bacteria that are more frequently resistant to aminoglycosides. Since the 1980s, it has been understood that colistin resistance was in part conferred by the chromosomal *mcr-1* gene mutation in bacteria. More recently, the *mcr-1* gene has been found on a plasmid in *E. coli* isolated from swine. Plasmid transfer can occur within bacterial species but also between different species, which allows it to be disseminated more readily. The reader is referred to the review by Rhouma et al. (2016) for further explanation of the relationship of colistin use and emergence of the plasmid-mediated resistance.

Prudent use guidelines

The widespread concern about antimicrobial resistance and the animal–human resistance link has led most major national veterinary organizations to improve antimicrobial drug use by development of prudent use guidelines. Such guidelines represent first steps in the more judicious use of antimicrobial drugs that may become considerably more complex over time if they address antimicrobial drug choice for diseases. An example of such guidelines, that of the American Association of Swine Veterinarians, is shown in Table 10.4.

Table 10.4 American Association of Swine Veterinarians (AASV) Judicious Therapeutic Use of Antimicrobials Principles for Swine Veterinarians.

1) Implement preventive strategies, such as appropriate husbandry and hygiene, routine health monitoring, and immunization to optimize pig health.
2) Recognize that in spite of best efforts toward preventive strategies, there are times when swine veterinarians need to prescribe treatment for individual and herd conditions. This is a part of the veterinarians' oath to "protect animal health and welfare." Use the following suggested steps to assess necessity for judicious therapeutic use of antimicrobials.
3) Consider other therapeutic options prior to, or in conjunction with, antimicrobial therapy.
4) Meet all requirements of a veterinarian–client–patient relationship (VCPR).
5) Prescribe extra-label antimicrobial therapy only in accordance with the Animal Medicinal Drug Use Clarification Act amendments to the Food, Drug, and Cosmetic Act and its regulations.
6) Work with those responsible for the care of pigs to use antimicrobials judiciously regardless of distribution system through which the antimicrobial was obtained.
7) Optimize regimens for antimicrobial therapy using current pharmacological information and principles.
8) Use antimicrobials following careful review.
9) Follow label directions or, when extra-label use is clinically necessary, follow AMDUCA regulations.
10) Use historical outcomes and clinical experience in the selection of antimicrobials.
11) Use adequate laboratory support for antimicrobial decision-making.
12) Devise a plan for treatment of ill or at-risk animals.
13) Minimize environmental contamination with antimicrobials.
14) Record all antimicrobial treatments.
15) Periodically reevaluate antimicrobial use.

Note: The AASV website elaborates on these basic guidelines (https://www.aasv.org/documents/2014AASVJUG.pdf).

Effects of antimicrobial treatment on immunity

Effects on the immune system of drugs intended to provide antimicrobial therapy must be considered as part of treatment plan development. For example, Pomorska-Mol et al. (2016) found that ceftiofur, doxycycline, and tiamulin decreased, while amoxicillin and tulathromycin increased, humoral immune response to *Erysipelothrix rhusiopathiae* vaccination. Treatment at the time of vaccination for influenza A virus (IAV) of swine and pseudorabies virus (PRV) affected the immune response of pigs (Pomorska-Mol et al. 2015). Ceftiofur hydrochloride administered at the time of vaccination delayed the humoral response and affected the cellular response to PRV. Ceftiofur hydrochloride also significantly suppressed production of antibodies against IAV. The effect of disease treatment on subsequent immunity is relevant in production scenarios where reexposure or recrudescence of disease is possible, and it may be necessary to balance treatment efficacy with development of immunity. For example, when pigs were infected with *A. pleuropneumoniae* serotype 2 for a second time, pigs treated with enrofloxacin during the first infection had the least immunity and the worst clinical disease. At the time of the first infection, treatment with enrofloxacin resulted in the best clinical improvement compared with tetracycline and penicillin. However, there was insufficient exposure of the immune system to produce protective immunity, and clinical performance at reinfection was worst among the antibiotic treatment groups. Tetracycline reduced clinical impact at the first infection and allowed pigs to develop immunity that protected them at reinfection (Sjölund et al. 2009). In another study, enrofloxacin treatment before low dose exposure did not interfere with infection, development of immunity, or subsequent protection against challenge. Enrofloxacin treatment after low dose exposure did impair development of immunity, and pigs were susceptible to subsequent challenge (Macedo et al. 2017).

Assessing outcomes or treatment failure

Treatment failure has many causes. The antimicrobial selected may be inappropriate because of misdiagnosis, inactivity at the site of infection, failure to culture infections, inaccurate or inapplicable laboratory results, resistance of pathogens, chronic nature of the infection (which may affect metabolic state of the pathogen), or errors in sampling. These factors are more likely to cause failure than inadequate dosage although this may also be important. It is important that producers comply with dosing instructions. When failure occurs, diagnosis must be reassessed, and samples collected for laboratory analysis.

Non-antimicrobial therapeutics and strategies

Manipulating passive immunity

Spray-dried animal plasma has been widely used in diets for newly weaned pigs and is associated with increased growth rates on the order of 27% (van Dijk et al. 2001). The mode of action of spray-dried animal plasma is not fully understood but is assumed to be at least partly due to the presence of immunoglobulins, which may provide a certain level of protection to the newly weaned piglet at a time when the supply of immunoglobulins from sow's milk has ceased. The ability of plasma proteins to neutralize the effect of specific organisms is dependent on the immunizations and disease history of the pigs from which the blood is collected.

Specific antibodies from chicken egg yolk have been examined as a source of passive immunity for newly weaned pigs as well. Laying hens are vaccinated against specific pig pathogens such as *E. coli*. Antibodies are secreted into the yolk of the egg (IgY) in large quantities (up to 200 mg/egg) (Marquardt and Li 2001), and dried yolk is incorporated in nursery pig rations. Trials using specific egg-yolk products to prevent post weaning *E. coli* diarrhea have produced inconsistent results (Chernysheva et al. 2004). Stability of the product during feed processing and passage through the pig's gastrointestinal system are major concerns.

Direct-fed microbials (probiotic)

Probiotics are defined as live microbials provided in the feed in an attempt to encourage proliferation in the intestine of the specific microorganism fed with the objective of providing health benefits to the host animals (Fuller 1989). The most commonly used probiotics include species of *Lactobacillus*, *Enterococcus*, *Bifidobacterium*, and *Saccharomyces* (Alvarez-Olmos and Oberhelman 2001; Holzapfel et al. 2001; Rolfe 2000). Most studies involving probiotics have concentrated on improving intestinal health, particularly during the weaning period when the pig gut microflora undergoes dramatic change.

It is generally accepted that with careful attention to the criteria used to select the probiotic strain, there may be a place for probiotics in the prevention of enteric disease, but results to date are inconsistent. There are several criteria that potential probiotic strains must meet in order to be considered for use as a probiotic, including the ability to demonstrate predictable and measurable health benefits. The screening and selection of a probiotic includes testing *in vitro* or *in vivo* of the following criteria:

It must be nonpathogenic and proven safe.
It must have stability in an acid environment, in the presence of bile, and resistance to degradation by digestive enzymes.
It must adhere to gut epithelial tissue and be able to persist in the gastrointestinal tract of the host.

In addition, the microbials used as probiotics must retain viability and stability during commercial production, feed processing, storage, and delivery and must be cost effective.

The main mechanisms whereby probiotics exert protective or therapeutic effects are not fully understood, but several ways have been postulated. Probiotics produce antimicrobial substances such as organic acids, free fatty acids, ammonia, hydrogen peroxide, and bacteriocins (Alvarez-Olmos and Oberhelman 2001). In addition, probiotics may enhance specific and nonspecific host immunity (Kailasapathy and Chin 2000), and probiotics may prevent colonization of pathogenic microorganisms by competitive inhibition for microbial adhesion sites.

Inconsistent findings have been observed when probiotics have been used in trials to control pig disease or improve growth performance (Conway 1999). It is unlikely they can replace antibiotics in the control of disease, but they may have a place alongside other techniques for improving the health of the gut microflora and reducing the shedding of pathogens such as *Salmonella*.

There is considerable interest in the use of fermented liquid feed, and there appears to be an association between its use and a reduction in *Salmonella* prevalence (van der Wolf et al. 2001). A possible explanation for the beneficial effect of fermented liquid feed is that the reduced pH of the diet and the presence of large numbers of organic acid-producing bacteria in the feed have a positive effect on the gut microflora and create an environment unsuitable for *Salmonella* and other coliform bacteria.

Bacteriophages

Bacteriophages or phages are bacterial viruses that invade bacterial cells and, in the case of lytic phages, disrupt bacterial metabolism and cause the bacterium to lyse (Sulakvelidze et al. 2001). From a clinical standpoint, phages appear to be innocuous to host animals, do not attack normal gut flora, and are extremely common in the environment. Recently, naturally occurring phages with activity against *Salmonella* species and *E. coli* were isolated from swine feces, and this may facilitate the development of a direct application to enhance food safety (Callaway et al. 2011). Phages appear to be specific to bacterial species or serovars. Albino et al. (2014) isolated specific autochthonous bacteriophages that were active against four *Salmonella typhimurium* serotypes (Abony, Enteritidis, Typhi, and Typhimurium but not Arizonae, Choleraesuis, Gallinarum, and Pullorum), reduced bacterial counts *in vitro*, and reduced prevalence of positive fecal samples among inoculated pigs.

Nutrients

There is a plentiful supply of physiologically active feed ingredients that can improve pig performance and health by modifying the environment of the digestive tract (Pettigrew 2003). Zinc oxide added to nursery rations at a level of 2500 ppm for 2 weeks will result in increased growth rate and reduced prevalence of diarrhea (Jensen-Waern et al. 1998). *In vitro* studies have shown that zinc has antimicrobial effects, but *in vivo* studies show no reduction in *E. coli* numbers and no change in the function of circulating neutrophils. There are concerns that high levels of zinc oxide will cause liver toxicity if fed longer than 3–4 weeks.

Likewise, copper sulfate at levels of up to 250 ppm has been added to pig feed to promote growth. However, the combination of zinc and copper does not result in an additive growth response (Hill et al. 2000). In the case of both copper and zinc, there are environmental concerns regarding their use because of the accumulations of these minerals in manure. The development of resistance is not specific to antimicrobials, and a transferrable copper resistance gene has been demonstrated in the fecal enterococci of swine in the United States.

The quest for alternatives to antibiotics in pig feed has caused interest in natural remedies, including herbs, spices, botanicals, and essential oils. These products may improve performance by improving feed palatability and by exerting antibacterial effects, but there needs to be further evidence of their effectiveness (Pettigrew 2003).

Organic acids (fumaric, formic, and lactic) are commonly added to feed or water to improve growth and reduce diarrhea during the post weaning period (Tsiloyiannis et al. 2001). Modes of action claimed for the growth-promoting effect of organic acids include decreased gastric pH, reduced coliform population, stimulated pancreatic exocrine secretion, increased pepsin activation, altered gut morphology, and improved intake and digestibility (Partanen 2001).

Response to acidification has been variable and may be attributed to feed and animal factors as well as differences in the properties of the various organic acids. Two problems that are associated with the use of high levels of organic acids are that the acids may have a negative effect on palatability and the feed is corrosive to cement and steel in swine housing (Canibe et al. 2001).

An alternative approach to altering the gut microflora is to feed nondigestible material that provides a substrate for beneficial bacteria such as lactic acid-producing bacteria. These products are often referred to as prebiotics. For a feed to be classified as a prebiotic, it must be neither hydrolyzed nor absorbed in the upper part of the gastrointestinal tract, must be a selective substrate for one or a limited number of potentially beneficial commensal bacteria, and must induce luminal or systemic effects that are beneficial to the host's health (Roberfroid 2001). Nondigestible oligosaccharides are the most common type of prebiotics, including fructo-oligosaccharides and mannan-oligosaccharides. In general, prebiotics are considered to provide small but positive improvements in growth rate. However, their role in providing health benefits, such as reducing *Salmonella* shedding, needs to be clarified.

Enzymes added to feed to encourage improved feed efficiency and, in some cases, potential health benefits are used widely. For example, feed can be supplemented with phytase to allow swine to digest plant phosphorus that is in the form of phytate. It has been hypothesized that the use of enzymes may allow the industry to utilize coarse feed particle size as a means of reducing both gastric ulcers and the prevalence of *Salmonella* while still maintaining acceptable feed conversion. There is a possibility that in-feed antimicrobials for growth promotion could be reduced through a combination of feeding manipulations, such as the use of various combinations of liquid feeds or coarse particle size, enzymes, probiotics, prebiotics, and acidifiers.

Antiparasitics

In modern confinement operations, there are few parasitic problems (Roepstorff and Jorsal 1989). Under conditions of good hygiene and management, the regular application of anthelmintics may be of little or no benefit (Roepstorff 1997). Ascariasis is generally the main concern, and strategic medication with a wide range of effective products can easily control this parasite.

External parasitism caused by mange mites and lice no longer needs to be a significant problem because of good husbandry practices and effective drugs, particularly the avermectins. Failure to control sarcoptic mange or lice infestation is generally due to a poor understanding of the epidemiology of the organisms and apathy on the part of the herdsman (Cargill et al. 1997). Antiparasitic products and their application are presented in Table 10.5.

Hormones

Oxytocin is widely used as an aid in stimulating parturition and milk letdown. Prostaglandin F_{2a} or a synthetic analogue can be used to induce parturition. Puberty can be induced in gilts by treatment with a single injection of 200 IU of human chorionic gonadotropin and 400 IU of

Table 10.5 Common swine anthelmintics and doses.

Product	Dosage
Dichlorvos	11.2–21.6 mg/kg body weight in feed with 1/3 of regular ration
Doramectin	300 µg/kg body weight IM
Fenbendazole	9 mg/kg body weight over 3–12 days via feed
Fenbendazole oral solution	2.2 mg/kg body weight for 3 days via drinking water
Ivermectin	300 µg/kg SQ or 100 µg/kg body weight for 7 days via feed
Levamisole hydrochloride liquid	8 mg/kg body weight in drinking water
Piperazine	275–440 mg/kg body weight in feed or water
Pyrantel tartrate	22 mg/kg of body weight as 1-day treatment or 96 g/t of feed as prophylactic dose

equine chorionic gonadotropin. The injection of follicle-stimulating hormone at weaning and an injection of luteinizing hormone approximately 72–80 hours later have been shown to induce a predictable ovulation (Barnabe et al. 2002) and can be used in artificial insemination programs where these hormones are licensed for this purpose. Estrus can be synchronized by administering a progestin for 14–18 days. The progestin inhibits follicular maturation until the progestin is withdrawn. Be aware that many of these represent extra-label uses that might be prohibited in some countries including the United States.

Triptorelin, a gonadotropin-releasing hormone (GnRH) agonist, applied as an intravaginal gel has been shown to be effective in advancing and synchronizing ovulation in weaned sows. While wean-to-estrus interval was not impacted, wean-to-ovulation interval was reduced in treated animals, and more sows ovulated 40 hours after treatment than controls (Knox et al. 2014). Further details are presented in Chapter 20.

Hormones are also used in certain countries for growth manipulation. Daily injection of porcine somatotropin (PST) strongly influences feed efficiency, growth, and carcass composition. Ractopamine, a phenethanolamine or β-agonist, is used as a feed additive in several countries. Its function is as a repartitioning agent causing improved feed efficiency and a lean carcass at slaughter.

Anti-inflammatory drugs

Anti-inflammatory drugs including ketoprofen, flunixin meglumine, dexamethasone, sodium salicylate, acetylsalicylic acid, indomethacin, and meloxicam have been evaluated in pigs as interventions for various clinical conditions with variable results that mostly suggest more investigation is needed. Meloxicam (Georgoulakis et al. 2006) was demonstrated to reduce the prevalence of clinical signs and the need for re-treatment in pigs with respiratory disease when used as an adjunct to antimicrobial treatment. Additionally, flunixin has an approved label indication for control of pyrexia associated with swine respiratory disease. Currently, there are two limitations to the use of most NSAIDs in swine: (1) pharmacodynamic information to inform selection of an effective dose, especially for analgesia, is lacking and (2) pharmacokinetic information in swine on the disposition of many formulations. A review of the pharmacokinetic information available for NSAIDs in swine indicates that elimination half-lives are generally very short, ranging from 0.19 (meloxicam) to 7.76 (flunixin meglumine) hours (Karriker 2014). A concern about the potential for NSAIDs to cause enteric lesions at higher doses coupled with a short half-life means that multiple doses per day may be necessary for pain relief.

Anesthesia and Surgical Procedures in Swine

David E. Anderson and Pierre Yves Mulon

Best practices for surgical procedures increasingly conflict with economic goals. The veterinarian must critically evaluate the economic benefit versus cost and prognosis of surgery. In most scenarios, services offered by the veterinarian are directed to the need of the enterprise. Surgery on an individual pig is not always cost efficient. However, pigs selected for genetic improvement, show pigs, pet pigs, etc. have individual value, and surgery may be performed with little regard to costs. Some spontaneous conditions such as inguinal and umbilical hernias, rectal prolapse, dystocia, and rectal stricture that can occur in large numbers of animals can be very costly and need to be investigated so that treatment and prevention solutions can be applied. In a commercial swine operation, the veterinarian is often a teacher, showing the manager and experienced personnel how to perform some minor surgical procedures during baby pig processing (castration, ear notching, teeth clipping, tail amputation) in a cost-effective fashion. It is the veterinarian's role to make sure that these procedures are done properly and humanely.

Among purebred pigs, pet pigs, or pigs used as animal models in biomedical research, the individual animal may be of high value, and surgery under conditions of idealized anesthesia and analgesia may be required. A veterinarian who is able to offer excellent surgical service to swine producers may have greater credibility as a herd consultant. The purpose of this chapter is to describe clinical swine anesthesia, routine surgical procedures done during baby pig processing, hernia repair, and some common surgical procedures of the digestive, urogenital, and musculoskeletal systems in swine.

Anesthesia

Minor surgical procedures (ear notching, teeth clipping, tail amputation, castration) in young swine often are performed without anesthetizing the animal. Performed skillfully, these surgical procedures are tolerated by young pigs without an anesthetic; however a recent study demonstrated that weight gain was greater at 3 and 6 days post surgery in piglets receiving local anesthesia prior to castration compared with non-anesthetized ones (Sturlini-Barticciotto et al. 2016). Sometimes economics has an influence on the use of an anesthetic. However, public scrutiny of management practices increasingly demands attention to pain and prevention of unnecessary distress. Management of swine anesthesia presents some difficulties. Swine resist mechanical restraint more and are usually more difficult to hold than other species. Strong assistance often is needed. When possible, adult swine should be withheld from all feed for 1–24 hours before general anesthesia, whereas piglets, which are prone to hypoglycemia, should be held from suckling for only 1–2 hours before anesthetic induction.

Readers are reminded that there are no FDA-approved drugs labeled for use in swine for the treatment of pain or for local or general anesthesia in the United States. The regulatory management of anesthesia drugs in pigs is specific to country and regions and beyond the scope of this chapter. The reader is encouraged to seek out knowledge of regulations for their jurisdiction and prioritize protection of the food chain.

Malignant hyperthermia or porcine stress syndrome is a heritable condition in swine that can be triggered in a susceptible pig by any stress and many injectable (acepromazine, ketamine, and succinylcholine) and inhalant anesthetics. Susceptible pigs are extremely muscular and usually have reduced subcutaneous fat. Halothane traditionally has been incriminated, but delayed onset of malignant hyperthermia can occur with exposure to isoflurane (Wedel et al. 1993). The clinical signs of malignant hyperthermia can be any of the following: a severe increase in body temperature, muscle rigidity, tachycardia, tachypnea, hypoxemia, cardiac arrhythmias, unstable blood pressure, and myoglobinuria. Death of an affected animal appears to be the result of peripheral

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

circulatory changes that are produced by severe acidosis, vasoconstriction, hyperkalemia, decreased cardiac output, and hypotension. The susceptibility to malignant hyperthermia is due to an autosomal recessive defect in the gene that codes for ryanodine receptor calcium channels in skeletal muscle (Rosenberg and Fletcher 1994). In response to a trigger, intracellular calcium rises abruptly, which causes muscle contracture and release of heat. Treatment of malignant hyperthermia is largely symptomatic. Early recognition is the key to successful treatment. Whenever malignant hyperthermia is suspected, volatile anesthetics should be discontinued. Aggressive cooling should be instituted using ice packs and alcohol baths. Dantrolene sodium is effective in the treatment of a malignant hyperthermia or as a prophylaxis when given before the anticipated trigger. Suggested doses for swine are 1–3 mg/kg IV for treatment and 5 mg/kg orally given prophylactically.

Anticholinergics (atropine and glycopyrrolate) are recommended before sedation and anesthetic techniques in pigs. Atropine sulfate (0.04 mg/kg IM) or glycopyrrolate (0.02 mg/kg IM) will decrease the risk of bradycardia, excessive salivation, bronchoconstriction, and excessive airway secretion. In healthy swine receiving light surgical anesthesia, administration of supportive fluids is not considered necessary, unless the animal was off feed and water for more than 24 hours.

Intravenous catheterization and support treatment

Long periods of general anesthesia are best managed with intravenous fluid support. In swine that are hypovolemic or showing other signs of shock, fluid therapy is essential preferably before or during anesthesia. Pigs have few superficial veins and arteries suitable for catheter placement and intravenous drug administration (Sakaguchi et al. 1996). In addition, variation in accessibility of these vessels exists among swine breeds. The auricular (ear) vein is the safest and most accessible vein (Figure 11.1). This vein is most easily catheterized along the caudal aspect of the dorsal surface of the ear. To inject or place a catheter in the ear vein, the pig can be restrained. The vein is held at the base of the ear by the fingers, forceps, or a rubber band to distend it. Rubbing the ear with alcohol and vigorous massage seem to create better visualization for needle insertion. Inserting a small catheter (20 gauge) will allow the administration of fluid or injection of additional anesthetic solution intravenously. The medial saphenous vein can be catheterized easily in the anesthetized or well-restrained pig (Figure 11.2). In pigs requiring maintenance of the catheter for intravenous therapy, the cranial superficial epigastric vein is, in our experience, the most easily managed (Figure 11.3).

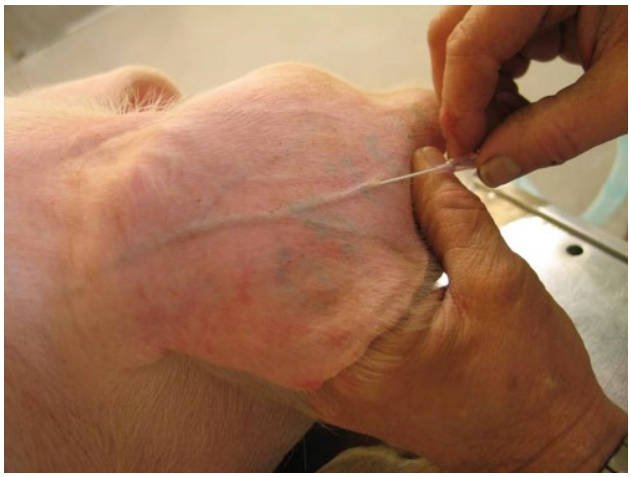

Figure 11.1 Intravenous catheterization of the ear vein (auricular vein) of a pig.

Figure 11.2 Intravenous catheterization of the medial saphenous vein in a pig.

Figure 11.3 Placement of an IV catheter in the caudal superficial epigastric vein of a pig using a "cutdown" method for placement.

Alternatively, intramedullary cannulation should be considered when vascular access is vital, but an IV catheter has not been established. An 18 gauge cannula can easily be inserted into the greater tubercle of the humerus or via the trochanteric fossa of the femur for intramedullary infusions. Fluid and drug administration is easily done in immature pigs. Older pigs usually have fat and fibrosis of the medullary canal to limit administration rate.

In the authors' experience, fluid therapy using balanced electrolyte solution before and during anesthesia is essential during Cesarean section with dead piglets *in utero*. Pigs have a diffuse epitheliochorial placenta. Sow–fetal drug distribution is quite complete. Therefore, it must be assumed that any drug in the maternal circulation reaches the fetus rapidly in relatively high concentration. Because the fetal blood–brain barrier is extremely permeable, these drugs exert a profound anesthetic effect on the fetus. In addition, anesthesia tends to persist after delivery because of the neonate's poorly developed liver enzymes and renal function. Anesthetic agents should be chosen that would minimize fetal depression. General anesthesia will induce greater neonatal depression than regional anesthesia.

Tranquilization and sedation

Acepromazine

Acepromazine decreases spontaneous motor activity. Used alone, it usually provides only slight inconsistent sedation in swine. It predisposes to hypotension and hypothermia and should not be used in debilitated pigs. Recommended dose is 0.1–0.2 mg/kg (Table 11.1). Acepromazine has been reported to decrease the incidence of malignant hyperthermia (Moon and Smith 1996). It is useful when combined with ketamine or tiletamine–zolazepam (Table 11.2).

Benzodiazepines (diazepam and midazolam)

Diazepam (1–2 mg/kg IM; Table 11.1) can be used in combination with ketamine or xylazine (Table 11.2). Midazolam can be absorbed more rapidly and completely than diazepam because it is water soluble. A dose of 0.5 mg/kg IM of midazolam has been associated with a sufficient level of sedation with minimal alteration of the cardiovascular functions (Bustamante and Valverde 1997). They both ensure a smooth recovery and have a longer effect than xylazine. Association with alfaxalone at 5 mg/kg IM can be used to increase the muscle relaxation and sedation levels.

Intranasal administration of 0.2 mg/kg of midazolam produced a significant and reliable sedation with an onset of 3–4 minutes (Lacoste et al. 2000).

Azaperone

Azaperone is a neuroleptic agent and can be given to tranquilize or immobilize swine (Table 11.1). The degree of sedation is dose dependent and should not exceed 1 mg/kg in large boars, because priapism has been reported (Moon and Smith 1996). Azaperone must be given intramuscularly, because intravenous injection often results in excitation. Excessive salivation, hypothermia, sensitivity to noise, and hypotension have been seen in pigs receiving azaperone (Greene 1979). Azaperone is not an analgesic and often is used in combination with other drugs for surgical procedure. Deep tranquilization from azaperone should be obtained before ketamine is given. If azaperone is used alone for surgical procedures, local or regional anesthesia should be administered.

Alpha-2 receptor agonists

Swine are more resistant to alpha-2 agonists (xylazine, dexmedetomidine) compared with other meat-producing animals (Table 11.1). Sedation will result, but animals are aroused easily. Xylazine usually is used in combination with other drugs to produce good muscle relaxation and a smooth recovery. Vomiting has been seen following the use of xylazine in pigs with digestive disturbances. Medetomidine is a more potent alpha-2 agonist than xylazine (Sakaguchi et al. 1992). Medetomidine in

Table 11.1 Sedative agents for swine.

Drug	Dose	Route	Onset (min)	Duration (min)
Acepromazine	0.1–0.5 mg/kg	IM	20–30	30–60
Azaperone	1–2 mg/kg	IM	5–15	60–120
Diazepam	0.5–1 mg/kg	IM	—	—
Midazolam	0.1–0.5 mg/kg	IM	2–4	40–60
Xylazine	0.5–3 mg/kg	IM	5	10
Medetomidine	10 µg/kg	IM	—	—

Table 11.2 Combination of injectable anesthetic agents for short-term anesthesia in swine.

Drug	Dose	Route	Onset (min)	Duration (min)
Thiopental	10–20 mg/kg	IV	Immediate	2–10
Acepromazine Ketamine	0.4 mg/kg 15 mg/kg	IM IM	5 min	15–30
Acepromazine Ketamine Telazol	0.03 mg/kg 2.2 mg/kg 4.4 mg/kg	IM	2–4	40–50
Diazepam Ketamine	1–2 mg/kg 10–15 mg/kg	IM IM	10	20–40
Midazolam Ketamine	0.1–0.5 mg/kg 10–15 mg/kg	IM	5–10	20–40
Azaperone	2–8 mg/kg	IM	5–15	60–120
Xylazine	0.5–3 mg/kg	IM	5	10
Xylazine Ketamine	2 mg/kg 20 mg/kg	IM	7–10	20–40
Xylazine Ketamine Tramadol	2.5 mg/kg 25 mg/kg 5 mg/kg	IM	7–10	30–60
Xylazine Ketamine Telazol	4.4 mg/kg 2.2 mg/kg 4.4 mg/kg	IM	1–2	60
Xylazine Ketamine Midazolam	2 mg/kg 20 mg/kg 0.25 mg/kg	IM	5–10	70–100
Medetomidine Butorphanol Ketamine	80 µg/kg 200 µg/kg 2 mg/kg	IM	1–5	60–120
Medetomidine Butorphanol Ketamine	80 µg/kg 200 µg/kg 10 mg/kg	IM	1–5	75–120
Xylazine Butorphanol Ketamine	2 mg/kg 200 µg/kg 10 mg/kg	IM	1–5	60–120
Propofol Fentanyl	11 mg/kg/h 2.5 mg/kg q30 min	IV IV	Immediate	Continuous infusion

combination with atropine induces deeper sedation than xylazine, and its effects are enhanced by butorphanol. The anesthetic state is characterized by profound somatic analgesia, but visceral analgesia is poor. Combination of medetomidine, butorphanol, and ketamine induces excellent surgical anesthesia in pigs (Table 11.2). This anesthetic regimen can be partially reversed by atipamezole (240 µg/kg), a selective and potent alpha-2 antagonist.

Injectable anesthetics

Injectable agents are most appropriate for field use. With injectable agents, a minimum of equipment is needed, requiring only a small investment. The drugs can be transported easily to the animal, compared with inhalation anesthetics, which are more expensive and can be difficult to transport to a field situation.

Anesthesia can also be induced using IM drug protocols or gas anesthetics via facemask followed by catheterization for IV fluid therapy or drug administration. Intramuscular injections should be given with a 2 in. needle in the cervical muscles of an adult commercial pig to assure that the drug goes into the muscle and not in the fat. To obtain the maximal effect with the drug, the pig should be in a quiet environment if possible. Combinations of anesthetic agents administered in appropriate doses are often superior to any one agent (Table 11.2).

Barbiturates

Barbiturates as a group are poor analgesics. Thiopental is the most commonly used barbiturate. It is a potent central nervous system depressant and should be administered intravenously. The shorter-acting barbiturate thiopental (10–20 mg/kg) is used sometimes for induction before inhalation anesthesia or for very short procedures. A 2.5–5% solution should be used, and one-half of the calculated dose quickly injected. When the pig lies down, incremental amounts are injected until the desired plane of anesthesia is achieved. Apnea often is observed, and means of assisting ventilation should be readily available.

Ketamine

Ketamine induces rapid onset of unconsciousness (Thurmon 1986). The anesthetic state is characterized by somatic analgesia, but visceral analgesia is poor. Ketamine has been used as a major component of many regimens to induce chemical restraint or anesthesia in pigs. It can be given IM, IV, or intratesticularly. Intratesticularly, a combination of ketamine (6 mg/kg) and xylazine (2 mg/kg) has been used successfully for castration (Thurmon 1986). When ketamine is used alone, it exerts some undesirable effects, such as poor muscle relaxation and analgesia emergence delirium, tachycardia, and hypertension. It commonly is combined with a muscle relaxant or sedative such as acepromazine, diazepam, xylazine, or droperidol (Table 11.2).

Propofol

This short-acting hypnotic agent has recently been used for IV anesthesia in pigs (Martin-Cancho et al. 2004). One dosage regimen reported was 11 mg/kg body weight (BW)/h for abdominal surgery. This was done in combination with fentanyl (2.5 mg/kg IV q30min). Compared with pigs anesthetized with isoflurane, propofol-anesthetized pigs required significantly longer to recover consciousness.

Guaifenesin

Guaifenesin is a centrally acting muscle relaxant. Because it produces little analgesia, it should not be used alone. Intravenous infusion of guaifenesin combined with thiobarbiturates and with ketamine and xylazine has been used for induction and maintenance of anesthesia (Thurmon 1986). The authors recommend adding 500 mg of ketamine and 500 mg of xylazine to each 500 mL of 5% guaifenesin in 5% dextrose in water. The mixture is given rapidly in a catheter in the ear vein at a dose of 0.5–1 mL/kg for induction. Anesthesia is maintained by continuous infusion at a rate of 2.2 mg/kg/h of ketamine, which also equals 2.2 mL per kg per hour of the triple-drip mixture. At the end of the surgery, recovery time may be hastened by administration of yohimbine (0.125 mg/kg) or tolazoline (2.5–5 mg/kg) to reverse the effect of xylazine (Thurmon 1986)

Combination injectable anesthesia

Combinations of injectable drugs have been used to increase quality, duration, and analgesia of anesthesia when they can be administered safely. A recent study compared three regimens for maintaining anesthesia in pigs induced using azaperone (1 mg/kg IM) and ketamine (2.5 mg/kg IM). These pigs were divided into three groups: (1) etomidate (200 µg/kg IV) and midazolam (100 µg/kg IV), (2) ketamine (2 mg/kg IV) and midazolam (100 µg/kg IV), and (3) pentobarbital (15–20 mg/kg IV) (Clutton et al. 1997). Pentobarbitone provided the least satisfactory anesthesia because of profound respiratory depression, difficulty completing orotracheal intubation, and prolonged time to standing. Another study compared medetomidine–butorphanol–ketamine (MBK) (80–200 µg/kg–10 mg/kg, respectively, all IM) with xylazine–butorphanol–ketamine (XBK) (2 mg/kg–200 µg/kg–10 mg/kg, respectively, all IM) (Sakaguchi et al. 1996). MBK was found to provide longer and more satisfactory anesthesia as compared with XBK.

Telazol is a unique combination of a dissociative molecule (tiletamine) and a benzodiazepine (zolazepam) that provides some muscle relaxation and sedation and immobilizes swine (Moon and Smith 1996). It requires a smaller volume of injectable compared with ketamine. It frequently is combined with a third sedative such as xylazine or acepromazine to provide better muscle relaxation and an easier recovery (Table 11.2).

Reversal agents

On occasion, reversal of anesthesia may be necessary. Yohimbine is an alpha-receptor antagonist that is commonly used to reverse the effects of xylazine. However, the selective nature of this drug in the reversal of alpha-agonists can be difficult to apply when combination anesthesia has been employed. In a study on the effectiveness of yohimbine to speed recovery of pigs anesthetized using tiletamine + zolazepam + xylazine, pigs were shown to recover more quickly when yohimbine was administered (Kim et al. 2007). In that study, pigs were given a combination of either xylazine + zolazepam or xylazine + tiletamine. Pigs attained sternal recumbency in significantly less time (52 minutes) when yohimbine was administered compared with pigs that did not receive yohimbine (76 minutes). Opioid toxicity (fentanyl patch) can be observed.

Inhalation anesthetics

For debilitated swine, for surgical procedures lasting more than 30 minutes, for difficult procedures, or for valuable swine, an inhalation anesthetic provides a more controlled plane of anesthesia. Inhalation anesthetics can be administered to small pigs by an open or semi-open method; in larger swine, the semi-closed or closed system is preferred. Swine weighing up to 140 kg can be anesthetized with an anesthetic machine designed for small animals (Tranquilli 1986).

Selection of induction technique and anesthetic protocol depends on the size and special needs of the swine, preference of the veterinarians, and availability of drugs and equipment. Sedation is desirable to reduce the stress of physical restraint before induction of anesthesia (Table 11.1). Swine up to 100 kg can be restrained in a webbed stanchion. Large swine can be restrained in a crate with a head catch or by a snare. Induction of anesthesia can be accomplished with a rapid bolus of injectable agent (barbiturate), by rapid infusions of a combination of drugs (Table 11.2), or by using a facemask delivering a high concentration of anesthetic agent (5% isoflurane) (Figure 11.4). Tracheal intubation assures a patent airway for delivery of anesthetic and protects the airway from aspiration pneumonia. In the authors' experience, facial, pharyngeal, and laryngeal anatomy of the pig makes endotracheal intubation more challenging than in other meat-producing species. It is often difficult to open the jaws wide enough for good laryngeal exposure, and the pig has a small narrow larynx that deviates ventrally, creating a sharp angle from the pharynx to the tracheal opening. Also laryngeal spasms occur frequently and are induced easily. Occurrence of spasms can be reduced by achieving a sufficient depth of anesthesia prior to intubation or by spraying the larynx with lidocaine.

Following induction, the pig should be placed in sternal recumbency, and the jaws should be held open with small rope. Orotracheal intubation has been shown to be significantly easier when pigs are in sternal recumbency as compared with dorsal recumbency (Theisen et al. 2009). Pigs in sternal recumbency were intubated by experienced personnel in a mean of 17 seconds as compared with 58 seconds for pigs in dorsal recumbency. The tongue is pulled forward by an assistant. A laryngoscope and blades of different lengths are needed. For adult swine, the blade length must be at least 25 cm. The blade of the laryngoscope is placed at the base of the tongue, and downward pressure is applied until an unobstructed view of the larynx is provided (Figure 11.5).

Endotracheal tubes should be available in sizes from 3 to 20 mm outside diameter and lengths of 25–50 cm. A malleable metal rod with the first 5 cm bent at a 30° angle is placed inside the endotracheal tube to act as a guide. With the laryngeal opening visualized, the endotracheal tube with the stylet extending slightly beyond the tip is placed into the laryngeal opening. The endotracheal tube is pushed over the tip of the stylet and with a twisting motion is passed through the larynx into the trachea. The tracheal diameter is surprisingly small in the pig. A 50 kg pig often requires only a 7–9 mm tube, and a 10–14 mm tube often is adequate for adult sows (Tranquilli 1986). In some cases, orotracheal intubation may not be possible. The authors have used facemasks as the sole means of administration of oxygen and gas anesthesia for various surgical procedures when tracheal intubation could not be achieved. This practice is not encouraged because of the inability to protect the airways

Figure 11.4 Facemask used for administration of oxygen, with or without inhalant gas anesthetic, during a Cesarean section in a sow.

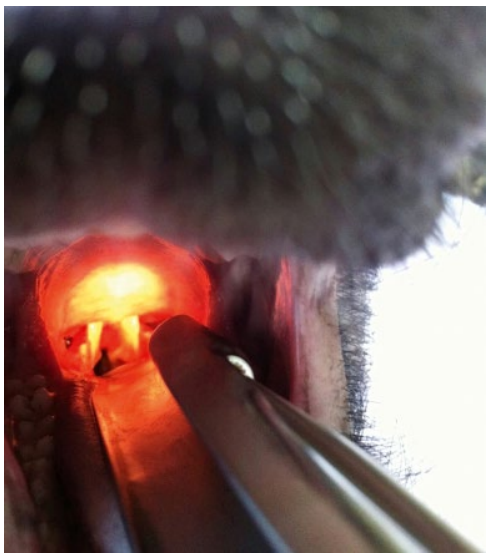

Figure 11.5 Use of a long blade laryngoscope to visualize the arytenoid cartilages during orotracheal intubation in a pig.

and the possibility of respiratory distress or obstruction if dorsal displacement of the soft palate occurs. However, facemask can be effective for short procedures (e.g. <60 minutes).

Safe maintenance of inhalation anesthesia requires knowledge of the signs associated with anesthetic depth and continual monitoring of the patient and anesthetic equipment. Routinely monitored signs should include pulse quality and rate, respiratory rate, color of mucous membranes, capillary refill time, blood pressure, and electrocardiogram. The body temperature should be evaluated regularly, and appropriate padding should be placed. The pulse can be palpated over the median auricular artery. Direct auscultation of the heart also should be done. The normal heart rate in swine ranges from 60 to 90 beats per minute and may vary greatly during inhalation anesthesia. During recovery from inhalation anesthesia, frequent and careful monitoring is necessary, because life-threatening complications can occur (Moon and Smith 1996). Recovery should be in a quiet place, and the pig should be placed in sternal recumbency as soon as possible. The endotracheal tube should be maintained until the pig is spontaneously moving its head or will not tolerate the tube. The pig should not be returned to the herd until it is fully awake.

Recently CO_2 anesthesia has been proposed as a tool to provide sufficient surgical anesthesia depth for castration in piglets aged less than a week. However this type of gas anesthesia did not inhibit all defensive movements in piglets undergoing surgical castration and should not be considered a sufficient tool for that aim (Langhoff et al. 2016).

Local anesthesia

The use of local anesthesia without additional chemical restraint is limited in swine. Pigs, even in the absence of pain, will resist physical restraint by continuing to struggle. In addition to chemical restraint, infiltration of 2% lidocaine around the surgical site will facilitate surgery involving the skin and superficial underlying tissues. Local infiltration of lidocaine is used commonly for surgical repair of umbilical and inguinal hernias and scirrhous cord removal.

Epidural regional anesthesia

Lumbosacral epidural anesthesia is the most commonly used form of regional analgesia in swine (Skarda 1996). Minimal equipment and expense are necessary to perform the procedure during epidural anesthesia. Compared with general anesthesia, the swine is in an awake state, so the risk of aspiration pneumonia is minimal. Local infiltration of lidocaine compared with epidural anesthesia has several disadvantages. Infiltration requires a larger amount of lidocaine and can retard wound healing and muscle relaxation, and analgesia is not as profound.

Lumbosacral epidural anesthesia is relatively easy to perform and greatly facilitates Cesarean section, repair of rectal, uterine or vaginal prolapses, repair of hernia, and surgery of the prepuce and penis or rear limbs (Skarda 1996). This should be avoided in patients that are in shock or toxemic because of sympathetic blockade and consequent depression of blood pressure (Skarda 1996). Also, general anesthesia may be more appropriate than regional anesthesia when the sow is very aggressive. Complications that may result from faulty techniques during lumbosacral epidural injection include cardiovascular and respiratory collapse after overdose or subarachnoid injection, meningitis associated with septic technique and tremor, and vomiting and convulsions after injection of the analgesic into the vertebral venous sinus.

The block can best be administered while the animal is standing and restrained with a hog snare, lariat, or head catch. Large hogs can be restrained by placing their heads in the head catch of a cattle chute. The site for injection for epidural anesthesia in the pig is the lumbosacral space. The conus medullaris of the cauda equina of the pig terminates in the region of the first or second sacral vertebra. The filum terminale terminates at the sixth or seventh coccygeal vertebra. Although the meninges extend beyond the lumbosacral articulation, there is only a very slight probability of entering the subarachnoid space. The lumbosacral space is on the midline and identified by drawing a line across the animal's back from tubes coxa to tuber coxa. This line will be just cranial to the point of the stifle joint (Skarda 1996). The line passes usually through the spinous process of the last lumbar vertebra. The injection site is usually 1–2 in. caudal to this transverse line. Clipping or shaving the hair, thoroughly scrubbing the site with a surgical soap, and applying a skin antiseptic prepare the site of injection. The location is infiltrated with a local anesthetic agent prior to needle insertion. A 6–8 cm 20 gauge needle is used for pigs up to 30 kg. A 10 cm 18 gauge needle is used for pigs between 35 and 90 kg, and a 12–16 cm gauge needle for pigs over 90 kg. The needle is inserted with the level directed cranially and at an angle of 10° caudal to perpendicular between the last lumbar and first sacral vertebrae. The needle penetrates the skin, backfat, muscle, and then the fibrous interarticular spinous ligament. The needle passes through a definite area of resistance as it encounters the ligament and a slight pop is felt as the needle passes into the epidural space and drops to the floor of the spinal canal. The lumbosacral space is large in the pig (1.5 × 2.5 cm) and allows for a relatively large margin of error (Skarda 1996). Aspiration should be attempted before injection of the anesthetic to ensure

that the subarachnoid space or a blood vessel has not been entered. Little resistance to injection will be encountered if the needle is located properly in the epidural space.

The anesthetic agent most commonly used is 2% lidocaine. The dose is calculated by either weight or length of the pig (Skarda 1996). Generally, a dose of 1 mL/9 kg of BW is adequate. Analgesia should be present within 10 minutes and last approximately 2 hours. A total dose of 20 mL must not be exceeded regardless of the weight. Four ml per 100 kg and 6 mL per 200 kg of BW are sufficient for standing castrations (Skarda 1996). Ten ml per 100 kg, 15 mL per 200 kg, and 20 mL per 300 kg have given satisfactory results for Cesarean section (Skarda 1996). If the pig is restrained in lateral recumbency, it is important that the head not be placed in extension. In swine with the head extended, the soft palate can occlude the airway, and the patient can suffocate (Benson 1986).

In 28–35 kg pigs, epidural injections of xylazine (2 mg/kg diluted in 5 mL of 0.9% NaCl solutions) at the lumbosacral intervertebral space induce immobilization, mild sedation, and regional anesthesia that extends from the anus to the umbilicus within 10 minutes and lasts at least 2 hours (Ko et al. 1992). The injection of a xylazine (1 mg/kg 10% solution) and lidocaine (10 mL, 2% solution) combination into the lumbosacral epidural space has produced excellent anesthesia for Cesarean in large sows (Ko et al. 1993). The forequarters in these sows were immobilized by IV injection of 0.003 mL of Telazol, mixture containing 50 mg of Telazol per mL, 50 mg of ketamine per mL, and 50 mg of xylazine per mL per kg of BW (Ko et al. 1993). In preparing the Telazol, ketamine, and xylazine combination, 2.5 mL of 10% ketamine (250 mg) and 2.5 mL of 10% xylazine (250 mg xylazine) were used as the diluent instead of sterile water. A mean of 3 mL of this combination was given per sow; the sows were quiet and immobilized for an average of 105 minutes (Ko et al. 1993). The sows were able to walk 12 hours after surgery, and the piglets were without signs of sedation or tranquilization. Intravenous tolazoline (2.2 mg/kg) partially reversed the Telazol-, ketamine-, and xylazine-induced sedation after surgery but did not antagonize the xylazine–lidocaine epidural effect (Ko et al. 1993). Epidural analgesia used in combination with general anesthesia allows a light plane of anesthesia with good muscle relaxation distal to the midthoracic region. Medetomidine (0.5 mg/kg diluted in 5 mL of 0.9% NaCl solution) injected epidurally in the lumbosacral space of swine produced sedation and decubitus but minimal analgesia caudal to the umbilicus. The onset of these effects occurred in 10 minutes, and they lasted for less than 30 minutes. Intravenous administration of atipamezole (0.2 mg/kg of BW) reversed epidurally administered detomidine-induced sedation and immobilization (Ko et al. 1992). Atipamezole had no effect on epidurally administered xylazine-induced sedation and immobilization (Ko et al. 1992).

Pain management

Nonsteroidal anti-inflammatory drugs

A recent study examined the effect of age on behavioral and physiological responses of piglets to tail docking and ear notching (Torrey et al. 2009). The authors found no age effect (1 day old vs. 3 days old) for suckling behavior, but piglets that had been processed had decreased passive transfer of immunoglobulin than sham-treated and control piglets. In a study of castration in 4- to 6-day-old piglets, local anesthesia was not found to be justified based on serum cortisol response (Zankl et al. 2007). A study examining the effect of nonsteroidal anti-inflammatory drugs found a beneficial effect in the use of meloxicam (Zöls et al. 2006). In that study, piglets were castrated between 4 and 6 days old. The piglets that received meloxicam before surgery had a markedly obtunded cortisol response similar to those that were control piglets. Another study examined the cortisol response in piglets (<7 days old) castrated with or without anesthesia and with or without the nonsteroidal anti-inflammatory drug meloxicam (Schulz et al. 2007). In that study, anesthesia was not found to have an effect on the cortisol response to castration, but piglets that received meloxicam did have significantly less cortisol response to being castrated. Thus, postoperative analgesia may be more beneficial than the use of transient anesthetics.

Administration of meloxicam to sows with the desire to use transmammary route of drug administration to the piglet via the milk recently has been demonstrated (Bates et al. 2014). Piglets had decreased blood cortisol and PGE2 concentration after piglet processing at 5 days of age.

Opioids

One study evaluated postoperative pain and compared transdermal fentanyl patches (25 and 50 µg/h) with buprenorphine (0.1 mg/kg, as needed) (Harvey-Clark et al. 2000). Assessment of analgesia was variable, but 50 µg/h transdermal patches placed on 26 kg pigs achieved blood concentrations similar to that considered to be in the analgesic range for humans.

Addition of butorphanol to meloxicam as a postoperative pain management for piglets undergoing tail docking and castration was associated with a lower plasma cortisol level than with meloxicam alone (Courboulay et al. 2014). Another study evaluated the use of isoflurane anesthetic gas for piglet castration at 14 days old

(Walker et al. 2004). In that study, piglets castrated under isoflurane gas had significantly fewer reactions to the surgical procedure, but stress hormone concentrations after castration were similar among groups.

Tramadol

Tramadol has recently been reported as a beneficial drug for combination anesthesia in pigs (Table 11.2). It is an analogue of codeine and has activity with opioid receptors. It acts as an agonist on μ-opioid receptors as well as stimulates the release of serotonin. As such, it is useful in mitigating moderate to severe pain. In combination with xylazine and ketamine in young piglets, tramadol increased the pain threshold of anesthetized piglets without having any adverse effects on duration of anesthesia or physiological parameters (Ajadi et al. 2009).

Mitigation of distress and/or pain will no doubt be a continued focal point for humane care of livestock. Research is required to provide objective assessment, maintain perspective without anthropomorphic bias, and establishment of meaningful guidelines. Nonsurgical methods of castration, such as immunization of boars against GnRH, may eliminate the necessity for surgical castration and thus eliminate many of these concerns (Thun et al. 2006).

Genitourinary surgery

Castration

Castration of male pigs is routinely performed with the intention to improve performance, feed conversion, and carcass traits (Kiley 1976). Also, management of castrated pigs through to finishing may be easier than for intact male pigs. With the onset of puberty, boar meat becomes tainted with an unpleasant odor and taste. However, recommendations for pig age at the time of castration are variable. Stress of castration was evaluated for pigs castrated at 1, 2, 4, 8, 16, and 24 days of age (White et al. 1995). This study indicated that pigs castrated after administration of lidocaine anesthetic subcutaneously and around the spermatic cords had lower heart rate and less vocalization than pigs castrated without local anesthesia. This effect was greatest for pigs castrated after 8 days old. Castration-associated behavioral changes were evaluated for pigs castrated at 1, 5, 10, 15, and 20 days old (McGlone et al. 1993). Castration caused reduced suckling, reduced standing, and increased lying time compared with intact male pigs at all ages. Pigs castrated at 14 days old were heavier at weaning and had a higher rate of gain compared with pigs castrated at 1 day old. Administration of aspirin or butorphanol failed to improve castration-associated reduction in feeding time and weight gain. Administration of lidocaine anesthesia prior to castration prevented castration-induced nursing behavior suppression (McGlone and Hellman 1988) in 2-week-old pigs. This effect was not observed for pigs castrated at 7 weeks old. Pigs castrated at 2 weeks old had less pronounced behavioral changes than pigs castrated at 7 weeks old. We recommend that baby pigs be castrated at 2 weeks old to minimize the stress of castration and maximize performance to weaning.

Castration of 14-day-old pigs is done by suspending the pig by the hind limbs while laying the pig across a smooth rail. The surgical site is wiped clean with alcohol or 2% tincture of iodine. If used, lidocaine anesthetic is injected subcutaneously (0.5 mL per site), overlying each testicle, and over each spermatic cord (0.5 mL per site) in the inguinal canal. A 1 cm long incision is made over each testicle, and the testicles are pulled from the scrotum. Hemorrhage is minimal at this age. Transfixation ligation of the spermatic cord is recommended for older pigs (see Castration of Older Pigs). Topical antiseptic ointment or spray may be applied at this time. Systemic antibiotics are usually not required, except when castrating older pigs. Castrated baby pigs are placed under a heat lamp in the farrowing crate for convalescence.

Castration of older pigs

Pigs are routinely castrated prior to or at 2 weeks old. However, veterinarians may be asked to castrate older pigs that are intended for show or mature boars that are no longer to be used for breeding. Castration of older pigs is best performed with the pig sedated or under general anesthesia (see ANESTHESIA section), but manual restraint and local anesthesia may be adequate for pigs weighing 50 kg or less (Becker 1986). The boar is restrained in lateral recumbency, and the surgical site aseptically prepared. A 4–6 cm incision is made overlying the testicle at the ventral aspect of the scrotum. The testicle should be removed with the vaginal tunic intact. Inguinal fat and soft tissue are stripped from the spermatic cord and evaluated for the presence of an inguinal hernia. The vaginal tunic and the spermatic cord are twisted until the cord is tightly compressed to the level of the external inguinal ring (Figure 11.6). Two transfixation ligatures (No. 1 chromic gut) are placed securing the vaginal tunic and spermatic cord to the medial aspect of the external inguinal ring. These sutures are intended to close the vaginal tunic and prevent the development of postoperative inguinal hernia. An emasculator may be used, but this method for orchiectomy does not result in closure of the vaginal tunic nor prevent inguinal hernia. Closure of the surgical wound should only be performed if asepsis has been maintained. Subcutaneous tissues may be sutured with No. 0 chromic gut in simple continuous pattern to reduce dead space and minimize

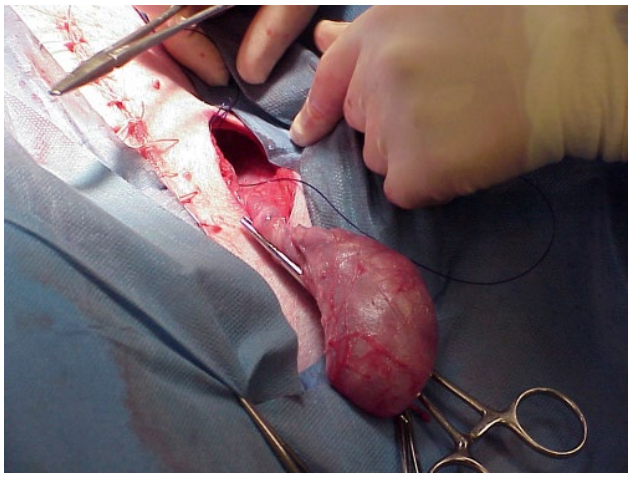

Figure 11.6 Inguinal castration using the twist technique to assist in closing the inguinal ring.

postoperative swelling. Skin sutures are placed in a Mayo (Ford) interlocking pattern. We prefer to administer antibiotics for 3 days, beginning the day of surgery, to reduce the incidence of postoperative infection. Also, the barrow should be kept in a clean, dry stall during this period.

Complications of castration

The most common complications following castration of pigs are hemorrhage, abscess, scirrhous cord, inguinal hernia, and seroma or hematoma formation. Fatal hemorrhagic shock has been reported after castration of 7-week-old pigs by a layperson (Libke 1967). The testicles had been pulled through a 10 cm incision and cut using a knife. Fatal hemorrhage occurred into the pelvic canal and abdomen; thus, the cause of death was not recognized until necropsy. This report emphasizes the need for routine necropsy examination of all deaths for which the cause is not apparent. Meat inspection of 131 pigs with post castration abscesses revealed that *Actinomyces pyogenes, alpha-hemolytic Streptococci, Streptococcus viridans, Staphylococcus aureus*, and *Pasteurella multocida* were the most common bacteria isolated (Százados 1985). Approximately 65% of the abscesses were monomicrobial, and 35% were polymicrobial infections. Evidence for bacteremia and septicemia was found in 28 and 11%, respectively. Of the 131 pigs inspected, 11% were judged to be unfit for human consumption. Bilateral hydronephrosis also has been reported as a complication of castration in a Hampshire pig castrated at 8 weeks old (McGavin and Schoneweis 1972). A ventral midline incision was used to remove both testicles, and tincture of iodine applied after castration. Infection of the soft tissues occurred, and the ensuing infection resulted in progressive occlusion of urethra at the level of the sigmoid flexure. Chronic resistance to urine outflow caused hydronephrosis, and the pig died 4 weeks after castration. This case illustrates the importance of adequate ventral drainage after castration.

Unilateral castration

Indications for removal of only one testicle include testicular trauma, hematoma, seroma, and orchitis or periorchitis (Becker 1986). The damaged testicle may cause enough swelling, heat, and pressure to reduce fertility. The boar is placed under general anesthesia, a 6 cm incision is made over the testicle starting at the most ventral aspect of the scrotum, and the testicle is removed by transfixation ligation and excision. The wound may be left open or closed. Strict asepsis and clean housing are required for closure of the wound to prevent abscess formation. We prefer to leave the wound open for second intention healing. Antiseptic ointment is placed in the defect, antibiotics are administered for 5–7 days, and daily hydrotherapy is used to minimize postoperative swelling. Affected boars may return to productive service 30–60 days after surgery.

Testicular abnormality (cryptorchidism, testicular atrophy, ectopic testicle)

Veterinarians may be presented with barrows demonstrating "boar-like" traits for removal of retained testicular tissues. The testicles of swine descend in the last 30 days of gestation and should be palpable at birth (Van Straaten et al. 1979). True cryptorchidism (testicle not descended at birth) is a common congenital defect in swine. A homozygous recessive trait involving two gene loci has been postulated based on a breeding trial of cryptorchid Duroc swine (Rothschild et al. 1988). Interestingly, the presence of cryptorchid piglets *in utero* has been associated with litter size and mortality (Dolf et al. 2008). In that study, litter size was found to increase with increasing number of cryptorchid piglets, and the number of stillborn piglets was greater in litters having a cryptorchid pig present. A progeny study of Lacombe and Yorkshire true cryptorchid boars resulted in 10.9 and 31.4 % of male progeny being cryptorchid (Fredeen and Newman 1968). Of boars with "late-onset" cryptorchidism (normal at birth but having only one testicle at 42 days old), 3.8% of male progeny were cryptorchid. Cryptorchid testicles are usually intra-abdominal and are usually found midway between the ipsilateral kidney and the inguinal ring (Thornton 1972). However, the affected testicle may be located within the inguinal canal and not readily palpable from either the inguinal region or the peritoneal cavity (Lachmayr 1966). Previous removal of the descended testis makes surgical removal of the retained testis more difficult because the incision is best made over the affected inguinal ring. Often,

determination of which testicle has been removed is difficult. Manual restraint and local anesthesia may be adequate for pigs less than 50 kg, but we prefer to perform cryptorchid surgery with the pig under general anesthesia. A 6 cm incision is made over the appropriate inguinal ring. Laparotomy may be performed by making a 4 cm incision 1–2 cm medial to the inguinal canal (parainguinal incision), or starting the incision at the cranial commissure of the external inguinal ring may enlarge the inguinal ring. The fingers of one hand are used to perform an exploration of the abdominal cavity starting at the pelvic brim and searching along the dorsal and lateral abdominal wall until the kidneys are encountered. For show pigs, we prefer to perform laparoscopic exploration and removal of abdominal testes because better cosmesis, fewer incisional complications, and more rapid incisional healing are achieved.

True cryptorchidism should be differentiated from testicular atrophy or degeneration ("late-onset" cryptorchidism) and ectopic testicular tissue. Pigs affected by testicular atrophy are reported to have palpably normal testicles at birth and weaning, but having only one testicle present at 42 days old (Fredeen and Newman 1968). Of 122 cryptorchids studied, 21 had "late-onset" cryptorchidism. At slaughter, only one testicle can be found, and, occasionally, a small mass of lymphoid tissue or epididymis is identified. Ectopic testicular tissue has been observed in numerous pigs at the time of slaughter (Todd et al. 1968). These tissues occur as smooth pink or tan nodules on the surface of the liver, spleen, mesentery, and other abdominal viscera. Initially, these masses may be interpreted as metastatic neoplasia, but histology reveals the presence of convoluted seminiferous tubules and interstitial cells. No evidence for neoplasia is seen. Ectopic testicular tissues may be found in castrated or intact male pigs.

Prolapsed penis

Penile and preputial prolapse has been seen after administration of neuroleptic drugs, but also may occur as a result of trauma to the penis or congenital defect. While prolapsed, the penis is at great risk of further injury. The penis and prepuce must be returned to their normal position as soon as possible after prolapse. Treatment of penile prolapse usually required that the boar be placed under general anesthesia. The penis is thoroughly cleaned with cold water, and a topical antiseptic ointment applied to the surface of the penis. If a penile wound is present, debridement may be done. Penile wounds typically are not sutured closed unless they have occurred recently (within 2–4 hours) because of the likelihood of formation of an abscess. The penis and prepuce are gently massaged until reduction into the sheath is completed. Use of hygroscopic agents (e.g. anhydrous glycerine) may help reduce the swelling by resolving edema. After the penis and prepuce have been repositioned, a purse-string suture may be used to prevent reoccurrence of the prolapse. The purse string should be removed in 5–7 days. If wounds or abrasions are present, daily preputial lavage or administration of systemic antibiotics and anti-inflammatory drugs is indicated. If wounds are not present, sexual rest should be enforced for at least 14 days. If wounds requiring treatment are present, sexual rest should be enforced for 30–60 days (depending on the severity of the wound). Reevaluation of the penile injury is advisable prior to use for mating.

Preputial diverticulum

Abnormalities of the preputial diverticulum may cause reproductive unsoundness. Preputial diverticulitis, diverticular ulcers, diverticular stones, urine retention, and penile deviation into the diverticulum may be found (Dutton et al. 1997; Tyler et al. 2000; Wieringa and Mouwen 1983). Preputial diverticulectomy may restore breeding soundness to affected boars. The boar is placed under general anesthesia and prepared for surgery. Any of three procedures for diverticulectomy may be performed: (1) Preputial diverticulectomy via the preputial orifice is done by passing forceps through the preputial orifice into one lobe of the bilobate diverticulum, gently everting the lobe out through the orifice, and repeating this procedure for the remaining lobe. After both lobes of the preputial diverticulum are everted, the diverticulum is excised. Suturing is not required for young boars, but the opening to the diverticulum may be sutured closed in adults. (2) A 6 cm incision is made overlying the lateral aspect of one lobe of the preputial diverticulum. The diverticulum is everted through the preputial orifice, excised, and sutured closed. (3) A 6 cm incision is made as above, but the diverticulum is dissected free from the surrounding soft tissues, excised, and sutured closed. For methods (2) and (3) above, extreme care must be taken not to perforate the diverticulum prior to removal because contamination will result in incisional infection. Flushing of the preputial diverticulum with antiseptic solutions before surgery is recommended to reduce this possibility. Also, filling the diverticulum with antiseptic solution or gauze pads before surgery makes identification of the diverticulum easier at the time of surgery.

Preputial prolapse

Prolapse of the prepuce may occur with penile prolapse or may result from preputial injury and swelling. If wounds to the prepuce are not present, the prepuce may be repositioned within the sheath, as described for penile prolapse, and a purse-string suture used to maintain

the reduction (Schoneweis 1971). Careful evaluation of the preputial swelling should be done to ensure that urination is possible. Preputial edema may be reduced by application of hygroscopic agents (anhydrous glycerine, saturated magnesium sulfate solution). A preputial retaining tube, constructed from rubber or polyurethane tubing, may be placed into the preputial space to prevent prolapse but allow exit of urine. Stay sutures are placed through the tubing and attached to the skin at the preputial orifice. Four sutures are placed 90° from each other suture to maintain the proper position of the tube. Alternatively, a 1.25 cm diameter Penrose drain may be sutured to the tip of the penis (No. 2-0 chromic gut suture) to ensure urine outflow. Often, the prolapsed prepuce has been traumatized, and surgical removal of the affected tissues is indicated. Preputial amputation may be performed, but the opening to the urethral diverticulum must be maintained. Alternatively, the preputial diverticulum may be removed at the time of surgery. The boar is placed under general anesthesia, the prepuce is pulled cranially until normal preputial epithelium is exposed, and stay sutures or crossed pins (7.6 cm 18 gauge needles) are placed through the exposed prepuce to prevent premature retraction into the sheath. The damaged tissues are amputated, and the two layers of the prepuce are sutured closed using an interrupted suture pattern (No. 2-0 chromic gut, PDS, or polyglycolic acid suture). After anastomosis, antiseptic ointment is placed on the prepuce, and it is replaced into the sheath. A purse-string suture is placed at the preputial orifice for 7–10 days, and sexual rest is enforced for 30–60 days. Systemic antibiotics should be administered perioperatively.

Vasectomy or epididymectomy

Vasectomy or epididymectomy is done to produce teaser boars used for heat detection in sows for artificial insemination or breeding to valuable boars or to promote onset of cyclicity in confined gilts (Becker 1986; Godke et al. 1979). For vasectomy, the boar is placed in dorsal recumbency under general anesthesia, and a 4 cm incision is made over each spermatic cord approximately 6 cm cranial to the ventral aspect of the scrotum. Each spermatic cord is elevated and incised, and the vas deferens is isolated. The vas deferens lies next to the spermatic artery and is firm and pale, and an arterial pulse is not present. A 3–4 cm segment of the vas deferens is excised, and each end is ligated. The incision through the tunic is sutured with No. 2-0 PDS or polyglycolic acid, and the skin is sutured with No. 0 polymerized caprolactam in a Mayo (Ford) interlocking suture pattern. An alternative technique for vasectomizing boars enables the surgery to be done with the boar in lateral recumbency (Althouse and Evans 1997a).

Epididymectomy may be done more quickly, more easily, and with similar results as vasectomy in boars (Althouse and Evans 1997b; Arkins et al. 1989). It is done by making a 2 cm incision in the scrotum overlying the tail of the epididymis. The tail and 1 cm of the body of the epididymis are isolated. Ligatures are placed between the testicle and the tail of the epididymis and around the exposed portion of the body of the epididymis. The epididymis is excised between these two ligatures. The skin is closed with No. 0 polymerized caprolactam in an interrupted pattern.

Persistent frenulum

The epithelial attachment of the penis and prepuce atrophies and these tissues separate between 4 and 6 months old in boars. Sexual maturity is achieved by 7–8 months old. Persistence of the frenulum attachment between the penis and prepuce beyond sexual maturity causes failure of breeding soundness and has been observed in boars (Roberts 1986). Surgical removal of the persistent frenulum is performed with the boar under general anesthesia or during a hand mating exercise. Resection of the tissue may be performed with scissors. Ligation is not required in most cases, and minimal bleeding is observed after excision. Sexual rest should be enforced from 7 to 10 days after surgery.

Vaginal prolapse

Vaginal prolapse can occur as a prepartum event but is uncommonly reported in pigs (Peek 1985). The cause of vaginal prolapse is unknown, but straining to urinate or defecate may be involved. Sows with lateral deviation of the bladder and difficulty urinating or with inflammation associated with cystitis and urethritis may develop vaginal prolapse because of straining. When the cause can be found, treatment should be aimed at resolving the initial lesion. The vagina is cleaned with cold water, hygroscopic agents (anhydrous glycerine, sugar, etc.) are applied, a towel is wrapped around the prolapsed portion, and constant gentle pressure is used to reduce the edema and swelling. The prolapse can usually be reduced in 15–20 minutes. The vagina should be cleansed, and topical antibiotic or antiseptic ointments are used to reduce the secondary bacterial vaginitis that invariably occurs. Administration of anti-inflammatory drugs may reduce straining and shorten convalescence. The bladder should be evaluated to ensure that it is in a normal position (see urinary bladder displacement). Often, partial rectal prolapse accompanies vaginal prolapse. The rectal prolapse should be treated appropriately (see rectal prolapse). A Buhner suture is placed around the vagina to prevent reoccurrence of the prolapse. The sow should be closely monitored, and the Buhner suture removed at the

first indication of farrowing. If excessive swelling of the soft tissues in the pelvic canal has occurred, a Cesarean section is indicated and should be performed early in the process of farrowing.

Bladder displacement (lateroflexed)

Displacement of the bladder occurs in multiparous sows in the latter stages of gestation (Greenwood 1989; Scott 1977). The bladder is displaced laterally and, occasionally, may become displaced caudally. When this occurs, urination is difficult. The displaced bladder may give the appearance of a vaginal prolapse when the sow is lying down. Affected sows may be seen straining because of the difficulty urinating, and this may lead to true vaginal prolapse. Decompression of the urinary bladder by cystocentesis or catheterization may allow permanent replacement of the bladder. When displacement recurs, an indwelling urinary catheter may be used to allow urination until after parturition. Ascending bacterial cystitis is a complication of the indwelling urinary catheter.

Urethral obstruction

Urethral obstruction has been observed in miniature pigs most commonly. Clinical signs include signs of abdominal pain, tail flagging, straining to urinate, blood in urine, decreased activity or restlessness, decreased appetite, and teeth grinding. Potential causes of urethral obstruction to be considered include urolithiasis, urethral polyps, and urethral stricture or trauma. Retrograde catheterization of the pelvic urethra and bladder is difficult because of the urethral recess and mucosal flap, which prevent passage of the catheter. Tube cystostomy with positive contrast urethrography was reported to be useful for diagnosis of obstruction of the distal urethra (Palmer et al. 1998). Urethral polyps were reported as a cause of urethral outflow obstruction in Vietnamese potbellied pigs (Helman et al. 1996). Surgical management of urethral outflow obstruction includes urethrotomy, cystotomy with normograde flushing, tube cystostomy, perineal urethrostomy, prepubic urethrostomy, and prepubic cystostomy. Prepubic cystostomy was successful in two Vietnamese pigs with urethral injury from castration or urethral stricture (Leon et al. 1997). In these two pigs, the pelvic urethra was exteriorized cranial to the brim of the pelvis with the urethra spatulated and the mucosa sutured to the skin. Both pigs maintained urinary continence. Urethroscopy with laser lithotripsy was used successfully in two potbellied pigs to alleviate urethral obstruction caused by uroliths (Halland et al. 2002).

Tube cystostomy procedure

Patients are placed in dorsal recumbency under general anesthesia. An 8–10 cm paramedian approach is made 4 cm lateral to the prepuce and extending from immediately caudal to the preputial orifice to 4 cm cranial to the brim of the pelvis. The bladder is exteriorized, and two stay sutures are placed near the apex. A cystotomy is performed near the apex, and suction and lavage is performed with saline used to evacuate urine and debris from the bladder. A gallstone scoop may be used to facilitate removal of stones if present. Particular attention is paid to suctioning the region of the trigone and urethral origin to remove debris, which may have migrated into the urethra during positioning for surgery. Normograde flushing is attempted to clear the urethra of debris. The cystotomy incision is then closed in two inverting layers using 0 or 2-0 absorbable monofilament suture materials. A purse-string suture is then pre-placed in the ventrolateral aspect of the bladder, near the apex on the same side as the celiotomy incision. A Foley catheter of size appropriate to the animal (range 12–18 F) is placed through a stab incision lateral to the paramedian body wall incision to enter the abdominal cavity. The end of the Foley catheter is then placed through a stab incision in the bladder within the purse-string suture. The purse-string suture is then tied tightly, and the catheter balloon inflated with saline. The bladder is pulled close to the body wall using tension on the Foley catheter, which was secured to the skin with a trapping suture pattern. The celiotomy incision is closed routinely using various suture materials, depending on surgeon preference.

Oophorectomy

Removal of the ovaries is rarely indicated in swine. However, oophorectomy may be requested to facilitate research or for pet pigs. For pet pigs, removal of the ovaries is easier, is faster, and has less risk of fatal hemorrhage than ovariohysterectomy (OVX). The blood vessels of the broad ligaments of the uterus are extensive and require ligation when OVX is chosen. Both ovaries may be removed from a paralumbar (flank), ventrolateral, paramedian, or ventral midline incision. We prefer to perform ovariectomy via a flank or ventral midline incision. Access to the abdomen is excellent with these incisions, and, in our experience, the risk of postoperative complications (incisional infection, hernia) is less. In either case, we prefer to use general anesthesia while performing the surgery. For ventral midline approach, the incision may be started immediately caudal to the umbilicus and extended caudally. For a paralumbar approach, the incision is started ventral to the transverse processes of the lumbar vertebrae, midway between the tuber coxae and the last rib. Each ovary is elevated through the incision, two hemostatic forceps are placed on the ovarian pedicle, two ligatures (No. 2-0 polyglactin 910) are placed proximal to the

first hemostat, and the pedicle is cut between the two hemostats and the ovary removed. Each ovarian artery must be observed for hemorrhage prior to closure. Closure of the ventral midline is done using No. 1 PDS or polyglactin 910 in an interrupted suture pattern. Chromic gut suture should not be used in the linea alba because of the increased risk of postoperative incisional hernia. The skin is closed with No. 2 polymerized caprolactam in a Mayo (Ford) interlocking suture pattern. Paralumbar incisions are closed in three layers (transversus abdominis m + peritoneum, internal + external abdominal oblique, skin). Ovariectomy, alone, may be performed in pet pigs that have not begun normal estrus cycles. Uterine atrophy is expected to occur after ovariectomy. We recommend OVX in sexually mature pigs because of the potential risk for pyometra in a uterus where the cervix has been open.

Uterus

Hysterectomy

Hysterectomy may be performed as part of Cesarean section and is discussed below. Elective hysterectomy is rarely done in swine. Hysterectomy has been reported for pet pigs having uterine neoplasia (Preissel et al. 2009). The authors have also performed hysterectomies on pet pigs because of chronic endometriosis. However, hysterectomy may be requested for research purposes or for pet pigs. When hysterectomy is performed for pet pigs, the ovaries also are removed. General anesthesia should be used during hysterectomy. The uterus may be removed via a flank, ventrolateral, paramedian, or ventral midline incision. We prefer to perform hysterectomy via either flank or ventral midline incision. The uterus is elevated through the incision, the ovaries are removed as described above, the broad ligament of the uterus is ligated using two to four overlapping simple interrupted sutures for mass ligation of the blood vessels, and transfixation ligatures are placed in the uterine body immediately cranial to the internal of the cervix. The uterus and ovaries are removed, and the incision is closed as described above. All sutured pedicles should be checked for adequate hemostasis prior to closure. Abnormalities have been found on 30.4% of 298 potbellied pigs undergoing ovariohysterectomies (unpublished data, Cypher, University of Tennessee 2017). Hemorrhage is the most common complication associated with this procedure. Recently, the authors have used minimally invasive surgery by laparoscopic OVX, and using a vessel-sealing device allows to minimize the risk the ligature slippage after the surgery (Figure 11.7).

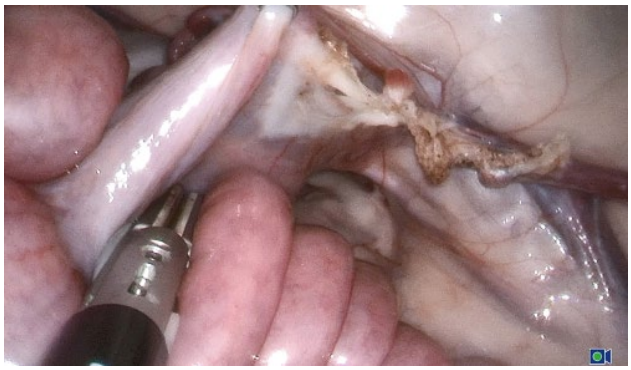

Figure 11.7 Laparoscopic image during a minimally invasive ovariohysterectomy in a pig.

Cesarean section: indication and decision analysis

Cesarean section is required when transcervical extraction of pigs from the uterus is not possible (complicated dystocia) and to obtain gnotobiotic or specific-pathogen-free (SPF) pigs. Cesarean section for gnotobiotic pigs is usually performed with the sow under general anesthesia and is discussed below. The most common reported causes of dystocia in swine are uterine inertia, small pelvic size, inadequate dilation of the birth canal, fetal-to-maternal disproportion, fetal malpresentation, and abnormalities of the birth canal (Titze 1977). Cesarean section for dystocia is usually chosen as a "last-resort" procedure for fetal extraction because of economic pressures. Therefore, the mortality rate among sows and gilts having Cesarean section is expected to be higher than for other species. This is not surprising because affected swine suffer extreme physical exhaustion, stress, and shock by the time the decision for Cesarean section is made. Interestingly, multiparous sows had a higher frequency of collapse (25.8%) prior to Cesarean section compared with primiparous pigs (16.4%) (Dimigen 1972). Owners and veterinarians may become reluctant to perform Cesarean section because of expense, previous experiences with fatalities, and the high rate of dead pigs delivered. It is our opinion that unnecessary delays in the decision for surgery are the principal cause of sow and baby pig mortality associated with Cesarean section. When the veterinarian is presented with a sow in dystocia, the decision as to whether the owner is willing to incur the costs of Cesarean section should be ascertained as early as possible during the initial examination. Other factors influencing the decision for Cesarean section include the cause of dystocia, how long the sow has been in labor, how long the owner has tried to manually extract the pigs, and how swollen or traumatized the sow's pelvic canal has become. Many owners are adept at extracting pigs, and their failure to successfully remove pigs may justify immediate Cesarean if the cause of dystocia is not

apparent. The most common indications for Cesarean section in pigs are undersized pelvic canal, inadequate cervical and soft tissue dilation, prolonged labor (including uterine inertia), fetal-to-maternal disproportion, and trauma to the birth canal (Titze 1977). In our experience, Cesarean section performed at the earliest indication has a high success rate for survival of the sow and a higher rate of live pigs obtained (Table 11.3).

Swine that are physically exhausted, stressed, or in shock must be stabilized prior to Cesarean section. Thirteen percent of sows in labor for less than 18 hours died or were salvaged compared with 30% of sows in labor for more than 18 hours (Dimigen 1972). Among sows necropsied after sudden death, retained fetuses and toxemia were found in approximately 10% (Sanford et al. 1994). Stabilization of the sow often is simple and readily achieved. We routinely place a 16 or 18 gauge 2 in. intravenous catheter in an ear vein. This catheter is sutured or glued in place, and intravenous fluids (0.9% saline or lactated Ringer's solution) are administered rapidly (initially 20–40 mL/kg of BW/h and then 4 mL/kg/h once stabilized) and continued for the duration of the surgery. The authors prefer to add dextrose (1.25% final solution) and calcium (1 mL/kg) to intravenous fluids *after* the patient has been stabilized. Further, the shock status of the sow may be improved by administration of dexamethasone (0.5–1.0 mg/kg IV) or flunixin meglumine (1 mg/kg IV). Because extensive manipulation of the intrauterine environment prior to Cesarean section increases the risk for postoperative septic peritonitis, we prefer to administer preoperative antibiotics (procaine penicillin G, 10,000 U/kg, IM; or oxytetracycline, 5–10 mg/kg, IM). In severely compromised sows, sedation (see anesthesia section) and local or regional anesthesia may be adequate for surgery. Intravenous fluids should be administered continuously. Epidural anesthesia (lumbosacral level) also may be useful. Overall, we prefer to perform general anesthesia rather than attempt Cesarean using physical restraint and epidural anesthesia. In our experience, this causes the least stress on the patient, surgeon, and assistants. The respiratory rate and heart rate should be monitored, and supportive therapy adjusted appropriately.

Surgical approach for cesarean section

Multiple surgical approaches have been described for Cesarean section. Selection of the surgical approach depends upon the preference of the surgeon, the condition of the patient, and means of restraint and anesthesia used for surgery. The most common approaches are paralumbar fossa, ventrolateral (horizontal low flank), ventral midline, paramedian, or paramammary (Figure 11.8) (Mather 1966; Turner and McIlwraith 1989). With a ventral or paramedian approach, movement by the sow must be prevented because of the risk for contamination of the incision. Also, the mammary veins must be carefully avoided or ligated to prevent excessive loss of blood during the procedure. In our experience, ventral and paramedian incisions have the highest risk for development of postoperative incisional infection (contamination on the floor and trauma from pigs searching for nipples). The authors advocate paramammary incisions for Cesarean section in sows. The paramammary incision is made parallel and ventral to the flank and lateral to the mammary chain (Figure 11.9) (Mather 1966). The sow is placed in lateral recumbency with the uppermost hind limb tied in adduction and extension. The incision is

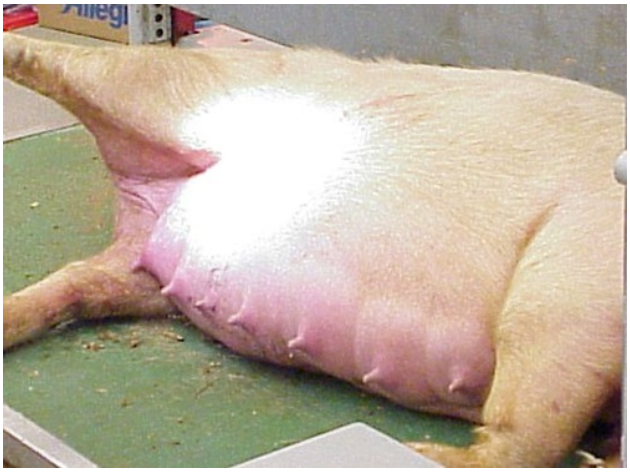

Figure 11.8 Sow positioned in left lateral recumbency with the right rear limb elevated and extended. This position is used to facilitate paramammary laparotomy.

Table 11.3 Outcome of Cesarean section in sows with respect to duration of labor.

Duration of labor	Number of sows	% sows having >50% live pigs	% sows having <50% live pigs	% sows having all dead pigs	% sows died or culled
<18 h	125	66.7	7.9	25.4	13.4
18–48 h	81	19.7	13.5	66.7	32.1
>48 h	21	0	4.7	95.3	28.5
Overall	227	43.7	9.7	46.6	21.5

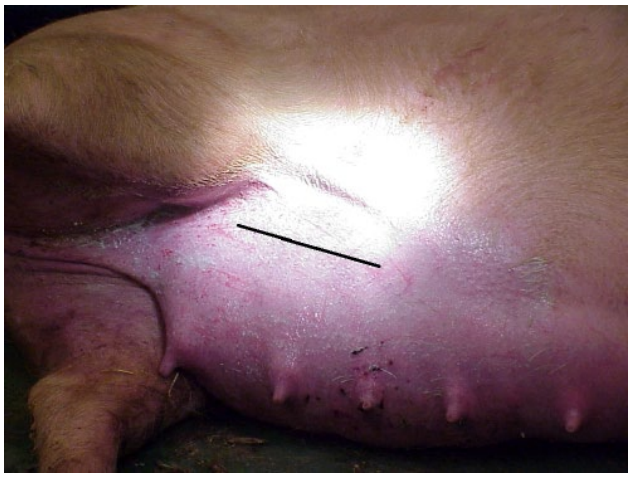

Figure 11.9 Location of the incision (black line) made for paramammary approach to the uterus.

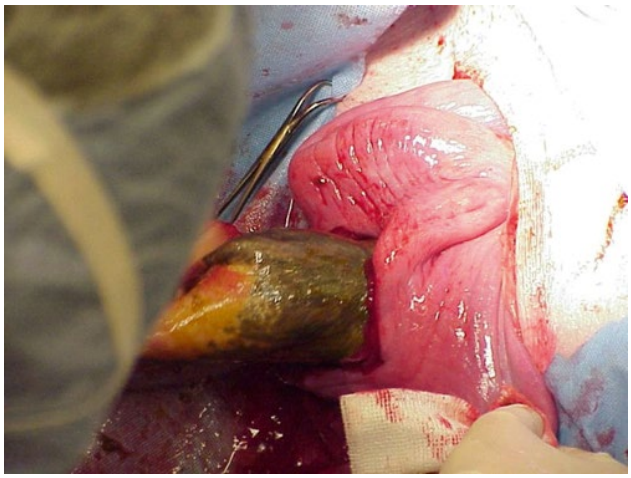

Figure 11.10 Exteriorization of the uterus during hysterotomy for fetal extraction during C-section via a paramammary laparotomy.

started approximately 10 cm cranial to the inguinal region and extended cranially for 15 cm. For paralumbar fossa incision, the sow is placed in lateral recumbency, and the incision is started cranial and ventral to the tuber coxae. The incision is extended ventrally to a point approximately 5 cm dorsal to the cranial skinfold of the flank. Paramammary and paralumbar incisions are relatively easy to perform, have little blood loss during surgery, and are less likely to become infected after surgery. Fewer fat deposits are encountered with paramammary incisions, and the meat portion of the flank is left undisturbed. The uterus can be easily exteriorized because of its proximity to the incision (Figure 11.10). After exteriorizing the closest uterine horn, a 6–8 cm long incision is made parallel with the uterine horn and as close to the bifurcation of the uterine horns as possible. All pigs may not be able to be removed from a single incision in the uterus.

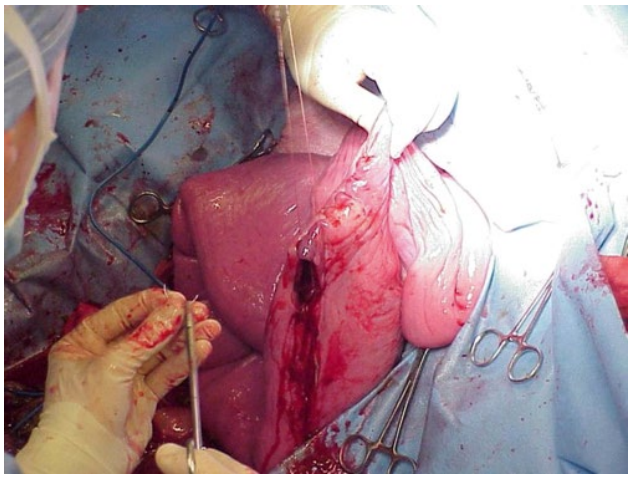

Figure 11.11 Hysterotomy closure after fetal extraction. A continuous inverting suture pattern should be done using absorbable suture material.

Closure of Cesarean section incision is based upon the conditions under which the surgery was performed. For a healthy uterus containing live or recently dead pigs, we use No. 1 chromic gut or No. 0 PDS or polyglycolic acid placed in a Cushing or Utrecht (modified Cushing) pattern for closure of the uterus (Figure 11.11). Some veterinarians have advocated hysterectomy when performing Cesarean section (Schoneweis 1971). This practice allows rapid removal of all pigs soon after entering the abdomen, ensures culling of the sow after the pigs have been weaned, and minimizes surgery time because an assistant does removal of individual pigs after removal of the uterus. The uterine arteries are ligated with No. 0 chromic gut, the broad ligaments are divided along the axis of the uterine horns, and the uterine body is ligated using rubber tubing. The rubber tubing may be secured to the uterine body using No. 1 chromic gut suture. Alternatively, sterile 1 cm cotton tape (umbilical tape) suture may be used to perform transfixation ligation of the uterine body. Then, the gravid uterus is removed. We urge caution with hysterectomy that precise hemostasis must be achieved prior to removal of the uterus. Ligation of abdominal bleeders after removal of the uterus is difficult, and life-threatening hemorrhage may occur if the uterine arteries are inadequately ligated. We close the transversus abdominis muscle and peritoneum together and the external abdominal oblique and internal abdominal oblique muscles together using No. 2 chromic gut or No. 1 PDS or polyglycolic acid placed in simple continuous pattern (Figure 11.12). For closure of ventral midline or paramedian incisions, we do not recommend the use of chromic gut because of the higher rate of postoperative hernia formation. We use No. 1 PDS or polyglycolic acid suture placed in simple interrupted or interrupted

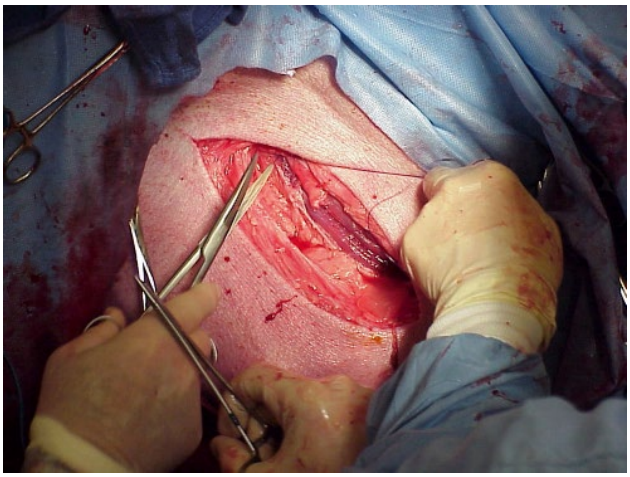

Figure 11.12 Closure of the abdominal wall of the paramammary incision after completion of laparotomy.

cruciate pattern. Skin is closed using No. 0 polymerized caprolactam in a Mayo (Ford) interlocking pattern. Alternatively, a subcuticular suture pattern may be placed to oppose the skin edges. This suture pattern eliminates the need for skin suture removal at a later date. The sow should remain confined for a minimum of 14 days after surgery.

Gnotobiotic pigs

The production of gnotobiotic or SPF pigs is an accepted model for scientific research. The selected sow should be placed under general anesthesia, and the surgery site aseptically prepared. Several methods have been described for obtaining gnotobiotic pigs including hysterectomy, closed hysterotomy (using a sterile chamber attached to the side of the sow through which surgery is performed), and open hysterotomy with germicidal trap. All methods are expected to have a baby pig mortality rate of less than 15%, except open hysterotomy performed with local anesthesia, which may have a 35% baby pig mortality rate (Miniats and Jol 1978; Tavernor et al. 1971). When a hysterectomy technique is selected, baby pig survival is better when the surgery is performed with the sow under general anesthesia rather than euthanasia of the sow prior to hysterectomy.

Uterine prolapse

Prolapse of the uterus is occasionally seen in sows during or up to several days after parturition. Excessive straining because of fetal malpositioning, fetal-to-maternal disproportion, or trauma with swelling and inflammation in the birth canal is thought to cause uterine prolapse. Prolapse of the entire uterus has the greatest potential for a life-threatening crisis because of profuse hemorrhage, but partial prolapse also may occur. The sow must be stabilized prior to attempts to replace the uterus into its normal position. If hemorrhage, hypovolemia, or shock (tachycardia, peripheral cyanosis) is present, the sow should be placed into a warm environment, IV catheter is placed into an auricular vein, and intravenous fluids are administered. Hypertonic saline may be administered rapidly (5–7 mL/kg BW, IV over 5–10 minutes) followed by isotonic crystalloid fluids (5–10 mL/kg/h). For replacement of the prolapse, the sow may be placed on an inclined floor or platform in sternal recumbency with the hindquarters elevated. Epidural anesthesia (administered at the lumbosacral space), sedation, or general anesthesia may be required to eliminate struggling, straining, and agitation of the sow. The uterus is thoroughly cleaned with cold water and assessed for the presence of lacerations and necrosis. Small lacerations may be cleaned, superficially debrided, and sutured closed (No. 0 chromic gut, simple continuous pattern). Hemorrhage may be stopped by ligating affected vessels or by performing en bloc tissue imbrication. Sutures may be placed over stents to increase the region of pressure to control hemorrhage. Then, hygroscopic agents (anhydrous glycerine, sugar, etc.) may be applied to the uterus to assist in reducing edema. The uterus is wrapped into a towel, and gentle pressure is applied, starting from the tip of the uterine horn and working toward the body of the uterus. After approximately 15 minutes, the edema should be sufficiently reduced to allow manipulation of the uterine horns. Each horn should be inverted starting with the tip and gradually reduced until the uterine body has been reached. Often, progress is impeded because of the extensive edema and swelling of the soft tissues of the pelvic canal. When this occurs, left paralumbar fossa laparotomy is indicated (Raleigh 1977). After appropriate preparation of the surgical site and surgeon, a 10 cm long, vertically oriented incision is made in the middle of the left paralumbar fossa. The left arm is passed into the peritoneal cavity and into the everted uterus. One of the uterine horns is grasped and pulled back into the peritoneal cavity. The right arm or an assistant helps by applying gentle pressure on the everted horn from the exterior. After the uterus has been repositioned, all remaining fetuses should be removed. The laparotomy incision should be closed in three layers (transversus abdominis m + peritoneum, internal + external abdominal oblique, skin). Chromic gut (No. 3) or a synthetic absorbable suture (polydioxanone, polyglactin 910, polyglycolic acid) is placed in simple continuous suture patterns in the muscle layers. Polymerized caprolactam (No. 2 braunamid) is placed in a Mayo (Ford) interlocking pattern in the skin. Antimicrobial and anti-inflammatory

medications are desirable, but strict attention should be paid to drug residues in the meat prior to slaughter. Finally, a Buhner suture should be placed around the vulva to prevent reoccurrence of the prolapse. The Buhner suture (6.4 mm wide sterile cotton tape) should be deeply placed at the junction of the labia and the skin of the perineum to recreate the function of the vestibular sphincter muscle. The Buhner suture may be removed in 7–10 days with minimal risk of prolapse. Oxytocin (20 units) is routinely administered to facilitate contraction and involution of the uterus and cervix. If prolapse reduction using laparotomy is not used as a "last-resort" treatment, sows should survive partial prolapse of the uterus (>75%), but complete prolapse carries a guarded prognosis (<50%).

Amputation of the uterus

Amputation of the uterus is indicated when excessive bleeding, extensive laceration, trauma, or necrosis of a uterine prolapse is found. The prognosis with uterine prolapse is guarded to poor for survival, and affected sows must be provided with supportive care as soon as possible (shelter, IV fluids via ear vein catheter, etc.). Focal lacerations and bleeders can be repaired, and the uterus replaced into the abdomen. When severe injury has occurred, amputation of the uterus provides the best option for salvage of the sow. Prior to amputation, the uterus should be closely inspected to ensure that the bladder or small intestine is not entrapped. Hypovolemic or hemorrhagic shock may be present and should be addressed during the course of treatment. If the uterus is swollen, it should be elevated above the pig to encourage drainage of venous congestion. We recommend placing towels around the uterus so that pressure may be applied without further trauma to the wall of the uterus. Hygroscopic agents (anhydrous glycerine, granular sugar, etc.) may be used to help resolve edema of the uterine tissues. After venous congestion has been reduced, amputation is more easily performed. Transfixation ligatures are placed around the circumference of the uterus. Heavy suture material (0.5 cm sterile cotton tape, No. 3 polymerized caprolactam) is used because the thickness of the uterus requires extreme tension to completely occlude the uterine arteries. Stay sutures or cross pins (using 15 cm long 18 gauge needles) are placed in the vital uterus, and the prolapsed portion is amputated. Then, any bleeders are ligated with No. 1 chromic gut before the remaining tissues are released and placed back into the pelvic canal. A Buhner suture or purse-string suture should be placed into the labia at the level of the vestibular sphincter to prevent prolapse of the remaining tissues. Affected sows are salvaged as soon as possible or after weaning of the litter.

Mastectomy

Mastitis caused by *Actinomyces suis* may cause formation of abscesses, granulomas, and mammary fistulas (Bollwahn and Meermeier 1989). The swellings may become large and problematic for the sow. Surgical removal of the mammae is indicated for return of the sow to production soundness. Sows with at least 12 intact mammary glands and that are not in the first week or last 4 weeks of gestation are suitable candidates for surgery. The sow is placed under general anesthesia, and the affected mammary gland prepared for surgery. An elliptical incision is made approximately 1 cm from the base of the swelling so that enough tissue remains to allow closure of the tissues with minimal tension. A combination of sharp and blunt dissection is used to extirpate the gland, granuloma, and abscesses. The cranial superficial epigastric vein (subcutaneous abdominal vein) should not be compromised, but hemostasis is essential. Using 2-0 chromic gut ligatures of transected blood vessels ensures hemostasis. The wound is closed in three layers: deep subcutaneous, superficial subcutaneous, and skin. Each subcutaneous tissue layer is sutured with a simple continuous suture pattern (No. 0 chromic gut, No. 2-0 PDS, or polyglycolic acid). Each suture is anchored to the deeper tissue layer in an attempt to close all dead space, thus minimizing the formation of postoperative seroma, hematoma, and abscess. Administration of perioperative antibiotics is indicated.

Abdominal surgery

Umbilical hernia

Umbilical hernia is a development defect of pigs that has recently been found to have a genetic cause (Ding et al. 2009). An umbilical hernia is a discontinuity of the abdominal wall at the umbilicus with protrusion of abdominal content into a hernia sac formed by the skin and surrounding connective tissue (Figure 11.13). In swine herds, the frequency of umbilical hernias ranges from 0.4 to 1.2% and varies with breed and sex (Searcy-Bernal et al. 1994). In addition to heredity, the etiology of umbilical hernia may be navel infection and umbilical abscess. After the umbilical cord is cut at birth, iodine should be applied to decrease the likelihood of infection. Pigs with umbilical hernias may suffer from growth retardation and may die from intestinal strangulation. In one study, pigs sired by American Spotted and Duroc boars were more likely to develop hernia than those sired by Yorkshire, and umbilical hernias often were detected in pigs between 9 and 14 weeks of age (Searcy-Bernal et al. 1994). One possible reason for the recognition of the condition at that age may be the rapid growth of pigs,

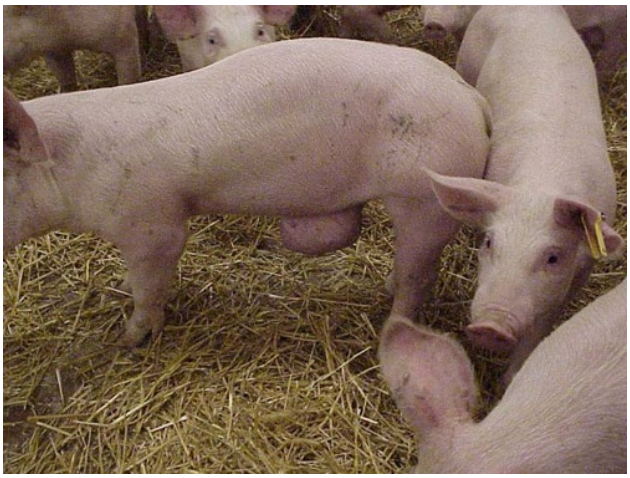

Figure 11.13 Clinical appearance of an umbilical hernia in a young pig.

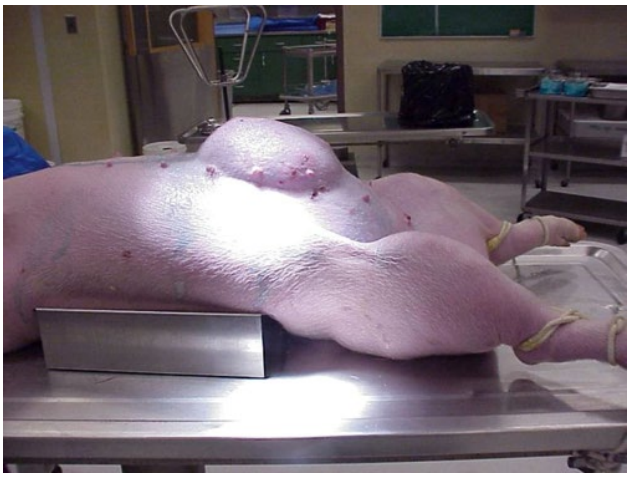

Figure 11.14 Positioning of a young pig in preparation for surgical treatment of umbilical hernia.

combined with increased weight of the abdominal contents, leading to a hernia of significant size. Females were at an increased risk of developing umbilical hernia. As with many other swine surgical conditions, the cost of treatment may preclude surgical correction. In that case, pigs should be consigned to an early slaughter soon (within 1 month) after detection of the hernia and before evisceration or intestinal strangulation or fistula occurs. A case of intestinal umbilical fistula has been described in a 30 kg castrated male pig (Lewis 1973). The risk of intestinal incarceration and strangulation is more frequent with an umbilical hernia of small dimension, (i.e. hernia, ring smaller than 8 cm). However, a pig with an umbilical hernia often will be discounted when it goes to slaughter.

Reduced growth rate in untreated pigs with umbilical hernias may encourage surgical correction of the defect. However, whether surgical correction of umbilical hernia will restore the growth potential is unknown. In purebred, show animals, and pigs kept as pets, surgical correction often is indicated. Herniorrhaphy should be performed early in life. Following anesthesia, the pig is restrained in dorsal recumbency in a V-shaped trough (Figure 11.14). The surgical area then is cleaned and prepared for surgery. If surgical correction is performed on a male, the prepuce, preputial diverticulum, and penis should be reflected posteriorly or to one side. The hernia sac then is isolated, and dissection is performed to the hernia ring. The hernia sac with an abscess, if present, should be removed, and the edges of the ring freshened. If intestinal contents are adhered to the hernia sac, the adhesions are separated, bowel viability is assessed, and if judged acceptable, the bowel is replaced in the abdomen. If intestinal viability is compromised, resection and anastomosis of viable intestine should be performed. If no infection is present, the hernia sac also can be inverted into the abdomen. The abdominal defect then is closed using an overlapping or simple continuous pattern. The prepuce, preputial diverticulum, and penis then are repositioned and sutured to the abdominal muscle with absorbable suture material. The skin then is sutured using a simple interrupted pattern of nonabsorbable suture material. For surgical correction of umbilical hernia in the female, an elliptical incision is made around the hernia sac, and the excess skin is discarded. With a combination of sharp and blunt dissection, the hernia sac then is cut and removed, and the abdominal muscle closed as in the male. The subcutaneous tissue and skin then are closed. Systemic antibiotic should be administered for 5 days, and the skin suture removed in 10 days.

Inguinal or scrotal hernia

Inguinal hernia and scrotal hernia are variants of a defect in which intestines or other abdominal organs pass into the inguinal canal (Figure 11.15). The hernia develops when there is an abnormally large and patent vaginal orifice through which the vaginal process and peritoneal cavity communicate. Scrotal hernia is the more exaggerated form of the defect in that the organs protrude into the scrotum (Vogt and Ellersieck 1990). These hernias are common in swine and have been the most common defect observed in swine (Vogt and Ellersieck 1990). The frequency of scrotal hernia among the porcine population varied between 0 and 15.7% with a realistic number of about 1% (Vogt and Ellersieck 1990). The development of these hernias seems to be genetically influenced (Ding et al. 2009). One study indicated that the variation associated with anatomic structures relevant to scrotal hernia is influenced polygenically. In that study, the heritabilities of susceptibility to scrotal hernia development were estimated to be

Figure 11.15 Clinical appearance of a right-sided inguinal hernia in a young pig.

Figure 11.16 Location of parainguinal incision for reduction and closure of a unilateral inguinal hernia in a young pig.

0.29, 0.34, and 0.34 in Duroc-, Landrace-, and Yorkshire-sired pig groups, respectively (Vogt and Ellersieck 1990). Inguinal and scrotal hernias need to be differentiated from hydrocele, scirrhous cord, and hematoma of the testicle. Taking a good history (e.g. a pig that has been castrated before is more likely to have a scirrhous cord) and direct manipulation often will give the diagnosis. If necessary, ultrasonography and needle aspiration can be used. Inguinal hernias often are encountered at the time of castration. Some of these hernias will reduce spontaneously but recur later. With chronic inguinal hernia, intestinal incarceration and strangulation may be observed.

Surgical repair of an inguinal or scrotal hernia is easier if done before the pig is castrated. With the pig restrained in dorsal recumbency and its rear quarters elevated, the inguinal and scrotal area is thoroughly cleaned and prepared for surgery. An oblique incision is made over the affected external inguinal ring. Once through the skin, the subcutaneous tissue is dissected bluntly. Also by blunt dissection, the tunica vaginalis is isolated. The tunica vaginalis should be kept intact, because this will keep the intestine contained. While external pressure is put on the scrotum, the tunics are gently pulled free from their scrotal attachment. The entire hernia sac is removed through the inguinal incision. The tunic and testicle then are twisted to force the intestines into the peritoneal cavity. The tunics and spermatic cord are transfixated as close to the inguinal ring as possible. The tunic and cord are cut, and the inguinal ring is closed with interrupted or horizontal mattress suture. The herniorrhaphy is then checked by applying external pressure on the abdomen. The skin then is closed using absorbable sutures (Figure 11.16). The authors always recommend checking the other side for possible bilateral herniation before performing a castration. If the surgery was done to repair a large hernia in which marked serum accumulation in the scrotum is expected, an incision in the most ventral aspect of the scrotum should be performed via the inguinal incision before suturing to provide ventral drainage. If intestinal adhesion and incarceration are observed during surgical correction of a scrotal hernia, the vaginal tunic should be opened and the intestine is dissected free or an intestinal resection and end-to-end anastomosis are performed. If an inguinal hernia occurs after castration, one needs to clean and lavage the herniated bowel, enlarge the inguinal ring and replace the prolapsed intestine (if it is judged to still be viable), and then suture the inguinal ring.

Visceral torsion or volvulus

In one series of cases, acute abdominal accidents were characterized clinically by sudden death and were observed more commonly in dry sows (Morin et al. 1984). It was proposed that feeding dry sows in large breeding units once a day or every other day might be an important provoking factor. This feeding method often will make sows ingest large quantity of feed and water rapidly. In swine with gastric torsion, death was preceded sometimes by a short period of anorexia, abdominal distension, shortness of breath, cyanosis, and salivation. At necropsy, clockwise torsions were more common than counterclockwise. The torsions were about the longitudinal axis of the organ, and the stomach was distended severely with fluid, gas, and food (Morin et al.

1984). The spleen had rotated with the stomach in some sows; affected spleens were congested severely, and some had ruptured, causing hemoperitoneum. Torsion of the liver also was seen occasionally (Morin et al. 1984). In eight sows, intestinal volvulus was observed, and it was more common in younger sows. In four sows, the entire small intestine was included in the volvulus, the posterior half of the small intestine in one, the small intestine and colon in one, and the cecum and colon in the last one (Morin et al. 1984).

Intestinal obstruction

In swine with intestinal obstructions from intussusceptions or foreign bodies, clinical signs observed may include depression, vomiting, abdominal distension, and decrease in the amount of feces sometimes with blood and mucus in it. These two conditions are diagnosed rarely in live animals. If the condition is diagnosed early, a ventral midline celiotomy and an enterotomy are performed for the foreign body obstruction, and an intestinal resection and anastomosis are done for the intussusception. Spiral colon obstruction was diagnosed in an 8-year-old potbellied pig with depression, inappetence, and abdominal distension (Gallardo et al. 2003). Exploratory laparotomy found a stricture at the proximal centripetal loop of the spiral colon and megacolon proximal to the stricture. A side-to-side colonic anastomosis was performed, and the pig returned to normal after surgery. A 7-month-old female potbellied pig was diagnosed with idiopathic megacolon based on abdominal palpation, abdominal radiographs, and exploratory surgery (Bassett et al. 1999). A subtotal colectomy was performed, and an ileocolonic anastomosis performed. The pig survived and, after a period of diarrhea, returned to normal stool.

Gastric ulcers

Gastric ulcers are common conditions of the gastrointestinal tract of the pig. Clinical signs are pale mucous membrane (anemia) and dark tarry feces. In valuable pigs, sometimes gastrotomy can be the best treatment option. With the animal in dorsal recumbency, an incision is made on the ventral midline starting at the xiphoid cartilages. The stomach is isolated from the rest of the abdomen, and the serosal surface is evaluated for changes in color and appearance that would indicate an ulcer. A gastrotomy then is done, and the stomach contents are removed. If an ulcer is found, it can be surgically dissected, and the edges electrocoagulated or ligated with some suture material. The wall of the stomach then is closed with a double row of suture material using an inverting pattern. If multiple bleeding ulcers are present, the prognosis is poor even with surgery.

Atresia ani and rectal stricture

Atresia ani occurs more frequently in the pig than any other species and is possibly the most important cause of intestinal obstruction. This congenital defect is transmitted genetically, but may occur spontaneously as well. Recently, atresia ani was reported in a piglet that was a clone derived by somatic cell nuclear transfer from a miniature pig that did not have atresia ani (Lee et al. 2005). The diagnosis is made by an absence of anal opening, abdominal distension, slower growth rate, and vomiting. Because the pigs vomit, the diagnosis of atresia ani is sometimes not made until 3–4 weeks of age. In the female piglet, a fistula may occur between the rectum and vagina so that the feces may be voided through the vulva. Surgical treatment of atresia ani is necessary for survival. Following anesthesia, a circular piece of the skin is excised below the tail over the bulging rectum. Feces usually are discharged immediately. If the rectum is not present at the skin opening, pelvic dissection may be necessary. Depending on the location of the rectum, or if atresia of the rectum is also present, surgical correction may not be possible. In these extreme cases, a celiotomy and colostomy may be necessary but rarely justifiable economically. Following correction of atresia ani or recti, the pigs should be fed until they reach slaughter weight. Pigs with rectal stricture often show similar clinical signs as pigs with atresia ani, except that they have an anus and are generally older. In one series of cases, pigs with rectal stricture were 16–18 weeks of age (Saunders 1974). These pigs after being affected for 2 weeks were suffering from weight loss compared with their herd mates, no feces were passed, and the abdomen continued to distend. These pigs were slaughtered or killed by other pigs (Saunders 1974). Most cases of rectal stricture are the results of a rectal prolapse that has constricted after repair causing an obstruction. At necropsy, these pigs show a distended cecum and colon. The rectum usually is occluded for 3–5 cm by a band of fibrous tissue. It is speculated that inflammation of the rectal mucosa leads to rectal scar formation with subsequent stenosis and eventually possible complete obstruction (Saunders 1974). Pigs with rectal stricture may respond to celiotomy with colostomy or ileocutaneous anastomosis. Ileocutaneous anastomosis has been successfully performed in pigs as young as 10 days old (Anderson et al. 2000).

Rectal prolapse and rectal amputation

Rectal prolapse is a common occurrence in swine. Prolapse of the rectal mucosa occurs following straining to defecate. The mucosa rapidly becomes edematous and often shows bleeding lesions. Many factors have been associated with the development of rectal prolapse including genetics, a birth weight of less than 1 kg, being male, diarrhea, coughing, short tails, autumn and winter piling because of chilling, chronic water shortage, certain antibiotics, zearalenone toxicosis, and a diet containing excess lysine (20% more than required) (Amass et al. 1995). Diagnosis of rectal prolapse is not difficult, but care should be taken that the prolapse does not contain other organs.

The simplest procedure for rectal prolapse is reduction by gentle massage and retention by application of a purse-string suture pattern using umbilical tape (Borobia-Belsue 2006). The suture is passed in and out through the skin around the anal opening at a distance of 1 cm from the anus. A one-finger opening should be left when tying the purse string. The suture usually is left in place for 5 days. This should be done only if the rectal mucosa is viable and no laceration is present on close inspection. If the mucosa is too necrotic to replace, correction of the prolapse can be approached in different ways (Vonderfecht 1978). One technique is a surgical amputation. For this surgery, required instruments are hemostats, blade, scissors, thumb forceps, two 18 gauge needles 3 or 4 in. long, suture material, and a small-diameter rubber tube. Following anesthesia, the tube is inserted in the rectum until 2 or 3 in. protrude. The tube is fixed in the rectum by inserting the two needles through the rectum at right angles to each other so that they pass through the rectum and tube and emerge from the opposite side. The dissection is started about a centimeter from the mucocutaneous border where the mucosa is still healthy, and the entire circumference of the exposed mucosa of the rectum is cut down to the serosa of the inner wall. Hemorrhaging is usually minor and controlled with gauge until all the layers have been dissected and the dorsal artery of the rectum is cut. Once the dissection is completed around the prolapse, the rectum is held in place because it is attached to the rubber tube with needles. Instead of using tubing and needles, one could use forceps applied at two or three places as the prolapsed rectum is amputated to prevent telescoping into the animal's body (Kjar 1976). To suture the ends of the rectum together, the authors suggest using size 0 absorbable suture material in an inside-out continuous pattern. After the simple continuous pattern has been placed around the rectum, the needles then are pulled from the tube, and the tube is removed from the rectum. The rectum then automatically retracts into place. An alternative method of rectal amputation is to use a prolapse ring, PVC tubing, syringe case, or corrugated tube (Douglas 1985). The ring or tubing is placed in the rectum, and the halfway point on the tube needs to be inserted as far as the anal sphincter. A ligature or rubber band then is applied over the prolapse as near as possible to the anus. The ligature or rubber band must be tight enough to disrupt blood supply to the prolapse. Feces may go through the tube or may block the tube. Usually, the necrotic prolapse falls in 5–7 days with the implant in place, and then fecal production returns to normal.

Three possible complications seen with rectal prolapse are bladder retroversion, eventration of the small intestine, and rectal stricture (Peyton et al. 1980). In a 1-month-old castrated pig, eventration of the small bowel was seen concurrently with a rectal prolapse. The rectal prolapse was 5 cm long, edematous, and purple black. A small tear was found in the rectum in the pelvic area, and eventration of small intestine was observed. It was speculated that the prolapse was of long duration, allowing necrosis to occur. This provided a friable area, and during straining to defecate, the small intestine perforated this necrotic area (Peyton et al. 1980). Surgical correction of small intestine eventration in pig is usually not economically feasible. If treatment is requested, preoperative medical management is often necessary, because these pigs are often in shock. Under general anesthesia, the intestine then is examined and most likely will have to be resected. A ventral midline incision then is made to occlude the lumen of the intestine that remained within the abdominal cavity, and the portion of the intestine that is going to the rectal laceration is resected close to the rectum. The viable end of intestine then is exteriorized through the ventral midline incision, and an end-to-end anastomosis performed (Peyton et al. 1980). Bladder retroversion with rectal prolapse has been observed in a sow 2 days after normal farrowing (Greenwood 1989). The sow had a grapefruit-sized rectal prolapse with protrusion and tension of the perineal area. The bladder was drained by passage of a polypropylene catheter. One week postpartum, the prolapsed rectum was amputated. The sow reared nine piglets to 6 weeks of age and was sent for slaughter 1 week after weaning the piglets (Greenwood 1989).

Musculoskeletal surgery

Musculoskeletal injuries, particularly lameness, are increasingly recognized in swine. Lameness represents a significant animal welfare issue and is justification for concentrated research into cause and prevention of these disorders. A recent Bayesian analysis of leg disorders in finisher herds identified the need for accurate data collection and analysis (Jensen et al. 2009). In that study,

three classes of leg abnormalities were examined: physical injury, inherited defects, and infectious agents. In a survey of musculoskeletal disorders in dead sows in Denmark, 72% of sows had a classification of locomotor abnormality (Kirk et al. 2005). In that study, the most common locomotor disorders were septic arthritis (24%), most commonly caused by *Arcanobacterium pyogenes*, and fractures (16%), most commonly of the proximal humerus or femur. Interestingly, that study also revealed that disorders of the hoof and sole are common. Risk factor analysis is critical in the prevention of limb injuries. The following focuses on treatment of pigs having such injuries.

Septic arthritis

Septic arthritis may be caused by bacteremia, direct inoculation of bacteria into the joint, or extension of a local infection into the joint. Septic arthritis caused by direct inoculation or local extension is treated by wound management, joint lavage, and systemic antibiotic therapy. Infected joints may require daily, or every other day, lavage for 7–10 days or until granulation tissue has covered the wound. Sterile isotonic electrolyte solutions (0.9 % saline, lactated Ringer's solution) are lavaged through the joint by inserting an 18 or 14 gauge needle into the joint, injecting the solution under pressure into the joint, and inserting a second needle into the joint with as much separation as possible between the two needles. Approximately 500 mL of the solution is flushed through the joint. After lavage, antibiotics may be instilled directly into the joint to achieve maximal local antibiotic concentration. Success of treatment is assessed by improvement in lameness and wound appearance.

Digit amputation

Digit amputation is indicated when severe foot abscesses or septic arthritis of the interphalangeal joints has caused unmanageable damage to a single digit. These injuries are most commonly caused by wounds from trauma on concrete flooring or metal side panels. The decision for amputation should not be delayed. If the infection has extended to the fetlock or more proximal on the limb, digit amputation will not be curative. Also, the soundness of the opposite digit should be assessed to determine if the pig would be able to ambulate on the remaining digit after amputation.

After induction of general anesthesia, the affected digit is cleaned and prepared for surgery. A tourniquet is placed proximal to the surgery site to prevent extensive hemorrhage during surgery. A circumferential incision is made through the skin and soft tissues at a 45° angle to the coronary band starting at the axial aspect of the digit and continuing proximally to the abaxial surface. The skin is reflected proximal to the site for amputation, and a sterile obstetrical wire is used to amputate the digit. The third phalanx and a portion of the second phalanx are removed by this procedure. The remainder of the second phalanx also should be removed. The remaining tissues are debrided and cleaned thoroughly, and the skin is opposed over the wound. A sufficient opening is left to allow drainage, or a Penrose drain is placed into the wound. The foot is placed in a padded bandage for 7–10 days. Then, the foot is cleaned daily with water until the wound is healed. Perioperative antibiotics and anti-inflammatory drugs are indicated.

Ankylosis of the proximal or distal interphalangeal joint

Septic arthritis of the proximal or distal interphalangeal joint is an indication for digit amputation. However, the lateral claw of the hind limb is important to normal ambulation and breeding activity. Salvage of the digit by facilitated ankylosis is an option to preserve normal ambulation. The affected pig is placed under general anesthesia, and the digit prepared for surgery. A 1 cm incision is made into the affected joint. Placing a 3.75 cm long needle into the joint by inserting the needle immediately proximal to the coronary band and inserting the needle distally approaches the distal interphalangeal joint. The proximal interphalangeal joint may be located by palpation or insertion of the needle in the mid-pastern region. After the arthrotomy has been made, a 4 or 6 mm diameter drill bit is used to destroy the articular surfaces of the joint. Curettes are used to debride the joint and remove all infected subchondral bone. A distinct difference in texture and hardness will be noted between the necrotic (gritty and irregular) and healthy (smooth and hard) bone. Thorough curettage of all infected bone is critical to establishing effective joint ankylosis. The tissues are extensively lavaged with normal saline, and antibiotics are administered for 10–14 days. Strict confinement for 6–8 weeks is needed for ankylosis to occur. A cast extending from the ground to the carpus or hock will hasten convalescence.

Fracture repair

Swine with fracture of long bones are often salvaged because economic considerations preclude treatment. However, veterinarians may be asked to treat fractures in swine of potential value for genetic improvement. Treatment of fractures can be rewarding, and Vaughan reported clinical experiences with fracture fixation in commercial swine (Vaughan 1966). Fractures were associated with breeding injury (two pigs), injury on concrete flooring (three pigs), and fighting injury (one pig) and were of unknown cause in five pigs. The most common

fractures treated were tibia and fibula (five pigs), femur (three pigs), humerus (two pigs), and tibiotarsal joint luxation with fracture of the fibula (two pigs). Affected pigs weighed between 64 and 168 kg and were 6 months to 2 years old. The fractures of the tibia and fibula were treated by an open reduction and internal fixation by using a bone plate and a full limb cast (three pigs) or by using a full limb cast alone (two pigs). Fracture of the femur was treated by application of a bone plate (three pigs). Humerus fracture was treated by confinement (one pig) or by application of a bone plate (one pig). Tibiotarsal joint luxation with fracture of the fibula was treated by application of a bone plate and use of a full limb cast (two pigs). Of these 12 pigs, 10 returned to normal production use and 2 were salvaged: 1 pig with tibiotarsal joint luxation developed *Escherichia coli* osteomyelitis, and 1 pig with humeral fracture repaired by internal fixation suffered permanent radial nerve damage.

Surgical repair of articular fracture of the humeral condyles have been reported for miniature pigs (Payne et al. 1995). The medial humeral condyle was most commonly fractured, but "Y"-type fractures and supracondylar fractures of the humerus have been found in some miniature pigs. Fractures were repaired using lag screw and Kirschner wire fixation. Five pigs were reexamined 2 months after surgery, and all were walking sound at that time.

The risk of suffering fracture of the femur has been associated with dietary deficiencies of calcium in market pigs (Hejazi and Danyluk 2009). These fracture result in significant economic losses, especially when they occur in valuable breeding stock. Femoral fractures were diagnosed in 20 pigs over a 6-month period (Rousseaux et al. 1981). Nutritional analysis revealed inadequate calcium and phosphorus (both in absolute concentration and in calcium-to-phosphorus ratio) in the feed. Affected pigs were approximately 20 weeks old and weighed between 80 and 90 kg. Pigs walked with a stilted gait and arched back. Necropsy found separation of the proximal femoral epiphysis from the femoral neck. After the correction of dietary calcium and phosphorus, clinical evidence of femoral fracture was not observed in any additional pigs. Femoral, pelvic, and vertebral fractures have been found in pigs after accidental electrical shock (Bildfell et al. 1991). Multiple trauma injuries and fractures associated with nutritional deficiency are poor candidates for surgical repair. Fracture of the greater trochanter of the femur also has been identified as cause of lameness in pigs (Blowey 1992, 1994). A simple oblique fracture of the mid-diaphysis of the femur was successfully repaired in a 10-month-old 150 kg Berkshire boar using a bone plate (Grisel and Huber 1996). The boar returned to normal breeding 190 days after surgery.

Canine tooth (tusk) removal and resection

Removal of the canine teeth of adult boars is challenging because of the long dental root embedded in the mandible. Canine tooth extraction is done with the boar under general anesthesia. The gingiva and periosteum of the mandible are reflected laterally and ventrally using a periosteal elevator. Then the lateral alveolar plate of the tooth alveolus is resected following the course of the tooth root. After the periapical region of the alveolus has been reached, a periodontal elevator is used to disrupt the periodontal membrane around the circumference of the tooth, and the tooth is removed. The alveolus is debrided, rinsed, and sutured closed. Alternatively, the alveolus can be left open to heal by second intention healing.

Resection of the mandibular canine teeth is an easy and rapid method of preventing tusk injuries to personnel and other pigs. The boar is placed under general anesthesia, and obstetrical wire is placed around the tooth. The wire is used to saw through the tooth approximately 3 mm above the gingival margin to prevent exposure of the pulp cavity. This procedure is repeated every 6–12 months as needed to restrict growth of the tusks.

Preharvest Food Safety, Zoonotic Diseases, and the Human Health Interface

Julie Funk and Elizabeth Wagstrom

Introduction

The ultimate purpose of rearing domestic swine is to supply wholesome and nutritious protein to humans. Although this high-quality protein has a positive impact on human nutrition, there is some risk for negative human health impacts. These impacts can occur via consumption of pork products, by occupational exposure to swine, or through environmental exposures. In this chapter we give an overview of potential negative human health risks associated with foodborne, direct contact, or environmental exposures associated with pigs.

Foodborne disease risks associated with pork

Physical hazards

Physical foodborne hazards are foreign objects that can cause injury to those that consume food products. Physical hazards associated with pork originate from two primary sources: preharvest practices on the farm, primarily from the use of hypodermic needles, and postharvest hazards associated with processing and packaging environments. Reports in the literature are scarce regarding the frequency and health implications of physical hazards. The scope of the problem can be estimated from records of meat and poultry recalls and reports from passive surveillance based on US Department of Agriculture Food Safety and Inspection Service (USDA FSIS) consumer complaint reporting systems. A review of recalls from 1994 to 2002 indicated that physical hazards accounted for 15% of total meat and poultry recalls (Teratanavat and Hooker 2004). Recent FSIS recall summaries published by the agency indicate that physical hazards may be becoming less common; from 2011 to 2015, extraneous materials (as physical hazards are characterized by FSIS) were responsible for 45 recalls, which was 8.9% of total meat and poultry recalls for that period. Of the 45, 11 were of pork products or mixed product containing pork – 7 for plastic material, 3 for metal material, and 1 as foreign material. Plastic contamination in most cases could be linked to a postharvest source; metal could not always be clearly linked to a pre- or postharvest source. Based on data from the US Food and Drug Administration (FDA) complaint recording system, the most common human illnesses/injuries associated with physical hazards are laceration or abrasion of the peri-oral area, gastrointestinal distress, and damage to teeth or dental prosthetics.

Preharvest control of physical hazards

The primary concern for physical hazard risk preharvest in swine is the risk of broken hypodermic needles and needle fragments in carcasses. Many factors contribute to the risk of broken hypodermic needles (Hoff and Sundberg 1999). The strength of a hypodermic needle contributes to the risk of breakage. Strength is determined by the length, gauge, hub material, and manufacturer. Studies indicate that hypodermic needles are very resilient to breakage under conditions of static load. Needles that were bent and restraightened were at greater risk for breakage. Needles that were reshaped twice post bending event had a 96.7% failure rate. Simulations of animal movement during injection impacted needle failure rates. Additionally, the location of the injection as well as animal movement impacts the needle puncture strength.

Appropriate restraint, needle selection, and injection techniques are critical to avoiding broken needle events in swine. Producer and worker education is a key intervention for prevention, and development of standard operating procedures for when a broken needle event occurs (including permanent identification of suspect animals and communication with the processor) is a best practice for control of physical hazards in pork. While education on broken needle avoidance has long been

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

included in the Pork Quality Assurance Plus® (PQA Plus®), in 2015 audit points on utilizing detectable needles and needle standard operating procedures were included in the Common Swine Industry Audit (https://lms.pork.org/CommonIndustryAudit).

Detection during processing is a second line of defense to prevent physical hazards in pork. Common methods for detecting/removing physical hazards during processing include physical separation using filters or sieves and magnets (not efficacious for whole meat products) and detection using X-ray. Needles have varying ability for detection by magnets and X-ray during processing depending on the metal alloys used as well as the needle orientation while being screened by the X-ray. A recent study on needle characteristics compared X-ray detection with detection from magnetic-based detectors and reported overall detection by X-ray of 62.5% compared with 21.4% for magnetic-based detection (Hoff 2016).

One way to decrease the risk of hypodermic needles as physical hazards is to remove them from the production system environment entirely. Needleless injection systems have been used in swine for control of physical hazards (Chase et al. 2008).

Chemical hazards

Chemical hazards are toxic substances and any other compounds that may render food unsafe for human consumption. At the preharvest level, primary concerns for control of chemical hazards involve veterinary drugs, pesticides, and environmental contaminants. Other potential preharvest chemical risks involve adulteration of animal feed for the purposes of economic fraud or intentional disruption of the food supply.

Codex Alimentarius represents the global food standard setting body, which establishes standards for residue limits in food, including meats. In the United States, the FDA is responsible for approval of all drugs for use in animals and animal feeds. The FDA sets the standards for tolerance determination of chemical hazards, while FSIS conducts the surveillance and detection of chemical residues in meats. The FDA is in charge of enforcement regarding chemical residues.

Control of chemical residues is managed by prohibition of use or, for chemicals approved for use in animals, determination of maximum residue limits (MRL), which are managed via withdrawal time periods prior to harvest. Codex Alimentarius standards may differ from those of their domestic regulations regarding chemical residues. This has significant implications for international trade of pork, a critical component for economic success of pork production, as pork destined to be exported to other countries may need to adopt different withdrawal periods in order to meet the standards of the importing country. It is important to be aware of these differences and implement on-farm practices that will meet export requirements. In the United States, label indications do not indicate these withdrawal differences. These differing withdrawal periods can be accessed via consultation with pharmaceutical manufacturers or referring to the National Pork Board chart of export MRL withdrawal times (https://www.pork.org/food-safety/maximum-residue-limit/).

Extra-label drug use

In the United States, the Animal Medicinal Drug Use Clarification Act of 1994 (AMDUCA) allows for veterinarians to prescribe some veterinary drugs, under specific clinical conditions, in ways that are not compliant with the label indication (extra-label drug use [ELDU]). While the availability of ELDU is important for animal health and welfare from a chemical hazard safety standpoint, this contributes challenges to establishment of appropriate withdrawal periods to avoid violative residues. In the case of ELDU, the sole burden of avoiding residue violations rests with the prescribing veterinarian. The AMDUCA compliance guide suggests veterinarians to establish extended withdrawal periods when ELDU occurs (Anonymous 1994). Resources for a decision-based algorithm for ELDU and determination for the duration of the withdrawal period for ELDU can be accessed via the Food Animal Residue Avoidance and Depletion Program (http://www.farad.org/).

Veterinary drug residues in pork

FSIS conducts three separate, but interrelated, residue sampling programs (Anonymous 2016): (1) scheduled sampling, which consists of the random sampling of tissue from healthy appearing food animals for the purpose of surveillance, (2) targeted sampling at the production or compound class level, and (3) targeted sampling at the herd/flock or compound class level. Scheduled sampling data serve as a baseline level for chemical residue exposure and can be used to identify marketed animals with violative levels of residues. Targeted sampling may be inspector generated when they suspect that animals may have violative levels of residues or generated by FSIS in response to information about misuse of animal drugs or exposure to environmental chemicals, as well as in response to Tier 1 scheduled sampling analytical results. Targeted herd sampling encompasses targeted testing at the herd or regional level when FSIS feels that it is necessary to test animals from the same herd or region to determine the level of chemical to which the livestock have been exposed.

In the United States, swine residue violation rates are very rare (Anonymous 2015a). Among swine production classes in the United States (market pigs, boars/stags, sows, and roaster pigs) in 2014, no violative residues from scheduled sampling were detected. Violative

residue rates for targeted sampling were 0.09, 0.0, 0.43, and 0.34% for market pigs, boars/stags, sows, and roaster pigs, respectively. The majority of the violations were for penicillin in sows, which followed deployment by FSIS of the more sensitive multi-residue test. These data suggest that at least in the United States, veterinary drug residues are well controlled in swine production. Continued vigilance on the part of veterinarians and producers to continue to ensure this level of food safety is necessary to protect public health.

Dioxins

Polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), and polychlorinated biphenyls (PCBs) are collectively referred to as dioxins due to their similar structures, their actions in biological systems, and their chemical properties. They are ubiquitous environmental contaminants that bioaccumulate in the food chain. They are often considered an industrial contaminant since they are formed as by-products of chlorine-containing manufacturing, but incineration and forest fires are significant contributors to dioxin loads. The majority of human exposure to dioxins is estimated to be from consumption of animal and fish products, especially fats (Liem and Furst 2000). Animals are exposed via air deposition of dioxin on forage and, to a lesser extent, soils (Huwe 2002).

Dioxin contamination of animal feeds has occurred sporadically around the globe including feed components contaminated by pentachlorophenol-treated wood and bakery waste contaminated during the drying process in Europe (Huwe et al. 2009). In the United States, ball clay used as an anticaking agent in poultry and catfish feed and mineral mix formulated with a smelting by-product used in swine feeds have also been identified as dioxin-containing feed contaminants (Huwe et al. 2009). Dioxin contamination of swine feed in Ireland prompted the recall of 2 months of production of pork products (Dixon 2009) and euthanasia of animals. In Germany, dioxin contamination of poultry and swine feed resulted in more than 4700 farms being closed, destruction of chickens and eggs, and the loss of exports of poultry and pork (Kupferschmidt 2011).

A single toxic equivalency value (TEQ), which is the sum of individual dioxin-like compounds, is used for intake assessments or residue determinations. The USDA has conducted surveys of commodities since the mid-1990s. There has been a decreasing trend in TEQs from the mid-1990s to 2013; although the significant decrease for pork was from the mid-1990s to 2002, TEQs declined to a lesser extent from 2002 to 2013 (Anonymous 2015b). The levels were similar to levels published from surveys in Europe and Asia (Huwe et al. 2009) and fall below the European Union regulation for accepted limits of dioxins in meats of 1–3 pg of TEQ per gram of lipid (Huwe 2002).

Biological hazards

Biological hazards are those foodborne hazards caused by bacteria, viruses, parasites, and other infectious agents. The following represent the most common biological hazards associated with pork consumption.

Salmonella

Salmonellosis is a major foodborne disease threat to public health in the United States and around the world. More than 1.2 million illnesses are associated with *Salmonella* infections in the United States annually (Scallan et al. 2011) *Salmonella* in humans most commonly results in gastrointestinal symptoms, such as diarrhea, abdominal cramping, and vomiting. The immunocompromised, young, and elderly are at greater risk for severe disease.

It has long been recognized that swine as well as many other species can be subclinical carriers of *Salmonella*. In essence all vertebrates and many invertebrates have been identified to be able to be colonized with *Salmonella*. *Salmonella* is considered to be ubiquitous in the environment and can survive indefinitely, particularly in farm environments (McLaren and Wray 1991; Plym-Forshell and Eskebo 1996). Its wide host distribution and indefinite environmental survival provide significant challenges for on-farm control. In the United States, the National Animal Health Monitoring Service (NAHMS) reported that in its Swine 2006 survey (Anonymous 2009a), the prevalence of *Salmonella*-positive production sites was 52.6% and the prevalence of positive pigs was 7.2%.

Salmonella is the only foodborne pathogen currently utilized by FSIS for process control during swine harvest. The passage of the Hazard Analysis Critical Control Point (HACCP)/Pathogen Reduction Act (Anonymous 1996) mandated the monitoring of contamination of carcasses for "generic" *Escherichia coli* as an indicator of contamination with gastrointestinal contents as well as testing for *Salmonella*. Recent data from FSIS monitoring indicate that the proportion of positive swine carcasses that are *Salmonella* positive was 1.66% in 2011, as compared with 8.7% in 1988, prior to implementation of the HACCP/Pathogen Control Act (Anonymous 2011). This indicates significant improvements in control of contamination at harvest and processing.

In the United States, control of *Salmonella* is primarily focused at the processing phase. Sweden since 1961 (Anonymous 1995) and Denmark as of 1993 (Mousing et al. 1997) have established *Salmonella* monitoring and control plans. These plans include routine herd surveillance as well as interventions at processing. There are mandatory intervention requirements on farms if they are identified as having high *Salmonella* prevalence. These interventions can include changes in hygienic

practices, feeding protocols, and pig flow (i.e. moving from continuous to all-in/all-out pig flow). Additionally, farms identified as high prevalence are penalized at harvest with decreased sales values, and product may be required to go into cooked final products. Additionally, high prevalence herds may be harvested at different facilities or as the final groups harvested at the end of the day or shift to prevent cross-contamination.

Despite a multitude of investigations, there is a lack of strong evidence for cost-effective preharvest (on-farm) interventions for *Salmonella* in swine. Review of the literature (Funk and Gebreyes 2004) suggests that a multitude of risk factors are associated with the *Salmonella* status of farms, including hygiene practices, production flows, feed form, and season. There is evidence that efforts at the farm level may be lost through reinfection during lairage at harvest (Hurd et al. 2002). There is an absence of studies that have evaluated *Salmonella* control measures in controlled on-farm trials. Systematic reviews of the literature suggest that vaccination (Denagamage et al. 2007) and feed form (O'Connor et al. 2008) may be important for *Salmonella* control. Unfortunately, both studies concluded that the quality of the reports was insufficient to strongly support these interventions. Mathematical models of *Salmonella* control strategies suggest that the greatest impact on *Salmonella* contamination of carcasses comes from interventions during harvest and processing (Alban and Stärk 2005; Goldbach and Alban 2006). In order to understand the role and efficacy of preharvest *Salmonella* interventions, on-farm controlled clinical trials are needed to evaluate these proposed interventions.

Campylobacter

Campylobacteriosis is considered one of the most common bacterial causes of foodborne disease in the United States (Mead et al. 1999) and in the developed world. Clinical symptoms in humans include gastrointestinal-related symptoms: bloody diarrhea, nausea, fever, headache, and abdominal cramps. Most human cases of campylobacteriosis are self-limiting, therefore requiring no antimicrobial treatment. Chronic sequelae are also possible, most notably Guillain–Barré syndrome. In the United States, most human clinical disease is caused by *Campylobacter jejuni*, although a small percentage is attributed to *Campylobacter coli* (Horrocks et al. 2009).

Campylobacter have been found in the intestinal tract of domestic and wild mammals, poultry, and wild birds and in untreated water (Horrocks et al. 2009). Swine are most commonly infected with *C. coli* (Horrocks et al. 2009). Most infected swine are subclinical. Pigs are thought to be colonized soon after birth, and the prevalence of *Campylobacter* reported in pigs is high. A recent review reported farm prevalence of 100% and individual pig prevalence ranging from 25 to 100%.

Campylobacter contamination of retail pork products has been reported to be low. The US FDA conducts a survey of retail meats and in 2008 reported that 0.3% of pork chops were *Campylobacter* positive (Anonymous 2008). Given the low rate of isolation, the USDA terminated sampling pork chops for *Campylobacter* after 2009.

Control strategies to prevent *Campylobacter* contamination of pork products focus on minimizing fecal contamination of carcasses during slaughter. Blast chilling of carcasses has been shown to reduce *Campylobacter* on swine carcasses better than traditional carcass cooling (Thakur and Gebreyes 2005).

Yersinia enterocolitica

The public health burden of *Yersinia enterocolitica* is estimated at 116,716 annually in the United States (Scallan et al. 2011). It is believed that most *Y. enterocolitica* infections are asymptomatic or at least mild enough to go unreported. The main clinical symptoms are self-limiting fever with diarrhea and/or vomiting. *Y. enterocolitica* clinical illness can also mimic appendicitis, which has resulted in unnecessary surgical interventions.

Yersinia enterocolitica has been recovered from several livestock species, but swine are the only species that have been consistently linked to human infections and are considered the primary reservoir for pathogenic *Y. enterocolitica* (Christensen 1980; Schiemann 1989; Toma and Deidrick 1975).

There have been few studies in the US swine population regarding *Y. enterocolitica*. Estimates of *Y. enterocolitica* prevalence in pigs at harvest are approximately 25%. The farm-level prevalence in the United States is likely high. Funk et al. (1998) found that 92% of market lots had at least one pig contaminated with *Y. enterocolitica*. In a study by Bowman et al. (2007), of the 2349 pigs sampled on 8 US swine farms, 120 (5.1%) tested positive for *Y. enterocolitica*, and of those, 42.5% harbored a virulence gene associated with the ability to cause human illness. At least one positive animal was found on seven of the eight farms. On all positive farms, there was a consistent trend of increasing prevalence as pigs mature, with market-ready pigs and sows having the highest prevalence.

Yersinia enterocolitica is a cold-loving (psychotropic) organism that can grow at refrigeration temperatures. It has the highest prevalence in swine during cooler seasons in temperate regions (Fukushima et al. 1983; Toma and Deidrick 1975; Tsubokura et al. 1976) and is more prevalent in regions with cooler climates (Fredriksson-Ahomaa and Korkeala 2003; Smego et al. 1999). Human disease is also more common during cooler months, but whether this is a factor of its psychotropic nature or human behaviors is not known (Ray et al. 2004).

Specific control measures for *Y. enterocolitica* have been primarily directed at control of contamination of carcasses with fecal contamination. The use of a plastic bag to seal the rectum during slaughter greatly reduced *Y. enterocolitica* contamination of carcasses (Nesbakken et al. 1994).

Shiga toxin-producing *escherichia coli*

Shiga toxin-producing *E. coli* (STEC) represents an estimated prevalence of 265,232 illnesses annually (Scallan et al. 2011) in the United States. Of these 96,534 are estimated to be caused by serogroup O157. Acute symptoms of STEC include severe stomach cramps, diarrhea (sometimes bloody), and vomiting. Of those diagnosed with STEC infection, 5–10% develop a potentially life-threatening complication known as hemolytic uremic syndrome (HUS).

Concerns regarding non-O157 STEC are important for pork production as current evidence suggests that pigs are more likely to be infected with non-O157 STEC as compared with the O157 serogroup.

STEC (stx_{2e} toxin producing) have long been known to be the etiological agent associated with edema disease in swine that cause gastrointestinal and central nervous signs in pigs post weaning. There is a lack of clarity in the literature regarding the role of stx_{2e} STEC strains from swine for human clinical disease (Beutin et al. 2008; Sonntag et al. 2005; Werber et al. 2008). Recent cross-sectional studies in the US swine herd have isolated STEC strains that have the potential to cause human illness (Fratamico et al. 2004). In the study by Fratamico et al. (2004), 31.8% of pigs were STEC positive. Of particular interest was the fact that all isolates were non-O157 serotypes. In fact, a total of 29 STEC serotypes harboring stx_1, stx_2, or stx_{2e} were identified. Tseng et al. (2015) in a descriptive study on one commercial swine farm found that 65% of finishing swine shed STEC at least once and that there was significant diversity of serotypes, with 19 different serotypes identified.

Epidemiologically, pork products are infrequently associated with foodborne illness as compared with food products contaminated with ruminant feces (Bettelheim 2007). Nonetheless, outbreaks and illnesses have been associated with pork products (Bettelheim 2007; Conedera et al. 2007; Honish et al. 2017). Further research is needed to assess pork's contribution to the burden of foodborne illness from STEC.

Trichinella spiralis

Trichinella spiralis is a nematode parasite that encysts in the tissues of a broad range of wild and domestic animals. Transmission is via the consumption of these tissue cysts in raw or undercooked meat products derived from infected animals. While there are eight species of *Trichinella*, only *T. spiralis* is considered important in domestic livestock. Pigs have traditionally been considered the domestic livestock most likely to be infected with *Trichinella* due to past practices such as feeding of uncooked meat containing waste products and outdoor access to wildlife carcasses. These risk factors are largely eliminated in modern confinement production systems.

Symptoms and clinical signs of trichinellosis in humans include eosinophilia, abdominal pain, fever, periorbital edema, myalgia, and, rarely, death (Kennedy et al. 2009). In the United States, reported trichinellosis cases have fallen from 393 during 1947–1952 to 15 annual case compatible reports in the period from 2008 to 2012 (Wilson et al. 2015). This decline in human cases has mirrored the decline in prevalence of *Trichinella* in commercial pork products that has resulted from the move to confinement rearing of pigs (Gamble and Bush 1999). The majority of trichinellosis cases in the United States are currently linked to consumption of wild game, especially bear (Wilson et al. 2015).

Cooking, curing, and freezing are used to inactivate *T. spiralis* in pork. *Trichinella* larvae can be killed at temperatures as low as 55 °C; however, uneven heat distribution should be taken into account during the cooking process to assure that all portions of the meat reach the proper temperature. Freezing remains effective in killing *Trichinella* in pork since freeze-resistant species of *Trichinella* in the United States have low infectivity and persistence in pigs (Kapel and Gamble 2000).

In the United States the NAHMS conducts a statistically based survey of pork production every 5–6 years. Since 1990 serology for *Trichinella* has been conducted on a portion of animals in the survey. The seroprevalence has fallen from 0.16% in 1990 to 0.013% in 1995, and no positive samples identified in the 2000 and 2006 surveys. This virtual elimination of *Trichinella* in the commercial pig industry has been accompanied by an increase in the number of production sites reporting adherence to good production practices that reduce the risk of *Trichinella* infection (Hill, personal communication). However, the move to non-confinement production systems may signal a potential increasing risk for human cases of trichinellosis. Gebreyes et al. (2008) reported 2 positive samples from 324 animals tested in niche-market, outdoor, antibiotic-free herds compared with 0 positive samples from 292 animals sampled in conventional US herds.

While individual carcass testing has historically been utilized by governments to assure freedom from *Trichinella*, international standard setting agencies for animal health and food safety (OIE and Codex Alimentarius, Anonymous 2015c) have published criteria to develop and maintain negligible risk compartments through consideration of a combination of historical data, serology, and audits of premises supplying animals.

Toxoplasma gondii

While felines are the definitive host of the protozoan parasite *Toxoplasma gondii*, a wide range of species have been shown to be susceptible to infection by *T. gondii*. Humans can become infected with *T. gondii* through three potential routes: exposure to oocysts shed in cat feces, consumption of under- or uncooked meat from infected animals, or congenitally when infection occurs in a susceptible pregnant woman. *T. gondii* is a public health concern, and in the United States it is estimated that 500–5000 newborns are born congenitally infected each year and that 1.26 million people are affected by ocular toxoplasmosis (Jones et al. 2009). Scallan et al. (2011) estimated that *T. gondii* was the second leading cause of foodborne illness deaths in the United States and the third leading cause of foodborne illness hospitalizations. This is largely due to reactivation of bradyzoites in immunocompromised patients.

Pigs become infected with *T. gondii* when they consume feedstuffs or other substances contaminated with cat feces containing infective oocysts. They can also be infected by consuming carcasses of rodents and other wildlife that have *T. gondii* muscle cysts or through cannibalism of infected swine carcasses. Traditionally, pork has been considered a source of human infection due to waste feeding and other dietary habits of swine that are largely eliminated by modern pork production methods.

Nationwide surveys of the US swine herd are conducted every 5–6 years by the USDA as part of NAHMS. In 1990 only sows were tested and 20% were seropositive, in 1995 15% of sows and 3.2% of finishers were seropositive, in 2000 6% of sows and 0.9% of finishers were seropositive, and in 2006, when only finishers were sampled, 2.6% were seropositive (Hill et al. 2009). It should be noted that the serological method changed in 2006 from the MAT to an ELISA that makes direct comparison of these results difficult. In 2012, utilizing the same laboratory methods as were used in 2006, seropositivity in finishers was 0.8% (Bush, personal communication). The NAHMS 2012 results are similar to what was observed by McKean et al. (2003) in 2002 who found a 0.75% seroprevalence in Midwestern market swine and Gebreyes et al. (2008) who found a 1.1% seroprevalence in confined pigs in three states.

The NAHMS surveys also gathered information on production practices that were considered to be potential risk factors for *Toxoplasma*, and analysis of that data found that farms where pigs were not housed in total confinement were 7.7 times more likely to be positive than total confinement farms (Hill et al. 2009). Additional risk factors included not using baits/poisons/traps for rodent control and certain carcass disposal techniques (Hill et al. 2009). Similar findings were reported by Gebreyes et al. (2008) with extensively raised pigs almost seven times more likely to be seropositive than pigs in confined herds. Breeding sites in NAHMS 2012 that utilized cats for rodent control were almost 70% positive compared with 39.1% for sites that did not use cats (Bush, personal communication).

It is uncertain what percentage of human infection is due to exposure to cat feces versus consumption of infected meat. A cross-sectional seroprevalence study compared Seventh-Day Adventist (non-meat eaters) with a control group (meat eaters) in one region of Maryland and found that seroprevalence was approximately 50% less for the non-meat-eating group (Roghmann et al. 1999). However, concerns with that study include that the seroprevalence of the control group (31%) was approximately twice the national average seroprevalence in the United States, while the non-meat-eating group had a similar seroprevalence to the national average (Jones et al. 2003). Additionally, the control group was recruited from commercial fishermen, seafood processing plant workers, and visitors to a seafood festival. This is important since bivalves such as oysters and clams can concentrate oocysts and consumption of raw oysters, clams, or mussels has been shown to be a risk factor for *T. gondii* seropositivity (Jones et al. 2009).

Retail meat sampled from 28 major geographical areas across the United States found that viable tissue cysts were isolated from 0.38% of pork samples and 0.57% of pork samples had antibodies to *T. gondii*. A case-control study of US patients with recent *T. gondii* infections identified eating raw ground beef, rare lamb, or locally produced cured, dried, or smoked meat, working with meat, drinking unpasteurized goat's milk, and having three or more kittens as significant risk factors (Jones et al. 2009). Consumption of pork was not a significant risk factor in that study; however, the move to niche pork from non-confined production systems may increase the risk of exposure to *T. gondii* in the United States.

Taenia solium

Taenia solium is commonly called the pork tapeworm, although the definitive host is actually humans. Swine are the natural intermediate host for the parasite. Humans acquire taeniosis by eating undercooked pork that contains cysticerci, the larval form of *T. solium*. The adult worm is found in the intestine of infected humans, and infective eggs are regularly shed in the feces. In endemic areas inadequate sanitation allows pigs access to human feces containing infective *Taenia* eggs. Upon ingestion the eggs hatch in the pig's intestine and migrate throughout the body preferentially encysting in the striated or cardiac muscle (Acha and Szyfres 2003a).

The main public health concern arises when humans ingest the eggs shed in the feces of infected humans. This can occur through fecal contamination of water or food

or autoinoculation. In this case, the *Taenia* larva migrates throughout the human as it would in the pig and forms cysticerci. In humans, the principal site of migration is the central nervous system, resulting in neurocysticercosis (NCC) (Carabin et al. 2005a).

The World Health Organization has designated cysticercosis a "major neglected disease" (Savioli and Daumerie 2010). NCC is reported to be one of the main causes of preventable epilepsy in low income countries. Coyle et al. (2012) estimate up to 7.65 million people have epilepsy due to NCC in Latin America, India, China, and Africa. Carabin et al. (2005b) estimated that the costs for medical care and lost productivity due to NCC in India were $634 million annually. It should be noted that more than 90% of Indians are either Muslim or Hindu and do not consume pork. However, the inadequate sanitation results in person-to-person transmission and allows for access of pigs to human feces completing the parasite life cycle.

In the United States cysticerci are identified in very few hog carcasses. In 1998, only 1 carcass of more than 75 million inspected by the USDA was condemned due to visible cysticerci. Although infection in pigs is rare, it is estimated that 18,584 hospitalizations for NCC with associated hospital charges totaling >$908 million occurred in the United States between 2003 and 2012 (O'Neal and Flecker 2015). Nearly 75% of the hospitalized patients were Hispanic, a growing immigrant population from areas of endemic cysticercosis.

Non-foodborne zoonoses

Many zoonotic diseases are a risk from direct contact with swine. Although many of the previously discussed foodborne diseases can be transmitted via direct contact, the following are those that are primarily transmitted via methods that do not include a food vector.

Methicillin-resistant *Staphylococcus aureus* (MRSA)

Staphylococcus aureus is a common organism found on the skin and mucous membranes of animals and humans. It can function as an opportunistic pathogen causing superficial and/or invasive infections. A subset of *S. aureus* are resistant to methicillin with this resistance encoded by the *mec*A gene, which codes for penicillin-binding protein 2a that confers resistance to all beta-lactam antimicrobials (Kluytmans 2010). Approximately 20–30% of healthy people in developed countries harbor *S. aureus* in the nasal cavity (Sivaraman et al. 2009), and it was estimated in the United States that 18.6% of people are colonized with *S. aureus* and 1.5% with methicillin-resistant *Staphylococcus aureus* (MRSA) (Gorowitz et al. 2008).

MRSA emerged as a health-care-associated infection in the 1960s, and in the late 1990s community-acquired MRSA was recognized (Naimi et al. 2003). In 2004 a new MRSA strain was identified in Holland that was resistant to digestion with the restriction endonuclease *Sma*1 when typing with PFGE was attempted and was associated with contact with pigs (Voss et al. 2005). This strain belongs to the multilocus sequence type ST398. MRSA ST398 is usually resistant to tetracycline and generally is resistant to a narrower range of other antimicrobials than most health-care-associated MRSA strains. MRSA ST398 has been referred to as the livestock-associated strain and has been found in several other food and companion animal species. Since the discovery of MRSA in Dutch swine herds, numerous studies have been conducted, and the presence of MRSA in pigs, pork producers, and veterinarians has been reported globally. This has led to the recognition that additional MLST sequence types of *S. aureus* are associated with pigs, particularly ST9 in Asia and ST5 in North America (Chuang and Huang 2015; Sun et al. 2015).

The European Food Safety Authority (EFSA) conducted a Europe-wide survey of swine farms in 2008, and 17 of 24 member states identified positive farms with a prevalence of 22.8% (EFSA 2009a). Positive farms that raised breeding stock were identified in 12 of 24 member states with a prevalence of 14% (range 0–46%), and 16 of 24 member states had MRSA-positive farms raising market hogs with a prevalence of 26.9% (range 0–51%) (EFSA 2009b). ST398 was the predominant type isolated with a mean of 1.4% of isolates being non-ST398 (EFSA 2009b). The first North American reports of MRSA in pigs were in 2008 when Khanna et al. (2008) reported that 9 of 20 farms and 24.9% of pigs were positive with the predominate spa type fitting into the clonal complex 398. In the United States, one published paper reported high levels of colonization in pigs (70%) within one production system, while another production system was negative for MRSA ST398 (Smith et al. 2009c). Subsequent studies in the United States have documented the presence of ST398, ST5, and ST9 MRSA in US swine, but current data indicate herd prevalence on the order of 10% or less (Smith et al. 2013; Sun et al. 2015).

Risk factors for MRSA-positive status of swine/swine farms include animal source, herd size, age/time in herd, transport and lairage, and perhaps others (Broens et al. 2009, 2010). The role of antimicrobial use in MRSA status is uncertain, with some studies suggesting an association and others not demonstrating a significant association (Broens et al. 2010). It has been suggested that due to the tetracycline resistance observed in ST398, tetracycline use contributes to its presence in swine herds. Aarestrup et al. (2009) analyzed methicillin-sensitive *Staphylococcus*

aureus (MSSA) ST398 and MRSA ST398 isolates from Danish swine. They found that a similar percentage of both MRSA and MSSA were resistant to tetracycline; however, 74% of MRSA ST398 were resistant to zinc chloride, while none of the MSSA ST398 showed zinc resistance. They concluded that use of non-antibiotic zinc compounds to prevent post weaning diarrhea in piglets may contribute to the emergence of MRSA in Danish swine herds.

Swine workers were sampled in several studies, and those working in facilities with positive pigs have higher than expected rates of nasal colonization, although there is little evidence to indicate that they have higher than expected rates of MRSA clinical disease. Veterinarians that work with all species of animals also have been reported to have higher rates of colonization with MRSA than the general public. Invasive illness with ST398 MRSA has been reported, albeit rarely, and published studies often make it difficult to determine if human cases are nasal carriers or indeed have clinical infection. It has been concluded in Europe that the potential for humans colonized with ST398 to contribute to the spread of MRSA in hospitals is less than for the healthcare-associated MRSA strains.

MRSA ST398, as well as other strains of MRSA, has been isolated from pork and other meats globally (de Boer et al. 2009; Kluytmans 2010; van Loo et al. 2007; Weese et al. 2010a). Public health agencies in the United States and Europe have not found evidence that contaminated meats contribute to an increased risk of MRSA (Centers for Disease Control and Prevention 2008). Weese et al. (2010a) quantified the amount of bacteria in positive samples purchased at retail stores throughout Canada and found that 37% of positive samples were below the detection threshold for quantification and <100 CFU per gram were found in most quantifiable samples.

Streptococcus suis

Streptococcus suis is common in domestic swine worldwide. Clinical signs in pigs include central nervous system signs (head tilt and paddling), arthritis, and polyserositis. A recent review and meta-analysis (van Samkar et al. 2015) identified 913 patients with *S. suis* meningitis included in 24 studies between 1980 and 2015. The mean age was 49 years and 82% of patients were male. Sixty-one percent had exposure to pigs or pork. Fever, headache, and neck stiffness were the most common symptoms, and 78 of 384 patients (20%) had a skin injury in the presence of pig/pork contact. The case fatality rate was 2.9%, and hearing loss was a common sequel occurring in 259 of 489 patients (53%).

In 2005 over 200 human cases of *S. suis* were reported in China. Human cases were largely associated with butchering and handling uncooked meat products from clinically ill animals (Gottschalk and Segura 2007; Yu et al. 2006). Twenty-eight percent of the Chinese cases of 2005 suffered a toxic shock-like syndrome (Yu et al. 2006). Investigation of the Chinese outbreak revealed that most cases had close contact with sick or dead pigs and many were involved in the slaughter or butchering of the animals (Gottschalk and Segura 2007; Yu et al. 2006). Furthermore, the investigation also identified that the human cases were caused by one clone of *S. suis* (Gottschalk and Segura 2007). A pathogenicity island has been found in the genome of isolates from the Chinese cases, but its exact role and function in *S. suis* virulence are poorly understood (Chen et al. 2007).

Clostridium difficile

The role of *Clostridium difficile* as a zoonotic agent from pigs is unknown. *C. difficile* is a gram-positive spore-forming anaerobe that is an important cause of enteric disease in humans. It is one of the most commonly diagnosed causes of hospital- and antibiotic-associated diarrhea in people and is emerging as a community-associated pathogen. *C. difficile* has also been isolated from numerous animal species (Gould and Limbago 2010; Jhung et al. 2008), meats (Norman et al. 2009; Songer et al. 2007; Weese et al. 2009), vegetables (Bakri 2009), hospital, barn and household environments (Baverud et al. 2003; Weese 2010), water (al Saif and Brazier 1996), pets (Borriello et al. 1983; O'Neill et al. 1993; Weese et al. 2010b), and healthy humans (McDonald et al. 2007; Rupnik 2010).

There are various schemes utilized to type *C. difficile* including PCR ribotyping, PFGE, and toxinotyping, and strains are often described using classifications from more than one of the different methods to improve discrimination. There are two strains of *C. difficile* that are of special interest in the apparently changing epidemiology of *C. difficile* in humans: a toxinotype III strain designated 027/NAP1 (NAP1) and a toxinotype V strain designated ribotype O78. NAP1 has emerged as an important hospital-acquired infection with increased incidence and severity that is thought to be influenced by the use of fluoroquinolone antimicrobials (McDonald et al. 2005). The second strain, ribotype 078, is an important strain associated with the increased recognition of community-associated *C. difficile* infection. Both of these strains, as well as others, have also been isolated from animal and food sources. The overlap of strain types between humans, animals, and meat has led some to hypothesize that animals may be an important source of *C. difficile* human infections. However, there are three possible explanations for this overlap that must be considered: (1) a common source causing infections in both humans and animals, (2) human-to-animal transmission, or (3) animal-to-human transmission.

Clostridium difficile colitis is not uncommonly diagnosed in neonatal pigs (Songer 2004), although diagnosis is complicated as results of commercial toxin tests in feces often poorly correlate with culture results (Rupnik 2010; Songer 2004). Several studies have examined the prevalence of *C. difficile* shedding among pigs in North America and globally. Methodological differences in sampling and isolation make comparison of apparent prevalence between studies impractical. If fecal shedding is considered as a source for contamination of pork that could potentially serve as a public health threat, it is important to note that prevalence of fecal shedding in piglets is higher than in adult swine. Weese et al. (2010c) noted that there was a significant decrease in colonization over time with 74% of piglets on day 2, 56% on day 7, 40% on day 30, 23% on day 44, and 3.7% shedding on day 62. This is similar to what Norman et al. (2009) observed with 50% of nursing pigs and only 3.9% of grower/finisher pigs with positive fecal cultures as well as Gebreyes (2009) who found 74.5% of pre-weaned piglets, 0.45% of nursery pigs, and 0% of finishing pigs to be shedding. The majority of the isolates in these studies were toxinotype V although other types were also isolated.

Studies of retail meats, including pork, have demonstrated the presence of *C. difficile*. Techniques vary between studies, so it is difficult to compare the prevalence between studies. Most of the studies also used enhancement steps that make enumeration of *C. difficile* spores in these products impossible. Weese et al. (2009) found that 71% of 14 ground pork samples were positive by enrichment culture only. Of the 4 that were positive by direct culture, 20 spores/g were present in 3, while 60 spores/g were present in 1. This would indicate that while *C. difficile* contamination of meat is not uncommon, levels of contamination are low. The infectious dose of *C. difficile* in either healthy or compromised humans is not known.

Influenza A viruses

Influenza A virus is an RNA virus, and its genome is composed of 8 separate segments that encode up to 11 proteins. Influenza is a common pathogen in numerous species, and interspecies transmission has been documented. Interspecies transmission provides the virus an opportunity to reassort, or exchange gene segments, when two or more strains infect a cell at the same time. The 2009 pandemic H1N1 virus was called a "quadruple-reassortant" virus because it contained neuraminidase (NA) and matrix (M) gene segments from Eurasian swine influenza viruses combined with triple-reassortant proteins of North American swine influenza viruses human-origin polymerase B1 (PB1), avian-origin polymerase B2 (PB2) and polymerase A (PA), and classical swine-origin hemagglutinin (HA), nucleoprotein (NP), and nonstructural (NS) genes. The evolutionary analysis of the 2009 pandemic H1N1 shows that the generation of this strain was not likely a recent event (Smith et al. 2009a). In fact, in order to facilitate human-to-human spread, it probably adapted to the human host through secondary reassortments in humans (Ding et al. 2009). Smith et al. (2009b) raised the possibility that the 1918, 1957, and 1968 pandemic strains were generated through a series of multiple reassortment events and emerged over a period of years prior to the pandemic recognition. They also noted that each of these strains was produced by reassortment of a previously circulating human virus and at least one virus of animal origin (avian or mammalian) (Smith et al. 2009b).

There were a total of 37 civilian human cases of zoonotic swine influenza virus infection (now referred to as variant influenza A virus) reported between 1958 and 2005 (Meyers et al. 2007; Van Reeth 2007). A majority of these infections were with classical swine H1N1 viruses, and the total does not include the Fort Dix cases in 1976 that resulted in 1 death and up to 230 infected soldiers (Meyers et al. 2007; Van Reeth 2007). Since 2005, over 400 cases of variant influenza A infections in humans have been reported in the United States (Anonymous 2017b). Persons identified as infected with the variant influenza A virus typically had close contact with pigs, and 8 of 11 cases had contact with pigs and often were children (Anonymous 2017b). Antibodies to swine influenza may be present in up to 23% of humans with occupational exposure to pigs, although the presence of antibodies is also associated with other factors such as age and previous influenza vaccination (Van Reeth 2007). It is not clear if the seropositivity of this population relates to exposure or clinical illness.

Hepatitis E virus

Hepatitis E virus (HEV) is the leading cause of enterically transmitted sporadic non-A and non-B hepatitis in tropical and subtropical countries. Inadequate sanitation had led waterborne HEV epidemics in these countries (Meng 2000). Mortality due to HEV infection is usually low (<1%) except in pregnant women where mortality in Asia and Africa approached 20%. While human cases of HEV are only sporadically reported in the United States and other industrialized countries, serosurveys indicate a larger proportion of the population has been exposed to the virus (Meng et al. 2002). Swine workers in the United States and Taiwan have been shown to be at increased risk of seroconversion, but history of clinical disease among these workers is largely lacking (Hsieh et al. 1999; Meng et al. 2002; Withers et al. 2002). Those working with young pigs on farms are at higher risk of infection than workers (Geng et al. 2011).

Meng et al. (1997) first reported an HEV from swine that was closely related to, but distinct from, human HEV isolates. An HEV was subsequently identified in swine in Taiwan that was distinct from the US swine

strain but similar to the human strains in Taiwan (Hsieh et al. 1999). Generally, HEV strains identified are genetically related, and molecular studies of human and swine HEV isolates globally found that swine and human isolates from the same geographic region are more similar to each other than they are to swine or human HEV isolates from other regions (Clemente-Casares et al. 2003; Meng 2003). Swine HEV appears to be ubiquitous with incidence of swine HEV antibodies in swine herds globally varying by geographical region and age of animals sampled, ranging from 4.1 to 79% (Smith 2001). Anti-HEV antibodies have also been identified in rodents, chickens, dogs, cattle, sheep, and goats (Meng 2000).

In 2003 in Japan, the first direct evidence of zoonotic transmission of HEV was documented in two separate incidents involving human consumption of undercooked pork liver and raw sika deer meat (Yazaki et al. 2003). HEV RNA was identified in 1.9% of raw pork livers in Japanese grocery stores and in 14 of 127 pork livers in US grocery stores (Feagins et al. 2007; Yazaki et al. 2003). While sporadic cases such as those in Japan and France provide strong evidence that HEV is zoonotic, it is uncertain what the contribution of swine HEV is to the human burden of illness due to HEV. In a study of young health adults at a university in the United States anti-HEV seroprevalence was 6.27% with odds of a subject who answered they "always" or "occasionally" consumed undercooked meat being positive for anti-HEV antibodies were 12.9 times the odds of those who answered "never" (Cossaboom et al 2016). The same study identified HEV RNA in 3 of 12 packages of chitterlings purchased in grocery stores in Southwest Virginia but not in the other 116 packages of non-liver pork products. Figatellu (raw pork liver sausage) has been implicated as the source of sporadic cases of HEV in France, and HEV-3 RNA has been recovered from supermarket-purchased figatelli samples, as well as anti-HEV antibodies detected in 7 of 13 humans consuming raw figatelli (Colson et al. 2010).

Meng et al. (1999) surveyed swine in four countries, two with a high prevalence of human HEV cases and two with a low prevalence of human cases. They found that swine HEV was endemic in all four countries regardless of the prevalence of human cases. Human exposure (as measured by antibody response) to HEV in both developed and developing countries is not uncommon, while clinical illness is rare in developed countries.

Japanese encephalitis

Even though Japanese encephalitis virus (JEV) in humans usually results in unapparent infections, it is the most frequent cause of mosquito-borne encephalitis globally (Oya and Kurance 2007; van den Hurk et al. 2009; Weaver and Reisen 2010). The distribution of JEV has expanded throughout East, Southeast, and South Asia and into the South Pacific (Oya and Kurance 2007; van den Hurk et al. 2009) and has been associated with increases in human population, irrigated rice production, and pig production.

Wading birds are considered the primary endemic hosts of JEV; however, pigs are important in the JEV transmission cycle as they are the only known mammals to fulfill the criteria as an amplifying host for the virus (van den Hurk et al. 2009). High levels of JEV infection in pigs often precede human epidemics (Acha and Szyfres 2003b), and sentinel pigs provide a useful system for estimating JEV risk in humans (Oya and Kurance 2007). In some regions of Asia, increasing pig populations have been linked to increasing human infections, but in Japan that trend was reversed. During the last 40 years, the number of pigs produced in Japan has increased, while the number of farms has decreased. As more pigs are raised in modern facilities that are segregated from residential areas, human cases of JEV have declined, demonstrating that pig farming can be maintained without increasing the transmission of JEV to humans (Oya and Kurance 2007). An Australian study (van den Hurk et al. 2008) determined that relocating domestic pigs did not prevent virus in mosquito populations.

Nipah virus

Nipah virus (NV) was first identified in 1999 in Malaysia during an outbreak of respiratory illness and encephalitis in pigs accompanied by an often fatal encephalitis in people with close contact with pigs as well as abattoir workers (Tee et al. 2008) and military personnel involved in culling infected herds (Ali et al. 2001). There were also reports of human-to-human transmission of NV among health-care workers (Tee et al. 2008). NV has also been diagnosed as the cause of fatal encephalitis cases in people without close contact with pigs in Bangladesh during the winters of 2001, 2003, and 2004 (Bellini et al. 2005).

NV belongs to the genus *Henipavirus*, in the family *Paramyxoviridae*, and is closely related to the Hendra virus of equines (Bellini et al. 2005). Fruit-eating bats (*Pteropus* and *Chiroptera* species) are considered the natural reservoir for NV, and humans are infected either through contact with an intermediate host such as pigs or the exposure to infected bats, material/foods contaminated by bats, or direct human-to-human transmission (Bellini et al. 2005; Tee et al. 2008). The implicated host species of bats is found across Southeast and South Asia (Tee et al. 2008). Outbreaks in pigs have not been observed since the 1998–1999 outbreak in Malaysia.

Reston ebolavirus

Reston ebolavirus (REBOV) is the only member of the filovirus family that is thought to be pathogenic in Asian monkeys but not in African monkeys or humans (Morikawa et al. 2007). Other filoviruses are associated with acute fatal hemorrhagic disease of humans or nonhuman primates.

In July 2008 REBOV was identified in swine diagnostic samples from the Philippines that were being tested at the USDA Foreign Animal Disease Diagnostic Laboratory. These samples were associated with clinically affected animals thought to be affected with highly pathogenic porcine reproductive and respiratory syndrome virus (PRRSV). REBOV was only found in samples that were also positive for PRRSV. Six humans of 141 with swine exposure in the Philippines had positive IgG titers to REBOV, but no human illness was detected (Barrette et al. 2009). There was no evidence of any involvement of swine in the 2014–2016 Ebola virus outbreak (caused by *Zaire ebolavirus*) in West Africa.

Antimicrobial resistance

Antimicrobial resistance (AR) in bacterial pathogens is a global public health concern. It is clear that human consumption of antimicrobials provides selection pressure for AR infections in humans. The scientific and political debate is focused on the contribution of animal antimicrobial use to the burden of AR infections in humans.

Evidence of the contribution of antimicrobial use in animals to AR infections in humans includes foodborne pathogens (e.g. multidrug-resistant (MDR) *Salmonella* Newport and fluoroquinolone-resistant *C. jejuni*) as well as emergence of community-acquired commensal infections associated with poultry and swine (e.g. vancomycin-resistant *Enterococcus* spp.) (Aarestrup et al. 2000). Because AR genes can be horizontally transmitted between bacteria, nonpathogenic bacteria may serve as a reservoir of AR. AR bacteria zoonoses have led to the ban of subtherapeutic antimicrobial use in the European Union (Casewell et al. 2003) and the removal of specific uses of fluoroquinolones in chickens in the United States (Department of Health and Human Services, US Food and Drug Administration 2005). In 2017, the US FDA implemented the changes outlined in Guidance #213 that eliminated the use of medically important antimicrobials for growth promotion and required a veterinary order or prescription for the remaining uses of those same antimicrobials (Anonymous 2017a).

The evidence regarding the impact of antimicrobial use in animals and the ultimate impact on human health is mixed. For example, in Denmark, the removal of avoparcin as a growth promotant for poultry and swine has decreased the prevalence of vancomycin-resistant *Enterococcus* (Anonymous 2009c). Yet, there was increased use of antimicrobials for therapeutic purposes in swine following the ban and certainly mixed results regarding AR changes in some pathogens as a result (e.g. *Salmonella*). A systematic review (Young et al. 2009) comparing organic production with antimicrobial-using production systems found that there was an association with antimicrobial use and fluoroquinolone resistance in *Campylobacter* from poultry and generally increased AR in bacteria isolated from other species, yet AR bacteria were also isolated from organically produced animals and animal products. Unintended consequences to food safety as a result of impaired animal health from subtherapeutic antimicrobial removal have been demonstrated (Singer et al. 2007). The use of macrolides in food animals has been suggested to present an extremely low probability of human treatment failure (Hurd et al. 2004).

A best practice for control of emergence of AR bacteria for both human and animal health is the judicious use of antimicrobials. Judicious use guidelines for antimicrobials have been developed (Anonymous 2009d).

Certification programs

There are certification programs within the United States that focus on production practices that will help to assure safe and wholesome pork products. All of these programs have some level of third-party oversight that certifies the education of, or adherence to, the production practices.

Pork Quality Assurance Plus

The Pork Quality Assurance (PQA) program was originally introduced in 1989 to address concerns over violative drug residues in pork. Subsequent revisions widened the scope of the program to address a broader range of physical, chemical, and microbiological hazards. The PQA Plus, an expanded version of the original PQA, was introduced by the Pork Checkoff in 2007. PQA Plus was developed as a continuous improvement program, retaining the original focus with added emphasis on the responsible use of antimicrobials in pork production, animal caretaker training, and animal care and well-being. Currently the PQA Plus program also addresses workplace safety, environment, and community. PQA Plus has been well accepted by the US meat packers, and most of them require either certification or site assessment status of the producers who supply them with pigs.

Safe Feed/Safe Food

The American Feed Industry Association (AFIA) established the Safe Feed/Safe Food Certification Program, which now operates independently of AFIA. The Safe Feed/Safe Food Certification Program is a voluntary, third-party-certified initiative aimed at feed mills and feed- and ingredient-related facilities in the United States and Canada. The program has established standards addressing documentation, training, facility planning and control, manufacturing and processing, monitoring devices, infrastructure, ingredient purchasing, traceability, and control of nonconforming products.

Special Considerations for Show and Pet Pigs

Amy L. Woods, Valarie V. Tynes, and Kristie Mozzachio

Show pigs

Size and scope of the show pig industry

The show pig sector is often overlooked by many in the swine industry since the overall numbers of animals are much fewer than the commercial swine production industry. However, the show pig industry is a significant business when the number of people and amount of money invested are considered. It is difficult to estimate the exact size and monetary value of the US show pig industry.

In February 2017, there were nearly 31,500 youth certified in the National Pork Board's (NPB) Youth Pork Quality Assurance program (NPB, personal communication, February 28, 2017). All of these youth are in the swine exhibition industry, as many shows require this certification for kids to show and sell their projects. There are nearly 14,000 youth involved as members of the National Junior Swine Association (NJSA), the youth sector of the National Swine Registry (NSR), which represents youth involved in showing Duroc, Hampshire, Landrace, and Yorkshire breeds at national shows (NJSA, personal communication, February 28, 2017). In addition, there are over 4200 youth members of Team Purebred, which represents youth exhibiting Berkshire, Chester White, Poland, Spotted, Hereford, or Tamworth breeds at national shows (Team Purebred, personal communication, March 1, 2017). These membership numbers have grown tremendously over the past few years, as more people become involved in the show pig industry. As seen in Figure 13.1, the number of pigs exhibited at these select national shows has grown tremendously over the past few years.

Ninety-nine percent of the NSR senior members are involved in production of animals for exhibition (NSR, personal communication, February 28, 2017). It is estimated that over 1 million pigs are raised for exhibition, or approximately 1% of the total swine industry in the United States (Warren Beeler, personal communication, February 28, 2017). However, that 1% has a big economic impact when considering the dollars spent not only on pigs, but specialized show feeds and supplements, show supplies, show pig semen, bedding, facilities, and travel costs for various shows. It has been estimated that this 1% of the swine population is a half-billion-dollar industry (Warren Beeler, personal communication, February 28, 2017).

With the growth of the show pig industry, a considerable "niche" market has developed for veterinary products and services. Because of the unique nature of show pigs, an awareness of some of the special considerations of the industry will allow practitioners to better address the needs of the pigs and the clients. There are different types of show pig clients – breeders that produce their own pigs to show and sell for exhibition projects. There are also those that purchase young pigs (typically purchased around 2 months of age) and only raise pigs to market size for exhibition. Some clients may be casual show pig producers with a goal of just having a project to show at a local fair. Others are extremely serious about the show pig industry and spend considerable time, money, and attention on their show pigs. Another type of show pig clients is the boar stud owners that market semen specifically to the show pig customer.

To be able to better serve show pig clients, a veterinarian should understand the show pig industry. First of all, it is important to realize that these individual animals can be extremely valuable – up to tens of thousands of dollars. Secondly, these animals are bred and raised primarily for exhibition, not necessarily for pork production. Thirdly, the same pigs may frequently be shown at various locations during a show season. The show season will vary depending on the geographical area of the United States, but typically lasts around 3 months. Many of the more serious show pig clients will participate in a jackpot show circuit, in which the pigs earn points and money for the placing they receive at numerous shows.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

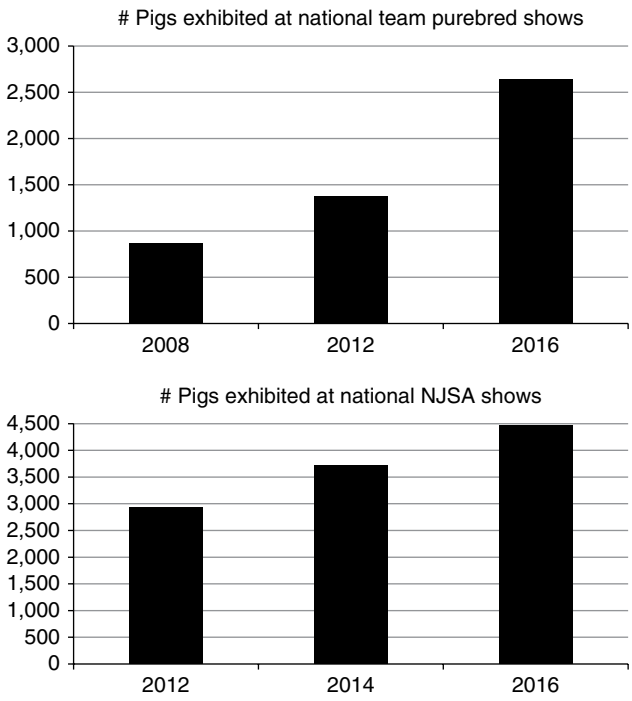

Figure 13.1 The recent growth of the show pig industry can be observed in these examples of the total numbers of pigs exhibited at these select national shows annually (NJSA and Team Purebred, personal communication, March 1, 2017).

Therefore, these pigs may be traveling to multiple shows per month throughout the show season. A survey conducted in 2014 of Midwest swine exhibitors indicated that an individual may exhibit swine at up to 50 shows in a single year (Bliss et al. 2017). At the culmination of the show season, pigs may be exhibited at a terminal show and go directly to harvest. Alternatively, many animals (particularly breeding animals) return home or are sold to another farm after the show season. This show schedule creates unique biosecurity and health concerns.

Biosecurity

As previously mentioned, show pigs are exposed to many other pigs from various sources when they are sold at auction and exhibited at shows. Figure 13.2 depicts the major events and opportunities for disease exposure in the life of a show pig. Some of the larger shows, such as Houston Livestock Show and World Pork Expo, will have 2000–3000 head of pigs on-site for a single show (NSR and Houston Livestock Show, personal communication, April 1, 2017). There is obviously a lot of opportunity for disease transmission in these situations.

When selecting a show pig to purchase, often health status or source is not considered. Pigs are purchased according to their pedigree and appearance. Veterinarians need to advise clients on proper biosecurity measures and the risks involved when comingling pigs from various sources. Prophylactic medication may also occur when purchasing these pigs and mixing them together for the first time, as respiratory and enteric disease is common in these situations. Veterinarians must also educate clients about taking proper biosecurity measures when bringing animals back home after a show. A survey conducted after the 2002 Indiana State Fair (at the end of the Indiana show season) indicated that nearly half of the pigs exhibited went back home or to another farm after the fair (Amass et al. 2004). Often there are no isolation or testing procedures in place for these animals returning from a show.

Veterinarians must be aware of the state and federal regulations regarding movement, identification, and exhibition of swine in their area since show pigs travel frequently, often crossing state lines. Veterinarians may also be hired by specific pig sales and shows to ensure compliance of all participants with any state and federal regulations regarding identification, certificates of veterinary inspection, and animal health. Since show pigs are primarily identified by ear notches, veterinarians must be proficient in reading standard ear notches to meet these regulations.

Zoonotic implications

Zoonotic disease potential is important in commercial pork production, but with show pigs there is increased risk due to the closer interaction between show pigs and their caretakers. Those caretakers are also children, which are more likely immunocompromised than adults working in commercial swine operations. In addition, members of the public can closely interface with animals at local fairs and exhibitions. Shiga-toxigenic *Escherichia coli* O157:H7 has been demonstrated to be present in cattle, pig, sheep, and goat feces at public fairs (Keen et al. 2006), and influenza A virus (IAV) infections have been documented in people with no swine exposure except for visiting a local fair in Wisconsin (Wells et al. 1991) and Ohio (Vincent et al. 2009). An outbreak of IAV at fairs occurred in Indiana and Ohio in 2012, resulting in numerous cases of IAV-positive pigs and humans (Boman et al. 2014). Bliss et al. (2016) found that IAV-positive pigs entered agricultural fairs in Indiana and Ohio at 5 out of the 9 (55%) fairs tested. Of those with IAV-positive pigs, prevalence ranged from 0.2 to 10.3% of incoming pigs testing positive via virus isolation on snout wipe samples. This virus can then spread rapidly through other pigs at the fair due to the close penning proximity and contacts with fomites such as scales, taggers, wash pens, etc.

Veterinarians must be available to quickly identify and treat and/or recommend removal of sick animals from a fair to minimize the zoonotic disease transmission risk. Veterinarians should also educate clients as well as the

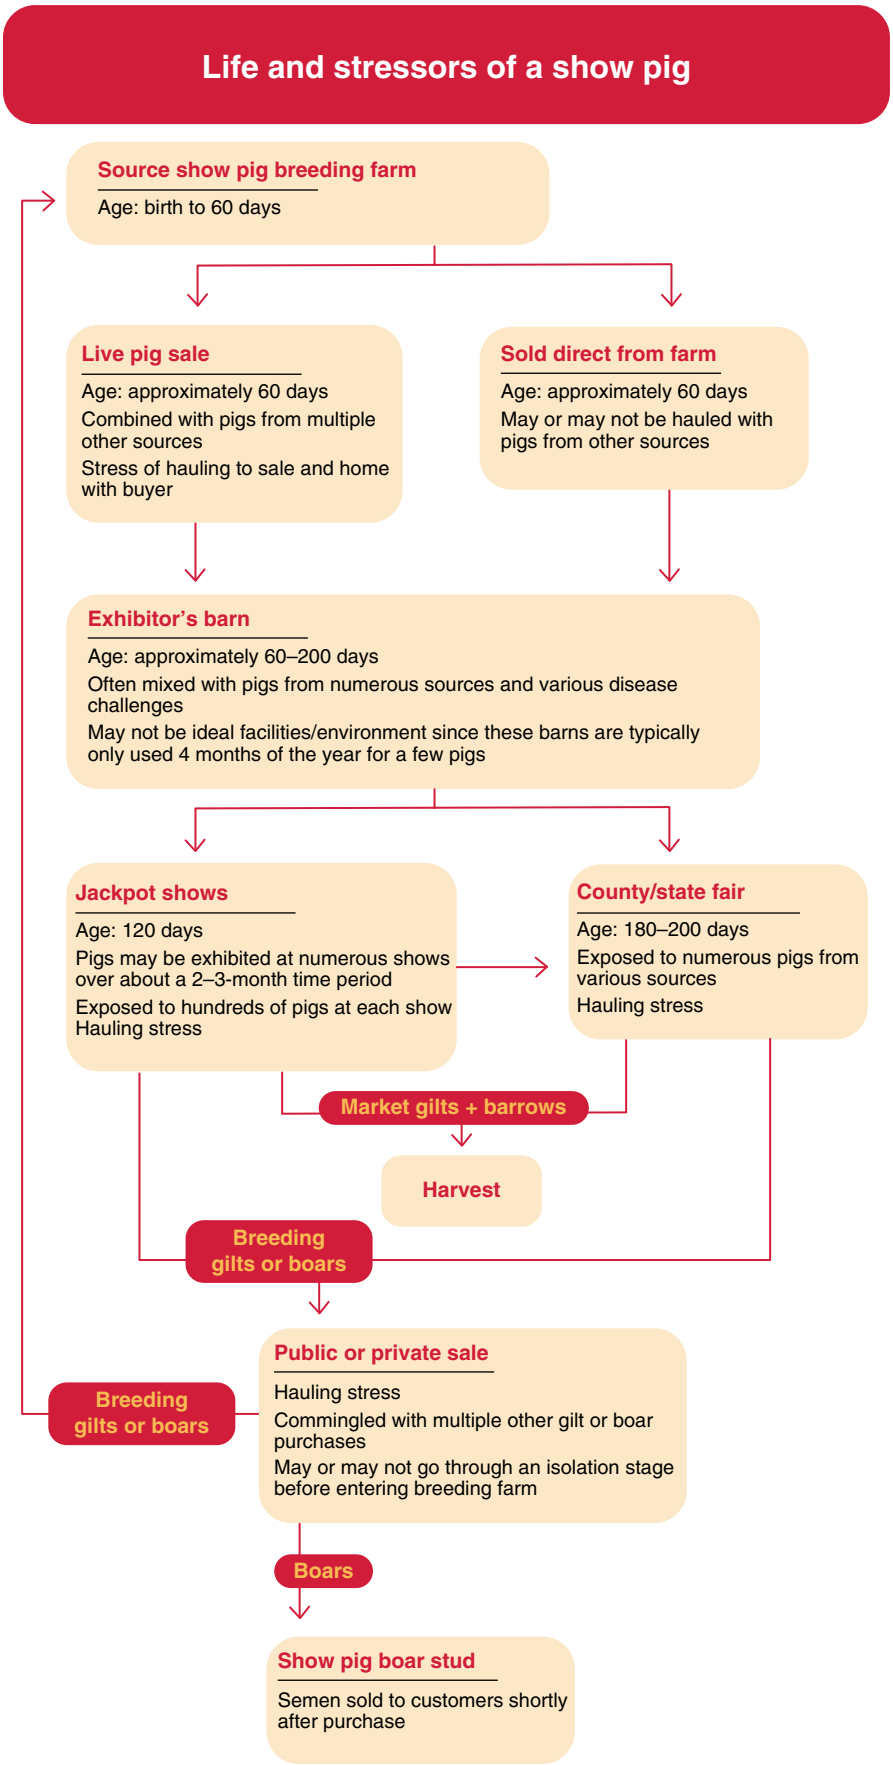

Figure 13.2 Timeline of major events and disease exposure of show pigs.

public about these zoonotic risks and may be expected to advise fair officials in the event of a zoonotic disease.

General health issues

Vaccination and health protocols

Veterinarians need to be involved with formulating a vaccination protocol for show pig clients. With most commercial farms, herd epidemiological information such as serology or diagnostics can be used to customize a vaccination and health management program. However, this is typically not practical when working with show pigs due to the small herd size. With federal changes mandating Veterinary Feed Directives (VFD) for many common feed-grade antibiotics, many show feed manufacturers have removed all antibiotics from their show feeds. Therefore, many small show pig clients will not have medicated feed for their pigs at any stage. This makes vaccination programs even more important at the breeder level to prevent common diseases such as ileitis or mycoplasma pneumonia.

Show pig health protocols must also include regular treatments for both internal and external parasites, as both are extremely common in show pigs. The risk of infestation with mange is higher in show pig herds due to the wide exposure to other animals at sales and shows. Show pigs are often housed and/or exercised on dirt lots or older barns where pigs have been present for many years, therefore increasing the exposure risk for internal parasites. It is common to utilize a rotation of antiparasitic products, such as fenbendazole, ivermectin, or doramectin throughout the growing period. Ensure that all show pig breeding herds are also routinely treated with antiparasitic products.

Individual animal medicine

Unlike commercial herds, where veterinarians are focused on population medicine, show pig veterinarians often focus on individual animal problems. Clients may call their veterinarian to examine a single sick, injured, or lame animal. Common problems such as pneumonia or scours should be treated the same as these issues are treated in a commercial farm. Lameness in show pigs is extremely common since they are exercised vigorously and are often very heavy muscled. Common lameness problems result from osteochondrosis (OCD) and osteoarthritis (OA), joint infections, hoof cracks, pad bruising, and traumatic injuries. Infectious causes of lameness in show pigs can often be related to *Mycoplasma hyosynoviae* or erysipelas. Lameness that would be of no consequence to a commercial pig can easily render a show pig unfit for their intended use. Most show pig clients are willing to invest in the best possible treatment as a first choice since they have a significant investment in the animal. Oral joint supplements containing glucosamine and chondroitin or hyaluronic acid are used extensively in show pigs to promote joint health and minimize problems from OCD and OA, although there is no efficacy data available for this practice. These supplements are often fed for several weeks leading up to a show or when an animal may start to show clinical signs of joint stiffness. In some cases, show pig owners will seek alternative therapies, such as chiropractic care, acupuncture, or laser therapy to address lameness. This is an opportunity for veterinarians that practice these alternative medicines.

In the past couple of years, there has been an increased prevalence of *Senecavirus A* (SVA) in the US swine industry, and the show pig industry has been affected with this virus as well. SVA typically presents in show pigs after they come home from a show, where they were exposed to numerous other pigs. It is the author's opinion that there are also many cases of SVA in show pigs that go undiagnosed due to the client's fear of reporting clinical signs to their veterinarian that may result in a subsequent foreign animal disease investigation. Veterinarians must encourage clients to always report any unusual clinical signs in their animals.

A common problem for outdoor show pig operations is sunburn. If burned severely enough, these pigs will have scabs and scarring across the back. In the acute stages, they will appear to have a neurological deficit, exhibiting an unusual gait in the rear legs induced by the pain across the back. Sunburns are often treated with over-the-counter aloe products and addition of shade in the pen. Many show pig producers prevent sunburn by applying a sunscreen to light-colored pigs before taking them outside. Veterinarians need to be aware of the use of these types of non-Food and Drug Administration (FDA)-approved topical treatments used by show pig producers.

Veterinarians are also asked to perform a variety of surgical procedures on show pigs. These procedures are not economically justifiable on most commercial farms. Examples of commonly requested surgical procedures for show pigs include the following:

1) Castration – Many show pigs remain boar prospects until an older age and require anesthesia for castration; or clients will grow the pig as a boar to maximize growth and muscling and not castrate the pig until 30–40 days before exhibition.
2) Scrotal hernia repair.
3) Abdominal hernias – May often also have abscess present and persistent umbilical structures.
4) Cryptorchidectomies – May be requested by breeder before castration if only one testicle is descended or requested by exhibitor after their pig starts exhibiting boar behaviors.
5) Abscess removal – Surgical cosmetic removal of abscesses resulting from castration, injections, etc.

6) Scirrhous cord removal – Due to post castration scarring when the vaginal tunic is not completely removed at castration.
7) Preputial diverticulectomies – Performed on boars or barrows to eliminate urine pooling, as many clients prefer not to manually express the contents routinely; also performed on boars that get their penis "balled up" in the diverticulum and do not extend their penis properly.
8) Penis problems – Examination and repair of a persistent frenulum or trauma; helpful to use 10 in. curved Bozeman uterine forceps to exteriorize the penis of an anesthetized boar.
9) Extra dewclaw amputation – Some breeds will not allow animals with extra dewclaws to be registered as purebreds, so the decision to perform this surgery may have ethical implications.
10) Rectal prolapse – Often after cool environmental conditions and piling of pigs, coughing or scouring, and gastrointestinal parasites – all conditions that are common when show pig prospects are purchased and brought home with pigs from other sources.

Anesthesia options and techniques for these surgical procedures can be found in Chapter 11.

Breeding management

Veterinarians are often consulted for assistance and advice on artificial insemination techniques and estrous management in show pig herds. Unlike commercial farms, show sows and gilts are typically bred to a specific boar based on the compatibility of phenotypes or predicted phenotypic outcome of the individual cross. Semen is purchased from boar studs that specialize in show pig semen, and doses can be very costly. Show pig boar stud biosecurity is not as stringent as most commercial boar studs, so clients need to be aware that there is a higher risk of disease transmission through semen. Boars in these studs have often been comingled at large shows before being purchased and brought into the stud, so disease risk is just as high as for all other show pigs.

Due to the timing of the show season, show pig producers desire to breed animals to farrow at very specific times. Veterinarians may need to aid and educate on heat synchronization options or breed and abort programs. In addition, many show pig herds are small and do not have a boar present to assist in heat detection and stimulation during breeding.

Farrowing management

Obstetrical difficulties are often more common in show animals for several reasons. Firstly, show pig producers tend to farrow more gilts in order to keep up with the most current genetic trends in the show industry. Secondly, there is often a disparity between the phenotypes of gilts that are successful in the show ring and the breeding herd. Thirdly, birth weights may be heavier due to lower litter size and/or the genetic type. Fourthly, show herd sows are often over-conditioned. The combination of these factors results in an increased rate of dystocia. Since many show pig producers are not as experienced at assisting sows with difficult dystocia as commercial producers and the animals have greater monetary value, veterinarians are called to provide obstetrical care. In extreme dystocia cases, Cesarean section may be indicated. Surgical techniques, as well as epidural and general anesthesia options, can be found in Chapter 11.

Nutrition

Nutritional aspects of the show pig industry are much different than the commercial industry since show pigs are fed to achieve a desired appearance and weight range for exhibition rather than for growth performance or efficient gain. Show pigs are typically fed much higher protein and fat diets than comparable commercial pigs. A wide variety of supplements and feedstuffs are utilized in show pig diets. Some of these include human foods or feedstuffs typically utilized by other species. Efficacy and safety of these supplements are generally not available. The desired appearance of successful show pigs tends to change every few years, and subsequently, the composition of feedstuffs and supplements also changes to produce the desired appearance. One common supplement that deserves special mention is ractopamine HCL, a repartitioning agent that promotes lean tissue production. Veterinarians can play an important role in educating clients on feeding the proper rate of this supplement in small batches of feed, as this supplement can easily be abused and fed at illegally high levels.

Veterinarians must be aware of some of these nontraditional feedstuffs and supplements, since there may occasionally be some health issues related to their use. For example, the increased fat in show pig diets has been known to result in steatitis in the inguinal and abdominal area. The desire to enter a pig in a specific weight class may result in withholding water or use of a diuretic, which can cause dehydration. It has also been common for show pig producers to feed altrenogest for increased feed consumption in not only gilts but also barrows and boars. This is not approved label use of this product and can negatively impact semen quality of boars (Kluber et al. 1985).

Education

The show pig veterinarian must be heavily involved in education of clients. Most show pig producers lack the

experience and knowledge of those producers in the commercial industry. Veterinarians must not only educate these producers on their individual pig projects but also on the swine industry and pork production. Veterinarians must be diligent in educating these clients about proper pharmaceutical use, administration, and withdrawal times since many pharmaceutical products are used in show pigs.

In addition to reaching individual clients, veterinarians are also asked to speak to 4-H or FFA groups about general pig care, health, and disease prevention. There are also opportunities to be involved in formal educational programs for show pig producers, such as the NPB Pork Quality Assurance Plus (PQA Plus) or Youth PQA Plus training sessions.

Ethics

Any veterinarian working with show pig producers must determine their own set of ethical standards concerning the procedures and recommendations they provide. As with many competitive industries, there are clients who will do anything to win and may ask their veterinarian to provide a service that is contradictory to good judgment or ethics. Practitioners must also be mindful of how their recommendations might affect all pork producers and consumers. Some categories of ethical dilemmas that veterinarians may face include altering animal identification, illegal drug use, and surgical procedures that alter conformation, among many others.

Drug use and testing in show pigs

Veterinarians working with show pigs must also understand drug testing regulations and procedures for various shows. Each show sets their own regulations regarding drug use, and this may vary greatly. Most shows will prohibit pharmaceutical products not approved by the appropriate state or federal agencies, which include the FDA in the United States. Others may also prohibit the use of any "performance-enhancing products," such as NSAIDS or corticosteroids, since they may mask a lameness problem. Even when these products are used according to label directions and meet legal withdraw times, pigs may be disqualified from shows for their use. Common substances such as caffeine may also be prohibited at certain shows. Some shows enforce a zero-tolerance policy on any drug residues found in an animal. Veterinarians and exhibitors must know the rules and regulations for a show before administering any treatments to a show pig. A veterinarian can prescribe treatment for an animal following all regulatory guidelines including established tissue withdraw times and still have that animal disqualified from a zero-tolerance show due to the extremely sensitive testing methods utilized. In addition to the extreme test sensitivity, most shows test urine samples, and the correlation between urine and tissue levels is not well established for all drugs.

Many shows will test animals for banned substances. Most of this testing is conducted on urine samples, although some shows may choose to test serum. For terminal shows, carcasses will often be detained, and multiple tissue samples (muscle, liver, retina, etc.) will be tested. Urine testing allows labs to test for not only the parent drug but also metabolites of that drug. Some of those metabolites can be detected in urine for much longer than in serum and may not be indicative of what drugs have been administered to the animal more recently. Most labs now test samples via liquid chromatography with mass spectrometry (LC-MS). LC-MS protocols often allow a lab to screen for multiple drugs simultaneously and detect very low concentrations of drug residues. Suspicious samples are re-extracted and analyzed with tandem mass spectrometry (MS/MS) for confirmation. Numerous drug classes are tested for, including but not limited to NSAIDs, corticosteroids, anabolic steroids, tranquilizers, sedatives, stimulants, antihistamines, antipsychotics, and muscle relaxers. It is not uncommon to find flunixin, dexamethasone, caffeine, theophylline, and theobromine to test positive in show pigs (Travis May, personal communication, February 21, 2017).

All practitioners working with exhibition swine must be aware of these drug testing policies and use extreme caution when treating or recommending treatment for any animal that will be attending a show with a drug testing policy. One sometimes must decide between treating an animal in the best welfare of the animal and the risk of getting an animal disqualified at a drug test.

Miniature pet pigs

While their diminutive size makes them more appropriate as pets, owners often need to be reminded that miniature pigs are still members of the family Suidae and share similar behaviors, environmental needs, diseases, and parasites. They are anatomically and physiologically much like the larger commercial varieties of swine, and, with a few exceptions, treatment will be similar.

Behavior and training

Aggression in the pet pig is a significant concern and results in the abandonment or re-homing of many pigs (Lord and Wittum 1997; Tynes et al. 2007). For that reason, pet owners should be counseled about the potential for problems as soon as possible after they acquire the pig. Most owners of pet pigs know little about the normal behavior of the pig, so they may miss

the initial signs of aggression. These signs may include lip smacking or chomping, stiffening and staring with piloerection of the hair along the back, and "head swiping." The head swipe is often, but not always, performed with a slightly open mouth and is a bite threat, probably often made with no intention to bite. It is a warning that says the pig wants you to stop doing what you are doing. If the warning goes unheeded, the behavior will likely escalate to an actual bite. No form of aggression directed toward humans, regardless of how mild, should be ignored in the hope that the problem will get better on its own. As is the case with most behavior problems, aggression rarely decreases without treatment, and it usually worsens with time if left untreated. Pet pigs usually begin displaying aggressive behavior toward humans as they mature socially (6 months to 3 years), and typically, the first victims of aggression will be visitors to the home (Tynes et al. 2007). This is believed to be a normal response to an unfamiliar individual, similar to how pigs behave when meeting unfamiliar conspecifics. Aggression toward familiar people within the home also commonly begins around the time of social maturity and appears to be a form of dominance aggression. The reasons for the behavior remain unclear, but it should be noted that pigs are animals that commonly use aggression among themselves in order to establish rank and ensure access to valued resources. When pigs become aggressive to their owners, it is usually in the context of resources such as resting places. If the owner's response is to punish the pig, aggressive behavior may escalate, due to the pig becoming fearful of the owner and using aggression in an attempt to stop what it perceives as a frightening threat. While many responses to this behavior have been described by pet owners and trainers, it is recommended that pig aggression be treated similarly to dog aggression; the animal should be taught that humans are the leaders of the group. Consistent, predictable reward-based interactions should be emphasized, and punishment avoided so that the pig learns to trust the owner. This is safest and easiest to accomplish by conditioning the pig to a harness and leash at a very early age; harnesses made specifically for miniature pigs are recommended and will fit better and be easier to use than harnesses intended for dogs. The pig should then be taught to respond to a simple verbal cue, such as "sit," before being given something that it desires. It is relatively simple to teach the pig to sit using a food lure, just as you would a dog. It should then be asked to sit before being fed, brushed, petted, invited onto furniture, allowed outside, etc.

The pig should always be wearing its harness when visitors are expected, and a responsible adult should have control of the leash whenever visitors arrive at the home. Once a visitor has been in the home for a few minutes, they can be allowed (if they desire to interact with the pig) to ask the pig to sit and reward it with small pieces of fruit, vegetables, dry cereals, or other food treats when it complies. Alternatively, the owners can simply be advised to separate their pig from all visitors by confining it to another room or pen whenever visitors arrive at the home. Avoidance of stimuli that lead to aggression is always the first and most important approach to problem behaviors. Notably, aggression directed toward humans seems to be a problem that occurs primarily in single-pig households (Tynes et al. 2007). As pigs are herd animals, the addition of a second pig can be an alternative method to alter undesirable behavior or, better yet, to avoid it altogether if another pig is introduced early. Many pig shelters and rescue groups require people to adopt two pigs at the same time, and this may prove to be an excellent method for decreasing the incidence of aggression. Additionally, it has been noted by some that a significant amount of outdoor exploration can improve aggressive tendencies.

Restraint

Physical

Just as with larger swine, miniature pigs resist firm restraint by struggling and vocalizing. Superficial examination and vaccination is possible using physical restraint, but for more thorough examinations, tusk trimming, and nail (hoof) trimming, chemical restraint is often necessary. Most owners of miniature pigs consider their pigs a pet and will be unhappy if their pig is treated as a farm animal. For that reason, most will prefer to pay for chemical restraint rather than see (or hear) their pig restrained while struggling and squealing. In addition, miniature pigs have a smaller, less stable cardiovascular system than large swine and can be stressed to the point of collapse. Due to their propensity to joint dislocation, they should never be lifted by their legs. Nose snares are rarely useful as the miniature pig may simply panic and thrash about; they do not reliably back away from the snare, and injuries have been reported with snare use.

To lift the small or medium-sized pet pig, place one arm in front of the front limbs and the other arm behind the rear limbs. Hold the pig firmly to your chest and move it as quickly and smoothly as possible to an examination table. Once the pig is on the table, do not try to firmly restrict its movements; it should simply be corralled with the arms. A rubber mat or other nonslip surface will greatly decrease the pig's distress and help keep it calm. If the person restraining the pig will scratch it firmly on the neck, flank, belly, or inner thigh, this will also help to keep the pig quiet and calm. Continuously feeding the pig small bites of food (if anesthesia is not planned) will typically keep it occupied and allow for examination and vaccination.

Larger pigs can be lifted by two people using a version of the "fireman's carry"; approaching the pig from each side, each individual places one arm in front of the pig's forelegs and the other arm behind the pig's rear legs. The two people then grasp elbows and lift the pig, squeezing it between them. The pig can then quickly be placed on an examination table.

Hammock-like slings with a hole cut for each of the pig's feet have also been used for pet pigs. The sling can be very useful for aiding restraint in some larger and less docile pigs. Many pigs will allow nail and teeth trimming while sitting in the sling.

Chemical

Achieving predictable results with injectable agents can be challenging in the miniature pig due to their thick layer of body fat. A 1½ or 2 in. needle may be required to deposit the injection in the muscle of adult pigs. The preferred site for injection of anesthetic agents is the semimembranosus or semitendinosus muscles. Injection into the gluteal muscles may lead to lameness. The commonly used dissociative anesthetic agents have been associated with prolonged and violent recovery and bizarre behavioral changes after recovery. However, when inhalation anesthesia is not available, dexmedetomidine (40 mcg/kg), butorphanol (0.3 mg/kg), and midazolam (0.3 mg/kg) combined in one syringe and administered IM have been found to be safe and reliable while offering a smooth recovery. In addition the effects of dexmedetomidine can be reversed with atipamezole to speed recovery.

Inhalation anesthesia has also been shown to be safe and effective and offers a quick and relatively predictable recovery. Most pigs can be easily masked down by including nitrous oxide with oxygen for 30–60 seconds initially and then very slowly turning on the anesthetic gas (isoflurane). Once the pig visibly relaxes, the nitrous should be discontinued.

Malignant hyperthermia has been rarely documented in the miniature pig and appears to be uncommon. The prevalence of the porcine stress syndrome (PSS) gene that predisposes a pig to malignant hyperthermia is currently unknown in the miniature pet pig population, although it is known to exist.

Miniature pigs should be monitored carefully during recovery from anesthesia as complications such as laryngeal edema, hypothermia, and cardiovascular compromise are not uncommon.

Vaccinations

In spite of the fact that many pet pigs will never be exposed to other swine, some vaccinations are still important to ensure their continued good health as well as prevent the potential spread of zoonotic diseases and diseases of economic interest to the commercial swine industry. No single vaccination protocol will be best for all pet pigs, but all of them should be routinely vaccinated against erysipelas (*Erysipelothrix rhusiopathiae*) as the organism is soilborne and has zoonotic potential. Swine are capable of contracting rabies although confirmed reports of rabid swine are quite small compared with other domestic mammals. Rabies has been reported in three miniature pet pigs between 1997 and 2003 (DuVernoy et al. 2008). Extra-label use of this vaccine should also be considered as a safety measure, in part because it may protect the pig from being euthanized by a local public health department in case of a bite to a human. Other vaccinations will depend upon the pig's age, prior vaccination status, the environment, and geographical area in which it resides as well as potential exposure to other pigs.

Parasites

Pet pigs are subject to the same parasites that can infect larger swine. Sarcoptic mange (*Sarcoptes scabiei*) is one of the more commonly seen problems. Miniature pigs often exhibit abundant dark crusty exudate in their external ear canals, but this appears to be normal, and ear mites (*Otodectes cynotis*) are rarely, if ever, found within the discharge. However, *S. scabiei* mites are often present in ear swabs of infested pigs.

Internal parasites such as roundworms, whipworms, and threadworms are less common in pigs acquired from reputable breeders, and large worm burdens are rare, as is clinical illness associated with endoparasites. All pet pigs should nevertheless have fecal flotations performed at 8–12 weeks of age. After reaching adulthood, fecal exams are less critical if the pig is maintained in a clean environment and is not exposed to environments where other swine have been. If parasites are identified on a fecal exam, the pet pig can be treated with the same anthelmintics at the same dosages as larger swine.

Teeth trimming

All miniature pigs have four permanent canine teeth that erupt at about 5–7 months and, in males, grow continuously. Even the tusks of castrated males can reach a dangerous length, although they usually grow more slowly than in intact males. The best-behaved pigs can do damage to furnishings and accidently harm humans with these long, sharp teeth, so regular occasional trimming may be needed. Anesthesia makes the procedure safer and easier for all involved. Obstetrical wire, high speed dental tools, and Dremel™ tools have all been used successfully. Crushing instruments should be avoided as they can fracture the tooth longitudinally causing pain and possibly infection. The teeth should be cut only as short as possible necessary for safety while avoiding the

pulp cavity, the length of which can vary between individuals. A sanding blade on a Dremel™ tool can be used to smooth the tooth so that no sharp edges remain. Removal of the canine teeth is extremely difficult and not recommended unless necessary due to fracture or infection.

Hoof trimming

Pet pigs that live in the home and get minimal exercise on rough surfaces usually have hooves that require regular trimming. Overgrown hooves hyperextend the joints of the legs and, along with obesity, are a common cause of lameness in pet pigs. Routine trimming is usually required and will be most easily performed when the pig is anesthetized. However, many pigs will tolerate the procedure while being restrained in a sling or held on their backs. Trimming is easily accomplished using trimmers, hoof nippers, and rasps as you might use for goats or horses. In some cases, especially where the hooves have become severely overgrown, the sensitive laminar tissue (the "quick") will be extended. Cutting deeply into the quick can cause lameness that lasts for several days and should be avoided when possible. After trimming, a Dremel™ tool can be used to smooth the nails and remove any rough edges.

Common surgical procedures

All female pigs not intended for breeding should be ovariohysterectomized. A high rate of reproductive tract neoplasia has been noted (Mozzachio et al. 2004) in pet pigs over 5 years of age. While these tumors are not usually malignant, they can reach extreme sizes, leading to discomfort, occasional colic-like signs, cardiovascular compromise, and death. Removal of the tract after the tumors have become very large is more difficult and places the patient at higher risk.

Ovariohysterectomy is easier for the surgeon and less stressful for the pig if performed prior to the pig reaching a weight of about 25 pounds. In a smaller animal, the immature reproductive tract can be more difficult to access within the deep ("potbellied") abdominal cavity, and in a heavier patient, the larger amount of subcutaneous and intra-abdominal body fat may make accessing exteriorizing the tract difficult. This can result in excessive bleeding and increase the risk of dehiscence. Obese patients are a greater anesthetic risk as well. A ventral midline approach is recommended. The use of a spay hook should be avoided as it can be damaging, leading to excessive bleeding within the fat, and is generally unnecessary. Closure of the skin using an absorbable suture and a buried subcuticular pattern and burying the knot alleviates the necessity of a later struggle to remove sutures.

All boars intended to be kept as pets should be castrated, preferably before 12 weeks of age. Intact boars are less likely to make good pets due to their unpredictable behavior and strong, objectionable odor. While early castration greatly reduces odor and leads to a decrease in size of the preputial diverticulum, odor and drainage can still occur in some pigs. Preputial diverticulectomy as described by Lawhorn et al. (1994) can greatly increases pet owner satisfaction in one author's experience. The procedure should be considered an option in all pet pigs castrated later than 2–3 years of age or any time that odor becomes an issue for the pet owner. Castration should be performed through a pre-scrotal incision using a technique similar to that used in the dog. The vas deferens and associated blood vessels should be ligated and excised. Removing the cremaster muscle, tunic, and extraneous subcutaneous tissues decreases dead space and reduces the chance of seroma formation. Closing the skin with absorbable sutures using a buried subcuticular pattern eliminates the need for the later restraint and struggle associated with suture removal.

Cryptorchidism and inguinal hernias are commonly occasionally seen in miniature pigs. Inguinal rings should be examined at the time of castration and surgically closed if patent.

Common disease problems and therapeutics

Physical exam on the pet pig should be conducted similarly to a physical exam on any animal. One of the noted differences between the miniature pigs and the larger commercial breeds of swine is that their normal resting rectal body temperature is likely to be lower, with temperatures as low as 37.6 °C (99.7 °F) reported in one study (Lord et al. 1999).

While subject to all of the same diseases that occur in other swine, illness is uncommon in the pet pig that is properly vaccinated, fed, and housed. However, health problems may include:

1) Obesity – Obesity is common in the pet due to lack of exercise and improper feeding. Many pet owners think obesity is a normal condition for all pigs, often purposely feeding to achieve over-conditioning; they are unaware of the numerous associated health problems associated with obesity in the pig. Obesity contributes to chronic lameness and blindness secondary to excessive fat accumulation around the eyes and places strain on the heart and lungs. Pet owners must be instructed as to the importance of feeding pet pigs a commercial diet made especially for miniature pigs. In addition, placing food in food dispensing toys (hollow balls or plastic jugs with holes cut in them), or simply broadcasting the ration over a clean, grassy area of the yard, requires that the pig expend more calories acquiring its food.

2) Arthritis – Miniature pigs have been reported to live as long as 23 years, with an average life span of 15–18 years. One of the more prevalent health problems associated with aging in the pig is OA. This is often secondary to chronic obesity and/or overgrown hooves but is also common with normal conformation. Ongoing lameness that eventually becomes nonresponsive to anti-inflammatories and painkillers is a common cause for euthanasia in the geriatric pig.
3) Dental disease – While pigs develop impressive amounts of dental tartar as they age, severe periodontal disease is uncommon. Regular teeth cleaning similar to that for a dog may be beneficial for some individuals. The most common dental problem seen in geriatric pigs is tusk root abscessation in males. This may present as chin or jaw abscesses that recur after initial treatment. Radiographs are diagnostic, often revealing extensive bone lysis. Successful treatment will require tusk removal.
4) Uterine neoplasia – See "Common Surgical Procedures" above.

Regulatory issues

Many pigs have been abandoned by their owners after they discover that zoning regulations prohibit the keeping of a pig in their community. In the eyes of many legal entities, a miniature pig is a farm animal and subject to the same federal rules and regulations governing the maintenance and movement of other swine. While most owners will deny the possibility of their pet pig ever entering the food chain, it has been reported (Lord and Wittum 1997; Mozzachio pers. obs.), and for this reason, caution must be used when administering or prescribing medications for the pet pig. Drugs illegal for use in food animals must be avoided, and discharge instructions should include mention of drug withdrawal times.

Acknowledgments

The authors gratefully acknowledge the assistance of Bruce Lawhorn, DVM, in the preparation of the pet pig section of this chapter.

Section II

Body Systems

14

Cardiovascular and Hematopoietic Systems

Nicholas A. Robinson and Alan T. Loynachan

Introduction

The cardiovascular and hematopoietic systems are essential components that conjointly aid in the distribution of oxygen, nutrients, minerals, proteins, and cellular constituents to the body systems. Disease or functional disruption of either system can have detrimental effects. This chapter will briefly highlight normal porcine anatomy and physiology and the pathology of frequently encountered porcine cardiovascular and hematopoietic diseases.

Anatomy and physiology

A thorough understanding of anatomy and physiology is essential for the appropriate detection and evaluation of porcine cardiovascular abnormalities. Further review of veterinary references, such as the *Textbook of Veterinary Anatomy* (Dyce et al. 2010) and *Duke's Physiology of Domestic Animals* (Reece et al. 2015), may be beneficial.

Hematopoietic system

There is approximately 56–69 mL of blood per kilogram of body weight in the pig (Fox et al. 1984). Blood is composed of both acellular and cellular components. Acellular constituents (water, minerals, electrolytes, gases, acid–base regulatory ions, proteins, lipids, and carbohydrates) are regulated by other body systems and are introduced into the cardiovascular system for tissue distribution and excretion. Both direct and indirect alterations of acellular biomarkers can be important indicators of locomotor, digestive, respiratory, urogenital, endocrine, cardiovascular, or nervous disease. Reference intervals for porcine acellular biochemical analytes can be found in Table 14.1.

The hematopoietic system generates the cellular components of the blood, which include lymphoid (lymphocytes) and myeloid (nonlymphoid leukocytes and erythrocytes) elements. Hematopoiesis is primarily localized to the bone marrow of adult animals but regularly occurs in extramedullary tissues in fetal and neonatal animals. Bone marrow is not frequently evaluated in swine, but myeloid to erythroid reference ratios of 1.77–2 : 1 are reported (Jain 1986; Sanderson and Phillips 1981). Porcine hematological parameters fluctuate based on age, breed, sex, diet, stage of gestation, lactation, management practices, and season. As a result, normal complete blood count (CBC) reference intervals are quite broad (Table 14.2). Friendship et al. (1984) and *Schalm's Veterinary Hematology* (Thorn 2010) are useful citations for reference intervals based on age, sex, gender, and other confounding factors.

Porcine erythrocytes typically circulate for 86 days before removal from the circulatory system. Morphologically, porcine erythrocytes average 6 µm in diameter, lack basophilic stippling, and commonly exhibit poikilocytosis (Brockus 2011; Thrall 2004). Immature forms of red blood cells (RBCs), nucleated RBCs, and reticulocytes normally circulate in healthy pigs but are found in higher proportions in suckling animals (Brockus 2011).

The structure and function of porcine leukocytes and platelets are similar to those seen in other domestic mammals. *Schalm's Veterinary Hematology* (Thorn 2010) is a useful reference for morphological and functional characteristics of pig leukocytes, particularly for age, castration, pregnancy, and parturition status-related differences.

Cardiovascular system

Anatomically, the heart is located in the mediastinum and extends from the second to fifth ribs and is essentially a one-way pump composed of four chambers: The low-pressure side consists of the right atrium and ventricle carrying blood to the lungs for oxygenation. The high-pressure side consists of the left atrium and ventricle carrying blood to the systemic circulation for metabolic

use. A series of heart valves (atrioventricular [AV] and semilunar) work to enable the one-way flow by restricting the backflow of blood into the preceding chamber. Arteries and arterioles carry blood to the peripheral tissues where oxygen exchange occurs at the capillary level. Deoxygenated blood then returns to the heart by a series of venules and veins. Fluid that escapes from the blood returns to the vascular system by lymphatic vessels.

The pericardium is a thin fibroserous sac that completely surrounds the heart. It acts to reduce motion within the thoracic cavity but at the same time allows almost frictionless movement within the sac. 1–2 mL of clear serous, lightly viscous fluid is normally located within the pericardium. The myocardium is located beneath the epicardium and is composed of specialized striated muscle, which generates the force necessary to pump blood. The endocardium lines the inner layer of the heart including valves and is composed of vascular endothelium with subjacent supporting collagen, elastin, and small caliber blood vessels. Specialized electrical conduction (Purkinje) fibers are distributed throughout the heart but are most prominent in the subendocardium. Conduction fibers coordinate the rhythmic depolarization of the cardiomyocytes, which results in muscular contraction. Cardiac electrical impulse is influenced by the autonomic nervous system and is generated by the pacemaker sinoatrial (SA) node. The SA node chronologically and subsequently transmits electrical impulse to the AV node, bundle of His, right and left bundle branches, and Purkinje fibers, which ultimately stimulate cardiomyocytes and result in the synchronized contraction of the heart.

Postmortem examination of the heart

The heart should be visualized in a consistent and methodical manner so that the pericardium, myocardium, mural and valvular endocardium, and great vessels are examined. All lesions identified should be grossly described and placed in fixative for microscopic examination by a pathologist. The thoracic cavity is carefully opened so that the lungs and heart can be visualized and the pericardial sac is examined and incised *in situ* before any organs are removed. Normal epicardium and pericardium are smooth and glistening due to the presence of a small amount of serous fluid. The pericardium is then examined for thickening, adhesions, the presence of

fibrin, and the volume and nature of the pericardial fluid. Swabs, fluid samples, and tissue samples should be taken if abnormalities are evident.

Next, the heart can be removed from the pluck and examined for abnormal shape, size, and color unless congenital defects of the great vessels (e.g. PDA) or thrombosis (particularly pulmonary artery) is suspected. Rigor mortis occurs rapidly in the heart compared with skeletal muscle and may give the heart a very firm or even rigid appearance. Prior to the onset of rigor mortis, the heart can appear flabby or enlarged as the chambers may dilate antemortem due to myocardial disease or secondarily to postmortem autolysis. Heart chambers that dilate prior to death frequently have endocardial fibrosis or thickening that appears as diffuse whitening. Histopathology should be performed on these sections to definitively rule out underlying myocardial disease.

A common method used to ensure consistency when examining the heart is to view myocardial structures in the direction of normal blood flow. The right atrium should be opened from the caudal vena cava to the auricle allowing a view of the atrial endocardium and tricuspid valve. The next cut should be a "U shape" through the tricuspid annulus and beneath it the valve, down along the septum to the apex of the right ventricle, and up along the septum of the attached free wall through the outflow tract to the pulmonic valve and pulmonary artery. The left atrium should be incised from the pulmonary vein return to the auricle allowing the same view as for the right atrium. The next incision should extend through the mitral valve and left ventricular free wall to the apex of the left ventricle. The aortic valve and outflow tract can be visualized after the mitral valve and aortic annulus is incised (with one incision). Clotted blood should be removed, the heart rinsed in water, and the endocardium observed for thickened regions, pallor, hemorrhage, and valvular changes. Incision through the ventricular free walls, atria, and septum can aid in visualizing myocardial lesions that do not extend to the epicardium or endocardium. Sampling of the papillary muscles located at the base of the chordae tendineae for histopathology is recommended as these muscles are highly active and susceptible to myocardial damage.

Cardiac pathology

Cardiac output is negatively influenced by conduction abnormalities, heart malformations, disease in noncardiovascular organs, and epicardial, myocardial, or endocardial lesions. The speed at which heart disease develops depends on the underlying etiology and the location of the abnormality or diseased tissue; this determines if the sequel is sudden unexpected death or the development of peripheral lesions secondary to congestive heart failure.

Congenital anomalies

Porcine congenital cardiovascular malformations have been reported to occur at an incidence of 0.49–14.6% (Salsbury 1970; Wang 1978) in conventionally raised swine. Malformations may have minimal pathological effects or result in fatal cardiovascular compromise.

Hsu and Du (1982) identified 122 cardiac anomalies in a study of 1906 crossbred and purebred pigs. This study identified anomalies in pigs ranging from 1 day to 4 years of age but found the highest incidence of malformations in animals 29–110 days old. Both single and multiple anomalies were frequently identified within individual pigs. Common porcine cardiovascular anomalies are listed in Table 14.3.

Diseases of the pericardium

Hemorrhage, transudate, modified transudate, or exudate can accumulate within the pericardium of swine. Increased pericardial fluid is capable of applying external pressure to the heart, resulting in decreased diastolic filling of the chambers and venous congestion (cardiac tamponade). While both acute and chronic congestive heart failure can ensue if the material is not removed, in most pigs, cardiac tamponade is usually fatal.

Hemopericardium

Hemopericardium is the expansion of the pericardial cavity with blood. This condition commonly develops from traumatic insult to the epicardium or major blood vessels within the pericardium, including bleeding needles. Idiopathic rupture of an atrium, coronary artery, or

the aorta is occasionally diagnosed in swine. Similar cardiovascular ruptures have been reproduced in experimental models of porcine copper deficiency (Shields et al. 1962).

Hydropericardium

Expansion of the pericardium with clear to yellowish watery transudate or modified transudate is termed hydropericardium. This condition most commonly develops due to nonspecific insult to the vascular endothelium with subsequent fluid and fibrin loss into the pericardial cavity. Hydropericardium, in swine, has been associated with edema disease, mulberry heart disease (MHD), cachexia, hypoalbuminemia, and congestive heart failure. Wispy fibrin strands in pericardial fluid can be from modified transudate and should not be overinterpreted as fibrinous pericarditis.

Pericarditis

Pericarditis is the expansion of the pericardial cavity with inflammatory exudate and is one of the most common causes of pericardial disease in swine. Exudate can be fibrinous, purulent, or fibrinopurulent based on the amount of fibrin, number of inflammatory cells, and the presence or absence of pyogenic bacteria. Pericarditis can arise from hematogenous dissemination of bacteria or lymphatic extension of inflammation from adjacent tissues such as the lungs or pleura. Grossly, the pericardium is typically expanded with fibrin that gives the pericardial surface a roughened either "ground-glass" or "shaggy" appearance. Granulation tissue will replace the fibrin if mesothelial damage is sufficient or the exudate is not promptly removed. Chronic constrictive pericarditis can lead to cardiac dysfunction and result in congestive heart failure. Causes of porcine epicarditis and pericarditis can be found in Table 14.4.

Diseases of the myocardium

Myocarditis

Inflammation of the myocardium can develop from hematogenous distribution of pathogens or extension of inflammatory lesions from the adjacent pericardium or endocardium. A number of bacterial and viral etiologies can induce porcine myocarditis (Table 14.4). Although less common, parasitic stages of *Toxoplasma gondii*, *Trichinella spiralis*, *Taenia solium*, and *Taenia saginata* may infest the myocardium and produce nodular or cystic lesions. While these intermediate parasitic stages do not often cause overt inflammation unless the cysts rupture, they do pose significant public health risks in locations where offal is consumed. Inflammation within the myocardium, regardless of cause, can alter cardiovascular function by inducing myocardial degeneration and necrosis, altering electrical conduction, and disrupting myocardial contraction. These factors can result in acute death associated with dysrhythmia or contribute to chronic heart failure.

Myocardial degeneration and necrosis

Porcine myocardial degeneration and necrosis can develop from a number of primary insults to the heart or secondarily from systemic disease. Primary causes in swine include ionophore, gossypol, or injectable iron toxicosis and nutritional cardiomyopathy. Myocardial necrosis may also develop secondarily from hypertrophic or dilated cardiomyopathy, fever, anemia, disseminated intravascular coagulation (DIC), toxemia, neurological lesions (brain–heart syndrome), porcine stress syndrome, systemic infections, or myocardial inflammation. The wide array of potential causes of myocardial degeneration and necrosis frequently make identification of a definitive etiology difficult.

Mulberry heart disease

MHD is a diagnosis historically associated with vitamin E and/or selenium deficiency in swine. Affected animals are usually found dead with hemorrhagic foci within the walls of the heart. The name was applied because of the distinct transmural hemorrhages that resemble a mulberry.

MHD occurs sporadically in young rapidly growing swine. Disease incidence is generally low, although

epidemics have been reported (Moir and Masters 1979). Clinical signs are uncommon as the disease primarily manifests as sudden death in well-conditioned animals. On rare occasion, affected animals may develop weakness, cyanosis, slight icterus, subcutaneous edema, tachycardia, and increased serum muscle enzymes (Gudmundson 1976). Death is thought to be associated with dysrhythmia that develops secondary to myocardial damage. Diagnosis of MHD must be confirmed by necropsy and histopathology.

To date, the definitive pathophysiological mechanism behind MHD development remains elusive. Current theory suggests that disease development is associated with the lack of balance between free radical development and scavenging, that is, uncompensated metabolic oxidative stress. Free radicals are highly reactive molecules generated during normal oxidative metabolism. Cells ordinarily neutralize free radicals with antioxidant scavengers such as superoxide dismutase, glutathione peroxidase, and vitamins E and C. Selenium is historically included in this list due to its essential involvement in glutathione peroxidase activity. Unscavenged free radicals are capable of inducing cellular damage by reacting with cellular proteins, membrane lipids, and nucleic acids. Deficiency of free radical scavengers can result in severe cellular injury and death.

Historically, vitamin E and/or selenium deficiency was thought to be essential component of disease development. This theory was developed based on the experimental reproduction of MHD in swine deficient of one or both of these constituents (Grant 1961); however, inconsistencies in identifying deficient levels of vitamin E, selenium, or glutathione peroxidase activity in animals with MHD are reported (Nielsen et al. 1989; Pallarés et al. 2002; Rice and Kennedy 1989), suggesting MHD has other risk factors. Current hypotheses suggest that animals that die of MHD lack a sufficient balance between free radicals and free radical scavengers, which predispose animals to oxidative damage. Associated predisposing factors associated with MHD include stressors of various types, rapid growth rate, increased iron tissue concentrations (Korpela 1990), increased calcium and decreased magnesium concentrations (Korpela 1991), and diets containing corn oil (Nolan et al. 1995). It has also been hypothesized that there may be genetic predispositions to free radical damage, altered vitamin E metabolism, or decreased vitamin E bioavailability influenced by polyunsaturated fatty acids or excess vitamin A.

Gross pathology findings typically include hydropericardium, pulmonary edema, excess pleural fluid, and epicardial and transmural cardiac hemorrhage (Figure 14.1). More specifically, the pericardium is often distended by a large amount of cloudy to straw-colored fluid that contains fibrin strands not firmly attached to serosal surfaces. Multifocal-to-coalescing ecchymotic hemorrhages are evident in the epicardium and myocardium and occasionally extend to the endocardium (Figure 14.2). Regions of myocardial necrosis may or may not be grossly evident.

Figure 14.2 Hemorrhage and necrosis extends into the myocardium. Mulberry heart disease. *Source:* Marie Culhane, University of Minnesota.

Histological hallmarks of MHD include interstitial hemorrhage, subserosal edema, and variable amounts of myofiber degeneration, necrosis, and mineralization. Histological lesions can vary based on chronicity of the lesions. In cases of acute death, hemorrhagic lesions may

predominate, and degenerative and necrotic lesions may be minimal or absent. Hemorrhage with myocardial degeneration, necrosis, and mineralization is typically present in subacute cases. Microscopic lesions consistent with dietary microangiopathy/MHD may also be found in arterioles and capillaries of the heart, kidneys, liver, stomach, intestine, mesentery, skeletal muscle, and skin. These systemic vascular lesions can vary in severity from nonspecific endothelial hypertrophy, capillary microthrombosis, or fibrinoid necrosis. Animals that die of MHD may also have lesions consistent with acute heart failure. Less common is centrilobular hepatocellular necrosis (hepatosis dietetica), with skeletal muscle degeneration and necrosis (white muscle disease) rarer still.

A diagnosis of MHD is typically made based on the presence of typical gross and microscopic lesions. Low tissue (i.e. liver) concentrations of vitamin E and/or selenium can support a diagnosis.

Treatment of affected animals is usually not plausible due to the lack of distinct clinical signs and rapidity of death. Van Vleet et al. (1973) suggested that parenteral injection of all pigs aged 1–4 months with commercially available selenium–vitamin E products may be beneficial in herds experiencing increased death losses due to MHD. Prevention generally relies on increased levels of vitamin E via injection, water, or feed supplementation. Evaluation of feed constituents for excess oxidants may be warranted. Supplemental vitamin E should be favored over supplemental selenium in feed since the latter is more associated with hepatosis dietetica and can cause toxicity at relatively low doses.

Diseases of the endocardium

A majority of endocardial lesions in swine involve the heart valves. Disrupted valve function negatively impacts hemodynamics, decreases cardiac efficiency, and may result in cardiac hypertrophy or chamber dilation. Sequelae include endocardial mural fibrosis, thromboembolism, or even chordae tendineae rupture.

Valvular endocarditis is a commonly acquired lesion of the porcine endocardium associated with a variety of bacteria (Table 14.4), with *Streptococcus suis* probably the most common. Sporadic epidemics with *Erysipelothrix rhusiopathiae* are reported. Fungal and parasitic causes are rare. The mitral valve is most commonly affected, followed in frequency by the aortic, tricuspid, and pulmonic valves. Regardless of the affected valve, postmortem findings typically consist of one or more irregular friable reddish-gray to yellow nodules that extend from the valve leaflets and may involve the adjacent mural endocardium. This lesion is typically referred to as "vegetative valvular endocarditis" based on the floret-like appearance of the inflammatory mass. Microscopically, acute lesions are composed of ulcerated valvular endothelium covered by concentric layers of fibrin, bacterial colonies, and variable numbers of inflammatory cells. Granulation tissue may cover the valves in chronic lesions. Valvular dysfunction can be auscultated as murmurs, and affected animals may die from heart failure. Tissue infarction can also result when vegetative nodules break free from the endocardium and form thromboemboli.

Valvular cysts can be found in swine and usually contain either blood (hemocyst) or yellow serous fluid (serous cysts). Both types may be congenital or acquired and have little clinical significance.

Diseases of the conduction system

Diseases of the conduction system are sparsely reported in conventionally grown swine. Abnormalities may result in myocardial dysrhythmia, which can alter the systematic contraction of the heart, disrupt circulatory hemodynamics, and result in acute death. A majority of conduction system diseases arise secondary to cardiac, central nervous system (CNS), or pulmonary disease; drugs (anesthetic agents); or systemic alterations such as hypo- and hyperthermia, anemia, shock, sepsis, excitement, and electrolyte imbalances (hyperkalemia, hypocalcemia). These diseases may induce ectopic impulses that result in premature complexes, tachycardia, flutter, and fibrillation or result in conduction alterations such as nodal arrest, conduction blocks, and pre-excitation. Electrocardiography is required for the diagnosis of conduction system diseases, which explains the lack of epidemiological data associated with these entities in swine.

Compensatory mechanisms

The heart is incapable of generating new cardiac muscle to cope with increased workloads or repair damaged myofibers. Consequently, the cardiovascular system utilizes compensatory mechanisms to temporarily increase cardiac output and meet systemic metabolic demands. Cardiac dilation, myocardial hypertrophy, and tachycardia are compensatory changes of the heart that increase cardiac output. Neurohormonal mechanisms also modify the vascular system by increasing vascular resistance, promoting vasoconstriction, and increasing the systemic blood volume.

Heart failure

Congestive heart failure ensues when the heart can no longer compensate to meet systemic metabolic needs. Mechanistically, heart failure can be characterized as a decrease in cardiac output and/or decrease in venous return of the blood. Heart failure may result from impaired myocardial function (cardiomyopathies, decreased myofiber contractibility, lack of distensibility, and dysrhythmia) or an increase in cardiac demand (cor

pulmonale, pressure overload, and volume overload). Heart failure may be characterized as left or right sided depending on the location of diseased tissue and underlying mechanisms. Left-sided heart failure results in stasis of blood and fluid in the lungs. This pathologically manifests as pulmonary congestion and edema and can become clinically evident as dyspnea and coughing. Pathological findings associated with right-sided heart failure include systemic congestion, ascites, edema, and tissue hypoxia.

Vascular pathology

Vascular pathology can arise from a magnitude of different etiologies and result in abnormal hemodynamics, fluid loss from the vascular compartment, hemolytic anemia (HA), and tissue ischemia.

Vascular rupture and aneurism

Iatrogenic laceration of large blood vessels is a common side effect associated with blood sampling in swine. Lacerations, as well as other causes of vascular rupture, can lead to hypovolemic shock and death.

Copper is an essential element utilized by lysyl oxidase to cross-link collagen and elastin in blood vessel walls. Copper-deficient swine are predisposed to arterial aneurisms due to the lack of sufficient vascular integrity (Coulson and Carnes 1963). Affected vessels may bulge, dilate, and rupture.

Vascular degeneration and necrosis

Atherosclerosis is a degenerative disease that naturally occurs in aged pigs fed high-cholesterol diets. It develops slowly over time and commonly affects larger arteries. The disease is characterized by the plaque-like narrowing of vascular lumens, which alter hemodynamics, predispose to thrombus formation, and can result in vascular occlusion and tissue infarction. Microscopically, vessel walls are expanded by lipid deposited in smooth muscle cells, aggregates of lipid-laden macrophages, and fibrous connective tissue. Due to similarities in the mechanism and development of human atherosclerosis, the pig has become a useful model to study the disease in man.

Vascular mineralization due to vitamin D poisoning is occasionally observed in swine and usually associated with accidental feed overdoses. Vitamin D toxicosis results in hypercalcemia and/or hyperphosphatemia. Increased serum concentrations of calcium or phosphate predispose to vascular and soft tissue mineralization, which hinders vascular elasticity and organ function.

Fibrinoid necrosis develops secondary to endothelial damage with subsequent fibrin and serum protein deposition into vessel walls. Edema disease, mercury toxicosis, and MHD are three diseases associated with fibrinoid necrosis in swine.

Toxic ergot alkaloids, produced by *Claviceps purpurea*, can also produce marked vasoconstriction by stimulating adrenergic nerves in the vascular smooth muscle. This results in endothelial necrosis and vascular thrombosis that may provoke infarction of limbs and extremities.

Vascular thrombosis

Thrombosis is characterized by intravascular coagulation and can be induced by endothelial damage, hypercoagulable disorders, and abnormal blood flow (Virchow's triad). If severe, it can completely occlude the vascular lumen and result in tissue infarction. Arteritis, regardless of the cause, can provoke endothelial cell damage and result in vascular thrombosis. DIC is a common cause of vascular thrombosis in swine. Thrombosis due to DIC can affect arterioles and capillaries in all organ systems. Septicemia, endotoxemia, viral infection, hemolysis, shock, and massive regions of tissue necrosis predispose to DIC development.

Vascular inflammation

Vasculitis is a collective term to indicate inflammation of the arteries, veins, or lymph vessels. Inflammation of the vessels can occur from primary insult by infectious agents, drug reactions, immune-mediated mechanisms or by expansion of inflammatory processes from adjacent tissues. Inflamed blood vessels have increased permeability and are predisposed to thrombosis. Infectious etiologies associated with porcine vasculitis are listed in Table 14.5.

Table 14.5 Infectious causes of porcine vasculitis.

Edema

Edema is the abnormal collection of transudate in the interstitium and/or intercellular spaces due to fluid loss from the vascular system. Edema can develop from increased vascular permeability, increased intravascular hydrostatic pressure, decreased intravascular osmotic pressure, or decreased lymphatic drainage.

Increased vascular permeability is a common cause of localized edema in swine and occurs secondarily to vascular damage, inflammation, type 1 hypersensitivity reactions, neovascularization, endotoxin, and DIC.

Increased vascular volume may result in generalized or localized edema by increasing the intravascular hydrostatic pressure. This mechanism of edema is commonly seen in congestive heart failure due to venous congestion and compensatory fluid retention mechanisms.

Intravascular osmotic pressure is maintained by plasma proteins such as albumin. Plasma protein loss reduces intravascular colloidal osmotic pressure and leads to increased fluid transudation into the interstitium. Causes of hypoproteinemia can include liver disease, malnutrition, and protein-losing enteropathies (PLE) and nephropathies (PLN).

Interstitial fluid is normally removed by regional lymphatic vessels. Lymphatic blockage by thrombosis, compression, or inflammation can reduce the effective drainage of the interstitium and result in localized edema.

Diseases of the body cavities

The pericardial, peritoneal, and pleural cavities normally contain small amounts of serous fluid. Normal cavity fluid should be colorless to yellow tinged and translucent to slightly turbid and contain less than 2.5 g/dL of protein and 5000 nucleated cells/μL (Rakich and Latimer 2011).

Characterization of cavity fluids can aid in the identification of ongoing disease processes. An increase in fluid volume and turbidity is abnormal and may result from increased cellularity, increased protein and lipid concentrations, fibrin, bacterial colonization, or ruptured organs. Abnormal fluid can be classified as transudate, modified transudate, or exudate. Characteristics of these fluids are presented in Table 14.6. Transudates commonly develop from decreased plasma osmotic pressure associated with hypoalbuminemia. Modified transudates are less diagnostic and can be associated with increased hydrostatic pressure and increased vascular permeability or secondarily result from heart or liver disease. Exudates commonly result from increased vascular permeability associated with inflammatory processes.

Table 14.6 Body fluid classifications and parameters.

	Fluid type		
	Transudate	**Modified transudate**	**Exudate**
Cellularity (cells/μL)	<1500	1000–7000	>5000
Color	Colorless	Variable	Yellow to tan
Protein (g/dL)	<2.5	2.5–5.0	>2.5
Turbidity	Clear	Variable	Cloudy to opaque

Shock

Shock is a rapidly progressive disturbance of hemodynamics and cellular metabolism. It can be characterized as hypovolemic, cardiogenic, or vasogenic based on the underlying mechanism. Despite the mechanism, it concludes with vascular hypotension, tissue hypoperfusion, cellular hypoxia, and acidosis and may lead to death.

Hypovolemic shock develops from a significant decrease in blood volume, which results in decreased vascular pressure. Blood volume can be decreased by the direct loss of whole blood (i.e. hemorrhage) or fluid components (i.e. dehydration) from the vascular system.

Cardiogenic shock is characterized by the heart's inability to efficiently pump blood. Lesions within the endocardium, myocardium, or pericardium may hinder efficiency and result in shock by decreasing stroke volume and cardiac output.

Vasogenic shock arises from peripheral vasodilation. Inadequate vascular tone leads to pooling of blood, reduction of circulating blood, and tissue hypoperfusion. Vasogenic shock is commonly identified in pigs and can result from trauma, stress, anaphylaxis, sepsis, endotoxemia, or insult to the CNS.

Diseases of the hemopoietic system

Anemia

Anemia is defined as a decrease in the hematocrit level, hemoglobin concentration, or RBC mass. A number of classification systems exist that categorize anemia based on physical properties (erythrocyte size and hemoglobin concentration), bone marrow response (regenerative vs. nonregenerative), or the underlying pathological processes (defective erythropoiesis, hemorrhage, and hemolysis). Clinical signs may be variable dependent on the severity of the anemia and the underlying mechanism. Anemia can clinically manifest as mucous membrane

Table 14.7 Causes of porcine anemia.

Thrombocytopenia

pallor, weakness, tachycardia, and/or tachypnea. Potential causes of porcine anemia are listed in Table 14.7.

Causes of porcine anemia

Defective erythropoiesis

Defective erythropoiesis is an important cause of porcine anemia and can develop due to nutritional deficiencies, chronic disease, or infectious agents. Suckling piglets are particularly susceptible to iron deficiency anemia (IDA) due to rapid growth, a low iron storage capacity, and a lack of sufficient dietary intake. Piglets require approximately 7 mg of iron daily and only obtain half of that requirement through milk. Modern indoor husbandry practices have reduced the amount of iron naturally obtained by piglets from the soil and have increased the need for neonatal iron supplementation. Affected piglets classically appear normal at birth but become unthrifty and pale and develop edema of the lungs, muscles, and connective tissues at approximately 1–3 weeks of age. IDA is characterized by erythrocyte microcytosis and hypochromasia. Bone marrow may be dark red and hyperplastic, and exhibit an erythroid shift, but may become hypoplastic with chronic deficiency.

Copper promotes iron absorption and is essential for the incorporation of iron into hemoglobin (Lee et al. 1968). Copper deficiency thus can result in a lack of iron availability and predispose to IDA.

Anemia of inflammatory disease (AID) can occur with multiple infectious, inflammatory, or neoplastic processes. Mechanistically, AID develops secondarily to the impact of inflammatory cytokines on iron availability, erythropoietin production, and the bone marrow's response to erythropoietin. Erythrocytes are typically normocytic and normochromic, but microcytosis and hypochromia may be evident. The primary disease process commonly dominates the clinical assessment, and anemia typically resolves once the primary disease has been alleviated. Certain viruses also play a direct role in the development of anemia. Porcine reproductive and respiratory syndrome virus can experimentally induce anemia in pigs (Halbur et al. 2002). The exact mechanism of anemia is not known, but the virus has been postulated to directly or indirectly disrupt erythropoiesis.

Hemolytic anemia

HA develops from the premature destruction of erythrocytes. In swine, it has been associated with immune-mediated mechanisms, erythrocyte parasitism, and erythrocyte fragmentation. Clinically affected animals may develop icterus and hemoglobinuria.

Neonatal isoerythrolysis is an immune-mediated disease of pigs and other animals. HA develops through the passive acquirement of maternal antibodies that have been primed against fetal erythrocytes. Once introduced into the neonatal circulatory system, material antibodies bind to piglet erythrocytes and activate the complement cascade. Complement lyses erythrocytes and releases hemoglobin into the plasma. Acquired immune-mediated anemia is rare but can result from haptens or autoimmune phenomena.

Hemotropic *Mycoplasma suis*, formerly known as *Eperythrozoon suis*, is capable of attaching to and infecting porcine erythrocytes. Extravascular hemolysis develops secondary to the removal of infected erythrocytes from the circulatory system.

Microangiopathic anemia results from the removal of injured erythrocytes from the circulatory system. Erythrocyte membranes may become fragmented by fibrin when passing through damaged blood vessels. Vasculitis, DIC, and vascular neoplasia are potential causes of microangiopathic anemia in swine.

Hemorrhagic anemia

Hemorrhagic anemia (HeA) frequently develops secondarily to an acute or chronic blood loss event. External evidence of hemorrhage is usually evident in cases of trauma or umbilical hemorrhage, but may be externally inconspicuous in cases of gastric ulceration, hemorrhagic bowel syndrome, enterocolitis, external or internal

parasitism, and thrombocytopenia. Clinical signs may or may not be present based on the amount of blood loss, chronicity of disease, and distribution of lesions. A regenerative response is evident within days of blood loss, but may become nonregenerative in chronic cases due to iron deficiency.

Hemoglobin disorders

Pathological alterations of hemoglobin reduce the erythrocyte's ability to carry oxygen to the tissues. Carboxyhemoglobinemia and methemoglobinemia are recognized hemoglobin disorders in swine. Both conditions typically result in cyanosis and anoxia.

Carbon monoxide poisoning is a potentially fatal disease that manifests in pigs housed indoors with defective heaters and improper ventilation. Carbon monoxide is a colorless, odorless, and tasteless gas generated from the partial or incomplete oxidation of carbon-based fuels. Carbon monoxide has a higher binding affinity to hemoglobin (approximately >200 times greater), in comparison with oxygen, and blocks the oxygen-carrying capacity of hemoglobin. Affected animals have bright cherry red blood as a result of the formation of carboxyhemoglobin. Animals that do not die can develop CNS disorders as a result of anoxia.

Swine exposed to excessive amounts of oxidizing agents, such as nitrate and nitrite, are at increased risk of developing methemoglobinemia. Normally, the iron component of hemoglobin must be in the reduced ferrous state to effectively bind to oxygen and form oxyhemoglobin, which transports oxygen to the tissues. Methemoglobinemia develops when ferrous hemoglobin is oxidized to methemoglobin and can no longer transport oxygen. Blood of affected animals classically turns a distinctive dark chocolate brown color.

Coagulation disorders

Bleeding disorders are fairly uncommon in swine but can develop due to maternal isoimmunization (thrombocytopenic purpura) (Nordstoga 1965) or consumption of anticoagulant compounds such as warfarin. Pathological lesions are restricted to multiorgan hemorrhage. Diagnosis is by identifying sow-derived isoantibodies to piglet platelets or the presence of anticoagulants in body tissues.

Cardiovascular and hematopoietic neoplasia

Naturally occurring neoplasia is infrequently diagnosed in swine due to the short life span of production animals. Porcine tumors do not frequently cause clinical signs and are typically found as incidental lesions in diagnostic specimens or in carcasses at slaughter. Tumors that are most frequently identified in the cardiovascular and hematopoietic systems of swine include lymphoma, hemangiosarcoma, hemangioma, and cardiac rhabdomyoma.

Lymphoma is the most commonly diagnosed and economically important neoplasia in swine. It develops from the neoplastic proliferation of T or B lymphocytes and most frequently develops in pigs less than 1 year of age. A number of factors, such as C-type viruses and hereditary genetic components have been associated with the development of lymphoma. Multicentric, thymic, and leukemic forms have been identified with the former being the most common. Porcine multicentric lymphoma is frequently of B-cell origin and when occurs most commonly does so in the spleen, liver, kidney, intestine, and bone marrow. Conversely, thymic lymphoma develops in the cranial mediastinum and is of T-cell origin. Leukemia is rarely identified in swine but can occur in late stages of either thymic or multicentric lymphoma.

Tumors of the porcine cardiovascular system are rare. Over an 11-year period, Fisher and Olander (1978) identified five vascular tumors in tissues and necropsy samples submitted to Purdue University. These tumors were diagnosed as cutaneous and testicular hemangiosarcomas and cutaneous and meningeal hemangiomas, respectively.

While cardiac tumors are rare, congenital cardiac rhabdomyoma is the only tumor identified in the porcine heart with any frequency. This tumor consists of nonneoplastic nodular proliferations of dysplastic myocardial fibers (Omar 1969). Given the misnomer, alternative names have been suggested such as porcine cardiac rhabdomyomatosis and purkinjeoma. Affected hearts may have well-demarcated white myocardial nodules that impede into the heart chambers. Most of these tumors are identified as incidental lesions at necropsy and are not thought to cause significant pathology.

Digestive System

Jill R. Thomson and Robert M. Friendship

Introduction

Conditions affecting the gastrointestinal tract (GIT) occur in pigs of all ages. Enteric diseases substantially compromise production efficiencies and profitability of pig production globally. Some diseases, such as highly virulent porcine epidemic diarrhea (PED), can result in epidemics of high piglet mortality and significant economic hardship to farmers. Such events gain global media coverage, stimulating international alerts and precautionary measures. However, recurring endemic enteric diseases have the greatest long-term impact on health and productivity globally. In addition to direct economic and productivity losses, there are concerns regarding animal welfare and the rate of antimicrobial use for endemic diseases. The latter fuels public health concerns regarding antimicrobial resistance, which sometimes results in legislated requirements to reduce antimicrobial use in pigs. Hence, there are ongoing and global efforts to seek innovative ways to prevent enteric disease expression, thereby limiting the need for antimicrobial use.

The complexity of the sciences, risk factors, and perceptions involved in our understanding of intestinal function that affect health and productivity cannot be overstated; the interface of anatomy, physiology, diet, endemic microflora, pathogens, and immune mechanisms allows for nearly infinite permutations of situations and outcomes. Fortunately, ever-improving quantitative molecular methods allow researchers to better understand the influence of the intestinal microbiota and explore how flora can be modulated through diet or other methods to optimize intestinal health, immunity, and the overall productivity of the pig.

Current research efforts increasingly acknowledge the role of intestinal flora in mitigating disease expression and addresses public expectations over food safety and antimicrobial issues. Successful control of enteric diseases requires a holistic view that considers factors such as nutrition, stress, immunity, intestinal microbiota, and management practices in the expression of disease. Research into these wider issues provides a foundation for future practical advances in enteric disease control and is briefly reviewed in the following sections. Thereafter there is an overview of the enteric system, with many of the specific diseases covered in depth in other chapters.

Anatomic and histologic features

Genetic selection has dramatically changed many characteristics of swine over the years; however, the gut anatomy apparently remains unchanged. Genetic selection does have some promise in selection for disease resistance for specific pathogens, one example being the development of swine genotypes lacking specific receptors, therefore resistant to F18 and F4 (K88) *Escherichia coli*.

Gut maturation occurs rapidly after birth in response to factors such as oxygenation, enteral nutrient presentation, development of microflora, and hormones such as cortisol and epidermal growth factor. Neonatal hypoxia is associated with intestinal dysfunction and an increased incidence in neonatal enterocolitis (Cohen et al. 1991; Powell et al. 1999). At birth, the sudden increase in blood arterial oxygen is a vital factor in gut development. Common occurrences such as delayed or prolonged parturition and congenital or periparturient pulmonary compromise or lung infections could be initiating factors for neonatal diarrhea. After birth, the small intestine undergoes a rapid growth in response to enteral presentation of nutrients (Burrin et al. 2000). This is stimulated by a wide range of factors such as hormones and growth factors (Sangild 2001). Good intake of colostrum and milk in the early stages of life is important for rapid gut growth, passive immunity, and piglet vigor.

Piglets are born with fully erupted "milk" or "needle" teeth. The majority of deciduous premolars erupt

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

between the first and fifth week of life (Tucker and Widowski 2009) followed by other deciduous teeth that are replaced by permanent teeth over time. The age at which the premolars erupt was found to affect piglets in different ways. Piglets that were less than 17 days of age were inhibited from feeding, presumably due to the associated discomfort. Piglets that were 21 days of age or older were actually attracted to feed, possibly getting comfort from the mechanical effects of feed against the gums (Tucker et al. 2010). The problems of weaning at very young ages could be compounded by anorexia associated with discomfort of tooth eruption.

Digestive enzymes are produced primarily by the pancreas and enterocytes. The production of enzymes by the pancreas, such as amylases and lipases, is under nervous and hormonal control and increases substantially during the first 6 weeks after birth (Pluske 2001). During the first 3–4 weeks of life, the fetal enterocytes that have high endocytotic activity are replaced by adult-type enterocytes devoid of such activity. The process occurs in a proximal-to-distal direction in the intestine and is an important part of intestinal maturation (Baintner 1986). Changes in enterocyte generation influence the expression of brush border enzymes. Lactase activity is high in the newborn pig and steadily decreases to become minimal after weaning, whereas sucrase and maltase activities are low in the newborn but increase after weaning (Pluske et al. 1997). Intestinal maturation may be hastened in the unweaned pig by stimulating additional milk intake (Pluske et al. 1996a,b) or feeding kidney bean lectin (*Phaseolus vulgaris*) (Biernat et al. 2001; Rådberg et al. 2001). This dietary means of promoting rapid gut maturation could be of value in reducing or preventing post weaning diarrhea problems in pigs in the future.

Weaning is associated with adverse effects, such as abrupt withdrawal of sow's milk, low and variable feed intake, growth stasis, and compromised integrity of the small intestinal epithelium. Changes in gut morphology at weaning include reduced villus height and increased crypt depth (Hampson 1986; Kelly et al. 1991). These adverse effects can be diet dependent and diet independent (Boudry et al. 2004; McCracken et al. 1995). Villus length reduces by 30–40% at days 4–7 post weaning but can be restored by 14 days post weaning (Verdonk et al. 2001a). Additionally, a reduction in the length of microvilli occurs by 3–7 days after weaning (Cera et al. 1988).

There are important impacts of voluntary feed intake and diet composition on mucosal architecture (Makkink et al. 1994; Pluske et al. 1996b). Low feed intakes or a period of starvation post weaning reduces the villus height throughout the small intestine particularly in the proximal jejunum. Moreover, feed ingredients that contain anti-nutritional factors such as antigenic proteins, protease inhibitors, or some types of (harmful) lectins and tannins or are poorly digestible can induce changes in gut morphology as well and can influence the rate of recovery. To minimize the changes, diets high in milk products, highly digestible ingredients, and low levels of anti-nutritional factors are often used.

Raw cereals and legume seeds adversely affect gut mucosa, especially in young piglets. Feeding properly heat-processed (e.g. cooked, extruded, micronized, pelleted) legume seeds and cereals can improve post weaning growth (Lawlor et al. 2001). The temperature of the feed presented to newly weaned pigs significantly influenced feed consumption and growth performance when mash was fed at a temperature of 34 °C as compared with 14 °C (Reiners et al. 2008).

Anorexia and other stress-related factors at weaning impair the normal barrier function, which increases mucosal permeability by adversely affecting the tight junctions between cells (McCracken et al. 1999). This increases over the first 4 days after weaning, which can contribute to the appearance of dietary toxins and endotoxins in the bloodstream and to local inflammation (Verdonk et al. 2001b). Early weaning heightens this effect (Smith et al. 2010). Recent studies suggest that these changes can extend beyond 1–2 weeks post weaning depending upon the degree of stress experienced (Moeser 2016).

The dietary changes at weaning and the resultant villous atrophy and crypt hyperplasia lead to decreased digestive and absorptive capacities in the intestine (Pluske et al. 1997; Rådberg et al. 2001). If severe, this can result in a malabsorptive form of diarrhea due to electrolytes, nutrient solutes, and osmotically associated water. Other factors of importance include poor feed consumption, inflammation in response to bacterial metabolites, rotaviruses, and hypersensitivity to antigenic components of the diet (Kelly 1990). These physiological changes can result in alterations in the numbers, types, and distribution of the enteric bacterial flora that can increase likelihood for enteropathogenic bacteria to proliferate, resulting in serious post weaning enteropathies such as colibacillosis. The morphological and functional changes in the small intestine of the newly weaned pig have been reviewed by Pluske (2001).

Transport-associated stress of pigs has been shown to lower the intestinal pH and result in increased intestinal permeability. Permeability is the highest immediately after transportation and decreases after 2–3 hours of rest (van der Meulen et al. 2001). Translocation of bacteria and/or endotoxins from the gut into the systemic circulation is possible due to increased permeability (Berg 1999; Zucker and Krüger 1998). This might explain the increase in disease problems seen after transportation (Berends et al. 1996). Similarly, in growing pigs, heat stress has been found to reduce the intestinal barrier

function and mucosal immunity emphasizing the need for effective thermoregulation of the pig's environment to maintain optimal gut health (Pearce et al. 2013).

Digestive physiology

The intestinal mucosa receives nutrients from two sources – the diet (brush border membrane) and the systemic circulation (basolateral membrane). The gut tissues have their own particular nutrient requirements for growth and function. The gastrointestinal tissues in the very young pig utilize up to 50% of the dietary intake of key amino acid such as lysine, glutamine, leucine, and threonine (Burrin et al. 2001). A substantial proportion of amino acid and glucose needs are derived from the arterial circulation rather than from direct dietary sources, while some enteric fermentation products such as butyric and lactic acid serve as nutrients and metabolic regulators of gastrointestinal tissues as well (Burrin et al. 2001). The amino acids are utilized in many ways, such as the formation of secretary mucins (Stoll et al. 1998), biosynthesis of other amino acids (Stoll et al. 1999), glutathione (Reeds et al. 1997), and nucleic acids (Perez and Reeds 1998).

Nutrient supply for the neonate is derived solely from colostrum and milk. Additionally, colostrum and milk contain a large number of biologically active peptides that have important functions in regulating growth and differentiation of intestinal tissues. Targeted expression of key genes for production of milk peptides holds potential for the future (Kelly and Coutts 1997). On low protein diets, the amino acid requirements of the gut remain relatively high and are preferentially met, which limits the systemic availability of amino acids for lean tissue growth (Ebner et al. 1994).

Dietary carbohydrates are composed of sugars, oligosaccharides, starch, and non-starch polysaccharides (NSPs), these being vital dietary components in addition to protein and fat. The enzyme activity responsible for carbohydrate degradation adapts according to the age of the pig and dietary composition. In the young pig there is efficient pre-cecal digestion of lactose during suckling and sucrose and starch after weaning. Carbohydrates that do not get digested in the small intestine are fermented in the large intestine by a diverse population of anaerobic bacteria.

Most of the starches used in pig diets are highly digestible, with up to 98% of digestion occurring in the small intestine of pigs with mature digestive systems (Bach Knudsen and Canibe 2000; Glitsø et al. 1998). NSPs (fiber) are present in cereals, such as barley, wheat, oats, and rye, and legume seeds, such as soybeans, peas, and faba beans. Although there is some digestion of NSPs in the small intestine, the major site of NSP degradation is in the large intestine. Passage of ingesta through the large intestine generally takes from 20 to 40 hours, allowing time for bacterial degradation. Fermentation of carbohydrates and NSPs in the large intestine results in the production of short-chain fatty acids, mainly acetate, propionate, and butyrate, and the gases H_2, CO_2, and CH_4. Studies using naturally occurring fermentable carbohydrates to promote fermentation and gut health have shown beneficial results (Aumiller et al. 2015; Jha and Berrocoso 2015). They also increase production of short-chain fatty acids, which are rapidly absorbed from the large intestine and may provide up to 24% of the maintenance energy requirements for growing pigs (Yen et al. 1991) and potentially even more for adults. The total tract digestibility of NSPs is influenced by a number of complex factors, such as the source of NSPs, the level of inclusion in the diet, the solubility, the degree of lignification, the age and weight of the animal, the transit time, and the microbial composition (Bach Knudsen and Jørgensen 2001).

Large volumes of fermentable substrate arriving in the large intestine can cause osmotic overload, with resulting diarrhea. This may result from excessive intake or malabsorption of carbohydrate in the small intestine. The increased volatile fatty acid (VFA) production can overwhelm the colonic buffering capacity, causing reduced pH and increased numbers of lactic acid-producing bacteria. As lactic acid is absorbed at a slower rate than VFAs, further acidification occurs, with the resulting influx of water and solute from tissue into the lumen. Diarrhea results from this process if acidification is excessive. Adult animals are more capable of degrading fiber than growing pigs due to the greater intestinal volume and slower transit times. Adaptation to dietary changes in terms of digestibility of NSP residues is considered to take 3–5 weeks (Longland et al. 1993).

In weaned pigs, the use of enzyme combinations has been found to increase the apparent ileal digestibility of feeds based on hull-less barley, which have high beta-glucan concentrations (Yin et al. 2001). Due to the improved apparent ileal digestibility, there was also a reduction in hindgut fermentation. Similarly, the addition of certain enzymes to wheat-based diets of growing pigs has been found to have beneficial effects (Hazzledine and Partridge 1996). There is increasing interest in the role of dietary factors, especially NSP and feed processing methods in so-called nonspecific colitis of pigs (Strachan et al. 2002; Thomson et al. 2004). This condition is thought to be an important precursor to other forms of colitis in pigs although the pathogenesis of this diet-associated form of colitis is poorly understood.

Immunology

For the first 24–48 hours postpartum, the pig intestine is capable of absorbing macromolecules, including immunoglobulins by pinocytosis, providing the neonate

with passive immunity from colostrum (Weström et al. 1984). This process commences prepartum and may form part of prenatal nutritional programming of the GIT (Guilloteau et al. 2010); however, the major absorptive function occurs postnatally (Sangild et al. 1999). This is a specific maturational process that is timed to maximize immunoglobulin uptake shortly after birth. Piglets born prematurely have a lower capacity for protein absorption than piglets born at full term (Sangild et al. 1997); therefore fetal maturity is an important factor in successful immunoglobulin uptake from the colostrum.

The intestinal immune system of the young pig is very immature, and its slow development may result in increased susceptibility to disease (Stokes et al. 2001). Intestinal lymphoid tissue is present in the form of mesenteric lymph nodes, intestinal Peyer's patches, and lymphocytes distributed through the mucosal lamina propria and intraepithelial sites. In the jejunum there are between 11 and 26 discrete Peyer's patches containing multiple lymphoid follicles (B lymphocytes), separated by T cells. Plasma cells containing IgM, IgG, and IgA are present in the subepithelial lymphoid dome and between the follicles (Brown and Bourne 1976). The dome region contains dendritic-type cells that express high levels of MHC II antigens. Microfold cells (M cells) that are thought to absorb luminal antigens occur in the overlying lymphoepithelium (Gebert et al. 1994).

In the mature pig the intestinal lamina propria is heavily populated with lymphocytes. Plasma cells and B cells predominate in the crypt area, whereas T cells are found mainly in the villi, $CD8^+$ cells occur in the subepithelial sites, and $CD4^+$ cells occur in association with capillary plexuses in the lamina propria (Vega-Lopez et al. 1993). The majority of intraepithelial lymphocytes express CD2, but in mature pigs a high proportion also express CD8 (Stokes et al. 2001). The general immune status of piglets can be influenced by factors such as weaning age, and photoperiod allowed for piglets after weaning. Niekamp et al. (2007) found benefits to piglet immunity from weaning at 28 days as compared with 14 or 21 days and from a daily photoperiod allowance of 16 hours as compared with 8 hours.

Functionally the intestinal immune mechanisms play a complex role in preventing and controlling harmful intestinal infections while tolerating many dietary antigens and nonharmful antigens from the intestinal flora. The surface epithelium serves as an effective barrier, providing it remains intact. For the neonatal piglet, exposure to new antigens is critical for the proper development of the gut mucosal immune system, which is characterized mainly by the establishment of IgA response (Levast et al. 2014). Significant quantities of dietary protein are absorbed across the intestinal mucosa (Telemo et al. 1991; Wilson et al. 1989).

So-called intestinal tolerance to dietary proteins has been demonstrated in the pig, whereby immune responses to the dietary proteins are regulated to prevent inflammatory reaction and tissue damage associated with foreign protein absorption (Bailey et al. 1993). The interaction between the different components of the intestinal immune system is complex, and the basis of inflammation and apoptosis versus downregulation of immune responses is the subject of ongoing research.

Development of the intestinal immune system occurs in response to antigen exposure. Full development of lymphoid tissue can take 7–9 weeks and can be delayed by early weaning at 3–4 weeks of age, a practice common in most modern pig-producing countries (Vega-Lopez et al. 1995). This, among many other factors, predisposes to post weaning diarrhea associated with enterotoxigenic *E. coli* (ETEC) or other pathogens. There is increasing interest in the role of glutamine in intestinal immune function. Glutamine is an important nitrogen source for enterocytes and plays a key role in maintaining mucosal cell integrity and gut barrier function (den Hond et al. 1999). Key functions of lymphocytes are dependent on glutamine provision (Graham et al. 2000); glutamine depletion results in immunosuppression, whereas glutamine administration has been found to have significant beneficial effects on the gut mucosal structure and intestinal immune function of piglets after weaning (Pierzynowski et al. 2001). Enhanced intestinal immune function of piglets at weaning by feeding nucleotides for 2–4 weeks after weaning was found to have an immune-enhancing effect on piglets through improving T-cell–mediated responses (Cameron et al. 2001).

The use of dietary immunomodulators including yeast extracts, plant extracts, and animal by-products in weaned pigs has been reviewed by Gallois and Oswald (2008). To date the most promising results have been obtained with the use of spray-dried animal plasma, particularly porcine plasma. A number of studies in which pigs were orally challenged with pathogenic *E. coli* have shown that pigs fed spray-dried porcine plasma (SDPP) had less adverse clinical signs and growth effects (Bosi et al. 2004; Niewold et al. 2007; Torrallardona et al. 2007; Yi et al. 2005). In addition to providing specific antibody protection, nonspecific binding of the plasma molecules to intestinal receptors for *E. coli* is also thought to occur in pigs fed SDPP. Starter diets containing 5% or more SDPP fed for 14 days after weaning were found to reduce intestinal barrier dysfunctions associated with weaning stress and increase feed intake and growth rate (Peace et al. 2011; Pujols et al. 2016).

The role of conjugated linoleic acid (CLA) in the prevention of bacterial-induced colonic inflammation in the pig was studied by using a swine dysentery challenge model (Hontecillas et al. 2002). Feeding CLA-supplemented diets for 7 or 10 weeks pre-challenge prevented clinical

signs and lesions of swine dysentery. Despite colonization by *Brachyspira hyodysenteriae*, the CLA-supplemented pigs maintained cytokine profiles and lymphocyte subset distributions in keeping with non-challenged control pigs. This suggests that CLA modulates the pig's immune effector mechanisms preventing the normal host response to infection, instead of targeting the bacterial agent. Finding cost-effective methods of enhancing immune responses that promote tolerance of intestinal pathogens in weaned and grower pigs under commercial conditions would bring significant benefits to the pig industry.

Gut flora

The intestinal flora of the pig is extremely complex and diverse, making it difficult to study quantitatively and qualitatively, but this is an area of increasing interest in relation to maintaining nutritional, physiological, and immunological functions (Lee and Mazmanian 2010, Brestoff and Artis 2013). Our knowledge of the gastrointestinal microbiota has dramatically changed with the development of new molecular tools to describe taxonomic compositions and distributions. The increasing realization that the microbial ecosystem of the gut strongly influences health and performance has sparked interest in this area. Isaacson and Kim (2012) have reviewed studies of the microbiome of the GIT of pigs and described the impact of diet changes, stress, and disease. In summary, they report that the majority of bacteria in the pig intestine belong to two phyla: *Firmicutes* and *Bacteroidetes*. There are distinct differences in the microbiome from region to region. For example, in the ileum, there are a high proportion of bacteria from the phylum *Proteobacterium*. Most of the studies reviewed by Isaacson and Kim (2012) are descriptive in nature, and there remains a need for research that investigates how the composition of the gut microbiome contributes to the health of the pig.

Marked changes occur in the gut environment (for example, pH and organic acids) and microbial activity along the GIT of pigs (Bach Knudsen et al. 1991, 1993). Differences in the diet composition can impose further changes and could affect the diversity of the gut microflora. In experiments involving diets containing different levels of soluble and insoluble NSPs, a medium to high content of NSP resulted in higher microbial diversity in the small intestine and rectum (Högberg et al. 2001, 2004). The high NSP diets induced a higher proportion of propionic acid, and the low NSP diets induced a higher proportion of acetic acid, suggesting that the balance of the microbial flora was altered accordingly by differences in the dietary carbohydrate composition. The ratio of soluble to insoluble NSP also influenced the coliform diversity in the large intestine. A higher proportion of soluble NSP increased the coliform diversity, reflecting a more balanced microbiota compared with that generated by the diets that were higher in insoluble NSP. In recent years, many studies have shown how the intestinal microbiota can be manipulated through dietary changes aimed to promote "beneficial" bacteria, such as use of a low fat/high fiber diet (Heinritz et al. 2016). It is a noteworthy reminder that the microbiota in the gut lumen is distinct from the bacteria that adhere to the mucosa. Levesque et al. (2012) showed that ileal mucosa-associated bacteria, but not the bacteria in the digesta, were influenced by nutrition and the use of antibiotics.

The quantity and quality of protein fed to pigs can also have an impact on the microbiota, particularly if there is an imbalance between fermentable carbohydrate and potentially fermentable protein in the large intestine (Bikker et al. 2006; Piva et al. 2006). Microbial protein digestion in the large intestine may result in increased levels of potentially toxic substances, e.g. ammonia, amines, and phenols, that can contribute to the adverse effects of enteropathogenic processes (Bikker et al. 2006; Nyachoti et al. 2006).

The potential value of prebiotics (compounds other than dietary nutrients that act as substrates for populations of beneficial microbial organisms in the gut) and probiotics (preparations containing beneficial bacteria) has been the subject of many studies in relation to gut health and prevention of enteric infections. Prebiotics achieve their beneficial effects in two ways. First, compounds such as fructo-oligosaccharides can be fermented by favorable bacteria (e.g. *Bifidobacteria* and lactobacilli), giving them competitive advantage (Bindels et al. 2015; Nemcová et al. 1999). Second, mannose-containing compounds added to the diet result in binding with pathogenic bacteria such as *E. coli* and *Salmonella* that may have mannose-specific lectins in fimbriae. This reduces attachment of pathogenic bacteria to receptor sites on gut mucosal cells (McDonald et al. 2002). Inulin is a natural polymer of fructose extracted from chicory that is considered to have prebiotic properties (Gibson and Roberfroid 1995; Roberfroid et al. 1998). Digestion of inulin in weaned pigs is mainly microbial and takes place in the large intestine where it modifies the profile of fermentation metabolites, resulting in an increase in N-valerate and propionate and a decrease in acetate and ammonia (Rossi et al. 1997). The short-chain fatty acids including butyrate stimulate the growth of *Bifidobacteria* and lactobacilli. Butyrate regulates processes associated with proliferation and differentiation of colonic enterocytes as well as apoptosis, thereby having a direct effect on colonic health (Tako et al. 2008). Using an *in vitro* adhesion assay for *E. coli*, 5% inulin was found to partially inhibit adhesion of F4-positive *E. coli* to the small intestinal villi. The study also suggested that inulin might have immunomodulatory effects by boosting IgA and

IgM antibodies in pigs exposed to foreign proteins (Rossi et al. 2001). In newly weaned pigs, addition of fructo-oligosaccharide and/or sugar beet pulp to the diet tended to increase the number of intestinal *Bifidobacterium* species and reduce the level of *E. coli*, although there was little difference in the incidence of diarrhea (Kleingebbink et al. 2001). The population of *Bifidobacterium* species is variable in piglets and constitutes less than 1% of the total bacterial population (Mikkelsen and Jensen 2001), so research to determine the full spectrum of beneficial bacteria in the microbiota will aid understanding greatly in years to come (Bindels et al. 2015). Certain plant metabolites may interact with short-chain fatty acids to create inhibitory conditions for pathogens such as *E. coli* 0157 (Duncan et al. 1998).

Probiotics, known as direct-fed microbials in the livestock industry, work on the principle of competitive exclusion of pathogenic bacteria and have been used successfully to control *Yersinia* infection in pigs (Asplund et al. 1996). Feeding probiotic bacteria, especially *Lactobacillus* and *Bifidobacterium*, may help with controlling enteric infections pre- and post weaning when the resident microflora are not yet stable (Hou et al. 2015; Pieper et al. 2010). They can enhance immune responses during infection (Naqid et al. 2015) and promote weight gain (Konstantinov et al. 2008). Probiotics may also inhibit adherence of enteropathogenic *E. coli* and other gram-negative bacteria to enterocytes through occupying receptor sites (Mack et al. 1999; Spencer and Chesson 1994). This has potential for improved control of a wide range of enteric infections, particularly those of zoonotic importance such as *Salmonella* and *Campylobacter*. However, the efficacy of probiotics is reported to be inconsistent, requiring continued application, with timing and correct dosing both playing a major role in their success (Fouhse et al. 2016). The use of probiotics is subject to regulatory control in many countries to ensure their safety and efficacy.

Dietary interventions

Following the European Union ban on the use of the majority of antibiotic growth promoters, alternative measures to control the number and activity of intestinal bacteria have been explored. These include changes in management, feeding, and hygiene practices; the use of products such as probiotics, prebiotics, enzymes, herbs and plant extracts, prefermented feeds, and organic acids (de Lange et al. 2010; Thomke and Elwinger 1998); selective breeding for resistance; improving the pig's immune response through the use of vaccines, cytokines, and other immunomodulatory agents; organic acids; inorganic chemicals such as zinc oxide; and the use of specific bacteriophages or bacteriocins (de Lange et al. 2010; Gallois and Oswald 2008). Different cereals (wheat-based vs. barley-based diets), methods of feed processing (mash vs. pellets), and factors including feed particle size have all been explored (Jansman 2016). Weaned pigs were found to have better uniformity of the mucosal microbiota when fed a barley-based diet as compared with wheat (Levesque et al. 2014). Furthermore, feeding barley-based diets with large particle sizes as a mash has been found to reduce shedding of *Salmonella* species, reduce intestinal *E.coli* numbers, and increase beneficial butyric and propionic acid levels in the cecum and colon (Pieper et al. 2012; Longpré et al. 2016). However, despite such benefits, in general, growth performance was found to be poorer on such diets, so they are commercially disadvantageous.

Dietary fiber and cereals

Different forms of fiber in the diet can influence the composition and metabolic activity of the large intestinal microflora in pigs (Bach Knudsen et al. 1991; Jensen and Jørgensen 1994; Reid and Hillman 1999). Little is known of mechanisms by which the commensal colonic microflora interacts with pathogenic bacteria; hence the basis of dietary control of infectious enteric diseases through manipulating the microbiota is not understood. Ways in which diet could influence pathogenic enteric infections include changing the amount or balance of substrates available for the organism at particular sites, influencing the viscosity, accessibility to receptor sites, and/or intestinal motility. For example, different cereal types and particle sizes were shown to alter epithelial cell proliferation and lectin binding patterns of the epithelium of the large intestine of pigs (Brunsgaard 1998).

The diet can also influence intestinal function. Components in boiled rice inhibit secretion in the small intestine and therefore reduce the magnitude of secretory diarrhea due to pathogens such as ETEC (Mathews et al. 1999).

One of the best-recognized examples of dietary effects on enteric pathology is gastric ulceration (complete discussion below), in which ulceration of the pars esophagea occurs, particularly in growing and finishing pigs. Such lesions can be associated with reduced growth rates (Ayles et al. 1996a) but more importantly can be a cause of gastric hemorrhage and perforation leading to acute illness and death. Many studies have demonstrated a strong association between finely ground high wheat diet and gastric ulceration (Accioly et al. 1998).

Early studies on the influence of diet in post weaning colibacillosis suggested that inclusion of fiber sources reduced the severity and incidence of diarrhea (Bertschinger et al. 1978; Bolduan et al. 1988). Later studies have compared the effects of feeding different post weaning diets in experimental *E. coli* challenge

models. Conclusions from research by different groups are inconsistent, revealing that this area is still poorly understood. For example, studies by McDonald et al. (1999, 2001) showed that diets supplemented with NSP increased the number of *E. coli* in piglet intestines and concluded that these diets were "provocative" in terms of causing diarrhea. Conversely, Wellock et al. (2008) found that inclusion of soluble NSP in the diet was beneficial to piglets challenged with ETEC. The occurrence of diarrhea was significantly reduced; there were lower cecal digesta pH and an increased *Lactobacillus* to coliform ratio when compared with pigs fed diets containing insoluble NSP. Clearly, this is a complex area where the quantity, nature, viscosity, and transport time of the small intestine contents influence the proliferation rate of intestinal microbes. This affects the rate of intestinal motility, fermentation processes, and ultimately the health of the newly weaned piglet. In studies comparing wheat- and barley-based diets in weaned pigs, better uniformity of the mucosal microbiota was found with barley-based diets (Levesque et al. 2014). *Salmonella* persistence and shedding can be reduced significantly through dietary changes, notably by feeding barley-based diets as a meal; however this is not practical for many feeding systems, and it can be disadvantageous economically.

The most work has been done on the influence of diet to manipulate expression of *Brachyspira* infections through altering the fermentation processes or the microbiota in the large intestine or a combination of both. Whereas a highly digestible cooked rice diet was found to be protective for swine dysentery in some studies (Siba et al. 1996), it was not in others (Kirkwood et al. 2000; Lindecrona et al. 2003). Feeding the cooked rice diet to pigs already affected with swine dysentery did not reduce the duration or severity of disease (Durmic et al. 2000). In porcine colonic spirochetosis, pigs on the cooked rice diet developed infection later and to a lesser extent than pigs on wheat-based diet (Hampson et al. 2000; Lindecrona et al. 2004). In a study of different cereal types, feeding steam-flaked maize or sorghum reduced the incidence of swine dysentery (Pluske et al. 1996a). Soluble NSP and resistant starch were identified as important factors promoting large intestinal fermentation and bacterial colonization, whereas with the addition of a source of mainly insoluble NSP (oat chaff), the diet remained protective (Pluske et al. 1998). Addition of enzymes to wheat-based diets and the use of heat extrusion to increase digestibility of starch in the small intestine were tested in terms of their potential protective effects in swine dysentery, but neither processes prevented colonization (Durmic et al. 2000). Likewise the use of a sorghum-based diet was tested as sorghum is inherently low in soluble NSPs, but this diet was not protective against swine dysentery (Durmic 2000). However, the grind size of diets was important with significantly more pigs developing swine dysentery with coarsely ground wheat or sorghum than with these grains finely ground (Hampson et al. 2001). In a comparative study using a barley/triticale-based diet supplemented with either rapeseed cake or dried chicory roots and sweet lupins, the latter diet was found to be completely protective when pigs were challenged with *B. hyodysenteriae* (Thomsen et al. 2007). The colonic microflora of those pigs had higher proportions of *Bifidobacteria* and *Megasphaera* species that might have inhibited colonization by *B. hyodysenteriae* (Mølbak et al. 2007). *In vitro* studies have shown that growth of *B. hyodysenteriae* can be inhibited by at least four different bacteria isolated from the pig GIT (Klose et al. 2010), but it remains to be seen if this effect can be achieved *in vivo*. Dietary factors that have been found to promote the onset of swine dysentery are high levels of soybean meal (Jacobson et al. 2004) and diets containing 30% distillers dried grains with solubles (Wilberts et al. 2014). The latter causes significant changes in the microbiome, reducing numbers of *Lactobacillus* species and increasing *Prevotella* species (Burrough et al. 2015).

Carriage of *Oesophagostomum dentatum* in pigs is enhanced by diets rich in insoluble fiber (Petkevicius et al. 1997), whereas colonization by *Trichuris suis* did not appear to be significantly influenced by diets that differed in terms of their carbohydrate properties (Thomsen et al. 2006). Addition of chicory roots and sweet lupins to the diet did not prevent colonization by *T. suis* in pigs that were challenged experimentally (Thomsen et al. 2007).

Dietary protein

The protein levels in commercial rations for newly weaned pigs are usually high in order to promote optimal growth rates. However, in early comparative studies using high (21%) and low (13%) protein diets, Prohaszka and Baron (1980) showed that the high protein diet, especially when the protein is of reduced digestibility, predisposed to post weaning colibacillosis. These findings have been supported by a number of subsequent studies in piglets with naturally acquired infections and also in experimental challenge studies using ETEC, as reviewed by Pieper et al. (2016). The role of bacterial fermentation of proteins in the hindgut as a potential risk factor for diarrhea in pigs has been demonstrated (Jha and Berrocoso 2016; Rist et al. 2013). The formation of toxic metabolites is believed to have adverse effects on the colonic epithelial cells, arising from the proliferation of proteolytic bacteria. The benefits of reducing protein level in weaners reared under large-scale commercial conditions require careful assessment. However, reduction in dietary protein (to less than 18%) or a total daily intake of less than 60 g could be beneficial in units where

repeated problems of post weaning diarrhea due to ETEC result in piglet losses (Heo et al. 2012, 2015).

Organic acids, inorganic compounds, and fatty acids

Alternatives to antibiotic inclusion in weaner diets include the use of organic acids such as potassium diformate (Roth et al. 1998). Addition of 1.8% potassium diformate to a piglet starter ration decreased the counts of total anaerobic bacteria, lactic acid bacteria, yeasts, and coliforms in the digesta from the stomach, distal small intestine, cecum, and midcolon over a period of 4 weeks after weaning (Canibe et al. 2001). The apparent antimicrobial effects were attributed to the protons and anions formed from formic acid passing through the bacterial cell wall. These have a disruptive effect on protein synthesis and inhibit bacterial enzymes, thereby reducing bacterial replication (Partanen and Mroz 1999). Other studies agree that coliform counts in the stomach and proximal colon decrease when levels of formic acid increase (Gabert et al. 1995; Kirchgessner et al. 1992) or when potassium diformate is used (Février et al. 2001).

Supplementation of weaner diets with organic acids or other salts has been shown to reduce the incidence of post weaning diarrhea and improve growth performance of piglets (Sutton et al. 1991). When the coliform inhibitory effects of various organic acids were compared, the results going from most effective to least effective were benzoic, fumaric, lactic, butyric, formic, and propionic acid. By far the greatest increase in the use of organic acids in pig rations has occurred in response to *Salmonella* control programs in European countries. Clinical trials have shown that including formic acid or lactic acid in the rations of growing and finishing pigs significantly reduces the seroprevalence to *Salmonella* when tested by "meat juice" ELISA at slaughter age (Creuz et al. 2007; Dahl 2008). A similar effect can be achieved by supplying organic acids to pigs via the drinking water (van der Wolf et al. 2001). The impact of these organic acids on other enteric organisms has not been closely studied. However, it seems probable that they lead to a general reduction in coliform numbers that could have additional benefits if other pathogens are prevalent.

Feed supplemented with 2500 ppm zinc oxide has been shown to reduce post weaning diarrhea and improve growth rates through limiting proliferation of enteropathogenic *E.coli* (Melin et al. 2001). However, some countries have legislation that bans its use or limits the maximum permissible level of zinc inclusion in pig diets. Mounting environmental concerns mean that the use of zinc oxide to control post weaning diarrhea is likely to be widely phased out in the coming years.

Phytogenics

Phytogenic feed additives comprise a wide variety of herbs, spices, and products derived from these materials (including essential oils) that have been shown to have antimicrobial properties *in vitro*. Generally the phenolic components of these products tend to be most active and appear to act by increasing the permeability of bacterial membranes (Burt 2004). A variety of essential oils have been tested against *Salmonella* Typhimurium and *E. coli* F4 (Si et al. 2006a), and although they retained their antibacterial activity in the presence of pig cecal content (Si et al. 2006b), pig challenge studies showed poor efficacy. One explanation for the lack of efficacy *in vivo* has been put forward by Michiels et al. (2008), who demonstrated that certain essential oils absorbed in the stomach of pigs therefore may not be available to act on bacteria in the small intestine.

Fermented liquid feeds

Liquid feeding can improve the feed intake, growth, feed conversion, and health of weaned pigs (Brooks et al. 1996). However, steeping feed in water promotes bacterial proliferation in the feed, which reduces the quality of the feed and presents health risks. Feeding fermented liquid feed has been used as a means of controlling enteric infections through acidification. As part of the diet for newly weaned pigs, fermented liquid feed has beneficial effects on the villus height and ratio of villus height to crypt depth in the proximal jejunum (Scholten et al. 1999). The mechanism is uncertain, but it could be due to a lower pH, increased levels of organic acids, and an altered microbiological status. The use of fermented liquid feed in newly weaned piglets caused a significant reduction in the coliform population in the terminal ileum, cecum, and colon compared with piglets fed dried feed (Jensen and Mikkelsen 1998; Moran et al. 2001). Feed was prepared by inoculating the diet with lactic acid bacteria (*Lactobacillus plantarum*) and steeping it for 5 days at 25 °C before feeding. Fermentation prevents bacterial colonization and spoilage of the liquid diet by enteropathogens and other spoilage bacteria. The fermentation temperature is important in relation to bacterial survival. *E. coli* was eliminated more effectively at 37 °C than 20 °C (Beal et al. 2001). There were also strain differences in terms of *E. coli* survival in fermented liquid feed, with F4 (K88) being the most resistant to killing by fermentation (Beal et al. 2001). The effect of temperature has implications for the management of fermented liquid feed systems. Cold-shock proteins help *E. coli* survive at lower temperature (Phadtare et al. 1999). Prefermented diets not only lower the acidity of the diet but also reduce the soluble NSP content of the diet (Hampson et al. 2001).

Piglets showed a significant preference for freshly prepared liquid feed over fermented liquid feed when given

the choice (Demeckova et al. 2001). To prevent spoilage, chlorine dioxide added at 300 ppm was found to eliminate coliforms from liquid feeds for young piglets without adversely affecting palatability or growth performance (Demeckova et al. 2001). Chlorine dioxide is a strong oxidizing agent with broad antimicrobial spectrum, being active against bacteria and viruses (Junli et al. 1997). Addition of chlorine dioxide to freshly prepared wet feed did not significantly alter the intake when compared with nonsanitized freshly prepared wet feed. Chlorine dioxide is reported to kill *E. coli* through loss of permeability control of the outer bacterial cell membrane (Berg et al. 1986).

Enzymes

The use of feed enzymes for swine has made great progress over the past decade. Their value in promoting growth and improving feed efficiency has been well recognized. Feed enzymes also affect the microbiome and thus impact gut health (Kiarie et al. 2013). Phytase is the most commonly used feed enzyme, but carbohydrase, proteases, and lipases are also used (Adeola and Cowieson 2011). It has been observed that supplementing weaner pig diets with phytase results in increased *Bifidobacterium* and *Clostridium* numbers in the ileum (Wang and Lei 2011). The potential for developing enzymes to aid in the control of enteric diseases including post weaning *E. coli* diarrhea, swine dysentery, and salmonellosis is reviewed by Kiarie et al. (2013). These authors emphasize that research is needed in this area in order to develop strategies to alter host–microbiome–diet interactions in favor of the host, but feed enzymes could have a role to play.

Rehydration of diarrheic piglets

Oral rehydration fluids are used in piglets with acute diarrhea especially during outbreaks of ETEC and rotavirus infections. Studies in rats and clinical studies in children have shown that reducing the osmolality of oral rehydration solutions has beneficial effects on the course of diarrhea and the clinical outcome (Thillainayagam et al. 1998). Using an experimental pig model, Kiers et al. (2001a) demonstrated that solutions with low osmolality promoted intestinal fluid absorption. However, ETEC infection resulted in a decrease in net fluid absorption independent of osmolality, as compared with that of unaffected tissue.

In an experimental model, mold-fermented soybean products were found to be beneficial in maintaining fluid balance during post weaning ETEC infection through preventing fluid loss (Kiers et al. 2001b). The mechanism is uncertain. It might interfere with the attachment of *E. coli* to epithelial cells or modulate the effects of toxin in the intestine.

Regional diseases and pathology of the digestive system

The oral cavity

There are several recognized congenital defects affecting the oral cavity. Cleft palate (palatoschisis) is a multifactorial developmental abnormality. Cleft palate in piglets has occurred with feeding poisonous plants such as poison hemlock (*Conium maculatum*) or wild tree tobacco (*Nicotiana glauca*) to sows or gilts in early pregnancy (Keeler and Crowe 1983; Panter et al. 1985). Likewise, accidental contamination of sow feed with seeds of *Crotalaria retusa* during pregnancy has resulted in palatoschisis in piglets (Hooper and Scanlan 1977). Brachygnathia superior (shortness of maxillae) is an inherited condition that is progressive and may be confused with progressive atrophic rhinitis; it is a normal characteristic for some breeds. Hypertrophy of the tongue is a rare congenital anomaly in pigs that interferes with normal suckling behavior. Prominent erectile marginal papillae are a normal feature of the lateral margins of the tongue of newborns. Epitheliogenesis imperfecta can affect the gingiva and tongue and is seen as irregular, well-demarcated red areas that are devoid of epithelial tissue.

Oral lesions arising from traumatic damage are relatively common. Clipping the teeth of baby pigs exposes the dental pulp. If the dental pulp becomes infected, pulpitis, dental abscesses, and osteomyelitis can ensue. Gingivitis and periodontal inflammation is usually associated with poor teeth clipping technique, resulting in damage to the gingival epithelium. Stomatitis and tooth root abscesses may follow. *Fusobacterium necrophorum* is a common isolate from such lesions. Pigs have a diverticulum of the pharynx in the posterior wall immediately above the esophagus. Barley awns and other fibrous materials can lodge there and penetrate the pharynx, causing pharyngeal cellulitis, which is usually only seen in young pigs. Stomatitis can also be caused by irritating chemicals, caustic substances, toxic compounds, and physical burns. Blistering and erosion of the snout epithelium can arise due to sunburn or vesicle-forming viruses. Oral "thrush" or candidiasis (*Candida* sp.) is occasionally seen in piglets, presenting as pale plaque-like lesions on the tongue, hard palate, or pharynx. In rare cases they can extend further, affecting the esophagus and stomach. Factors such as frequent antibiotic administration or intercurrent diseases such as porcine reproductive and respiratory syndrome (PRRS) virus infection can promote the onset of candidiasis.

A number of important infectious diseases show lesions on the snout and oral tissues. These are primarily the viral vesicular diseases, including foot-and-mouth disease, swine vesicular disease, vesicular stomatitis, and

Senecavirus A. Lesions include blanching of the epithelium, vesicles, erosions, and epithelial flaps. Sunburn and perhaps other viruses (i.e. parvoviruses, picornaviruses, Aujeszky's disease virus) can occasionally cause lesions on the snout resembling vesicular diseases.

Ulcerative glossitis and stomatitis have been reported in piglets with exudative epidermitis. Piglets may also develop ulcers on the dorsum of the tongue and occasionally on the hard palate associated with *Staphylococcus hyicus* infection (Andrews 1979). Oral erosions and ulcers can also be seen in piglets with congenital swinepox. *Actinobacillus lignieresii* can cause swelling and inflammation of the tongue, with nodule and ulcer formation. Soft tissues of the pharynx and neck can also be affected. Of the parasitic infections, cysticercosis and *Trichinella spiralis* can affect the tongue and muscles of mastication. In grazing pigs, *Gongylonema* species has been found in the mucosa of the tongue where they cause mild, localized inflammation (Zinter and Migaki 1970).

The tonsils have a strategic role in immune surveillance of the oropharynx (Horter et al. 2003). A host of bacterial agents, including many types of *Streptococcus suis* and *Pasteurella* species, are frequently carried in the tonsils (Torremorrell et al. 1998). Crypt inflammation and lymphoid hyperplasia are associated with bacterial infections. Necrotizing tonsillitis occurs with pseudorabies, the tonsils being the site of primary virus replication (Terpstra and Wensvoort 1988). Tonsillitis is also a feature of swine vesicular disease. Hemorrhagic necrotizing tonsillitis can occur in pigs with anthrax. In pigs clinically infected with porcine circovirus type 2 (PCV2), the lymphoid tissue of the tonsils is involuted (Chae 2004). The altered status of the tonsillar lymphoid tissue in particular is thought to facilitate bacterial infections of the tonsils, with an increased likelihood of bacteremia.

There are few reported problems concerning the salivary glands in pigs, but sialoadenitis occurs in vitamin A deficiency (Uzal et al. 2016). The interlobular ducts of the salivary glands undergo squamous metaplasia, leading to salivary stasis, secondary infection, and purulent inflammation. This results in pronounced swelling of salivary glands. Epithelial degeneration of salivary ducts is seen in swine vesicular disease.

The esophagus

Conditions affecting the esophagus are uncommon but include hyperkeratosis, parakeratosis, mycotic infection, obstructions, and traumatic lesions. Hyperkeratosis and thickening of the epithelium are associated with vitamin A deficiency or chlorinated naphthalene toxicity. Parakeratosis of the esophagus occurs in pigs with cutaneous parakeratosis due to zinc deficiency. Parakeratotic thickening of the epithelium of the distal esophagus, with basal hyperplasia of the epithelium, is commonly seen in pigs with ulceration of the pars esophagea of the stomach. Reflux esophagitis is recognized in some pigs with ulceration of the pars esophagea. The gastric secretion has corrosive effects on the squamous epithelium, resulting in mucosal erosion, ulceration, and inflammation. Some cases develop annular scarring as part of the healing process, leading to stenosis and muscular hypertrophy of the distal esophagus. As mentioned previously, mycotic esophagitis caused by *Candida albicans* can occur in suckling piglets and weaners that are immunocompromised or have microflora disruption.

Obstruction and/or perforation of the esophagus is associated with ingestion of large objects such as stones, potatoes, apples, or corncobs. Perforation can result from ingestion of sharp objects such as fence wire or nails. Inflammation and subsequent stricture are sequelae that affect the esophagus at the site of perforation. Such conditions lead to dysphagia and distension of the esophagus cranial to the site of obstruction or stricture. Encephalitis affecting the medulla oblongata and/or the nuclei or tracts of the cranial nerves involved in swallowing (V, IX, X, XII) also results in dysphagia. Such conditions are very rare in the pig. Nematode parasites (*Gongylonema* species) occasionally occur in the esophageal mucosa leaving serpentine-shaped tracts. However, these parasites do not appear to have any adverse effects in pigs.

The stomach: gastric ulceration

Conditions affecting the stomach are mainly physical or functional in nature, the most important being gastroesophageal ulceration affecting the pars esophagea. Abattoir surveys demonstrate that the prevalence of stomach lesions, including parakeratosis, erosions, and ulcers, often approaches 90%, depending on the feeding and husbandry practices (Driesen et al. 1987). There is great herd-to-herd variation in prevalence and severity. Ulceration of the pars esophagea can affect any age of pig, but the highest rate of ulceration occurs in pigs 3–6 months of age. Mortality due to gastric ulceration among grower/finisher pigs has been reported to be about 1–2% on some farms, with much higher levels occurring sporadically (Deen 1993; Melnichouk 2002). Sows at the time of parturition are also a relatively high-risk group. Examination of culled sows revealed 60% with stomach lesions and 10–15% with ulcerations (Hessing et al. 1992; O'Sullivan et al. 1996). Frequently, sow stomachs have extensive scar tissue, indicating previous severe ulcerative episodes. Gastric ulceration has been reported as a common cause of sow mortality (Chagnon et al. 1991; Sanford et al. 1994).

Lesions associated with ulceration of the pars esophagea rarely extend into the contiguous esophagus or the glandular region of the stomach. Ulcerations and erosions of the pars esophagea may involve only a small portion or all

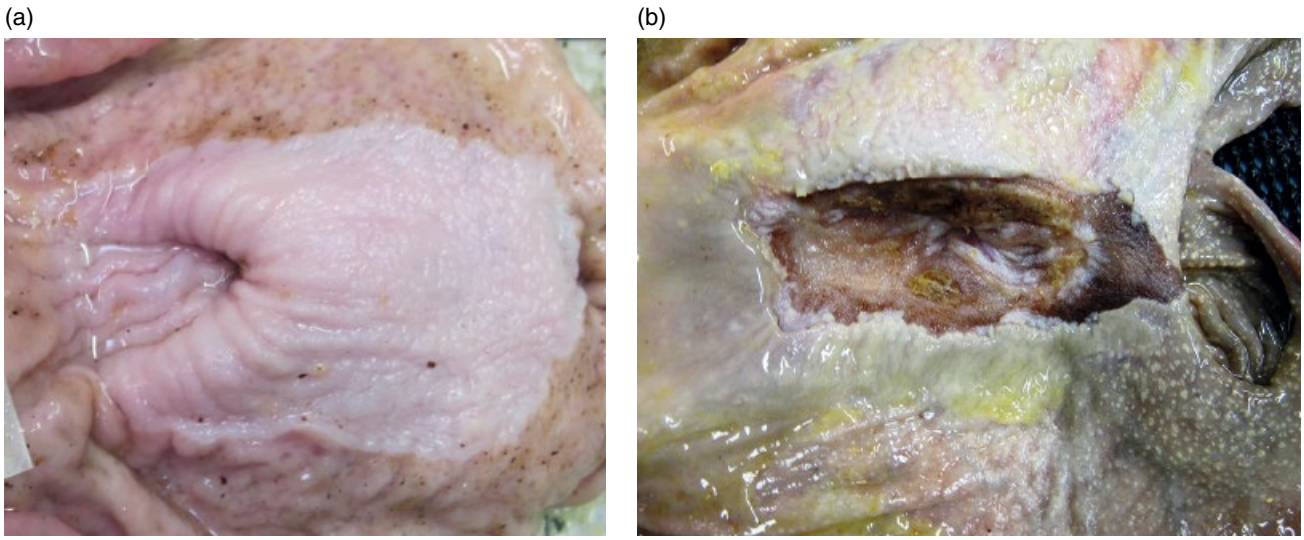

Figure 15.1 Pars esophagea of the stomach. (a) Normal appearance. (b) Extensive ulceration of the squamous epithelial tissue.

of the gastric squamous mucosa. The most common site for ulceration is at the junction of the pars esophagea and the cardiac mucosa (Penny and Hill 1973). The normal epithelium of the pars esophagea is smooth, white, and glistening and is easily distinguished from the surrounding glandular mucosa (Figure 15.1a). It is believed that lesions usually progress from hyperkeratotic parakeratosis that causes a thickened, rough appearance to fissuring and peeling that result in erosion and eventually ulceration (Figure 15.1b).

Frequently, the hyperplastic epithelium of affected pars esophagea is greenish yellow as a result of bile staining, particularly when the surface is rough and thickened due to parakeratosis. This type of corrugated surface may flake and peel off readily. When ulceration involves the entire pars esophagea, the lesion has a punched-out or crater-like appearance with elevated ridges at the margin of the circular ulcer. The floor of the ulcer may be so smooth that it is misinterpreted as normal tissue (Uzal et al. 2016).

Gross evaluation of stomach lesions is commonly incorporated into an abattoir surveillance program to monitor disease status. To examine the pars esophagea, the stomach should be incised along the greater curvature and inverted. Emptying the contents and rinsing the stomach before examination will improve the accuracy of the inspection. Morphological scoring guides have been published (Kopinski and Mckenzie 2007).

Histologically, the lesion is the result of thickening and parakeratosis, with nucleated cells present on the mucosal surface. Rete pegs and proprial papillae are elongated, and neutrophils and eosinophils are often present at the tips of the proprial papillae. Epithelial separation and erosion usually occur beneath a band of cells with cytoplasmic pallor and nuclear degeneration (Embaye et al. 1990). Ulcers of the pars esophagea usually involve only the submucosa, but they may advance to the muscularis externa and occasionally to the serosa.

In the case of a pig that has died acutely of gastric ulceration, postmortem diagnosis is usually straightforward. The carcass is typically pale but in good body condition. The stomach may contain clotted or unclotted blood and fibrinous exudate enclosing a variable amount of food. Blood may be found in the intestine as well but is generally dark and seen as melena in colon. A blood clot may be adhered to the surface of the ulcer, which is generally deep and extensive in the case of a fatal hemorrhagic episode. Clinical signs tend to reflect the degree of blood loss associated with the gastric lesion. Frequently, a pig that had appeared to be healthy only a few hours earlier is found dead, and the carcass is extremely pale. If blood loss occurs more slowly, signs associated with anemia will be apparent, such as paleness, lethargy, weakness, increased respiratory rate, and anorexia. In addition, black tarry feces may be noted, and some pigs show signs of abdominal pain by grinding their teeth and arching their backs. Vomiting may occur. Rectal temperatures of affected pigs are often below normal. It is important to remember that not all pigs that die from gastric ulcers will have clotted or fresh blood present in the stomach. To differentiate gastric ulcers from other causes of anemia or hemorrhagic enteric diseases, especially porcine hemorrhagic enteropathies, one must always examine the pars esophagea grossly for evidence of ulceration.

Sporadic outbreaks of gastric ulceration tend to occur among grower/finisher pigs, and frequently when one pig has suddenly died, careful observation will reveal others in the group that are showing signs of anemia. When ulceration occurs without significant blood loss,

animals will generally appear to be in normal health. Evidence that subclinical ulceration reduces growth rate is inconsistent. Various researchers have attempted to correlate severity of stomach lesions at slaughter with growth performance during the grower/finisher phase. Certain studies have found no relationship (Backstrom et al. 1981; Pocock et al. 1969), whereas Elbers et al. (1995) observed a 50–75 g/day decrease in growth rate for pigs with ulcers versus pigs with normal stomachs. This last result is in agreement with findings of a trial that followed pigs using endoscopic examination to measure gastric lesions (Ayles et al. 1996b).

Ulcers can occur rapidly and heal quickly, making it difficult to relate lesions at slaughter with performance during the grower/finisher stage. Evidence of past ulceration can sometimes be seen as cicatrization or fibrosis with a reduction in size of the pars esophagea. In extreme cases, the pars esophagea is entirely destroyed, and stenosis of the esophagus at its entry to the stomach occurs. Pigs afflicted with stenosis are observed to vomit shortly after eating but are hungry and therefore will immediately resume eating. These pigs tend to grow more slowly than pen mates despite maintaining good appetites.

The exact cause or causes of gastric ulceration are not completely understood, but many of the risk factors are well known, relating to the fluidity of the stomach content and the speed of passage of ingesta through the stomach. Generally, factors that increase the firmness of the stomach content help prevent gastric lesions, and factors that cause increased fluidity of the contents increase the risk of ulcers (Nielsen and Ingvartsen 2000).

Fine particle size of feed has been shown to increase the prevalence of gastric lesions (Ayles et al. 1996b; Wondra et al. 1995a). In addition, pelleting of feed may also increase the likelihood of ulcers developing (Potkins and Lawrence 1989). The prevalence and severity of ulcers vary with the cereal component of the diet. Generally, oats and barley appear to have a sparing effect (Reese et al. 1966), and corn and wheat tend to be more ulcerogenic (Smith and Edwards 1996).

The method by which the grain is processed affects the prevalence of ulcers. Grain that is ground using a hammer mill tends to be more ulcerogenic than if a roller mill is used (Nielsen and Ingvartsen 2000; Wondra et al. 1995b). Feed particle size is affected by grain component, milling procedure, and processing. Grains such as wheat are more likely to shatter during grinding and result in finer particle size compared with oats or barley. If grain is processed using a roller mill, there is less chance of the grain kernel shattering and creating "fines."

In addition, the pelleting process causes a further decrease in particle size. Nielsen and Ingvartsen (2000) showed that, in general, barley and rolling prevented stomach lesions, while wheat grinding and pelleting increased the prevalence and severity of ulcers. The overall effect of a feed with very fine particle size is that the stomach content is fluid and the emptying time is relatively rapid (Regina et al. 1999), and as a result, the pH gradient between the neutral proximal part of the stomach and the acidic distal region is lost.

The method of feeding may be as important as feed processing and composition. A major risk factor of ulcer development is an interruption of feed intake. Fasting of pigs has been a consistent method of experimentally producing gastric lesions (Lawrence et al. 1998; Pocock et al. 1968). Various workers have noted dramatic increases in ulcer severity and prevalence at slaughter in pigs examined after a 24 hour holdover period compared with pigs from the same herds slaughtered on the day of arrival at the abattoir (Davies et al. 1994; Lawrence et al. 1998). However, at least one study documented no association between a 24 hour feed withdrawal and an increased prevalence or severity of ulcers (Eisemann et al. 2002). Presumably, there are interactions between factors affecting stomach emptying, such as feed particle size and the effect of feed withdrawal that can explain the differences in findings between these studies.

Interruption of normal feed intake commonly occurs on almost all farms because of mechanical problems or human error. Periods of transition in feeding patterns, such as when gilts are transferred to the breeding herd from a finishing barn or when sows approach the time of parturition, should be viewed as high risk for ulcerogenic events. Hot weather resulting in dramatic reduction in feed intake is associated with gastric ulcer outbreaks (Deen 1993).

It is likely that factors such as acute infectious disease and season influence ulcer development in a similar manner to management practices that interrupt feed intake. Acute respiratory disease is associated with an increased likelihood of gastric ulceration (Dionissopoulos et al. 2001). In addition to respiratory disease causing inappetence, it is possible that increased levels of histamine as a result of infection could play a role, in that histamine is a powerful stimulant of gastric acid secretion. Injection of histamine has been shown to experimentally produce ulceration of the pars esophagea (Hedde et al. 1985). Experimental infection of gnotobiotic pigs with various viral pathogens, including PRRS virus, does not result in gastric ulceration; however, experimental infection of concurrent PRRS virus and PCV2 in Cesarean-derived colostrum-deprived pigs has caused gastric lesions (Harms et al. 2001).

Research clearly demonstrates that ulceration of the pars esophagea is not mediated by glucocorticoids (Zamora et al. 1980). Chronic elevation of corticosteroids in response to stressful conditions has been shown under controlled trials to not result in an increase in ulcer prevalence or severity (Jensen et al. 1996). Genetic susceptibility may play a role in ulcer development.

Researchers have reported a link between fast growth rate and/or low backfat and a high prevalence of gastric ulcers (Berruecos and Robinson 1972). It has also been reported that injection of swine with porcine somatotropin causes an increase in prevalence and severity of ulcers (Smith and Kasson 1991).

There has been considerable interest in finding an infectious cause of porcine gastric ulcers similar to the situation in humans. *Helicobacter*-like organisms have been identified in the glandular region of the stomach (Mendes et al. 1990) and appear to be widespread in the pig population with possibly more than half of all market hogs infected (Foss et al. 2013; Hellemans et al. 2007; Szeredi et al. 2005). Isolates of these tightly coiled spiral bacteria have been successfully cultured and given the name *Helicobacter suis* (Baele et al. 2008). Whereas some workers have observed a correlation between the presence of these bacteria in the pyloric region and the prevalence and severity of lesions in the pars esophagea (Barbosa et al. 1995; Queiroz et al. 1996), other researchers have not (Magras et al. 1999; Melnichouk et al. 1999; Szeredi et al. 2005). Bacterial colonization of the glandular stomach causing gastritis and the development of ulcers in the pars esophagea region have been observed in experimental challenge studies (Haesebrouck et al. 2009; Krakowka et al. 2005). It has been hypothesized that because *H. suis* are found in the antrum in close contact to hydrochloric acid-producing cells, gastritis due to *Helicobacter* infection may result in parietal cell stimulation causing hyperacidity and indirectly damage the unprotected epithelium of the pars esophagea or modifying the stomach microbiome. Recently, a novel *Fusobacterium* sp. was demonstrated to colonize the pars esophagea in *Helicobacter*-infected pigs and was found in higher numbers in pigs with ulceration, leading researchers to speculate that this novel *Fusobacterium* sp. may play a role in creating the ulcer lesion (De Witte et al. 2016).

Many of the factors associated with an increased risk of ulcer development are closely tied to economic competitiveness such as the use of finely ground feed and fast-growing, lean genetics. Therefore, steps to reduce the prevalence of gastric ulcers need to be carefully balanced between economic considerations and welfare concerns. Treatment for the most part is prohibitively expensive, laborious, and often unsuccessful. In addition, early diagnosis of gastric ulcer disease is difficult. Therefore, prevention of stomach lesions is generally considered the most appropriate approach to handling this problem. Many causative factors and complex interactions of nutrition, environment, and management contribute to the expression of this disease, but a coordinated effort by feed providers, owners, production personnel, and herd veterinarians can result in feed preparation standards and management that limit gastric ulceration as a swine production problem without reducing animal performance. The use of roller mills instead of grinding feed appears to be one of the best methods of reducing ulcers (Nielsen and Ingvartsen 2000). Feeding practices must be carefully monitored. An interruption of feed intake appears to be a major contributing factor to ulcer formation. Blocked feeders or waterers, heat stress, unpalatable feed, or the presence of vomitoxin in the feed can lead to ulcer problems. Good management practices can minimize the occurrence and influence of these factors.

Various attempts have been made to incorporate protective substances in swine feeds to prevent ulcer development. Increasing levels of antioxidants such as vitamin E and selenium beyond physiological requirements does not appear to be useful (Davies 1993). There is some evidence to suggest that the inclusion of S-methylmethionine sulfonium chloride (sometimes referred to as vitamin U) reduces the prevalence and severity of ulcers, but in general the slight ulcer score improvement may not be economically justified (Kopinski et al. 2007). Alfalfa has been used at levels of up to 9%, because it is high in vitamins E and K, as well as a source of increased fiber. Alfalfa was not effective in reducing the level of severity of ulcers in pigs treated with porcine somatotropin (McLaughlin et al. 1997). The addition of sunflower hulls to diets was shown to be effective in reducing lesions (Dirkzwager et al. 1998).

Products that reduce gastric emptying have been examined and found somewhat effective, at least in an experimental setting. Melatonin has been reported to slow gut motility and when included at levels as low as 2.5 g/ton results in less ulcer development (Ayles et al. 1996a). Similarly, diets containing sodium polyacrylate are retained for longer periods of time in the stomach of swine, and gastric ulceration is reduced (Yamaguchi et al. 1981). There may be circumstances in which various therapeutic agents are useful for treatment or prevention, but because of the many contributing factors and the interactions of these factors, it is unlikely that a single pharmaceutical product or management technique will be found that completely prevents gastric ulceration caused by various combinations of factors in different herds.

The stomach: other gastric conditions

Gastric over-distension can occur in adult pigs, especially in sows, but the cause is uncertain. It is thought to be associated with excessive intake of finely ground grain and water, resulting in excessive fermentation and gaseous distension.

Gastric volvulus is thought to be due to rapid intake of large quantities of feed and water followed by physical activity in a competitive group situation. Clockwise

torsion is apparently most common, although torsion can occur in either direction about the long axis of the stomach. The spleen is often involved and becomes extremely enlarged due to blood engorgement (Morin et al. 1984). The stomach becomes massively distended with gas and fluid, and intense mucosal congestion develops. This condition is rapidly fatal.

Gastric foreign bodies such as stones are frequently found in stomachs of outdoor sows that are maintained on stony ground. Stone chewing is a regular activity, and swallowing of the stones is thought to be accidental. Large quantities of gastric stones have been recorded in some sows, limiting the capacity of feed intake and resulting in loss of body condition.

Gastric venous infarction occurs in pigs, usually in association with bacteremia such as salmonellosis, erysipelas, or Glässer's disease or with toxemia. The lesion can also be seen in classical swine fever (CSF) (Elbers et al. 2003). The mucosa in the fundic area becomes reddish black in color, and caseous mucosal necrosis may be evident. Thrombosis of capillaries and venules in the mucosa and submucosa with fibrin plugging is the cause of infarction. Multifocal areas of gastric infarction have also been recorded in cases of porcine dermatitis and nephropathy syndrome (PDNS), due to fibrinoid vasculitis of capillaries.

Edema of the stomach wall is a characteristic change in edema disease caused by specific strains of *E. coli*. Edema affects the submucosa, particularly on the greater curvature of the stomach. Other conditions causing gastric edema include hypoproteinemia, arsenic toxicity, and portal hypertension. In these conditions, edematous changes are less pronounced than those of edema disease.

Gastritis in pigs is most commonly associated with ulceration of the pars esophagea and the inflammatory sequelae affecting tissue in the cardiac zone of the stomach, as previously mentioned. Candidiasis of the pars esophagea may occur in association with pre-ulcerative epithelial hyperplasia and parakeratosis. Gastritis could occur due to accidental intake of toxic compounds – such as arsenic, thallium, formalin, bronopol, and phosphatic fertilizers – and by the toxic principles in bitterweed (*Hymenoxys odorata*) or the blister beetle (*Epicauta* sp.). In commercial farming, such conditions are very rare and should be easy to exclude. Mycotic gastritis is occasionally seen in piglets, usually in association with repeated use of antibiotics. Lesions present as multifocal yellowish plaques on the gastric mucosa, with intense congestion of the peripheral gastric mucosa. Fungal hyphae colonize the mucosa and invade tissue and capillaries, resulting in thrombosis. Agents are usually zygomycetes such as *Rhizopus*, *Absidia*, or *Mucor* species. *Aspergillus* species involvement is rare (Mahanta and Chaudhury 1985).

Parasitic gastritis is now rare in large commercial pig farms but can be problematic in organic units, small holdings, and backyard piggeries, in instances where anthelmintics are seldom used. Affected pigs show poor body condition due to chronic gastritis. Of the parasites that can cause gastritis, *Hyostrongylus rubidus* is of most importance because it is associated with poor growth rates in young stock or loss of body condition in adult pigs.

Other parasites that can cause gastritis in heavy infections include *Ascarops* sp. and *Physocephalus* sp. These parasites are common in many parts of the world, in feral pigs and those kept under extensive conditions with access to grazing and foraging conditions. *Simondsia* sp. are found in Europe, Asia, and Australia and are associated with nodular gastritis in pigs. The parasite *Gnathostoma* sp. occurs in Asia. It invades the mucosa and undergoes development within inflammatory cysts in the submucosa. In heavy infestations this parasite can cause thickening of the stomach wall.

The intestinal tract

Congenital defects

Atresia ani is the most common congenital defect of the intestinal tract of pigs, and it is believed to be hereditary (Norrish and Rennie 1968). It arises due to failure of perforation of the membrane separating endodermal hindgut from ectodermal anal membrane. Evident at birth, the defect can be corrected by minor surgery unless atresia of the rectum is also present. Persistent Meckel's diverticulum is a rare anomaly in which there is persistence of the omphalomesenteric duct. It presents as a tube of intestinal tissue similar to ileum that branches from the intestine to the umbilicus. Occasionally, it can be involved in abdominal catastrophes such as intestinal strangulation.

Intestinal displacements

Intestinal displacement and obstruction are common in pigs, and a number of different conditions arise.

Rectal prolapse and rectal stricture

Rectal prolapse is relatively common and an important condition affecting growing pigs and adults that gives rise to welfare and management problems. The rectum is held in place by a complex matrix of fascia, collagen fibers, muscles, and ligaments, and rectal prolapse will occur if the support mechanism is either overcome by pressure or is weakened for some reason. Pressure on the support mechanism may be brought about by straining (proctitis, urethritis, constipation, coughing, and farrowing) or by physical pressure (excessive slope on the floor or increase in abdominal pressure for any reason).

Brockman et al. (2004) produced rectal prolapse in ten anesthetized 49–74 kg pigs by insufflating the abdominal cavity with water at pressures of 222–343 mmHg (mean 292 mmHg).

Pigs of all ages can be affected by rectal prolapses, and outbreaks do occur and can be prolonged. The incidence has been reported as 1–10% (Kjar 1976), 0.7–4.7% (Garden 1988), and as high as 10–15% (Becker and Van der Leek 1988). Perfumo et al. (2002) found that rectal prolapse was responsible for 7.7% of deaths that occurred in pigs from weaning to market. Daniel (1975) noted that rectal prolapse in sows could occur in all sizes of units and that the incidence varied from 0.5 to 1%.

Rectal prolapse is sometimes associated with enterocolitis caused by viral, bacterial, parasitic, or mycotic infection (Pfeifer 1984; Straw 1987). In cases where the inflammation is severe and irritation of the rectum occurs, tenesmus results, and rectal prolapse may be a sequel. At the recto-anal junction, the rectal mucosa changes abruptly to stratified squamous epithelium of the anus. This junction is often the site of inflammatory changes in growing pigs when examined microscopically (JT, personal observations). Intense inflammatory changes at this site could lead to irritation-related straining and rectal prolapse. In older swine, urethritis and vaginitis from any cause may lead to straining, which may in turn lead to prolapse of the rectum or vagina or both.

Sudden changes in the diet (e.g. from meal to whey) may lead to occasional cases of rectal prolapse. Constipation caused by chronic water shortage or low fiber diet may result in straining and rectal prolapse. Other nutrition-related associations that have been reported include high lysine levels (Amass et al. 1995) and lupin bean meal toxicosis with megacolon observed as well (Casper et al. 1991).

Injury to the rectum or urethra from service by the boar may also lead to tenesmus and prolapse. In addition, gradual weakening of the pelvic diaphragm may arise as sows age or during pregnancy as the abdominal contents become heaviest. Rupture of one or more of the supporting structures may then occur, with prolapse of either rectum or vagina or both as a sequel. Rectal prolapses were recorded in sows housed in inappropriate gestation crates but not in group-housed sows in the same unit (Papatsiros et al. 2012).

Guise and Penny (1990) noted that rectal prolapses occurred when pigs were transported at high stocking density.

It is generally agreed that rectal prolapse occurs more commonly during winter months, and there is some evidence to support this (Gardner et al. 1988; Kjar 1976; Prange et al. 1987; Wilson 1984). It has been suggested that cold weather causes pigs to pile, thus increasing the likelihood of prolapses. Rectal prolapse is a common sequel to vulvovaginitis caused by mycotoxicosis (see Chapter 69).

Muirhead (1989) noted that a behavioral aberration, anal nuzzling, in recently weaned pigs led to a rectal prolapse problem (4–6% incidence). Improving the climatic environment prevented further cases from arising. Another outbreak associated with anal nuzzling was reported by van Sambraus (1979).

When pigs cough, the rectal mucosa often protrudes temporarily. As with piling, it has been suggested that coughing may precipitate rectal prolapse, but there are no objective data to support this hypothesis. In another study, the prevalence of rectal prolapse was dramatically reduced from 4.7 to 0.7% when weaners (30–35 kg) were placed in a strawed yard for 3 weeks between being held in the second-stage flat decks and the fully slatted finishing accommodation (Garden 1985). Occasionally, severe intestinal prolapse can accompany vaginal prolapse, via laceration to the vaginal fornix.

For sporadic cases of rectal prolapse, it was not considered worthwhile to implement any specific control or preventive measures apart from treatment and noting risk factors. It was common practice to isolate feeder pigs with rectal prolapse to allow the prolapse to resolve naturally in 10–14 days. However, this practice is not good welfare, and a simple nonsurgical amputation technique such as described by Douglas (1985) should be considered. Many surgical procedures for treating rectal prolapses have been described (Daniel 1975; Grosse-Beilage and Grosse-Beilage 1994; Ivascu et al. 1976; Kjar 1976; Kolden 1994; Moore 1989; Schon 1985; Vonderfecht 1978).

Some prolapses resolve spontaneously, but more commonly the tissue becomes traumatized or is removed by pen mates, followed by scar formation as part of the healing process. This can result in rectal stricture (Becker and Van der Leek 1988; Häni and Scholl 1976; Jensen 1989; Prange et al. 1987; Von Muller et al. 1980) and progressive obstruction leading to a marked distension of the colon known as megacolon. In a study of 25 pigs with rectal prolapses that were allowed to heal naturally without treatment, Smith (1980) noted that three developed complete rectal stricture and died and the remainder grew normally, but in every case there was evidence of partial rectal stricture at slaughter. Treatment of rectal stricture is rarely cost effective, but a surgical technique has been described (Boyd et al. 1988). Visibly affected pigs should be euthanized at an early stage for welfare reasons.

Wilcock and Olander (1977a) noted cases of rectal stricture preceded by enteric disease, and ulcerative proctitis from which *Salmonella enterica* Typhimurium was isolated was a possible precursor. In later studies Wilcock and Olander (1977b) produced rectal strictures experimentally by injecting chlorpromazine into the cranial hemorrhoidal artery and suggested that rectal prolapses may be a sequel to ischemic proctitis induced by thrombosis associated with salmonellosis.

Intestinal obstruction, impaction, and hernia

Intestinal impaction and obstruction can occur in a variety of situations, for example, deaths have occurred in piglets maintained on wood shavings or other fibrous materials such as peat due to impaction of the ileum or colon with such materials. Sand impactions of the colon have caused deaths in gilts newly arrived in outdoor breeding units with sandy soil, having been raised in slatted buildings. On occasions, heavy infestations of *Ascaris suum* have been found to cause small intestinal impaction in grower pigs.

Herniation of the intestine is most commonly associated with a patent umbilicus. This occurs when weakened supporting muscles around the navel or umbilical stump impede umbilical closure. Genetic and environmental factors can contribute to this (Searcy-Bernard et al. 1994; Zhao et al. 2009). Suggested environmental factors include excessive stretching of the umbilical cord during farrowing, placing navel clips too close to the skin, and neonatal bacterial infections of the umbilicus. Close inspection of the lesion often reveals evidence of chronic bacterial infection in growing pigs. Small lesions are of little consequence unless expanded by trauma or infections. The larger, pendulous lesions are regularly traumatized, with increased risk of adhesions, particularly when the peritoneum is breached. Intestinal strangulation within the hernia can follow unless the defect is corrected surgically.

Hernias via the inguinal and vaginal rings into the scrotal sac can also occur. Should the gut become incarcerated within the hernia site, life-threatening intestinal infarction occurs. The wisdom of keeping pigs with umbilical or scrotal hernias through to finishing is questionable for welfare and economic reasons. Though there is little specific data on this, one study showed a 15% mortality rate for affected pigs in the finisher and significantly lower growth rates than unaffected pigs (Straw et al. 2009). Most of the pigs that survive to reach slaughter weight are subject to condemnation for peritonitis (Keeliside 2006).

Intestinal torsion (volvulus) and hemorrhagic bowel syndromes

Torsion of the long axis of the mesentery is a common condition in pigs and leads to rapid death. The torsion may involve small intestine or both small and large intestines (Figure 15.2a). Often, the stomach and duodenum are unaffected with an abrupt transition to the affected congested intestine (Figure 15.2b). Rotation is usually counterclockwise when viewed from the ventrocaudal aspect and may be a full 360° twist or a partial twist sufficient to disrupt blood flow. Torsion is associated with pigs having disruptions of feed intake leading to engorgement coupled with making sudden unpredictable movements, such as sudden deceleration combined with abrupt changes in direction, particularly when the gut is filled. Feed or water engorgement following out-of-feed events, sorting, or commingling are considered risk factors, as well as the gaseous dilatation of intestines in pigs fed a highly fermentable ration. Once torsion occurs, pigs rapidly develop distension of the abdomen. The intestinal loops, apart from the first 20–30 cm of duodenum, become very turgid and reddish black in color. The lumen is distended with gas and contains dark red, watery fluid. The mesenteric vasculature is extremely engorged due to obstruction to the venous return.

In pigs with "intestinal hemorrhage syndrome" (also called "hemorrhagic bowel syndrome," "porcine intestinal

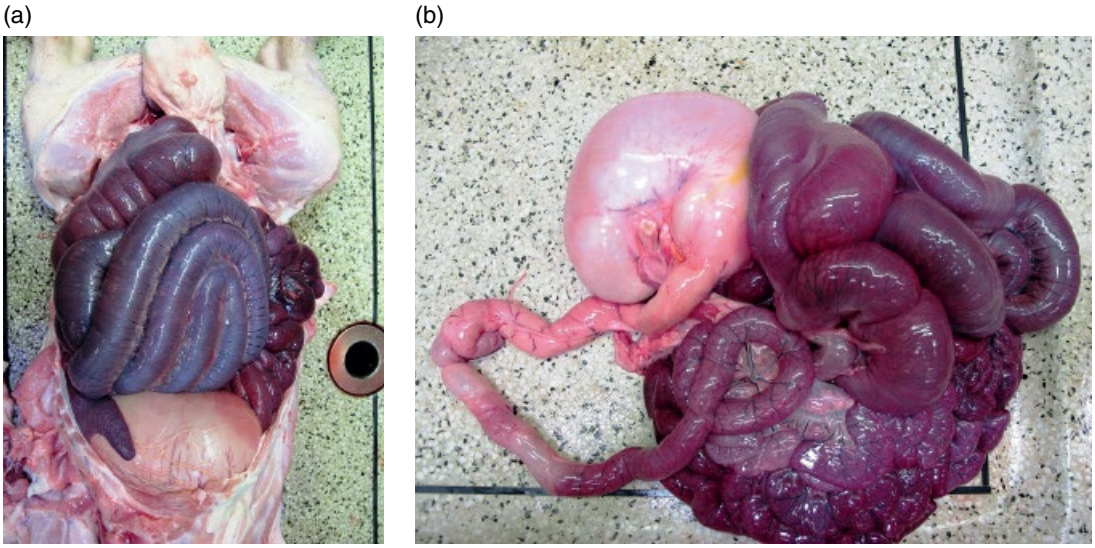

Figure 15.2 Volvulus affecting both small and large intestines. (a) Organs *in situ* in the abdominal cavity. (b) Organs removed to show unaffected stomach and duodenum, with abrupt transition to affected jejunum.

distension syndrome," or "bloody gut"), the intestines have a similar appearance to cases of intestinal torsion, but no obvious displacement of the intestines or mesenteric torsion is detected at necropsy. Typically, this occurs under circumstances similar to cases of intestinal torsion, where pigs receive a highly fermentable ration, particularly fed in liquid form. Feeding fresh whey ad libitum has been associated with increased risk of intestinal torsion and/or "hemorrhagic bowel syndrome," such that the term "whey bloat" is given to the condition. The hypothesis that such pigs can die due to excessively high intra-abdominal pressure in the absence of intestinal torsion was supported by pressure measurements in the order of 40 mmHg being recorded in pigs immediately after death (Thomson et al. 2007). In biomedical research studies involving pigs, artificially induced pressures of this magnitude were found to cause occlusion of the mesenteric veins and obstruction to venous return with fatal consequences (Gudmundsson et al. 2001). Prevention of "whey bloat" can be achieved by allowing the whey to ferment before feeding, limiting intake to no more than 20% of the ration and feeding it as part of a complete diet to avoid preferential ingestion of excessive quantities. In instances where non-whey rations are associated with the problem, efforts to reduce the rapidly fermentable properties of the diet or use "little and often" feeding strategies help to reduce the incidence of cases. The role of *Clostridium* sp. or other bacterial infections in this condition has been discounted by many authors. The potential causes and pathogenesis of "porcine intestinal distension syndrome" have been reviewed by Martineau et al. (2008). Other forms of intestinal catastrophe, such as volvulus of a short length of small intestine followed by strangulation of the affected portion, occur more rarely.

Muscular hypertrophy of the ileum

Muscular hypertrophy of the ileum can be seen as an incidental finding in finishing pigs at slaughter. Approximately 30–50 cm of the terminal ileum is thickened, pale, and firm. Internally the lumen is narrowed, the mucosa and submucosa are normal, but both internal and external muscular layers are hypertrophied, suggesting that the process is secondary to a functional obstruction. Some cases show an annular stricture in the terminal ileum or at the ileocecal orifice. Many samples of ileum submitted for examination do not extend to the junction with normal tissue, so the cause cannot be confirmed. Although the basis of this condition is unknown, it is possible that a previous focus of inflammation and ulceration has led to stricture formation. Externally, and on palpation, the lesion can be confused with porcine proliferative enteropathy (PPE)/necrotic ileitis associated with *Lawsonia intracellularis* infection. Histopathology readily differentiates the two conditions.

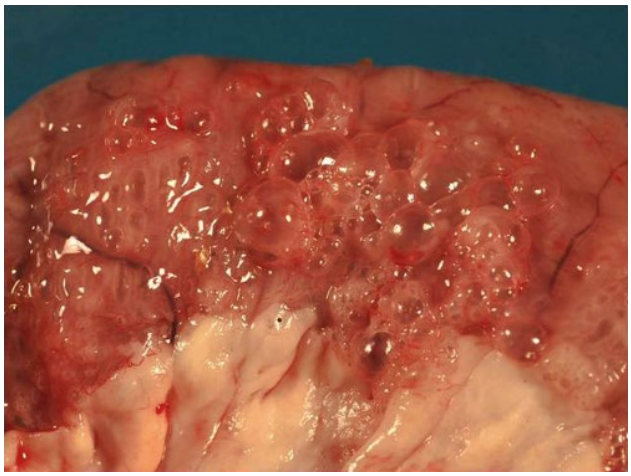

Figure 15.3 Intestinal emphysema (pneumatosis, "bubbly gut") in a 5-month-old slaughtered pig. *Source:* Courtesy of M. Hazlett.

Intestinal emphysema

Intestinal emphysema, pneumatosis intestinalis, or "bubbly gut" is another apparently incidental finding at slaughter (Lazier et al. 2008). The serosal surface shows numerous gas-filled, thin-walled cystic structures along the intestinal wall, in the mesentery, and occasionally in the mesenteric lymph nodes (Figure 15.3). Lazier et al. (2008) described a 20% incidence of cases from one herd, and although there were no clinical signs of illness in affected pigs, condemnation of the intestines caused significant financial loss for the packer. The pathogenesis of the condition involves gas accumulation in the lymphatics, but the cause is unknown.

Infectious conditions affecting the intestines

Many forms of inflammatory and degenerative changes can affect small and large intestines. Mechanisms of diarrhea include hypersecretion, malabsorption, inflammation, and increased intestinal permeability (Table 15.1). Hypersecretory diarrhea is watery, without gross lesions, and is associated with enteropathogenic *E. coli* and sometimes rotavirus. Enterocyte necrosis and loss of surface enterocytes occur with *Cystoisospora* (previously *Isospora*), some of the enteropathogenic *E. coli*, and viral infections, including rotaviruses and coronaviruses. Fluid exudation is a consequence of epithelial loss and results in watery diarrhea and dehydration. Villous atrophy is particularly associated with coronavirus and rotavirus infections. In these conditions, the intestines are fluid filled and flaccid, with no gross evidence of inflammation. Intestinal erosion and necrotizing, hemorrhagic enteritis in young pigs are often associated with *Clostridium perfringens* type C infection. *Cryptosporidium* (*C. parvum*) infection in neonatal piglets is an infrequent cause of villous

Table 15.1 Mechanisms of diarrhea.

	Primary pathophysiologic mechanism of diarrhea		
Infectious insult	**Hypersecretion**	**Malabsorption**	**Inflammation**
Escherichia coli	+++	+	
Clostridium perfringens A	+		+
C. perfringens C		+	+++
Clostridium difficile	+	+	+++
Cystoisospora		++	++
TGEV/PEDV		+++	
Rotaviruses	+	++	
Salmonella	+		+++
Lawsonia		++	++
Strongly hemolytic *Brachyspira; B. pilosicoli*		+	++

atrophy, stunting, and fusion of villi, with diarrhea due to malabsorption. Intestinal ulceration is associated with salmonellosis and *L. intracellularis* infection. Large intestinal ulcerative typhlocolitis is present with swine dysentery, *Salmonella*, and *L. intracellularis*. So-called button ulcers alert concerns of CSF, but they are also associated with *Salmonella* infections. Infrequent reports have implicated PDNS, bovine viral diarrhea virus (Terpstra and Wensvoort 1988), and other insults as well. Degeneration of intestinal crypt epithelium is associated with coccidial infection and bovine viral diarrhea virus infection. In coccidiosis, due to *Cystoisospora suis*, damage caused by coccidial development in the villus epithelium will result in villous atrophy, intestinal erosions, and fibrinonecrotic enteritis, mainly affecting the distal jejunum and ileum. The enteric lesions of pseudorabies are characterized by foci of crypt necrosis that extend to necrosis of the mucosa, submucosa, and the muscular layers of the intestinal wall (Narita et al. 1998). Hyperplasia of crypt epithelium is the major feature of *L. intracellularis* infection and leads to thickening of the mucosa in the ileum, cecum, jejunum, and/or colon. While this is generally a widespread and fairly uniform change in the affected areas, occasionally it can cause polypoid-like growths or larger protruding lesions resembling intestinal tumors or in some cases fibrinonecrotic enteritis.

Inflammatory cell infiltration occurs in response to any cause of disruption to the epithelial barrier as well as enteropathogenic infections. Mucosal microabscesses are a feature of yersiniosis; both *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* affect pigs. Granulomatous inflammation is associated with viral enteropathogens such as PCV2 and certain coronavirus infections. Hemorrhage into the intestinal tract can occur with acute clostridial enteritis in unweaned piglets. Porcine proliferative hemorrhagic enteropathy (*L. intracellularis*) results in major blood loss into the ileum and is uniquely associated with large clots of fresh blood that can be found in the absence of any obvious intestinal ulceration. Watery, port-wine-colored colonic contents and diarrhea may be seen. Gastric ulcers can give rise to mild subclinical blood loss or major hemorrhage resulting in obvious melena. In ulcerative typhlocolitis due to swine dysentery, there is hemorrhagic colonic content and increased mucus production resulting in mucohemorrhagic diarrhea containing fresh-looking blood. *T. suis* (whipworm) may also cause mucohemorrhagic diarrhea in heavy infestations. Fresh blood in feces can also occur in pigs that have suffered anorectal trauma, such as rectal prolapse cases. Anticoagulant or dicumarol poisoning can cause intestinal hemorrhage. All these hemorrhagic conditions are eminently life threatening and require prompt diagnosis and treatment where possible. Severe intestinal blood loss occurs in intestinal torsion and intestinal hemorrhage syndrome, but death occurs before fecal hemorrhage is seen.

Diseases affecting the intestinal tract are among the most important economic problems affecting pig production. The prevalence of diseases in pigs varies between countries, farming systems, and units with different health status. Within farms, the disease situation is dynamic, and the prevalence can change quite dramatically between batches for no apparent reason. Multiple enteric infections can occur concurrently, giving rise to complex clinical disease patterns and difficulties in arriving at successful control measures. The major diseases are mentioned only briefly here; detailed descriptions of all are given in respective chapters (Tables 15.2 and 15.3).

Table 15.2 Differential diagnosis of some common gastrointestinal conditions of swine.

Cause	Age	Key clinical signs
Escherichia coli (*ETEC, EPEC*)	Neonatal: 1–4 days old	Watery, yellowish diarrhea; dehydration
	Post weaning: 2–3 weeks after weaning	Diarrhea, ill-thrift, sudden deaths; eyelid edema; neurological signs
Rotavirus	1 day to 7 weeks; most frequent at 2–3 weeks of age	Watery to pasty diarrhea; dehydration; may be subclinical
Clostridium perfringens type C	1–14 days	Hemorrhagic or watery diarrhea; sudden death
Clostridium perfringens type A	3–28 days	Creamy diarrhea; usually mild but can affect growth rate
Clostridium difficile	5–21 days, rarely older	Creamy diarrhea; dehydration
Cryptosporidium spp.	3 days to weaning	Mild to moderate yellowish diarrhea
Cystoisospora suis (*Isospora*)	5–21 days (sometimes older)	Watery yellowish diarrhea to no diarrhea; retarded growth
Coronaviruses: TGE, PED, PDCoV	All ages	Watery diarrhea; rapid dehydration; vomiting; rapid increased mortality
Porcine circovirus type 2	6–12 weeks, sometimes older	Ill-thrift; depression, diarrhea; wasting; often multisystemic signs
Gastric ulceration	Any age after weaning	Asymptomatic; dark feces; melena; sudden death with anemia and pallor
Lawsonia intracellularis (PE, PHE, PIA)	5 weeks old to young adults	Broad range of severity of diarrhea; can be hemorrhagic
Strongly hemolytic *Brachyspira* spp.	Approximately 6 weeks old to adult	Mucoid diarrhea; usually mucohemorrhagic
Brachyspira pilosicoli	5 weeks to 4 months of age	Pasty, sloppy, mucoid diarrhea
Salmonella spp.	All ages, usually after weaning	Variable; watery to bile stained; mucohemorrhagic with fibrin flecks
Oesophagostomum dentatum	From weaning to adult	Mild diarrhea
Trichuris suis	From weaning to adult	Mucoid, occasionally mucohemorrhagic diarrhea
Yersinia spp.	From 6 weeks to 4 months of age	Pasty, sloppy diarrhea

ETEC, enterotoxigenic *E. coli*; EPEC, enteropathogenic *E. coli*; TGE, transmissible gastroenteritis; PED, porcine epidemic diarrhea; PDCoV, porcine deltacoronavirus; PE, proliferative enteropathy; PHE, proliferative hemorrhagic enteropathy; PIA, proliferative intestinal adenomatosis.

Enteric diseases in suckling piglets

Accurate diagnosis relies on differentiating endemic and epidemic infectious agents of neonatal diarrhea as well as noninfectious risk factors for disease expression. Although infectious agents are discussed in detail in respective chapters, it is important to realize that many are endemic herd infections, seizing opportunity to proliferate and express disease. ETEC remains a very important disease. *C. perfringens* type C causes characteristic lesions of segmental hemorrhagic necrosis, usually in the proximal two-thirds of the small intestine (Figure 15.4). This disease is somewhat restricted geographically, mostly in outdoor farming systems. Both bacterial diseases can be controlled by vaccination of breeding stock, provided piglets receive adequate and timely colostrum intake and ongoing adequate milk intake. The availability of breeding stock that is genetically resistant to *E. coli* F4 (K88) strains offers a control option through genetic selection, but the uptake of this technology in commercial pig farming has been very limited.

Other infections that are commonly reported in young unweaned piglets include rotavirus types A, B, and C and coccidiosis (*C. suis*), with cryptosporidia also being implicated in some production units. It is relatively rare for *Salmonella* infection to cause significant enteric disease in unweaned pigs though subclinical infection and shedding can occur as a result of contact with sow feces. The enteric coronavirus diseases, including transmissible gastroenteritis (TGE), PED, and porcine deltacoronavirus, can cause severe morbidity and mortality in susceptible piglets and have reportable status in many countries. *Clostridium difficile* is a recognized cause of toxin-mediated necrotizing colitis and mesocolonic edema in suckling pigs. Likewise, *C. perfringens* type C has been long associated with segmental necrohemorrhagic enteritis. Neonatal enteric disease has not been

Table 15.3 Pathology and diagnostic confirmation of some common gastrointestinal conditions of swine.

Cause	Gross lesions	Histological lesions	Common laboratory tests
Escherichia coli (*ETEC, EPEC*)	Fluid ingesta; intestinal congestion; neonates have milk in stomach	Mucosa congestion, edema; bacteria attached to epithelium	Culture; serotype; PCR virulence genes; IHC
Rotavirus	Fluid-filled and pale intestines	Moderate villous atrophy	Detect with PCR, ELISA, or PAGE; lesion with FAT; IHC
Clostridium perfringens type C	Segmental hemorrhage and necrosis	Necrosis and gram-positive rods associated with lesions	Histopath; isolation; toxin ELISA; PCR testing
Clostridium perfringens type A	Watery, creamy intestinal content; no gross lesions	Mild; loss of epithelium from villus tips; neutrophils; inflammation	Histopath and isolate high numbers; toxin ELISA; PCR testing
Clostridium difficile	Mesocolonic edema; watery to creamy diarrhea	Colitis with multifocal ulcers and suppuration	Histopath; toxin A/B via ELISA and LFDs; isolation
Cryptosporidium spp.	Fluid intestinal content	Cryptosporidia oocysts intimate with surface epithelium	Histopath; high oocysts with smear or fecal float
Cystoisospora suis (*Isospora,* coccidiosis)	Thick ileum; fibrinous enteritis; feces variable	Villous atrophy, fibrinonecrotic enteritis, intracellular coccidial forms	Histopath (lesions and coccidia); impression smear; fecal float
Coronavirus (TGEV, PEDV, PDCoV)	Thin-walled intestine; watery; rapid dehydration	Severe and diffuse villous atrophy	IHC, ISH, or FAT to visualize; PCR to detect virus
Porcine circovirus type 2	Lymph node enlargement, edema of mesocolon, pneumonia	Histiocytic lymphadenitis with lymphoid depletion; granulomatous enteritis	Histopath; IHC or ISH to visualize; qPCR is suggestive
Gastric ulceration	Ulceration or fibrosis of pars esophagea; hemorrhage in stomach; dark blood/melena in intestines	Hyperkeratosis (mild to severe) to necrosis, hemorrhage, fibrosis, granulation	Gross exam (examine pars esophagea); histopath; occult blood in feces
Lawsonia intracellularis (PHE)	Proliferation or necrosis in small or large intestine; PHE can have fresh blood clots in ileum; pallor	Crypt enterocyte hyperplasia; cryptitis; small curved rods in epithelial cells	Histopath; IHC, ISH, or FAT to visualize; detect with PCR on feces or mucosa; serology
Brachyspira hyodysenteriae; strongly hemolytic *Brachyspira* spp.	Lesions only in large intestine; mucohemorrhagic typhlocolitis; erosions with fibrinous exudates	Erosion of epithelium; goblet cell hyperplasia, inflammation, fibrin exudate	Histopath; IHC stains; ISH to visualize; detection by culture or PCR
Brachyspira pilosicoli	Mucoid colitis is mild to moderate	Mild mucoid colitis; end-on attachment of spirochetes	Histopath; IHC stains; ISH to visualize; detection by culture or PCR
Salmonella spp.	Fibrinous or hemorrhagic colitis or enteritis with focal ulcers	Ulceration, suppuration, fibrin thrombi; paratyphoid nodules in liver	Histopath; detect with culture or PCR; serotype; mix-ELISA serology
Oesophagostomum dentatum	Erosions, edema, granulomas in cecum and proximal colon	Granulomatous typhlocolitis with nematode parasites	Histopath; parasitology; fecal float
Trichuris suis	Typhlocolitis, erosions; parasites visible 3 weeks after infestation	Mucoid mixed typhlocolitis; embedded nematodes	Histopath; gross exam; parasitology; fecal float
Yersinia spp.	Mild enteritis and/or colitis	Chronic active enterocolitis; microabscesses, granulomas	Histopath; bacterial culture

ETEC, enterotoxigenic *E. coli*; EPEC, enteropathogenic *E. coli*; PHE, proliferative hemorrhagic enteropathy; TGE, transmissible gastroenteritis; PED, porcine epidemic diarrhea; PDCoV, porcine deltacoronavirus; PCR, polymerase chain reaction test; IHC, immunohistochemistry; FAT, immunofluorescence; ISH, *in situ* hybridization; PAGE, polyacrylamide gel electrophoresis; LFDs, lateral flow devices.

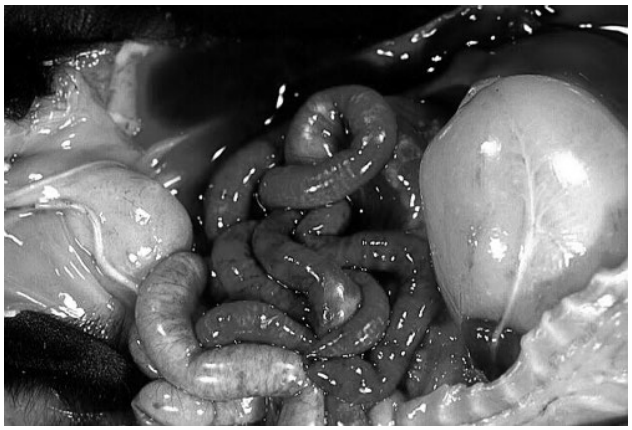

Figure 15.4 Necrosis and hemorrhage in the jejunum of a 4-day-old piglet caused by *Clostridium perfringens* type C.

reproduced with *C. perfringens* type A. The diagnosis of clostridial diseases relies in large part on demonstrating compatible lesions by histopathology. In general, the detection of endemic agents by culture or PCR (bacteria, viruses, protozoans) without typical or compatible gross and/or microscopic lesions is of dubious diagnostic significance.

Recombinant strains of enteric coronaviruses have been recently reported in Europe, which raises concerns over future potential virus transformations (Belsham et al. 2016, Boniotti et al. 2016).

Strongyloides sp. can affect pigs ranging from 10 days of age up to 3 months old. Parasites colonize the anterior half of the small intestine and cause villous atrophy and granulomatous enteritis, resulting in diarrhea and ill-thrift. *Enterococcus durans* has been associated with enteropathy in suckling piglets (Cheon and Chae 1996) by virtue of heavy enterocyte colonization, usually secondary to other pathogens or risk factors. Similarly, other organisms cited as occasional causes of diarrhea include *Bacteroides fragilis* (Collins et al. 1989) and *Chlamydia suis* (Rogers and Andersen 2000). Hemagglutinating encephalomyelitis virus is reported to cause vomiting and wasting in suckling piglets but is rarely a cause of clinical disease. The ongoing reports of porcine adenovirus, bovine viral diarrhea virus, kuboviruses, astroviruses, and a host of other viruses that have been detected by sensitive techniques such as PCR or metagenomic sequencing have not been serious or ongoing disease threats. To reiterate, detection of common endemic agents by sensitive techniques such as PCR is not sufficient to establish causation or definitive diagnosis in absence of well-defined history and clinical presentation or ideally collaborative lesions, as these organisms can be carried by normal healthy piglets and are expected to be present in the population. That stated, new and emerging diarrhea syndromes in suckling pigs can result in major economic losses until the cause and specific control measures can be devised. Investigation of serious diarrhea syndromes merits considerable effort to characterize the condition and determine the cause (Astrup et al. 2010; Gin et al. 2010).

Diseases from weaning onward

A number of the aforementioned preweaning infectious agents are also capable of causing disease in young weaners. *E. coli* continues to be a major cause of post weaning diarrhea, enterotoxemia, and mortality. Edema disease caused by Shiga toxin-producing strains of *E. coli* results in sudden deaths or neurological signs in weaner and grower pigs. Intestinal mucosal lesions are not apparent, although edema of the gastric submucosa, mesocolon, eyelids, and forehead can be prominent. Diseases such as rotavirus, coccidiosis, and cryptosporidiosis can affect piglets up to 6 weeks of age or older. Edema of the mesocolon has been reported in weaner pigs affected with PCV2 systemic disease. Diarrhea is a feature of some PCV2 disease outbreaks and can be a direct consequence of the viral enteritis associated with PCV2 infection (Kim et al. 2004; Ségales et al. 2004). The distal small intestinal and colon mucosa may be thickened, sometimes with edema of the mesocolon. Histologically, there is villous atrophy, granulomatous inflammation, and histiocytosis with multinucleated giant cells. The gut-associated lymphoid tissue shows lymphocytolysis and atrophy of the follicles, as also occurs in other lymphoid organs. PCV2 viral inclusions can be visualized microscopically, and antigen deposits can be demonstrated readily by immunohistochemistry. Coinfection with other agents such as *Salmonella* spp., *Brachyspira* spp., and/or *L. intracellularis* can be common (Järveots et al. 2016; Zlotowski et al. 2008). Grossly, PCV2-associated enteritis can resemble PPE; hence differentiation by histopathology is warranted (Jensen et al. 2006). Another equally important feature associated with PCV2-associaed enteritis is the presence of mild nonspecific colitis. Often bacterial cultures fail to show any recognized bacterial pathogen but yield a mixed growth of commensal-type organisms. Histology of the colon shows mixed bacterial infection of crypts and surface epithelium, accompanied by crypt inflammation and goblet cell hyperplasia in chronic cases. This suggests that there is an opportunistic bacterial overgrowth or dysbacteriosis in the colon of affected pigs, possibly associated with altered enteric immune processes.

Through growing and finishing periods, the most important economic-limiting diseases continue to be swine dysentery, PPE, salmonellosis, and porcine colonic spirochetosis. Prevention and control of PPE caused by *L. intracellularis* include vaccination, the timing of which has improved with modern diagnostic testing technologies. The development of serological tests allows herd

profiling for best application of oral or intramuscular vaccines. In contrast, no commercially available serological tests for swine dysentery or porcine colonic spirochetosis are available, and to date, vaccine efficacy is limited. *Brachyspira* infections are important causes of diarrhea and reduced growth rates in many countries, particularly those caused by strongly beta-hemolytic pathogenic *B. hyodysenteriae* and *Brachyspira hampsonii* that cause typical swine dysentery. Infections with these may also be mild, subclinical, or asymptomatic, depending upon the presence or absence of virulence factors and/or interactions with diet and enteric flora. The prevalence of pathogenic *Brachyspira* spp. varies between countries. Of the most recently described species, *B. suanatina* appears to be limited to Scandinavia, and *B. hampsonii* mostly limited to North America (Råsbäck et al. 2007, Chander et al. 2012). Mixed infections involving *Brachyspira* sp., *L. intracellularis*, *Salmonella* sp., and *Yersinia* sp. are common. Achieving the correct diagnosis and finding effective control measures pose significant challenges for the swine veterinarian.

The disease patterns in swine production units change dramatically when immunosuppression is a feature and the global emergence of PCV2-associated diseases in the first decade of the twenty-first century dramatically illustrated the pathogenic potential of endemic potential pathogens as well as coinfections with other agents such as *Salmonella*, *Brachyspira*, and/or *L. intracellularis* (Zlotowski et al. 2008). Histopathology is critical to confirm a pathologic role for the multitude of agents detected in combined infections (Jensen et al. 2006). Histopathology is also critical to confirm dysfunction when no specific causal agent is demonstrable, as in cases of nonspecific colitis associated with opportunistic bacterial overgrowth or dysbacteriosis.

The prevalence of parasitic infections varies considerably between units. Many units have achieved total freedom of enteric parasites, such as *A. suum*, *Oesophagostomum* sp., *Trichuris* sp. and *Hyostrongylus* sp. However, the threat of parasitism remains, particularly on small farms that may be enrolled in niche or organic markets, in outdoor production status where routine anthelmintic use is not permissible, or where recycled lagoon water is utilized. *A. suum* is a zoonotic parasite.

Trichuris suis and *Oesophagostomum* sp. can be causes of colitis that are easily overlooked until no response to antibiotic agents results in further investigation. Heavy infestations with *T. suis* can cause mucohemorrhagic typhlocolitis that grossly resembles swine dysentery. Differentiation by gross lesions is difficult until the parasites become visible, starting about 3 weeks after infestation. Diarrhea, dehydration, and chronic ill-thrift can all ensue. Recent studies have shown that immunity to *T. suis* is established by 8–9 weeks postinfection due to T2 helper cell immune responses (Andreasen et al., 2015). *O. dentatum* infection is more persistent than *T. suis*, possibly due to the immune-suppressing abilities of the parasite that delay development of the host's T2 helper cell immune reaction (Andreasen et al. 2016).

Some *Eimeria* sp. are considered to be potentially pathogenic, causing villous atrophy and enteritis, and can affect older pigs when exposed to yards and pasture contaminated with oocysts. Infrequently, coccidiosis (*C. suis* or *Eimeria* sp.) can cause acute enteritis and colitis, including hemorrhage, in naive young adult pigs that are introduced into a heavily infected environment and must be differentiated from the hemorrhagic enteropathy form of PPE.

Macracanthorhynchus hirudinaceus, the thorny-headed worm, is a zoonotic acanthocephalan that can be found in the small intestine of grazing pigs. It can cause granulomatous nodules; affected pigs suffer ill-thrift, anemia, and occasionally intestinal perforation. *Balantidium coli* are commonly present in the large intestine of pigs as commensals that can invade degenerative or necrotizing lesions from other causes. Other incidental parasites that can occur in the colon are the paramphistomes *Gastrodiscoides* and *Gastrodiscus* that require aquatic snails to complete their life cycle. They are not considered to be of any pathogenic significance in pigs, but they are zoonotic and heavy infestations can cause serious illness in humans.

Serious epidemic diseases such as CSF and African swine fever (ASF) have an important enteric component. Suspected outbreaks should be reported to proper authorities and aggressively investigated to obtain a rapid, accurate diagnosis to limit spread and control the outbreak. TGE and PED can cause severe diarrhea in all age groups of pigs in addition to the serious morbidity and mortality that occur in suckling piglets. Pseudorabies virus (PRV) can cause necrotizing enteritis in distal small intestine, but less commonly than the more typical necrotizing rhinitis and tonsillitis. Prevention and control strategies for TGE, PED, CSF, ASF, and PRV vary considerably. Vaccination is used in some countries where disease eradication is not possible or feasible.

The peritoneal cavity

The peritoneal cavity is intrinsically involved with the health and normal function of the digestive system. The area of the peritoneal lining is considerable, exceeding the area of skin. When normal, it is smooth, and its moisture is maintained by hydrostatic peritoneal fluid that moves readily across serosal surfaces.

The most common congenital abnormalities that affect the peritoneal cavity of pigs are umbilical or inguinal hernias as discussed above. Occasionally, the remnants of vestigial structures can be encountered as incidental findings at postmortem examination. Rarely,

these can be responsible for intestinal entrapment, with fatal consequences.

Abnormal contents of the peritoneal cavity include blood, excess serous fluid, inflammatory products, intestinal contents, or urine. Severe trauma and rupture of organs can lead to abnormal intra-abdominal contents. Hemoperitoneum associated with a ruptured liver is a common finding in piglets overlain by sows. Ascites can arise for a number of reasons including hypoproteinemia, anemia, uremia, hepatic diseases, heart failure, systemic illnesses, intoxications, and endotoxemia. Discussions of all these circumstances are beyond the scope of this chapter, but the basis of ascites in relation to specific conditions is discussed in the relevant chapters.

Peritonitis may be associated with systemic bacterial infections, the most common of which are *Haemophilus parasuis* (Glässer's disease), *S. suis*, *Actinobacillus suis*, and *Mycoplasma hyorhinis* infections. Pigs that recover spontaneously or following treatment may develop fibrous abdominal adhesions that impair normal gut function, cause discomfort, reduce appetite, and lower growth rates that affect the overall productivity of the unit if significant numbers are involved. Other circumstances that can give rise to peritonitis are umbilical infection in neonatal piglets and infection associated with castration wounds. Environmental or opportunist types of organisms such as *E. coli*, *Trueperella pyogenes*, *Staphylococcus*, and *Streptococcus* spp. are usually involved. Peritonitis can occur secondary to colonic serositis in pigs with over-distension of the organ secondary to rectal stricture and in pigs with enteritis or typhlocolitis associated with invasive bacterial infections. Rare forms of peritonitis in pigs include intestinal anthrax, where the mesentery is gelatinous and hemorrhagic associated with lymphatic spread of infection, and tuberculosis, where lesions are more localized and often adhered to the spleen. In pigs with *Stephanurus dentatus* infection, localized peritonitis with inflammation and edema of perirenal tissue can be caused by larval migration from the liver to the kidneys. Neoplastic lesions affecting the peritoneum can occur in aged pigs due to metastatic spread from primary sites.

Ossification of the mesentery or the peritoneal lining is seen occasionally in adult pigs. The lesion is usually confined to a focal area and is thought to arise as a long-term consequence of tissue injury or scarring. At the root of the mesentery, there can be radiating spicules of calcification and bone formation. The cause is uncertain, but we postulate that it could result from "stretch and shear" damage. Generally these lesions are limited in extent and of no consequence. However, intestinal obstruction, perforation, and mesenteric torsion involving heterotopic mesenteric bony elements have been described (Forsythe 1987; Sanford and Rehmtulla 1994). In the latter reference, a y-shaped bony lesion measuring approximately 28 cm served as a fulcrum for the mesenteric torsion.

Tumors involving the peritoneal cavity are relatively rare in pigs. Cases of multicentric lymphoma invariably involve the mesenteric lymph nodes in addition to the liver and spleen. Marked edema of the mesentery can result from obstructions to the efferent lymphatic drainage caused by tumor metastasis. Uterine, ovarian, and intestinal carcinomas have all been found to cause extensive peritoneal lesions.

Splenic torsion involving the lengthy gastrosplenic ligament in pigs is a common finding. Complete torsions are rapidly fatal as the spleen becomes engorged with blood and ultimately ruptures. Pigs with partial torsions can survive successfully, depending upon the amount of spleen affected. The resulting lesions can be seen as incidental findings in slaughtered animals or those that have died from other causes. Typically, one-third to half of the spleen has been entrapped by the ligament and mesentery, resulting in chronic adhesions and atrophy of the affected portion of the spleen.

The liver

Congenital anomalies affecting the pig liver are rare. One recognized condition is a cystic anomaly affecting bile ducts in which the liver is enlarged and shows numerous fluctuating cystic lesions containing bile. The enlarged liver causes abdominal distension, and piglets have poor viability.

Traumatic conditions affecting the liver are important. In neonatal piglets, rupture of the liver and fatal hemorrhage is a consequence of trauma, usually inflicted accidentally by the sow. Torsion of one or more liver lobes can affect pigs of any age. It usually affects the left lateral lobe and results in infarction of the lobe (Figure 15.5a and b). Death occurs due to shock or hepatic rupture and hemorrhage.

Hepatosis dietetica is a noninfectious diet-associated condition in which there is massive hepatic necrosis. Experimentally, concurrent deficiencies of sulfur-containing amino acids, tocopherols, and selenium are required for development of hepatosis dietetica. The pathogenesis is not fully understood, but it is thought to be associated with formation of free radicals and their subsequent adverse effects similar to the related condition "mulberry heart disease" in which there is acute cardiomyopathy and myocardial hemorrhage results in congestive heart failure and marked congestion of the liver. Enlarged, heavy, and turgid livers occur with various causes of congestive heart failure, including vegetative endocarditis.

Many systemic diseases cause nonspecific changes in the liver, including congestion and inflammatory cell infiltration. Hemorrhages are a feature of septicemia. Salmonellosis, especially when caused by *Salmonella* Choleraesuis, can cause multifocal white pyogranulomatous nodules, often referred to as "paratyphoid nodules."

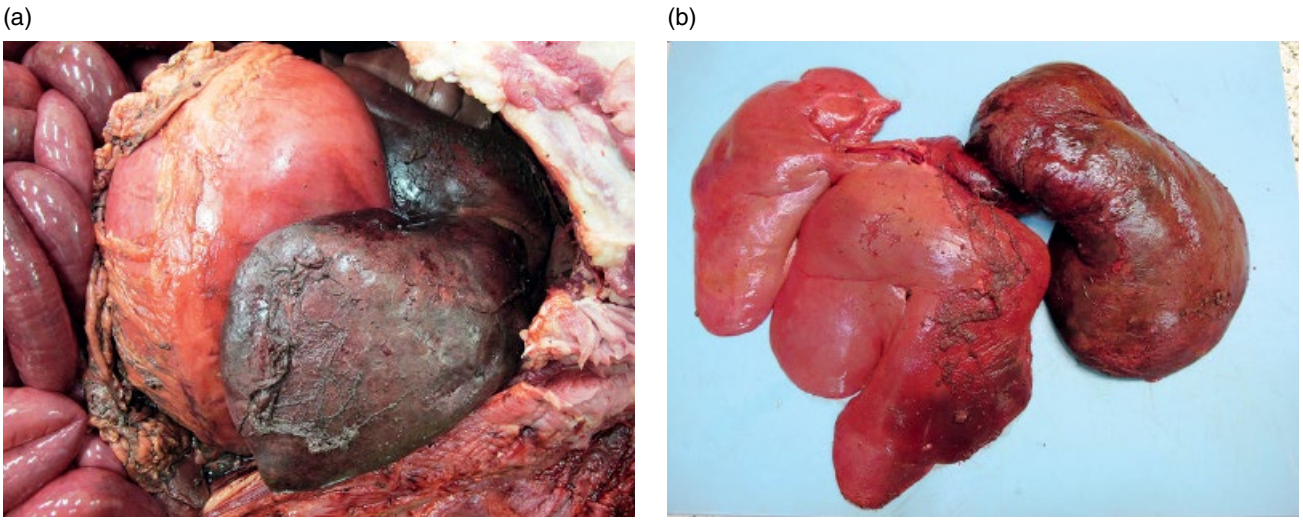

Figure 15.5 Torsion of liver lobe. (a) Liver *in situ* showing necrotic left lobe with fibrin coating. (b) Liver removed, showing appearance of affected and unaffected lobes. *Source:* Courtesy of Fiona Howie.

Parasitism is the most common condition affecting the liver. Migrating *A. suum* larvae cause mechanical damage in the form of hemorrhagic tracts that initiate intense inflammation. Reactive changes, both repair of tissue and hypersensitivity reaction to excretory and secretory products of larvae, cause eosinophil infiltration and fibrosis seen grossly as "white spots" or "milk spots," resulting in economic losses to the farmer. In heavy infestations, adult ascarids can migrate up the bile duct or pancreatic duct, causing obstruction, jaundice, and cholangitis. Other parasitic infections affecting the liver include *Cysticercus tenuicollis*, the metacestode of the tapeworm *Taenia hydatigena* (of dogs). Cysts can sometimes be found in the pig peritoneal cavity, often attached to the liver. *S. dentatus* infection results in migratory tracts and hepatitis. Portal phlebitis with thrombus formation in the portal vein are additional features following oral infection. *Fasciola hepatica* and *Fasciola gigantica* are both capable of infecting pigs, though this is rare. The lancet liver fluke *Dicrocoelium dendriticum* has resulted in nodular hepatic lesions causing liver condemnations in outdoor-reared pigs. The latter is a fascinating parasite that requires two intermediate hosts (aquatic snail and ant).

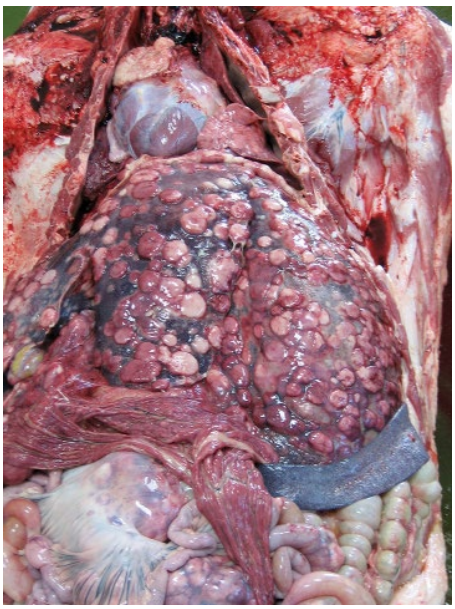

Figure 15.6 Hepatic lymphoma in a 4-month-old gilt. The mesenteric lymph nodes were also severely infiltrated.

Toxicities affecting the liver can be acute or chronic in nature. Cresol toxicity is caused by exposure to tar compounds that might have been used in construction of piggery buildings, accidental environmental spillage, road materials, or "clay pigeons" used as shooting targets. Lesions include severe hepatocellular necrosis leading to sudden death. Chronic cresol toxicity results in jaundice, ascites, and anemia on account of chronic, progressive destruction of hepatic tissue. Iron toxicity occurs occasionally in neonatal piglets, with deaths occurring within 24 hours of iron-dextran administration. Toxicity is associated with marginal or deficient vitamin E and selenium status. Iron-catalyzed lipoperoxidation occurs in the liver and muscle, resulting in hepatic necrosis and hepatic hemorrhages.

Aflatoxicosis is caused by the use of cereals contaminated with *Aspergillus* species or *Penicillium puberulum*. Lesion development is a chronic process in which there is liver hypertrophy and progressive fibrosis. The condition results in reduced growth rates and liver condemnations.

Tumors of the liver are uncommon apart from metastatic lymphoma (Figure 15.6).

The pancreas

There has been little focus on pancreatic conditions in pigs. Pancreatic hypoplasia is rare and associated with poor growth in individual weaner pigs. The pancreatic duct can be invaded by *A. suum* in piglets with heavy infestations. This can lead to obstruction of the pancreatic duct, resulting in pancreatic necrosis and acute pancreatitis. Inflammation of the pancreas can be observed in some cases of mycotoxicosis (fumonisin B2) or systemic viral infections (PCV2).

Immune System

Christopher Chase and Joan K. Lunney

Introduction

The continuing explosion of knowledge on the immune system has substantial implications for swine health. This contains key concepts, including immune proteins and cell subsets, genetics, microbiome–immune interactions, and vaccine responses. The immune system develops in the fetus, and immune responses begin where microorganisms and/or their products interact with epithelial cells of the mucosa and skin. This interaction is necessary for proper development including immune system maturation and regulation and maintenance of homeostasis.

The immune response starts where microorganisms breech the various barriers and engage the immune system (Figure 16.1). The first line of defense is the innate immune response with phagocytic cells and production of various cytokines, chemokines, and proteins that provide antimicrobial protection, recruit T cells through the inflammatory process, and activate the adaptive, or acquired, immune response (Figure 16.2). Natural killer (NK) cells, like many cellular components of the innate immune system, have a dual function: an innate response to attack virus-infected cells and to produce cytokines for assisting in the activation of acquired immunity (Gerner et al. 2009; Mair et al. 2014). The adaptive immune response, with its myriad of B cells, T cells, cytokines, and antibodies, provides the pathogen-specific memory for protection from subsequent infections with the same pathogen (Figure 16.2). Pattern recognition receptors (PRR), including Toll-like receptors (TLRs), monitor pathogen-associated molecular patterns and induce different signaling pathways to activate the immune system against infection.

The mucosal barrier and microbiome

The mucosal epithelium is important for secretion and absorption in the gut and clearance of particulates and pathogens for proper lung function in the upper respiratory tract (URT). In addition, the enterocytes in the gut and ciliated epithelial cells (CEC) in the URT are the first responders to microorganisms at those surfaces. The goblet cells in the mucosa secrete mucus and mucins that provide the initial barrier (Pelaseyed et al. 2014; Varum et al. 2010) with the mucosal epithelial cells (Johansson and Hansson 2014). The mucosal barrier contains antimicrobial peptides (AMPs) produced by the enterocytes and CEC (Figure 16.3). Secretory immunoglobulin A (sIgA) is produced when dimeric IgA is secreted by the plasma cells in the lamina propria (LP) and is transported to the mucosal surface of the epithelial cell. The inner mucus layer along with the AMP and sIgA form a "killing zone" that only a few pathogens or commensals have evolved strategies to penetrate (Figure 16.3). The "killing zone" along with the tight junctions that knits the enterocytes and CEC form a "barrier" against pathogens.

The microbiome is essential for immune development in the neonatal pig after which the microbiome–gut–immune–brain axis maintains the health of the pig (Kim and Isaacson 2015; Mayer et al. 2015; Sherman et al. 2015). As piglets develop, there is a "succession" of microbes that culminates in a "climax" community as the gut transitions to an anaerobic environment (Kim and Isaacson 2015). The outcome of succession is influenced by nutrition, stress, and environment. The microbial community of commensals and their metabolites influence the health of the gut mucosa and the underlying immune cells in the LP (Figure 16.1) (Fouhse et al. 2016; Kim et al. 2016). The composition of the microbiome varies by gut location, with the numbers and diversity of populations increasing dramatically from the stomach to the colon and to the ileum, a key organ for microbial–immune development. An understanding of the complexity of the gut microbial ecosystem (the microbiome), which has evolved to help protect the pig by improving barrier and immune function, is essential (Benis et al. 2015; Stokes 2017).

Diseases of Swine, Tenth Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson.

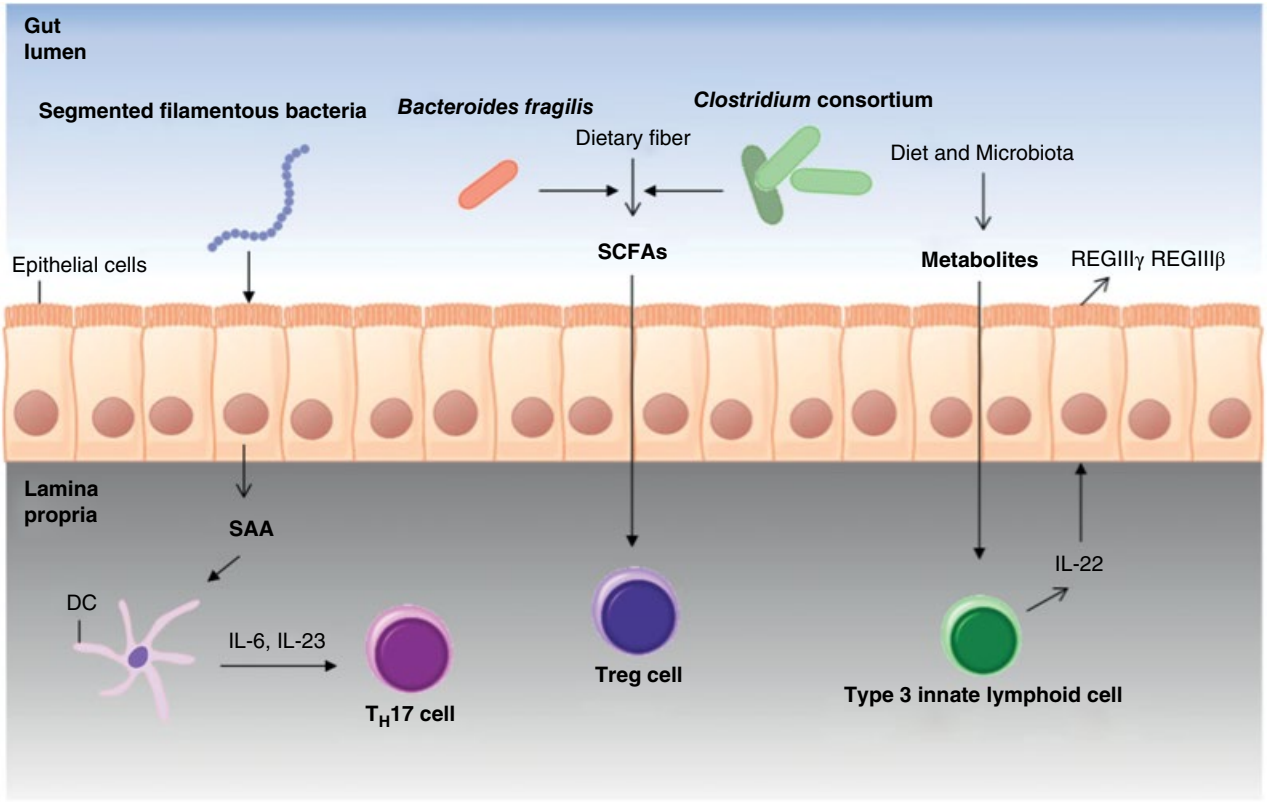

Figure 16.1 Gut microbiota and their products shape the development of epithelial cells and immunity. Segmented filamentous bacteria (related to *Clostridium*) promote the production of serum amyloid A (SAA) protein from epithelial cells, which activates dendritic cells (DCs) to produce IL-6 and IL-23, resulting in the generation of Th17 cells that are important for T-cell development. *Clostridium* consortium and *Bacteroides fragilis* produce short-chain fatty acids (SCFAs) from dietary carbohydrates that induce the differentiation of Treg cells to help minimize inflammatory response. Diet- or microbiota-derived metabolites upregulate the number of IL-22-secreting type 3 innate lymphoid cells (ILC3s) that induce the production of antimicrobial/host defense peptides (AMP/HDP-REGIIIB and REGIIIγ) from epithelial cells. *Source:* Adapted from Kim et al. (2016). Reproduced with permission of Springer Nature.

Piglet age and the act of weaning result in major microbial population shifts (dysbiosis) in the microbiome because of the stress of sudden removal from the sow, the mixing of pigs in a new environment, and the abrupt diet changes. Microbiome shifts can lower defenses against pathogen entry, leading to increased risk of disease because it results in depletion of the "killing zone." The mucus layer becomes thinner, and the amount of sIgA and AMP declines precipitously, weakening the barrier to allow pathogens to interact with the mucosa and cause disease. Low feed and water intake also contribute to dysbiosis and post weaning diarrhea (Fouhse et al. 2016). There is a reduction of lactic acid-producing bacteria (*Lactobacillus*), which raises intestinal pH, increasing susceptibility to pathogens because low gut pH is bactericidal to *Escherichia coli* (Fouhse et al. 2016). Applied research aims to minimize dysbiosis by increasing symbiotic microbes and decreasing opportunistic pathogens.

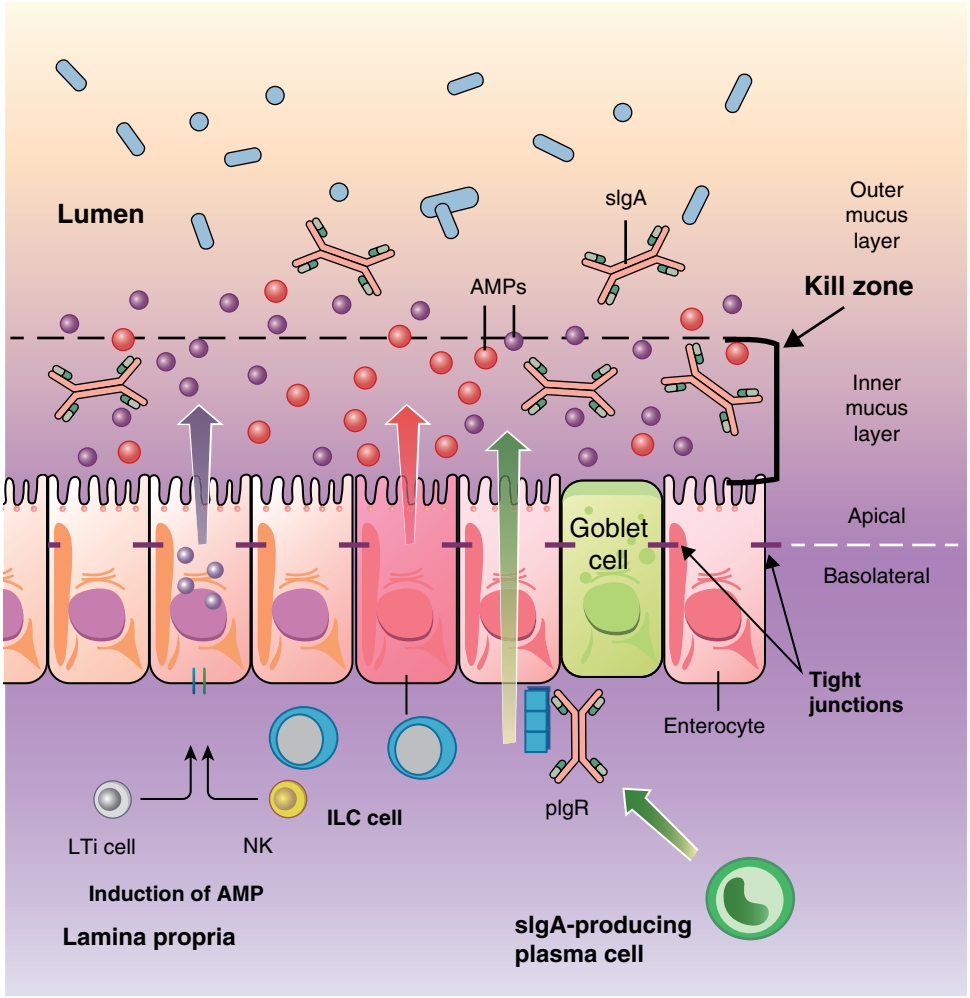

Figure 16.3 Mucosal defenses. Distinct subpopulations of intestinal epithelial cells (IECs) enterocytes are integrated into a continuous single-cell layer that is divided into apical and basolateral regions by tight junctions. Epithelial cells sense the microbiota to induce the production of antimicrobial peptides (AMPs). Goblet cells produce mucin that is organized into a dense, more highly cross-linked inner proteoglycan gel that forms an adherent inner mucus layer and a less densely cross-linked outer mucus layer. The outer layer is highly colonized by constituents of the microbiota. The inner mucus layer is largely impervious to bacterial colonization or penetration due to its high concentration of bactericidal AMPs, as well as commensal-specific secretory IgA (sIgA), which is moved from their basolateral surface, where it is bound by the receptor, to the inner mucus layer. Responding to the microbiota, innate lymphoid cells (ILC), lymphoid tissue inducer cells (LTi), and natural killer (NK) cells produce cytokines, which stimulate AMP production and maintain the epithelial barrier. A similar scheme is in respiratory mucosa. *Source:* Adapted from Maynard et al. (2012). Reproduced with permission of Springer Nature.

Unique features of the swine lymphoid system

The swine lymphoid system consists of five major organized tissues: lymph nodes, lymphoid follicles, tonsils, thymus, and spleen (Rothkotter 2009; Wilson and Obradovic 2015). The structure of porcine lymph nodes is inverted compared with other domestic species; the B-cell germinal centers are in the interior of the node rather than the cortical regions, and there is a much larger cortical and paracortical region that normally contains the T cells (Binns et al. 1986; Pabst and Binns 1986). The lymphoid follicle organization of the gut is also unique. Rather than the discrete lymphoid follicles (Peyer's patches [PP]) present in the ileum in many species, the pig has discrete follicles in the jejunum and a continuous PP in the ileum (Liebler-Tenorio and Pabst 2006). The lymphoid follicles and germinal centers within the PP were significantly smaller in formula-fed compared with sow-fed piglets, suggesting less immune stimulation (Yeruva et al. 2016).

The tonsils are the first contact point to the immune system for many pathogens. The largest tonsils are those of the soft palate, but the pig also has pharyngeal and lingual tonsils. The tonsils contain many lymphoid elements in crypts and interfacing with the surface, often

described as lymphoepithelium. The tonsil is a very important sample for the detection of infectious disease agents (Horter et al. 2003) as well as a source of their continued shedding (Stenfeldt et al. 2014). The thymus is the primary lymphoid organ for the development of T cells in the prenatal and neonatal pig. The spleen, like other mammals, has two main functions: red blood cell management in the red pulp and induction of immune responses against bacterial sepsis in the white pulp.

Innate defense mechanisms

Innate defense mechanisms are present in normal animals and do not require previous exposure to antigen and have no "memory." Innate immunity enables the pig to respond almost immediately to an infectious agent (Figure 16.2). The innate immune system controls infection until the adaptive immune system (with memory) can be activated. Components of the innate system help activate the adaptive immune system to produce antibody- and cell-mediated immune responses.

Physical, chemical, and microbial barriers

Physical, chemical, and microbial barriers to infection at body surfaces are a very important part of resistance to disease (Figure 16.4). These factors include the epithelial cells, bactericidal fatty acids, normal flora, and the mucus layer, which are modulated by the flow of mucus, low pH, bile, and numerous enzymes.

Cells

An important function of the cells of the innate immune system is phagocytosis to remove pathogens. Phagocytic cells engulf, kill, and digest invading bacteria and also play important roles in controlling viral infections and fungal infections and killing cancer cells. The two main types of phagocytic cells are the granular leukocytes, including neutrophils, basophils, mast cells, and eosinophils, and the mononuclear phagocytes, which include the circulating blood monocytes and tissue macrophages (Mair et al. 2014) (Figure 16.5). Phagocytic cells are capable of all the reactions described below for neutrophils. Macrophages are also important in processing antigens as they are critical antigen-presenting cells (APCs) that interact with lymphocytes to stimulate cell-mediated and humoral immune responses.

Granulocytes

Neutrophils (polymorphonuclear neutrophils, PMNs) produced in the bone marrow are released into the bloodstream with a half-life of approximately 8 hours. In healthy pigs PMNs are eliminated via the intestinal tract and lungs. PMNs tend to marginate in the capillaries by loosely associating with endothelial cells and are activated very early in the inflammatory response. The principal function of PMNs is the phagocytosis and destruction of invading microorganisms.

The PMNs are attracted to the vicinity of the invading microorganism by chemotaxis. Chemotactic factors are produced directly by microorganisms, by the cleavage of complement (C′) components, by endothelial activation with inflammatory mediators and chemokines, or by factors released by lymphocytes at the site of infection or inflammation. These factors diffuse in a gradient from the inflammatory site, cause increased expression of adhesion molecules in capillary endothelial cell membranes, and result in an increase in PMN numbers in the capillaries. PMNs enter the tissues, migrate along the gradient toward the site of infection, and ingest those microorganisms susceptible to phagocytic activity. Most pathogens must be opsonized by the attachment of specific antibody and/or C′ to their surface before they can be ingested by PMNs.

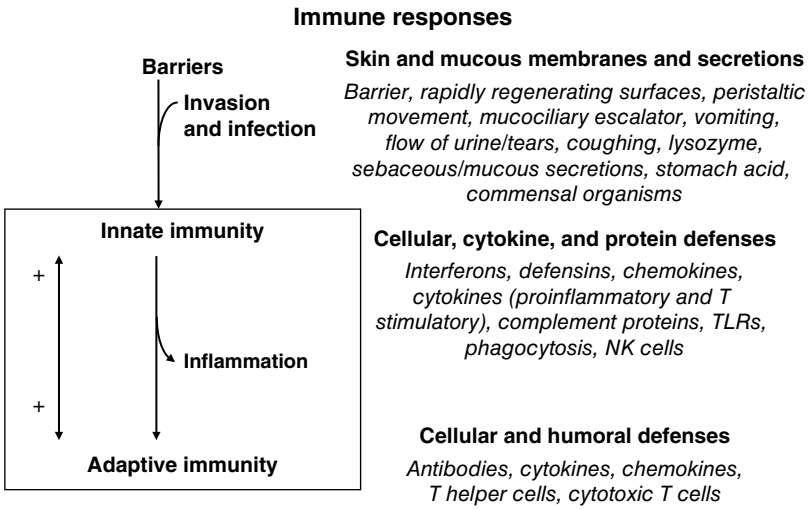

Figure 16.4 Immune responses: the barrier, innate, and adaptive immune components. *Source:* Courtesy of D. Topham, PhD, Rochester, NY, from Introduction to Viral Immunology: Part I.

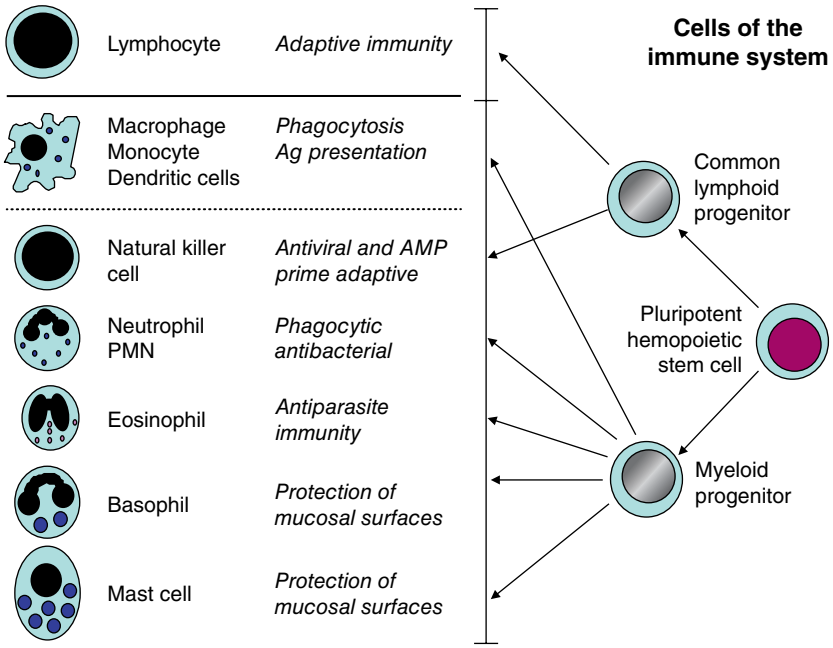

Figure 16.5 Mononuclear blood cells of the immune system. The innate and acquired immune cell lines have overlap with the macrophages and natural killer cells having important innate and acquired responses. AMP, antimicrobial peptides; Ag, antigen. *Source:* Courtesy of D. Topham.

The PMN cytoplasm contains membrane-bound lysosomes with numerous hydrolytic enzymes with bactericidal activity and antibacterial peptides (Sang and Blecha 2009). PMNs die after a short time at sites of inflammation, with release of hydrolytic enzymes to contribute to the inflammatory response and tissue destruction. PMN granule proteins induce adhesion, attract inflammatory monocytes to the site of inflammation, and create extracellular defenses by the formation of neutrophil extracellular traps (NETs) (de Buhr et al. 2017). PMNs use a potent oxidative metabolism system to kill bacteria; when stimulated by an opsonized particle, a burst of oxidative metabolism results in the production of reactive oxygen intermediates (ROI) that are the most potent of bactericidal mechanisms of PMNs, potentially fungicidal and virucidal. PMNs control certain viral infections via a mechanism referred to as antibody-dependent cell-mediated cytotoxicity (ADCC) in which antibodies form a bridge between the PMN and the virus-infected target cell. Porcine PMNs are very active at ADCC, even in the fetus and newborn (Yang and Schultz 1986).

The eosinophil is capable of the same phagocytic and metabolic functions as the PMNs but focuses the host's defense against the tissue phase of certain parasitic infections (Figure 16.5). Eosinophils are more capable of exocytosis by efficiently attaching to and killing migrating parasites that are too large to be ingested. Eosinophils are also important in helping to control certain types of allergic responses and maintaining an anti-inflammatory environment.

Basophils and mast cells have been associated primarily with allergic reactions because of their binding of IgE. These cells have an important regulatory role by release of inflammatory mediators necessary for the activation of the acquired immune response (Abraham and St. John 2010; Galli and Tsai 2010). In pigs, mast cells also have a major effect on intestinal barrier integrity particularly in early weaned pigs (<21 days) (Moeser et al. 2007; Smith et al. 2010). Early weaned pigs have higher numbers of mast cells in the intestinal LP, and treatment of early weaned pigs with a mast-cell degranulation blocker inhibits intestinal mucosal dysfunction.

Mononuclear phagocytes: macrophages and monocytes

The mononuclear phagocytic system consists of circulating monocytes, tissue macrophages, migrating macrophages (histiocytes), and dendritic cells (DCs) (Figure 16.5). Monocytes are produced in the bone marrow, released to the bloodstream, and circulate before migrating into the tissues to become macrophages and DCs (Ezquerra et al. 2009). Fixed macrophages line the endothelium of capillaries, particularly in the lungs, as well as in the sinuses of the spleen, bone marrow, and lymph nodes. Tissue macrophages trap and remove foreign antigens from the bloodstream and lymph as well as serve as APC for T-cell stimulation. Migrating macrophages are derived from blood monocytes and are found throughout the tissues of the body. In certain locations, they differentiate into DCs and act as APCs. Specialized APCs include the glial cells in the nervous system, Langerhans cells in the skin, and Kupffer cells in the liver. Immature DCs located in various tissues will, upon activation, migrate to the peripheral lymphoid organs where they mature and become the focus for the activation and differentiation of T lymphocytes

(Auray et al. 2016; Bautista et al. 2002; Summerfield and McCullough 2009). Macrophages are capable of all the bactericidal activities described for PMNs and act as the second line of innate cell defense. They are slower to arrive at sites of inflammation and are not as aggressive as neutrophils following infection. However, unlike neutrophils, macrophages sustain activity against pathogens, allowing them to kill bacteria that are resistant to killing by neutrophils. This is especially true if activated by cytokines secreted by T lymphocytes. Macrophages and DCs as APCs provide an essential step in the initiation of a cell-mediated acquired immune response and facilitate an efficient antibody response by B lymphocytes.

Alveolar macrophages are specialized to phagocytize inhaled particles or pathogens, including low numbers of bacteria that they may encounter (Chitko-McKown et al. 1991) and then leave the alveolus by one of two pathways, either through the airways and then up the mucociliary escalator or out of the alveolus between alveolar epithelial cells entering the lymphatic drainage. The latter route leads alveolar macrophages to local lymph nodes where they present captured antigens to lymphocytes to initiate an immune response. Alveolar macrophages are a major target of porcine reproductive and respiratory syndrome virus (PRRSV) infection, thus preventing effective antiviral responses and leading to secondary bacterial infections (Gómez-Laguna et al. 2010; Jung et al. 2010; Loving et al. 2015).

Pulmonary intravascular macrophages adhere to endothelial cells in the blood vessels of the lungs (Chitko-McKown and Blecha 1992). They are prominent in pigs, primarily involved in defense against septicemia rather than protection from respiratory disease. Pulmonary intravascular macrophages that are actively clearing bacteria (especially gram-negative bacteria) or free endotoxin from the bloodstream may release cytokines and arachidonic acid metabolites that contribute significantly to pulmonary inflammation.

Natural killer cells

NK cells are lymphoid cells of the innate immune system and can kill a variety of nucleated cells without previous antigenic stimulation. They are activated quickly (within 1–2 days) following infection. Like macrophages, NK cells are an important component of the innate defense mechanisms and participate in activating the adaptive immune response (Shekhar and Yang 2015) (Figures 16.2; 16.5). NK cells can be detected with monoclonal antibodies (mAbs) (Mair et al. 2016) and differ markedly from NK cells found in other species in that their activity is mediated by small granular lymphocytes that have the cluster of differentiation 2 (CD2) T-cell marker (Gerner et al. 2009; Kim and Ichimura 1986). The killing activity of swine NK cells is enhanced in the presence of a variety of cytokines: interferon-γ (IFN-γ), interleukin (IL)-2, human IFN-α, human IL-1α, and interferon (IFN) inducer (poly I:C) (Gerner et al. 2009). Stimulated NK cells produce IFN-γ that activates components of the cell-mediated immune system, such as cytotoxic T lymphocytes (CTLs), macrophages, and NK cells, and also induces T helper (Th) cell differentiation to the Th1 pathway important for cell-mediated immunity and memory (Pintaric et al. 2008). In swine influenza infection, IFN-γ production by NK cells was not increased, but tumor necrosis factor-α (TNF-α) was increased in the lung, which may enhance the proinflammatory response and exacerbate disease (Forberg et al. 2014). Overall, NK cells are an important part of the innate defense mechanisms and participate in a cell-mediated immune response by enhanced activity through cytokine activation.

Innate immune factors

Defensins

AMPs or host defense peptides (HDPs) are a family of molecules that form a chemical barrier to limit infection at epithelial surfaces and attack invading bacteria (Figure 16.3). The HDPs are relatively small cationic peptides found predominantly at mucosal surfaces and in phagocytic cells that vary in structure and antimicrobial functional activity. AMPs/HDPs are induced by the microbiota in the lumen of the gut and respiratory tracts (Maynard et al. 2012; Yeoman and White 2014) and by NK and innate lymphoid cells (ILC) known as lymphoid tissue inducer (LTi) cells. It is likely that HDP antimicrobial and immunoregulatory functions are separate, thus providing opportunities for new designs for antimicrobial drug alternatives (Xiao et al. 2015).

Complement

The complement (C′) system is an enzymatic cascade system that, via at least 20 serum proteins, greatly amplifies its multiple innate functions during the cascade. The C′ system is divided into the classical pathway, the alternative pathway, and the mannan-binding pathway and involves the membrane attack complex and regulatory proteins. The C′ system mediates the inflammatory response, controls bacterial infections, and plays a prominent role in allergic and hypersensitivity reactions. The trigger for the classical C′ pathway is antigen–antibody complexes (IgG and IgM). The alternative C′ pathway is activated by antigen–antibody complexes (IgA and IgE), certain bacterial products such as endotoxin, and proteases released by tissue damage. The mannan-binding pathway recognizes molecules on the surface of bacteria that differ from those present on the host cells. All three pathways end in the splitting of the third component of C′ and start the formation of the membrane attack complex. Activation of any of these C′ pathways causes

vasodilation and increased vascular permeability, resulting in serum components (including antibody and C′) entering the tissues to help control infection. C′ components produced during activation are chemotactic and attract phagocytic cells to the site of infection, as well as coat or opsonize infectious agents to increase their uptake by phagocytic cells. The C′ system is important for mediating inflammation and controlling bacterial infections, but it is also capable of causing serious and even life-threatening damage if unregulated; therefore it is closely regulated to control and stop the C′ reaction once it has started.

Toll-like receptors

TLRs are a family of cell surface molecules (Table 16.1) that bind to various microbial molecules such as lipopolysaccharide, peptidoglycans, cytosine guanine dinucleotide (CpG)-rich unmethylated oligonucleotides, and double-stranded RNA and are a key component of innate immunity (Uenishi and Shinkai 2009). They are the primary method for early detection and response to microbial invasion. Binding of microbial components to TLRs initiates an inflammatory response that helps to activate other aspects of innate immunity and to initiate the acquired immune response.

Bacteria-derived vaccine adjuvants can enhance immune response to vaccines through binding to TLRs, 10 of which are affirmed in the swine genome (Dawson et al. 2013) and are similar to humans. Major efforts are under way to identify functional single nucleotide polymorphisms (SNPs) that may identify pigs with improved innate responses against pathogens associated with SNPs in TLR genes (Clop et al. 2016; Shinkai et al. 2012). Toka and Golde (2013) demonstrated that TLR7 and TLR8 agonists indirectly or directly activate porcine NK cells but that optimum levels of activation require cytokine secretion by accessory cells activated by these compounds. Such activated NK cells were cytotoxic against foot-and-mouth disease virus (FMDV)-infected cells *in vitro*.

Table 16.1 Ligand and pig pathogen responses associated with TLRs and NLRs in pigs.

Gene	Ligand	Effect on immune response	References
TLR1	Lipopeptides	Response to gram-positive bacteria	Uenishi and Shinkai (2009)
TLR2	Peptidoglycan, lipoteichoic acid, heat shock protein	Increased TLR2 in gnotobiotic pig intestine with *Escherichia coli* and *Lactobacillus*	Willing and Van Kessel (2007)
TLR2, TLR6		Recognition of *Mycoplasma hyopneumoniae* cell bodies in porcine alveolar macrophages	Muneta et al. (2003)
TLR3	Double-stranded RNA	Response to viruses. Activate TLR3 with increase IFN-α to decrease PRRSV in macrophages	Miller et al. (2009)
TLR4	Lipopolysaccharide (LPS) (endotoxin), heat shock protein	Response to gram-negative bacteria (LPS and *Salmonella* spp.) and damaged host tissue	Burkey et al. (2009)
TLR5, TLR9	Flagellin, DNA containing high unmethylated CpG	Upregulation after feeding of *Salmonella* spp.	Burkey et al. (2007)
TLR6	Lipopeptides	Response to gram-positive bacteria	Uenishi and Shinkai (2009)
TLR7	Single-stranded RNA	Response to viruses. Transcriptional activation of TLR7-induced genes in swine macrophages	Fernandez-Sainz et al. (2010)
TLR7, TLR8	Single-stranded RNA	Response to viruses. NK cells activated by TLR agonists were cytotoxic against FMDV-infected cells	Toka et al. (2009)
TLR9	DNA containing high unmethylated CpG	Response to bacteria and viruses. PCV2 via CpG–TLR9 signaling of cytokine inducers and inhibitors	Hasslung et al. (2003), Vincent et al. (2007), Wikström et al. (2007), Shimosato (2003)
NOD1	Immunobiotic. Peptidoglycan of lactic acid bacteria	Induction of proinflammatory cytokines	Tohno et al. (2008)
NOD2	Immunobiotic. Muramyl dipeptide (MDP) response	Induction of proinflammatory cytokines	Jozaki et al. (2009), Tohno et al. (2008)

Cytokines: Type I IFNs, tumor necrosis factor-α (TNF-α), IL-6, and IL-8

Cytokines are small protein or glycoprotein molecules secreted by cells and serve as intercellular signaling molecules; all cells of the immune system are capable of secreting and being influenced by cytokines. Cytokine secretion is usually transient, occurs in response to specific stimuli, and typically acts locally in low concentrations. A cytokine will only act on a cell that has specific receptors for it; regulation of cytokine receptor expression is an important mechanism for controlling the response to cytokines. Much is known of porcine cytokines because of the economic and biomedical research importance of pigs (Bailey 2009; Charley et al. 2006; Dawson et al. 2005; Murtaugh et al. 2009). One group of cytokines, important in mediating innate immunity, includes the type I IFNs (IFN-α/β) and the proinflammatory cytokines (IL-1β, IL-6, and TNF-α). Porcine type I IFNs are composed of at least 39 functional genes with diverse expression profiles and antiviral activities (Sang et al. 2010). Type I IFNs can be detected within a few hours of infection, increase cell resistance to virus infection, increase NK cell activity, and increase the major histocompatibility complex (MHC) or swine leukocyte antigen (SLA) molecule expression on cell surfaces, thus increasing antigen presentation to T cells (Lunney et al. 2009). Other cytokines and IFN-γ are discussed below in adaptive immunity.

The proinflammatory cytokines (IL-1, IL-6, and TNF-α) require no previous pathogen exposure and are produced by either macrophages in response to bacterial infection or TNF-α by NK cells (Figure 16.6) in response to viral, protozoal, or fungal infections and tissue damage. The proinflammatory cytokines stimulate the liver to produce acute-phase proteins, stimulate the release of amino acids from muscle tissue, and may induce cachexia or wasting in chronic infections. In addition, they induce fever, loss of appetite, and fatigue if present in high enough concentrations. In low levels, these cytokines promote leukocyte adhesion to endothelial cells, diapedesis of leukocytes into the tissues, and migration of macrophages and DCs to the secondary lymph nodes, resulting in the activation of the adaptive immune response. Their presence in small amounts is required for effective stimulation of adaptive immune responses; however, in large quantities, they can induce hypovolemic shock and death.

Adaptive immunity

Lymphocyte populations

B and T lymphocytes and their products are the components of the adaptive immune response system, an antigen-driven system that requires 2–3 weeks after first exposure to antigen to reach optimal functional capacity (Figure 16.2). With second exposure to antigen, the immune response reaches optimal activity much more rapidly due to the anamnestic, or memory, response. B and T lymphocytes also enhance resistance to disease by activating the innate defense mechanisms (phagocytic cells, NK cells, and C′), thus increasing their efficiency (Figures 16.4 and 16.6).

Pigs have high blood lymphocyte counts compared with most other mammals (approximately 10^7/mL), and lymphocyte subpopulations in the blood of young pigs

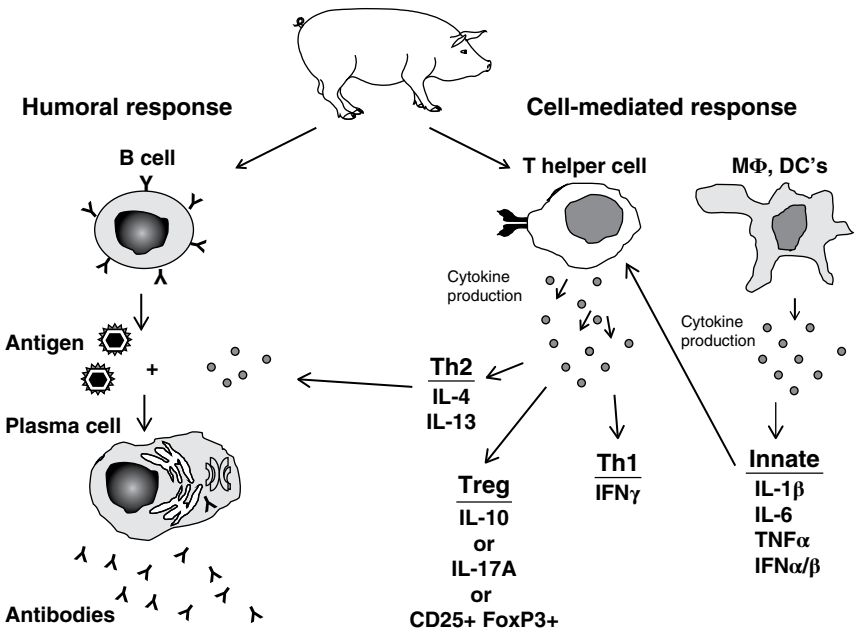

Figure 16.6 Cell-mediated (T-cell) and humoral (B-cell) activation of the adaptive immune response of the pig. T-cell subsets express certain polarizing cytokines, the interleukins (ILs) or interferons (IFNs), as the immune response matures.

differ markedly from other species (Sinkora and Butler 2016). Porcine T cells are divided into subpopulations, which includes the most abundant T cells expressing T-cell receptors (TCR) with αβTCR chains (αβT cells) as well as a prominent fraction of T cells with γδTCR chains (γδT cells) (Duncan et al. 1989; Hirt et al. 1990; Saalmüller and Bryant 1994). Pigs and ruminants have a much higher population of γδT cells in the blood than other mammals. γδT cells do not recirculate between the blood and lymphatic tissues and do not have NK cell activity. Like αβT cells, these γδT cells can express CD8α and SLA class II, potential activation markers of T cells, suggesting that they express cytolytic activity or are involved in antigen presentation (Gerner et al. 2009). As in other species, αβT cells are SLA class-I-restricted CD8+ CTL, CD4+ Th, or regulatory T (Treg) cells. In pigs, Th cells express other activation-related markers, including CD8α, SLA class II, and CD45RC. Certain pig Treg cells have a phenotype similar to humans and mice and can suppress proliferation of other T cells and produce IL-10 (Gerner et al. 2009, 2015).

Swine αβT lymphocytes have three unusual properties compared with other species (Lunney and Pescovitz 1987). First, approximately 25% of swine peripheral blood T cells express both the CD4 and CD8 antigens on their surface rather than just a single antigen like most other species; the functional significance of having both CD4 and CD8 on the same cells is not known (Pescovitz et al. 1994; Zuckermann and Husmann 1996). Second, the normal ratio of CD4+ to CD8+ T cells is approximately 0.6 in pigs, which is reversed compared with other species. Third, resting CD8+ cells in swine preferentially express class II MHC antigens. The significance of these differences between swine T lymphocytes and those of other species is not understood.

γδT cells are located predominantly along mucosal surfaces, especially as intraepithelial lymphocytes in the intestine. They are thought to be important in protecting mucosal surfaces from infection and perhaps in oral tolerance (Thielke et al. 2003). γδT cells proliferate in the intestine and actively recirculate through the intestinal lymphatics to the bloodstream and then to the gut. The role of the thymus and intestinal epithelium in the development of γδT cells is not known. A subset of circulating porcine γδT cells can act as APCs and are capable of producing IFN-γ, proliferating in response to recall antigens *in vitro* and being cytotoxic (Lee et al. 2004; Takamatsu et al. 2002).

Lymphocyte circulation

The inverted lymph node structure provides for recirculation of lymphocytes from blood to lymphoid tissues, important for antigen presentation and facilitating cellular interactions needed for the induction of the immune response (Figure 16.7). Lymphocytes produced in the bone marrow mature in the thymus (αβT cells) or the secondary lymphoid tissues (B cells) and circulate in the blood for approximately 30 minutes before entering the tissue. Lymphocytes enter lymph nodes via afferent lymphatics from tissues or directly from blood by adhering to high endothelial venule (HEV) cells of the lymph node and then migrating into the node. In contrast to other species where lymphocytes exit the lymph node and return to circulatory system via the thoracic duct, lymphocytes in swine directly reenter the blood rather than go to the next draining lymph node through the efferent lymphatics (Binns et al. 1986; Roth and Thacker 2006).

Lymphocyte subpopulations in swine show a distinct preference for circulation to either gut-associated lymphoid tissues (GALTs) or surface nodes (Figure 16.7). For instance, mesenteric lymph node cells (both T and B lymphocytes) preferentially home to the gut (Salmon 1986). In swine, approximately equal numbers of lymphocytes in the mammary gland come from GALT or from peripheral lymph nodes. The dual origin of mammary lymphocytes suggests that the local mammary immune response may not depend solely on oral immunization (Salmon 1987).

Cell-mediated immunity

Antigen presentation

APCs (macrophages and DCs) phagocytize and process antigens and then present these antigenic fragments bound to SLA molecules as they contact T lymphocytes (Figure 16.6). CD4 Th cells can only efficiently recognize foreign antigens that are on a cell surface bound to SLA class II molecules. CD8+ CTL are important for killing cells infected with intracellular pathogens and cancer cells. CTL recognize the foreign antigens processed intracellularly and transported to a cell surface bound to SLA class I molecules. T cells do not respond to free soluble antigen or to whole bacteria or viruses; thus SLA class I and class II molecules play a key role in antigen presentation and have significant influence on the nature of the immune response. The SLA genes are highly polymorphic, differing genetically between individuals (Chardon et al. 1999; Lunney et al. 2009). The set of SLA molecules that a pig inherits can influence their immune response to pathogens and vaccinations and their ability to resist some infectious diseases.

In addition to antigen and class II MHC molecule contact, the Th cell requires the presence of cytokines released by the APCs and other T cells and contact with costimulatory molecules on the surface of the APC for complete activation. IL-1 released by macrophages is a key mediator of the host response to infection through its ability to induce fever and neutrophilia. IL-1 acts on

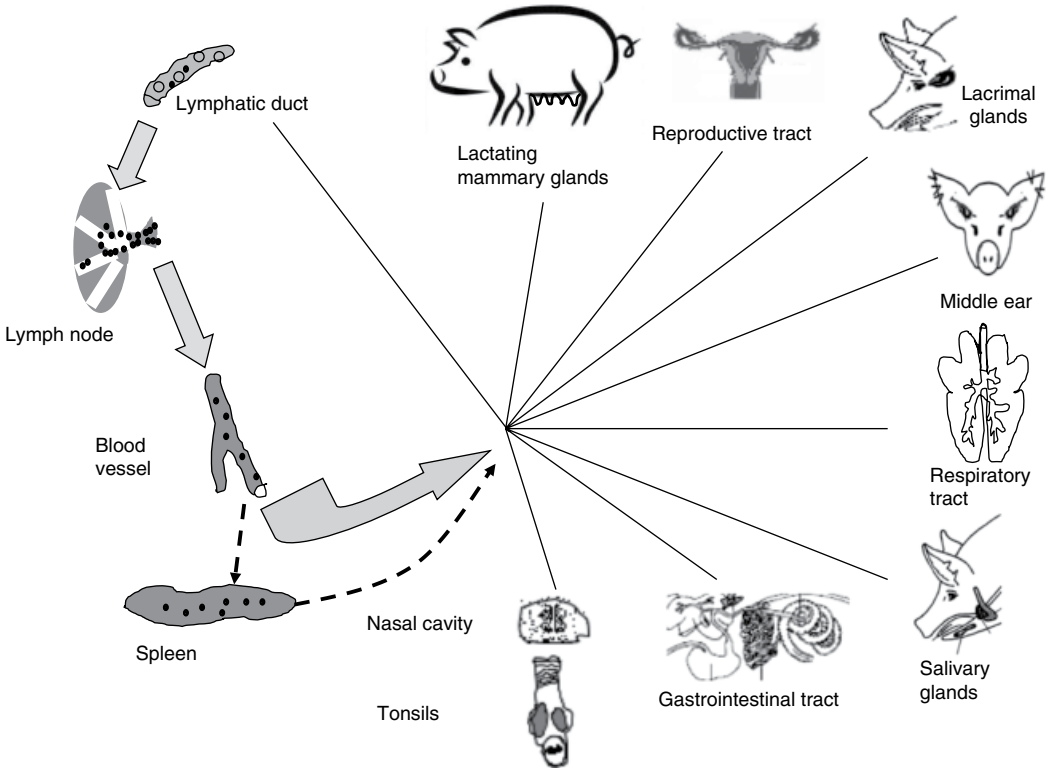

Figure 16.7 Lymphocyte circulation and common mucosal immune system of the pig. As illustrated on the left side of the figure, the pig has unique lymphocyte circulation with lymphocytes entering the lymph nodes by afferent lymphatics but exiting via blood vessels rather than efferent lymphatics. The common mucosal system involves the circulation of B and T cells between lymphoid tissues on mucosal surfaces.

Th cells to cause secretion of IL-2 that induces T cells to undergo mitosis and clonal expansion. B cells are also capable of processing antigen and presenting it to Th cells on MHC II molecules. During secondary immune responses, B cells are thought to act as APCs.

Th cells are critical in initiating the B-cell response resulting in antibody production (Figure 16.6). B cells contact antigen through immunoglobulins (Igs) bound to their surface, which act as the B-cell receptors (BCR). B-cell antigens do not need to be presented on MHC class II molecules by macrophages, although optimal B-cell response to antigen requires Th cell release of cytokines and contact with costimulatory molecules on the Th cell surface. This Th cell help is needed for B-cell mitosis and clonal expansion and for switching the class of antibody produced from IgM to IgG, IgA, or IgE.

Clonal selection and expansion

Clonal selection is basic to understanding the immune response. Each mature T or B lymphocyte in the body has receptors on its surface that it uses to recognize an antigen. All the antigen receptors (TCR and BCR) on each single lymphocyte recognize exactly the same antigen. All the lymphocytes that recognize exactly the same antigen make up a "clone," and they are from the same ancestor cell. Lymphocytes are in a resting stage as they circulate through blood, migrate through the lymph nodes, and reenter the bloodstream. In the lymph nodes or secondary lymphatic tissues, T lymphocytes come into contact with antigen on APC (DCs or macrophages) following their activation in the periphery. B lymphocytes can directly bind antigen that enters the lymph node. Each lymphocyte's TCR or BCR responds to only one specific antigen that it recognizes through its antigen receptor. Swine T-cell specificity is defined by the TCR variable regions as they interact with foreign antigen peptides presented by SLA molecules on the APC (Gerner et al. 2009; Piriou-Guzylack and Salmon 2008).

The vast majority of lymphocytes that contact an antigen in the lymph node cannot respond to it. Thus, in an animal never exposed to a particular infectious agent, there are relatively few lymphocytes in each clone that can recognize a particular antigen. The first step in producing an effective primary immune response is

expansion of the clone of lymphocytes that recognize the antigen. Within a few days, there will be enough lymphocytes in the clone to mount an effective humoral and/or cell-mediated immune response. Animals exposed previously to the antigen will have an expanded clone of lymphocytes, so fewer cycles of cell division are required to produce enough lymphocytes to mount an immune response. The cells present in the expanded clone are called memory cells. If the previous exposure has been relatively recent, there will still be circulating antibody and effector T lymphocytes that can act immediately to control the infection.

Th1, Th2, and Treg cells

Cytokines secreted by macrophages, DCs, and other T cells play crucial roles in the initiation and maintenance of immune responses against both viral and bacterial pathogens in pigs (Dawson et al. 2005; Thanawongnuwech and Thacker 2003; Thanawongnuwech et al. 2000, 2001; Zuckermann et al. 1998). Similar to other species, CD4+ T cells differentiate into Th cells with characteristic cytokine secretion profiles including the production of IFN-γ by Th1 cells, activating macrophages and stimulating T- and B-cell proliferation. Release of IL-10 is associated with the induction of one subset of Treg cells and is important in suppressing macrophage function and maintaining homeostasis of the respiratory tract. The timing and balance between cytokine expression following PRRSV infection clearly affect the efficiency of the antiviral response and likely viral persistence (Charerntantanakul et al. 2006; Loving et al. 2015; Lunney et al. 2010b, 2016; Suradhat and Thanawongnuwech 2003).

A group of cytokines regulates lymphocyte activation, growth, and differentiation. IL-2 stimulates T and B cells that have recognized antigen to proliferate and activates NK lymphocytes to have increased cytotoxic activity. IL-4 is important for effective IgE–mast-cell–eosinophil inflammatory reactions required to control some parasites and may result in allergic signs to nonparasitic antigens. In other species, IL-12 activates NK lymphocytes and induces CD4+ cells to differentiate; in swine, the lack of upregulation of the IL-12 receptor means that such activation is less prominent (Solano-Aguilar et al. 2002). IFN-γ causes cells to be resistant to virus infection (similar to IFN-α/β) and is a potent activator of macrophages, neutrophils, and NK cells. TNF-α often acts synergistically with IFN-γ to activate phagocytic cells. TNF-α can also activate endothelial cells, resulting in diapedesis of leukocytes into sites of inflammation.

Another group of cytokines, the colony-stimulating factors (CSFs), stimulates hematopoiesis through the expansion and differentiation of bone marrow progenitor cells. They include IL-3, which stimulates the production of all types of leukocytes; granulocyte–macrophage CSF (GM-CSF), which stimulates the production of granulocytes and macrophages; and granulocyte CSF (G-CSF), which stimulates the production of granulocytes only. The CSFs also enhance the antimicrobial activities of mature neutrophils and macrophages.

Acquired immune defense mechanisms

T lymphocytes are the predominant population of cells that secrete cytokines; some are cytolytic to abnormal cells through secretion of perforins and granzymes. Antibodies produced by B cells are very specific for their respective antigens, whereas cytokines are not. The cytokines produced during an immune response play an important role in orchestrating host defense against pathogens, partially through their direct activities and partially by enhancing the activity of both the innate immune system (i.e. C′, phagocytic cells, and NK cells) and the adaptive immune response by Th cells as described earlier.

CTLs are an important part of the cell-mediated immune response to virus infection and tumors. CTLs are CD8+ and recognize antigen associated with MHC class I molecules on a cell surface. MHC class I molecules present peptide antigens derived from proteins synthesized within the cell, such as viral proteins. CTLs directly attack host cells that have foreign antigen (e.g. viral antigen) presented on MHC class I molecules on their surface; they do not attack free bacteria or viruses. CTL activity specific for hog cholera virus, African swine fever virus, and pseudorabies virus (PRV) has been demonstrated in pigs that have recovered from infection (Martins et al. 1993; Pauly et al. 1995; Zuckermann et al. 1990), but there are limited CTL responses to PRRSV infection (Costers et al. 2009). CTLs kill target cells by making direct contact, releasing granzymes onto the cell surface, and inducing apoptosis (programmed cell death) in the target cells. Production of cytokines, including IL-12 and IFN-γ, by Th1 cells is required for the activation of CTL and elimination of cells infected with intracellular pathogens, especially viruses.

Humoral immunity

Immunoglobulins (Igs)

Swine B-cell development is a function of Ig gene rearrangement and modification (Butler et al. 2009a,c, 2017; Schroeder and Cavancini 2010). After birth, B-cell development begins in the bone marrow and is independent of antigen stimulation, and its fate becomes increasingly dependent on its response to antigen. Immature B cells express IgM but leave the bone marrow and become mature B cells that begin to express both IgM and IgD (Figure 16.8). The secreted pre-immune antibodies of

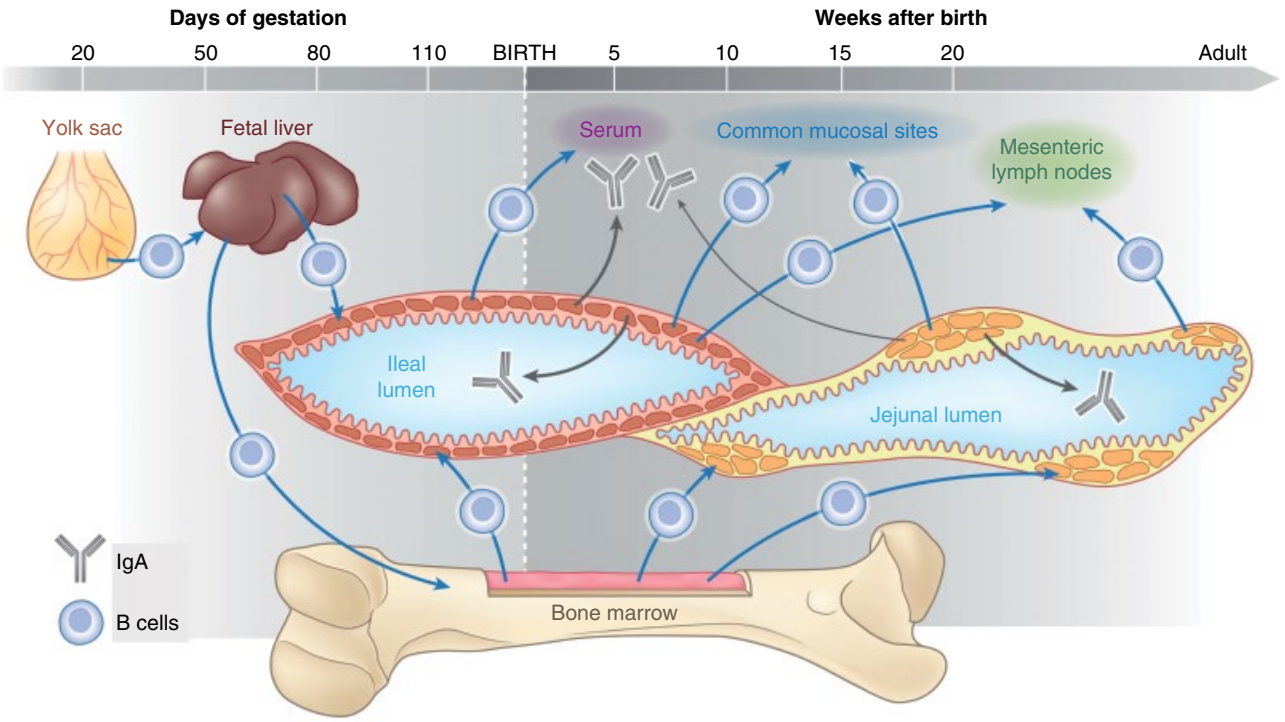

Figure 16.8 B-cell development and antibody production during the pig's lifetime. B-cell lymphogenesis begins in the yolk sac and fetal liver and continues in the bone marrow. The ileal lumen is lined with continuous Peyer's patches (IPP) as the fetal mucosal immune system develop; it is the source of T-independent natural immunoglobulin A (IgA) responses in newborn piglets. Bacterial colonization of the newborn promotes migration of IgA+ B cells to other mucosal sites and secretion of natural IgA antibodies. Several weeks later the segmented jejunal Peyer's patches (JPP) develop with associated T-dependent mucosal IgA responses. *Source:* Butler et al. (2017). Reproduced with permission of Annual Reviews.

the fetus include mainly IgM, IgA, and IgG3; this last isotype may provide a type of first responder mucosal immunity (Butler et al. 2017). Pigs are unique in that their light-chain loci rearrange before the heavy-chain loci, resulting in the Ig light chain selecting the heavy-chain repertoire (Sinkora et al. 2017).

B cells recirculate through the blood, the secondary lymphoid organs, and the bone marrow. An encounter with compatible antigen can cause the B cell to become a memory B cell or a plasma cell. B cells from clones that have never been stimulated by antigen have monomeric IgM (their BCR) on their surface; all of the IgM molecules on one B cell are specific for the same antigen. When stimulated by antigen and cytokines produced by CD4+ Th cells, a B cell begins to undergo mitosis, resulting in many more B cells with IgM recognizing the same antigen; some differentiate into plasma cells that secrete IgM. As the antigen-specific IgM level begins to increase in the blood, activated Th cells produce the cytokines that signal B cells to undergo class switch from IgM to IgD, IgG, IgA, or IgE production (Figure 16.9) (Crawley et al. 2003; Sinkora and Butler 2016). These B cells then rearrange their genetic material to produce antibody molecules with the same antigenic specificity (i.e. the same light-chain structure and variable portion of the heavy chain) but of a different antibody class (i.e. the constant heavy portion of the antibody molecule is changed). Changing the antibody class or isotype gives the antibody molecules different properties. The class of Ig that the Th cells induce the B cells to produce depends on the nature of the antigen and the location in the body where the antigen was trapped. Th cells located in lymph nodes and the spleen tend to induce B cells to switch to IgG production; those located in PP or under other mucosal surfaces tend to induce B cells to switch to IgA and/or IgE production, depending on the nature of the antigen and the genetic predisposition of the individual (Figure 16.8).

The molecular cascade involved in swine Ig expression has been explored in depth by Butler and his colleagues (Butler 2009a–c; Butler and Wertz 2012; Butler et al. 2017; Lunney et al. 2010a). Regions of each Ig heavy-chain gene are encoded by genes (e.g. IGHV, IGHD, IGHJ, IGHG1) that must be joined to form the

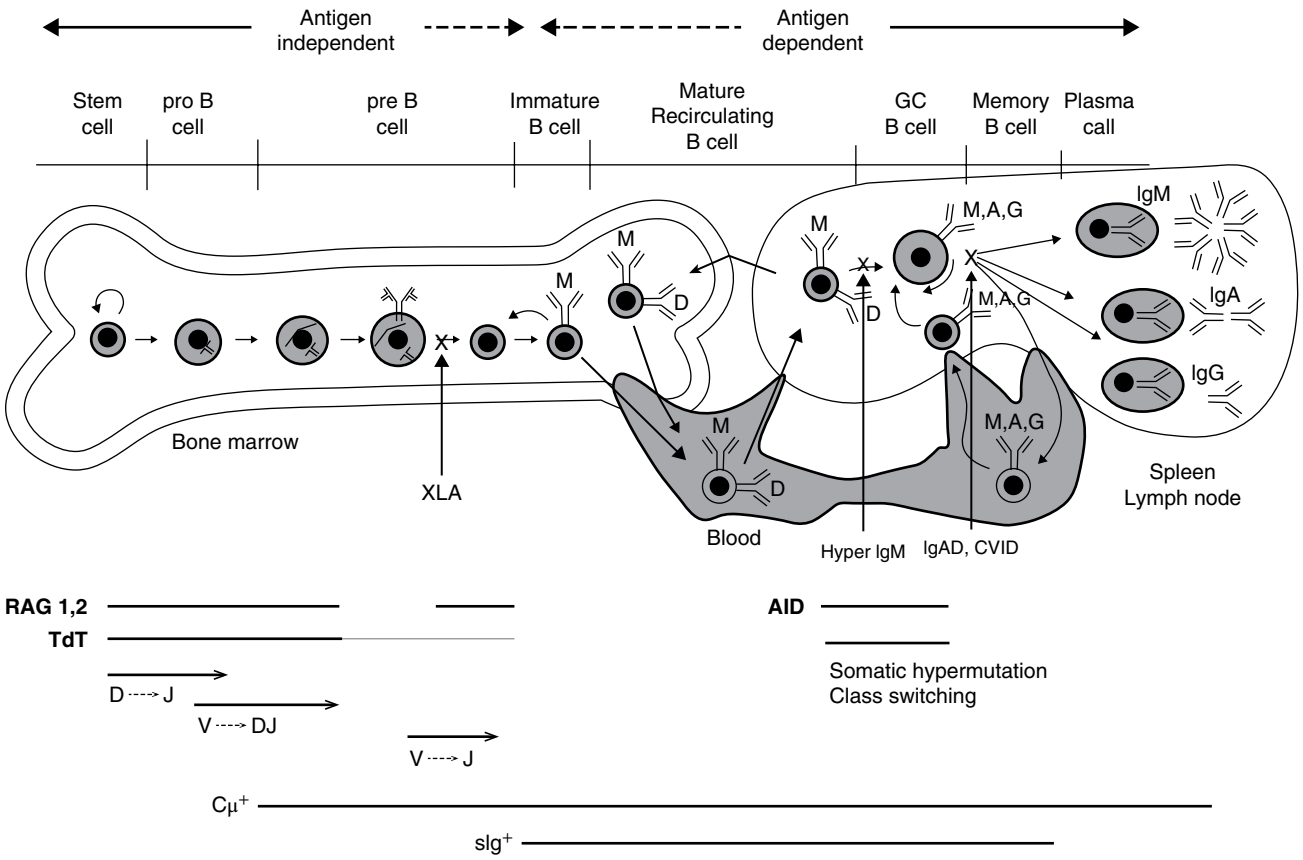

Figure 16.9 B-cell development and antibody production. *Source:* Adapted from Schroeder and Cavancini (2010). Reproduced with permission of Elsevier.

mature IgG antibody molecule (Figure 16.9). There are six expressed IgG subclass genes in swine. As in other mammals, major differences among swine subclasses are located in the hinge region. B-cell lymphogenesis is initiated when lymphocyte stem cells begin to rearrange their Ig genes. For IgG, this starts with IGHD to IGHJ (D-J) rearrangements followed by rearrangement to an IGHV gene. Recombination–activating gene (RAG)-mediated somatic hypermutation of Ig gene segments involves the excision of the intervening sequences between exons. Because swine have only two functional IGDH segments and one functional IGJH segment, the process of B-cell lymphogenesis is much easier to follow than in mice or humans (Butler and Wertz 2012).

Antibody molecules have a variety of activities in host defense, although they alone cannot kill infectious agents. Antibody molecules can coat infectious agents to prevent them from attaching to or penetrating host cells, agglutinate infectious agents to reduce their infectivity, and directly bind to and neutralize toxins. A very important function of antibody is that it marks infectious agents for destruction by C′, phagocytic cells, and/or cytotoxic cells.

Classes of immunoglobulins

Characteristics of the various classes of porcine Igs were thoroughly reviewed in a previous edition of this book (Porter 1986) and in more recent reviews (Butler et al. 2009b,c, 2017; Crawley et al. 2003). IgG is the predominant Ig class in the serum of the pig and other species, accounting for more than 80% of the Ig in serum and colostrum. As in other mammals, IgA is the major mucosal Ig for swine, including in mature milk (Klobasa and Butler 1987; Porter 1969). The IgA and IgM repertoires were more diverse in ileal than in jejunal piglet PP, reflecting a more diversified microflora in the ileal PP (Levast et al. 2010). IgM accounts for approximately 5–10% of the total Ig in serum and colostrum; it is a large pentameric protein held together by disulfide bonds. Zhao et al. (2002) affirmed the presence of IgD genes in artiodactyls, suggesting that IgD may have some as yet unknown biological properties, distinct from those of IgM.

The porcine immune system produces far more IgA than any other class of antibody; however, most of the IgA is found on mucosal surfaces rather than in the serum (Figure 16.8). IgA is present in swine serum as monomers and dimers (two monomers bound together

with a J chain) (Porter and Allen 1972). IgA at mucosal surfaces is mostly dimeric IgA with a J chain and associated secretory component (see section "MUCOSAL IMMUNITY").

Porcine IgE has the same physicochemical properties as other species, including the characteristic of losing biological activity when serum is heated to 56°C (Roe et al. 1993). A polyclonal antiserum for porcine IgE inhibited a passive cutaneous anaphylaxis reaction, identified a sparse population of plasma cells in the LP of the gut and mesenteric lymph nodes of parasitized pigs, and reacted with human IgE in Western blotting (Schmied et al. 2013).

Polyclonal and monoclonal antibodies (mAbs)

Antibodies produced by an animal in response to an infection or vaccination are polyclonal and recognize multiple antigens. Infectious agents are complex antigens with many different antigenic specificities (epitopes) on their surface; therefore, they stimulate many clones of B and T lymphocytes to respond. This results in a heterogeneous mixture of polyclonal antibodies that recognizes a wide variety of surface molecules on the microorganism.

The broad spectrum of antibodies produced and present in serum is most helpful to the animal in overcoming infection. This is a disadvantage, however, for using serum for developing diagnostic reagents for certain diagnostic tests. Moreover, the polyclonal antibodies produced in response to one infectious agent may cross-react with another infectious agent and thus interfere with the specificity of the assay.

mAbs are produced in research laboratories to overcome the disadvantages of polyclonal antisera for diagnostic and (less commonly) for therapeutic purposes. Mouse mAbs are the result of hybridoma production and expansion of one clone from a single B lymphocyte; therefore mAbs are identical and specific for a single antigenic determinant. Hence the problem of cross-reactivity between microorganisms in diagnostic tests is reduced.

mAb can be produced against a protective antigen on a microorganism and then used in therapy or for prevention of disease. mAbs can also be produced against immune cells (CD antigens) and proteins (ILs, IFNs, etc.), providing a means to track the complexity of swine immune responses and helping to delineate protective from pathogenic responses to vaccination and infection (Haverson et al. 2001; Lunney et al. 1994). Since mAb can be produced in very high concentrations and purity, a much lower volume of mAb compared with a polyclonal antibody solution can be used to passively immunize or treat animals. This reduces the risk of serious reaction to the passively administered antibody and its extraneous protein.

Mucosal immunity

Mucosal immunity: Role of the mucosal epithelium

The mucosal immune system provides the first immune defense barrier for over 90% of potential pathogens. The gut mucosal immune system contains more than 10^{12} lymphocytes and has a greater concentration of antibodies than any other tissue in the body (Burkey et al. 2009). It protects against harmful pathogens yet must also induce immune system tolerance to dietary antigens and normal microbial flora (Levast et al. 2014). The mucosal immune system is very rudimentary in the newborn pig and gradually develops in four stages over the first 6 weeks of life (Table 16.2).

In addition to actual immune cells, the mucosal immune system includes epithelial cells that help with antigen recognition and immune modulation. The epithelial cells are coated with mucus–glycocalyx layer that helps in barrier functions but at the same time allows the epithelial cells of the mucosa to be continually in contact with commensal and pathogenic organisms (Figure 16.2). Epithelial cells express TLR on their inner cell membranes, not on their surfaces, and will only be upregulated when the cell is infected (Philpott et al. 2001). Epithelial cells express chemokines such as CCL25 that is chemotactic and binds the chemokine receptor CCR9 on mucosal system T cells (Cheroutre

Table 16.2 Stages in the development of the mucosal immune response in the neonatal pig.

Stage	Pig age	Immune status
1	Newborn pig	Rudimentary Peyer's patches
		Small numbers of mucosal APCs and T cells
2	1–14 days	Nonspecific expansion or Peyer's patches and B cells
		Appearance of some conventional activated helper T cells
		Influx of MHC II+ cells in lamina propria
3	2–4 weeks	Appearance of mature helper T cells in lamina propria and IgM+ B cells in intestinal crypt areas
4	4–6 weeks	Expansion of B-cell repertoire to IgA+ B cells in intestinal crypt area
		Appearance of memory cytotoxic T lymphocytes in the epithelium (intraepithelial T cells) and in lamina propria

Adapted from Bailey et al. (2005b) with permission from Elsevier and Bailey and Haverson (2006).

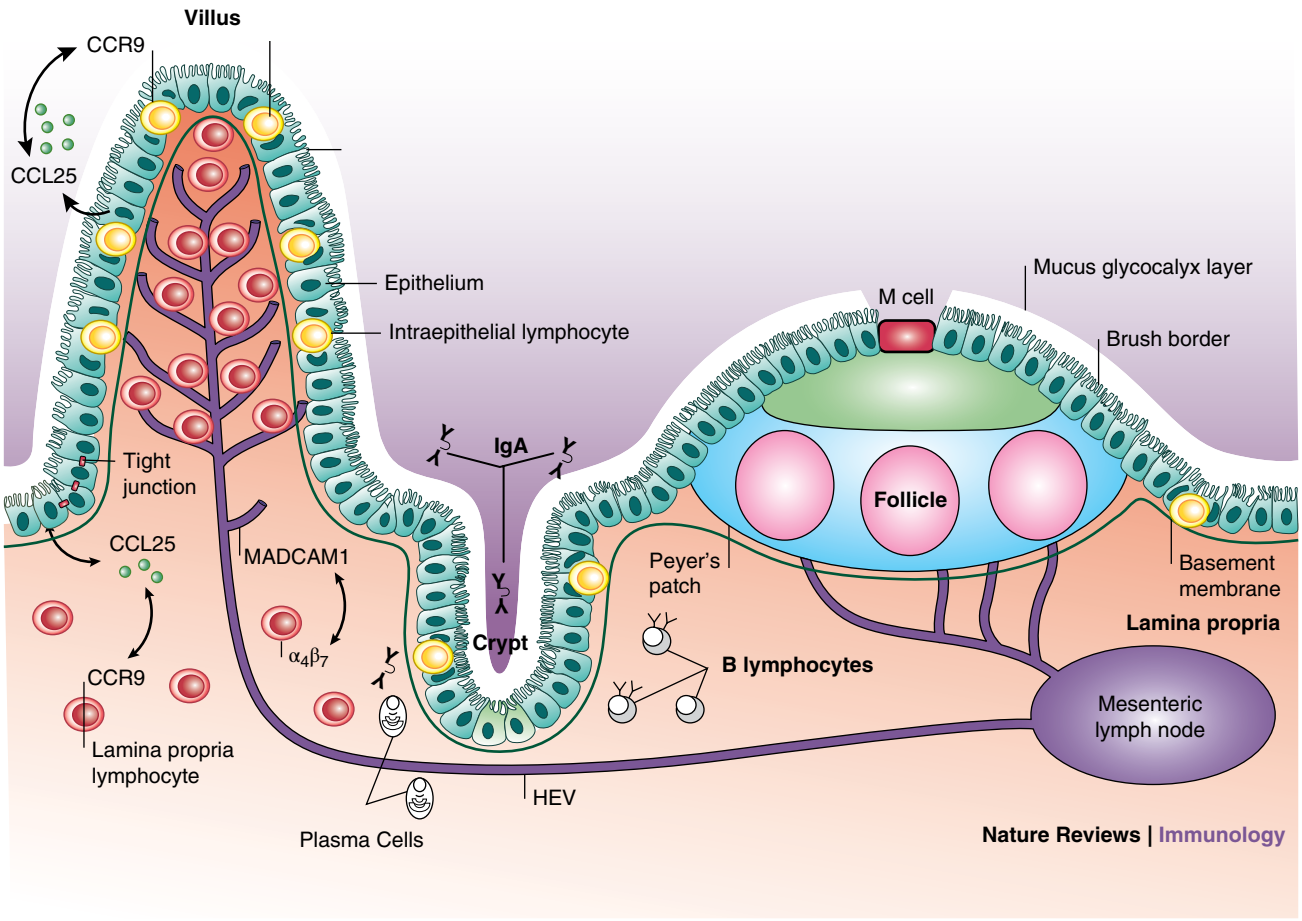

Figure 16.10 Mucosal immune system of the gut epithelium. The lamina propria (LP) contains scattered T cells and lies beneath the epithelium that contains intraepithelial lymphocytes (IEL). B cells are scattered in the LP but are more frequent in the crypt regions along with plasma cells that produce IgA that is transported and secreted into the lumen. M cells facilitate antigen uptake and delivery to the organized lymphoid tissues. T cells activated in the Peyer's patch and mesenteric lymph node express the $\alpha_4\beta_7$ integrin, which interacts with cell adhesion molecule MADCAM1, on the high endothelial venules (HEVs), assisting in homing these T cells to the mucosal LP. The chemokine CCL25 produced by epithelial cells recruits lymphocytes expressing CCR9 receptors to the LP. *Source:* Adapted from Cheroutre and Madakamutil (2004). Reproduced with permission of Springer Nature.

and Madakamutil 2004) (Figure 16.10). The production of CCL25 by epithelial cells recruits these lymphocytes to the LP and into mucosal epithelium.

Another important component of the mucosal immune response is neutrophils, which migrate into the intestinal lumen in large numbers in response to antigen–antibody complexes. The recruitment of neutrophils into the intestinal lumen is dependent on the presence of circulating IgG antibody (Bellamy and Nielsen 1974), colostral antibody (Sellwood et al. 1986), or locally induced IgA class antibody (Bhogal et al. 1987). The migration of neutrophils into the lumen of the gut and their subsequent destruction resulted in increased concentrations of lactoferrin, lysozyme, and cationic proteins. These substances may also contribute to immunity to bacterial infections in the gut.

Intraepithelial lymphocytes and LP immune cells

Intraepithelial T lymphocytes are important mediators of immunity at mucosal surfaces (Figure 16.10) (Burkey et al. 2009; Dunkley et al. 1995). This is especially true for respiratory and enteric infections. T lymphocytes also play a role in immunity in the intestinal tract. Pigs have high numbers of intraepithelial lymphocytes that are predominantly γδ T cells and CTLs (Salmon 1987; Thielke et al. 2003). These intraepithelial cells appear at 4–6 weeks of age. CTLs in contact with intestinal epithelial cells are likely to be important in destroying virus-infected epithelial cells. The γδ T cells proliferate in the intestine and recirculate through the lymphatic and blood vessels back to the intestine. They can produce IFN-γ, be cytotoxic, and act as APCs through MHC II molecules (Lee et al. 2004; Takamatsu et al. 2002).

The LP is the thin layer of connective tissue that lies beneath the mucosal epithelium of the respiratory, gastrointestinal, and urogenital tracts. Besides the smooth muscle cells, blood vessels (including HEV), and lymphatics, the LP contains many immune cells including macrophages, DCs, neutrophils, mast cells, and lymphocytes (Figure 16.10). DCs are the first cells to appear in the LP, increasing in the first few weeks. Mast cells also appear in the LP within the first few weeks, and their numbers are much higher in early weaned pigs (<21 days) than in pigs weaned at 28 days (Moeser et al. 2007; Smith et al. 2010). LP lymphocytes appear within the first week of life, while mature Th cells appear at 2–3 weeks of age (Table 16.2). LP T lymphocytes require more signals for activation, produce higher levels of cytokines, and are memory cells; CTLs appear later, at 4–6 weeks of age, and are also memory cells. B cells first appear near the crypt areas in the LP at 2–4 weeks of age (Table 16.2) and IgA+ B cells do not appear until 4–6 weeks of age(Figure 16.8; Table 16.2).

Homing is an important function of LP lymphocytes (Bailey 2009; Cheroutre and Madakamutil 2004). After T and B cells recognize antigen and mature in mucosal lymphoid follicles like PP, they express adhesive molecules like α4β7 integrin. The lymphocytes then travel to mesenteric lymph nodes, enter the blood circulation, and home back to the LP where the lymphocyte adhesion molecule binds to homing receptors like mucosal addressin cell adhesion molecule 1 (MADCAM1) on the HEV. The lymphocytes then emigrate out of the venules into the LP (Figure 16.10).

Secretory IgA

The predominant Ig secreted by the mucosal immune system is IgA. Dimeric IgA is secreted by plasma cells in the LP, binds to the polyimmunoglobulin receptor on the basal membrane of mucosal epithelial cells, and is transported to the mucosal surface of the epithelial cell (Figures 16.3 and 16.10). The cleavage product is called the secretory component and remains bound to the dimeric IgA. The secretory component is important for protecting the IgA molecule from proteolytic enzymes and also serves to anchor the IgA into the mucus layer so that it forms a protective coating on the mucosal surface. sIgA plays an important role in immunity at mucosal surfaces by agglutinating infectious agents, preventing attachment of infectious agents to epithelial cells, and neutralizing toxins.

Organized and diffuse mucosal lymphocytes

Organized mucosal-associated lymphoid tissues (MALT) are widely distributed in mucosal surfaces throughout the body (Liebler-Tenorio and Pabst 2006). MALT is the initial induction site for mucosal immunity for antigens sampled from mucosal surfaces (Figure 16.10). These mucosal aggregates or follicles of B cells, T cells, and APCs are covered by the epithelium that contains specialized epithelial cells called dome or M cells that are found in the gut and bronchus-associated lymphoid tissues (BALT). Dome cells pinocytose antigen and transport it across the epithelial layer. The antigen may then be processed by APCs and presented to T and B lymphocytes; indeed, intestinal APCs play a central role in the induction and maintenance of mucosal immunity (Inman et al. 2012). These follicles are organized like lymph nodes with T-cell areas and B-cell germinal centers. The lymphocytes that emigrate from these organized areas into the surrounding LP are referred to as diffuse lymphocytes (Bailey and Haverson 2006). The hallmark of this system is that local stimulation will result not only in memory T and B cells in the nearby mucosal tissue but also in other mucosal tissues.

Common mucosal system

Lymphocytes can be divided into two populations, those that circulate between the bloodstream and the systemic lymphoid tissues and those that circulate between the bloodstream and lymphoid tissues associated with mucosal surfaces. In the mucosal lymphoid tissues, mature T cells and B cells that have been stimulated by antigen and induced to switch to produce IgA will leave the submucosal lymphoid tissue and reenter the bloodstream (Wilson and Obradovic 2015). These lymphocytes will exit the bloodstream through HEV as described above and locate in the LP. B cells will differentiate into plasma cells that will secrete dimeric IgA. Many of these cells will return to the same mucosal surface from which they originated (Bailey 2009), but others will be found at different mucosal surfaces throughout the body. This homing of lymphocytes to other MALT sites throughout the body is referred to as the "common immune system" (Figure 16.7). Therefore, oral immunization can result in the migration of IgA precursor cells to the bronchi and subsequent secretion of IgA onto the bronchial mucosa. There is a special affinity for lymphocytes sensitized in the gut of the sow to migrate to the mammary gland to become plasma cells and secrete IgA into the milk.

Environmental influences, nutraceuticals, and development of mucosal immunity

Mucosal immunity, particularly the GALT, is greatly influenced by environmental factors on the surface of the mucosa (Bailey et al. 2005a,b; Bailey and Haverson 2006; Inman et al. 2010). The GALT of the neonatal pig is poorly developed and undergoes a rapid period of development and expansion (Table 16.2), which

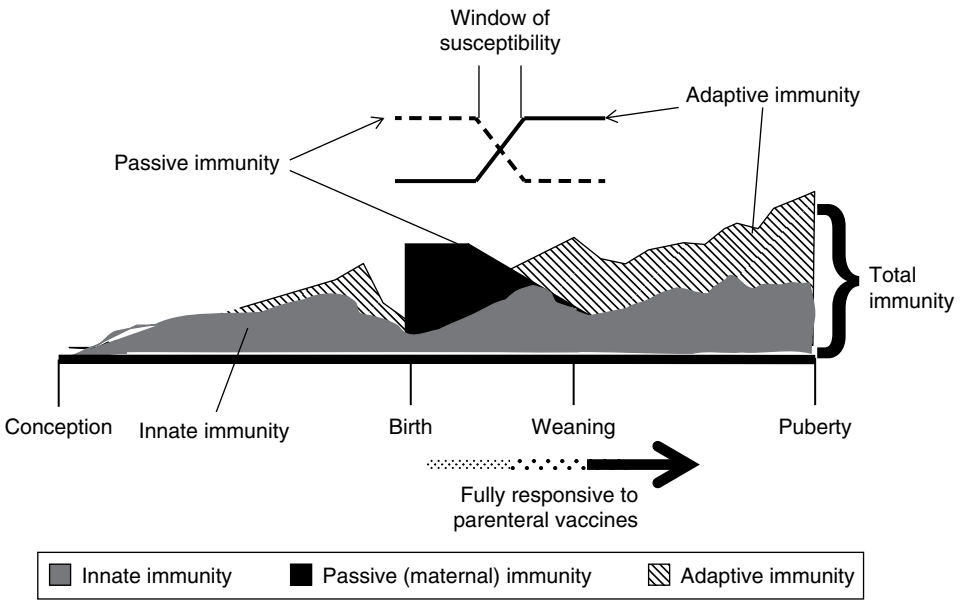

Figure 16.11 Development of the immune response in the pig: from conception to puberty. The pig's passive maternal immunity is only transferred after birth due to its unique placenta. *Source:* Adapted from Chase et al. (2008). Reproduced with permission of Elsevier.

remains incomplete when commercial pigs are weaned at 14–24 days (Lalles et al. 2007). The developing GALT makes one of two different responses to antigens, either an active protective response against pathogens or an active tolerance to commensal organisms and dietary antigens (Levast et al. 2014). The two critical control points for environmental influences in the GALT are immediately after birth and at weaning (Bailey et al. 2005a). Colostrum is important for gut development and growth and for non-antigen-specific immune development (Bailey and Haverson 2006). Colostrum is also important for providing pathogen-specific Ig. It contains high levels of IL-4 and transforming growth factor-β (TGF-β) that has anti-inflammatory effects and accelerates the switch of IgA antibody to common food proteins along with preventing expression of active immune responses and promoting the development of tolerance against nutrient antigens (Bailey et al. 2005a; Nguyen et al. 2007). The presence of commensal microbial flora (microbiome) is essential for the development of GALT in the neonatal pig (Bailey and Haverson 2006). Studies in rearing conditions using either high hygiene (pigs reared in an isolator) or low hygiene (pigs nursed on the sow) demonstrated that a substantial number of the low-hygiene pigs had a more complex microbial flora similar to older pigs raised in low hygiene, and they had more DCs (Inman et al. 2010). These pigs also had higher levels of IL-4, a cytokine associated with an anti-inflammatory effect and the production of IgA.

The second major environmental control point for GALT is weaning. At weaning, the pig is capable of active immune responses (Figure 16.11) (Bailey et al. 2005b). The weaning period is characterized by diet change and sometimes accompanied by low feed intake, poor growth and development, diarrhea, and increased risk for disease from enteric pathogens. Unfortunately, the maternal milk factors that modulate the immune response (TGF-β) and provide specific immunity in the newborn (Ig) are no longer available at weaning, and the balance between tolerance and active immunity at weaning is disturbed. The magnitude and severity of this "weaning" GALT crisis is dependent on how much the immune system was expanded during the pre-weaning period (Bailey et al. 2005a). Unfortunately, the weaning age imparted by a swine production system does not match when the immune system is "ready" for weaning. Managing the immune system for optimal disease prevention at early weaning ages will continue to be problematic.

The effect of nutraceuticals, probiotics, and other dietary supplements on swine mucosal immunity and health has generated much interest. Prebiotics (oligosaccharides and fiber), fiber metabolites (butyric acid and other short-chain fatty acids [SFCA]), organic acids (i.e. formic acid, citric acid), and botanicals (i.e. vanilla, oregano, pepper oil) may enhance the tight junctions in mucosal barrier and have an anti-inflammatory effect on the mucosa (Grilli et al. 2015, 2016; Heinritz et al. 2016; Melo et al. 2016; Zou et al. 2016). Probiotics (i.e. yeast, *Lactobacillus, Bifidobacteria* and their metabolites) increase sIgA and decrease local inflammatory and TLR responses to improve mucosal immunity (Deng et al. 2013; Vlasova et al. 2016).

Immunity in the fetus and neonate

All components of the native and acquired immune systems of the pig develop *in utero* and are functional at birth; however, they are generally less efficient than in the adult (Hammerberg et al. 1989). Since the normal newborn piglet has not yet been exposed to antigens, the humoral and cell-mediated immune responses to infectious agents have not yet been developed. After exposure to infectious agents, it will take 7–10 days for a primary antibody- or cell-mediated immune response to develop.

During this time, resistance to infection depends on the actions of the innate defense mechanisms and the antibody or immune components passively transferred from the sow to the piglet through colostrum and milk (Figure 16.11). There is virtually no transfer of antibody across the placenta prenatally due to the epitheliochorial placentation of the sow; the tissue layers between maternal and fetal circulation effectively prevents all antibody transfer prior to parturition. The sow concentrates antibody in the colostrum during the last weeks and days of gestation that, when ingested, will be transferred intact across the gut epithelial cells into the circulation of the newborn piglet. The passive transfer of antibody from sow to piglet in the colostrum and milk is very important for neonatal survival. The presence of high concentrations of Th2 cytokines like IL-4 or immunoregulatory cytokines such as TGF-β in colostrum is thought to play a critical role in allowing acquisition of the normal commensal microflora in the intestine (Chattha et al. 2013; Nguyen et al. 2007).

Innate defense mechanisms

The newborn piglet has low levels of hemolytic C′ activity, with relative concentrations related to birth weight; heavier pigs have significantly higher C′ concentrations in the serum (Rice and L'Ecuyer 1963). Piglets allowed to suckle colostrum have higher titers of hemolytic C′ than colostrum-deprived piglets during the first 3 weeks of life. The level of natural IFN-α production by porcine peripheral blood mononuclear cells (PBMC) is low at birth and gradually increases until adult age, with a significant increase around puberty (Nowacki et al. 1993).

Phagocytic cells are present in newborn animals but generally have reduced phagocytic activity as compared with adult animals (Osburn et al. 1982). Alveolar macrophages from 1-day-old pigs had reduced oxidative killing mechanisms compared with adult pigs, but by 7 days of age, these aspects of alveolar macrophage function had reached adult levels (Zeidler and Kim 1985). Neonatal pigs have low numbers of pulmonary intravascular macrophages that can increase up to 14-fold by 30 days of age (Winkler and Cheville 1987). Since phagocytes depend on C′ and/or antibodies to opsonize many infectious agents, the overall efficiency of phagocytosis in young pigs may be reduced due to inadequate levels of C′ and antibodies. Neutrophils from fetal pigs have ADCC activity that is comparable with that of adult pigs. Neutrophils from neonatal pigs rapidly emigrate into the lumen of the gut in response to the presence of *E. coli* and colostral antibody (Sellwood et al. 1986; Yang and Schultz 1986).

Adaptive immune mechanisms

The percentage of CD2+, CD4+, and CD8+ blood T lymphocytes increases with age over the first several weeks of life in specific-pathogen-free pigs (Bianchi et al. 1992; Joling et al. 1994). The PBMC blastogenic responsiveness to mitogens is low at birth and increased by 4 weeks of age (Becker and Misfeldt 1993). The mucosal lymphoid system is also less developed at birth and matures over the next few weeks of life (Jericho 1970; Ramos et al. 1992). NK cell activity is absent in peripheral blood of fetal pigs and low in pigs of less than 2 weeks of age (Yang and Schultz 1986).

Passive transfer in the neonate

Pigs are born with almost no serum antibody. Antibody is absorbed from colostrum that is three- to fourfold higher in IgG3 and IgA than serum (Butler and Wertz 2012; Roth and Thacker 2006). Colostrum has approximately the same concentration of IgM as serum. After initial suckling, colostrum ceases and is replaced with milk that has fivefold lower IgG content. From 3 days of age until the end of lactation, IgA is the predominant Ig found in sow milk. The majority of milk Ig is synthesized in the mammary gland, whereas colostral Ig is mostly derived from serum, although this varies by Ig class.

All three major classes of Ig (IgG, IgA, and IgM) are absorbed from the colostrum into the circulation of newborn pigs (Curtis and Bourne 1971; Porter 1969). IgA is absorbed less efficiently than the other classes of antibody (Hill and Porter 1974; Porter 1973) because porcine colostrum is dimeric IgA lacking secretory component. Neonatal colostrum-deprived piglets express secretory component in the gut that tends to localize in the mucus of the crypt areas. Because of the affinity of the dimeric IgA and IgM for secretory component, it has been suggested that IgA and IgM are bound in association with secretory component and held in the mucus of the crypt areas and are, therefore, less efficiently absorbed from the colostrums (Butler et al. 1981). The IgA present in sow's milk throughout the suckling period may also bind to the secretory component in the crypt areas and provide relatively continuous protection against intestinal pathogens.

Intestinal absorption of Ig from the colostrum normally ceases by 24–36 hours after birth. If pigs suckle

normally, the efficiency of absorption decreases with a half-life of about 3 hours (Speer et al. 1959). Lecce and Morgan (1962) found that the period of time that the intestine could absorb antibodies was extended up to 5 days in starved pigs that were maintained by parenteral administration of nutrients. Therefore, piglets that have not had an opportunity to eat during the first 24–36 hours may still benefit from colostrum ingestion. Neonatal pigs absorb colostral lymphocytes from their intestinal tract into the bloodstream (Tuboly et al. 1988; Williams 1993). By 24 hours, cells derived from colostrum were found in the liver, lungs, lymph nodes, spleen, and gastrointestinal tissue. Pigs that had absorbed the colostral lymphocytes had higher lymphocyte blastogenic responses to mitogens than control pigs. It is not clear if the passively transferred lymphocytes also transfer clinically significant cell-mediated or antigen-specific immunity from the sow to the piglet.

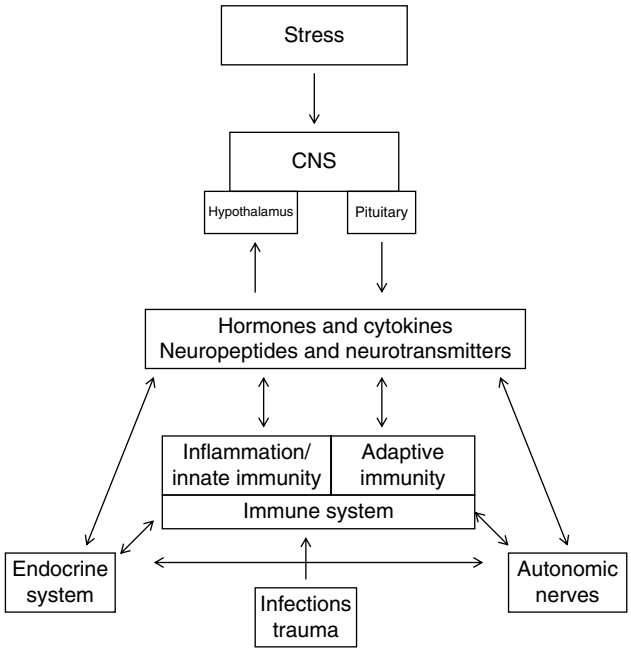

Figure 16.12 Stress effects on immunity. Network of bidirectional communication among central nervous system (CNS) and peripheral nervous system, endocrine system, adipose tissue, and immune systems. *Source:* Adapted from The Lancet Oncology, Reiche et al. (2004). Reproduced with permission of Elsevier.

Stress, immunosuppression, nutrition, and immunity

Physical and psychological stress: Interactions of the central nervous, endocrine, and immune systems

There is ample evidence that both physical and psychological distress can suppress immune function in animals, which may lead to an increased incidence of infectious disease. Excess heat or cold, crowding, mixing, weaning, limit feeding, shipping, noise, and restraint are stressors that are often associated with intensive animal production and influence immune function in various species (Blecha et al. 1985; Kelley 1985; Miró et al. 2016; Westly and Kelley 1984; Yen and Pond 1987). Also, social status, genetics, age, and the duration of stress (chronic vs. acute) are important in the pig's response to stress (Salak-Johnson and McGlone 2007).

The immune system and the central nervous system (CNS) are a bidirectionally linked "two-way street," each influencing the other (Borghetti et al. 2009; Miró et al. 2016) (Figure 16.12). In particular, there is a critical balance that exists between hormones such as growth hormone (GH), glucocorticoids (GC), prolactin (PRL), catecholamines, and insulin with the proinflammatory mediators (IL-1, IL-6, and TNF-α) of the immune system.

The immune system and CNS interaction is influenced through two pathways of the nervous system: the neuroendocrine (hypothalamic–pituitary axis) and the autonomic nervous systems (hypothalamic–sympathetic) (Borghetti et al. 2009; Miró et al. 2016; Salak-Johnson and McGlone 2007). Stress on the CNS affects both inflammatory/innate and adaptive responses through the neuroendocrine activation of the hypothalamic–pituitary–endocrine responses. Activation of the hypothalamus results from either stressors or the acute-phase response following infection when proinflammatory cytokines, IL-1, TNF-α, and IL-6, are released (Figure 16.12). This hypothalamus activation then stimulates hormones from the pituitary gland. The hormones released by the pituitary include thyroid-stimulating hormone (TSH), PRL, and GH, which are linked to insulin-like growth factor 1 (IGF-1) activity, and adrenocorticotropin (ACTH), which activates a number of different endocrine systems including GC from the adrenal gland.

The study of these multisystem endocrine interactions initially focused on the secretion and influence of GC, which suppress several aspects of immune function directly and indirectly by the production of anti-inflammatory cytokines like IL-10. However, pigs are more resistant to the immunosuppressive effects of GC compared with some other species (Flaming et al. 1994), and other mechanisms exist whereby the neuroendocrine system can alter immune function. Neurotransmitters (catecholamines, acetylcholine, neuropeptides, vasoactive intestinal peptide, and substance P) affect the immune system. Catecholamines inhibit IL-12 and enhance IL-10 production (Salak-Johnson and McGlone 2007). Somatotropic hormones like GH and IGF-1 have a positive effect on the immune response including increased proliferation of immune cells in the bone marrow, production of the proinflammatory cytokines, increased cytotoxic activity of CTL and NK cells, and

T-cell development in the thymus, to name a few (Borghetti et al. 2009). TSH, GH, ACTH, PRL, and neuropeptides influence the thymus and the development of T cells.

Recently, the importance of adipokines, the cytokines produced by adipose tissue, has been recognized (Borghetti et al. 2009). Leptin, the most well-studied adipokine, has many positive effects on the immune system including survival of T cells in the thymus, increased killing activity in monocytes and neutrophils, and maturation of DCs. Adipose tissue also produces proinflammatory cytokines. Interestingly, runt pigs have higher adipokine gene expression prior to weaning including higher proinflammatory cytokines (Ramsay et al. 2010).

The immune system is capable of altering the activity of the neuroendocrine system (Kelley 1988; Miró et al. 2016). Immune activation at very early age (10–16 days of age) resulted in much lighter pigs at 28 days of age (Fangman et al. 1998; Schinckel et al. 1995). Pigs receiving high levels of antigens had decreased weight gain, feed efficiency through 107 days of age, and took 5.6 more days to reach 230 lb and 3.6 days to reach market weight of 264 lb (Schinckel et al. 1995). This likely involves an effect of immune cytokines on IGF-1 production. Activated Th, CTL, and thymic cells, like thymic epithelial cells, can produce hormones like GH, PRL, ACTH, and TSH. A thymic hormone, thymulin, can have a direct effect on the pituitary to release endocrine hormones (Borghetti et al. 2009).

One of the most important areas in immune development affected by stress is Th1/Th2 balance. In most cases, a balanced Th1/Th2 response means that both a cell-mediated response (Th1) and a humoral response (Th2) will be produced. Skewing it in one direction or the other may be inappropriate for certain pathogens. Typically, extracellular organisms require a Th2 response, while intracellular organisms require a Th1 response, for eliminating the pathogen. Mixing, cold stress, heat stress, crowding, restraint, and weaning age all affect the Th1/Th2 balance (Salak-Johnson and McGlone 2007).

Weaning is a stressful event for the young pig. Research indicates that weaning before 3 weeks results in long-term negative effects on the immune system and mucosal development (Davis et al. 2006; Hameister et al. 2010; Moeser et al. 2007; Niekamp et al. 2007; Smith et al. 2010). Weaning at 2, 3, or 4 but not 5 weeks of age decreased the *in vivo* and *in vitro* response of porcine lymphocytes to undergo clonal expansion to initiate an immune response (Blecha et al. 1983). These same parameters were suppressed in artificially reared neonatal piglets compared with their sow-reared littermates (Blecha et al. 1986; Hennessy et al. 1987). Early weaning of pigs at 3 weeks of age suppressed the ability of mesenteric lymph node cells to produce IL-2 (Bailey et al. 1992). Immunizations 24 hours after weaning at 5 weeks of age decreased the antibody response, while vaccinating 2 weeks prior to weaning did not decrease the antibody response (Blecha and Kelley 1981). Early weaning results in prolonged increase in corticotropin-releasing factor (CRF) as well as increases in mast cells, which results in intestinal mucosal dysfunction (Moeser et al. 2007; Smith et al. 2010). However, successful vaccination strategies at the time of weaning are anecdotally but frequently reported in the field. Recent work in 10-week-old grower pigs indicated that chronic social stress from mixing pigs and increasing density resulted in decreased growth, impairment of the epithelial barrier, and immunosuppression (Li et al. 2017).

An area of increased interest is the effect of stress on the pregnant sow and its subsequent effects on the immune system of the developing piglet (Bate and Hacker 1985; Bellinger et al. 2008; Tuchscherer et al. 2002). Cold stress 2 days prior to parturition resulted in increased serum IgG in the piglet but decreased the ability of the piglet to produce IgG. Heat stress in the last 2 weeks of gestation resulted in decreased serum IgG through 21 days of age (Machado-Neto et al. 1987). Restraint stress (5 minutes a day for 35 days prior to farrowing) resulted in decreased IgG serum levels in the 1- and 3-day-old pigs; the thymus was smaller in 1- and 35-day-old pigs. In an assessment, a variety of T- and B-cell proliferation responses, along with NK killing activity, were lower at 35 days of age in pigs from the stressed sows (Tuchscherer et al. 2002). Another report indicated that tethering (continuous restraint) of sows suppressed antibody synthesis, which reduced the amount of antibodies that were transmitted through the colostrum into the blood of the piglets (Kelley 1985).

Social stress (mixing gilts together twice a week for 4 weeks) resulted in significant decrease in the total numbers of white blood cells, lymphocytes, and granulocytes from 26 days of age to study termination at 60 days of age (Couret et al. 2009). It also decreased the CD4+/CD8+ T-cell ratio on day 4. Endotoxin induced TNF-α production on day 60 and increased the mitogen-induced lymphocyte proliferation on D4 and D60. Another social stress study in sows with a similar design demonstrated that there was an increase in pituitary and hypothalamus neurotransmitters of the piglets both at 28 days of age (weaning) and at 60 days of age following a relocation stressor (Otten et al. 2010). Although this study did not directly show an effect on the immune system, changes to neurotransmitters can influence the immune system both directly and indirectly (Figure 16.12).

Immune dysfunction and infectious agents

Many infectious agents are capable of inducing immune dysfunction, particularly of the innate response, making the animal more susceptible to secondary infections and/or enhancing immunopathology. For example, infection with *Mycoplasma hyopneumoniae, Actinobacillus*

pleuropneumoniae, virulent or vaccine strains of hog cholera virus, PRRSV, or PRV increases the severity of *Pasteurella multocida*-associated pneumonia (Fuentes and Pijoan 1986, 1987; Pijoan and Ochoa 1978; Smith et al. 1973). The functions of neutrophils, another innate cell, are compromised following bacterial infection with *M. hyopneumoniae, Salmonella typhimurium*, or *Salmonella choleraesuis* (Roof et al. 1992a,b). Excessive NET formation also results in collateral damage (Bardoel et al. 2014; Döhrmann et al. 2016; Porto and Stein 2016). Porcine epidemic diarrhea virus (PEDV) inhibits IFN (Ding et al. 2014), while PRRSV effect on IFN varies with PRRSV strain (Overend et al. 2017). A number of swine pathogens impair or kill tissue macrophages (often alveolar macrophages) and monocytes including *A. pleuropneumoniae* (Dom et al. 1992; Tarigan et al. 1994), PRV (Chinsakchai and Molitor 1992; Iglesias et al. 1989a,b, 1992), influenza A virus(IAV) (Kim et al. 2009), PRRSV (Bautista et al. 1993; Charley 1983), and PCV2 (Chang et al. 2006). PRV and PRRSV infection also inhibit IFN-α (Brukman and Enquist 2006; Lunney et al. 2016). CD163 genetically modified pigs or alveolar macrophages are resistant to PRRSV infections (Burkard et al. 2017; Whitworth et al. 2016). IAV increases production of proinflammatory cytokines in macrophages, resulting in a "cytokine storm" and causing severe immunopathology (Janke 2014; Tisoncik et al. 2012). IAV also reduces NK cells in the lung (Forberg et al. 2014). Porcine parvovirus replicates in alveolar macrophages, as well as lymphocytes and impaired macrophage phagocytosis and lymphocyte proliferation (Harding and Molitor 1988).

PRRSV and PCV2 both modulate the immune response at many levels as discussed elsewhere in this book. However, it is important to recognize that much of the impact of PRRSV and PCV2 on the swine industry is due to their ability to modulate or alter the ability of the immune system to control other pathogens (Loving et al. 2015; Lunney et al. 2016). This applies not only to PRRSV infections but also to modified live vaccines (MLVs), thus reducing vaccine efficacy (Wang et al. 2016). *M. hyopneumoniae* coinfection increases PCV2 Th1 and Treg responses that were correlated with increases in PCV2 antigen and lung lesions (Zhang et al. 2011).

Nutritional influences on immunity

Immune system functions require energy, protein, vitamins, and trace minerals. Both malnutrition and overfeeding may result in impairment of immune function and increased susceptibility to disease. Swine in modern production typically have a completely controlled diet. Key vitamins and minerals for optimal immune function include vitamins A, C, E, and B complex and copper (Cu), zinc (Zn), magnesium (Mg), manganese (Mn), iron (Fe), and selenium (Se). The balance of these constituents is especially important since an excess or deficiency in one component may influence the availability or requirement for another (Wintergerst et al. 2007).

Zinc metabolism is greatly influenced by the acute-phase reaction (APR) following infection (Borghetti et al. 2009). Zn is an essential cofactor for the thymic hormone thymulin and T-cell development. High levels of GC and IL-1 and IL-6 result in hypozincemia due to redistribution of Zn among various tissues, particularly the liver, and the consistent loss of Zn in urine and feces. Zn deficiency associated with stress and high levels of GC causes a decrease in the resistance to infection and a continuous imbalance of Th1/Th2 favoring Th2 bias. Zn deficiency also decreased recruitment of naive T cells, NK cell activity, and the precursors of CTL and hypoplasia of lymphoid organs, including lymph nodes, thymus, spleen, and PP (Borghetti et al. 2009).

There are very little research data to predict the optimal diet for immune function for swine. The dietary requirements for optimal immune function may differ from the requirements to avoid deficiencies as judged by traditional methods. In addition, stress or the demands of rapid growth may change dietary requirements for optimal immune function.

Vaccines and immunity

General principles regarding vaccine efficacy and vaccine failure are found here. Information regarding protective immunity and vaccination for specific diseases are found in respective chapters of this book.

Developing a vaccination program

A swine vaccination program should first start with assessment of the disease risks in a particular herd. The common "blanket vaccination" programs suggested for many pathogens are not appropriate for all herds. A careful review of endemic disease agents and risks of external introduction of agents is warranted before recommending a vaccination program.

Secondly, the effect of maternal immunity and the age of the pig should be considered. The relationship is generally linear for efficacy of vaccination for active immunity. The younger the pig, the poorer the response, and the older the pig, the better the immune response. However, for protection derived from passive maternal immunity, the younger pig generally has better protection than the older pig because of the high initial levels of maternal antibody derived via colostral transfer that wane as pigs get older (Figure 16.11).

Thirdly, certain management practices such as minimizing exposure of piglets to pathogens via high hygiene, using all-in/all-out systems, and executing an effective biosecurity program can provide enhanced protection

and give an extended window before vaccination is necessary. However, in those swine management systems where continuous flow and lower biosecurity is in place, a more aggressive vaccination program may be warranted.

Herd immunity

Herd immunity is often used to describe the threshold proportion of immune individuals that should lead to a decline in incidence of infection attributable to immunity acquired via infection and/or vaccination. An implication is that the risk of infection to susceptible individuals in the herd is reduced because of the presence, proximity, and number of immune individuals present in the population. With regard to swine vaccination, one of the key factors to consider is that the level of protection conferred by most vaccines does not fully protect the herd against infection (Rose and Andraud 2017). In this case, there may be a "critical threshold," that is, the fraction of the population that should be immunized (according to the level of immunization conferred by the vaccine) to mitigate a disease outbreak. The partial protection of a herd from vaccines results from a variety of factors: the vaccine can reduce the susceptibility of pigs to the infection; it can decrease pathogen disease severity once the pig is infected, or it can accelerate the elimination of the pathogen by reducing pathogen replication or duration of shedding. Vaccine efficacy varies by pathogen and formulation. For example, PCV2 herd immunity following vaccination is generally high. In contrast, PRRSV vaccines only provide a limited protection from an epidemiological point of view and would be generally called a "leaky vaccine" (Rose and Andraud 2017).

Interval between vaccinations

Vaccination incites expansion in the populations of responding T- and B-cell clones (Figure 16.13). However, to have a complete and mature immune response, this clonal expansion must not only stop, but an active process of cell death (apoptosis) must also occur. This period allows for "culling" by apoptosis of those T or B cells that may be poor responders or err toward autoimmunity (Wagner 2007). The whole process from vaccination to achieving mature immune response homeostasis takes at least 3 weeks, at which time the response can be boosted to get a true anamnestic secondary response. In practice, swine vaccine primary and booster doses are often administered at 2-week intervals. In young pigs, occasionally this is done to provide an opportunity to assure that the pigs develop a primary response in the face of maternal immunity. The adjuvants that are used with most commercial vaccines usually provide superior immune development over older-generation adjuvants

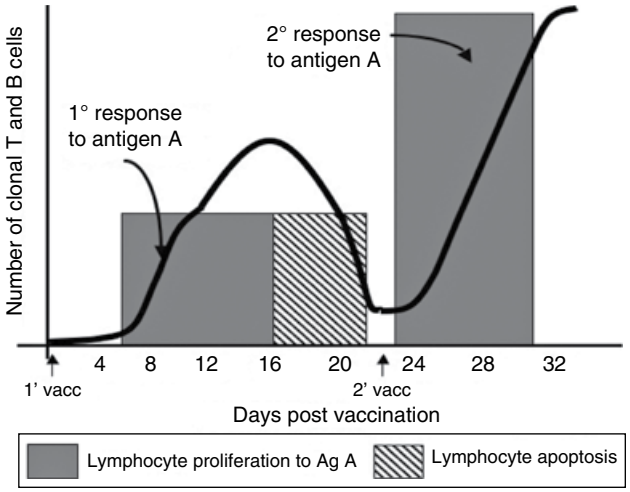

Figure 16.13 Importance of vaccine timing and the booster response. The primary response to vaccine antigen (Ag A) and the anamnestic response to secondary challenge. *Source:* Courtesy of D. Topham.

like alum (Awate et al. 2013; Wilson-Welder et al. 2009). Therefore, in most instances, if primary vaccination occurs after 3 weeks of age, booster vaccination beyond 3 weeks and even longer will be efficacious. The dogma that revaccination must occur within 2 weeks of the primary vaccination is simply not true; the anamnestic response will be better if the interval between vaccinations is longer.

Route of vaccination

Vaccination protection of the animal from infection at mucosal surfaces such as the intestinal tract, respiratory tract, mammary glands, and reproductive tract is especially difficult for the immune system. The antibodies responsible for humoral immunity and the lymphocytes responsible for cell-mediated immunity are predominantly in the bloodstream and tissues; they are typically not found on the mucosal surfaces. Therefore, while lymphocytes assist in preventing systemic invasion through the mucosal surface, they are often not very effective at controlling infection on the mucosal surface. Even in the lungs and the mammary gland where IgG and lymphocytes are found in relative abundance, they are not able to function as effectively as in the tissues. Protection on mucosal surfaces is due in large part to sIgA, CTL, and γδ T cells as discussed earlier.

The route of vaccine administration can be important when attempting to induce mucosal immunity (Wales and Davies 2017). To induce sIgA production at mucosal surfaces, it is best for the vaccine to enter the body via a mucosal surface (Zhu et al. 2017). This can be accomplished by feeding the vaccine to the animal, aerosolizing the vaccine so the animal will inhale it, or

by intramammary exposure. If a sow is exposed to an infectious agent in her intestinal tract, the sow may respond by producing sIgA not only in the intestinal tract but also in the mammary gland (Figure 16.7). The sow passes the IgA against the infectious agent to the piglet via milk when it suckles, thus protecting the piglet from infectious agents present in the sow's intestine. This protection will only last as long as the piglet continues to suckle. Enteric infections by many organisms are not controlled by the presence of IgG and IgM in the bloodstream or by a systemic cell-mediated immune response. If an MLV is given by injection, but goes to a mucosal surface to replicate, it may also induce a sIgA response. In addition, killed vaccines with newer adjuvant formulations have proven to stimulate mucosal IgA and CTL cell response for the respiratory pathogens *M. hyopneumoniae* and IAV (Kitikoon et al. 2006; Marchioro et al. 2013).

Adjuvants and nanoparticles

Adjuvants provide several opportunities to improve vaccine performance (Awate et al. 2013; Wilson-Welder et al. 2009). They are used with inactivated vaccines to enhance innate immune response and antigen presentation. They can be immunostimulants that can direct the immune response to either Th1 or Th2 responses. Adjuvanted parenteral vaccines are often used to overcome preexisting immunity (maternal or active immunity) (Awate et al. 2013; Morein et al. 2002). There are more adjuvants available for veterinary use than human use, with the most commonly used adjuvants in swine being alums, oil in water, and Carbopol (Table 16.3).

Adjuvants are sometimes used to enhance the immature immune system, to stimulate a Th1 response for balance of the skewed Th2 response in young pigs, or for immunosuppressive pathogens like PRRSV (Awate et al. 2013; Charerntantanakul 2009). Two experimental vaccine systems have demonstrated the ability to break the Th2 bias in very young pigs. Small DNA sequences called oligodeoxynucleotides (ODN) containing one or more unmethylated CpG motif (CpG ODN) are potent stimulators of Th1 immune responses when used as vaccine adjuvants. One-day-old piglets vaccinated with attenuated PRV with an adjuvant system containing CpG ODN induced significant cellular proliferation and IFN-γ production in response to vaccine antigen within the first week after vaccination (Linghua et al. 2007). This vaccine also induced significant antibody titers. An even better Th1 immune response was obtained by adding a plasmid expressing the proinflammatory Th1-inducing porcine IL-6 to CpG ODN adjuvanted PRV vaccine (Linghua et al. 2006).

Nanoparticles (NP) are biodegradable polymers that contain encapsulated antigens (Dhakal et al. 2017). The NP protects the antigen from degradation under physiological conditions, which is critical when vaccine is delivered to mucosal sites as they are protected from proteolytic degradation and are readily taken up by immune cells at the mucosal sites of the respiratory tract. NP intranasal PRRSV and IAV vaccines protect pigs from clinical disease (Binjawadagi et al. 2014; Dhakal et al. 2017). NP have the benefit of slow release of the antigen for a long period of time (4–8 weeks) when administered by parenteral route that helps in prolonged immune activation (Dhakal et al. 2017).

Use of autogenous vaccines and "planned exposure"

Autogenous vaccines are composed of agents or antigens that are derived organisms present in the individual herd in which they are to be used. The use of autogenous vaccines for a variety of bacterial and viral agents is a common practice in swine production (Chase 2004; Geldhof et al. 2013). The greatest value of autogenous

[a] Many livestock adjuvant–vaccine formulations are proprietary, and their compositions have not been disclosed.

vaccine is when diagnostic or molecular techniques are able to detect immunologically applicable differences in the field strains from those strains in commercial vaccines. The science-based application of autogenous vaccines is important for prevention of certain diseases; any cost savings from using autogenous vaccines should not be the major factor in selecting an autogenous vaccine over a commercial vaccine.

Infectious agents do not uniformly infect all animals simultaneously. The intention of a planned or controlled exposure procedure is to expose all animals in a population to a live infectious agent derived from the herd while minimizing the impact of any associated disease. From the immunology perspective, this practice is simply letting an infection (rather than vaccine) generate an immune response. An example is the management practice of using serum containing live PRRSV to infect certain populations of pigs, such as gilts prior to their introduction into the breeding herd. This is done to achieve uniform exposure and immunity against PRRSV. This practice is not without risks. Careful consideration of benefits and risks is warranted before executing controlled exposure programs.

Vaccination failure

There are many reasons why animals may develop disease even though they have been vaccinated (Roth 1999). The major reasons for these failures include (1) vaccine administered in the face of maternal immunity, (2) vaccine administered after natural infection has occurred, (3) improper handling of vaccines and/or administration equipment, (4) improper timing of vaccination and/or age when administered, (5) poor cross-protection against heterologous pathogens, and (6) immune dysfunction or compromise at the time of vaccination.

One of the major challenges in developing an active immune response in young pigs has been interference from maternal immunity (Hodgins et al. 2004; Ma and Richt 2010; Opriessnig et al. 2008; Rose and Andraud 2017). The timing of many vaccines administrated by the parenteral route involves estimating when the level of maternal antibody is low enough for an active immune response to progress sufficiently to provide vaccine immunity (Hodgins et al. 2004; Opriessnig et al. 2008). Maternal antibody half-life in pigs ranges from 11.3 to 20 days compared with bovine half-life of 16–28 days (Fulton et al. 2004). Specific examples for half-life for swine maternal antibodies include 16.2 days for PRRSV (Yoon et al. 1995), 14 days for AIV (Fleck and Behrens 2002), 19 days for PCV2 (Opriessnig et al. 2004), 11.3 days for PRV (Mueller et al. 2005), 11 days for classical swine fever virus (Mueller et al. 2005), 20 days for parvovirus (Paul et al. 1982), and 15.8 days for *M. hyopneumoniae* (Morris et al. 1994).

The optimal window for vaccination can range from a few weeks of age to 3 months. As illustrated in Figure 16.11, this can vary by animal and depends on the level of maternal antibody and the particular vaccine antigen. Maternal interference can present a major obstacle for achieving an adequate vaccine response. Antibody levels often decay to a level still high enough to block responses to vaccine, but not high enough to resist a field infection, which creates a window of opportunity for infecting organisms.

The pig requires several days after vaccination before an effective immune response will develop. If infection occurs prior to or near the time of vaccination, the vaccine may not have time to induce immunity (Rose and Andraud 2017); hence the animal may develop clinical disease. Disease that occurs shortly after vaccination may easily be misinterpreted as vaccine failure or even falsely attributed to the vaccine itself. Some MLVs consisting of attenuated organisms may be capable of producing disease in immunosuppressed animals. Improperly handled and administered vaccines may fail to induce the expected immune response in normal healthy animals.

Modified live bacterial and viral vaccines are only effective if the agent in the vaccine is viable and able to replicate in the vaccinated animal. Observing proper storage conditions and proper methods of administration are very important for maintaining vaccine viability. Failure to store the vaccine at refrigerator temperatures or exposure to light may inactivate the vaccine. Even when stored under appropriate conditions, many vaccines lose viability over time. Therefore, vaccines that are past their expiration date should not be used. The use of chemical disinfectants on syringes and needles can inactivate MLVs if there is any residual disinfectant.

The use of an improper diluent or the mixing of vaccines in a single syringe may also inactivate MLVs. Diluents for lyophilized vaccines are formulated specifically for each vaccine. A diluent that is appropriate for one vaccine may inactivate a different vaccine. Some vaccines and diluents contain preservatives that may inactivate other MLVs. For these reasons, and many others, different vaccines should not be mixed and given as a single dose.

The timing of the vaccination is important. Vaccination of young animals may be ineffective due to age of the animal and/or because of the presence of maternal antibody. However, if the vaccine is administered after all maternal antibodies are gone, there may be a period of vulnerability to infection before they develop their own immune response. Although considered impractical to vaccinate young pigs frequently because of economic and logistical constraints, frequent vaccination may be justified in cases of unusually high disease incidence or pressure.

Immune dysfunction or decreased immunocompetence can be due to a variety of factors including stress, malnutrition, and concurrent infections; immaturity or senescence of the immune system may also lead to vaccination failure. If the immune dysfunction occurs at the time of vaccination, the vaccine may fail to induce an adequate immune response. If the immune dysfunction occurs some time after vaccination, then disease may occur due to reduced immunity in spite of an adequate response to the original vaccine. Therapy with immunosuppressive drugs, for example, GC, may also cause this to occur.

Acknowledgments

The authors have adapted their chapter from that written for the 9th (Roth and Thacker 2006) and 10th editions.

Integumentary System

Skin, Hoof, and Claw

Jerry Torrison and Ranald Cameron

Structure and function of skin

The skin acts as a barrier to provide protection of the interior environment from exterior environment. The skin and its cellular or adnexal adaptations provide both specialized structures (hoof, claw, secretory glands, specialized cells) and functions (e.g. temperature regulation, electrolyte balance, vitamin D production, immunoregulation, antimicrobial actions, secretions, excretions, and sensory perceptions). The skin is the site of microbial flora, with the ecology influenced by pH, salinity, moisture, and albumin and fatty acid levels. There is an ongoing competitive balance between normal nonpathogenic resident flora and (potential) pathogens. The skin is the largest body organ in the pig. Skin represents between 10 and 12% of body weight at birth and around 7% in adult animals, although in some breeds such as the Meishan, skin can be 10–12% of adult body weight.

The histologic structure is similar to that of other domestic animals and, compared with other species, has many more similarities to human skin. There are two primary layers of the skin, the epidermis and dermis. The epidermis is relatively thick, the major cells being the keratinocytes in the stratum basale, the polyhedral cells in the stratum spinosum, the flattened cells in the stratum granulosum, and the cornified cells in the stratum corneum; the stratum lucidum is absent except in the snout. The thickness of the epidermis varies considerably in different areas of the body (Meyer et al. 1978), with the skin of the cranial and dorsal regions generally thicker and hairier than the skin of the ventral and caudal regions. Maximum thickness is between the toes and on lips, snout, and the shield uniquely found on the scapular and costal region in older boars. The thinnest layers are in the axilla, eyelids, and ventral areas of the thorax and abdomen (Marcarian and Calhoun 1966).

The dermis consists of two ill-defined layers overlying a prominent layer of adipose tissue (hypodermis). The two layers of the dermis, stratum papillare and stratum reticulare, are composed of connective tissue containing blood vessels, nerves, lymphatics, and associated epidermal appendages. Cells found in the dermis include fibroblasts, melanocytes, and mast cells. The origins of hair follicles and sweat glands are in the hypodermis.

The holocrine sebaceous glands of the pig are branched alveolar and open into the neck of the main hair follicle. The coiled, tubular apocrine sweat glands are present in all areas except the snout, but there are relatively few (about 25/cm^2) compared with other species. The short, stout hair follicles possess *arrectores pilorum* muscles attached to the outer root sheath. The bristles occur either singly or in groups of two or three. The hair coat consists of 60–70% bristles and 30–40% fine downy hair. Specialized forms of hair are the tactile hairs in the region of the snout (Marcarian and Calhoun 1966; Mowafy and Cassens 1975). Specialized seromucoid glands are in the carpal glands located behind the carpus and in the mental (mandibular) organ located in the intermandibular space.

Examination and diagnosis of skin

Skin diseases either only involve skin or can be cutaneous manifestations of internal disease. Examples of diseases restricted to the skin are ear necrosis, pityriasis rosea, and swinepox, whereas skin lesions symptomatic of a more general pathophysiological condition are erysipelas, classical swine fever (CSF), and dermatitis/nephropathy syndrome. It is essential to gather an accurate history and perform a thorough clinical examination of the population and affected individuals to get an accurate individual or herd diagnosis. Characterization of the lesions (i.e. specific types, distribution, and progression) is essential in formulating the differential diagnosis. Collection and preservation of appropriate samples for laboratory testing often is warranted to confirm the primary diagnosis.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

History

On-farm examinations with due consideration of available verbal and recorded history provides valuable insight. The type of husbandry or housing system influences disease expression: extensive or free-range systems may predispose to environmental hazards, whereas intensive indoor housing may predispose to conditions such as pressure sores in sows, ear necrosis in pigs, or certain bacterial disease. Evaluation of environmental conditions regarding hygiene, variation in ambient temperatures or relative humidity, and high stocking density provides clues to risk factors for outbreaks of bacterial infections. A seasonal pattern may be evident for some skin lesions such as insect bites. Signs and sources of trauma, including self-inflicted trauma due to pruritus associated with sarcoptic mange or lice infestation, are useful clues. Recent movement of pigs, commingling of ages or groups, and introduction of new stock are risk factors because mixing of pigs results in fighting, which provides sites for bacterial infection, as well as may introduce or expose pigs to new or different infectious agents.

Evaluation of nutrition and diet may be helpful, as deficiencies of the B vitamins, zinc, or essential fatty acids can result in dry, scaly, dandruff-like dermatitis or parakeratosis. Predilection to particular breed, genotype, or lineage may indicate a congenital or hereditary condition such as pityriasis rosea, dermatosis vegetans, or epitheliogenesis imperfecta.

Some diseases are more frequent in certain ages or age groups. For example, exudative epidermitis rarely affects pigs older than 6 weeks of age, pityriasis rosea is most common in pigs between 2 and 10 weeks of age, and teat necrosis usually occurs within 24 hours after birth, but nutritional deficiencies are unlikely to occur before weaning.

The onset, duration, and location of lesions that define the disease progression or clinical evolution are important to note. Poxviruses and some vesicular lesions follow the progression of macules to vesicles that rupture and form pustules and dark circumscribed crusts before healing. Exudative epidermitis often commences as macules and pustules around the eyes before spreading over the entire body of piglets.

Clinical examination

A thorough clinical examination at the herd, pen, and individual animal level (see Chapter 1) is necessary to determine overall character and impact of the disease on individuals and the population. Proper examination of the skin lesions requires proper restraint with careful examination and a thorough description of character and variation of skin lesions present. Although the skin lesions may be visible and obvious, other clinical signs such as anorexia, depression, loss of body condition, reluctance to move, or diarrhea may indicate that the skin lesions are the result of an internal disease. It is important to determine whether the skin disease is a symptom of an internal disease (e.g. erysipelas, salmonellosis, CSF) or is a primary skin insult (e.g. vesicular diseases, poxvirus, trauma, bacterial or mycotic infections). Many septicemias or toxemias can cause erythema or cyanosis characterized by red to purple discoloration, especially on the extremities, which are easy to see in the white breeds. The number of animals affected over time may suggest a contagious nature, and the presence of mortalities may suggest an infectious disease. Diseases such as exudative epidermitis or erysipelas tend to spread more rapidly, whereas congenital and hereditary conditions such as pityriasis rosea usually occur at a constant rate within a herd. A critical appraisal of the response to therapy can aid in differentiating viral, bacterial, and fungal infections. Pityriasis rosea does not respond to any treatment, whereas parakeratosis responds dramatically to the addition of zinc and essential fatty acids to the diet, and erysipelas responds quite predictably to injected antimicrobials.

Primary lesions

Skin lesions are either primary, the direct result of the disease insult type, or secondary as result of evolutionary changes to the skin dictated by factors such as the cause of the disease, secondary infection, self-trauma, and chronicity. It is important to differentiate between primary lesions and secondary lesions because often the first animals presented with most dramatic lesions may only have secondary lesions present. Examination of the entire body of several animals may be necessary to locate primary lesions of acute cases. Familiarity with terms to describe skin is useful, particularly when visual images are not available.

Macules are defined as circumscribed flat discolorations less than 1 cm in diameter, and papules – more solid, raised areas of skin of varying color – are seen in the early stages of exudative epidermitis, erysipelas, and swinepox. Plaques are elevated superficial lesions more than 0.5 cm in diameter, scattered over the whole body surface of young growing pigs, and have been associated with erysipelas and pityriasis rosea.

Vesicles are well-demarcated, dome-shaped lesions (<1 cm) usually containing serum or inflammatory exudates. They are pale or translucent and are characteristic of a number of the viral skin diseases in swine, such as swinepox, foot-and-mouth disease, and a potpourri of swine vesicular diseases, including recently emerging *Senecavirus A* (SVA) (Segales et al. 2016) and likely infrequent porcine parvovirus infection (Kresse et al. 1985).

Pustules are elevated lesions filled with inflammatory cells (leukocytes) and can be follicular or epidermal.

They are white, yellow, or red (hemorrhagic) and often surrounded by erythema. Pustules in swine are commonly associated with streptococcal infections, exudative epidermitis, and later stages of SVA or swinepox.

Wheals are circumscribed, raised, round or oval areas of the skin due to edema in the dermis. They may be blanched or slightly erythematous. Fly and mosquito bites frequently cause wheals. Urticaria, seen as multiple pink to purple raised areas of the skin, commonly occurs in cases of erysipelas, beta-hemolytic streptococcal infections, food allergy, or insect bites.

Secondary lesions

Blue to black skin discoloration with necrosis can indicate gangrenous dermatitis, cellulitis, or myositis. Necrosis of the ears and tail of piglets is also often black. Skin pallor is often an indication of anemia, with iron deficiency or blood loss anemia still all too common. Skin icterus (jaundice) is a yellowish discoloration due to increased red cell breakdown or liver compromise occurring with hepatic disease or diseases causing extravascular hemolysis.

Hemorrhage is often blotchy red to purple to black, depending on location and extent from extravasation of blood from dermal blood vessels as seen with contusions, bruises, or thrombocytopenic purpura.

Scales are flakes of keratinized epidermis indicating chronic inflammation or irritation. They may be due to nutritional (e.g. parakeratosis) or hormonal dysfunction or caused by ectoparasites, such as *Sarcoptes scabiei*, or by bacterial skin diseases. They occur on the thinner skin of piglets with exudative epidermitis, on the inner side of the margin of the ringlike lesions of pityriasis rosea, and on the outer periphery of ringworm lesions. They also may be mixed with sebum and sweat, giving a greasy or oily appearance known as seborrhea.

Crusts are a very common secondary skin lesion of swine and are due to a combination of serum, sebum, blood, and cutaneous debris adhering above the normal skin surface. They are seen following bacterial infections and viral vesicular diseases, especially swinepox, and as a result of pruritus associated with sarcoptic mange or lice infestation.

Hyperkeratosis, an increased thickening of the stratum corneum, develops with nutritionally related metabolic disorders such as vitamin A, zinc, and fatty acid deficiencies or with local callus formation due to trauma associated with pressure and friction. Erythema and intense pruritus with hyperkeratosis and acanthosis have been associated with in-feed tiamulin (macrolide) therapy (Laperle et al. 1988).

Erosions involve the epidermis only and are localized loss of partial thickness of epidermis that occurs with trauma, irritants, sunburn, or mild exudative epidermis. Ulcers are localized full thickness loss of epidermis from loss of vitality of epidermis, with necrosis and sloughing, and are seen with trauma or pressure (decubital ulcers) or certain deep bacterial infections (*Staphylococcus* spp., *Streptococcus* spp., *Fusobacterium necrophorum*, and the spirochete *Treponema pedis*).

Edema of the skin can indicate a systemic disease, for example, hypoproteinemia, vasculitis, and increased vascular permeability such as in malignant edema caused by *Clostridium septicum* and in edema disease associated with *Escherichia coli*.

Pruritus results in scratching that occurs with a variety of conditions, most notably sarcoptic mange or lice infestation. The presence of sarcoptic mange in ears can manifest as shaking of the head and can result in aural hematomas. Aural hematoma is the acute distension of the ear with blood, usually the result of trauma from fighting or head shaking. Ear hematomas are more common in breeds with longer ears. Intervention beyond segregation usually is not warranted since draining or lancing the hematoma usually results in continued hemorrhage or infection.

Alopecia and excoriation may also be an indicator of intense scratching seen in chronic sarcoptic mange. Severe scratching will result in alopecia, commonly seen over the shoulders and hindquarters in pigs with sarcoptic mange or lice and in pigs irritated by insects such as flies and mosquitoes.

Thorough lesion characterization should allow the clinician to formulate a differential diagnosis. Laboratory tests may be warranted to confirm a diagnosis (skin scraping, culture, or biopsy) in order to decrease uncertainty or increase confidence of an accurate diagnosis. Obtaining an accurate diagnosis aids in development of effective interventions, treatments, and prevention strategies and likely will save time and money in the longer run (Table 17.1).

Diagnostic tests

Frequently used tests to confirm a diagnosis of skin disease in swine include skin biopsy for histopathological examination, direct smears or scrapes for PCR or isolation for detection and identification of bacteria, viruses, and fungi, and euthanasia and necropsy to submit tissues sufficient to address all differentials. Antimicrobial sensitivity testing is sometimes appropriate and requires isolation of the organism; PCR detection does not provide that information unless resistance genes are targeted or sequencing is performed.

Skin biopsy and direct examination

Skin biopsy is appropriate for most lesions, including suspected neoplasm, persistent ulceration, and lesions not responding to treatment. Fully developed primary lesions or early vesicles and pustules are best for biopsy, whereas biopsy of chronic or secondary, lesions from

Table 17.1 Differential diagnosis of skin lesions by location.

Location	Lesions and signs	Diseases
Head and neck	Macules, pustules, greasy exudate (seborrhea), crusts; in suckling pigs and weaners	Exudative epidermitis (*S. hyicus*)
	Pustules, crusts, and abscesses	Streptococcosis
	Plaques, pustules, crusts, alopecia with pruritus; ear pinnae common	Sarcoptic mange
	Pustules, erosions, necrosis, crusts below the eye, cheek, and lips in suckling piglets	Facial necrosis
	Edema: palpebral, forehead; in weaners and young growers	Edema disease (*E. coli*)
	Edema of the head and throat; injection site necrosis	Malignant edema (*Clostridium* sp.)
	Vesicles, pustules, erosions on the snout, lips, mouth, and tongue	Vesicular diseases; *Senecavirus A*; other viruses; idiopathic
	Multifocal vesicles, erosions, "spots" of black crusts	Swinepox; poxviruses
Ears	Black necrosis, ulcers on the tips and posterior edge of the pinna in piglets	Ear necrosis, salmonellosis, erysipelas; idiopathic
	Deep ulcers at the base of the pinna in growers; often bilateral	Ulcerative spirochetosis; trauma
	Erythema, red to purple blotchy discoloration	Systemic bacteria and viruses; sunburn; photosensitization
	Plaques, brown or gray crusts on the inner ear, ear shaking, pruritus	Sarcoptic mange
	Macules, pustules, and black crusts	Exudative epidermitis, streptococcosis
	Circular macules, patches, small scales, pink to red discoloration	Ringworm (microsporosis)
Dorsum and shoulder	Hyperkeratosis, dry scales along spine, some alopecia	Parakeratosis (Zn); fatty acids; vitamin A, C, or E; mange
	Complete absence of epithelium (large red shiny areas) in newborn piglets	Epitheliogenesis imperfecta
	Pressure necrosis or deep ulcer or crust over spine of scapula, last ribs, and lumbar area in sows	Pressure necrosis from trauma; recumbent sows in poor body condition; confinement
	Large deep discrete ulcer, necrosis, and crust over spine of scapula in sows often in poor body condition	Pressure sore from poor condition, due to confinement on solid or mesh floors; low energy intake
Ventral abdomen	Erythema, pustules, dark brown crusts, exudate	Exudative epidermitis, streptococcosis, sarcoptic mange, candidiasis, biotin deficiency,
	Erythema, round to diamond-shaped red plaques, fever, anorexia, arthritis	Erysipelas, *Actinobacillus suis*
	Papules; ringlike lesions; collarettes, flakes and scales (3- to 14-week-old pigs)	Pityriasis rosea
	Circular pink to red macules, scales, or crusts around periphery	Ringworm (microsporosis, trichophytosis)
	Papules, thick crusts, fissures, exudate	Zinc deficiency (parakeratosis), dermatosis vegetans, exudative epidermitis
	Vesicles, pustules, black scabs, round raised areas with depressed centers	Swinepox; poxviruses
	Necrosis (red or black scabs) of teats, especially pectoral teats in piglets	Trauma and bacterial infection due to rough floors

Table 17.1 (Continued)

Location	Lesions and signs	Diseases
Lateral abdomen and flank	Erythema, round to diamond-shaped red plaques, fever, anorexia, arthritis	Erysipelas, *A. suis*, flank biting – vice
	Pustules, scales, thick wrinkled skin, alopecia	Sarcoptic mange
	Erythema, erosion, or ulcer on flank; poor hair coat	Niacin, pantothenic acid, riboflavin, fatty acid, or vitamin A deficiency
	Circular pink to red macules varying in size, scales or crusts around periphery	Ringworm (microsporosis, trichophytosis)
Hindquarters	Erythema of the scrotum, vulva, and perineum	Septicemia, sunburn
	Tail necrosis, ulceration, abscesses (growers)	Tail biting; tail necrosis (piglets)
	Erythema, expanding and coalescing purple spots, perineal area, and flanks	Porcine dermatitis and nephropathy syndrome (PDNS)
	Small round raised wheals, urticarial reaction	Insect bites: flies, mosquitoes, fleas
Legs (limbs)	Erythema, red to purple discoloration	Septicemia
	Plaques seen as ringlike lesions, collarettes	Pityriasis rosea
	Papules, thick crusts, fissures, papillomas	Parakeratosis (Zn def), exudative epidermitis
	Complete absence of epithelium in newborn piglets	Epitheliogenesis imperfecta
	Thick fibrotic areas over joints (hocks, elbows)	Callosities, bursitis, adventitious bursa
	Necrosis of carpus and hocks in suckling piglets	Trauma due to rough farrowing crate floors
Distal limb, coronary band, feet	Vesicles, pustules, erosions around the coronary band and accessory digits, with lameness	Vesicular diseases; *Senecavirus A*; other viruses; idiopathic
	Thick, dry crusts, deep fissures	Parakeratosis, mange, exudative epidermitis, dermatosis vegetans
	Abscesses, discharges, swelling of the coronary band	Bush foot, ascending infections of hoof
	Hoof lesions	Biotin, mineral and vitamin deficiency, trauma
	Thickening, ridges and furrows parallel to coronary band	Dermatosis vegetans

previously medicated animals may be of little value. Proper restraint and local anesthetic aid in collection. Immerse the portion of the biopsy for histopathology immediately in a fixative such as 10% neutral phosphate-buffered formalin.

The technique usually involves removal of 6–9 mm of skin using a biopsy punch or with surgical excision of a wedge biopsy, which may be more suitable for larger lesions, vesicles, and pustules and where the skin is very thick. It is important to include the transition zone representing affected and normal skin in submitted biopsies; multiple samples may be appropriate.

Skin biopsies that are chilled and not fixed can be used for isolation or PCR for detection and characterization of bacteria, fungal agents, or viruses. For microbial isolation, the skin should be cleaned with water or saline only and not with alcohol. Samples should be stored and transported at 4 °C in appropriate transport medium.

Direct examination of smears from a biopsy or skin scraping is common for identification of bacteria, parasites, or fungi. For bacteria, smear samples of pus or exudate from pustules, macules, or ulcers on glass slides, air-dried, and stained with methylene blue, Gram stain, or Diff-Quik for light microscopy. Skin scrapings or direct touch impressions can be used for suspected fungal diseases, which are best collected after removing fat from the skin with alcohol. Scrapings are warmed in a 20% solution of sodium hydroxide, and spores appear as round highly refractile bodies in chains or mosaics in hair follicles, in epithelial scales, and on the surface of hair fibers. Skin scraping is useful for identification of mange (see section on "Parasitic Diseases").

Culture and PCR

PCR is often preferred to confirm the presence of specific pathogens because of the high sensitivity and specificity. However, interpretation of PCR results should be in context of clinical signs, lesion type, and particular agent since endemic agents or potential pathogens are readily detected irrespective of whether they have a role in disease present.

Cultures of open sores (erosions, ulcers, and sinuses) generate confusion because lesions often contain mixed environmental flora that can be difficult to interpret.

Best results are obtained by aspirating samples from intact pustules, vesicles, or abscesses with a needle and syringe.

Clearly communicate history, clinical signs, sample identification/location, and testing expectations with the reference laboratory as approaches to testing often depend greatly on the differential diagnosis.

Bacterial diseases of skin

See the respective chapters for details of various bacterial diseases. A few comments specific to skin diseases caused by bacteria are discussed here.

Exudative epidermitis (greasy pig disease, impetigo contagiosa, seborrhea contagiosa)

Exudative epidermitis occurs with those strains of *Staphylococcus hyicus* that produce a heat-labile exfoliative toxin (Andresen et al. 1993). Lesions can occur at any age, but severe disease in individuals or outbreaks generally occur in pigs less than 8 weeks of age, with suckling piglets the most commonly and severely affected age group. The morbidity varies considerably, up to 80% in some groups. The disease can occur sporadically in older swine as well. Disease may be acute, subacute, or chronic. Lesions most frequently occur around the eyes, nose, lips, and gums and behind the ears as macules increase in size to form damp and oily greasy exudates of sebum, sweat, and serum (Figure 17.1). Erythema is marked, and in some pigs the lesions become generalized, affecting nearly the entire body. Occasionally there are lesions in the kidney involving the renal pelvis and tubules (Blood and Jubb 1957). Ulcerative glossitis and stomatitis were associated with *S. hyicus* by Andrews (1979), and nervous signs (sepsis) were observed in an outbreak of exudative epidermitis by Blood and Jubb (1957), supporting occasional septicemia that can occur with this organism. The differential diagnosis includes sarcoptic mange, parakeratosis associated with zinc and other nutritional deficiencies, swinepox, pityriasis rosea, pustular dermatitis, and ringworm.

Figure 17.1 Exudative epidermitis.

Pustular dermatitis (contagious pyoderma)

Pustular dermatitis is a result of streptococcal infections that cause skin necrosis and pustular dermatitis. Transmission of pyogenic streptococci is directly from sows to newborn piglets. Disease results when organisms colonize breaches in integument, such as skin abrasions from fighting and environmental hazards or from traumatic tissue damage associated with tail docking, ear notching, castration, or clipping needle teeth. Infected wounds on any region of the body can result in cellulitis, necrosis, abscess formation, ulceration, and occasionally sepsis. Differential diagnosis includes ulcerative dermatitis, exudative epidermitis, sarcoptic mange, swinepox, and erysipelas.

Ear necrosis

Ear necrosis is a syndrome seen in pigs, usually from one to 12 weeks of age, characterized by bilateral or unilateral necrosis of any part of the ear (Figure 17.2). In young pigs, the tips of ears are commonly affected, but it can also affect the posterior edge of the pinna or base of the ear. In growers, necrosis at the base of the ears or tips of the ears can occur, with outbreaks that can have up to 80% of a pen affected and high morbidity within the group. A major consequence of ear necrosis is septic embolic that may cause infection and abscesses in lung and joints.

The etiology and pathogenesis of ear necrosis is obscure, is likely multifactorial, and may vary from outbreak to outbreak. Some lesions are the result of a mixed

Figure 17.2 Ear necrosis (spirochetosis).

infection following damage to the skin, for example, toxin-induced epidermitis from *S. hyicus* followed by the more invasive streptococci and spirochetes (see "Ulcerative Dermatitis" below), which results in necrosis and ulceration (Fraser et al. 1991; Park et al. 2013). Biting following mixing of pigs is a common predisposing factor. Ear biting can be a vice similar to flank and tail biting, leading to infections. Risk factors such as high stocking rate, high ambient temperature, or high humidity were associated with outbreaks of ear necrosis (Busch et al. 2002); the same study reported no association with porcine reproductive and respiratory syndrome virus (PRRSV) or PCV2-associated disease or with concurrent tail lesions. Self-inflicted trauma resulting from the irritation of *S. scabiei* infection in the ears can initiate the early lesions. Systemic toxemia (e.g. ergot) and frostbite are unusual causes of ear tip necrosis.

Frequently, however, infectious agents are not consistently found in outbreaks of bilateral symmetrical ear necrosis, suggesting the possibility of a vascular- or immune-mediated ischemia (Figure 17.3). Arruda et al. (2015) investigated an ear necrosis outbreak using histopathology and metagenomics techniques. Aseptically collected punch biopsies were obtained for histopathology, molecular diagnostics, and metagenomics from acutely affected, chronically affected, and unaffected ears of pigs. Histologic examination of the epidermis and dermis of acutely affected pigs revealed deep dermal inflammation with minimal changes to the epidermis and no lesions in age- and site-matched internal controls, suggesting a primary lesion of vascular damage rather than epidermal insult. Metagenomics analysis found increased *Actinobacillus* and *Haemophilus* genera in acutely affected pigs compared with unaffected controls. However, the roles for bacterial sepsis and immune complex mechanisms remain speculative.

Figure 17.3 Ear tip necrosis (idiopathic).

Ulcerative dermatitis

Ulcerative dermatitis can occur as ulcerative, necrotic, or tumor-like lesions found on the body surface. Common sites include the buccal cavity of pigs and sites of ear necrosis, facial necrosis, infected bursa, or ulcers and calluses over joints and bony prominences.

The etiology involves initial trauma of the skin, followed infection, often involving several organisms. In the more proliferative or granuloma-like lesions from ears, feet, legs, or shoulder ulcers, microscopy may demonstrate spiral-shaped organisms. *T. pedis* is implicated as having a contributing role for shoulder, flank, ear (Figure 17.2), and tail ulcers (Clegg et al. 2016; Karlsson et al. 2014; Park et al. 2013; Pringle and Fellstrom 2010). The lesions usually contain *S. hyicus* and beta-hemolytic streptococci as well, with *Trueperella pyogenes* a common secondary invader (Cameron 1984). Skin trauma or damage that results in infections can be associated with bite wounds, especially around the face and head and on the flank and tail. Infection following castration, pressure sores, and ulceration of swollen bursas and calluses can lead to spirochetosis. Gum damage following teeth clipping can result in lesions in the buccal cavity. A differential diagnosis would include foreign body abscesses, neoplasms, other infectious granulomas, and pressure necrosis.

Facial necrosis (facial pyemia)

Facial skin necrosis is a common condition in suckling pigs less than 1 week of age, characterized by bilateral necrotic ulcers usually covered by hard brown crusts that extend from the side of the face to the lower jaw area. The condition is the result of infection of wounds inflicted by piglets by "needle teeth" on each other during feeding. Although clipping of needle teeth has been widely practiced, perhaps a more important risk factor is mammary gland availability and milk flow for each pig. Facial necrosis is more common in disadvantaged weaker piglets in large litters or in litters where sows have agalactia or hypogalactia.

Facial necrosis occurs during the first few days of life. Initially lesions are striated lacerations caused by bites from other piglets, which then are infected with organisms such as *F. necrophorum*, *Streptococcus* spp., and *T. pedis*, resulting in shallow ulcerations covered with hard brown crusts. The encrustation may extend over a large area involving the lips and eyelids, making it difficult for the piglet to open its mouth or eyes. These animals have

difficulty in feeding and may starve. Facial necrosis can predispose to outbreaks of exudative epidermitis.

The condition is easily diagnosed by the nature and distribution of the lesions on the face of young piglets. Careful removal of the crusts and application of a mild disinfectant or antibiotic cream will help remove the infection as well as soften the lesions. Prevention is assuring healthy underline and milking capability of dams through proper genetic selection and feeding and by fostering piglets to minimize teat competition. The clipping of the canine and lateral incisor teeth just above the level of the gum surface during the first 24 hours of life with instruments thoroughly cleaned and disinfected between litters has been a common practice but is not considered necessary.

Specific bacterial diseases

Erysipelas, the disease caused by *Erysipelothrix rhusiopathiae*, occurs as septicemia, acute or chronic arthritis, vegetative endocarditis, skin lesions, or abortion. In acute septicemia, the skin of the extremities is erythematous or cyanotic, particularly in younger pigs. The color varies from pink to purple, typical of many systemic infections and not necessarily diagnostic of erysipelas. Skin lesions more specific for erysipelas but not consistently present in outbreaks first appear as small pink or red raised areas (papules) or larger plaques ranging from 3 to 6 cm in diameter (Figure 17.4). Many of these lesions will develop the characteristic diamond or rhomboid shape and are raised, firm, and easily palpated, with the outer area pink in color and the center becoming blue to purple (necrosis) as the disease progresses. These discrete lesions are result of arteritis characterized microscopically by small arterioles having acute suppurative infiltration and cellular thrombi (Jubb et al. 1985). In the chronic stage, skin lesions become more necrotic and appear dark, dry, and firm; the superficial skin may easily peel away from the underlying tissues, and, occasionally, sloughing of the ears, tail, or a foot can occur.

Figure 17.4 Erysipelas ("diamond skin disease").

Figure 17.5 Cyanosis – acute bacterial septicemia. (erysipelas).

Actinobacillus suis causes septicemia, pneumonia, and rapid deaths and occasionally will cause skin lesions virtually identical to those of erysipelas. Salmonellosis, most notably *Salmonella choleraesuis*, also causes septicemia and skin lesions (necrosis) or changes in skin color (cyanosis). Pigs from weaning to 4 months of age are most frequently affected, but all age groups can be affected. Skin necrosis is uncommon but can involve the ears, tail, and feet in young pigs.

Erythema, cyanosis (Figure 17.5), or other patterns of skin discolorations occur with gram-negative sepsis or systemic diseases, including those with bacterial, viral, metabolic, toxic, or parasitic involvement, which emphasizes the need for thorough clinical assessment and laboratory testing to confirm diagnosis.

Viral diseases

Swinepox (contagious impetigo, louse-borne dermatitis) is a typical poxvirus infection mainly affecting young pigs. There is little to no systemic illness, and lesions are usually confined to the ventrolateral abdomen and thorax. The lesions follow the typical pox evolution of erythematous macules becoming papules and then vesicles progressing to pustules, which rupture and form crusts. Lesions occur mainly on the side of the body, ventral abdominal wall, and inner thighs. Occasionally lesions occur on the back, face, and udder. Piglets infected *in utero* may be born with generalized pox lesions affecting any portion of the skin as well as oral cavity and esophagus (Figure 17.6). Poxviruses from other species are suspected to induce lesions in

Figure 17.6 Swinepox (congenital swinepox).

some cases but are rarely characterized since disease is generally very sporadic and self-limiting.

CSF (hog cholera) can cause diffuse erythema followed by purplish discoloration of the skin over the abdomen, snout, ears, and thighs in acute cases. Necrosis of the edges of the ears, tail, and vulva may develop, with purple blotching of the ears often present. Generalized hypotrichosis is reported in the chronic form of the disease. Congenital alopecia has been reported in piglets infected *in utero* (Carbrey et al. 1966).

The vesicular diseases include foot-and-mouth disease, swine vesicular disease, vesicular stomatitis, and vesicular exanthema, with other members of the family *Picornaviridae* such as SVA all capable of causing vesicular skin lesions in swine; all produce very similar lesions with similar distribution. Aggressive diagnostic investigation is warranted when vesicles are present, particularly when lesions are present on snout or coronary bands, as many of these diseases are reportable or under regulatory authority.

African swine fever causes general signs of fever, depression, anorexia, and incoordination similar to hog cholera, both of which can have skin changes that include cyanotic blotching and purple discoloration of the limbs, snout, abdomen, and ears. Hemorrhages may also occur on the skin of the ears and flanks. Another syndrome, porcine dermatitis and nephropathy syndrome (PDNS), is thought to be associated with viral infection(s) as discussed as follows.

Porcine dermatitis and nephropathy syndrome

PDNS is widely reported in pigs (Cameron 1995; Hélie et al. 1995; Smith et al. 1993; White and Higgins 1993) and is characterized by multifocal skin lesions, weight loss, edema of the limbs, vasculitis, and glomerulonephritis. See Chapter 22 for additional discussion of the renal component.

The causes and mechanisms by which PDNS occurs are not completely understood; however, histopathological and immunological findings suggest that the pathogenesis involves an immune complex disorder (antibody–antigen complex deposition) associated with infectious agent(s). Thibault et al. (1998) suggested that PRRSV infection might play a role in the pathogenesis of the disease because of detection of PRRSV antigens by immunochemistry in macrophages located around vessels of skin and kidney tissue examined in acute and chronic cases. However, Wellenberg et al. (2004) considered that PCV2 was more likely to be a more common agent in the development of PDNS. They reported excessively high PCV2 antibody levels in a case–control field study of PDNS and hypothesized that PCV2 plays an important clinical and immunopathological role in the development of PDNS. They suggested that the excessive high levels of PCV2 antibodies trigger the development of immune complex deposition in kidneys that initiate an inflammatory process in the vascular or glomerular capillary walls. They also found an epidemiological association with herds that experienced post weaning multisystemic wasting syndrome (PMWS), also caused by PCV2. Porcine circoviruses (PCV2, PCV3) have a strong association with occurrence of PDNS (Opriessnig and Langohr 2013; Palinsky et al. 2016).

Seen mainly in growing swine from 20 to 65 kg, the most obvious clinical signs are skin lesions and a rapid loss in body weight with concurrent depression. The skin lesions range from large areas of erythema, macules, and hemorrhagic papules to dark brown to black thick crusts of necrosis on the ears, face, lower limbs, hindquarters (Figure 17.7), scrotum in boars (Figure 17.8), and vulva of

Figure 17.7 Porcine dermatitis and nephropathy syndrome (PDNS) in a grower pig.

Figure 17.8 Porcine dermatitis and nephropathy syndrome (PDNS) in a mature boar.

Figure 17.9 Ringworm (*Microsporum nanum*).

sows. Other clinical signs include subcutaneous edema along the ventral abdominal wall extending to limbs, sometimes with swelling of the joints.

The condition could be confused with erysipelas or other causes of skin necrosis, but another serious concern is that the clinical signs and lesions closely resemble those of CSF and African swine fever. Necropsy reveals enlarged, pale, spotted kidneys with petechiae, excess fluid in the body cavities, subcutaneous edema, and perhaps excessive synovial fluid in the joints. The frequency of gastric ulceration and gastric hemorrhage may be increased. The histopathology of the kidney lesions is consistent with a diffuse necrotizing and proliferating glomerulonephritis, including formation of hyaline/granular casts and distended tubules. Microscopy of skin reveals necrotizing vasculitis of arterioles in the dermis and subcutis. Small-vessel vasculitis also occurs in other organs, including lymph nodes, spleen, stomach, liver, bladder, brain, and joints (Higgins 1993). Control is difficult because the actual causative agent(s) and disease mechanism(s) are poorly understood. Anecdotally, refining the PCV2 vaccination program (age of administration as well as the frequency or number of doses of vaccine given to grower pigs, gilts in development, and/or the sow herd) has usually mitigated occurrence of PDNS.

Fungal diseases (ringworm)

Fungal diseases of swine tend to be superficial mycoses involving the keratinized epithelial cells and hair only. Fungi reported in swine include *Microsporum nanum, Microsporum canis, Microsporum gypseum, Trichophyton mentagrophytes, Trichophyton rubrum, Trichophyton tonsurans, Trichophyton verrucosum*, and *Candida albicans*.

Ringworm occurs in both extensively and intensively reared swine. All age groups can be affected, and the incidence appears to be higher where sanitation is poor and stocking densities are high with moderate temperatures and high humidity. Bedding may be an important source of infection. Fungal spores can remain viable for many years in a dry and cool environment. Mycelial growth is optimized when the environmental conditions are warm and humid with a slightly alkaline skin pH. Ringworm fungi are strictly aerobic.

Ringworm lesions associated with *Microsporum* spp. (most commonly *M. nanum*) can be found on almost any part of the body. Lesions begin as circumscribed spots, which tend to enlarge in a circle, some to enormous size covering the complete side of the pig. The skin is reddish to light brown in color, roughened but not raised. Dry crusts form around the periphery, the hair is usually not lost, and no pruritus develops (Figure 17.9). Experimental infection with *M. nanum* (Connole and Baynes 1966) produced lesions that first appeared as pustules or moist brown areas of desquamated tissue 2 cm in diameter. As the lesions extended, fresh pustules were often seen near the periphery. Scales, crusts, and deposits of black material similar to the natural infection appeared. Lesions developed in 2–3 weeks and resolved by 9 weeks. Chronic infections are often seen behind the ears of adult swine and appear as thick brown crusts that spread over the ear and neck.

Trichophytosis is most commonly associated with *T. mentagrophytes*, but *T. rubrum, T. tonsurans*, and *T. verrucosum* also cause ringworm in swine. Lesions are found on the thorax, flank, and neck, behind the ears, and on the legs. The size and shape of lesions vary; some measure up to 12.5 cm across and are roughly circular. Typical lesions are red or covered by a thin brownish dry crust. The disease tends to be self-limiting and lasts about 10 weeks (McPherson 1956). Arora et al. (1979) described lesions caused by *T. rubrum* as rough and reddish and appearing on several sites; 10% of piglets and 4% of sows in a herd were affected.

Cutaneous lesions caused by the yeast *C. albicans* can occur when host resistance is compromised. Disease with 40% morbidity was reported in grower pigs fed garbage and kept in unsanitary conditions. The lesions on the most severely affected animals consisted of circular areas approximately 2 cm in diameter coated with moist gray exudate. Lesions were found on all limbs and the lateral and ventral surfaces of the abdomen. The skin was thickened, wrinkled, devoid of hair, and hung loose in folds (Reynolds et al. 1968).

Diagnosis of ringworm is by biopsy, by microscopic examination of scrapings, or by fungal culture. Treatment of fungal infections, if indicated, consists of removal of the crusts and local application of antifungal products. Control is by maintaining good sanitation, nutrition, and strategic disinfection of premises.

Parasitic diseases

Sarcoptic mange (scabies) is the most commonly encountered parasitic skin disease of swine, is of major economic importance globally, and is caused by the mange mite *S. scabiei var. suis*. The first skin lesions appear about 3 weeks after contact with mites as small encrustations around the ears, eyes, and snout that develop into plaques about 5 mm in diameter. The lesions in the ear may regress and disappear in 12–18 weeks. Early pruritus is due to the local irritation from the mites establishing themselves in the skin. As the initial lesions regress, focal erythematous papules associated with hypersensitivity occur on the rump, flank, and abdomen. Mites are not usually found in these lesions but often remain present and detectable in ear scrapes. The hypersensitivity causes further pruritus, which results in excessive rubbing and the liberation of tissue fluids, giving the animal a greasy or shiny appearance. This is followed by coagulation and drying of the serum, sebum, and sweat to form crusts. In more chronic cases, excessive keratinization and proliferation of the connective tissue occur, with the result that the skin becomes thickened and wrinkled. A common sign seen in grower pigs is shaking of the ears and, in some, the development of large hematomas on the inner surface of the ear. Chronic cases, usually adults, will develop thick gray-colored, loosely attached scales lining the inner surface of the ears, around the neck, and down the lower limbs, especially over the hock joints. Considerable loss of hair is associated with chronic mange (Figure 17.10).

Demodectic mange (follicular mange) is of little economic importance in swine. Clinical signs occur when pigs are in a poor or debilitated condition. The disease is caused by *Demodex phylloides*, which lives in the hair follicles or sebaceous glands of the skin. The mites can invade the soft skin of the snout and around the eyes but can spread over the entire body. Infection is not uncommon on the abdomen between the legs. Lesions start as small red spots, which become scaly with a nodular appearance. The nodules contain white caseous material and many mites. Treatment is usually not successful, and severely affected animals should be culled.

Figure 17.10 Sarcoptic mange.

Haematopinus suis, a louse that affects pigs only, causes severe irritation, resulting in continual scratching and rubbing against objects. Adult lice are easily visible around the neck, base of the ears, and inner ears and inside the legs and flank, and the white eggs can also be seen on the bristles, especially in colored pigs. The blood feeding causes considerable irritation, scratching, and rubbing against objects, resulting in lacerations and hemorrhage. Lice tend to congregate around the areas where skin damage has taken place. The continual irritation results in loss of body weight and reduces weight gains. Lice may spread swinepox virus, erysipelas, and likely other disease agents.

Fleas (*Ctenocephalides canis, Ctenocephalides felis, Pulex irritans*, and *Echidnophaga gallinacea*), mosquitoes (*Aedes* spp.), and flies (*Musca domestica, Stomoxys calcitrans, Culicoides* sp.) commonly affect swine. Clinical signs can include varying degrees of rubbing, scratching resulting in alopecia, excoriations, and bleeding from the skin and circumscribed, raised, rounded (wheal) lesions or edema associated with urticarial reactions.

Environmental diseases

Sunburn

Sunburn caused by the direct effect of ultraviolet rays on skin occurs in white pigs managed under open-range conditions without adequate protection from sunlight. Young pigs and pigs not previously exposed to sunlight are often seriously affected. Erythema occurs within a few hours of exposure and develops most commonly on the back and behind the ears. Edema can develop, and affected areas become warm and painful to the touch. Severely affected pigs walk very carefully, may have sudden bouts of muscular twitching, may jump into the air, or may suddenly drop to sternal recumbency, presumably in response to pain. The skin becomes dry, scales develop, and the skin peels. In young pigs the tail and ears become necrotic and slough. A simple and effective treatment is to cover the skin with bland oil, for example, vegetable oil or light mineral oil. Animals should be removed from direct sunlight, and adequate shade provided for prevention.

Photosensitization

Photosensitization is a condition seen in extensive, free-range-managed swine exposed to photodynamic agents and sunlight. Photosensitivity (hypersensitivity to light) results from the ingestion of photodynamic agents such as hypericin found in St. John's wort (*Hypericum perforatum*) and fagopyrin found in buckwheat (*Fagopyrium esculentum* and *Polygonum fagopyrum*). Other plants, including rape (*Brassica* sp.), lucerne (*Medicago sativa*), and *Trifolium* sp., cause photosensitization of unknown etiology. Other substances reported to cause photosensitization in swine are phenothiazine, tetracyclines, sulfonamides (Amstutz 1975), and possibly aphids (McClymont and Wynne 1955).

Lesions are seen in white-skinned breeds and on areas most directly exposed to the sunlight. The severity of the condition depends on the concentration of the photodynamic agent and the length of exposure to light (Jubb and Kennedy 1970).

Erythema and edema develop and serum may exude from the skin and become dry and matted in the hair. Pain causes swine to walk carefully; severely affected animals may suddenly drop into sternal recumbency and immediately rise again or stagger sideways (Hungerford 1990), similar to acute sunburn. The ears become thickened, and congestion of the conjunctiva may occur with matting together of the eyelids (Amstutz 1975). Skin becomes dry, hard, and fissured and extremely pruritic. Areas of the skin may become necrotic and peel off in strips. Ears and tail may slough.

Sunburn, erysipelas, and sarcoptic mange have to be included in a differential diagnosis. The typical lesions confined to unpigmented or white areas of skin exposed to sunlight and a history of ingestion of a photodynamic agent or plants known to cause photosensitization will suggest a diagnosis.

Affected animals should be placed in darkened housing. Treatment is palliative, and control is by preventing access to photodynamic agents, grazing only at night, or keeping pigs indoors.

Frostbite

Frostbite can develop in pigs exposed to severely cold temperatures. Ear tips and other extremities are common sites for frostbite in all pigs, and the scrotum can be affected in boars. Boars affected by frostbite may also become infertile. Lesions develop due to the freezing of tissues, with skin turning white and then red initially and, in severe cases, black and necrotic thereafter. Frostbite arises in extensively raised swine housed without adequate shelter and dry bedding or during transport in extremely cold conditions.

Skin necrosis and trauma in piglets

Skin necrosis in piglets most frequently affects the knees, fetlocks, hocks, elbows, teats, coronets, and soles of the feet. Necrosis of the hocks, vulva, and tail is common in piglets with splayleg. Necrosis of the knees (carpus) is very common in weaker and smaller piglets in large litters or with sow agalactia or hypogalactia. In piglets, necrosis starts as small abraded areas often developing 12–24 hours after birth and reaching maximum severity in 7 days (Penny et al. 1971). Lesions are due to trauma from hard abrasive floors, especially rough concrete in farrowing crates. The alkaline pH of new concrete floors and slats may also affect older pigs. Necrosis of the soles of the feet can be caused by the abrasive surface of rusting wire mesh or metal floors.

Teat necrosis is most noticeable at 3 days of age (Stevens 1984) with the lesions consisting of blackish-brown scales or crusts that easily peel off, leaving a new, fresh wound. It usually affects the pectoral (first four) teats, resulting in blind, nonfunctional teats. The highest incidence was found in pigs on heated concrete floors, with decreasing incidence on expanded-metal floors, rubber mats, and plastic-coated wire mesh. A genetic basis for teat necrosis associated with sire lines was demonstrated, but nongenetic causes were more common than genetic causes (Stevens 1984). Females are most commonly affected. Besides environmental abrasion, estrogenic stimulation has been postulated as a risk factor. Necrosis of the tail starts at the base, usually encircling the whole tail, which becomes black and may slough. Cause is not known but may be related to risk factors already stated.

Control in piglets should be aimed at avoiding rough, wet contact surfaces and providing bedding or rubber mats in the creep area of farrowing crates.

Skin necrosis and trauma in older swine

In sows, skin necrosis is common on the shoulder, over the hip region, and on the side of the jaw and is generally due to a combination of pressure from lying for long periods on hard floors (both concrete and mesh) and poor body condition associated with rapid weight loss during lactation, limit feeding, or old age. The condition can occur in young sows after their first litter.

Skin necrosis of sows is best prevented by maintaining good body condition through appropriate feeding before and during lactation, using plastic-coated floors in farrowing crates, and encouraging sows to stand and exercise frequently.

Calluses

Calluses are epidermal hypertrophy with fibrosis of the skin over joints and bony prominences. They are seen mainly over the fetlocks, elbows, hocks, and tuber ischii.

A callus may become very large, hard, or fluctuant and may contain fluid that is termed an adventitious bursa. The bursa may become infected and result in subcutaneous abscesses. Pigs with leg weakness, foot lesions, or muscular weakness or that spend a lot of time lying down due to illness frequently develop callosities or bursitis.

Parakeratosis and nutritional diseases of skin

Swine parakeratosis is a nutrition-related metabolic disorder of growing pigs characterized by a generalized nonpruritic crusting dermatosis (Figure 17.11). The cause of this condition is considered to be complex, involving deficiencies of zinc and essential fatty acids or high levels of calcium, phytates, and other chelating agents that affect zinc absorption. Gastrointestinal diseases may also predispose to a more severe zinc deficiency and parakeratosis.

Early lesions (macules and papules) develop on the ventral surface of the abdomen, medial thighs, and distal parts of the legs (Figure 17.11). The lesions rapidly become covered with scales and then hard dry keratinized crusts that get progressively thicker and form deep fissures. The surface of the skin may be dry and rough, but moist brownish sebum, dirt, and debris accumulate in the fissures. In severe cases animals will have reduced growth rates and reduced appetite, diarrhea, and in some cases vomiting. Testicular development may be affected. Mortalities are rare.

The condition has to be differentiated from chronic sarcoptic mange, exudative epidermitis, and deficiencies of the B vitamins and iodine. A history of feeding a diet likely to be deficient in zinc and essential fatty acids, or including factors that may interfere with zinc absorption together with the characteristic lesions and their distribution, will suggest parakeratosis.

Figure 17.11 Parakeratosis.

Skin biopsy from animals early in disease course for histopathology to demonstrate typical and severe parakeratotic hyperkeratosis is valuable for confirming diagnosis. Serum alkaline phosphatase and zinc levels may be decreased in serum and liver. Response to supplementary zinc and essential fatty acids will support a diagnosis.

A host of nutrients can affect skin and hair health. Dietary levels or ratios of fat-soluble and B vitamins, microminerals, fatty acids, and amino acids all have impact on skin integrity and healthy appearance (see Chapter 67).

Congenital and hereditary diseases of skin

Pityriasis rosea

Pityriasis rosea in swine is the name used to describe a dermatitis with quite characteristic gross lesions. This condition is seen only in young swine and mainly on the ventral abdomen and inner thighs. The disease is self-limiting and has little clinical or pathologic similarity to pityriasis rosea in humans. Although the actual cause is unknown, the condition appears to be at least partially heritable; individuals that have had the condition themselves are more likely to produce affected progeny, and incidence may be higher in Landrace breed. Attempts to transmit the disease or demonstrate an infectious agent have failed. Pityriasis rosea has been reported in piglets derived by hysterectomy and reared in isolation.

The disease affects young pigs 3–14 weeks of age. Entire litters or only a few piglets in a litter may be affected. It begins as small erythematous papules on the skin of the abdomen and inner thighs. The papules are raised with a central crater and rapidly expand to produce a ring, or collarette, with a raised bright red periphery behind, which are scales. As the ring expands, the central area returns to normal. The rings coalesce as they expand to produce mosaic patterns. The hair is usually not lost and pruritus is not present (Figure 17.12). The condition usually lasts about 4 weeks, regressing slowly and leaving normal skin as lesions heal. Lesions may become infected with bacteria and resemble an exudative dermatitis. The condition has to be differentiated from ringworm, dermatosis vegetans, and swinepox.

Skin biopsy will show psoriasiform epidermal hyperplasia and superficial perivascular dermatitis. There is mild to moderate mucinous degeneration of the superficial dermis, and the predominant inflammatory cells are eosinophils and neutrophils. Parakeratotic hyperkeratosis is usually prominent, with an eosinophilic

Figure 17.12 Pityriasis rosea.

inflammatory component not present in nutritional parakeratosis.

Treatment does not appear to affect the course of the disease. Good hygiene will reduce the chance of secondary infections, whereas overstocking with high humidity and high temperatures appears to increase the incidence. It may be best to cull breeding stock known to produce progeny that develop the condition from the breeding herd.

Dermatosis vegetans

Dermatosis vegetans is a hereditary and often congenital disease of swine due to a semilethal autosomal recessive factor believed to have originated in the Danish Landrace breed (Don et al. 1967). The condition occurs as an erythematous maculopapular dermatitis with lesions on the coronary band and hoof together with giant cell pneumonia. The main features of the condition are skin lesions, abnormalities of the feet, poor growth, and respiratory dysfunction. The skin lesions may be present at birth or, more commonly, develop within 2–3 weeks of birth. They first develop on the abdomen and inside the thighs as small (0.5–2.0 cm in diameter) raised pink swellings that enlarge rapidly. The lesions spread over the flanks and back of the pigs and become covered with yellowish-brown, brittle, papillomatous crusts that are easily removed, leaving a pink granular surface. The lesions become very thick with a hard, horny surface that develops cracks and fissures, giving a characteristic papillomatous appearance. Swine may die after 5–8 weeks, but some will survive and the skin lesions regress.

Lesions of the hoof are usually present at birth consisting of marked swelling and erythema over the coronary band of both the main and the accessory digits and covered with a yellowish-brown greasy exudate. The walls of the hooves are thickened with ridges and furrows parallel to the coronary band. The horn becomes discolored and blackened.

The condition has to be differentiated from pityriasis rosea, chronic exudative epidermitis, and vitamin deficiencies. The clinical appearance of the skin and hoof lesions seen in young pigs 2–3 weeks of age is characteristic. The very thick papillomatous crusts of the skin lesions are typical and, together with respiratory distress, will suggest a diagnosis of dermatosis vegetans. Skin biopsy reveals intraepidermal pustular dermatitis and microabscesses containing eosinophils and neutrophils, with parakeratotic hyperkeratosis. Older lesions show hyperplastic superficial perivascular dermatitis with multinucleated giant cells in the dermis (Percy and Hulland 1967, 1968).

There is no treatment for the condition, and prevention is aimed at detection and removal of breeding stock known to have produced affected progeny.

Epitheliogenesis imperfecta (aplasia cutis)

Epitheliogenesis imperfecta is an inherited congenital condition of both white and colored swine, caused by a simple autosomal recessive trait thought to result in a primary failure of embryonic ectodermal differentiation. The lesions appear as clearly demarcated discontinuities of the squamous epithelium of varying sizes and shapes but usually on the back, loins, or limbs. The condition may be seen in individual piglets or with a familial incidence in litters. The defect may also affect the dorsal and anterior ventral surface of the tongue with concurrent hydroureter and hydronephrosis (Jubb and Kennedy 1970). Lesions develop as large ulcers and frequently become infected; they may fail to heal or cause septicemia, which may lead to death (Figure 17.13).

Neoplastic diseases of skin

Tumors are reported relatively rarely in swine; however, a variety of neoplastic conditions have been reported, including lymphangioma, rhabdomyoma, papilloma, sweat gland adenoma, fibroma, and hemangioma.

Melanomas, the result of proliferation of melanoblasts, have been reported most commonly in the Duroc breed and are often found at birth. The tumors are frequently

Figure 17.13 Epitheliogenesis imperfecta.

seen on the flank or mammary region but can occur at any location. The tumors are usually 1–4 cm in diameter, raised with an irregular black shiny surface. Metastases have been seen in lymph nodes, kidney, liver, lung, heart, brain, and skeletal muscle. Rhabdomyosarcomas have been reported as solitary or multiple tumors on piglets less than 1 week old in at least 25 piglets in a short period of time in one herd in the Netherlands, indicating a common, possibly genetic cause (Vos et al. 1993).

Swine papillomas occur as small fibrous polyps or wartlike lesions and have been observed on sows and growing pigs, especially around the neck, along the back, and on the ears. These lesions frequently bleed and can easily be removed under local anesthetic.

The feet, hoof, and claw

Introduction

Lesions of feet (hooves and claws) are frequently associated with lameness, which can adversely affect growth rates and reproductive performance due to early culling in the breeding herd as well as having a significant impact on welfare (Allerson et al. 2008; Anil et al. 2005; Bradley et al. 2008; Penny et al. 1963, 1965). Reports suggest that the prevalence and severity of lesions of the feet and claws have increased over the last half century with production trends toward increased population density in confined housing with solid or slotted floors, particularly those of concrete. More recently, increased foot lesions and lameness are reported in production systems transitioning from individually housed sows back to group housing systems (Johnston and Li, 2013). Foot lesions have been reported in suckling piglets (Zoric et al. 2009), post weaned pigs (Gillman et al. 2009), and finisher pigs (Mouttotou et al. 1997, 1999) as well as sows and boars (Anil et al. 2007). Factors influencing the prevalence or severity of lesions include foot, claw, and skeletal conformation, housing and floor surfaces, nutrition, population density and commingling, and infectious agents.

Structure and function of the hoof and claw

The pig is tetradactylous, having two large weight-bearing digits (third and fourth) and two non-weight-bearing accessory digits (second and fifth digits or "dewclaws"). The first digit is absent in the pig, the third digit is medial, and the fourth is lateral on each foot. The term "foot" usually refers to the entire region from the toe to the top of the dewclaws. Each digit includes the claw or hoof, which is the keratinized horny tissue of the hard wall, hard sole, and soft heel. Each claw covers the third phalanx and the distal part of the second phalanx. The accessory digits are caudal to the larger digits and have a full complement of phalanges. The volar surface of the claws consists of the large and prominent heel (which houses the digital cushion), the sole, and the wall. The sole in the pig covers a relatively small area, and a nonpigmented soft wall (white line [WL]) forms the junction between the wall of the claw and the sole. The lateral digit is usually larger than the medial digit on both the front and hind feet. The disparity in size is usually more prominent on the hind feet.

A cross section of the claw consists of bone of the phalanx, subcutis, corium or dermis, vascular basement membrane, and epidermis. The corium located just below the epidermis forms the supportive connective tissue layer for the epidermis, containing blood vessels and nerves. From this layer nutrients and hormones are provided to the stratum basale or germinal layer for the production of the epidermal cells. All distal layers of the epidermis are derived from these cells by a process of proliferation and differentiation. The corium and its basement membrane are critical structures for keratin or soft/hard horn formation. Keratins are produced by complex processes of differentiation of the epidermal cells. Formation and biochemical binding of keratin proteins and synthesis and exocytosis of intracellular cementing substance are the hallmarks of keratinization (Tomlinson et al. 2004).

The corium is covered by the densely arranged cells of the stratum basale, which are pushed into the next layer and enter the process of differentiation to make up the stratum spinosum. Toward the end of differentiation, basophilic dense keratohyalin granules accumulate in the cells, forming the stratum granulosum. It is this layer that forms the border of cornification in which the cells die (cornify) and turn into horn cells, which is known as the stratum corneum. The process is dependent on an appropriate supply of nutrients, including vitamins, minerals, and trace elements. These nutrients are essential for the integrity of hoof horn. Decreasing nutrient supply to keratinizing epidermal cells can lead to inferior horn quality and increase its susceptibility to chemical, physical, or microbial damage from the environment, which may result in clinical lesions of the claws and lameness.

Classification, pathology, and scoring of foot lesions

Foot and claw lesions can involve the heel, sole, WL, wall, and accessory digits. Virtually anything that predisposes to breach of integrity of parts of the foot and claw will increase the risk of pododermatitis, arthritis, osteomyelitis, or cellulitis. Anil et al. (2007) generally characterized claw lesions as erosion, cracks, and overgrowths.

Heel lesions start as dark discolored areas or bruises under the volar surface, followed by erosions usually seen as a rough "ragged" lesion with underlying hemorrhage. Ulceration of the heel may follow. Continuous trauma can result in hyperkeratinization, excessive granulation, and necrosis (Penny et al. 1963), often extending to the interdigital cleft. Bradley et al. (2008) described heel erosion occurring in a circular pattern resembling tissue degeneration or irritation with cracks resembling a cut or tissue separation crossing the heel diagonally from the WL to the rear of the heel.

Sole lesions also occur as bruising with dark brown to red areas of hemorrhage under the surface, most frequently along the junction of the heel and sole. Hyperkeratinization of the sole can be a sequel to erosion and ulceration.

WL lesions of the claw, either axial or abaxial, start as hard tissue wear (erosion) and separation between the hard and soft tissue of the hoof wall and sole or heel or both (Bradley et al. 2008; Penny et al. 1965). The lesions can cause extensive separation with impaction with dirt, feces, and foreign material often resulting in deformity of the claw and separation of the wall. WL lesions provide a site for infection to enter the hoof and corium.

Cracks of the wall can be vertical, starting at the WL (false sand cracks) or at the coronary band (true sand cracks). Horizontal cracks can also occur. False sand cracks can vary in severity from a fine crack to a deep fissure with necrotic edges (Penny et al. 1963).

Coronary band abscesses (bush foot) are most likely an infection of the laminae with an abscess-like lesion along the coronary band. The area above the coronary band becomes very swollen, and a granulating sinus develops, producing a purulent discharge. Infection may also involve deeper areas of the hoof and joints of the foot, causing severe lameness. Accessory digit (dewclaw) lesions, more common in adult sows and boars, can involve loss of the horn with hemorrhage and infection of the underlying tissue or lengthening of the digit (overgrowth).

Da Silva et al. (2010) found a number of claw lesions to be highly correlated with inflammation of the corium in lame sows. Although the pathology and etiology of inflammation of the corium is not the same for each lesion type, there is potential for claw lesions to contribute to additional inflammation of the corium. Due to the large number of nerves associated with the corium, inflammation is likely to result in pain and lameness. Indeed, the histologic changes in sow claws are consistent with laminitis in other species (Newman et al. 2015; Varagka et al. 2016a).

Deen and Winders (2008) have suggested using a consistent scoring system of 0–3 (i.e. none, mild, moderate, severe) for the types of pathology. First, score the heel overgrowth and erosion (HOE), which is a common lesion ranging from slight overgrowth and/or erosion of the soft heel tissue to severe overgrowth and cracks. Next, score heel–sole crack (HSC) lesions at the junction between the heel and the sole with severe lesions involving all or most of the junction. A third score is for WL lesion involving separation along the WL in the juncture of the claw wall. Fourth, score the cracked wall horizontal (CWH), cracks horizontally along the claw wall with severe lesions involving multiple or deep cracks. A fifth score is for the cracked wall vertical (CWV), vertical cracks in the claw wall and severe lesions involving multiple or deep cracks. Sixth, score toe (T) lesions involving excess lengthening of one or more claws where severe lesions significantly affect gait. Finally, score dewclaw (DC) involving moderate or severe lengthening of the claw (score 1 or 2) or torn or missing claw (3).

Prevalence of foot and claw lesions

Foot lesions are common, reported in all age groups of swine. The prevalence in suckling piglets of sole bruising ranged from 49.4 to 100% and sole erosion from 15.5 to 49.1% in the studies of Mouttotou and Green (1997) and KilBride et al. (2009), respectively. Zoric et al. (2004) found 87% of suckling piglets with sole bruising at 3–10 days of age and 39% still affected at 17 days. Prevalence in weaner pigs has been reported as 50.2% with at least one digit affected (Mouttotou et al. 1998) and an overall prevalence of 39.6% reported by Gillman et al. (2009).

In two studies the prevalence of lesions in finisher pigs were reported as 65.1 and 93.8% of pigs with at least one lesion by Penny et al. (1963) and Mouttotou et al. (1997), respectively. Lesions in weaners and finishers were similar and included heel, sole, and toe bruising and erosions, heel flaps, WL lesions, wall separation, and false sand cracks.

The early reports (Hogg 1952; Osborne 1950; Penny et al. 1963) noted a high prevalence of foot lesions in sows. A more recent study found that more than 96% of culled sows from loose housing and 80% from confined housing had at least one lesion (Gjein and Larssen 1995a). Anil et al. (2007) found that out of 184 gestating sows, 88.6% had at least one wall lesion and 86.4% had one heel lesion. Lesions between the junction of the heel and sole were seen in 66.3% of sows, and 60.9% had WL

lesions. Lesions were more severe on the forelimbs, and a higher proportion of sows had lesions on the lateral claws than the medial claws.

Surveys are prone to bias. The reported prevalence from surveys and studies is heavily dependent on scoring system used and the study design and definitions applied. Ultimately, a high rate of lesions is likely the result of the cumulative effects of various flooring types and management practices experienced over the lifetime of the pigs surveyed.

Association between foot lesions and lameness

Lameness in sows is an important welfare issue that has many risk factors, including group housing. Pluym et al. (2017) performed a longitudinal study in 15 randomly selected herds to investigate the incidence of sow lameness and risk factors present within the first days of group housing. They found a mean lameness incidence of 13.1% and that increased floor area decreased risk of lameness, while floor characteristics and degree of sow aggression did not influence development of lameness.

The presence of a lesion does not equate to the presence of lameness or pain, since not all lesions result in perceptible lameness in pigs. Studies of lesions in sows (Hogg 1952; Osborne 1950; Penny et al. 1963) reported an association between the severity of claw lesions and presence of lameness, especially in sows and boars. Lameness is more likely when lesions are visibly infected or when lesions (heel erosions, WL cracks, infected vertical cracks, abscesses of the coronary band) are classified as severe.

Anil et al. (2007, 2008) found a significant association between lameness and WL lesions in sows and later reported that lesions of the heel as well as of the WL were associated with lameness. In a study of the prevalence of lameness and claw lesions in two commercial herds where the prevalence was relatively low (<4% had serious lameness), the most common lesions related to lameness were heel erosions and overgrowth of dewclaws. WL and sidewall lesions were not a feature of lameness in these herds (Sonderman et al. 2009).

Early recognition and assessment of lameness in sows is important for early intervention and treatment. However Anil et al. (2008) showed that clinical assessment in correctly grading lameness scores was difficult for mild cases and non-lame sows. Accurate assessment of lameness requires experience and specific training. Heinonen et al. (2013) reported within herd incidence of all lameness causes of 8.8–16.8%, to which the hoof and claw contribute only a portion. Lameness due to other causes may predispose animals to skin, hoof, and claw lesions by restricted motion or postural effects.

Foot lesions in sows have also been correlated with performance and behavior in sows, with reduced numbers of pigs weaned per litter for sows with outer hoof wall cracks and lighter weaning weights for sows with elongated toes (Fitzgerald et al., 2012).

Factors affecting prevalence of foot and claw lesions

Research into the prevalence and severity of foot and claw lesions has identified a number of associated factors including claw conformation, environment (in particular housing type and floor type), nutrition, and infectious agents.

Claw conformation

The lateral claw is generally larger than the medial claw, particularly in hind limbs, and lesions tend to be more prevalent and/or more severe on the lateral claw, particularly of the hind limbs (Penny et al. 1963). They surmised that the larger lateral claw somewhat protected the smaller medial claw, such that the medial claws take less weight and hence suffers less trauma, while the lateral claw is subject to more trauma due to its size and position. Subsequent reports are in general agreement with these earlier findings (Anil et al. 2007, 2009; Bradley et al. 2008; Gjein and Larssen 1995b; Van Amstel and Doherty 2010).

Anil et al. (2007) found lesions more severe on forelimbs than on hind limbs and that the proportion of sows with lesions on the lateral claws was greater than the proportion of sows with lesions on the medial claw. In discussion and with reference to other studies, Anil et al. (2007) considered that weight distribution of sows may be important in determining the development of lesions on different claws and different limbs (Kroneman et al. 1993). Hoof lesions may be more common on lateral claws because of a greater weight-bearing surface than medial claws (Tubbs 1988). More than 75% of the weight of the pig is born by the lateral digit, and 80% of the injuries affect these digits (Webb 1984). Kroneman et al. (1993) suggested that the strength of different parts of the foot varies, whereby junctions between hard and soft areas may be more susceptible to injury. Maximum weight is born by the heel bulb, followed by the junction between the heel bulb and abaxial hoof wall of the lateral digit. The tip of the toe is the greatest weight-bearing region on the medial digit.

Amstel et al. (2009) found that the front feet have better weight-bearing stability than the rear feet with the rear medial claw least stable. It was suggested that this may result in more weight being transferred to the more stable rear lateral claw, which may explain the higher reported incidence of lesions observed in that claw.

The disparity in claw size in piglets was suspected in part to be hereditary (Penny et al. 1963) and was considered to have low heritability by others. Jörgensen and Andersen (2000) found values of 0.13 and 0.19 in Landrace and Large White pigs, respectively. Tarres et al. (2006) examined sow longevity and feet and leg scores in Large White sows in Swiss herds and concluded that culling on extreme feet and leg scores from 1999 to 2003 has contributed to the improvement of sow longevity in these herds.

Type of flooring

The association between housing and type of flooring and the prevalence of foot/claw lesions has been the subject of many reports in suckling piglets, weaners, finishers, and sows. Foot lesions in suckling piglets are more likely to occur where farrowing crate floors and creep areas are solid, especially solid concrete (Mouttotou et al. 1999; Zoric et al. 2004, 2009). By reducing the roughness and abrasiveness of farrowing crate floors or by covering with sufficient straw, the prevalence and severity of lesions in piglets can be reduced (Zoric et al. 2009). Sole bruising increases in prevalence in piglets on slatted floors compared with solid concrete floors even with bedding. Slatted floors increase the risk of sole erosions (KilBride et al. 2009).

Gillman et al. (2009) reported the prevalence of lesions in weaners up to 14 weeks old and held on solid, totally or partially slatted floors, or outside on a soil base (all with bedding). They found that toe erosion was positively associated with deep bedding and that deep bedding on a soil base was negatively associated with the prevalence of heel and sole erosion. Heel flaps and heel–sole bruising were also associated with slatted floors.

Claw lesions, especially wall cracks and WL cracks, were more common in finisher pigs kept on solid concrete floors (Osborne 1950). Finishers kept on straw-bedded floors had fewer sole–heel erosions and heel flaps but more WL lesions, false sand cracks, wall separation, and toe erosion compared with pigs on bare concrete. Lesions increased when floors were partially or fully slatted (Mouttotou et al. 1999). Smith and Morgan (1998) found that finisher pigs kept on totally or partially slatted concrete had claw lesions on both floor types. The prevalence of lesions rose as floors became more abrasive. The prevalence on good quality totally slatted floors (low to moderate values of abrasion, slipperiness, slat edge, slat gap, and nature of slat edge) was lower than on floors with unsuitable slat quality. The authors recommended that the edge of slats should be rounded and smooth, a slat width of 13–14 cm, a void width of 1.8–2.4 cm, and a total linear edge of 10.0–17.7 m/pig. The effect of floor type on claw health in group-housed sows was recently reviewed (Pluym et al. 2013; Vermeer 2014).

The prevalence of claw lesions in pregnant sows reportedly is higher in loose housing systems compared with sows confined in stalls, especially where the floors are partially or fully slatted. However deep litter based on straw reduces the incidence and severity of lesions, while poor floor hygiene and high stocking density increase the severity of claw lesions (Gjein and Larssen 1995b; Holmgren et al. 2000).

Roughness of floors contributes to a higher incidence of claw lesions and increased lameness. The pH of concrete from 7.4 to 8.3 did not appear to influence prevalence; however, dirty wet conditions may soften the volar aspect of the feet, making them more susceptible to trauma (Penny et al. 1965). All types of claw lesions tend to be higher in sows kept in loose housing with fully slatted floors compared with sows confined to fully slatted stalls (Anil et al. 2007). The use of electronic feeders, which may contribute to aggression on entry to the feeder, may further increase prevalence of claw and foot lesions. Increase body weight has been associated with increased wall lesions, and higher backfat was associated with more heel lesions but less overgrowth of heels (Anil et al. 2007).

Nutrition and hoof horn integrity

In a review of keratins and hoof horn development in the bovine, Tomlinson et al. (2004) stated that keratinization of hoof epidermis is controlled and modulated by a variety of bioactive molecules and hormones dependent on an appropriate supply of nutrients including vitamins, minerals, and trace elements. The quality and functional integrity of hoof horn are dependent on nutrient flow to the epidermal cells. Hormones are important in horn growth with insulin, epidermal growth factor, prolactin, and glucocorticoids, all with impact on nutrient flow.

Nutrients required for horn growth include amino acids (cysteine, histidine, methionine), minerals (calcium, zinc, copper, selenium, manganese), and vitamins (A, D, E, and biotin). Except for biotin, very little peer-reviewed literature related to nutritional requirements for hoof growth in the pig is available; hence present knowledge is often an extrapolation from research in cattle and horses. Subsequent studies (Misir and Blair 1986; Webb et al. 1984; Simmins and Brooks 1988) also reported the benefit of biotin-supplemented rations in relation to hoof lesions, hoof wall hardening, and foot pad resilience.

Amino acids play key roles in establishing the structural integrity of the keratinocyte. Calcium, zinc, and copper are all important in the keratinization and cornification process. Zinc is important for tissue healing and, as with copper, strength and elasticity of the hoof tissue. Zinc supplementation in dairy cows has shown a reduction in cases of foot rot, heel cracks, interdigital dermatitis, and laminitis (Moore et al. 1989). Also in cattle, copper

deficiency can result in heel cracks, foot rot, and sole abscesses. Selenium is an antioxidant and may contribute to the protection and maintenance of physiological function of the lipid-rich intracellular cementing substance (Tomlinson et al. 2004). Excessive selenium and selenium toxicity will result in inferior hoof horn, resulting in lameness and deformed claws. The form or salt of a supplemented mineral may have some physiologic impact. Varagka et al. (2016b) reported that partial substitution of the inorganic zinc, copper, and manganese in sows' diet with their chelated complexes provided a comparative advantage against a conventional inorganic mineral source diet. Manganese is essential for skeletal and tendon development, joint, and cartilage strength. Vitamins A, D, and E all play an integral role in developing the structure and quality of keratinized horn tissue. Vitamin D is also important in calcium metabolism.

The role of biotin for hoof and claw integrity was extensively researched in the pig (Hill 1992). Tomlinson et al. (2004) considered biotin the vitamin of greatest importance to the keratinization process and in the integrity of keratinized tissues (skin, hair, claws, and footpads). Biotin is essential for the formation of the complex lipid molecules in the intracellular cementing substance (Mülling et al. 1999). Hill (1992) cites a number of early experiments involving individual biotin deficiencies in pigs resulting in alopecia, dermatosis, cracked hooves, and lameness. Penny et al. (1980) reported using biotin supplementation in a herd of 116 sows and gilts with severe lameness problems and found no improvement in animals already affected, but gilts entering the herd as replacements and receiving biotin supplement showed significantly fewer lesions of heel and WL. The authors suggested that biotin was an essential vitamin for young stock entering the breeding herd as the hoof horn would be better able to withstand the trauma of the environment. Kornegay (1986) reviewed evidence that biotin increases the hardness of the hoof wall and was of the opinion that numerous environmental and nutritional factors may influence the occurrence of biotin deficiency in swine and alter biotin required in the diet. Watkins et al. (1991) considered that the discrepancy in the efficiency of biotin supplementation seen in the literature most likely reflects the wide range of environmental, nutritional, and management practices used in the swine industry. Availability of biotin for the pig may vary significantly depending on the type of grain and storage conditions. Presence of mold can reduce availability of biotin in corn (Hamilton and Veum 1984). Biotin in grains has been reported to be poorly absorbed in the pig, and diets based on wheat or barley may not contain adequate levels of bioavailable biotin (Misir and Blair 1986). Other factors such as age, lactation, antibiotic medication, enteric disease, and access to feces (coprophagic pigs) may also influence biotin levels in the pig.

Overgrown hooves

The length and the vertical angle of the wall of the hoof are a balance between growth and wear of the hard and soft tissues of the hoof as well as foot and leg conformation. Floor type (abrasiveness) and level of physical activity influenced the rate of wear; hence overgrowth of hoof can occur in pigs housed on soft nonabrasive surfaces. Seedstock genetically selected to avoid poor foot and leg conformation is common.

Mammary System

Chantal Farmer, Dominiek Maes, and Olli Peltoniemi

Mammary gland anatomy

The microscopic and macroscopic anatomy and morphology of the porcine mammary gland was described by Barone (1978), Schummer et al. (1981), Calhoun and Stinson (1987), and Balzani et al. (2016b). The 12–18 mammary glands of swine are located in 2 parallel rows along the ventral body wall (Labroue et al. 2001), and the Meishan breed can have up to 22 mammary glands. Data from France indicates that in 2010, 65% of purebred sows had 16 or more functional teats compared with 18% in 2002. As suggested by Muirhead (1991), boars and gilts retained for breeding should have 14 well-placed normal teats to provide proper teat presentation and accessibility to the piglets since poor teat placement is a major reason for failure of sows to rear all their piglets. In fact, the number of teats has become one limiting factor for productivity with the current hyperprolific gilt lines (Rozeboom 2015). The cranial and posterior teats are generally more distant from each other compared with the middle teats, which in turn are located further away from the midline than the cranial and posterior teats (Balzani et al. 2016b).

The glands (two rows of two thoracic, four abdominal, and one inguinal) each normally have one teat (nipple) with two separate teat canals. When the teat orifice is not visible (inverted teat), it has a 50% chance of remaining blind. Functional supernumerary smaller teats can also be found. Paired vestigial nonfunctional accessory teats, not connected to glandular tissue, may also occur (Molenat and Thibeault 1977; Labroue et al. 2001).

In the nulliparous sow, the mammary gland consists of cell buds distributed among fat and connective tissue, whereas in the lactating gland, the connective tissue is largely displaced by glandular parenchyma. Mammary glands of the lactating sow are composed of tubuloalveolar tissue with the secretory units arranged in lobules. The lobules are lined by epithelial cells (lactocytes), which synthesize milk and are connected by a nonsecreting duct system to an ostium found on the teat. There are usually two complete gland systems within each mammary gland of the pig. The glandular tissue of one system usually interdigitates with the other, but the components of the two systems are independent, emerging as two orifices within each nipple (Figure 18.1). There is no muscular sphincter around the teat orifice; therefore intramammary treatment by way of the teat opening is not feasible. Diagnostic imaging by real-time ultrasound scanning allows visualization of the different tissues of the mammary gland, such as skin, subcutaneous fat layer, parenchyma, and underlying tissues (Björkman et al. 2017).

The arterial, venous, and lymphatic circulation is provided on each side of the ventral midline by a network that extends longitudinally from the axillary to the inguinal regions (Barone 1978; Schummer et al. 1981; Lignereux et al. 1996). Moreover, in swine there is a venous anastomosis between the right and left mammary gland of each pair of glands. Nerve supply to the cranial mammary glands differs from that to the inguinal glands. Cranial mammary glands receive their innervation from the last eight or nine thoracic nerves, while inguinal mammary glands receive their innervation mainly from the pudendal nerve (Gandhi and Getty 1969a,b; Ghoshal 1975). A more complete anatomical and histological description of the porcine mammary gland can be found in the seventh edition of *Diseases of Swine* (Smith et al. 1992).

Mammogenesis

Mammary growth is a major determinant of potential sow milk yield. It starts in fetal stage but occurs mainly postnatally in three periods, namely, from approximately 90 days until puberty, in the last third of gestation, and during lactation.

The mammary glands of newborn piglets have a poorly developed duct system and are largely composed of

subcutaneous stromal tissue (Hughes and Varley 1980). Accumulation of mammary tissue and mammary DNA (which is indicative of cell number) is slow until 90 days of age, at which time the rate of accretion of mammary tissue and DNA increases four- to sixfold (Sorensen et al. 2002). By the time the gilt is mated, the mammary gland is still very small, but it consists of an extensive duct system with various bud-like outgrowths (Turner 1952).

In pregnant gilts, almost all accumulation of mammary tissue and DNA takes place in the last third of gestation (Hacker and Hill 1972; Kensinger et al. 1982; Sorensen et al. 2002; Ji et al. 2006). Wet weight of the total mammary gland increases approximately 10-fold between days 45 and 112 of gestation (Ji et al. 2006). The mammary glands undergo major histological changes as the adipose and stromal tissues are replaced by lobuloalveolar tissue to become the milk secretory apparatus (Hacker and Hill 1972; Kensinger et al. 1982). The composition of mammary tissue shifts from a high lipid content to a high protein content between early and late gestation (Ji et al. 2006); this shift is reported to be around day 90 based on DNA accretion (Sorensen et al. 2002) or day 75 based on protein accretion (Ji et al. 2006). This breakpoint is undoubtedly related to the increases in circulating concentrations of mammogenic hormones such as estrogen, relaxin, and prolactin (Ji et al. 2006). Mammary growth in pregnancy is affected by anatomical location, the largest glands generally being the middle (third, fourth, and fifth pairs) and the smallest ones being the posterior (sixth, seventh, and eighth pairs) glands (Ji et al. 2006).

Mammary development continues during lactation. Average weight of suckled glands increases linearly by 57% between days 5 and 21 of lactation, and the weight of mammary DNA per gland increases by 100% during that same period (Kim et al. 1999c). The period of maximal mammary mass coincides with the estimated peak of lactation (Hurley 2001), which occurs between weeks 2 and 4. Mammary growth in lactation is also related to the position of the gland. It is greater for the five more anterior teat pairs than for more posterior teat pairs because of their greater chance of being selected by piglets (Kim et al. 2000). Parity can affect mammary development in lactation; primiparous sows show greater development than second- or third-parity sows (Beyer et al. 1994). In first-parity sows, the increase in mammary volume during lactation is due to both cellular hyperplasia and hypertrophy (Kim et al. 1999a), whereas in multiparous sows it appears to be mainly due to hypertrophy (Manjarin et al. 2011).

Factors affecting mammary gland development

Estrogens are important for mammogenesis in growing gilts, as evidenced by the increased rate of mammary development occurring at puberty (Farmer et al. 2004; Sorensen et al. 2006). Prolactin also plays a key role for prepubertal mammary development via an increase in the number of milk secretory cells (Farmer and Palin 2005).

During the last third of pregnancy, the drastic increase in metabolic activity of mammary glands is associated with an increase in estrogens of fetal origin and decreasing progesterone concentrations (Kensinger et al. 1986). An inhibition of prolactin in that period drastically decreases mammary development in gilts (Farmer et al. 2000), and this specifically from days 90 to 109 of gestation (Farmer and Petitclerc 2003). Increasing prolactin concentrations from days 90 to 110 of gestation using the dopamine antagonist domperidone stimulates mammary epithelial cell differentiation (VanKlompenberg et al. 2013). Relaxin is another hormone that promotes mammogenesis in gilts during the last third of pregnancy. It increases growth of parenchyma and decreases the mammary fat pad while having no effect on the cellular composition of mammary parenchyma (Hurley et al. 1991).

Nutrition in the two periods of rapid mammary development (i.e. from 90 days of age until puberty and during the last third of gestation) impacts the extent of development. Gilts should be fed ad libitum from 3 months of age to puberty in order to maximize their mammary growth (Farmer et al. 2004; Sorensen et al. 2006). Decreasing energy intake of gilts between 9 and 25 weeks of age also reduces weight of parenchymal tissue and decreases mammary DNA at the end of gestation (Lyvers-Peffer and Rozeboom 2001). On the other hand, feeding a lower protein diet (14.4 vs. 18.7% crude protein) from 90 days until puberty does not hinder mammary development of gilts (Farmer et al. 2004). Providing the phytoestrogen genistein in the diet of gilts from 90 days until puberty stimulates mammary hyperplasia, most likely through its estrogenic properties (Farmer

et al. 2010b). If body conditions of gilts differ at mating and these differences are maintained during gestation, composition of parenchymal tissue will be affected (Farmer et al. 2016a). Yorkshire X Landrace gilts that are thinner (12–15 mm backfat) will have greater concentrations of protein, DNA, and RNA in their mammary parenchyma compared with fatter animals (17–19 mm backfat) at the end of gestation.

Increasing dietary protein or energy between days 75 and 105 of pregnancy does not benefit mammary development; in fact, increasing dietary energy has a negative effect (Weldon et al. 1991). Howard et al. (1994) also observed no beneficial effect of increased energy intake in gestation on mammary development. Furthermore, in the study of Kusina et al. (1995), even though protein intake in gestation favorably affected milk yield, this was not due to an improvement in mammary development. In contrast, manipulating body condition of gilts by changing their protein and energy intakes during pregnancy showed that overly fat gilts (36 mm backfat) have drastically less mammary DNA (i.e. less epithelial cells) at the end of gestation and subsequently produce less milk (7.0 vs. 9.0 L/day) than leaner gilts (24 mm backfat) (Head and Williams 1991). Decaluwé et al. (2013) indicated that changes in backfat thickness during late gestation were associated with colostrum yield in sows. They also showed (Decaluwé et al. 2014b) that sows entering the farrowing house in a moderate body condition (averaging 19.7 mm backfat) had the greatest colostrum yield and the most beneficial colostrum composition. In a recent study, feeding level of pregnant gilts was adjusted to create three body conditions at the end of gestation. Mammary development of gilts that were too thin (12–15 mm backfat) was lesser compared with that of gilts with 17–26 mm of backfat (Farmer et al. 2016b). When 2-week-old piglets were fostered onto gilts that differed in terms of number of milk secretory cells at the onset of lactation, due to overt changes in body condition, milk output was greater in gilts with 27 mm compared with 36 mm of backfat. This clearly shows that the number of secretory cells at the beginning of lactation can have a very strong effect on the amount of milk produced (Pluske et al. 1995a).

Sow nutrition during lactation has a great impact on mammary growth. Kim et al. (1999b) demonstrated quadratic effects of both total energy and protein intakes on wet weight, protein, and DNA amounts in suckled glands. There are also recent indications that feeding during pregnancy and lactation can affect postnatal mammary development of the offspring. Supplementing the diet of late-pregnant and lactating sows with 10% flaxseed tended to increase parenchymal weight and increased parenchymal protein in the mammary tissue of their female offspring at puberty (Farmer and Palin 2008). Research is needed to establish the impact of such early life events on mammogenesis and lactation performance in swine. More information on mammogenesis in swine is provided in Farmer and Hurley (2015).

Mammary gland involution

Suckled mammary glands undergo dramatic changes during the initial 7 days after weaning, with significant changes occurring as early as 2 days post weaning (Ford et al. 2003). Mammary gland involution involves losses of over two-thirds of the parenchymal mass and cells present on the day of weaning (Ford et al. 2003). Individual mammary glands that are not regularly suckled during lactation undergo involution during lactation and become nonfunctional, with no further reduction in parenchymal tissue during the first 7 days after weaning (Ford et al. 2003). Mammary gland involution is reversible within 24 hours of a teat not being used. Yet, even if it is reversible, a gland unsuckled for less than 24 hours will have a lower milk yield for the remainder of lactation (Kim et al. 2001). Involution is irreversible after 3 days of a teat not being suckled (Theil et al. 2005). Mammary gland involution in early lactation could be affected by dietary nutrient levels. Kim et al. (2001) reported a much lower regression rate of unsuckled mammary glands in sows fed a high energy and high protein diet compared with sows fed a low energy and low protein diet.

Mammary glands that are suckled during lactation are larger than the nonsuckled glands at the end of involution, suggesting that more mammary tissue is available for redevelopment in the next lactation (Ford et al. 2003). Farmer et al. (2012) demonstrated that an unused teat in first parity will produce less milk in second parity. At 56 days of age, piglets that suckled a previously unused teat weighed 1.1 kg less than piglets that suckled a previously used teat. It appears that use of a teat for 2 days in early lactation during the first parity is enough to avoid any negative effect on milk yield in second parity (Farmer et al. 2017).

The abrupt cessation of lactation when milk production is at a maximum (3–4 weeks) brings about drastic changes in metabolic activity and endocrine status. There is a decrease in milk lactose and a transient decrease in milk glucose followed by an increase in plasma lactose and glucose (Atwood and Hartmann 1995). This is likely due to alterations in the tight junctions between mammary epithelial cells. In the week following weaning, the mammary alveoli regress (Hacker 1970), and the secretory glandular mass is replaced by adipose tissue in which a new alveolar system will develop in the following pregnancy (Delouis 1986). The absence of stimulation of the mammary glands stops the regular secretion of prolactin (Benjaminsen 1981), while the concentrations of gonadotropic hormones start to increase, allowing ovarian cycles to resume (Stevenson et al. 1981).

Weaning age affects the process of mammary involution because tight junctions between mammary epithelial cells become leaky as lactation advances from 22 to 44 days (Farmer et al. 2007). It was suggested that completion of the functional changes occurring in mammary glands during involution may be required for the gland to redevelop fully in the subsequent lactation (Hurley 1989), but this was never demonstrated.

Physiology of milk production

Lactogenesis

Lactogenesis is the ability of the mammary gland to synthesize milk components such as lactose, casein, and lipids and is often described as a two-phase process. Lactogenesis phase I refers to preparation of the mammary tissue for the synthesis of milk components, and lactogenesis phase II describes the start of milk synthesis and secretion around parturition (Hartmann et al. 1995).

Milk components appear in the alveoli between days 90 and 105 of gestation, indicating the beginning of phase I (Kensinger et al. 1982); however, little secretion can be obtained until parturition. At the end of gestation and during the colostral phase, the junctions between epithelial cells surrounding the alveoli are not tight. This allows serum transudate to leak from the bloodstream into the mammary secretions and milk components from the mammary gland alveoli to leak back to the bloodstream (Figure 18.2). Although serum transudation may contribute to the volume of colostrum obtained by the piglets, its contribution is most likely very short in duration.

During lactation, plasma lactose concentrations are low (<100 mmol/L) (Hartmann et al. 1984), and most of the immunoglobulins present in the mammary secretions are synthesized locally (Bourne and Curtis 1973). Plasma concentrations of milk whey proteins (α-lactalbumin and β-lactoglobulin) are also low during the lactation phase.

The onset of milk component synthesis is closely related to the decline in serum progesterone concentrations at farrowing (Robertson and King 1974; Hartmann et al. 1984). However, exogenous progesterone administration during late pregnancy delays the onset of parturition without inhibiting lactogenesis (Whitely et al. 1990; Foisnet et al. 2010b). Nevertheless, progesterone withdrawal (i.e. lysis of the corpora lutea via prostaglandins) is a major hormonal signal that primes the mammary glands, and withdrawal of colostrum from the glands then triggers the initiation of copious milk secretion (Hartmann et al. 1995).

Relaxin is involved in the onset of parturition since its concentrations always increase before those of progesterone begin to decline at the end of pregnancy. The pre-parturient rise in prolactin followed by the decline in both progesterone and relaxin appears to form important components of the lactogenic hormonal complex (Whitely et al. 1990). Prolactin is a key hormone for the onset of lactation (Tucker 1985). In the pregnant sow, suppression of the prepartum peak of prolactin inhibits subsequent milk production (Whitacre and Threlfall 1981; Taverne et al. 1982; Farmer et al. 1998a).

Colostrum production

Colostrum is essential for piglet survival (Declerck et al. 2016a) as it provides the energy necessary for thermoregulation and body growth (Herpin et al. 2005; Le Dividich et al. 2005), passive immunity needed for

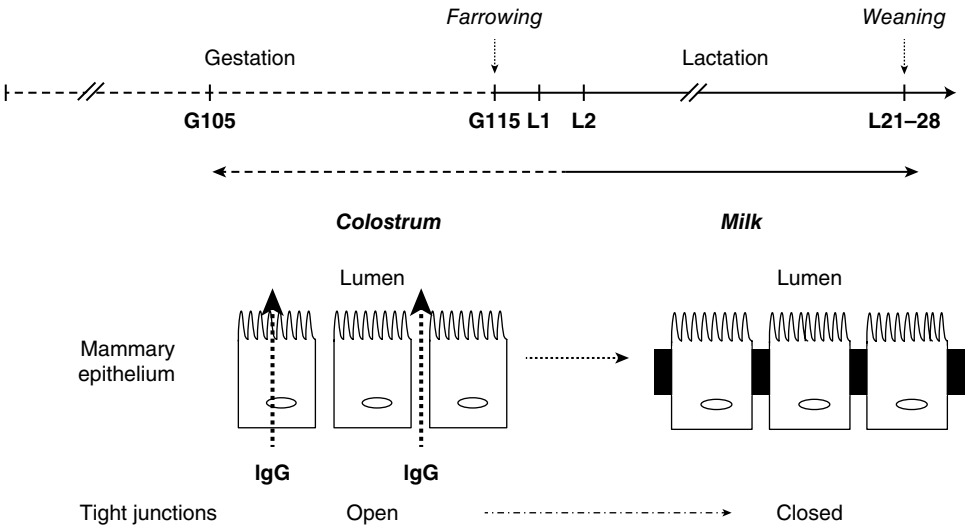

Figure 18.2 Status of mammary epithelial tight junctions in lactogenesis and galactopoiesis. *Source:* Adapted from Foisnet (2010).

Table 18.1 Contents of lipid, protein, lactose, and dry matter in colostrum, transient milk, and mature milk.

	Colostrum					
	Early	Mid	Late	Transient milk		Mature milk
Time postpartum	0 h	12 h	24 h	36 h	3 d	17 d
Chemical composition (g/100 g)						
Lipid	5.1	5.3	6.9	9.1	9.8	8.2
Protein	17.7	12.2	8.6	7.3	6.1	4.7
Lactose	3.5	4.0	4.4	4.6	4.8	5.1

protection against pathogens (Rooke and Bland 2002), and growth factors that stimulate intestinal growth and maturation (Xu 2003).

Colostrum composition

Colostrum is the first secretion of the mammary glands, and it contains more proteins (mainly immunoglobulins), less lipid, and less lactose than milk (Table 18.1; Theil et al. 2014a). During the colostral phase, lactose is present in high concentrations (>200 mmol/L) in the plasma of sows (Hartmann et al. 1984), and immunoglobulins (mainly IgG) found in mammary secretion originate from the plasma (Salmon et al. 2009). The transition between colostrum and milk occurs between 24 and 36 hours after the onset of parturition and is characterized by a drop in immunoglobulin concentrations with concomitant rises in fat and lactose (Table 18.1; Theil et al. 2014a).

Colostrum composition is affected by various sow and litter factors. A study using 10 commercial herds showed that colostral fat differs depending on breed, parity, and number of live-born piglets, whereas colostral protein and lactose are not affected (Declerck et al. 2015). Attempts were made at altering colostrum composition via sow management (see review by Farmer et al. 2006), and nutrition is undoubtedly the most successful tool since dietary fat affects both colostral fat content and composition.

Colostrum yield and quality

It is quite difficult to quantify colostrum yield because there is no direct measure. The most commonly used method is to obtain birth weight and individual weight gains of piglets for a specific period in early lactation and to fit these into a prediction equation (see details in Devillers et al. 2004; Theil et al. 2014b). However, this is labor intensive and requires being present at farrowing. It was established from a number of studies that sow colostrum yield is very variable and ranges between 2 and 5 kg over the first 24 hours postpartum for a litter of 8–12 piglets (see review by Farmer et al. 2006), with an average of approximately 3.3–3.6 kg (Devillers et al. 2007; Foisnet et al. 2010b; Quesnel 2011; Decaluwé et al. 2013, 2014b). Quesnel et al. (2012) indicated that piglets need to ingest a minimum of 200 g of colostrum during the first 24 hours after birth to have significantly lower preweaning mortality, acquire adequate passive immunity, and show a slight weight gain. A consumption of 250 g was recommended for piglets to achieve good health and pre- and post weaning growth. Findings using a more recent model suggest that this value is underestimated by approximately 30%, so that a minimum consumption of 325 g would be more adequate (Theil et al. 2014b).

The IgG content of colostrum is usually measured with methods that are time consuming and expensive for everyday use on the farm. Recent data suggest that a Brix refractometer could be a practical and valid method to assess colostrum IgG content in swine. It may be used during the early parturition to measure IgG levels when peak values are expected (Hasan et al. 2016). However, there are great variations between herds, indicating a significant impact of herd management (Hasan et al. 2016), and even within herds due to sow-to-sow variation (Farmer and Quesnel 2009).

Factors affecting colostrum yield

Colostrum yield over the first 24 hours postpartum is not correlated with litter size and litter birth weight and is only moderately related with litter vitality at birth (Le Dividich et al. 2005; Devillers et al. 2007; Quesnel 2011; Decaluwé et al. 2014a; Declerck et al. 2015). On the other hand, it is positively correlated with mean piglet birth weight and negatively correlated with within-litter variation in birth weight (Devillers et al. 2007; Quesnel 2011). Results suggest that colostrum yield may be influenced by general vitality of the litter at birth, i.e. the ability to reach and extract colostrum from the udder (Quesnel et al. 2015; Declerck et al. 2015). Yet, the capacity of the sow to produce colostrum also limits intake by piglets (Devillers et al. 2004).

Various nutritional, hormonal, and environmental factors affect colostrogenesis in swine (Farmer and Quesnel 2009), and it is beyond the scope of the present chapter to cover all these. One important factor is the endocrine status of the sow. Delays in progesterone decrease and prolactin increase relative to farrowing are associated with reduced colostrum yield (Foisnet et al. 2010a). Furthermore, the relative concentrations of prolactin and progesterone prepartum influence colostrum yield (Loisel et al. 2014).

An injection of azaperone at the time of expulsion of the placenta was shown to facilitate nursing behavior, increase colostrum intake by piglets (Biermann et al. 2010), and, consequently, improve piglet conditions (Miquet and

Viana 2010; Tseng et al. 2010). Parity affects colostrum yield with older sows (parity 4 and more), producing less colostrum than younger sows (Devillers et al. 2007; Decaluwé et al. 2013; Quesnel et al. 2015). Backfat gain during the last week of pregnancy appears to be positively correlated with colostrum yield, whereas backfat gain between days 85 and 109 of gestation seems to be negatively correlated with colostrum yield (Decaluwé et al. 2013).

Milk ejection

During parturition and the first hours afterward, colostrum is continuously available. At parturition, distension of the cervix for the passage of the piglets, triggering Ferguson's reflex, and movements of the sow lead to oxytocin release from the pituitary so that colostrum is available (Fraser 1984; Castren et al. 1989). After parturition, nursing can be divided in five phases: initiation, pre-ejection teat massage, milk ejection, post ejection massage, and termination of nursing. In early lactation the sow is usually initiating the nursings by vocalization (grunting). This is followed by piglets assembling at the udder for pre-ejection teat massage, which takes up to 3 minutes. Actual milk letdown then takes place with milk ejection lasting no longer than 20 seconds. This is followed by post ejection teat massage lasting several minutes (Spinka and Illmann 2015).

Following parturition, nursings are progressively developed until cyclic letdowns occur around 10–12 hours after the start of parturition (de Passillé and Rushen, 1989b; Devillers et al. 2006, 2007). Colostrum ejections are as frequent as every 10–20 minutes, and the period of high intramammary pressure permitting colostrum withdrawal may be sustained for a minute or more. Once 50–100 mL of colostrum is removed, the intramammary pressure is reduced to the point that further withdrawal is difficult (Fraser 1984). After the colostral phase, and for the rest of lactation, milk ejections are cyclical and actively synchronized by sow gruntings (Lewis and Hurnik 1985; Castren et al. 1993; Chaloupková et al. 2007). The removal of milk from the alveoli and ductal system of the mammary glands requires a neuroendocrine milk ejection reflex. This is elicited by piglets massaging the udder (Fraser 1980) and stimulating release of oxytocin, leading to milk ejection (Hartmann and Holmes 1989). Oxytocin stimulates the contraction of myoepithelial cells surrounding the alveolar lumen to force milk through the ductal system to the teats (Ellendorf et al. 1982). Udder stimulation is needed to trigger oxytocin release (Algers et al. 1990), but growth rate of piglets is not affected by the peak amplitude in intramammary pressure (Kent et al. 2003) that is linked to oxytocin levels. The increase in circulating oxytocin concentrations can occur up to 30 seconds before milk ejection (Ellendorf et al. 1982), which lasts only 10–20 seconds (Fraser 1980).

Not all nursing attempts are successful during lactation. Failed nursing attempts may affect some or all piglets in the litter. Among the latter, one must distinguish between sucklings terminated by the piglets and those terminated by the sow (Illmann and Madlafousek 1995). Unsuccessful sucklings affecting the whole litter become more frequent after the colostral phase (Castren et al. 1993; Fraser 1977). These are characterized by an absence in rise of intramammary pressure associated with no increase in plasma oxytocin (Ellendorf et al. 1982). During the first 10 days of lactation, the proportion of unsuccessful sucklings is between 20 and 40% (Fraser 1977; Jensen et al. 1991). Although frequent and requiring energy expenditure from the piglets, ejection failures may still play a role in maintaining lactation (Algers 1993) because plasma concentrations of lactogenic hormones tend to rise after an unsuccessful nursing (Rushen et al. 1993). Rushen et al. (1995) demonstrated that external stress, such as placing sows in a novel environment, increases the chance that the subsequent nursing attempt will fail. This was not due to increased concentrations of cortisol or adrenocorticotropic hormone (ACTH), but was more likely caused by an opioid-mediated inhibition of oxytocin. Another useful indicator of nursing success is when nursings are terminated by the sow instead of the piglets. Recent data suggests that at 4–6 weeks of lactation, sows terminate nursings approximately every hour, whereas piglets terminate nursings only once in 4–5 hours (Thomsson et al. 2016).

Measuring milk production

Measuring milk production in the sow is difficult because of the small and numerous teats and because milk is not available continually after the colostral phase. Milk ejection must therefore be stimulated with exogenous oxytocin. There are three ways to quantify sow milk yield, namely, using the weigh–suckle–weigh technique, the deuterium oxide (DO) dilution technique, or a prediction based on piglets or litter weight gains. The weigh–suckle–weigh implies that piglets are weighed before and after suckling seven to eight times over a 24 hour period and values are extrapolated to obtain daily milk production (Salmon-Legagneur 1965; Mahan et al. 1971). A major drawback is that one must estimate the losses due to urination and defecation between the weighings; hence milk yield may be underestimated. Milking machines are reported to give more repeatable estimates of milk production and were used to compare milk production between teats (Fraser et al. 1985) and breeds (Grun et al. 1993a). However, they are not available commercially. The DO dilution technique quantifies the water intake from colostrum by piglets. It is most accurate (Theil et al. 2007), yet its cost is exuberant and it is very labor intensive. The third method is most often

used. It estimates milk yield based on piglet growth (Noblet and Etienne 1989). However, it is essential to standardize litter size and ensure that piglets do not have access to solid feed. The amount of milk required per gram of piglet weight gain was first reported to be approximately 4.5 g (Lewis et al. 1978; Noblet and Etienne 1989). It was later shown to be affected by stage of lactation, being 3.8 g on day 3, 4.6 on day 10, and 4.9 on day 17 (Theil et al. 2002).

Pattern of milk production

Sow milk production is usually described in four phases: the colostral, ascending, plateau, and descending phases. Typical sow milk production curves are presented in Figure 18.3 (Toner et al. 1996) and are similar to those presented by others (Noblet and Etienne 1986; Shoenherr et al. 1989; Grun et al. 1993b; Hansen et al. 2012). As mentioned previously, mammary secretions are available continuously during the early colostral phase to then be episodic in release. During the ascending phase, nursing frequency doubles, going from 17 to 35 per day (Jensen et al. 1991), and the amount of milk obtained at each nursing increases from 29 to 53 g between the first and third week of lactation (Campbell and Dunkin 1982). The end of the ascending phase ranges from 10 to 28 days postpartum, its timing likely related to differences in breed, nutrition, and parity of the sows (Elsley 1971; Harkins et al. 1989; Toner et al. 1996; King et al. 1997).

During the plateau phase, piglet growth is limited by an insufficient milk supply (Reale 1987; Wolter et al. 2002), which is magnified by longer lactation and larger litters. Indeed, milk production is proportional to the number of suckled mammary glands (Auldist et al. 1998). In a 21-day lactation, the growth limitation of suckling piglets can be more than 2 kg per pig (Harrell et al. 1993). Most sows in commercial swine units do not reach the descending phase because weaning is done before 28 days of lactation.

Control of milk production

Milking frequency

Cyclical nursings start approximately 10 hours after the onset of farrowing (Lewis and Hurnik 1985) and develop gradually (Algers and Uvnäs-Moberg 2007). Nursing frequency has a major role in determining milk output. It reaches a maximum around days 8–10 of lactation and decreases thereafter (Puppe and Tuchscherer 2000). Nursing intervals of 36–40 minutes were reported in early lactation (days 5–6) and of 39–48 minutes in later lactation (days 18–20) (Farmer et al. 2001; Fisette et al. 2004). Nursing frequency appears similar in day and night on day 10 of lactation, whereas it decreases during the night after day 17 (van den Brand et al. 2004).

Suckling and milk removal are the major stimuli for mammary growth (Hurley 2001; Farmer 2013) and milk output (Sauber et al. 1994; Auldist et al. 2000) during lactation. The stimulus of piglets suckling or massaging the mammary glands leads to increases in circulating prolactin, a galactopoietic hormone (Spinka et al. 1999; Farmer 2001). Refilling of the mammary glands is almost complete within 35 minutes after suckling (Spinka et al. 1997), which emphasizes the importance of shorter nursing intervals to maximize total milk yield. Milk stasis in alveolar spaces triggers the end of lactation and involution of alveoli (Boyd et al. 1995). It causes an increase in intramammary pressure, which reduces blood flow to the tissue (Hurley 2001).

Sows within a farrowing room will synchronize their nursings (Wechsler and Brodmann 1996) due to the auditory stimulus from the other animals. Recorded sow suckling grunts can stimulate nursings (Stone et al. 1974), but effects of playing recordings at 35–42 minute intervals on piglet growth were only minor in a commercial farrowing house setting (Cronin et al. 2001; Fisette et al. 2004). Sow nutrition (feeding level or energy source) does not affect nursing frequency (van den Brand et al. 2004), but sow breed has an effect. The interval between nursings is shorter for Meishan-derived sows than for European white sows (Farmer et al. 2001; Fisette et al. 2004).

Hormonal control

The activation by piglets of neural receptors within the mammary glands stimulates oxytocin from the posterior pituitary as well as the release of prolactin, growth hormone (GH), ACTH, and thyroid-stimulating hormone from the anterior pituitary. Hormones from the anterior pituitary maintain the synthesis of milk from the mammary epithelial cells (Delouis 1986).

The role of GH for milk production is both direct, as a regulator of nutrient partitioning for milk component synthesis, and indirect, via IGF-1 that acts upon the mammary epithelial cells (Flint and Gardner 1994). In lactating sows, a reduction in circulating concentrations

of GH and IGF-1 by immunization against GH-releasing factor significantly decreased milk yield, yet growth rate of piglets was unaltered (Armstrong et al. 1994), suggesting that GH may have a facilitative rather than an essential role. Mammary transgenic overexpression of IGF-1 in sows also did not affect their milk yield (Ruan et al. 2005).

When the secretion of prolactin was systematically inhibited during various weeks of lactation, weight gain of piglets was suppressed (Farmer et al. 1998a); hence prolactin is considered essential for the maintenance of lactation in swine. Indeed, Plaut et al. (1989) showed that the binding of prolactin to its mammary receptor is a major effector of milk production in sows.

Thyroid hormones are required for various metabolic functions and for protein synthesis by the mammary gland (Tucker 1985). Yet, their role for lactation in swine has not been demonstrated. When thyrotropin-releasing factor was injected to lactating sows, prolactin concentrations were increased, but lactation performance was not altered (Dubreuil et al. 1990).

Water availability

Water intake increases from approximately 1 L/hour at the end of gestation to 2.6 L/hour 12 hours before the end of parturition (Klopfenstein 2003). It can be very low (less than 10 L/day) in some sows during the first 24 hours following parturition. After this period of transition, it increases gradually to reach 20–35 L/day during lactation (Figure 18.4a). The increased water intake just prior

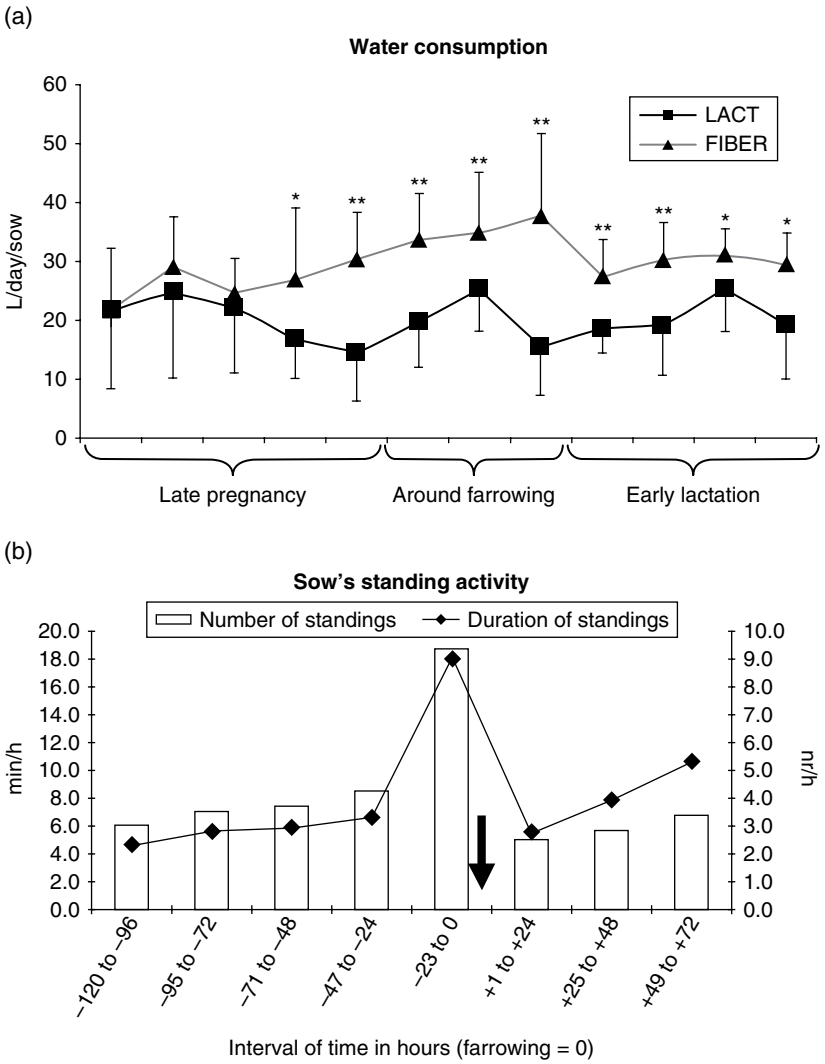

Figure 18.4 (a) Individual average daily water intake of sows fed a lactation diet low (3.8%) in crude fiber (LACT) and high (7%) crude fiber (FIBER) diet before farrowing. *Source:* Adapted from Oliviero et al. (2009). Reproduced with permission of Elsevier. The asterisk symbols indicate the power of statistical results (*0.05 and **0.01). Reproduced with permission of Elsevier.

to farrowing is partly due to greater water needs. During the hours preceding parturition, there is a rapid increase in water content of the reproductive system to allow the process of parturition (Dobson 1988). Water intake can be increased via greater dietary fiber during the transition period (Figure 18.4a, Oliviero et al. 2009).

Composition of sow milk

Sow milk contains more than 100 chemical components (reviewed by Xu 2003). The major components are water, lactose, proteins (casein, alpha-lactalbumin, beta-globulins, serum albumins, immunoglobulins), lipids, lactocytes, leukocytes, bivalent ions (calcium, phosphorus, and magnesium) and electrolytes (sodium, potassium, and chloride). The relative concentrations of these components vary according to the stage of lactation (Table 18.2). During the first 24 hours after parturition, lacteal secretions contain more immunoglobulins, microminerals, vitamins, hormones, and growth factors and lower concentrations of lactose than in later lactation (Table 18.2). Wu et al. (2010) reported that concentrations of immunoglobulins and lactoferrin are greater in milk from anterior glands than from posterior glands. Diet may have an impact on the concentrations of some milk components such as fat, fat-soluble vitamins, minerals, and fatty acids (Hurley 2015).

Somatic cells of normal and mastitic milk

The somatic cell count (SCC) of mammary secretions from healthy sows is 1–4 million cells/mL (Evans et al. 1982; Schollenberger et al. 1986; Hurley and Grieve 1988; Magnusson et al. 1991; Drendel and Wendt 1993; Klopfenstein 2003), compared with less than 100,000 cells/mL in cows (Smith et al. 2001). Milk somatic cells are primarily leukocytes and epithelial cells shed from the lining of the mammary glands (Harmon 1994). The relative concentrations of the various cell types vary with stage of lactation. During the colostral phase most cells are leukocytes (>98%), whereas during the rest of lactation (days 7, 14, and 28), they are predominantly epithelial cells (Evans et al. 1982; Schollenberger et al. 1986; Magnusson et al. 1991).

The SCC found in milk of infected mammary glands is similar to that observed during the colostral phase or during mammary involution (Drendel and Wendt 1993). Somatic cells found in milk of infected glands are mainly leukocytes (>75%). During sow lactation, a cellular content over 12 million cells/mL with an increased proportion of leukocytes is suggestive of mammary gland alteration. Persson et al. (1983) used SCC in mammary secretions to differentiate subclinical from clinical cases of mastitis; however, the use of SCC as a diagnostic tool has no practical clinical application due to lack of sensitivity, specificity, and low predictive value.

Table 18.2 Variation of sow milk composition (mean ± SD) between the first days (days 1–2) and the plateau phase (days 10–15) of lactation.

	Day	Day

Manipulation of milk production

Feeding strategies

It is generally accepted that sows should maintain their body condition throughout the reproductive cycle (Einarsson and Rojkittikhun 1993). This is difficult due to increasing litter sizes and milk production (Foxcroft et al. 2007) and because low parity sows are expected to gain weight and grow over the first two parities. Top priorities for nutrient use by sows are fetal growth, colostrum production, mammary growth, and milk production (Theil et al. 2014a). Toward the end of gestation, important targets for sow nutrition can be set, such as maximizing energy intake of newborn piglets (Theil et al. 2014a) and minimizing piglet weight variation (Campos et al. 2012). Sows that are catabolic one week prior to farrowing seem unable to produce colostrum to their full potential (Decaluwé et al. 2013). Colostrum yield and composition appear optimal when sows enter the farrowing unit with a moderate body condition and are provided a high amount of feed peripartally (Decaluwé et al. 2014b). Maximizing energy intake of piglets through colostrum is a challenge because an increasing proportion of piglets (current estimation of 30%) in hyperprolific sows may not ingest enough colostrum (Foisnet et al. 2010a; Decaluwé et al. 2013; Declerck et al. 2015). Common recommendations are either a stepwise feed increment protocol in early lactation to avoid drops of feed intake during any part of lactation (Koketsu et al. 1996a,b; Soede and Kemp 2015) or ad libitum feeding with a step-down response if a drop in feed intake is observed. Milk production requires substrates derived from the diet and the sow's body reserves, the relative importance of which changes as lactation progresses. Body reserves might be sufficient in early lactation to compensate for inadequate nutrient intake, but not in late lactation (Pettigrew 1995). Accordingly, severe restriction of feed intake during lactation has no impact on litter growth in the first week postpartum, whereas it markedly decreases litter growth in later lactation (Mullan and Williams 1989; Pettigrew 1995). The magnitude of reduction depends on the dam's body reserves at farrowing; gilts with lower body reserves are affected most (Mullan and Williams 1989). Feed restriction during lactation may also lead to subsequent problems in the weaning-to-estrus interval, ovulation rate, and embryo survival.

The intake of protein/amino acids by gestating and lactating sows is critical for lactation performance. Lysine is the first limiting amino acid for lactating sows, with 26 g of dietary lysine needed per kg of litter growth/day (Sohn and Maxwell 1999). To achieve a zero protein (nitrogen) balance, Dourmad et al. (1998) demonstrated that 45–55 g/day of crude lysine is required for normal and high-yielding sows, respectively. Exceeding recommended protein values in the diet may decrease feed intake; however, in young sows, when demand for protein is at its highest, a further increment may be warranted (Smits et al. 2012; Soede and Kemp 2015). Valine and isoleucine, but not leucine, appear to increase milk production as indicated by increased litter weight gain (Kerr 1997, as cited by Sohn and Maxwell 1999). These amino acids can be metabolized to succinyl-CoA and potentially serve as a source of energy for the mammary gland (Sohn and Maxwell 1999).

Using studies designed to determine the relation between milk production and dietary energy, Williams (1995) noted that each suckling piglet grows an extra 1 g/day for each MJ of metabolizable energy consumed by the sow. Matzat et al. (1990) showed a linear relationship between milk output and energy intake of sows, whereas Pluske et al. (1995b) demonstrated that piglet growth did not respond beyond 75 MJ of metabolizable energy in gilts. Such a ceiling for lactational performance was also observed in first-parity sows offered increasing amounts of protein (King et al. 1993).

Various feeding managements were used to maximize lactational feed intake of sows and allow sufficient lean tissue gain during pregnancy in order for milk production not to be compromised. Increasing sow feed consumption by 8% with wet feeding had no impact on average daily gains (ADG) of piglets over an 18-day lactation period (Genest and D'Allaire 1995). Similarly, feeding a bulky diet in gestation increased lactational feed intake of sows by 8% without improving litter weight (Farmer et al. 1996). Increasing daily feeding frequency from 2 to 3 (Genest and D'Allaire 1995) or 2 to 4 (Farmer et al. 1996) during lactation also had no effect on feed intake. However, the use of self-feeders, whereby sows may visit the feeder up to 13 times a day, increased lactation feed intake by 10% (Hoofs and Elst-Ter Wahle 1993; van der Peet-Schwering et al. 2004; Peltoniemi et al. 2009). The addition of fat to the sow's diet did not lead to a less negative energy balance in the sows but resulted in fatter piglets when sows were fed at a high feeding level (van den Brand et al. 2000). Lactation diets with more fat may offer additional benefits under hot conditions by increasing energy intake without compromising sow comfort (Soede and Kemp 2015).

Exogenous hormones

An early study showed that exogenous GH in lactation increased milk yield by 15–22% (Harkins et al. 1989), but those results could not be reproduced (Michelchen and Ender 1991; Smith et al. 1991). A greater feed efficiency in sows was consistent in all studies.

Sows with spontaneous lactation failure have abnormally low concentrations of prolactin (Whitacre and Threlfall 1981), and a single injection of porcine prolactin to gilts (but not sows) on day 1 of lactation led to an 8% increase in litter weight gain (Dusza et al. 1991).

Prolactin injected from day 107 of gestation through lactation had no effect on milk yield (Crenshaw et al. 1989; King et al. 1996), perhaps because injections were started before there were piglets to remove milk from the mammary glands, leading to premature involution of the secretory units (Boyd et al. 1995). Prolactin injected to sows daily from days 2 to 23 of lactation did not improve piglet growth rate (Farmer et al. 1999), likely because most prolactin receptors were saturated in control sows, thereby preventing any beneficial effects of increased prolactin concentrations. Prolactin is under negative dopaminergic control, and the dopamine antagonist domperidone was used to increase secretion of prolactin in late-pregnant sows. Twice-daily feeding of domperidone from 90 to 110 days of gestation accelerated mammary cell differentiation and increased sow milk yield by more than 20% (VanKlompenberg et al. 2013), offering an avenue that merits further investigation.

Sow behavior

Sow behavior can be used to monitor their status (Oliviero et al. 2008a) and to identify animals at risk for postpartum dysgalactia syndrome (PDS). Although eating activity of sows decreases in the 24 hours preceding parturition, healthy animals seldom go completely off feed (Peltoniemi et al. 2009; Quesnel et al. 2009), whereas sows contracting PDS often go completely off feed. Loss of appetite is part of a general response to systemic inflammatory mediators (cytokines and interleukins) that may be stimulated by endotoxins (lipopolysaccharides). Products of inflammation induce fever and promote immune functions for the body to recover (Johnson 2002; Weary et al. 2009). Water intake substantially increases prior to parturition, and a decrease in water intake may be taken as a sign of greater risk of PDS. Piglets that spend more time nuzzling the udder of the sow is an indication of hunger, malnourishment, and perhaps PDS, leading to a greater risk of being crushed by the dam (Weary et al. 1996).

Under natural conditions, sows isolate themselves from the rest of the group for building a nest during the last 24 hours of pregnancy. After parturition, they stay close to the nest and piglets for the first day, leave the nest temporarily in search for food during the first week, and eventually abandon the nest with the piglets after 10 days (Jensen 1986; Stangel and Jensen 1991; Jensen et al. 1993). In confinement, the number and duration of standing incidences increase considerably (Figure 18.4b) the day before parturition. In the first 24 hours after farrowing, sows are inactive; their activity increases daily thereafter. After day 3, sows gradually spend less time in lateral recumbency (Oliviero et al. 2009).

Nursing behavior changes over lactation and is likely related to the milk supply. Piglets suckle for the first time within 20–40 minutes of birth (Tuchscherer et al. 2000; Vasdal et al. 2011; Balzani et al. 2016a). In the early colostral phase, mammary secretions are continuously available, but availability becomes cyclical later on (de Passillé and Rushen 1989a). Within 48–72 hours postpartum, piglets establish a teat order whereby each piglet consistently sucks from one or two specific teats (Fraser 1976; de Passillé et al. 1988).

In the first days after parturition, milk production exceeds the needs of piglets, and most (>85%) of the sucklings are initiated by the sow and are terminated by the piglets. When milk supply becomes limiting (weeks 3–4), most sucklings are initiated by the piglets and terminated by the sow (Jensen 1988; Jensen et al. 1991). Sows terminate suckling by leaving the piglets or by limiting teat access by lying on their belly (de Passillé and Rushen 1989b). Both the duration and intensity of teat stimulation by individual piglets influence milk production during the first 3 days of lactation (Algers and Jensen 1991), and nursing frequency also affects piglet weight gain (Spinka et al. 1997; Auldist et al. 2000; Valros et al. 2002).

Piglet growth

The main energy source for piglets over the first 12 hours postpartum is colostrum, followed by glycogen reserves until day 2 when milk becomes their sole energy source (Theil et al. 2014a). The efficacy of conversion of milk into live weight gain ranges from 3.5 to 4.2 (Noblet and Etienne 1986; Beyer et al. 1994; Pluske et al. 1998; Le Dividich et al. 2007) and is lower in restricted-fed piglets due to a greater proportion of intake devoted to maintenance (Le Dividich et al. 2007). Energy and nitrogen in sow milk have an apparent digestibility of approximately 98% (Le Dividich et al. 2007) and digestibilities of colostral lactose and fat approximate 100% (Le Dividich et al. 1994b).

Piglets that are bottle-fed with colostrum in the first 24 hours after birth have a voluntary intake exceeding 450 g/kg of birth weight, being twice the average consumption of sow-reared piglets (210–370 g/kg of birth weight), which suggests the sow is limiting colostrum intake by the piglets. However, 60–88% of sows produce enough colostrum to ensure survival of their litters since an intake of 160 g of colostrum per kg of birth weight is required for piglet survival.

Colostrum intake has lifelong effects on piglet growth. A study using multivariable analyses, correcting for the effect of birth weight, demonstrated that colostrum intake affects weaning weight as well as weight at the onset and end of the fattening period, with effects more pronounced in lightweight piglets (Declerck et al. 2016a). From birth to weaning, piglets from larger litters tend to

be lighter than piglets from smaller litters (Dyck and Swierstra 1987; Van der Lende and de Jager 1991; Le Dividich et al. 2004; Declerck et al. 2016a). This is mainly due to differences in piglet birth weight and/or lower milk supply per piglet in large litters later in lactation. Hyperprolificacy affects growth rate because the number of live piglets exceeds the number of mammary glands and low birth weight piglets are often less vigorous for nursing.

Growth rate, usually measured as ADG, is directly related to individual piglet weight at birth (Tyler et al. 1990; Castren et al. 1991; Le Dividich et al. 2004). When piglet weights are corrected for birth weight, the effect of litter size is absent on day 3, is small on day 7, and becomes greater as lactation proceeds (Klopfenstein 2003). Klopfenstein (2003) also showed that milk production becomes a limiting factor for piglet growth when the sow has reached her maximal milk production capacity (days 10–15).

Heterogeneity or variation of piglet birth weights within a litter is an increasing concern. As litter size increases from less than 10 to more than 15, mean litter birth weight decreases by 0.5 kg, and the coefficient of variation (SD/mean) increases by 10% to reach 24%. For a given sow, there is no repetition of the coefficient of variation in subsequent parities (Quesnel et al. 2008). Homogeneity is greater in young sows (parities 1 and 2) than in older sows (Table 18.3) in both normoprolific (Bolet and Etienne 1982) and hyperprolific sows (Quesnel et al. 2008) regardless of litter size, thereby indicating a parity effect that is important because the majority of published scientific data used young sows. The loss of body condition during the previous lactation and body condition in early gestation both have an impact on heterogeneity of piglet birth weights (Hultén et al. 2002; Wientjes 2013). Heterogeneity increases as sows are heavier at mating or farrowing.

The correlation between mammary gland wet weight and ADG of piglets is high, from 0.59 to 0.68 (Nielsen and Sorensen 1998; Kim et al. 2000), and significant correlations also exist between ADG of suckling piglets and mammary cell number and secretory activity per cell (Farmer et al. 2010a). This suggests a strong relationship between pig growth and mammary size. The milk production differences between mammary glands are believed to be a major source of variation in piglet weight gain (Fraser and Jones 1975). Mammary glands have different shapes depending on their anatomical location, with the anterior and middle glands only being able to expand laterally and medially, hence lacking space to grow, whereas posterior glands may be better able to expand elliptically in a longitudinal manner. Newborn piglets show preferences for certain teats and will choose the upper row of the anterior or posterior part of the udder more frequently than the middle section of the udder or the lower row (Balzani et al. 2016b). Scheel et al. (1977) showed that pigs with greater birth weight had a preference for anterior glands, but Hemsworth and Winfield (1976) and Kim et al. (2000) showed no significant relationship between birth weight of pigs and the preference for mammary glands. Overall, pigs nursing the well-developed anterior and middle mammary glands have a greater ADG than pigs nursing the remaining glands.

Piglet mortality

Despite improved production efficiency in modern swine production, piglet losses at birth and during lactation increase as litter size increases (Boulot et al. 2008). Neonatal mortality averages over 15%, and the vast majority of these deaths occur during parturition or the first 3 postnatal days (English and Morrison 1984; Dyck

Table 18.3 Effect of parity (P) on piglets' characteristics at birth (French observations on 1596 litters from a single herd).

	P1	P2	P3–4	P5–6	P7+

and Swierstra 1987; de Passillé and Rushen 1989b; Le Cozler et al. 2004; Oliviero et al. 2008b; Edwards and Baxter 2015). Leading causes of death in the neonatal piglet include stillborn, crushing by the sow and low viability/starvation (Vaillancourt et al. 1990; Koketsu et al. 2006; Oliviero et al. 2009). The effect of litter size on mortality is quadratic, with piglet losses increasing in larger litters (Fahmy and Bernard 1971; Dyck and Swierstra 1987; Guthrie et al. 1987; Boulot et al. 2008), and is probably related to an insufficient number of functional mammary glands (Chertkov 1986; Bilkei et al. 1994). Lower birth weight piglets also have poor thermoregulation since their skin surface/kg body weight is greater than for heavier piglets. They may also be less mature at birth therefore they may be more susceptible to disease or have a slower start due to compromised colostrum and milk intake (Edwards and Baxter 2015). Greater colostrum intake is associated with lower mortality rates of suckling and weaned piglets (Declerck et al. 2016a). Energy deficit is one of the main predisposing risk factors for piglet mortality, and it was recently shown that energy supplementation could be a way of increasing survival of lightweight piglets (Declerck et al. 2016b).

Immune protection of the piglet

Newborn piglets rely on ingestion of colostrum for passive transfer of immunity (Bourne 1976), and up to a third of piglets in litters from hyperprolific sows may not ingest adequate amounts of colostrum. Management strategies are therefore needed to maximize colostrum intake, especially for small piglets and piglets born late in the birth order. Split suckling, where early-born and heavier piglets are separated from the udder to allow the small and late-born piglets to suckle, is one such management tool. Another practice is cross-fostering, where litters are standardized within the first 24 hours after parturition (Edwards and Baxter 2015). The absorption of immunoglobulins from colostrum stimulates the closure of the intestine for the passage of these large proteins (Klobasa et al. 1991) within 48 hours after birth. Le Dividich et al. (2004) showed that colostrum IgG content decreases by 31% within 3 hours after birth of the first piglet. Passive immunity in 48-hour-old piglets was 50% greater in the first than in the last-born piglet, and the difference remained significant at weaning. Piglets artificially reared and receiving 6 hourly feedings of 25 mL of sow colostrum followed by hourly feedings of cow's milk had plasmatic immunoglobulin concentrations similar to those of naturally fed piglets at 24 hours of age (Klobasa et al. 1991). Increasing the number of hourly feedings of colostrum from 6 to 12, 18, or 24 did not increase the concentrations of plasma immunoglobulins in piglets. Fasting newborn piglets for periods of up to 24 hours after birth before giving them access to their first colostrum intake did not decrease concentrations of serum immunoglobulins 12 and 18 hours after feeding (Klobasa et al. 1990). Therefore, closure of the gut system for the passage of immunoglobulins is dependent on the quantity of colostrum ingested rather than on time since birth. Six feedings of colostrum should be sufficient to give adequate immune protection to the piglets.

Studies based on radioactive labeling of immunoglobulins in colostrum showed that almost 100% of IgG, 40% of IgA, and 85% of IgM are derived from sow serum (Bourne and Curtis 1973). IgG is preferentially transferred from the blood into mammary secretions during colostrogenesis, resulting in a marked decrease in sow serum IgG levels at this time. This seems to take place both through transudation and by specific receptor-mediated transport (Schnulle and Hurley 2003; Devillers et al. 2004). The uptake of colostral immunoglobulins in neonatal piglets may not be mediated by a receptor, although FcRn is present in gut epithelial cells. Indeed, IgG, IgM, and IgA (not secretory IgA) undergo selective transcytosis into enterocytes (Devillers et al. 2006).

The quantity of IgG ingested by each piglet is affected by birth order due to the rapid changes in colostrum composition taking place between onset of farrowing and birth of the last piglet (Klobasa et al. 2004; Le Dividich et al. 2004). Piglets dying before weaning had lower plasma immunoglobulin concentrations after parturition (Hendrix et al. 1978; Tyler et al. 1990); yet this association disappears when birth weight is used as a covariate (Tyler et al. 1990). Moreover, the probability of dying is not increased among last-born piglets, even though they obtain less immunoglobulins than firstborn piglets (Le Dividich et al. 2004). These results, although surprising, suggest that most mortalities are the consequence of inadequate ongoing milk intake rather than infectious diseases.

Mastitis and postpartum dysgalactia syndrome (PDS)

Mastitis may be limited to one or a few mammary glands (uniglandular mastitis) or may involve all mammary glands (i.e. multiglandular effects, hard udder syndrome). Acute mastitis is usually accompanied by systemic and local signs, whereas the hard udder syndrome does not have systemic signs in the sow. Both conditions occur mainly within the first 3 days of parturition and rapidly lead to piglet starvation. It can be difficult to differentiate between acute multiglandular mastitis and the hard udder syndrome. Post weaning or dry-sow mastitis usually affects one or a few glands, but drying off mastitis is uncommon in sows (compared with cows). Chronic mastitis is characterized by the formation of abscesses

and granulomas in the mammary tissue, usually seen at the time of weaning or shortly after (Hultén et al. 2003). Common environmental bacteria can enter the mammary glands through teat wounds inflicted by piglets during suckling, by entry from traumatic wounds of sows that are group-housed post weaning, or by trauma associated with the particular anatomy of inguinal mammary glands of old sows.

PDS is a general term to describe a pathological condition in the postpartum sow characterized by insufficient colostrum and milk production, leading to growth retardation, starvation, and/or mortality of the piglets.

Mastitis

Acute or chronic uniglandular mastitis is common in lactating or weaned sows and is most often seen in older sows and in inguinal glands. The microorganisms involved are the same as in acute multiglandular mastitis. Important risk factors are traumatic lesions to teats and glands or inaccessibility of teats to piglets. Piglets suckling inguinal mammary glands of old sows are often unable to reach the teat during milk ejection, and a nonsuckled mammary gland is a candidate for infection. Usually, piglets have selected a specific gland by 24–72 hours after birth; hence a piglet suckling an affected gland will show growth retardation, while littermates retain a normal growth. Milk secretion may be restricted by acquired problems of mammary conformation (as in old sows), traumatic lesions, or other teat abnormalities such as blind teats. Since teat lesions and blind teats may develop anytime, integrity of the mammary glands should be checked before each farrowing.

Traumatic teat lesions can be the consequence of injuries induced by piglets, other sows, or trauma from the environment. Cranial teats appear to be more at risk of trauma than other teats (Hultén et al. 2003). Unfortunately, primary lesions often go unnoticed; hence the gland is lost for the ongoing lactation(s). In that case, the number of nursing piglets should be limited to functional glands, or the sow should be culled. Gerjets et al. (2011) found the following to be risk factors for coliform mastitis (CM) in a case–control study: a greater number of piglets born alive and stillborn piglets, gilts compared with older sows, and birth interventions.

Mastitis is a pathological entity. Infected glands have inflammation, edema, and skin congestion with fever (>40.3–40.5 °C) and anorexia in the sow (Van Gelder and Bilkei 2005). Mastitis can affect individual, multiple, or all mammary glands. Gram-negative coliform (*Escherichia*, *Enterobacter*, *Citrobacter*, and *Klebsiella)* bacteria are most frequently isolated from mastitis-affected sows (Klopfenstein et al. 2006), with gram-positive bacteria (*Streptococci*, *Staphylococci*, *Aerococcus* spp.; Menrath et al. 2010) being less frequent. Pyogenic organisms (*Trueperella*, *Streptococci*, *Staphylococci*) can be isolated from chronic infections. Because coliforms predominate, the word "coliform mastitis" was commonly reported (Gerjets and Kemper 2009); however, most studies on CM were conducted between 1970 and 1990. Data from Kemper and Gerjets (2009) showed that the prevalence of different types of common bacteria in mammary glands in PDS-positive and PDS-negative sows do not differ.

Postpartum dysgalactia syndrome (PDS)

PDS in sows is characterized by insufficient colostrum and milk production during the first days after farrowing, the consequences of which depend on its severity. Acute cases with clinical signs in sows lead to high piglet mortality, whereas subclinical PDS leads "only" to poor growth of neonatal piglets or "problem litters" (Foisnet et al. 2010a). Clinical variation confounds diagnosis as well as estimates of prevalence of PDS. Estimates of within- or across-herd prevalence depend on the criteria used for assessment of occurrence and severity, and the variations in criteria, assessments, and reporting prevent a precise definition of PDS. The multifactorial nature of PDS makes implementation of preventive and therapeutic measures very challenging for pig veterinarians.

Pathophysiology of PDS

The pathophysiology of PDS has not yet been fully elucidated, and a single pathway is unlikely to exist (Figure 18.5). There are at least three different pathways in connection with lactogenesis and galactopoiesis (Martineau et al. 2013). One is mediated by endotoxins and acts via the innate immune system. Another one is mediated by stress, and the last one is linked with the "body building syndrome," the latter further subdivided into the "fat sow syndrome" (FSS) and the "over-muscled sow syndrome" (OMSS). As illustrated in Figure 18.5, it is necessary to consider the impact on lactogenesis and galactopoiesis (step 2) in order to understand the links between the suggested mechanisms of action of PDS (step 3) and homeorrhesis and behavior (step 1).

Clinical signs and symptoms

Martineau et al. (1992) summarized a list of early and late signs of PDS that may be present in sows, piglets, and herds. Scalable measures in sows include local signs (structurally absent nipples or glands, udder edema, mastitis, agalactia, vaginal discharge) and/or general signs (absence of any milk secretion, fever, prostration, anorexia). In piglets, early signs include mortality, inanition, diarrhea, or poor growth among the litter, whereas late signs consist mainly of variation in growth within the litter and lower weaning weights. At the herd level, measures include the consequences of PDS on

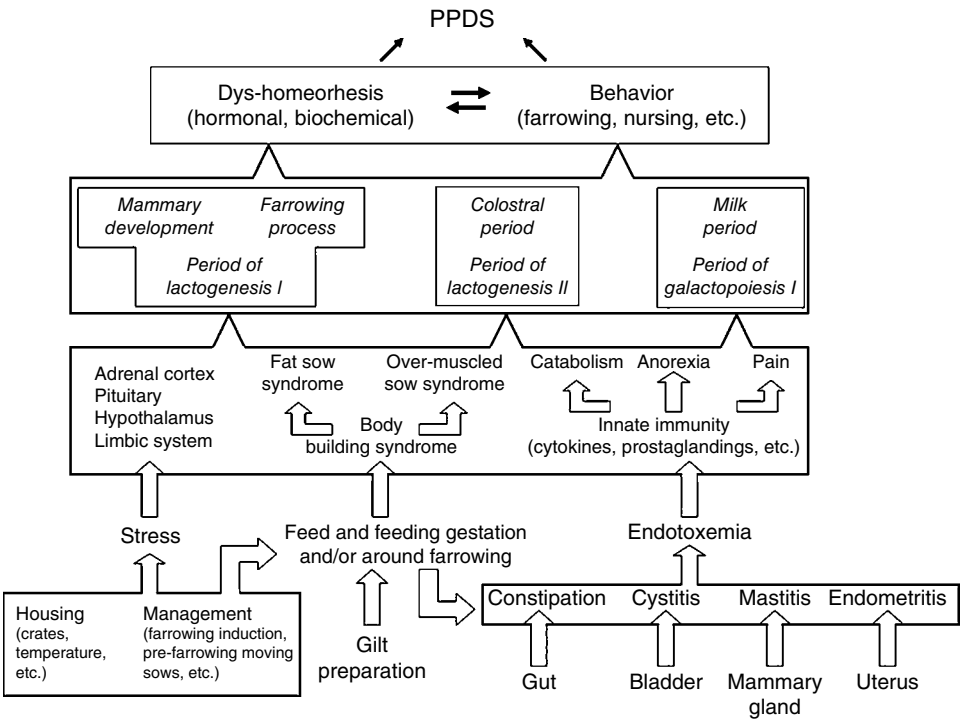

Figure 18.5 Pathophysiology of PDS. Homeorhesis is defined as "the orchestrated or coordinated changes in the metabolism of body tissues necessary to support a physiological state" (Bauman and Curie 1980). Of particular importance, the three main characteristics of homeorhetic control are (1) its chronic nature, that is, hours or days versus seconds or minutes required for homeostatic regulation; (2) its simultaneous influence on multiple tissues and systems with apparently unrelated functions; and (3) its mediation through altered responses to homeostatic signals.

productivity (number of piglets weaned/sow/year) as well as all other consequences associated with low or variable weaning weights.

The number of affected sows may vary, as does range and intensity of clinical signs. Growth retardation is the major sign of insufficient milk, identified with certainty only after passing of time. Close observation of the behavior of piglets is one of the best methods for early detection of problem litters. These piglets fight more and for longer periods, lose weight, and remain close to the sow between sucklings (Algers and de Passillé 1991). Detecting early signs in sows is difficult because most do not show differentiable signs (Klopfenstein 2003) even though milk production of sows nursing such litters is less. As reported by Foisnet et al. (2010a), the clinical presentation of sows with poor colostrum production is apparently normal.

Criteria for assessing mastitis reported in the literature can be confusing. Although the normal rectal temperature of healthy gestating sows is between 38.3 and 38.5 °C (Elmore et al. 1979; Klopfenstein et al. 1997; Messias de Bragança et al. 1997; Klopfenstein 2003), healthy lactating sows vary considerably in rectal temperature, with observed values as low as 38.4 °C and as high as 40.5 °C (Messias de Bragança et al. 1997). Elmore et al. (1979) reported a normal increase of 1–1.5 °C in rectal temperature starting approximately 24 hours before birth of the first piglet and remaining elevated until weaning (Figure 18.6a); however, there are conflicting reports (Hendrix et al. 1978; Bories et al. 2010), and Decaluwé et al. (2013) observed an increase in rectal temperature from 1 day before farrowing (38.1 °C) to day 1 of lactation (38.9 °C). This wide variation in rectal temperature is most likely the consequence of heat stress induced by the increased internal heat production and high environmental temperatures in the farrowing rooms. Some, but not all, historical reports used postpartum rectal temperatures greater than 39.3 or 39.5 °C to categorize sows as being affected by PDS (Hermansson et al. 1978b; Goransson 1989; Persson et al. 1989; Madec and Leon 1992; Hoy 2004). A Canadian study showed that rectal temperatures of sows nursing "problem litters" and characterized as PDS were similar to those of sows nursing "normal litters" both in late gestation and early lactation (Klopfenstein 2003). The greater rectal temperature observed in lactating sows must be considered as physiological hyperthermia and should not be confused with fever. Body temperature should not be misinterpreted or used as a single tool in clinical evaluation of PDS (Pepys and Hirschfield 2001; Marnell et al. 2005; Meisner 2005). The belief that higher rectal

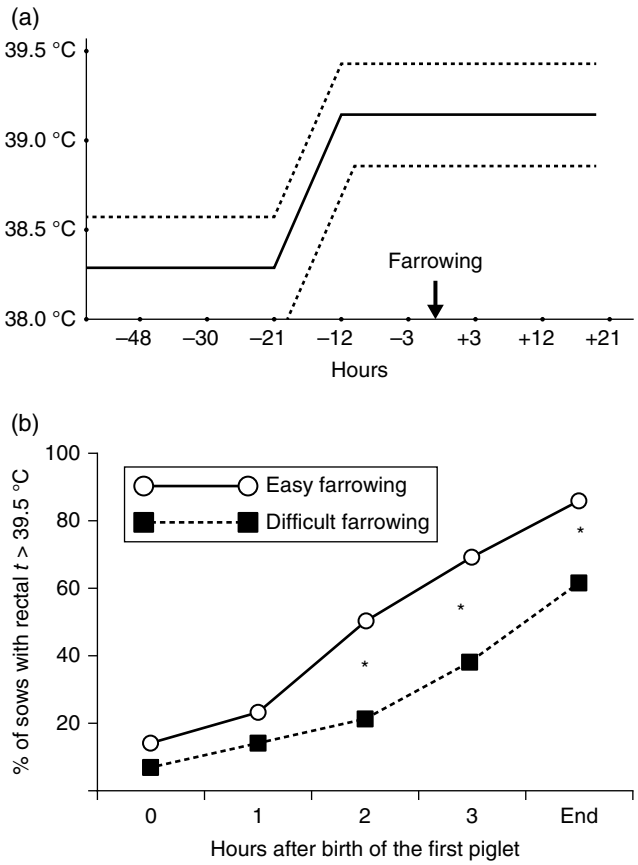

Figure 18.6 Body temperature. (a) Body temperature of preparturient sows detected by radio telemetry. The area between the dotted lines shows the range of preparturient body temperatures. *Source:* Adapted from Elmore et al. (1979). (b) Rectal temperature before and after farrowing measured in 14 sows with "difficult farrowing." Using a 39.5 °C threshold, a significantly greater proportion of sows in the "difficult farrowing" group were above this threshold after birth of the second piglet. The asterisk symbol indicates the power of the statistical results (*0.05). *Source:* Adapted from Bories et al. (2010) and Sialelli et al. (2010).

temperature identifies sows with mastitis or PDS is so generally accepted that many researchers use this criterion without estimating piglet growth and preweaning mortalities; hence many such published results on the PDS syndrome are not included in this chapter.

PDS Prevalence

The prevalence of PDS either at the animal or herd level depends upon the criteria used to assess the occurrence and the severity of the syndrome. Symptoms and criteria used to define PDS vary largely depending on the study (reviewed by Papadopoulos 2008), with diagnostic criteria including agalactia, anorexia, constipation, vaginal discharge, inflammation of mammary gland, rectal temperature higher than 39.8 °C (Jorsal 1986), or milk SCC greater than 10 million/mL even if rectal temperature is normal (<39.5 °C) and no clinical mastitis is present (Persson et al. 1996).

Generalizations regarding PDS are difficult because of the variation in criteria used for classification of hypogalactia, agalactia, mastitis, fever, appetite, piglet condition, or other clinical signs in sows or piglets (Bäckström et al. 1984; Hirsch et al. 2003; van Gelder and Bilkei 2005). As a result of this variation, prevalence data are difficult to compare and likely overestimate actual values. Bäckström et al. (1984) reported PDS in 6.9% of 16,405 farrowings recorded over 1 year in 31 swine herds in Illinois with in-herd prevalence ranging from 1.1 to 37.2%. Threlfall and Martin (1973) studied 27,656 farrowings in the state of Missouri and found that 13% of the sows were affected by PDS. The range of incidence of PDS in Swedish herds varied from 5.5% in small herds to 10.3% in large herds (Bäckström et al. 1984). More recently, in Denmark, Larsen and Thorup (2006) used a definition of PDS as one or more of the following – inappetence, abnormal mammary glands (reddening, swelling), or temperature >39.4 °C – and found an occurrence of 32.5% on the first day post farrowing, 31.5% on the second day, and 10.1% on the third day. In a survey including 110 pig herds, 34% reported to have experienced PDS problems during the year preceding the study (Papadopoulos et al. 2010).

PDS Risk factors and prevention

Risk factors for PDS are typical of multifactorial diseases, where many factors are sufficient to increase the probability of occurrence of PDS but by themselves are not necessary for causation. One of the keys in reducing the incidence of problem litters in a herd is the identification and correction of risk factors. Because different pathophysiological pathways may lead to PDS (Figure 18.5, originating from stress, feeding and endotoxemia), there are many potential risk factors identified for each of these pathways. Recent studies (Maes et al. 2010; Papadopoulos et al. 2010) suggest that modern pig herds should utilize control measures including optimization of management and feeding practices.

Animal factors and body type

The role of genetics in the occurrence of PDS is limited; Awad et al. (1990) reported a genetic predisposition for CM, and Preissler et al. (2012) showed a heritability of 0.10 for PDS, suggesting the possibility of genetic predispositions.

Sow constipation is a risk factor for PDS. One closely linked factor is endotoxemia. As sows approach farrowing, water absorption in the intestine increases due to the fluid needed for the onset of milk production (Mroz et al. 1995), which, in turn, alters feces consistency. Daily fecal scores (Oliviero et al. 2009) allowed diagnosis of constipation at both the sow and the herd level, and constipation was observed in some sows nursing problem

litters (Hermansson et al. 1978b). Feeding high fiber diets in late gestation has been widely used to decrease the incidence of early-lactation constipation related to PDS (Wallace et al. 1974). Offering feed that is low in volume and fiber can worsen constipation and increase the risk of absorbing bacterial endotoxins (Smith 1985a, b). Studies with constipated sows showed direct effects on the occurrence of PDS (Hermansson et al. 1978a; Persson et al. 1996). Constipation can result in a solid mass of feces as a physical obstacle for birthing (Cowart 2007) and perhaps be a source of intestinal pain for the sow, thus jeopardizing animal welfare. This pain induces opioid production that suppresses oxytocin release and might compromise the farrowing process (Oliviero et al. 2010b). Insufficient water intake just before farrowing can enhance postpartum constipation. Low postpartum water intake and low activity level of sows were proposed as risk factors for early lactation problems (Fraser and Phillips 1989).

Two "body building syndromes," namely, FSS and OMSS, are recognized as risk factors for PDS. Visual body condition scores only approximate true body condition (Charette et al. 1996; Maes et al. 2004). Sows that are fat at farrowing have a greater risk of peripartal hypophagia, prolonged farrowing, and PDS (Goransson 1989; Oliviero et al. 2009) and have a lower colostrum yield than nonfat sows (Decaluwé et al. 2014b), but high backfat thickness does not necessarily lead to severe PDS problems (Cools et al. 2014). Control of the FSS is not easy because small errors in the amount of feed distributed over the whole gestation period can lead to overweight or underweight sows at the time of parturition (Martineau and Klopfenstein 1996). Sows maintained in pens without individual feeding have more variable body weights, the most aggressive sows often being overweight, while submissive animals are underweight (Martineau 1990; Marchant 1997).

Control of the OMSS is also challenging as it is a new emerging syndrome (Solignac et al. 2010) and there is no consensus on the best feeding strategy for the modern hyperprolific sow. This OMSS is the direct consequence of genetic improvement and hyperprolificacy (Solignac 2008; Solignac et al. 2010). Modern and hyperprolific sows are leaner, thereby increasing the risk of an early catabolism phase before farrowing. An important contributor to this catabolism is the increased accretion rate in terms of weight of individual fetuses during the last 10 days of gestation, i.e. 50 versus 4–5 g/day during early gestation (Ji et al. 2005), with faster protein deposition (Whittemore 1998). Mammary gland growth also increases during the last third of gestation (Sorensen et al. 2002). Therefore, around and often before farrowing, the sow has already switched to a catabolic state, which continues during lactation, using her body reserves to produce large quantities of milk (van den Brand and Kemp 2006).

Rising levels of blood nonesterified fatty acids (NEFAs) are a clear indicator of a catabolic state associated with severe loss of body weight and low feed intake (Messias de Bragança and Prunier 1999). Le Cozler et al. (1998) and Oliviero et al. (2009) found that circulating concentrations of NEFAs increased rapidly a few days before farrowing, reaching a peak on the day of parturition. A catabolic state can also be quantified by circulating urea and creatinine concentrations; creatinine is a more efficient indicator of muscle catabolism than urea since it is a direct product of creatine metabolism in the muscles (Mitchell and Scholz 2001). It was found that increasing the dietary energy in late pregnancy can negatively affect feed intake during early lactation due to a reduction in glucose tolerance and to insulin resistance (Boren and Carlson 2006). Sows with high backfat levels have greater leptin concentrations, which is also a risk for reduced feed intake (Cools et al. 2013).

Housing and environment

Oliviero et al. (2010a) showed that the farrowing process lasts longer in crates than in pens, implying a potential indirect effect of housing conditions on PDS via farrowing duration. The incidence of PDS was also greater in sows housed in crates 60 cm wide compared with 67 cm wide (Cariolet, 1991). Despite numerous reports over the last 30 years, there is no clear conclusion regarding impact of housing, environment, or movement of sows prior to parturition (Klopfenstein et al. 1995; Papadopoulos et al. 2010), but a short period of adaptation of the sow to the new farrowing–lactation environment appears to be warranted. The use of slatted floors in the farrowing pens was associated with a decreased risk of chronic mastitis in sows (Hultén et al. 2004). Fully slatted floors may be hygienic, but they do not appear to support social behavior (Munsterhjelm et al. 2008) and may sometimes reduce air quality.

The effects of heat stress on lactating sows include decreased feed intake and milk production (Quiniou and Noblet 1999). High ambient temperatures have a direct effect on milk production, independent of the reduction in feed intake (Messias de Bragança and Prunier 1999). Newborn piglets require a localized warm environment, but the temperature requirement of the sow is less since her zone of thermoneutrality is much lower. It is generally recommended that room temperature be maintained warm (20–22 °C) for the 2–3 days after farrowing to favor piglet survival. However, after this crucial period, room temperature can be gradually decreased to attain 18 °C or even 15 °C on day 10 of lactation as long as a draft-free heated creep area is provided for the piglets (Farmer et al. 1998b). Overheating of the mammary glands by inappropriate placement of heating lamps decreases milk production (Muirhead and

Alexander 1997). Supplementary heat should be directed away from the sow and her udder and be removed when not needed to favor the sow's well-being and maximize her milk production.

Providing plenty of space and adequate enrichment material for nest building may reduce the incidence of PDS compared with housing sows in farrowing crates (Bäckström et al. 1984; Oliviero et al. 2009). Improving the level of hygiene of the farrowing unit was reported to be associated with lower preweaning mortality (Ravel et al. 1996).

Nutrition, feed, and feeding

Reducing feed consumption in the first days of lactation decreased the incidence of lactation failure, and gradually increasing feed intake of sows in the first week postpartum (rather than ad libitum) decreased the risk of PDS (Moser et al. 1987; Neil et al. 1996; Papadopoulos et al. 2010), but feeding ad libitum peripartally resulted in greater colostrum yield (Decaluwé et al. 2014b).

The inclusion of fiber in the feed is an often cited nutritional factor to reduce PDS. However, if the basic feed contains sufficient fiber, no extra beneficial effects on lactation are expected by adding extra fiber, whether as fermentable or inert carbohydrates (Guillou et al. 2016). Further research on the inclusion level of fibers and on the effects of different types of fibers (soluble vs. insoluble, degree of fermentability) in sow diets is needed. According to Papadopoulos (2008), a diet with a low $n-6:n-3$ ratio (fish diet) provided 8 days before expected farrowing improved feed intake during the first days postpartum and was associated with a better metabolic adaptation and inflammatory profile in periparturient sows.

The relationship between dietary selenium or vitamin E and sow lactational problems was explored because these antioxidant micronutrients can alleviate the effects of endotoxins (Elmore and Martin 1986). A low level of vitamin E (16 or 33 IU/kg vs. 66 IU/kg) was reported as a risk factor for PDS (Mahan 1991), but Mahan et al. (2000) later reported that increasing dietary levels of vitamin E from 30 to 60 IU did not decrease the prevalence of MMA diagnosed at parturition. In another study, injections of vitamin E (400 IU) and selenium (3 mg) to sows three times during gestation, on days 30, 60, and 100 of gestation, while fed normal levels of these nutrients, increased the survival rate of piglets but did not affect litter weights at weaning (Chavez and Patton 1986).

Mycotoxins are often suspected by swine veterinarians as a risk factor for PDS, yet the only well-recognized mycotoxin contributor is ergot (Kopinski et al. 2007). Grains contaminated with ergot derivatives of *Claviceps purpurea* hinder milk production in sows. Indeed, sows fed 1.5% ergot for 6–10 days preceding farrowing produced no milk, while ergot inclusions of 0.6–1.2% caused lesser problems in milk release and neonatal piglet mortality (Kopinski et al. 2007). The effects are likely due to suppressed prolactin secretion by ergot toxins. Böhmer et al. (2006) reported that diets containing probiotics at the end of gestation and around parturition may lead to a reduction in the incidence of PDS (6 vs. 13%) and to greater feed intake during lactation.

Both the sow and piglets should have easy access to fresh, good quality water. Slippery and dirty floors are one of the main causes of low activity of lactating sows and may lead to many health problems including PDS or reduced feed and water intakes.

Management

In a survey done by Papadopoulos (2008), two of the four significant risk factors for PDS were related to management: (1) moving pregnant sows to the farrowing unit 4 days instead of 7 days or earlier before expected farrowing and (2) farrowing induction, the latter with conflicting results. In some herds with a significant percentage of gilts and sows showing PDS, induction of parturition with prostaglandins was effective in reducing the incidence of PDS (Cerne and Jochle 1981; Holtz et al. 1983), whereas it had no effect in other herds (Ehnvall et al. 1977; Hansen 1979). Prostaglandins could be effective in treating PDS caused by retarded lactogenesis since incomplete luteolysis of corpora lutea can lead to high progesterone concentrations that could potentially inhibit lactogenesis. However, farrowing induction at 113 days of pregnancy did not modify the chronology of endocrine changes taking place during the peripartum period, nor did it affect colostrum yield and IgG concentrations (Foisnet et al. 2010b).

Postpartum administration of prostaglandins may have a beneficial effect on uterine involution and prevention of severe clinical endometritis (Waldmann and Heide 1996) because they are luteolytic agents causing a prepartum decline in progesterone and the release of relaxin from the corpora lutea. Vanderhaeghe et al. (2008) saw no beneficial effects of administering a prostaglandin F2α analogue to sows within 24–48 hours after farrowing on preweaning mortality and litter ADG, but litter size was greater the next parity in older sows.

Papadopoulos et al. (2010) reported that frequent farrowing supervision and neonatal care given by the stockperson compared with no farrowing supervision decreased the risk of PDS. Obstetric intervention, especially if not done properly (e.g. unhygienic), is, however, among the infectious factors increasing the occurrence of CM in sows (Bostedt et al. 1998). Depending on the criteria used to define the problem of PDS (mastitis or dysgalactia), interpretation of observations may differ. Assisting a sow showing signs of dystocia may reduce the occurrence of PDS. Similarly, sow productivity was positively correlated with procedures associated with enhanced supervision, including frequent manual

assistance, frequent use of pharmaceuticals, and alternative options for cross-fostering piglets, such as using sows from other farrowing batches and artificial suckling machines (Martel et al. 2008). With new technology such as photosensors, prediction of the onset of parturition becomes feasible (Oliviero et al. 2008b).

Treatment of the diseased sow

Treatment of affected sows needs to be done early and given a high priority while also considering risk factors and preventative measures for PDS. Since the disease is a multifactorial clinical condition with changing environmental and management contributors, treatment protocols need critical and frequent updating. In any case of PDS, the use of nonsteroidal anti-inflammatory drugs (NSAID) is indicated, as is the use of oxytocin for milk letdown. Antimicrobials may be warranted, depending on individual situations.

NSAID are used to alleviate the effects of inflammation and endotoxemia and show benefits for affected sows. Drugs used include flunixin (2 mg/kg) (Cerne et al. 1984), tolfenamic acid (2–4 mg/kg) (Rose et al. 1996), and meloxicam (0.4 mg/kg) (Hirsch et al. 2003). Treatment strategies usually consist of one treatment on the day of parturition and sometimes a second treatment one or two days later. With a 1% improvement in piglet mortality expected from the treatment, the benefits outweigh costs of the NSAID treatment (Hirsch et al. 2003).

Initiation of antimicrobial treatment should be based on the clinical picture as a whole rather than relying on increased body temperature, which may reflect simply physiological or normal variations. Use of antimicrobials is indicated if generalized signs are present. The selection of an antibiotic should be based on its spectrum of activity against those bacterial organisms identified or thought to be responsible for the problem. Identifying the most important bacteria in the diseased sows is difficult.

Another important objective in treatment is to stimulate milk flow to minimize the consequence of PDS. Repeated use of oxytocin in clinical cases of PDS is likely to be the most frequent treatment administered to stimulate milk production. Oxytocin may be given at 5–10 IU/sow (IV) for 4–5 times at 2–3 hourly intervals (Martineau 2005). There should be at least 30 minutes between two subsequent injections. In fact, in most cases, 5 IU appears to be enough to induce milk letdown, and when using this concentration, repeated doses may be given without side effects. Parenteral administration of synthetic oxytocin is a very efficient way to trigger milk ejection. The intramuscular route of administration is most common, but using the intravenous route may further improve the effect. Although efficient and considered as safe, repeated use of oxytocin might have some detrimental effects on sows. Overuse may be associated with poor piglet growth (Bilkei Papp 1994; Ravel et al. 1996) and increased SCC in milk (Garst et al. 1999).

Vaccination for PDS is not widely practiced. *Escherichia coli* strains causing neonatal diarrhea are not those usually detected in sows with PDS, but at least one report found vaccination to be useful (Fairbrother 2006). The variation in bacteria found in farrowing units as well as the lack of randomized, blinded controlled studies brings into question the use of vaccination for PDS.

Supportive treatment for the sow and piglets, especially fluid therapy, is an important part of treatment in serious cases of PDS. The main target of supportive therapy is to alleviate dehydration, common in sows with endotoxemia (Reiner et al. 2009). If monitoring determines that the sow is not drinking, then fluids can be administered intravenously or per rectum (Peltoniemi and Hälli 2004). Daily fluid requirement is considered to be approximately 7% of the body weight. If given per rectum, a backflow of about 50% is expected, and therefore volumes need to be larger than for intravenous administration.

In the case of piglets, the first step is to provide an alternative source of energy and/or to transfer piglets to another healthy sow. Piglets of heavier birth weights are cross-fostered with greater success because they have some energy reserves. Piglets may drink appreciable amounts of water on the first day following birth, particularly if milk supply is limited (Fraser et al. 1988). Water with electrolyte and glucose supplementation may help to prevent dehydration and promote survival of the piglets. Intraperitoneal infusion of approximately 15 mL of 5% glucose will temporarily alleviate dehydration and starvation (Fairbrother 2006). The piglets may thereafter be alert enough to find a teat and start suckling. Piglets may also be raised with a combination of milk replacers and highly digestible adapted feed. However, immunoglobulins included in some milk replacers are unlikely to contain antibodies specific for a farm and cannot be considered as replacement for colostrum. Providing additional heat for piglets suffering from hypothermia is always of utmost importance.

Nervous and Locomotor System

Darin M. Madson, Paulo H.E. Arruda, and Bailey L. Arruda

Introduction

Disorders, diseases, and deficits related to mentation and locomotion are both production and welfare concerns. Clinical diseases linked to the muscular, skeletal, and nervous systems are not as prevalent as those affecting the respiratory or enteric system; however, when they do occur, there is often substantial economic impact.

Potential etiologies of clinical and subclinical locomotor or nervous disorders are numerous and occur as either sporadic individual animal afflictions or affecting large populations. Etiologies can be infectious, noninfectious, or multifactorial and hence can be difficult to differentiate without a detailed history, proper clinical assessment, and proper diagnostic investigation, including sample selection and laboratory submission. Nervous disorders commonly occur with sudden onset or acute outbreaks, whereas most disorders of the skeletal system can be insidious, with faulty bone formation, structural loss, poor conformation, protracted inflammation, or trauma all contributing. Locomotor disorders contribute to losses in all stages of production with considerable variation between individual farms and are associated with numerous contributing risk factors (D'Allaire 1987; D'Allaire et al. 1987; Jones 1967; Smith and Robertson 1971; Svendsen et al. 1979).

Normal structure and function

The fundamental resources for the anatomy, physiology, and pathology necessary for the effective study of the four body systems presented in this chapter are listed in Table 19.1. The combined systems (nervous and locomotor) are responsible for perception, locomotion, reflex, and voluntary movement.

Nervous system components

The brain is normally white to light yellow in color and weighs about 35 g in the newborn piglet and 110–120 g in the adult (Widdowson and Crabb 1976). The spinal cord weighs about 4 g in the newborn and 30–40 g in the adult. The wild pig may have a brain that is 20% heavier (Rohrs and Kruska 1969). The brain grows rapidly from 5 weeks before birth to 8 weeks after birth; thereafter the ratio of brain weight to total body weight decreases.

Myelination begins about 55–60 days of gestation and peaks around birth. There is a surge in the myelination rate at about 3 weeks of age (Dickerson and Dobbing 1967; Patterson and Done 1977; Sweasey et al. 1976), and myelination is usually complete by around 6 weeks. The neuronal complement of the central nervous system (CNS) is complete by about 6 weeks of age; neurons lost after this are not replaced. Once mobilized, Schwann cells can provide limited repair of myelin.

Bone

Bone is metabolically active in mineral metabolism and is dynamically changing as a result of the mechanical forces of muscles and tendons as well as the homeostatic process of remodeling (Goff 2010). In the pig, skeletal growth is still visible at three to three and a half years of age because the growth plates continue to be functional (Getty 1975). The physeal closure times are provided in Table 19.2.

Growth plates are the site of endochondral ossification and composed of layers of maturing chondrocytes. There are resting, proliferating, hypertrophic, and mineralizing zones that ultimately form a lattice called the primary spongiosa within which mineralization occurs. The secondary spongiosa forms nearer to the diaphysis where the trabeculae are remodeled to produce the medullary cavity.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

	Distal	Before birth		Distal	Before birth

Growth plates have many shapes and sizes; some bones have a single physis, while others have multiple. The epiphyseal growth component of the articulo-epiphyseal cartilage complex is responsible for the increase in size of the secondary centers of ossification such as the head and greater trochanter of the humerus. Not all long bones have epiphyses.

The metaphysis is mainly cancellous bone and surrounded by a thin shell of cortical bone. The metaphysis merges with the diaphysis seen grossly as thicker area in cortical bones. In the diaphysis, cancellous bone is virtually absent, creating a medullary or marrow cavity filled with marrow. In older animals, bone marrow is replaced by fat except in the ribs, vertebrae, and pelvis. The surface of bone is covered by the periosteum except on the articular surfaces and sites where tendons are inserted.

Joint and muscle

The joints are composed of articular cartilage supported by bone, synovial membrane that secretes synovial fluid, joint capsule, and insertions of tendons and ligaments and may communicate with tendon sheaths. The joints incur the most stress in the locomotor system and are prone to infection following local trauma or bacterial septicemia.

The muscles of the pig are described in Sisson (1975). There are no special features of porcine mycology compared with the other species regarding pathology and medicine. Muscle mass is influenced by genetics and factors in fetal development as well as postpartum nutrition. Well-fed animals without deficiencies or overdoses of essential nutrients have greater muscle mass than those fed incorrectly. Importantly, many myopathies of skeletal muscle can affect cardiac muscle as well as the smooth muscle of other organ systems.

Clinical examination of the locomotor systems

Assessing the animal(s) within their environment is essential to identifying the root cause(s) of locomotor deficits. A complete clinical history and objective determination of all body systems affected are a major part of a locomotor clinical investigation. The six sites of the locomotor system (brain, spinal cord, peripheral nerves, bones, muscles, and joints) each should be considered as potential sites of involvement. The objectives of a clinical investigation are to record all clinical signs or lesions present in the group; quantify the number or percentage of animals affected with each specified clinical sign, lesions, or limb deficit; determine the age and age range of group(s) affected; determine onset, duration, and prevalence of the predominant clinical signs; and inform the course of action. This is best accomplished by systematic observation and asking questions of those providing the animal care. Determine if disease onset in the group was abrupt or gradual, as well as assess progression of disease in individual pigs. Quantify the number and percentage of animals with a particular limb or joint involvement. Determine the impact of the affliction on individual animals and the group, including productivity, mobility to acquire water and feed, and welfare. Animals may appear lame and reluctant to move yet improve with exercise and perform normally. For growing animals, determine the range in severity of clinical signs, examine animals that are either acutely or chronically affected, observe their movement, and palpate the joints and then each leg looking for heat, swelling, and response to pain. Careful observation for pain, wounds, visible swellings, muscle tone, fasciculation tremor, gait abnormalities, proprioceptive deficits, or altered mentation requires patience and practice. Assessment of the brain and spinal cord as part of a neurologic examination is discussed in the section below on neurologic examination.

Treatments and medication history as well as the response to specific treatments are important considerations when investigating potential causes of lameness. An assessment of overall impact is useful to determine if the condition is a sporadic individual animal affliction, involves multiple animals as a herd issue, or is creating an animal welfare concern.

Floor type and housing are important risk factors. Slick, rough, wet, or damaged floors as well as flooring type (solid vs. slatted floors), flooring material, flooring texture, and the overall environment in which pigs are housed are important risks factors to consider when investigating locomotor compromise.

The likelihood of specific etiologies of locomotor disorders can vary depending on the age, weight, or production stage of pigs affected. As pigs get heavier, body weight can exacerbate lameness etiologies. Infectious disease risk is higher when pigs of different sources are commingled or new animals are introduced to the group or herd. Abrupt onset of unique clinical disease is sometimes the result of a recent diet change or new feed delivery. If commercial milling is used, it is useful to know if the mill prepares feed for other species that may serve as source of error or intoxication. A thorough clinical assessment and history, along with necropsy of affected animals, should generate a list of possible causes or differential diagnosis. For confirmation of diagnosis, collection and preservation of proper samples for appropriate testing will continue the diagnostic investigation.

Evaluating locomotory issues in the breeding herd can be more challenging depending on how the animals are

housed. Often, subtle early changes can go unnoticed until there is substantial involvement. Assessing the adult herd starts by examining animals in all stages of gestation, lactation, and pre-breeding with close attention to hoof cracks, hoof wall damage, sole lesions, foot rot, long toes, dewclaw damage, and soft tissue damage. Hoof and claw disorders are discussed in Chapter 17. Note the number of sows that are lame, the severity, whether the clinical signs involve one or more limbs, and the parity and stage of gestation of the sows affected. Palpate limbs, joints, and soft tissue of the affected limbs, and take the sows out of the crates to observe their gait. Specifically look for reluctance to move, degree of difficulty in standing, stiffness, stance with legs under the body, and weight bearing on all limbs.

Weight distribution of forelimb and hind limb is approximately 60 and 40%, respectively. Changes in posture such as an arched back, slow to rise, or reluctance to move are indications that joint or bone diseases are present. Clinical examination should be performed in all age groups and not be limited to the most severely affected animals. Importantly, not all causes of lameness are infectious; environment factors can play an important role in the manifestation of clinical locomotor issues.

Bone examination

Clinical examination of bones is difficult because they are covered by muscle or other soft tissue. Obvious fractures and separation of epiphyseal heads are detectable, but other changes may depend on history, progression, and postmortem examination with detailed dissection. Many bone abnormalities are a result of nutritional inadequacies or developmental compromise magnified by cumulative trauma and specific deficiencies in later life, particularly in the sow. Common diseases affecting bone are listed in Table 19.3.

Alterations in bone shape or size are not uncommon in swine. Reduced bone length can be associated with oversupplementation of vitamin A and premature closure of growth plates. There may be enlarged ends to the long bones as seen with rickets, enlarged costochondral junctions may indicate fluorine toxicity, or rickets and localized enlargements can result from osteomyelitis or partially healed fracture (callus) sites.

Bone strength is reduced in the most common metabolic bone disease disorders, including rickets, osteomalacia, fibrous osteodystrophy, and osteoporosis. Pathological fractures of fragile bones are found in osteoporosis, maternal copper deficiency, and *osteogenesis*

Table 19.3 Selected diseases affecting bones.

Insult/disease	Clinical/comment
Osteomyelitis	Bacterial infections, abscesses
Fracture	Traumatic or nutritional
	Acute: sharp edges with crepitus, hemorrhage (long bones, ribs, vertebrae)
	Chronic: calluses/enlargement, with fibrosis (ribs, long bones)
Electrocution	Fractures (e.g. lumbosacral vertebrae, femur)
Osteochondrosis (includes related epiphysiolysis or apophysiolysis)	Primary effect on growth plates. These conditions can be manifested as joint disease, including physeal separation and hemorrhage
Metabolic bone disease	Rickets, osteomalacia, osteoporosis, fibrous osteodystrophy variably present depending on age and stage; caused by interactions of Ca, P, vitamin D_3, and other dietary contributors or risk factors. Enlarged metaphyses and growth plates; decreased bone strength; pathological fractures; soft, brittle, or friable bones. Deaths with acute hypocalcemia and tremors
Vitamin A toxicity	Shortened bones; congenital deformities
Vitamin C deficiency	Subperiosteal hemorrhages
Copper deficiency	Fragile bones
Manganese deficiency	Limb deformity, decreased length
Fluorine toxicity	Enlarged costochondral junctions
Chondrodystrophic dwarf	Shortened bones; genetic
Congenital hyperostosis	Thickened limb bones, heritable, fatal
Congenital porphyria	Brown discoloration of bones
Vitamin D toxicity; Solanum	Vitamin D_3 or analogues: excessive calcification of soft tissues and bones
Classical swine fever virus	Lines of discoloration in metaphysis parallel to physis

imperfecta. Fractures of long bones and vertebrae can also be caused by trauma, electrocution, or stunning, but the likelihood of such fractures increases when there is inadequate mineralized bone present. Antemortem physeal separation seen in epiphysiolysis and apophysiolysis will have associated hemorrhage. Ascorbic acid (vitamin C) deficiency can present with bone hemorrhages, both at subperiosteal and metaphyseal locations. Limb deformity and reduced bone length in pigs can result from manganese deficiency. Classical swine fever may cause lines of discoloration in the metaphysis parallel to the physis.

Joint examination

Joint swelling, enlargement, or dysfunction has various causes. The nature of the capillary bed in joints allows for trapping of circulating organisms, especially in young animals. In older heavier muscled animals, joint enlargement can be difficult to discern. Increased time spent in recumbency because of locomotor deficits can result in adventitious bursa formation over bony protuberances on the lower limbs, mainly the hock. The presence of an adventitious bursa is commonly misinterpreted as joint swelling, but bursae do not communicate with joint spaces. Prevalence of adventitious bursae can be present in up to 85% of animals within a particular barn (Mouttotou et al. 1998a,b) and is most common on the lateroplantar aspect of the hock. Prevalence varies considerable based on floor type, availability of bedding, and breed.

Synovial fluid supplies nutrients to the articular cartilage, lubricates joint surfaces, and is normally clear to slightly yellow and viscous. The amount of fluid within the joint can vary by location and does increase following injury to the joint. Normal synovial fluid contains few cells; however, neutrophils and hemorrhage are common following insults, either infectious or noninfectious. In disease states the synovial fluid increases, has less viscosity, and can become turbid with fibrin or inflammatory cells, depending on the insult type.

The synovial membrane is accessible to bacteria via bacteremia, sepsis, or penetrating surface abrasion. Synovitis follows and can progress to suppurative arthritis and osteomyelitis. If not resolved, villous hypertrophy of the synovial membranes and degenerative joint disease with articular cartilage roughing or erosion can occur. Pannus formation, which is vascular granulation tissue spreading across the surface of the articular cartilage, can be a sequel and often follows chronic suppurative arthritis with pyogenic bacteria or *Erysipelothrix* or, occasionally, in chronic *Mycoplasma hyosynoviae* infections.

Common joint insults are provided in Table 19.4. Useful specimens for laboratory analysis include aseptically collected smears, swabs, joint fluids, and synovium used for microscopy, PCR, or bacterial culture. Examination of joints and collection of laboratory specimens require aseptic technique to prevent contamination. Collection of these samples should have priority and performed first when performing a necropsy or pathological examination.

Muscle Examination

Examination of muscle is by visual inspection and palpation to give an overall impression of size, tone, strength, normal contours, symmetry, and normal motion or function. Generally, clinical abnormalities of muscle involve excess muscle or muscle bundles, paucity of muscle, trauma, denervation, inflammation, degenerative disease, metabolic dysfunction, and fatty degeneration that may be the result of traumatic, infectious, toxic, or inherited insults.

Table 19.4 Selected joint diseases.

Disease/insult type	Clinical/comment
Osteochondrosis	The result of defective bone and growth plate; shifting joint pain
Bacterial infections *Erysipelothrix* *Haemophilus parasuis* *Streptococcus* spp. *Actinobacillus suis* *Mycoplasma hyosynoviae* *Mycoplasma hyorhinis* *Trueperella pyogenes* Other sporadic bacteria	Most are localization of septic bacteria. Usually abrupt onset of joint pain, joint swelling, fever, lethargy, reluctant to move
Trauma: acute athletic injuries, chronic insults	Limb lameness with or without joint swelling; afebrile
Anticoagulant/vitamin K deficiency	Joint hemorrhage
Viruses, toxins, unknowns	Congenital arthrogryposis; bone deformities

Neurological examination

The primary purpose of the neurological examination is to determine the extent of the neurologic deficits and the potential anatomical location(s) affected. First observe affected animals within pens, and segregate them from their normal environment to determine visual impairment, behavior changes, proprioceptive deficits, purposeful movements, mental status, gait, posture, and evidence of trauma (Kornegay and Seim 1996). Detailed examination of multiple acutely affected animals is important to determine the range and consistency of the clinical signs. A normal gait requires proper neural networking between the cerebrum, cerebellum, brain stem, spinal cord, and peripheral nerves. Descriptive terms used to communicate clinical signs of CNS disease are listed in Table 19.5.

Cerebral cortex and forebrain

The cerebrum is responsible for voluntary movement, consciousness, and behavior. Diseases affecting the cerebral cortex or thalamus (forebrain) cause altered mental behaviors, seizures, blindness with a pupillary light reflex, circling, compulsive walking, or head pressing (Kornegay and Seim 1996). The four types of altered mental attitude are depression or a decreased responsiveness, stupor where animal is unresponsive but arousable, coma where animal is unresponsive and not arousable, and mania or delirium with excessive motor activity. Stupor and coma are often associated with cerebral cortex dysfunction. Mania can be due to diseases of the cerebral cortex, particularly the limbic system. Depression may be due to any systemic disease and may not involve the brain.

Cerebellum

The cerebellum controls unconscious proprioception with dysfunction seen clinically as truncal ataxia, broad-based stance, dysmetria, or intention tremor (Kornegay and Seim 1996). Intention tremor is the involuntary trembling caused by intentional movement. Dysmetria is the improper measuring of distance in muscular acts, either overstepping (hypermetria) or underreaching (hypometria).

Spinal cord

The degree of spinal cord damage can be determined by severity of functional loss. Functional loss from spinal cord injuries follow a sequential progression: proprioception deficit is followed by loss of voluntary motor function, then loss of superficial pain reflex, and finally loss of deep pain sensation. The return of function follows the reverse order.

Spinal or myotatic reflexes test the sensory and motor components of the reflex arc and the descending motor pathways. It is easier to localize spinal reflexes to the hind limbs than to the thoracic limbs (Table 19.6). Lower motor neuron (LMN) disease is an interruption of the reflex arc from neurons of the ventral horn to effector muscles with signs that include poor strength, flaccid muscle tone, muscle fasciculation, early neurogenic muscle atrophy, and easy bladder expression. Spinal reflexes can be normal, absent, or depressed with LMN disease. Reflexes often are exaggerated with upper motor neuron (UMN) compromise because of the compromise in the descending pathways from the brain and spinal cord that would normally inhibit the reflex.

Deep pain perception tests the functional integrity of the spinal cord. It is the most important prognostic test but should be applied at the end of the physical examination to get reliable responses to the prior tests. Apply painful stimuli to each limb and the tail. The pig will vocalize, look, or attempt to move away. The withdrawal of the limb is not a behavioral response. Loss of deep pain sensation indicates a poor prognosis.

Eyes

Visual assessment is often limited to observations of behavior indicating blindness and testing of simple reflexes. The blink and fixating reflexes are both dependent on the integrity of pathways from the retina to the visual cortex. These reflexes are all lost in conditions affecting the cerebrum or in arsanilic acid poisoning, which specifically damages the optic nerve and tract. Some of the clinical signs related to the eye are listed in Table 19.7.

Diagnostic investigation

A complete history and clinical assessment, usually accompanied by necropsy and differential diagnosis, will determine appropriate samples for laboratory testing to confirm a specific etiology for the disease process at hand. Steps in animal selection and sample collection that will improve diagnostic accuracy include the following: (1) Sample acutely affected pig(s) that accurately represent the predominant clinical signs. (2) Sample only pigs that have received no medication by any route. (3). Accurately assess, record, and aseptically collect samples from likely locations of lesions, including specific limbs, joints, bones, muscle, and portions of the nervous system (cerebrum, cerebellum, brain stem, spinal cord, peripheral nerves). (4) Collect and rapidly chill fresh samples as well as collect and preserve tissues in 10% neutral buffered formalin.

Table 19.5 Descriptive terms and clinical signs affecting the nervous system.

Descriptive terms	Clinical signs	Possible location of lesion
Blind, loss of smell, loss of control of eye movement, pupil reflex	Impaired smell, vision, eye reflexes, eye control	Cranial nerve deficits (CN1–4, 6)
Loss of sensation of the face	Facial sensory deficit, mastication muscle deficits	Cranial nerve deficit (CN5)
Facial paralysis	Facial muscle deficits, expression	Cranial nerve deficit (CN7)
Seizure	Episodic uncontrolled brain activity, convulsion	Cerebrum
Depression, stupor, coma, mania	States of mental awareness	Cerebrum
Tremors	Involuntary rhythmic muscle contraction, shaking	Cerebrum, cerebellum, spinal cord, peripheral nerve; cold/pain
Fasciculation	Muscle twitch, involuntary muscle contractions	CNS, muscle, systemic, metabolic, or toxin
Nystagmus	Involuntary, rapid and repetitive movement of the eyes	CN6–8, brain stem, meningitis
Vestibular syndrome	Circling, head tilt, lateralizing signs, recumbent, and paddling	Brain stem, CN8, otitis
Pain	Reluctant to move, vocalization	Report location
Incoordination	Abnormal gait, hypermetria, postural defects	Cerebellum, spinal cord
Proprioceptive deficits	Improper positioning of legs and feet, knuckling	Cerebellum, spinal cord, peripheral nerves
Flaccidity	Decreased muscle tone	Spinal cord
Spasticity	Increased muscle tone	Cerebrum, spinal cord
Placing deficits	Abnormal foot placement due to visual or tactile deficits	Reposition foot based on tactile or visual queues
Proprioceptive deficit	Inaccurate foot placement; abnormal foot position; scuffed hoof	Any level of CNS
Ataxia	Lack of coordination	Cerebellum, vestibular system, or spinal cord
Plegia/paralysis	Complete loss of motor function, failure of withdrawal reflexes	Spinal cord
Paresis	Complete or partial loss of voluntary motor function	Cerebrum, vestibular system, spinal cord
Hypermetria	Exaggerated movement; "high stepping"	Cervical cord, brain stem, or cerebral cortex
Tetraplegia	All four limbs paralyzed	Spinal cord
Paraplegia	Both hind limbs paralyzed	Spinal cord
Hemiplegia	Front and hind limbs on one side	Spinal cord, brain stem
Monoparesis	A single limb paralyzed	Peripheral nerve, spinal cord
Anal tone	No sphincter response, unable to pass feces or urine	Spinal cord
Incoordination	Lack of coordination of muscle movement	Cerebellum, spinal cord, muscle
Truncal ataxia	Broad-based stance, dysmetria, intention tremor	Cerebellum

Table 19.6 Influence of location of spinal cord lesion on expected reflex response.

Approximate location of lesion (vertebra number)	Expected neurologic reflex
Craniocervical: Cl–C4	Forelimbs and hind limbs: UMN reflex deficits to all limbs
Caudocervical: CS–Tl	Forelimbs: LMN reflex deficits
	Hind limbs: UMN reflex deficits
Thoracolumbar: T2–L3	Forelimbs: normal
	Hind limbs: UMN reflex deficits
Lumbosacral: L4–L6	Forelimbs: normal
	Hind limbs: LMN reflex deficits
Sacral: L5	Forelimbs: normal reflexes
	Hind limbs: normal reflexes
	Anus/tail: LMN reflex deficits

Source: Adapted from Kornegay and Seim (1996).
UMN, upper motor neuron problem; LMN, lower motor neuron problem.

Antemortem sampling

Serum collected from affected and non-affected animals can be useful to determine antibody status and the presence of viremia/bacteremia for certain infectious agents or for serum chemistry and nutritional assays for metabolic or nutritional parameters of concern. Joint fluid can be collected antemortem via surgical preparation of the site and aspiration, usually with benefit of chemical restraint. Synovial fluid is useful for bacterial culture, cytological microscopic examination, or PCR detection of specific pathogens of interest. Urine is another antemortem sample. Urine calcium, phosphorus, and creatinine values reported are useful to estimate calcium and phosphorus dietary status related to bone disease (Hagemoser et al. 2000).

Postmortem sampling

Postmortem sampling from typically affected euthanized or dead animals is common in swine production settings. Collection of serum from euthanized pigs as well as normal cohorts can be quite useful samples. In cases of suspected joint or CNS disease, it is recommended to collect samples from joints or neural tissue first to reduce contamination. Alternatively, intact but rapidly chilled limbs, joints, heads, and vertebral columns can be submitted to a diagnostic laboratory for a thorough investigation. Whether performed in the field or in the laboratory, gross examination of bone, joint surfaces, synovium, and muscle is essential as part of the sample collection process. Tips for examination and collection of samples to improve accuracy of diagnosis of suspected joint disease include:

Clean affected joint regions, carefully remove skin, and then tap the joint with a sterile needle and syringe.

A synovial swab is collected after aseptically opening the joint.

Larger joints (stifle and elbow) have more synovial fluid and commonly have infectious pathogens if this is the cause of lameness.

Changes in synovial fluid color (i.e. red tinged from the normal clear to yellow) is an indication of disease along with changes in viscosity (normal synovium has high viscosity).

Table 19.7 Clinical signs and potential causes of diseases related to the eye.

Observed signs	Possible cause
Discharges: serous, mucoid, purulent	Ammonia, other gases, rhinitis, atrophic rhinitis, PCMV, *Staphylococcus hyicus*, streptococci, pseudorabies
Swelling (edema) of the eyelids	ASF, CSF, PRV, PRRS, edema disease, *Haemophilus parasuis*
Cloudy conjunctiva	Expected change by 24 hours after death
White conjunctiva	Anemia: blood loss, aplastic (iron deficiency)
Yellow conjunctiva	Jaundice: liver diseases (toxin, bacteria, virus)
Dehydration/starvation: globe sinks into orbit	Reflection of systemic illness, dehydration, diarrhea, starvation
Hemorrhagic conjunctiva	ASF, CSF, septicemia, coagulopathy, trauma
Facial staining (tears)	PRV, CSF, blocked tear ducts, atrophic rhinitis, irritating gases (ammonia)
Conjunctivitis (reddened, inflamed)	CSF, IAV, PRV, PRRS, PCMV, other viruses *Chlamydia*, *Mycoplasma,* other bacteria
Cataracts	Riboflavin deficiency
Blindness	Toxic (organic As, Pb, Hg, Na); PRV; botulism; vitamin A deficiency

Carefully examine the articular cartilage noting roughened, indented, or lost regions. Elbow, stifle, and tibiotarsal joints are the most common location of osteochondrosis.

Collect both fresh and formalin-fixed synovium from affected joints. Synovium can be difficult to visualize at times, but collection of the soft, often fatty tissue, directly adjacent to the joint, will help ensure inclusion of the synovium.

Collection of the brain and spinal cord can be difficult without the proper tools. If the brain and spinal cord are collected during a field necropsy, the following should be considered:

Cerebrospinal fluid can provide basic information via cytology, culture, or PCR if collected with a needle and syringe first, prior to disarticulating the head.

Aseptic collection of multiple sections of brain stem and spinal cord is essential given the endemic nature of multiple viral or bacterial pathogens. Swabbing sites or lesions of interest prior to removal reduces contamination. Spinal cord sampling should include fresh and formalin-fixed sections from cervical, thoracic, and lumbar areas.

Once removed, the brain and spinal cord can be examined for hemorrhage, defects, or gross indication of infection. Examine the calvarium and spinal canal after organ removal for gross pathology or palpable masses.

The brain can be sliced in half longitudinally, with one half placed in formalin and the other chilled for laboratory testing. Be sure to collect brain stem and cerebellum as well as cerebrum.

Continue with a complete and systematic necropsy, collecting fresh and fixed samples of major internal organs. The viscera can be removed from the body to visualize the ribs and ventral vertebral bodies. Examine ribs and vertebral bodies for fractures or fracture calluses, and collect those if needed. A simple assessment technique is to isolate individual ribs and access breaking strength. The second rib has recently been used as a standard for assessing bone density, ash, and mineral content (Madson et al. 2012). Growth plate alterations can be assessed by microscopic examination of sections of costochondral junctions.

Muscle samples should be collected soon after death when suspecting primary myopathy with source or name of the muscle noted. When possible, clamp ends of the sample before excision to reduce artifacts and to assure there are both a longitudinal section and a cross section of the muscle fibers since diagonal sections are impossible to interpret (Bradley 1978). For investigation of a specific disorder, it may be necessary to target specific muscles for typical lesions or fiber-type variations. For example, the diaphragm, the *gastrocnemius*, and the *supraspinatus* muscles are useful to assess type I fibers and the *psoas* and *longissimus* muscles to assess type II fibers (Ruth and van Fleet 1974). The *psoas* is an excellent muscle to use as a control as it is deep in the abdomen protected by the spinal column and is therefore unlikely to be affected by trauma and surface infection.

Samples useful for investigation of locomotor disease include serum; urine; affected limb(s) or synovial fluid and fresh and formalin-fixed synovium; brain and spinal cord (fresh and formalin-fixed brain stem, cerebellum, cerebrum; cervical cord, thoracic cord, lumbar cord); second rib and costochondral junctions; and fresh and formalin-fixed tissue representing other organ systems including skeletal muscle from multiple different locations. And lastly retain a feed sample from the site for possible future investigation. More details regarding formulation of the diagnostic question, diagnostic sample selection and collection, selection of diagnosis assays, and general guideline for diagnostic interpretation are in Chapters 6 and 7.

Mere detection of endemic agents should not necessarily indicate causation; pathogen detection should be associated with compatible clinical signs and identification of histopathologic lesions.

Congenital conditions

Congenital and newborn locomotor diseases can result from myriad insults affecting gestating sows or newborn pigs (Table 19.8.).

Splayleg

Splayleg is a congenital condition characterized by posterior paresis in newborn pigs. In severe cases the forelimbs may also be involved. Splayleg is usually found at or within hours of birth (Figure 19.1.). Although sporadic on individual farms, the problem is widespread, is common, and typically affects 1–4 pigs per litter and just a few litters at a time. Usually individual herd prevalence is less than 1%; however, prevalence of 8% or higher has been reported (Ward and Bradley 1980). Males may be predisposed based on reports where incidence in males was 174–233% greater than in females (Holl and Johnson 2005; Vogt et al. 1984). As many as half of piglets affected with splayleg die due to starvation or crushing by the sow. Piglets have a difficulty competing with their littermates for milk and are less able to move out of the sow's lying space. With nursing care and interventions, affected pigs can survive if provided with supplemental colostrum, milk, and heat or are assisted to nurse or cross-fostered to reduce competition. Often, piglets benefit from having their limbs taped or supported in a natural standing pose. Pigs that survive the first week of life can recover completely.

Table 19.8 Congenital and neonatal diseases affecting the locomotor system.

Viral	Clinical sign/lesion
Atypical porcine pestivirus	Intentional tremors at birth, variable severity (Table 19.9)
Classical swine fever virus	Tremors at birth, cerebellar hypoplasia, microencephaly
Japanese B virus	Cerebellar hypoplasia, hydrocephalus
Menangle virus	Arthrogryposis, craniofacial defects, mummies, stillbirths,
Feed, toxin, other	Clinical sign/lesion
Congenital tremors	Tremors at birth (see Table 19.9)
Splayleg	Posterior paresis, muscle hypoplasia, hypomyelinogenesis
Hypoglycemia	Vocalization, lethargy, recumbent, convulsions, coma
Hypoxia	Huddle, fail to suckle, "squawking" vocalization
Actinobacillus suis	Lameness, found dead, serositis, arthritis; acute sepsis
Arthritis (bacterial)	Lameness, swollen joints, arthritis
Vitamin A deficiency or toxicity	Deformities, cerebellar hypoplasia, stillbirths, blindness, arthrogryposis, flaccid paralysis
Trichlorfon toxicity	Cerebellar hypoplasia
Manganese deficiency	Arthrogryposis
Conium (hemlock)	Cleft palate, arthrogryposis
Nicotiana (tobacco)	Cleft palate, arthrogryposis
Datum (jimsonweed)	Arthrogryposis
Heat stress	Microencephaly
Genetic	References
Congenital tremors	Tremors at birth (see Table 19.8)
Kinky tail, fused vertebrae	Donald (1949), Nordby (1934)
Limbless pig	Johnson (1940)
Clubfoot, absence of fibula, extra toes	Palludan (1961), Nordby (1939)
Polydactyly	Hughes (1935), Malynicz (1982)
Syndactyly	Detiefsen and Carmichael (1921), Leopold and Dennis (1972), Ross et al. (1944)
Chondrodysplasia	Jensen et al. (1984)
Congenital hyperostosis	Doige and Martineau (1984), Roels et al. (1996)
Hydrocephalus	Hereditary, multiple causes
Meningocele, meningoencephalocele	Multiple causes
Hemivertebrae	Done et al. (1998)
Hyperostosis	Dalton (1992), Gibson and Rogers (1980), Kaye (1962)
Cleft palate	Painter et al. (1985)
Congenital muscle hyperplasia	Done et al. (1990)

The condition has been associated with low birth weight, slippery floors, congenital tremor, *Fusarium* toxins, certain genotypes, and short gestation lengths (Ward 1978 a,b). More recently, it was found that increased litter size can significantly increase the likelihood of splayleg pigs (Holl and Johnson 2005). Farrowing induction may result in a higher prevalence of splayleg especially if producers do not first determine the average gestation length in their herd (Sellier et al. 1999). Some older studies suggested that splayleg incidence was higher when sow diets were deficient in choline or methionine, which are essential for normal myelin production (Cunha 1968; Kornegay and Meacham 1973). However, in clinical trials on two farms, Dobson (1971) showed that adding 3 g choline and 5 g methionine to the sows' daily ration had no effect on the occurrence of splayleg.

Some suggest muscle hypoplasia is a feature of splayleg; however myofibrillar hypoplasia is common if not normal in newborn pigs. At 1 day of age, myofibrils do not fill the muscle cells completely in splayleg or in normal pigs (Ward and Bradley 1980), and no differences in vasculature, nervous supply, neuromuscular bundles, and the myelination of the intramuscular nerves were observed between healthy and affected pigs over the

Figure 19.1 Splayleg; newborn piglet. *Source:* Image courtesy of the Iowa State University Veterinary Diagnostic Laboratory.

clinical course of disease. Szalay et al. (2001) reported a reduction in the axonal diameter and myelin sheath thickness of the fibers that innervate the hind limb adductors of piglets affected by splayleg. Myelination is required for conduction of normal impulses along nerve fibers and appears to occur in two phases. The first peak occurs 2 weeks prior to birth and the second 3 weeks after birth. If pigs live past the first couple of weeks, the myelin sheath is properly developed during this second phase. It is unknown why this problem with myelination occurs in splaylegged pigs.

Congenital tremor

Congenital tremor (CT), also known as "myoclonia congenita," "trembling pig syndrome," or "jumpy pig disease," is a disease of newborn pigs that is characterized by bilateral clonic contractions of skeletal muscle that cease when piglets are at rest (Done 1968). Early reports of this clinical malady were by Kinsley (1922) in the United States, Payen and Fournier (1934) in France, and Hindmarsh (1937) in Australia. Although sporadic, CT is widely distributed and reported in most swine-producing countries and likely occurs globally. Tremors vary in intensity from mild to severe repetitive contractions that can completely impair the piglets' ability to stand or walk; vision, reflexes, and pain response are normal. Gross examination and histopathology of affected piglets is unremarkable, with an absence of inflammation in the CNS. Hypomyelination and dysmyelination have been described in some affected piglets, but lesions are subtle and not consistent and often do not correlate with the severity of clinical signs.

Survival of severely affected piglets is decreased due to nursing and ambulation difficulties, and deaths may result from starvation, inadequate colostrum intake, or crushing by the sow. Pigs born with CT may also have features of splayleg. Treatment for CT is aimed at reducing mortality. Affected pigs may be provided with additional heat and assisted to feed. The severity of the tremors decreases over time (Schwarz et al. 2017) and is usually resolved by 4 weeks of age.

Historically, clinical signs of CT occurred with fetal infections with classical swine fever virus (CSF) (Harding et al. 1966), inherited disorders (Harding et al. 1973; Patterson et al. 1973), and metrifonate/trichlorfon toxicity (Knox et al. 1978). Based on the eradication of CSF, genetic variability in swine herds, and current production practices, a majority of outbreaks of CT have been attributed to an unidentified virus (Table 19.9).

Clinical signs consistent with CT occurred in newborn piglets by intramuscular or intrauterine inoculation of pregnant sows with brain suspensions from piglets with CT (Done et al. 1986; Vandekerckhove et al. 1989), yet the viral etiology of CT type AII remained elusive. Through the use of next-generation sequencing, a divergent lineage pestivirus provisionally identified as atypical porcine pestivirus (APPV) was detected in pigs with CT in the United States (Arruda et al. 2016), Germany (Postel et al. 2016), the Netherlands (de Groof et al. 2016), Spain (de Groof et al. 2016), and Austria (Schwarz et al. 2017). Clinical signs consistent with CT have been experimentally reproduced by independent research groups through inoculation of gilts or sows and fetuses with APPV-containing inocula (Arruda et al. 2016; de Groof et al. 2016). There is limited information concerning the transmission, pathogenesis, carriage, and epidemiology of APPV. APPV was detected in the serum of one male and one female with CT out to 14 weeks of age at which time clinical signs had resolved (Schwarz et al. 2017). This finding suggests the likelihood of chronically and/or persistently infected animals. APPV was also detected in the semen of the male (Schwarz et al. 2017).

Hypoxia

Hypoxia is probably more common than recognized and vaguely characterized clinically as depression, inability to nurse, inappetence, huddling, lethargy, shivering, squealing or peculiar "squawk" when moved, coma, convulsions, and death. It is often associated with starvation or/and chilling, but, currently, it is not possible to definitively differentiate hypoxia or hypoglycemia. Umbilical cord rupture, cord occlusion during birth, dystocia, slow farrowing, or porcine reproductive and respiratory syndrome virus (PRRSV) lesions in the umbilical cord may be associated with the condition. The last pigs born in the litter may be more likely affected. Heated buildings with high levels of carbon monoxide may also cause hypoxia.

Hypoglycemia

Hypoglycemia is a common problem, both in weak newborn pigs who do not nurse regularly and in sows with limited functional mammary glands. Early clinical

Table 19.9 Causes, key features, and reference for types of congenital tremors described.

Type	Cause	Key features	References
A1	Classical swine fever virus (CSF)	Dysgenesis, cerebellar hypoplasia, small cord, demyelination	Harding et al. (1966), Bradley et al. (1985), Done (1976b), Done et al. (1984)
AII	Atypical porcine pestivirus (APPV)	Endemic globally; few lesions; sporadic	Done (1986), Arruda et al. (2016), deGroof et al. (2016)
AIII	Genetic: sex-linked recessive (Landrace and males)	Demyelination, hypoplasia of the spinal cord	Harding et al. (1973)
AIV	Genetic: autosomal recessive (Saddleback and Landrace/Saddleback)	Demyelination; CNS hypoplasia	Berge et al. (1987), Kidd et al. (1986)
AV	Trichlorfon toxicity	Cerebellar hypoplasia at 65–79 days' gestation	Pope (1986)
B	Unknown	No special features	Gedde-Dahl and Standal (1970)

signs include tachycardia, tremor, nervousness, vocalization, and irritability. As the hypoglycemia progresses, hypothermia, visual disturbances, mental dullness, confusion, depression, and seizures occur. Causes of hypoglycemia include sow factors such as nutrition, presence of disease, fewer functioning mammary glands than piglets, and poor presentation of both rows of mammary glands. Cold or wet creep areas and poor crate design will exacerbate hypoglycemia by increasing the demand for energy.

Hydrocephalus

Hydrocephalus is an accumulation of cerebrospinal fluid within the brain. It may be congenital or acquired – secondary to encephalitis or meningoencephalitis. Congenital hydrocephalus may be caused by vitamin A deficiency or a lethal defect that is inherited as an autosomal recessive trait in Durocs (O'Hara and Shortridge 1966). Clinical signs vary from compulsive walking, head pressing, blindness, and seizures to a more mild form indicated by strabismus and stunted growth. Animals with a primary encephalitis will have signs of multifocal brain involvement.

Cerebellar hypoplasia

Cerebellar hypoplasia causes pigs to sit with their forelimbs extended or to assume a tripod sitting position. The clinical signs are nonprogressive, and other CNS signs are not present. Cerebellar hypoplasia can occur with viral (CSF and possibly other pestiviruses) infection in the sow and is reported as a sequel to trichlorfon poisoning (Pope 1986). Once common, vitamin A deficiency has serious effects on the nervous system. In pregnancy, low vitamin A levels caused herniation and constriction of dorsal and ventral nerve roots. It results in abortion with stillbirths and small or absent eyes. Other abnormalities include cleft palate, edema, high morbidity, or high mortality.

Cerebellar abiotrophy

Cerebellar abiotrophy is a condition where pigs are normal at birth but develop ataxia and a fine tremor by 3–8 weeks of age. This condition, found in Yorkshire and Large White pigs, is probably an autosomal recessive trait. It is progressive over days to weeks until affected pigs are recumbent and unable to rise. It is a condition diagnosed on histopathology as premature degeneration of neurons (Purkinje cells).

Vitamin A

Vitamin A deficiency can manifest as a generalized flaccid congenital paralysis of all four limbs, head tilt, incoordination, stiff gait, lordosis, excitability, muscle spasms, night blindness, progressive dysfunction with incoordination, swaying gait, restlessness, dog-sitting, reduced growth or spasm, and perhaps paralysis due to degeneration of portions of the spinal cord and sciatic and femoral nerves. At postmortem there may be hydrocephalus, a small cranium, and herniation of spinal cord in the lumbar region. Deficiency can also be associated with eye lesions including anophthalmia, microphthalmia, and entropion.

Miscellaneous joint, muscle, and bone disorders

Bone changes are unusual with infectious diseases but can occur with Menangle virus and CSF. Abnormalities of endochondral ossification include "bullhead," bent legs, deformed feet, congenital carpal flexion, and

Figure 19.2 Hyperostosis; newborn piglet. *Source:* Image courtesy of the Iowa State University Veterinary Diagnostic Laboratory.

kyphosis associated with a congenital hemivertebrae. A second group causing fetal or neonatal abnormalities is associated with the consumption of toxic plants during pregnancy. Consumption of *Conium maculatum* will produce bone abnormalities, particularly cleft palate, as will tobacco poisoning. Arthrogryposis is characterized by rigid and hyperflexed or hyperextended limbs. Congenital hyperostosis (Figure 19.2) is a lethal, rare autosomal recessive condition where leg bones are thickened (Kaye 1962). Congenital abnormalities affecting muscles are rare in pigs.

Neurological conditions

The list of agents or insults that can affect neural and locomotor function is long yet not complete. Common infectious agents, nutritional deficiencies, and toxicities are discussed in respective chapters. APPV associated with CT is discussed above.

Viral pathogens

Swine are the natural host of porcine herpesvirus 1 (PHV-1), also known as pseudorabies virus (PRV) or Aujeszky's disease, but can infect a wide range of species, often fatally. Pseudorabies is eradicated in some swine-producing countries, whereas in others it may be notifiable as a controlled disease or may simply be endemic. Although eradication at local or national level is successful within commercial herds, PRV can remain widespread in populations of non-domesticated swine. Neurological signs are observed predominantly in young piglets, with clinical signs including ataxia and convulsions, whereas infection of pregnant sows can result in fetal death and reabsorption, mummification, and/or abortion.

Classical swine fever is a highly contagious viral disease of major worldwide importance; the disease belongs to the World Organization for Animal Health (OIE)-listed diseases. Swine are the only known reservoir. CSF is endemic in parts of Eastern Europe, Southeast Asia, and Central and South America. The domestic swine population in Australia, New Zealand, North America, and Western Europe are considered CSF-free. Severe systemic illnesses including depression, fever, anorexia, conjunctivitis, death, weak staggering gait, skin hyperemia, watery diarrhea, convulsions, and death have been described 1–3 weeks after infection. Mortality can reach up to 90%; mortality associated with less virulent strains range from 1 to 60% with nonspecific clinical signs and lesions. Petechiae in kidneys, larynx, urinary bladder, and mucous membranes, infarcts in spleen, and hemorrhage of lymph nodes are gross lesions observed in affected animals.

Eastern equine encephalomyelitis is infrequently reported in domesticated swine; clinical signs are age dependent with younger pigs being more susceptible to develop clinical disease. Infection of pigs older than 2 months of age is usually subclinical but causes incoordination, depression, seizures, and death in pigs of less than 2 weeks of age (Elvinger et al. 1994). Pathologic lesions include focal necrosis of the cerebral cortex and multifocal myocardial necrosis. Diagnosis is made after a history of mosquito swarming and positive EEEV serum virus neutralization assay.

Japanese encephalitis virus (JEV) has historically been associated with reproductive failure including increased rates of stillborn, mummies, and weak neonatal piglets (Daniels et al. 2002). Recent evidence has suggested that JEV may lead to a wasting syndrome with associated lymphoplasmacytic encephalitis with varying degrees of depression and hind limb tremors (Yamada et al. 2004). The virus is amplified in the pig and then transmitted via mosquitoes to other species.

Malignant catarrhal fever (MCF)-like condition is sporadically described in swine. The condition has been reported in Germany (Pohlenz et al. 1974), Norway (Loken et al. 1998; Okkenhave and Kjelvik 1995), Finland (Syrjala et al. 2006), the United States (Alcaraz et al. 2009; Gauger et al. 2010), and Brazil (Azevedo Costa et al. 2010). Clinical signs resemble those described in ruminants affected with MCF (lethargy, anorexia, fever, recovery, or death) and are associated with ovine herpesvirus type 2 (OHV2). Histologic lesions include mucopurulent tracheitis, interstitial nephritis and pyelitis, necrotizing arteritis, and lymphocytic meningoencephalitis with perivasculitis and vasculitis (Li et al. 2012). Diagnosis should be based on a combination of clinical signs, histologic lesions, and detection of the virus by PCR or virus-specific antibodies in the blood.

Encephalomyocarditis (EMC) virus infection is not uncommon; however, clinical disease is rare. Acute

myocarditis in young pigs and reproductive failure in sows are the most common clinical signs described; however, lymphoplasmacytic meningoencephalitis has been described (Maurice et al. 2005).

Blue eye disease is caused by the blue eye paramyxovirus (BEP). To date this virus has only been reported in Mexico. The disease is primarily described as causing a sharp increase in preweaning mortality and CNS signs (Ramirez-Herrera et al. 2001). Clinically affected pigs show incoordination, hind limb paralysis, and convulsions. Corneal opacity (edema) and conjunctivitis are described in pigs of all ages and can be observed without other clinical signs; corneal lesions usually resolve spontaneously. Histologic lesions are primarily concentrated in the brain and spinal cord and have been described (Stephano et al. 1988). Diagnosis should be made based on clinical signs, macroscopic (corneal opacity highly suggestive) and histologic lesions, serological assays, and/or detection of the virus by PCR.

Teschovirus A is one cause of polioencephalomyelitis. The virus has a worldwide distribution and is considered endemic in domestic pigs with swine the only known host. Despite the endemic nature of this virus, clinical disease is sporadic. Clinical signs vary but can include fever, depression, anorexia to more severe muscle tremor, nystagmus, opisthotonos, ataxia of the rear legs, paralytic symptoms, trembling, recumbency, paddling of the rear legs, and convulsions (Mills and Nielsen 1968). Histologic lesions are predominately found in the spinal cord. Diagnosis is by typical clinical signs, characterization of histologic lesions, and detection of viral RNA by PCR within affected spinal cord segments. Spinal cord used for viral RNA detection should be collected aseptically given the ubiquitous nature of this virus in feces. More recently, sapelovirus A has been detected in the CNS of pigs with similar clinical signs and histopathologic lesions (Schock et al. 2014; Arruda et al. 2017).

PRRSV will occasionally produce CNS signs with associated encephalitis, myelitis, or meningitis (Cao et al. 2012; Rossow 1998) or can exacerbate neurologic signs in pigs coinfected with pseudorabies (Narita and Ishii 2004). PCV2 does not typically cause encephalitis; however, Seeliger et al. (2007) have identified PCV2 as a potential etiologic cause of neurologic disease.

Rabies is rare in swine but when occurs is usually manifested as the "dumb" form with posterior paresis and prostration.

Bacterial agents

Major diseases caused by bacteria or their toxins are discussed in respective chapters. Edema disease is an acute, often fatal, enterotoxemia of recently weaned pigs. It is associated with multiple genotypes of *Escherichia coli* (see Chapter 52) that usually possess F18 or F4 (K88) fimbriae and elaborate Shiga-like verotoxin SLT-IIE (STx2e).

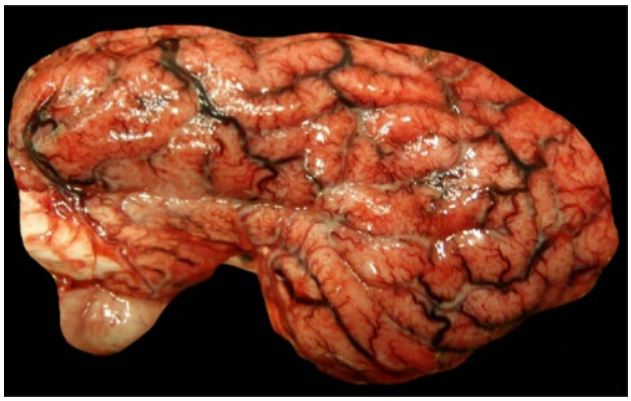

Figure 19.3 Suppurative meningitis (leptomeninges); bacterial sepsis. Note the injected meningeal vessels and the white exudate in sulci. *Source:* Image courtesy of the Iowa State University Veterinary Diagnostic Laboratory.

Systemic bacterial infections are common. *Haemophilus parasuis* is particularly common following PRRSV or PCV2 infections, with leptomeningitis (Figure 19.3) and polyserositis typical of Glässer's disease. *Streptococcus suis* septicemia is very common in young piglets but can occur in growing pigs as well. Streptococcal septicemia can lead to similar clinical signs and macroscopic and histologic lesions as Glässer's disease.

A variety of other opportunistic bacteria can cause sporadic disease in the nervous system in individual animals. Erysipelas can cause acute deaths in naïve pigs or when first introduced to a system or when vaccination is discontinued. It produces fever, difficulty in rising, and lameness due to arthritis and pain. *Actinobacillus suis* can cause septicemia, arthritis, and subsequent nervous infections as does *Trueperella pyogenes. E. coli* is a common cause of septicemia in neonates. Stachybotryotoxicosis, caused by the toxin of *Stachybotrys atra* acquired from hay or straw, could potentially cause toxemia but is rarely reported in swine. Moldy hay or straw can result in depression, vomiting, tremors, sudden death, and abortion. *Listeria monocytogenes* can cause encephalitis, but disease is rare. Many cases are diagnosed solely on brain culture or through histopathology. Lymphoplasmacytic meningitis in addition to encephalitis with perivascular cuffing and microabscessation is reported (Lopez and Bildfell 1989).

Spongiform encephalopathy

There is no evidence for naturally occurring transmissible spongiform encephalopathies (TSE) in swine (Ryder et al. 2000). Despite the lack of natural cases, typical histologic lesions and intracellular and neuropil-associated

pathological prion protein (PrPSc) deposition corroborated by Western blot (WB) have been described in pigs challenged with BSE-derived material via three simultaneous distinct routes such as intraperitoneal, intravenous, and intracerebral (Hedman et al. 2016; Konold et al. 2009; Ryder et al. 2000). A recent study demonstrated that pigs can become infected when intracranial and orally inoculated with scrapie isolates. At 6 months' postchallenge, no evidence of scrapie infection was noted by any diagnostic method. However, after 51 months swine were positive by either immunohistochemistry (IHC), WB, or enzyme immunoassay (EIA). No neurological signs or histologic spongiform changes were observed in experimental animals (Greenlee et al. 2016).

Parasitic

Toxoplasma gondii infection can cause stillborn piglets and prolonged gestation. Toxoplasmosis rarely may produce tremors, weakness, staggering, and mortality, and survivors may be ataxic and blind.

Toxins and deficiencies

Salt poisoning (water deprivation, sodium ion intoxication)

Risk factors for sodium intoxication occur with excess sodium chloride ingestion (e.g. brines, whey, salted fish, feed mixing error) or water deprivation (e.g. not available, frozen) and are exacerbated by water engorgement when water becomes available. Clinical signs vary by severity and stage of disease. Animals may be found dead, while others have signs that include epileptiform seizures, snout twitching, contraction of neck muscles, head pressing, stepwise movements of head, walking backward, dog-sitting with nose upward, twitching of face/ears, and blindness. Signs can progress to tremors, lateral recumbency, running movements, prostration, coma, and death. Eosinophilic meningoencephalitis is a transient microscopic lesion in the brain quite useful for diagnosis when present. Polioencephalomalacia may be present in chronic or nonfatal cases. Sequelae include blindness and polioencephalomalacia. The most important intervention when water deprivation has occurred is to limit water intake, with gradual introduction of water, gradually increasing to ad libitum over a several hour period.

Hepatic encephalopathy

Hepatic encephalopathy may have multifocal lesions in the CNS, but the clinical signs are primarily due to forebrain involvement. Hepatic encephalopathy occurs when neurotoxic substances (e.g. ammonia) build up in the blood due to liver dysfunction. Clinical signs include blindness, ataxia, head pressing, seizures, and aggression. There will also be signs referable to liver disease, such as anorexia, weight loss, or diarrhea.

Micronutrient deficiencies

Several mineral deficiencies will produce signs in the CNS, peripheral nerves, and special senses. Calcium and phosphorus deficiency can produce hyperesthesia, tremors, tetany, or posterior paralysis depending on magnitude and duration. Magnesium deficiency will produce hyperirritability and tetany. Copper deficiency can cause swayback, ataxia, posterior paralysis, and paraplegia in pigs (Bennetts and Beck 1942; Fletcher and Banting 1982; McGavin et al. 1962; Wilkie 1959). Histopathology reveals marked spinal demyelination affecting the dorsal spinocerebellar tracts (Pritchard et al. 1985).

Vitamin B_6 (pyridoxine) deficiency produces a mincing gait, hyperexcitability, ataxia, waddling, "goose-stepping," and epileptiform convulsions. Naturally occurring pantothenic acid deficiency was described (Doyle 1937; Goodwin 1962) as incoordination, poor growth, and "goose-stepping." Nicotinic acid deficiency has been induced in pigs by feeding the antimetabolite 6-aminonicotinamide (O'Sullivan and Blakemore 1980) when maize is low in tryptophan or high in antimetabolites.

Micronutrient toxicities

The risk of selenium toxicity (see Chapter 68) from mixing errors is common because the toxic dose in feed is low despite a 10× safety margin from the legal fortification limit of 0.3 ppm (Stowe et al. 1992; Stowe and Herdt 1992). Doses of >10 ppm are usually required to cause demyelination or ambulatory dysfunction. Acute toxicity occurred when 25 g/kg was accidently fed (Nathues et al. 2010), with clinical signs of apathy, paralysis, and death within 36–72 hours after exposure. Bilateral symmetrical focal myelomalacia particularly in the cervical and lumbar spinal intumescence (Casteel et al. 1985; Harrison 1983; Penrith and Robinson 1996; Stave et al. 1992) and in the nuclei of the facial nerve in the medulla oblongata is seen histologically. Polioencephalomalacia is suggestive of selenium toxicosis, but it can also follow nicotinamide deficiency (Wilson and Rake 1972) or other conditions.

Arsanilic acid has been fed to pigs to promote growth or treat swine dysentery. Overdoses of arsanilic acid can decrease growth rate and cause head tremor, progressive blindness, ataxia, and paresis. Other clinical signs are seen in pigs poisoned with 3-nitro-4-hydroxy phenyl arsonic acid (Rice et al. 1980). After exercise there is trembling of the muscles of the shoulders, hams, and backs followed by violent tremors, incoordination, and extreme agitation and screaming. Diagnosis is by the

detection of arsenicals in the urine and observation of degeneration of the optic nerves, optic tracts, and peripheral nerves (Harding et al. 1968).

Insecticide

Organophosphate and organochlorine poisoning occurs in pigs due to inadvertent mixing or spilling of insecticides (Frank et al. 1991). Most pigs (70%) consuming contaminated feed die within hours of ingesting these products. Organophosphates cause pulmonary edema, myocardial hemorrhage, and cholinesterase inhibition. Organochlorines cause convulsions. Chemical analysis of the feed is needed for the definitive diagnosis. Orthocresyl phenols are organophosphates with delayed effect of demyelination and posterior paresis and paralysis, also known as delayed organophosphate toxicity.

Plant poisoning

Majority of plant poisonings are diagnosed by finding plants in the environment or in the digestive tract. They often occur when adult swine are raised in derelict land or woodland. *Cassia* spp. seeds cause incoordination, ataxia, staggering, decreased weight gain, and increased mortality in grower pigs (Colvin et al. 1986; Flory et al. 1992). Only a few seedlings of cocklebur (*Xanthium strumarium*) may cause depression, nausea, weakness, ataxia and spasms of neck muscles, convulsions, and death. Mortality is sporadic and limited to when plants are emerging numerously. Solanaceae (nightshade) causes stupefaction, depression, ataxia, muscle tremors, loss of appetite, convulsions, and coma with dilation of pupils. Hyperexcitement can be observed initially; animals may lie on their side and kick their feet as the clinical signs progress. Water hemlock ingestion causes nervousness, pawing, spasmodic twitching and contraction of muscles, paralysis, and death. The pigs squeal before and during the convulsions (Barlow 2006).

Poison hemlock ingestion produces rapid trembling of the flank muscles followed by paralysis caused by damage to ends of the motor nerves (Hayashi and Muto 1901). Bracken poisoning results in muscle weakness and can lead to death in 4–5 days. Buttercups will cause muscle twitching in the ears, nervousness, and paralysis in two to three days followed by death. Pigweed (*Amaranthus* or redroot) poisoning is typically observed in the late summer and fall, with clinical signs 5–10 days after exposure. Signs include trembling, weakness, incoordination, kicking, almost complete rear leg paralysis, and sternal recumbency. The morbidity is variable and the mortality can be high. Death is usually within 48 hours of onset of clinical signs. Red squill ingestion causes hyperesthesia, depression, weakness, ataxia, paralysis, and death usually within three days. Ergot affecting the nervous system was described by Chennells et al. (2006).

Gases

Carbon monoxide poisoning will produce lethargy, incoordination, coma, and death due to hypoxia; abortion has also been reported (Dominick and Carson 1983; Jennings 2001; Wood 1978). Carbon dioxide produces anxiety, staggering, coma, and death. Hydrogen sulfide produced listlessness, incoordination, spasms, coma, and death. All are discussed in respective chapters.

Vestibular disease

Vestibular disease causes a head tilt toward the affected side, horizontal nystagmus, and ataxia, which may include circling or falling. The condition is widespread but sporadic. Peripheral lesions are not associated with the ascending or descending tracts, so there is no paresis or proprioceptive deficit, animals are not depressed, and nystagmus is always rotatory or horizontal with the fast phase opposite the head tilt and does not vary with head tilt. The animals remain bright and the appetite is normal (Buddle 1987). Alternatively, central lesions frequently cause depression, tetraparesis, and nystagmus that varies with head position and may cause other cranial nerve deficits. Most lesions cause ipsilateral clinical signs, but the paradoxical vestibular disease causes contralateral signs. Rupture of the tympanic membrane usually follows inflammation of the middle ear.

Otitis media (peripheral vestibular disease) is usually due to progressive external otitis (Kornegay and Seim 1996). The external ear is inflamed and contains debris, and the pig may be sensitive to manipulation of the ear. Various bacterial species have been recovered from infected ears (Shimada et al. 1992), yet otitis media and interna may be common sequelae to *Mycoplasma hyorhinis* (MHR) and *S. suis* infections. Multiple reports have isolated MHR in approximately 80% of young swine with otitis media (Friis et al. 2002, Kazama et al. 1994), whereas MHR was recovered in over 50% of normal swine without otitis media (Friis et al. 2002), suggesting this bacterium may be an opportunistic invader. A majority of pigs (20 out of 28) diagnosed with meningitis due to *S. suis* had either otitis media or otitis interna (Madsen et al. 2001). Exudative otitis interna with a positive IHC for *S. suis* was found in 71% of the pigs. Most of these pigs had a perineuritis along the vestibulocochlear nerve. This nerve is likely a conduit to the CNS. Half of the pigs with both ears available for evaluation were affected bilaterally. Otitis interna can be the result of infection via either meningeal or auditory canal via tympanic membrane breach. Pigs recovering from *S. suis* meningitis may have residual hearing and vestibular dysfunction due to chronic otitis interna.

Eyes and vision

In the day-to-day life of the pig, excessive lacrimation and conjunctivitis may be associated with dust, ammonia, hydrogen sulfide, or obstruction of nasolacrimal duct secondary to rhinitis. Important infectious causes of conjunctivitis include CSF and ASF. Pseudorabies is another primary cause of conjunctivitis, retinitis, and optic neuritis. Other agents sometimes associated with outbreaks of conjunctivitis include *Chlamydia*, *Mycoplasma*, porcine cytomegalovirus (PCMV), influenza A virus (IAV), and PRRSV, among other viruses. PCMV (Edington et al. 1988) can cause a severe rhinitis with nasal discharge, conjunctivitis, and sneezing. Rarely, occasional fractures of the orbital bones may distort the eyes.

Gross lesions are rare in the optic nerve and globe; histopathology is needed for conditions affecting these structures. Hypopyon, rare in pigs, is suppuration in the anterior chamber of the eye. Corneal edema is associated with blue eye disease (Stephano et al. 1988) or following trauma. There are other unusual conditions such as riboflavin deficiency that will cause cataracts. Enteroviral encephalomyelitis can cause retinitis and neuritis, and swine vesicular disease can cause optic neuritis.

Histologically, organic arsenical poisoning produces degeneration of the optic nerve, optic tracts, and peripheral nerves. Mercury poisoning will produce blindness, and organophosphate poisoning will produce lacrimation. Hygromycin B toxicity will produce cataracts. Lead poisoning is rare but will cause blindness. Excess vitamin A to sows will produce cataracts in piglets.

Keratosis is rare in the pig but reported following trauma, noxious gas exposure, pseudorabies, and *Chlamydia* infection. Pigs with GM2 gangliosidosis may have multiple white foci in the retina.

Bone disorders

Metabolic bone diseases

Metabolic bone disease broadly categorizes disturbances related to bone formation and remodeling. Disease is associated with inadequate calcium, phosphorus, vitamin D, or problems related to parathyroid hormone. Clinical manifestations within a population are generally gradual but can be abrupt in individual animals depending on the mechanism and degree of the insult.

Common mechanisms related to disease development include inadequate dietary supplementation of vitamin D_3 (Pepper et al. 1978), inadequate available phosphorus in the diet, inadequate dietary calcium, or an imbalance of available calcium and phosphorus ratio, which should be roughly 1.2 : 1. Calcium uptake and utilization is dependent on adequate levels of vitamin D; therefore the consequence of vitamin D deficiency is calcium deficiency.

Rickets and osteomalacia are the disease names associated with metabolic bone disease in growing animals and adult animals, respectively, and characterized by decreased mineralization of bone. The mechanisms are similar for these two diseases, the difference being that rickets involves growing bones and osteomalacia occurs by remodeling of mature bone. If metabolic demands for calcium or phosphorus are greater than intake, reduction and retardation of bone growth or remodeling follows.

Metabolic bone disease in swine is usually related to ration formulation or feed mixing errors, but a rare hereditary form of rickets has been described where the enzyme to convert D_2 to D_3 is absent in the kidney (Fox et al. 1985).

Growing pigs with rickets will have weak bones that bend before breaking with weak snap, have increased propensity for bone fractures, and have enlarged growth plates giving a clinical appearance of swollen joints. Since the bones bend or fracture easily, there often is evidence of recent or healing fractures and calluses. The joint surfaces may be folded, and growth plates are thickened and irregular. Hemorrhages occur in the growth plate cartilage or adjacent bone. Lameness can be a common occurrence, and conformation may be abnormal because of bending or bowing of bones. Although nonspecific, long hair and decreased appetite have also been reported for vitamin D-deficient pigs. Rortvedt and Crenshaw (2012) experimentally reproduced and reported kyphosis or "humpback" in pigs as a manifestation of rickets.

Gross lesions can take months to develop in swine fed deficient diets; however, the onset, progression, and prevalence of disease are dependent on the severity of the deficiency. Chronic nutrient imbalances can have acute clinical presentation as pathologic fractures, rubbery, weak bones, or less frequently acute hypocalcemia (Madson et al. 2012). Individual or multiple growing pigs with acute hypocalcemia can unexpectedly develop one or more of the following clinical signs: tremors, tetany, seizure-like muscle fasciculation, weakness, lameness, painful gait with reluctance to move, or bone fractures (macroscopic and/or microscopic). Sometimes the first clinical sign observed is animals reported with central nervous signs or simply found dead. In a large population of pigs, many of these signs may be present simultaneously.

Osteomalacia can be present in late finishing or adult swine (Doige 1982; Gayle and Schwartz 1980) since this is a condition of increased absorption of previously formed bone. Fractured femurs, vertebrae, or ribs at load-out or at slaughter occur with increased frequency when there is osteomalacia.

Table 19.10 Metabolic bone diseases.

Term	Abnormality	Age	Cause	Clinical signs	Lesions
Rickets	Abnormal endochondral ossification, defective bone mineralization	Growing pigs	Deficiency of available vitamin D, P, Ca; Ca/P ratio discrepancy	Lameness, pathological fractures, sudden death, tremors, kyphosis	Soft rubbery bones (ribs), enlarged epiphyses, and growth plates; fractures and calluses (ribs)
Osteomalacia	Abnormal bone remodeling, defective bone mineralization	Postpubertal and adult pigs	Deficiency of available vitamin D, P, Ca; Ca/P ratio discrepancy	Pathological fractures, lameness	Cortices thin, spongy, soft with deposition of matrix at sites of mechanical stress
Fibrous osteodystrophy	Excessive bone resorption, defective bone mineralization	Growing and adult pigs	Calcium and/or vitamin D deficiency; excess P	Lameness, stiff, reluctant to rise, fractures, jaw swelling, movable teeth	Soft bone
Osteoporosis	Reduced bone mass	Growing and adult pigs	Starvation; Ca deficiency; more resorption than bone formation	Pathological fractures, possible tremors, tetany, death	Brittle bones with thin cortices and reduced cancellous bone; bones easily break
Lactational osteoporosis	Reduced bone mass	Adult pigs, weaned sows	Inadequate Ca; intake or bone reserves during lactation	Hind limb weakness and fractures; slow farrowing, uterine prolapse, tremors, death	Brittle bones with thin cortices; bones easily break

Osteoporosis is a disorder of bone classified under the umbrella of metabolic bone disease. This term is a lesion rather than a process as in rickets or osteomalacia and denotes overall decreased bone mass. Osteoporosis is caused by an excess resorption of bone and results in endosteal thinning of the trabeculae and cortices (Spencer 1979). Bones are structurally normal but become increasingly brittle (easily snap). Osteoporosis results from decreased caloric intake, decreased dietary calcium, lactation, disuse, copper deficiency, vitamin A toxicity, or increased stress (Thompson 2007). With lactational osteoporosis (Spencer 1979), large amounts of calcium and phosphorus are preferentially resorbed from the skeleton to provide high levels of calcium and phosphorus in milk. This process typically occurs in mid- to late lactation or the early post weaning period (Gayle and Schwartz 1980). This can manifest clinically as lameness or "downer" sow syndrome. Complicating factors include absence of sunlight and periods of restricting exercise (sow stall, farrow crates), particularly for first litter gilts that are still growing.

Osteomalacia and osteoporosis have been described in diagnostic surveys of paretic or paralyzed sows (Doige 1982; Gayle and Schwartz 1980). Sows may become lame or unable to stand and may have fractures (particularly of the humerus, femur, and vertebrae) and paraplegia. Crepitus can be heard and felt when clinically examined. At necropsy most frequent sites for lesions are the proximal one-third of the humerus and proximal one-third of the femur. Comminuted spiral fractures extend from the metaphysis to the diaphysis. It is a result of an imbalance between bone formation (osteoblast activity) and bone resorption (osteoclast activity). There is usually due to calcium deficiency (Spencer 1979). Metabolic bone disease conditions are summarized in Table 19.10.

Micronutrient disorders affecting bone

Copper is required for linking collagen molecules. Deficiencies have been associated with skeletal development, osteoporosis, and osteochondrosis. Suboptimal levels can result in widened growth plates, mimicking rickets-like changes in growing pigs, or spontaneous fractures.

Vitamin A toxicity is a well-recognized problem associated with lameness in swine. Toxicity is most often associated with diet formulation/mixing errors and is associated with osteoporosis, exophyte formation, and premature growth plate closure in growth. Affected growing pigs typically lay down more and can have an arched back appearance when standing and hoof placement is altered to reduce pain. Long bones can be reduced in length with flaring of the physeal region.

Jensen et al. (1983) described inherited vitamin C deficiency in a group of 9–10-week-old pigs with radiodense metaphyses of the long bones and ribs, widening of the metaphyses, and lipping over the epiphyseal plates. There were also subperiosteal hemorrhages around the edge of the shafts of the long bones, and histopathology revealed reduced osteoid in the growth plates. It is

Table 19.11 Nutritional contributors to locomotor dysfunction.

Insult/disease	Clinical signs	Comment
Vitamin D deficiency	Rickets, enlarged joints, lameness, weak bones, brittle bones, fractures, "humpbacks"	Interactions with calcium, phosphorus, phytase, sunlight, growth rate, and age can complicate identification of cause
Vitamin E deficiency	Nutritional myopathy	Mulberry heart disease
Selenium deficiency	Nutritional myopathies	Mulberry heart disease
Calcium and phosphorus	Metabolic bone disease	See text
Biotin deficiency	Lameness, hoof lesions	Hamilton and Veum (1984), Simmins and Brooks (1988), Penny et al. (1980)
Calcium – hypocalcemia	Abrupt onset of tremors, prostration, low serum calcium	Chapman et al. (1962), Storts and Koestner (1965), Madson et al. (2012)
Copper deficiency	Incoordination, paralysis, aortic rupture	Teague and Carpenter (1951), Follis et al. (1955), Fletcher and Banting (1982), Pritchard et al. (1985)
Manganese deficiency	Weak, incoordination, lameness, bowed legs, reproductive effects	Rare; Neher et al. (1956)
Magnesium deficiency	Hyperirritable, tetany	Miller et al. (1940), Plumlee et al. (1954)
Zinc deficiency	Parakeratosis, lameness	Brink et al. (1959)
Vitamin C deficiency	Joint hemorrhage	Wegger and Palludan (1994)
Vitamin A deficiency	Stillbirth, deformities, incoordination, blind	Rare; Dobson (1969), Pryor et al. (1969)

probably an autosomal recessive single-gene deletion mutation, leading to a deficiency of L-gulonolactone oxidase.

Table 19.11 defines nutritional disorders related to locomotion. See Chapter 68 for additional information regarding nutrient-related conditions.

Fractures of bone

Fractures can occur in all ages but are more common in gilts and sows during late lactation or post weaning. Highly productive sows are at risk for osteomalacia, and subsequent fractures, if feed intake is not adequate during lactation (Tubbs 1988). Piglets often have fractures if laid on by sows if they are hypoglycemic or weak. Older piglets may fracture bones when they are stuck in gates or equipment or during transport (Vaughan 1977). An increased rate of fractures in a particular age group should elicit a broad investigation of risk factors, including dietary factors for metabolic bone condition, housing and flooring effects, mechanical sources of trauma, transport trauma, and handling practices by caretakers. Fractures related to improperly formulated rations may become evident at slaughter; electrical stunning may increase the frequency of fractures in femurs and spine, leading to hemorrhage and subsequent increase trimming of meat.

Fractures found in several animals at the same time may be a result of accidental electrocution or outdoor lightning strike (Van Alstine and Widmer 2003). Lumbosacral vertebra and thoracic vertebrae, femur, neck of the femur, humerus, neck of the scapula, or pelvis are the usual sites. Sometimes the fractures in the lumbosacral junction result in separation of spinal cord and nerves and, if sublethal, cause posterior paresis, retroperitoneal and perirenal hemorrhage, and distension of urinary bladders from inability to urinate. Fractures were described in the outbreaks of osteoporosis (Douglas and Mackinnon 1993) that occurred in gilts when they were moved from the farrowing quarters and involved pelvis, spine, femur (Blowey 1994b), and other bones. This was considered a multifactorial occurrence with early mating, rapid growth, high milking yield, large litters, and insufficient nutrients in the diet to provide both milk and sow growth being potential risk factors.

Kyphosis/lordosis

Kyphosis/lordosis is a disease process that results in curvature of the spinal column. The condition occurs sporadically within herds and mainly affects individual animals. However, reports have indicated there can be outbreak scenarios in which 30% of pigs are affected. The disease is idiopathic, but congenital, heredity, or nutritional implications are suggested. The condition is not readily apparent at birth, but typically develops 8–16 weeks of age (Straw et al. 2009). The curvature is most prevalent at the 14–16th thoracic vertebrae and associated with abnormal ossification of the epiphysis (Nielsen et al. 2005). Recent genetic investigations have

indicated moderate hereditable and multiple loci affecting development (Holl et al. 2008, Lindholm-Perry et al. 2010). Lordosis or kyphosis has also been associated with precocious behavior causing relaxation of the spinal ligaments (Done and Gresham 1998). Genetic selection for an extra vertebrae in the spinal column (Pearson and Done 2004) resulted in too much muscle weight for the skeleton.

Kyphosis also occurs as a metabolic bone disease, particularly vitamin D deficiency (Madson et al. 2012; Rortvedt and Crenshaw 2012). In a controlled experiment, the latter group reproduced kyphosis with 20–30% incidence by omitting vitamin D from gestating sow and/or weaned pig diets. In field outbreaks, affected piglets are sometimes apparent in the first 3 weeks of life, suggesting dietary compromise in dams.

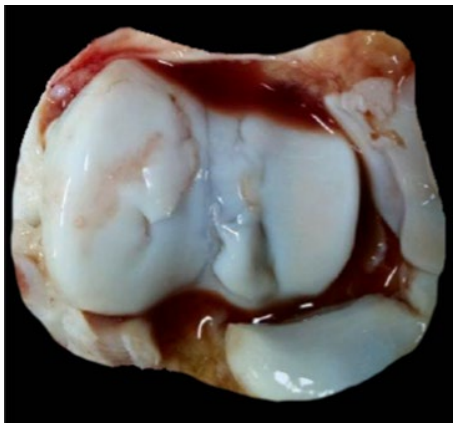

Figure 19.4 Osteochondrosis dissecans; articular cartilage thickening, necrosis, folding, and flap formation with serosanguinous joint fluid. *Source:* Image courtesy of the Iowa State University Veterinary Diagnostic Laboratory.

Spondylitis

Ankylosing spondylitis was identified by Grondalen (1974a, b) in culled sows and boars at abattoirs, but it is thought that the condition starts as early as the first year of life. Pigs have a painful lumbar region and may develop kyphosis and waddle when walking or drag the hind feet. The cause is probably multiple effects of wear and tear, spine trauma, poor nutrition, genetics, arthritis of spinal joints, etc. (Grabell et al. 1962; Grondalen 1974a, b). Vertebrae may eventually fuse and alleviation occurs.

Osteochondrosis

Osteochondrosis is a noninfectious and degenerative disorder affecting growth cartilage, previously referred to as osteochondritis or osteochondrosis dissecans (OCD). The disorder is most accurately defined as a dyschondroplasia affecting either the articular epiphyseal cartilage complex (AECC) or the physeal growth cartilage (Olsson 1978; Ytrehus et al. 2007) and can result in subsequent bone lesions.

Disease is usually progressive lameness affecting one or more limbs (Hill 1990a,b; Reiland 1975), due to localized failure of endochondral ossification and necrosis of cartilage. The condition can also be stratified based on the lesion advancement; osteochondrosis *latens* is a focal microscopic region of epiphyseal necrosis, osteochondrosis *manifesta* is macroscopic endochondral failure, and OCD is applied when there is fissure and cartilage flap formation (Ytrehus et al. 2007).

Osteochondrosis typically affects pigs from 6 to 20 weeks of age but can extend to 18 months or older, and microscopic changes have been reported in neonatal pigs. The growth plates that close last are the ones that are most susceptible, which includes the medial condyles of humerus and femur, ulna, costochondral junctions, and the sixth to eighth lumbar vertebrae. The medial condyle of the humerus appears to be the most consistent anatomic location for detecting or confirming lesions (Jorgensen 1995). Visible articular lesions start as cartilage thickening and then advance to wrinkling followed by flap formation or even detachment (Busch and Wachmann 2011). These gross changes are frequently bilateral and symmetrical (Figure 19.4). The disorder occurred in 10% of breeding animals (Grondalen 1974a) and 40% of boars in a testing station (Reiland 1978b), 47% of culled sows in Canada (Dewey 1996), and 100% of commercial pigs by 6 months (Walker and Aherne 1987). Recent investigations show that the presence of osteochondrosis *latens* and *manifesta* were about 65% but OCD was much lower at 7% (Busch et al. 2007) and 14% (Ytrehus et al. 2004).

Some features of osteochondrosis are summarized in Table 19.12. There remains confusion as to extent of the association between osteochondrosis and lameness (Brennan and Aherne 1986; Farnum et al. 1984; Fredeen and Sather 1978; Hill et al. 1984a,b; Hill 1998; Jorgensen et al. 1995; Jorgensen and Nielsen 2005; Lundeheim 1987; Reiland et al. 1978a,b). Most animals with lesions of osteochondrosis are subclinically affected, and lesions may resolve with time; however, in some animals, the pathologic changes can lead to synovial proliferation, even when lesions are small at the growth cartilage (Busch and Wachmann 2011). There is generalized belief that clinical lameness is dependent on multiple factors and can be complicated or enhanced by secondary processes or infections such as osteomyelitis, fractures, and damage to greater trochanter and tubercle (Blowey 1992, 1994a).

In the past, many of the lesions affecting the AECC have been examined at a stage when degenerative joint disease has become established. However, examination of early lesions shows microscopic foci of chondrolysis at

Table 19.12 Classification and gross pathology of osteochondrosis.

Definitions	
Osteochondrosis	Failure of endochondral bone formation; articular and/or physeal cartilage
Osteochondritis *dissecans*(OCD)	Cleft or fissures in articular cartilage that protrude into underlying bone; grossly visible
Osteochondrosis *latens*	Lesion confined to epiphyseal cartilage; visible microscopically but not grossly
Osteochondrosis *manifesta*	Lesions accompanied by delay in endochondral ossification; visible by radiographic or gross examination
Epiphysiolysis	Separation of proximal femoral epiphysis
Apophysiolysis	Bilateral separation of physes of ischiatic tuberosities; sitting with hind legs extended forward
Distribution of lesions	Can be unilateral or bilateral and symmetrical
Joint locations	More common in sites with later epiphyseal closure; humerus, femur, distal ulna and thoracolumbar vertebrae, costochondral junctions, glenoid of scapula
Joint surface	Lesions particularly found on medial surfaces (greater weight bearing)
Additional changes	Increased synovial fluid; serosanguinous joint fluid, ruptured ligaments; hemorrhages in joint capsule; thickened joint capsule

or near the interface of the articular cartilage and epiphyseal growth cartilage. The lesions may progress at this site, and lysed cartilage persists in the deeper layers of the AECC at the chondro-osseous interface and within the bone of the epiphysis. The recently replicated cells die, and there is either failure of matrix production, or formed matrix is disrupted. Clusters of chondrocytes develop at the periphery of the lesion in an attempt to repair. The soft denatured cartilage is further damage during joint movement so that flaps, fissures, and craters develop. When the AECC is breached, subchondral bone is in contact with the joint space, the joint becomes painful, and lameness develops. There is a consensus that vascular injury within cartilage canals initiates the disease process (Bullough and Heard 1967; Carlson et al. 1986, 1989, 1990; Kincaid and Lidwall 1982; Kincaid et al. 1985; Visco et al. 1991; Woodard et al. 1987b; Olstad et al. 2015). Without normal vascularization, there is no subsequent ossification.

Numerous risk factors for disease development include high growth rates, body conformation, hereditary factors, dietary stress, vascular defects, and trauma or athletic injuries. There is widespread belief that trauma may initiate the process of vascular necrosis, yet no single factor or etiology has been identified or confirmed as causal. Increased growth rate is commonly thought to be a risk factor. Multiple large epidemiological investigations have associated increased incidence of OCD association with growth rate (Lundeheim 1987; Busch and Wachmann 2011); however, there are also conflicting studies that show no association (Ytrehus et al. 2004; Stern et al. 1995). Dietary factors such as calcium and phosphorus, vitamin D, vitamin C, improper nutrient balance (energy and protein), and feeding practices have been investigated but are not found to have consistent roles in disease development. Deficient copper levels increase disease incidence in horses, but this has not been demonstrated in swine. Current information concerning swine osteochondrosis suggest that hereditary and anatomic characteristics could be important factors for disease progression as there are differences in prevalence between lines of pigs (Jorgensen and Andersen 2000) and certain conformational traits such as joint shape. The heritability of osteochondrosis in swine is moderate (Stern et al. 1995; Lundeheim 1987).

Joint disorders

Arthritis is very common in swine with multiple risk factors associated with both infectious and noninfectious causes. Many of the infectious causes are opportunistic resident microflora; however commingling pig sources increases the likelihood of introduction of new or variant strains of those potential pathogens. Effects of flooring, trauma, handling, management, and nutrition as risk factors greatly influence the occurrence and magnitude of joint diseases in modern production systems.

Infectious arthritis is often caused by bacteremic organisms capable of causing septicemia with tissue localizations in joints (synovitis and arthritis), meninges, serosal surfaces (polyserositis), lung, or other organs. Infectious arthritis can occur at any age but is most common in pigs 4–12 weeks of age, perhaps more prevalent in autumn and winter (Miniats et al. 1986). Clinical signs include pyrexia, lameness, inability to rise or move, and death. Joint lesions include increased synovial fluid, inflamed synovial membranes, fibrinous periarteritis, and joint swelling due to the exudation, sometimes with abscesses. Excess synovial fluid with color change, cloudiness, or change in viscosity is an important indicator of pathology (Figure 19.5). The hock, stifle, carpal, elbow, and hip joints are the joints most often affected.

Figure 19.5 Acute fibrinous arthritis; bacterial infection. *Source:* Image courtesy of the Iowa State University Veterinary Diagnostic Laboratory.

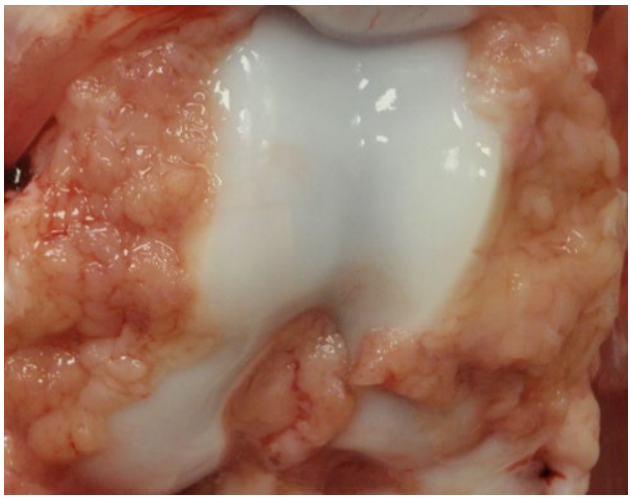

Figure 19.6 Proliferative synovitis; chronic joint irritation, multiple etiologies. Most often seen with *Mycoplasma hyosynoviae*, *Erysipelothrix rhusiopathiae*, or osteochondrosis. *Source:* Image courtesy of the Iowa State University Veterinary Diagnostic Laboratory.

The most common organisms of herd significance associated with arthritis will vary with age but include *S. suis, H. parasuis, Mycoplasma* spp., *Erysipelothrix rhusiopathiae,* and *A. suis* and are discussed in respective chapters. A potpourri of other organisms, especially pyogenic *Streptococcus* spp., *T. pyogenes*, and coliforms, are opportunists that affect individual pigs or are a result of poor hygienic practices in suckling piglets.

M. hyosynoviae is widespread in pig populations; disease is usually an uncomplicated, nonsuppurative arthritis of stifles with hocks, shoulder, and elbow in pigs greater than 30 kg and after 12–14 weeks of age (Hagedoorn-Olsen et al. 1998, 1999a, b; Gomes Neto et al. 2012). Reluctance to rise or inability to stand occurs within 24 hours of infection (Ross et al. 1971; Ross and Duncan 1970; Ross and Spear 1973) and is difficult to differentiate from other causes of severe lameness, particularly *E. rhusiopathiae*. Diagnosis is observation of typical gross and microscopic lesions, usually with excess serosanguinous synovial fluid (Figure 19.6), with agent confirmed present by culture or PCR (Platts et al. 2008; Gomes Neto et al. 2012).

MHR typically affects pigs younger than 10 weeks of age (Ross and Spear 1973; Friis and Feenstra 1994; Gomes Neto et al. 2012). Most pigs are colonized, but disease is relatively uncommon, usually with low morbidity (5–15%) and mortality (<10%) (Buddle 1987). Organisms acquired from dams or other pigs colonize in the nasopharynx and can produce bacteremia. Occasionally the organism localizes, with a strong predilection for serosal surfaces or synovium of tarsal, carpal, shoulder, stifle, hock, or atlanto-occipital joints (Ross et al. 1973; Ross and Spear 1973, Roberts et al. 1963a,b). More detail can be found in Chapter 56 or review by Rosales and Nicholas (2010).

Haemophilus parasuis is a widespread infection and resident of the nasopharynx of pigs (Oliveira and Pijoan 2004). It is a common cause of multisystemic disease manifested as acute lameness, depression, fever, dyspnea, hot swollen joints, reluctant to stand or move, tremor, paralysis, meningitis, or sudden death (Hoefling 1994; Nielsen and Danielsen 1975; Smart et al. 1986). Experimental infections produce severe lesions within 60 hours (Vahle et al. 1997). The bacteria are fastidious, and therefore, PCR assays are useful to improve the sensitivity of detecting bacteria in clinical cases (Oliveira et al. 2003), preferably from a site of a compatible lesion. Disease control has been difficult due to serovar diversity and the lack of cross-protection between strains (Oliveira and Pijoan 2004).

Streptococcus suis are ubiquitous early colonizers of the nasopharynx of suckling pigs (Sanford and Tilker 1962) and persist on mucosal surfaces indefinitely (Torremorell and Pijoan 1998; Walsh et al. 1992). Organism diversity includes at least 33 serovars, which confounds efforts to establish solid immunity. Consequently, this opportunist is a very common yet sporadic cause of polysystemic diseases, including arthritis, meningitis, serositis, and pneumonia.

Erysipelothrix rhusiopathiae affects all ages of swine as the disease erysipelas, as well as causes carcass condemnations at abattoirs. Acutely affected animals are

pyrexic, prefer to lie down because of pain, have a stiff gait, and shift their weight from foot to foot (Grabell et al. 1962). Chronic erysipelas results in a progressively increasing lameness and weight loss as a rheumatoid-like proliferative arthritis in the joints of the long bones or vertebrae. A hypersensitivity reaction with pannus formation, periarticular fibrosis, and exostoses (Vaughan 1969) occurs in chronically affected joints. Granulation tissue forms in the articular cavity, and there is proliferation of the connective tissues with elongated tags attached to the synovial membrane (Grabell et al. 1962). Diagnosis is by culture, PCR, or IHC and is enhanced with samples from acutely affected and nontreated animals.

Polyarthritis

Polyarthritis is a common reason for locomotor dysfunction prior to weaning. Routes for bacterial infection are via the tonsil, small intestine, navel ill, or abrasions of the integument. Navel infections are also a risk factor for development of umbilical hernia. Management and hygiene in farrowing including trauma from competition for nipple, abrasions, and clipping of teeth, tail docking, or ear notching are risk factors. There is a lower incidence of polyarthritis in female pigs and in pigs from multiparous sows, small litters, and closed herds (Nielsen et al. 1975; Smith and Mitchell 1976). *Streptococcus* spp., particularly *S. suis and S. equisimilis*, have been reported to cause 63% of the cases, but *T. pyogenes*, *Staphylococcus* sp., and *E. coli* are also frequent causes (Nielsen et al. 1975; Smith and Mitchell 1976).

Skin and hoof abrasions commonly occur bilaterally on hind limbs and forelegs and can be evident within a few hours of birth. Skin of the neonate is very soft with minimum keratin and is easily eroded over the joints. Floor abrasiveness increases the chance of skin lesions and therefore the opportunity for the invasion of microorganisms. Lesions are more common in the forelimbs (Furniss et al. 1986). Depending on environmental conditions, 98% of 3-day-old pigs can have skin abrasions, but only 11% of pigs are severely affected, and most lesions heal within 2–3 weeks of life (Svendsen et al. 1979; Furniss et al. 1986). The incidence of skin abrasions is highest on old cement floors, intermediate on punch metal and new cement floors, and lowest on plastic-coated woven wire. The incidence increases if the size and shape of the slot is large compared to the piglet's foot size and in litters of hypogalactic sows (Smith and Mitchell 1976). Joints involved in polyarthritis are often swollen and contain fibrinous exudates, with carpal, elbow, and hock joints the most frequently affected. *Trueperella pyogenes* is also associated with abscesses, tenosynovitis, and vertebral infections, which are suppurative and which can cause complete collapse of the vertebral body, often following tail biting.

Muscle disorders

Myopathies can be developmental (congenital, hereditary) or acquired. Acquired myopathies are by a variety of mechanisms including toxins, autoimmune mechanisms, endocrine dysfunction, parasite insult, neurogenic atrophy, cachexia, or metabolic dysfunction. Muscle atrophy is rapid and severe in cases of denervation but can be protracted with repair by fibrosis in cases of nerve injury. In slow progressive muscle disorders, muscle changes are progressive and irreversible. All structures of the lower limb (nerves, tendons, ligaments, bones, and muscles) are liable to ascending infections from the foot because of the permanent exposure to bacteria and trauma.

Primary myopathies are uncommon since porcine stress syndrome (PSS) has largely been mitigated. Myopathies may affect different groups of muscles. The most common signs are muscular weakness, trembling while standing, pain, muscle swelling, or muscle wasting. All manifest as locomotor or postural disorders. There is usually a rise in the plasma CPK levels that indicates muscle damage, followed by a transient myoglobinuria. Elevation in serum troponin is also a prognostic indicator of myocardial degeneration or necrosis. Table 19.13 summarizes some conditions primarily affecting muscle.

Porcine stress syndrome

PSS and pale, soft exudative (PSE) is a complex of conditions associated with an autosomal recessive gene of variable penetrance (Bradley and Wells 1978; Bradley and Fell 1981; Swatland 1974). Positive steps by breeders to reduce the prevalence of the gene have reduced its incidence and prevalence that was once at 95% in Pietrain and 35% of Landrace. Recent data from dead or nonambulatory animals at slaughter facilities revealed a prevalence of approximately 5% (Ritter et al. 2008). Well-muscled pigs die suddenly from a variety of stressors under natural conditions. Susceptible animals must have a hereditary predisposition that is then triggered by an exertional stress in the form of transportation, mating, excessive preslaughter tension, high environmental tension, or excitement. Exposure to halothane is a particularly effective stimulant that can be used to test for the predisposition.

Clinically, pigs have abrupt onset of respiratory distress, staggering, rigid firm muscles, and discolored skin. Pyrexia, muscle rigidity, and increased lactate in muscles cause rapid death. The pig enters a premature rigor with pyrexia that persists for an hour or so after death. If pigs have high glycogen levels at death, the meat particularly from the loin and ham take on the appearance of PSE muscle (Briskey 1964). There is an excess of watery leakage from the muscle (drip). If there is little

Table 19.13 Diseases and insults of muscle.

Insult/disease	Clinical signs/lesions	Common age
Splayleg	Hind legs adducted; myofibrillar hypoplasia	Congenital/neonate
Nutritional myopathy (vitamin E and/or selenium deficiency)	Myocardial hemorrhages with pericardial fluid; hepatosis dietetica; less common, gritty pale white streaks in muscle	Early post weaning (3–8 weeks of age usually)
Trauma/injection sites granuloma or abscess	Bruising, hemorrhage, inflammation, fibrosis, abscess	Any age
Bacterial infections	Usually initiated by trauma or by sepsis	Any age
Clostridium spp.	Necrosis, hemorrhage, edema; poor injection techniques and/or trauma	Any age
Porcine stress syndrome (PSS/PSE/DFD)	Muscle rigidity, skin flushed, pyrexia, rapid rigor, lactic acidosis, malignant hyperthermia	Any age but more common in finisher and young adult
Hemorrhages from stunning at slaughter	Muscle petechiae and hemorrhages in carcasses at slaughter	At slaughter; euthanasia by electrocution
Hemorrhages: ASF, CSF	Focal hemorrhages in muscle	Any age
Acute hypocalcemia	Weakness, tremors, muscle fasciculation	Post weaning to adult
Steatosis	Excess fat in the muscle; heritable	Adult
Gossypol toxicity	Cardiomyopathy: toxin found in cottonseed meal	Any age
Ionophore toxicity	Myopathy: synergism with tiamulin or salinomycin	Any age
Congenital muscle hypertrophy	Ataxia at birth with very large hams; heritable	Congenital
Parasites (*Taenia*, *Trichina*)	Myalgia, inflammatory nodules	Post weaning to adult

glycogen, the pH rises, and the muscle does not store well and ends up as dry, firm, and dark (DFD) meat. Essentially the stress has induced an accelerated glycolysis.

This complex is an inherited defect in the uptake, storage, and release of calcium in the muscle fibers that is triggered by exertional stress. Bonca (2009) has recently described the small changes in the normal RYR1 gene encoding for the protein ryanodine that is responsible for the calcium channel control in the skeletal muscle fibers. Animals with the normal gene can properly adjust the ion transfer, but those with the mutation cannot.

Back muscle necrosis seems to be a special manifestation of the PSS (Bradley et al. 1979). The condition is sporadic and affects predominately pigs over 50 kg. There is pain, difficulty in moving, and swelling of the back muscles (*Mm multifidi* and *longissimus*) with heat and pain on palpation. There is loss of sensation over the affected area, and pigs may be reluctant to stand and eventually dog-sit. The body curves toward the affected side in unilaterally affected animals, but bilaterally affected animals cannot stand and may die. There may be knuckling of the lower limb joints. Muscle damage is pronounced with high enzyme levels, and diagnosis is easily performed by sectioning the spine across the longissimus muscles, which appear dark and hemorrhagic.

A novel stress syndrome in pigs was recently reported and associated with a dystrophin gene defect (Nonneman et al. 2012). Affected 12-week-old pigs were from a single herd and exhibited open-mouth breathing, loss of mobility, vocalization, and skin discoloration following transport-induced stress. The clinical condition was similar to RYR1 mutation pigs with elevation of CPK, acute death, and an anesthetic trigger. The dystrophin protein was reduced when muscle tissue was analyzed and microscopic changes could be seen in skeletal and cardiac muscle (Nonneman et al. 2012).

Nutritional myopathy

Vitamin E and selenium are major antioxidants, and deficiency may lead to a generalized myopathy in skeletal muscle (Lannek and Lindberg 1975; Mortimer 1983; Nafstad and Tollersrud 1970; Trapp et al. 1970) but more likely manifests as mulberry heart disease or hepatosis dietetica. Previous disease names include microangiopathy and white muscle disease. Affected animals are typically 3–7 weeks of age and found dead with transmural myocardial hemorrhage, gelatinous pericardial material, and pulmonary edema (Pallares et al. 2002). There does not appear to be sex, breed, time of year, or known viral infection associated with the process (Rogers et al. 2017; Shen et al. 2011). Disease can occur when diets are constructed from plants that are grown in selenium-deficient soils or soils containing selenium antagonists. It may occur with increased frequency with ingestion of plants high in inhibitors of vitamin E, diets high in polyunsaturated fatty

acids or copper, low vitamin A, or possibly mycotoxins that can destroy vitamin E or make it less available. Previous investigations have also suggested that iron, calcium, magnesium, or sodium may have a role in disease development, but this appears to be inconsistent (Korpela 1990, 1991; Shen et al. 2011).

Swine appear to be less susceptible to nutritional muscular dystrophy in skeletal muscle than other domestic species. If it does occur, it is seen as pallor in the skeletal muscles with white streaks (gritty, calcified myofibrils, and muscle bundles) particularly in the *longissimus dorsi*. It is usually in pigs of 50–60 kg and clinically presented as ataxia, stiff gait, staggering gait, weakness, paralysis, depression, anorexia, and recumbency prior to death. Chronic cases have lameness and shedding of hooves.

Grossly, the muscle is edematous with white streaks, and histologically there is loss of myocyte structure with vacuolation, fragmentation, and mineral deposition in individual fibers. The primary change is selective destruction of type I fibers and lack of phosphorylase activity in type II fibers (Ruth and van Fleet 1974). Gorham et al. (1951) described yellow fat disease where there was pale skeletal and cardiac muscle in animals fed fish or fish products, and it was thought that these rations were deficient in vitamin E.

Other myopathies

Pigs are sensitive to ionophore toxicity, and this is enhanced with concurrent tiamulin administration. Affected pigs develop anorexia or feed refusal within days of consuming contaminated feed and progressively have diarrhea, lethargy, dyspnea, stiffness and painful gait, posterior ataxia or reluctance to stand, trembling, myoglobinuria, and sudden death (Umemara et al. 1985; Plumlee et al. 1995; Van Vleet et al. 1983). Skeletal muscle fibers are preferentially affected with myocardial fibers less so. Muscle enzymes, particularly CPK and AST, are elevated and provide a method of diagnosis. Serum troponin levels can also aid in a diagnosis when cardiac muscle is affected. The highly active muscles are more severely affected (tongues, diaphragm, thigh muscles, intercostal, longissimus, and the triceps), and these may show areas of pallor corresponding to the areas of myodegeneration. Microscopically there is hyaline necrosis of myofibrils with macrophage infiltration in acute stages that chronically may have muscle regeneration and fibrosis.

Asymmetric hindquarter syndrome is principally a disorder of slaughter weight pigs, though recognized as early as two to three months (Bradley and Wells 1978; Done et al. 1975). Viewed from behind, the affected leg has reduced muscle mass, particularly in semimembranosus, semitendinosus, and biceps femoris, and the other leg is larger. The discrepancy is due to a reduction in the reduced number of myocytes in the affected limb. The cause is unknown.

Pietrain creeper syndrome was first described by Bradley and Wells (1978, 1980; Wells et al. 1980) and is a familial disease characterized by progressive muscular weakness. It starts at about 3 weeks and ends with permanent recumbency at about 12 weeks of age. It may be an autosomal recessive gene with about one-third to one-fourth of pigs affected in each affected litter. There is tremor, followed by collapse to sternal recumbency, and then tremor stops. Progressively there is an increased reluctance to stand, muscular weakness, loss of condition, and finally a creeping type of gait using flexed limbs.

There is a very low incidence of *Trichinella spiralis* (Chapter 67) when there is a proper food inspection (Kapel et al. 1998). It has a predilection for the active striated muscles such as the diaphragm, intercostal, masseter, and ocular muscles. The clinical signs include intense muscle pain, decreased weight gain, itching, loss of appetite, paralysis of the hind limbs, and stiff muscles. At postmortem examination, the encysted parasites are easily observed. Viable cysts are able to remain intact for years, but calcification begins gradually to destroy the larvae and capsules. The subject has recently been reviewed by Gottstein et al. (2009) and a description of a diagnostic test using PCR by Guenther et al. (2008). *Taenia solium* may cause "measly pork" where there are cysts in the heart, tongue, diaphragm, and generalized body muscles. *Sarcocystis* sp. can be found in any striated muscle. Each cyst is double walled and contains many spores, given the name Rainey's corpuscles. Most infections are asymptomatic, but pyrexia, weakness in the loins, and posterior paralysis are sporadically described. At postmortem examination there may be watery, light-colored, small white cysts in the muscle. Avargal et al. (2004) have recently described the infection in wild boars.

An injection administered with poor hygiene, improperly placed, or with an inappropriate hypodermic needle size may damage muscle as well as vital nerves or the spinal cord. Injections in leg (ham) muscles are discouraged, with cervical muscles the preferred injection site. Injection sites can be secondarily infected with opportunists, particularly if hygiene is poor, needles are reused, vials are contaminated from previous use, or injected animals are wet or soiled. The outcome of these infections depends on the nature of the contributing organisms. Most common infections are the pyogenic (abscess-forming) bacteria such as streptococci, staphylococci, and *T. pyogenes* but may include gram-negative bacteria and *Clostridium* spp.

Clostridium septicum, C. chauvoei, and other *Clostridium* spp. can infect traumatic sites and produce gross swelling with crepitation and necrosis of the skin and underlying muscle (Figure 19.7). Lesions are typically

Figure 19.7 Necrotizing myositis and dermatitis; *Clostridium* spp. *Source:* Image courtesy of the Iowa State University Veterinary Diagnostic Laboratory.

on ventral abdomen, head, and ventral cervical regions. While usually sporadic in occurrence, epidemics of clostridial myositis and cellulitis can occur. *Bacillus anthracis*, although unusual in swine, can cause marked swelling, edema, and hemorrhage in sub-pharyngeal connective tissues. A myositis affecting the masseter muscles in association with *H. parasuis* has also been described, resulting in the swelling of the head.

Tetanus (*Clostridium tetani*) is rare but was often associated with castration or tail docking in poor hygienic conditions. Affected pigs have a rapid clinical course to death with signs that include a stiff gait, muscle rigidity, erect ears, straight tail, lateral recumbency, opisthotonos, and legs extended backward as "extensor rigidity syndrome." Loud noise will often produce tetanic spasms. The actual site of the lesion is difficult to detect; signs are an elaboration of a potent neurotoxin.

Botulism (*Clostridium botulinum*) rarely affects pigs as they are fairly resistant by oral ingestion. Type C strains have caused death in pigs after eating dead fish. Doutre (1967) described botulism in pigs fed swill with decomposing brewers' waste. Affected pigs have a progressive flaccid paralysis of voluntary muscles.

Muscle atrophy is not uncommon. Focal or extensive atrophy may follow nerve damage, disuse, senility, and undernutrition and usually will require microscopic evaluation for diagnosis. Focal myopathy of individual muscle cells is seen under the microscope (Bradley and Wells 1978) and occurs in less than 1% of muscle cells. Wasting with generalized muscle atrophy is commonly associated with PCV2 or other specific diseases, but wasting can be linked to over 30 different disorders, so care still has to be made in making a specific diagnosis.

Myositis ossificans was described by Hulland (1974), and it is a generalized familial disease in which bony lesions develop in the muscles adjacent to the spinal column, ribs, and tarsal bones at around 2 months of age. The muscles atrophy near the lesions, and the cause is unknown.

Cassia plant seeds in grain sorghum cause decreased appetite, incoordination, ataxia, staggering, decreased weight gain, and increased mortality in grower pigs (Flory et al. 1992). The plant causes muscle atrophy and pallor.

Many pigs are born with or acquire hernias that involve muscle or connective tissues. These are natural openings that have not formed correctly. There are four possibilities for these – umbilical, inguinal or scrotal, perineal, and diaphragmatic – but only inguinal and umbilical are common. Umbilical hernias are generally related to umbilical infections acquired in the early postnatal period, perhaps exacerbated by trauma, whereas an inguinal hernia has good evidence for hereditary predisposition. Perineal hernia is likely of traumatic origin. Epidemics of diaphragmatic hernias have been reported (Schwartz 1991).

Unusual is muscular steatosis (Bradley and Wells 1978), which is found incidentally at slaughter. It is replacement of muscle by fat. Inflammation of fat, steatitis, was described by Kirby (1981). Very old animals may have deposits of lipofuscin in the muscles, but often this can only be detected by histopathology and using special stains.

Lameness in sows and boars

Lameness is a major welfare concern and the second most common cause of culling for breeding animals within a herd, representing 10–20% of all culled sows (Dagorn and Aumaitre 1978; Dewey et al. 1992; Friendship et al. 1986; Heinonen et al. 2006; Karlberg 1979; Kilbride et al. 2009; Reiland 1975; Walker et al.1966) and 8–24% of boars (D'Allaire and Leman 1990; Koketsu and Sasaki 2009). Leg weakness is nonspecific term used to describe lameness associated with osteochondrosis, arthrosis, epiphysiolysis, apophysiolysis, or poor conformation. These diseases as well as foot lesions, leg injuries, fractures, and osteomalacia are common reasons for removal of breeding animals from the herd (Penny 1979, Wells 1984). Diagnosis is by clinical examination, necropsy of cull animals, and appropriate testing to rule out other causes of lameness.

Culling for lameness is more common for gilts and parity-one sows than in older animals (D'Allaire 1987; Dagorn and Aumaitre 1978), important because these animals are removed from the herd before peak reproductive performance is achieved (Ritter et al. 1999). Lameness between 30 and 40% at a performance station and approximately 24% of boars at artificial insemination

units are culled because of leg weakness; 75% of the latter are less than 18 months of age (Grondalen 1974e; Reiland 1975).

Lameness is frequently a cause of herd culling or euthanasia in sows (D'Allaire et al. 1987) and is more common during the lactation period and winter months (Anil et al. 2005). In one study, locomotor problems caused 9% of the culling and 28% of sow deaths (D'Allaire et al. 1987). Sow herds in France with a lameness prevalence of at least 15% had higher mortality rates than herds with less lameness (Abiven et al. 1998). Reiland (1975) examined 230 boars and sows culled for lameness and found few cases of foot rot and concluded that hoof lesions were of secondary importance in leg problems.

The culling rates due to lameness varies from farm to farm, implying leg weakness is a concern on certain farms. In a survey of Ontario farms, it ranged from 0 to 38%, with an average of 11%, and was associated with a high culling rate for sows and high proportions of gilts to sows in the breeding herd (Dewey et al. 1992). The culling rate due to lameness in start-up herds (26 ± 13%) was higher than in established herds (8 ± 6%) (Dewey et al. 1992). Herds that are repopulating have a larger proportion of young breeding-age animals and a higher level of culling for lameness. Farms in which stockman were responsible for higher numbers of breeding animals had an increased risk for lameness and subsequent culling (Willgert et al. 2014).

The housing factors associated with high levels of culling due to lameness were slatted floors for finisher pigs and sows (Kilbride et al. 2009), the use of individual sow stalls, and a high density of pigs in the finishing area. These findings suggest that a change of housing design may result in reducing the culling rate due to lameness and that attention to the way young replacement stock are housed and handled may be important with respect to subsequent longevity and soundness. Floor type and quality, the size of the space between the slats, the width of the slat, the flooring material, the slipperiness, and the type of ground for outdoor housed pigs all impact the prevalence and cause of lameness. Housing pigs indoors on concrete is associated with lameness in pigs (Barnett et al. 2001), and sows are more prone to develop lameness with slatted versus solid concrete flooring (Kilbride 2009).

Group housing of gestating sows is now required in some countries due to welfare concerns, and this trend extends globally. The prevalence of lameness in group-housed sows has been reported to be 8–27% (Bonde et al. 2004; Cador et al. 2014; Heinonen et al. 2006; Kilbride et al. 2009; Pluym et al. 2011); lameness prevalence can be higher in grouped scenarios compared with individual housing systems. Lameness development in pens typically occurs shortly after grouping. A recent study reported that 13.1% of penned sows developed lameness within 3–5 days of grouping and that fecal soiling of the animal may be an indicator of lameness (Pluym et al. 2017; Zurbrigg and Blackwell 2006). Sows housed in pens for a portion of gestation are expected to have reduced farrowing time (Ferket and Hacker 1985), reduced lameness in gilts (Hale et al. 1984), and less joint damage (Fredeen and Sather 1978).

Many sows culled for lameness have more than one cause for the clinical signs. Lameness has associations with genotype, type of feed ingredients, housing type (specifically, intensive versus extensive), floor type, and effluent drainage. Associations between the culling rate due to lameness in sows and various housing factors involving finisher pigs indicate that the environment of the young growing animal may have an impact on the skeletal system that becomes apparent only later in life. This would suggest that managers of herds with higher than acceptable levels of lameness in the sow herd should examine the flooring, management, and housing systems used for the young replacement animals in addition to factors in the sow herd.

Epiphysiolysis and apophysiolysis

Epiphysiolysis and apophysiolysis are conditions related to osteochondrosis and associated with abnormalities of the AECC. These conditions result in separation of weakened epiphyseal sites or physes. Epiphysiolysis is separation of the proximal femoral epiphysis (femoral head) from the remaining bone. It generally occurs between 5 months and 3 years of age because epiphyses fuse at three to seven and a half years of age (Cunningham 1966; Duthie and Lancaster 1964; Grondalen 1974c; Nemeth and van der Valk 1976; Reiland 1975). The cause is a combination of excess tension in the hip joint across a weakened physeal region in the femur that then separates. Clinical lameness is often severe and sudden but is occasionally insidious. It may be unilateral or bilateral and manipulation reveals crepitation.

Apophysiolysis is the bilateral separation of the ischiatic tuberosities along their physes. It has been recognized in young sows (Done et al. 1979; Petterson and Reiland 1967; Van Alstine and Toben 1989). Most affected animals are heavily pregnant, most dog-sit with hind limbs forward, and palpation elicits crepitus. It is associated with slippery floors excessively pulling the *biceps femoris* tendons from the *tuber ischidicum*. Unilateral lesions cause a moderate to severe lameness, but bilateral separation may prevent the sow from rising or walking (Done et al. 1979).

Osteomyelitis

Depending on location, osteomyelitis may result in lameness or cause pathological fractures, affecting long bones, physes, or vertebrae with subsequent compression

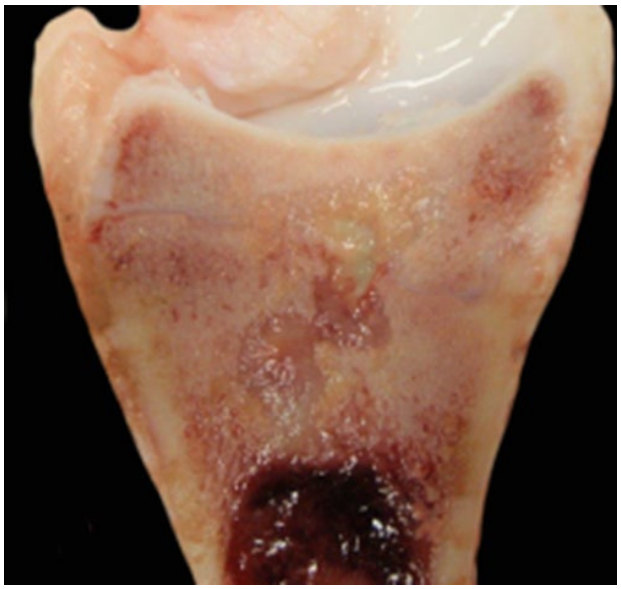

Figure 19.8 Purulent osteomyelitis with physitis (growth plate involvement); bacterial sepsis, multiple possible etiologies. *Source:* Image courtesy of the Iowa State University Veterinary Diagnostic Laboratory.

of the spinal cord. It can follow bacterial septicemia or be a local progression as in ascending myelitis from tail biting. It may be associated with apophysiolysis, with the marrow and metaphysis of a long bone (Figure 19.8) or with pathological fractures. Sows are prone to arthritis that is often by extension from septic feet (Reiland 1975) or other surface abrasions such as shoulder sores. It complicates spondylitis and may develop into osteoarthritis.

Infectious arthritis

Infectious arthritis is a modest cause of sow culling and affects 2.5% of culled boars (Grondalen 1974a, d; Grondalen and Vangen 1974; Nakano et al. 1979a). In Reiland's (1975) study of animals culled for lameness, the clinical signs were due to infectious arthritis in 18% of the sows that were less than 18 months of age and in 64% of the sows that were older than 18 months. Most of these animals had spondylitis, osteomyelitis, and/or arthritis of the hock joint associated with the presence of *E. rhusiopathiae,* streptococci, or *T. pyogenes*. In the vertebral column, the chronic proliferative arthritis and discospondylitis were secondary to lesions of osteochondrosis.

When lesions such as fractures or epiphysiolysis are coinfected with osteotropic bacteria such as streptococci or *T. pyogenes,* primary insult often cannot be determined (Reiland 1975). Suppurative arthritis of single joints is more likely to be the result of bacteria acquired by direct penetration, whereas bacteria from a source of sepsis, such as infected hoof lesions, fight wounds, skin abrasions, or uterine infections, can often cause polyarthritis. The clinical signs of bacterial arthritis are heat, swelling, pain, refusal to bear weight on the leg, pyrexia, and anorexia.

Proliferative osteitis

Proliferative osteitis is a lesion described at the femoral greater trochanter and medial epicondyle of the humerus (Blowey 1992), usually affecting gilts after the first weaning. Affected animals are found "dog-sitting" with obvious pain and discomfort when attempting to stand. Locally extensive hemorrhage within muscle is reported.

Arthrosis

Arthrosis, sometimes called arthropathy, osteoarthrosis, or osteoarthritis, is a nonspecific degenerative condition of cartilage that develops in chronic joint disease (Palmer 1985). In one report, animals less than 18 months had 7% prevalence, but those over 18 months had 82% (Reiland 1975), suggesting increased prevalence with age. This condition is generally considered a result of joint instability from osteochondrosis whereby the surface lesions in the joint fill with osseous repair tissue (Grondalen 1974a; Nakano et al. 1979a; Palmer 1985). Pathologically, the lesions include fibrillation of joint cartilage, ulceration of the articular surface, osteophyte production, and thickened synovial membrane and joint capsule (Palmer 1985).

Hoof and claw

A discussion of hoof and claw lesions, common in sows and a risk factor for lameness (Cador et al. 2014), is found in Chapter 17.

Neoplasms

Neoplasms are not common but include osteosarcoma of the maxilla occluding the nasal cavity (S. Done, personal observation), osteogenic sarcoma (Harcourt 1973), metastasis from malignant melanoma, congenital melanoma, glioblastoma, and multiple myeloma (Fisher and Olander 1978; Rintisch et al. 2010).

Diseases of the Reproductive System

Gary C. Althouse, Johannes Kauffold, and Stephanie Rossow

Female reproduction

Diseases of the ovaries

Primary ovarian diseases are rather uncommon in swine. The vast majority of ovarian disorders are secondary to risk factors related to management or environment. Cystic ovaries are less common than currently believed (Weitze et al. 1998; Kauffold et al. 2004a) but certainly can be of higher or lower incidence on different farms. Ovarian cysts can be found as single or multiple cysts with oligocystic ovarian degeneration (OOD) or without normal ovarian bodies, known as polycystic ovarian degeneration (POD) as described by Kauffold et al. (2004a). For cysts to develop, a partial or complete lack of preovulatory luteinizing hormone (LH) and/or follicle LH receptors must occur. This disruption can be caused by several extrinsic factors such as stress (i.e. high ambient temperature) or incorrect therapeutic hormonal treatments (e.g. gonadotropins at times when corpora lutea [CL] are present). Mycotoxins, specifically from the family of zearalenone produced by *Fusarium* spp., have estrogen-like activity, thus acting as endocrine disruptors. Lactational estrus has also been associated with the development of ovarian cysts, presumably due to an insufficient preovulatory LH secretion.

The presence of a single ovarian cyst generally has negligible effects on reproduction. Females with conditions such as OOD may experience higher return rates and/or lower litter size. Females with POD generally exhibit clinical signs of anestrus and infertility.

Other ovarian disturbances include inactive ovaries and pseudopersistent CL (pCL), both of which are associated with anestrus and/or pseudopregnancy. Inactive ovaries are most often seen in first-parity sows after weaning, especially when sow body condition is poor, but may also be observed in pregnancy-checked negative females, usually caused by an insufficient gonadotropin secretion (Kauffold et al. 2004a). Both gilts and sows can develop pCL, usually precluded with events such as late embryonic death, endometritis, or zearalenone exposure.

Intersexuality may occur in single pigs and is likely a multigene-based outcome. Pseudohermaphrodites have gonads of one sex with the physical presence of genital organs from the opposite sex, which is a rare condition. More commonly seen are true intersex (hermaphrodite) animals that have both testicular and ovarian tissues. The external genitalia of intersex pigs are phenotypically female, albeit variable in appearance (e.g. normal vulva or prepuce-like or underdeveloped; variable enlargement of the clitoris). Some individuals show male behavior, while others may show estrus and ovulation and even become pregnant.

The diagnosis of ovarian disorders in the live animal is by using B-mode, real-time ultrasonography (RTU). From a production standpoint, postmortem examination is also an option. Currently, the best decision is still to cull animals with POD upon detection; however, a treatment with a gonadotropin-releasing hormone (GnRH) analogue twice at a 12 hour interval can be applied with reported success (Cech and Dolezel 2007). There is preliminary evidence that a multi-day regimen using altrenogest may aid in resolving POD with a complete reestablishment of fertility (Kauffold et al. 2014a).

Females with inactive ovaries can be treated with gonadotropins either in combination with 400 IU equine chorionic gonadotropin (eCG)/200 IU human chorionic gonadotropin (hCG) or, where available, with pure eCG preferably at a dosage of 1000 IU eCG. Resolution of pCL may be tried using prostaglandin F2α (PGF2α) or similar analogue, with estrus exhibited within one-week post-treatment; daily boar contact can be beneficial with the success of this treatment. Importantly, normal CL observed during diestrus will not respond to prostaglandin treatment until around day 12 of the estrous cycle, making it of very limited use in "short-cycling" sows.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Diseases of the oviducts

The diseased oviduct has received little attention in the scientific literature. From early studies, tubal disorders such as hydrosalpinx and pyosalpinx can occur in swine (Wilson et al. 1949). Salpingitis can occur in the sow and is quite often the result of an ascending bacterial infection ascending from the uterus (Kauffold et al. 2006). Bacteria that cause salpingitis have not been well defined but in general are similar to those pathogens that can cause endometritis and myometritis in the sow. *Chlamydia* spp. have been detected in the pig oviducts (Kauffold et al. 2006) that, while they may not necessarily cause morphological damage, may alter the tubal secretory profile, leading to an undesired milieu for gametes and early embryo development (Debattista et al. 2003). Zearalenone mycotoxicosis may also affect tubal function, with preliminary data indicating that it can change gene expression of tubal epithelial cells (Kauffold and Wehrend 2014b).

Cysts of the mesosalpinx (i.e. paraovarian cysts) can be a frequent finding at necropsy. These cysts are residual to remnants of the Wolffian ducts and are considered negligible in causing disturbances to reproduction.

The clinical relevance of tubal diseases can be quite straightforward. If bilateral tubal occlusions are present, females will be unable to become pregnant, leading to regular returns and, thus, infertility. A definitive diagnosis of a tubal disease can only be done through a postmortem examination. Although appropriate antimicrobial treatment may be of value when treating a salpingitis, treatment for tubal occlusions carries a poor prognosis. Antimicrobials may help clear an infection caused by susceptible bacteria, but occlusions cannot be resolved.

Non-puerperal diseases of the vagina, cervix, and the uterus

Diseases specific to the vagina and the cervix occurring outside of the window of parturition are sparse. A study from Finland reported cervicitis/vaginitis in 19/824 (2.3%) of discharging sows (Oravainen et al. 2006). The most common non-puerperal genital disease in the pig is endometritis and usually is the result of an infection with gram-negative (e.g. *Escherichia coli* spp., *Klebsiella* spp., *Proteus* spp.) or gram-positive bacteria (*Streptococcus* spp., *Staphylococcus* spp., *Enterococcus* spp., *Trueperella pyogenes*). Other bacteria, such as *Chlamydia* spp., anaerobic microbes (i.e. *Fusobacterium necrophorum, Prevotella* spp.), and fungi (i.e. *Candida* spp.) may be involved (Oravainen et al. 2006). Viral pathogens typically do not cause uterine inflammation, although their presence in the endometrium has been documented (Olanratmanee et al. 2011). Bacteria usually enter the uterus at breeding or in the periparturient period via the lower portion of the genital tract. Ascending infections from the urinary bladder are also possible. A systemic infection through the bloodstream may occur for some bacteria but is considered the main route of infection for viruses. In the majority of cases, infections are cleared by the local immune system, but in some circumstances when the immune system is compromised, such as during deoxynivalenol exposure or hormonal downregulation (e.g. diestrus when progesterone is at high concentrations or exogenously with altrenogest administration to animals already subclinically infected), an ensuing inflammation may develop.

Non-puerperal endometritis, not associated with the aforementioned, can occur with varying severity and can be an acute, subacute, or chronic situation. Acute and subacute conditions are commonly associated with the presence of a vulvar discharge. Chronic endometritis, however, can be more clinically evasive, with regular returns most often being the only clinical sign (Dalin et al. 1997, 2004; Kauffold et al. 2005). Besides infectious agents, zearalenone exposure can also elicit uterine disease that presents (but not always) as an endometrial and gross edema.

Other diseases of the uterus such as atrophy, degeneration, or adenomyosis can occur, but their incidence in swine is unknown. Uterine neoplasms are possible and may include leiomyoma, fibroma, cystadenoma, fibroleiomyoma, and carcinoma (Akkermans and van Beusekom 1984), but these findings tend to be geriatric conditions reported in older potbelly or miniature pigs (Golbar et al. 2010; Höltig et al. 2015). Congenital disorders of the uterus, vagina, and cervix (i.e. duplex uteri, segmental or complete aplasia) may also occur.

The clinical relevance of uterine diseases will be infertility in a clear majority of cases, but the clinical presentation can vary. For instance, cases of endometritis may or may not be associated with vulvar discharge or with returns and largely depend on the severity of inflammation, including the innate ability of the endometrial tissue to produce sufficient PGF2α.

Uterine diseases, particularly inflammation, typically present for diagnosis based on clinical signs such as pathological vulvar discharge. A vaginal examination is performed to determine the origin of discharge. In cases of reproductive irregularities in the absence of vulvar discharge, return to estrus can be of value in a diagnostic workup, for example, for anestrus associated with zearalenone exposure. In other still inconclusive cases, a postmortem examination will be necessary. If findings suggest a bacterial component to uterine disease, then identification and antimicrobial susceptibility testing is useful if deemed a herd problem.

A treatment decision clearly depends on the type of disease present. For example, animals with congenital

disorders should be culled immediately as well as those animals with a proven, non-recoverable zearalenone exposure. In contrast, a non-puerperal genital endometritis can be treated with antimicrobials systemically and/or locally; however, an intrauterine infusion using a post cervical artificial insemination (PCAI) catheter may be difficult to perform due to the usually tight cervical closure. Drugs that may help to evacuate uterine contents (e.g. oxytocin or PGF2α) can be ineffective due to a presumably limited responsiveness of the myometrium at the time of treatment.

Reproductive problems on a herd level

General diagnostic approach

The diagnostic procedure addressing herd fertility problems is comprehensive and must include a critical assessment of the tripartite contributors to herd reproductive performance: (1) farrowing personnel, (2) breeding personnel, and (3) sow and semen management. Diagnosticians must be aware of the multitude of factors and their interrelatedness that might be causative of the problem, including facility type, the building environment, seasonality, nutrition, sanitation/hygiene, and disease-related occurrences or interventions. While different types of reproductive failure would need different differential diagnoses, there can certainly be overlap. For instance, if conception rates are low, breeding may have been performed at improper times or poor quality semen has been used. Similar factors can also be associated with cases of low farrowing rate, with added differentials driven by clinical signs such as abortion or sows confirmed pregnant but fail to farrow (irregular returns to estrus). Critical evaluation of herd performance data, including flow diagrams and in-depth anamnestic investigations, is part of any diagnostic approach and has priority ahead of other diagnostic procedures (Almond et al. 2006; Carr 2008).

Numerous software programs are currently available for assessing herd performance data. While all provide summaries of most relevant production data related to breeding, farrowing, and lactation, they may be different in terms of data entry, report format, and content, as well as the accessibility to specific data that could be of value in some troubleshooting processes. Current software development is being driven to capture real-time production- and veterinary-related data in order to quickly recognize performance disruptions that then allow for immediate investigation or intervention. A proper analysis of the recorded data relies on correct and comprehensive data entry, but the level of detail desired may not be available. For instance, when investigating sow removals or late pregnancy losses ("fallouts"), it is critical to have not only the day of fallout available but also the correct cause inputted (i.e. death, cull, abortion, etc.).

After records analysis, a farm walk-through and clinical examination of the animals and their surroundings are performed. The execution of the actual examinations required is greatly influenced by the problem presented. For example, pregnancy losses in late gestation require examining the late gestating sows, whereas in losses from poor conception rate, the assessment of both semen quality and ovulation patterns is a logical starting point given how crucial both are in terms of proper mating times and conceiving. If still undiagnosed, attention should next focus on diagnostic assessment of the reproductive tract in females exhibiting inciting clinical signs. This can be performed using RTU or postmortem examination and sample collection. As uterine infections are often related to immunosuppression along with sufficient bacterial pressure, diagnostic procedures may also include investigations for causes of immunosuppression (i.e. mycotoxins, systemic pathogens such as porcine reproductive and respiratory syndrome virus [PRRSV], porcine circovirus type 2 [PCV2], porcine parvovirus [PPV], and bacteria).

Individual pig examination

Examination of representative individual female pigs exhibiting reproductive disorders is often warranted. The examination should start with assessment of estrus activity, body condition, and an overall physical examination with focus on genital and mammary gland health. It is important to use a boar for estrus determination, but single animals may not immediately respond to the presence of a boar, but rather may need additional duration and frequency of boar exposure to elicit a sufficient stimulation. A vaginal inspection may follow using a metal, plastic, or disposable cardboard speculum (Oravainen et al. 2008), which can be particularly useful in cases where discharges of the urinary tract have to be differentiated from uterine discharges. Although uncommonly performed today given the wide availability of RTU, a rectal examination may be of diagnostic value for determining pregnancy and ovarian functional status (Meredith 1977). From a go-to diagnostic tool, RTU generates the most conclusive results in the live animal. The examination can be performed transrectally and transcutaneously. Manual transrectal RTU is more applicable when examining sows, but not in gilts due to the narrow pelvis. When performing transrectal RTU, probe guidance is facilitated using a transducer stabilizing rod. Transcutaneous RTU is approached via the inguinal area dorsally to the last pair of teats. Linear, sector, and convex probes are all feasible, with sector and convex being the preferred probes. Frequencies of 3.5–7.5 MHz are most commonly used; however, a 5.0 MHz transducer provides the most versatility when it comes to penetration depth and image resolution.

RTU can be used to assess for both physiological and pathological conditions. Tissues frequently examined include gravid and nongravid uteri, the ovaries, and the urinary bladder (Table 20.1). Additionally, RTU is utilized to measure backfat thickness as a more objective measure of body condition and nutrition impact in females suffering fertility issues (Quesnel 2009).

Pregnancy can be diagnosed with most commercially available ultrasound units starting on day 20/21 postbreeding and, when using superior quality units, as early as day 16 by a skilled practitioner. Accuracy of diagnosis increases as pregnancy progresses due to conceptus growth. Pregnancy failures to be detected by RTU include embryonic/fetal deaths, resorptions, and mummified fetuses. Fetal viability testing can also be performed by visually assessing the heart beating in the developing conceptus as early as day 24 of pregnancy.

Parameters currently used by RTU to define uterine functionality are fluid echogenicity, echotexture, and size. For example, a flocculent fluid echogenicity or extremely heterogeneous echotexture is indicative of a severe acute or subacute endometritis. Similarly, an extremely heterogeneous echotexture may also be expected after zearalenone mycotoxicosis. Interpretation of uterine echotexture should be performed in concert with ovarian findings as the uterine architecture physiologically depends on endogenous steroids and thus is related to the ovarian status. For instance, if the uterine echotexture is heterogeneous at a time when it should be homogeneous (i.e. *in situ*ations where CL or small follicles are present and endogenous estrogens are expected to be low), the uterus is likely to be pathologic and, thus, fertility decreased (Kauffold and Althouse 2007). The determination of the uterine size provides valuable information for the assessment of puberty in gilts, with prepubertal gilts having a smaller uterus than pubertal gilts (cross-sectional areas of the uterine horns of $\leq 1.0\,cm^2$ and $\geq 1.2\,cm^2$ in prepubertal versus pubertal gilts) (Kauffold et al. 2004b).

All typical ovarian structures are readily imageable, including follicles of different sizes, corpora hemorrhagica (CH), and CL (Figure 20.1). Also, pathological conditions such as ovarian cysts are clearly visible, so are cases of intersexuality (i.e. ovotestes).

A complete RTU examination includes the assessment of the urinary bladder for uniformity, thickness, and the presence of bladder sediment. Presence of bladder sediment in sows and gilts can be a prognostic indicator of animals predisposed for urogenital infections (Kauffold et al. 2010).

If bacterial infections are suspected, a specimen obtained directly from the site of interest should be collected using a disposable double-guarded swab (commonly used in mares) to avoid inadvertent bacterial contamination.

Table 20.1 Applicability of ultrasonography in female swine reproduction and for troubleshooting of "on-farm" fertility problems.

Applicability in female swine reproduction[a]	Applicability for troubleshooting of "on-farm" fertility problems[a]
Diagnosis of pregnancy and pregnancy failure	Low conception rate
Assessment of health of the nonpregnant uterus	Low farrowing rate
Monitoring of ovulation and ovulation failure	Late fallouts
Assessment of puberty and failure to attain puberty	High rate of returns
Assessment of follicle growth and failure to grow	Delayed puberty/high cull rate of gilts for "no heat"
(Measurement of backfat depth)	Vulval discharges
(Evaluation of health of the urinary bladder)	Reduced litter size
	Long wean–estrus interval
	(Body condition monitoring)

[a] Non-fertility-associated applications are in parentheses.

Problems associated with puberty attainment

In general, attainment of puberty in gilts is expected to occur around 180 days of age. If ≥5% of the gilts in a group show delay or failure to cycle, an investigation is warranted. Typically, investigations reveal these scenarios as multifactorial, frequently including numerous intrinsic as well as extrinsic factors.

Gilt birth weights may have an effect on puberty. Gilts weighing 0.9–1.3 kg at birth had delayed puberty compared with gilts with a birth weight of approximately 1.6 kg. However, in another study heavier gilts at birth (i.e. ≥1.8 kg) were less often found to have been pubertal at 200 days of age via RTU when compared with lower birth weight gilts (Kauffold et al. 2010), presumably due to relatively lower body fat. While there might be breed-specific recommendations for a desired backfat thickness at breeding, it should at minimum be 14 mm across breeds. To achieve this target, proper feeding strategies will facilitate more fat deposition and less muscle while achieving optimum daily gain. For instance, gilts with a growth rate of 724 versus 577 g/day between birth and 144 days of age reached puberty earlier and to a higher percentage by day 190 and were culled less often for anestrus (Kummer et al. 2009). Seasonality may also have an effect on puberty attainment. During long-day periods such as during summer and early autumn in the Northern Hemisphere, puberty is typically delayed (Peltoniemi and Virolainen 2006). In addition, high ambient temperatures during that time will lower voluntary feed intake that may additionally contribute to this delay. Field evidence suggests that diseases and toxin

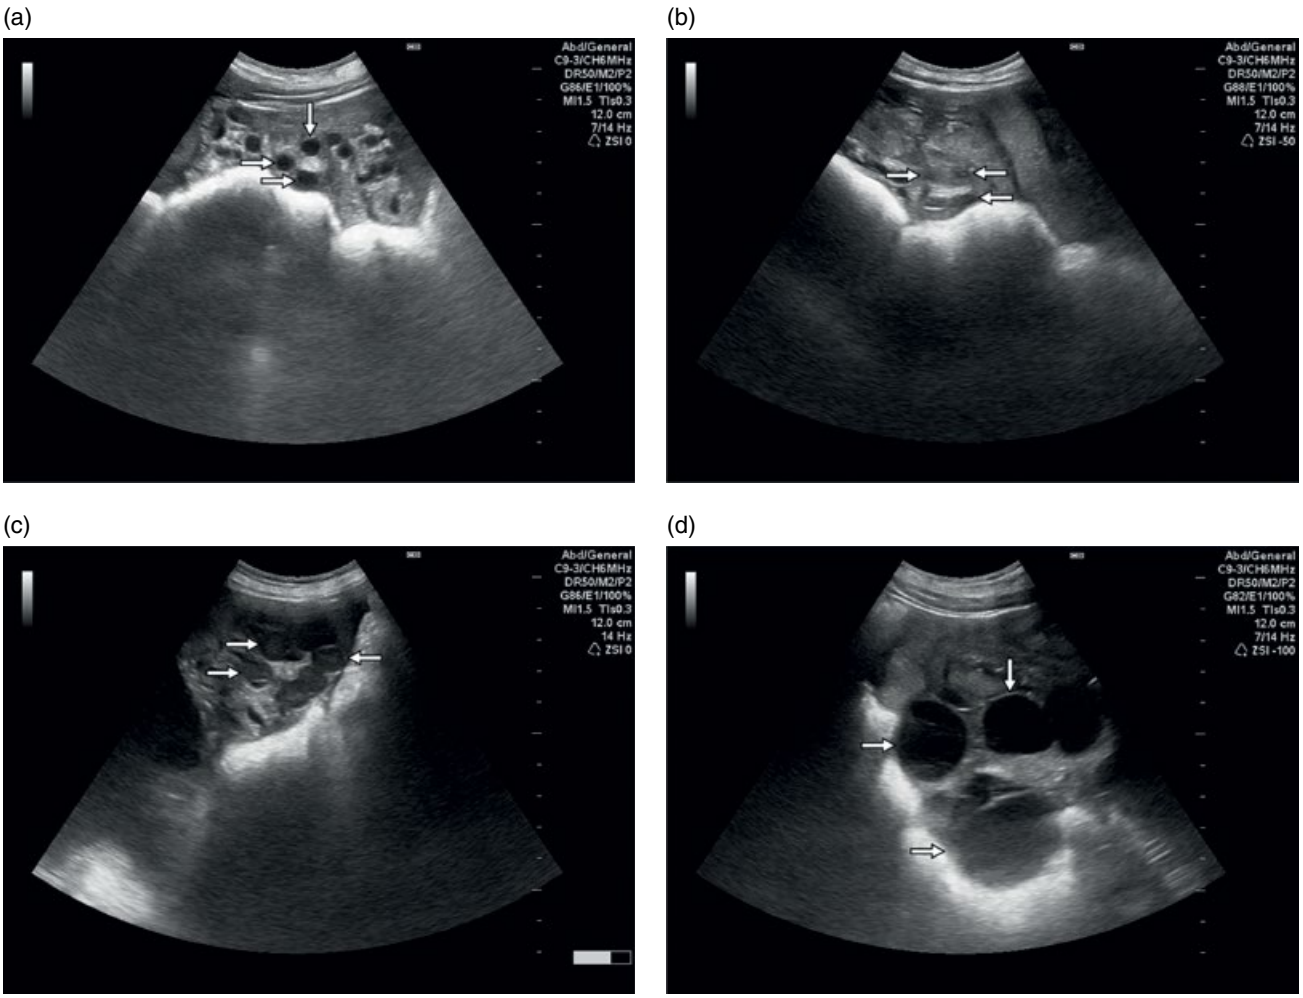

Figure 20.1 Ultrasound images of ovaries from gilts and sows with medium-sized follicles (a), corpora hemorrhagica (b), corpora lutea (c), and follicle cysts (polycystic ovarian degeneration) (d). Example ovarian bodies are marked with arrows, respectively. Scanning was performed with a Fujifilm Fazone CB and a convex probe (FZT C9-3) at a background frequency of 6 MHz and a penetration depth of 12 cm.

exposure (such as with zearalenone) during any time of gilt development have a detrimental effect on puberty.

If done properly, boar exposure is an effective means of inducing early puberty in gilts. Adequate stimulation of estrus generally requires direct physical contact, while estrus detection may only need fence-line contact. If the efficacy of boar exposure appears inadequate, it is important to evaluate whether the rules of boar contact are being followed (Kirkwood 1999). The rules are related to age of gilts and boars as well as the contact and environment provided for gilts and boars.

Gilts must be at least 160 days of age with maximal response when contact starts at 180 days (see Figure 20.2). There is evidence that gilts exhibiting a more rapid response to boar exposure are innately more fertile. The corollary is that gilts not pubertal within 28 days of boar contact are likely less fertile and may be culled. However, any culling policy has to be carefully leveraged, with cost

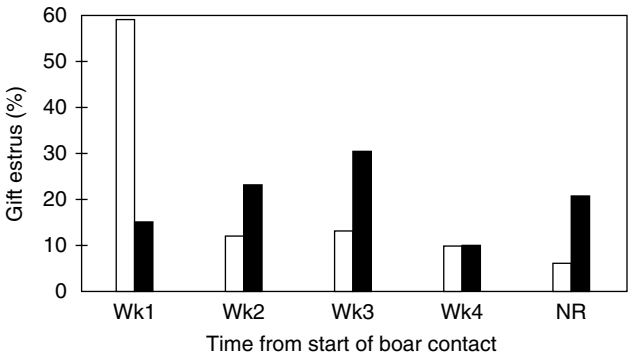

Figure 20.2 Influence of starting boar contact at a gilt age of 180 days (open bars) or 160 days (black bars) on pubertal responses. Increasing the age of gilts at first boar contact improves the timing and synchrony of the pubertal response but does not affect potential litter size. *Source:* Adapted from Van Wettere et al. (2006). Reproduced with permission of Elsevier.

for new purchases as well as gilt acclimation/vaccination put against losses through a potentially reduced productivity and longevity being part of the equation.

Boars must be mature enough (≥10 months of age) in order to adequately stimulate the female. The stimulus value of a boar depends on his ability to produce sufficient stimulatory pheromones from his submaxillary salivary gland that achieves adult proportions by 10 months of age. While this physiology may argue that it not be necessary to use the oldest and smelliest boar, there is evidence to suggest that boars may be different in their olfactory-stimulating ability. Minipig boars, for instance, seem to stimulate more effectively than commonly used production boars, presumably because of much higher concentrations of testosterone and pheromones in their saliva (Dehnhard et al. 2013).

Gilts should be in physical contact with the boar for at least 15–20 minutes per day to allow enough time for all gilts to interact with the boar. If gilts are housed in large groups, use at least 1 boar per 12 gilts. Since a fertile mating at puberty is likely not desired, boar contact should be supervised, or sterile boars (vasectomized or epididymectomized) should be used and mating allowed (Althouse and Evans 1997a, b). Indeed, a sterile breeding at puberty may enhance fertility to a fertile breeding at the subsequent estrus, with a 5–10% increase in farrowing rate and a 0.5–1.5 increase in litter size.

For boar exposure, gilts should be housed at least one meter away from potential stimulus boars and preferably downwind. Gilts housed adjacent to boars are stimulated to an earlier puberty. Understand though that if further separation postpuberty is not implemented, low estrus detection rates can occur as gilts will have stood previously and are, thus, refractory at the time of supervised boar contact.

Gilts should be taken to the boar and not vice versa. If this is not manageable, than fence-line stimulation can be a practical alternative. In the event of poor estrus detection management, the use of a separate detection-mating area should be considered.

Other variations, such as using different boars on different days or housing gilts with a boar continuously, will not usually improve the response over that obtained by daily contact with a single mature boar. However, if the pubertal response is considered inadequate, consider twice-daily boar exposure and/or rotating stimulus boars every 2–3 days. This is because some boars have a low stimulus value that may be compensated by rotating boars. After puberty, boar exposure should continue at least every other day in order to promote a regular estrous cycle.

If appropriate boar exposure does not appear to be effective, hormonal treatment of either 750–1000 IU of eCG or a combination of 400 IU eCG/200 IU hCG may be considered. In some studies, the eCG/hCG combination has proven more effective at inducing estrus in gilts than has eCG alone (Manjarin et al. 2009), suggesting that LH-like activity may be required for more robust follicle development. If a group of gilts is administered the 400 IU eCG/200 IU hCG combination and the response is poor (e.g. 10–15% exhibit estrus), it is likely that the gilts were already cyclic and their prior estrus was missed. If after treatment up to 30% do not exhibit behavioral estrus, and of those about 30% fail to recycle, then gilts may have been treated while immature. Although gilt fertility will improve if bred at a subsequent natural estrus, it is generally recommended to breed gilts at the induced estrus because of the relative unpredictability of cyclic estrous behavior after exogenous gonadotropin use. However, if experience on an individual farm indicates that gilts have a high regular return rate (e.g. >90%), then delaying breeding to the following natural estrus is the preferred option.

If puberty is delayed, a diagnostic workup may start with scanning gilts using RTU in order to determine their pubertal status starting at around 180 days of age and continuing at 20-day intervals for at least 2 months. Older gilts with reported "no heat" can be imaged using RTU. This approach may allow in-depth understanding of the magnitude of the problems and to aid in ruling in/out poor estrus detection management. It can also be of value in determining the effectiveness of different stimulation interventions.

Within a diagnostic workup, the entire gilt's life between birth and puberty has to be evaluated for factors that may have had a negative effect on puberty. This includes diseases as well as toxins, but most importantly nutrition. Gilts of known age should be weighed periodically, and backfat thicknesses measured to ensure that daily gain and body composition are optimum at the time of desired puberty age.

Problems associated with wean–estrus interval (WEI)

Ideally, weaned sows are expected to exhibit estrus any time before 5 days post weaning. If no estrus is observed, then one needs to consider whether they are a "missed heat" or "truly not in heat" sows. Estrus may not be detected in sows exhibiting a silent heat or if heat detection was done incorrectly, hence not observed. Errors in heat detection include use of heavy boars (especially for gilts that could be intimidated), reduced boar libido, incorrect placement of the boar, rushing to perform heat checking, and/or incorrect testing by personnel. Sows found "truly not in heat" hence with no estrus activity can be caused by absence of ovarian inactivity or having previously had a lactational estrus. Ovarian inactivity may be the result of insufficient gonadotropins during late lactation and around weaning. This has been linked to an

excessive body mass loss during lactation due to a combination of insufficient feed intake and excessive milk production and is mediated by the insulin/IGF system (Quesnel 2009). Other factors for ovarian inactivity may include parity (as it is observed predominantly in first-parity sows), seasonality/high ambient temperature (as it is observed more often during the summer period), and insufficient boar stimulation post weaning. In contrast, for a lactational estrus to occur, gonadotropins must have been sufficiently available while lactating for follicles to grow and ovulate. In theory, gonadotropin secretion and follicle growth in lactation are inhibited through mechanisms induced by piglet suckling (Quesnel 2009). At the end of lactation and post weaning, when the frequency of suckling decreases and suckling finally ceases, gonadotropin secretion reemerges, leading to follicle growth and ovulation (Quesnel 2009). In fact, lactational estrus is most often seen in late lactation at the end of the third and into the fourth week. Moreover, in nurse sows or sows submitted to intermittent suckling (e.g. suckling continuity is interrupted), lactational estrus is more often seen than in continuously lactating sows (Soede et al. 2012). Also, management factors that unintentionally lead to temporary cessation of suckling, such as piglet vaccination in late lactation, are also suspected to facilitate lactational estrus. Observations from the field suggest that lactational estrus increasingly occurs in the Northern Hemisphere in late autumn and lasts until early spring (i.e. during times when the ambient temperature is lower and feed intake higher than during the hot summer season).

RTU of the ovaries of sows not exhibiting estrus by day 7 post weaning can help to accurately direct diagnostic efforts and treatment strategies. For instance, in cases of missed heats, all procedures surrounding heat detection should be carefully evaluated, while in cases of ovarian inactivity, major diagnostic emphasis needs to be placed on nutrition in lactation.

Treatment options depend upon the outcomes of RTU imaging. Sows with observed inactive ovaries may be treated with gonadotropins. If CL are observed, an initial treatment with PGF2α can be used. If no response within 7 days is observed upon this initial PGF2α treatment, the CL may have been early in diestrus when treated. A second PGF2α treatment approximately 7 days later is therefore recommended. If RTU imaging is unavailable, a random treatment approach may consist of a PGF2α injection followed by a gonadotropin application 24 hours later, with the intention of consecutively addressing both ovarian conditions (i.e. presence of CL and inactive ovaries). This option is not without consequences; however, the risk of inducing cysts in sows may occur if gonadotropin treatment is performed while normal cyclic CL are present. Preventative measures to consider in these cases are supplementation of carbohydrates (e.g. dextrose or sugar) pre- and post weaning in order to stimulate follicle growth (Chen et al. 2016). If lactational estrus is observed, sows can be bred. Data indicates that fertility results from lactational estrus breedings are similar to those in normally weaned/bred sows (Soede et al. 2012). Alternatively, sows may be bred upon their next estrus, but the number of sows available per week and the expected dates of their estrus are unpredictable.

Problems associated with conception and farrowing rates

In modern production systems, conception (pregnancy) and farrowing rates should be at a minimum of 90 and 88% rate, respectively. Conception failures and loss of pregnancy in either early or late in gestation can be caused through both infectious and noninfectious mechanisms, the latter of which usually involves management issues related to the female as well as the male and semen qualities. For an animal to conceive and maintain pregnancy beyond day 25, there must be a minimum number of conceptuses, starting with matured oocytes that have ovulated and were fertilized by capacitated sperm. Embryos enter the uterus approximately 48 hours after ovulation. Intrauterine migration of the embryos is essential to maternal recognition of pregnancy. For this process, a minimum number of embryos must be present in the uterus to adequately migrate throughout the tract while releasing sufficient amounts of estrogens (E2), which is the embryonic signal in the process of pregnancy recognition. E2 is produced biphasically in two signals with the first appearing at around day 10 and the second at days 14–18 of pregnancy (Geisert et al. 1990). Both signals are required for pregnancy to be maintained. If there is conception failure, early embryonic death, or less than 4 viable embryos present before the first signal at day 10, animals will exhibit a regular return (e.g. 17–24 post breeding). If significant embryonic deaths occur between the first and second signals, the animal will be classified as an irregular return to estrus after post breeding day 24. Conceptus deaths after the second signal but before day 35 of pregnancy may result in late returns. Most but not all conception failures associated with a regular return to estrus are usually due to noninfectious reasons, while later returns (>35 days' gestation) are more likely to be related to infectious insults. If there is an intrinsic or extrinsic pathophysiological disruption in the reproductive hormonal cascade, pseudopregnancy may result. For instance, short- or long-term exogenous treatment with estradiol starting at day 11 of the estrous cycle can induce pseudopregnancy for up to several weeks. Also, zearalenone is capable of not only interfering with early embryonic development but also inducing pseudopregnancy (Tiemann and Dänicke 2007) when provided in biologically relevant mycotoxicotic doses.

Ovulation failure (no or delayed ovulation) will curtail conception efforts with the animal showing a regular return to estrus. Appropriate insemination timing is also critical to achieving acceptable conception rates. It is not uncommon to find farms implementing AI programs where insemination timing with respect to ovulation is inappropriate. Usually, inseminations are being performed post ovulatory, when oocytes are aged and have reduced viability; oocyte viability only lasts for approximately 8 hours after ovulation. The goal of an AI program is that insemination occurs within 24 hours (preferably within 12 hours) prior to ovulation (Waberski et al. 1994; Nissen et al. 1997). Within an existing breeding program, it is hard to anticipate a sudden change in the herd's ovulation patterns, which is typically caused by alterations to pre and post weaning follicle growth. Typical situations that cause this are reduced feed intake during lactation (possibly confounded with hotter times of the year), breed/genetic line changes, and changes to existing hormone programs and products. Lastly, insemination with poorly handled, aged, or poor quality semen can interfere with conception rates.

Uterine disease and tubal disorders may contribute to conception failure; however, their incidence is unknown. Other aspects to consider when diagnosing low conception rates include seasonality (due to increased melatonin and its suppressive effect on GnRH/LH), high ambient temperature (reduced voluntary feed intake), or moving sows from breeding into pen gestation at critical times, especially during the phase of maternal recognition of pregnancy that occurs between 9 and 18 days of gestation.

If pregnant, anything that can disrupt pregnancy will cause reduced farrowing rates. The most likely cause of pregnancy loss is infectious insults (see abortion). Clinical signs associated with reduced farrowing rates due to pregnancy loss are abortions, the passage of stillbirths, or mummified fetuses as well as pseudopregnancy and fetal resorptions.

Incorrect pregnancy diagnosis by personnel when performing heat detection can lead to low conception and farrowing. False positives for pregnancy can occur with respect to POD, inactive ovaries, or pseudopregnancy. A false-negative pregnancy diagnosis is possible when truly pregnant animals display estrus-like behavior at the time of regular estrus return. If pregnancy diagnosis is being performed with Doppler-mode ultrasound, false-positive results may occur in sows tested during proestrus/estrus or when animals have a significant endometritis. False-negative diagnosis using Doppler may occur when examinations are conducted in a noisy environment or if feces become packed around the probe. Amplitude-depth instruments (A-mode or pulse echo) may yield false-positive results in cases of a fluid-filled urinary bladder, pyometra, hydrometra, or cystic ovaries. False-negative results can occur if animals are examined before 28 days of gestation or after day 80. Although B-mode ultrasound (RTU) is very reliable for pregnancy testing, false-positive and false-negative diagnoses have been occasionally noticed, with causes associated with technician skill, day of gestation, equipment, and probe type (e.g. frequency) being the main influencing factors.

When initiating a herd reproductive investigation, a first step is to assess production records, paying particular attention to the ratio of regular versus irregular returns (suggested target 4 : 1) to obtain initial insight as to whether the causes are likely infectious or noninfectious. On-site, ovarian activity should be assessed using RTU. Multiple scanning sessions at intervals of approximately 24 hours are usually necessary for an accurate assessment of ovulation patterns in sows. These results can be used in conjunction with assessing the farm's estrus detection programs. Appropriateness of semen handling, semen quality, insemination technique, and timing should be assessed.

Very early pregnancy using RTU can be performed as early as day 16 when using a higher-quality diagnostic ultrasound unit. Such early assessment may be helpful in objectively diagnosing early embryonic deaths. Open animals should be scanned for pathological conditions (i.e. cystic ovaries or endometritis) and, along with suspected animals typical of the clinical signs being observed, should be considered for further postmortem examination. If there is indication for infectious disease or mycotoxicosis, respective analyses should be performed. Treatment or management decisions clearly depend on the nature of the problem. Those issues related to semen, insemination procedures (including breeding times), and pregnancy testing are relatively easy to correct. If ovulation patterns are wide and, thus, difficult to capture in a breeding protocol, exogenous hormonal use should be strongly considered in order to simplify an insemination protocol that will provide timely deposition of semen in concert with ovulation. Successful programs have included single or double fixed-time insemination programs with or without the use of follicle-stimulating substances (i.e. eCG, combinations of eCG/hCG, select GnRH analogues) given peri-weaning, followed by a timed ovulation-inducing hormone (i.e. GnRH analogues, pLH, hCG) given afterward (Brüssow et al. 2001; Kirkwood and Kauffold 2015).

Problems associated with vulvar discharge

Vulvar discharges are typically observed for up to 48 hours post farrowing as the sow attempts to expel placental remnants and debris from the uterus. A scant mucopurulent vulvar discharge can be observed in pregnant sows during the last 2–3 weeks of gestation. Slight amounts of a usually nontransparent peri-estrous

discharge are also considered normal. Milky to creamy discharges can occasionally be seen immediately post-insemination in up to 50% of inseminated animals on a farm. These discharges can be considered a normal mechanism of evacuating fluids post-insemination. Using ultrasonography, the uteri in these discharging sows appear perfectly normal. These discharges usually disappear shortly after occurrence and do not affect an animal's fertility. Along with evacuating the uterus, other possible inciting factors for discharge may be as a response to certain components in the extended semen and/or the insemination equipment.

After ruling out the aforementioned, all other vulvar discharges are classified as abnormal. A fresh, bloody discharge is usually indicative of vulvar lacerations from biting by sows (particularly in pen housing), trauma, natural mating, or improper AI procedures.

Purulent vulvar discharges that occur several days post breeding are indicative of a pathological condition. It is not uncommon to see some abnormal discharging on a farm. If, however, discharging rates are present in ≥3% of the breeding group, an investigation is warranted. Discharges may originate from the urinary tract in the case of cystitis and pyelonephritis or, more commonly, from the genital tract due to an endometritis or myometritis. Discharges from the urinary tract are usually viscous, contain mucus and occasionally blood, and are associated with urination, especially at the end of the stream. Discharges from an inflamed uterus are usually of high volume, are milky or creamy, and usually are observed as a passive discharge in recumbent animals. These type discharges are usually associated with a bacterial infection that could have been introduced via improper breeding hygiene and technique. Other predisposing factors that could contribute to bacterial infections are building cleanliness, solid versus partly slatted concrete floors, excessive drafts, high ambient temperatures, overcrowding, or any factor that could lead to an immunosuppressed animal. Sows with a previous puerperal endometritis may be at higher risk of discharging at their next post breeding, usually due to a subclinical situation that is then exacerbated by the breeding process.

Although the characteristics of the discharge itself may be indicative toward a urinary versus a genital tract infection, a vaginal examination and urine analysis should be performed in order to confirm the diagnosis. Discharges from the uterus can be clearly diagnosed by RTU based on observation of flocculent uterine echogenicity. If inappropriate insemination timing (i.e. post ovulatory inseminations) is a differential diagnosis, ovulation should be monitored by RTU in animals that were recently identified in estrus and bred. Farm hygiene and sanitation during the breeding process should be evaluated as well. If puerperal discharge is a problem, procedures around farrowing should be critically addressed (e.g. hygiene, vaginal examination, treatments, etc.).

If untreated animals with abnormal discharge express estrus, it is best to not breed the animal, but to wait until their next estrus. As far as treatment options, both medicated feed and injectable antibiotics are commonly used. To obtain the best effect with antimicrobials, accurate identification of pathogens involved and their antimicrobial sensitivity patterns should be determined prior to selecting the product and treatment regime. When treating a single animal with discharge, provide therapeutic levels of antimicrobials for at least 3 continuous days. If discharges are a herd problem, a common protocol is to prophylactically treat all animals at risk at the most likely time that bacterial entry occurs, i.e. around breeding, for an interval of at least 5 continuous days. This preventative therapeutic approach should be considered short term until identification and resolution of the underlying causes can be performed.

Problems associated with parturition

A solid knowledge of the normal process of parturition is essential to determine when to intervene. Swelling of the vulva occurs within 4 days prepartum. The mammary glands become more turbid and tense during the last 2 days before farrowing, with mammary secretions being serous approximately 48 hours prior to parturition and then becoming milky within 24 hours of farrowing. Restlessness and nesting behavior usually start 24 hours pre-farrowing, with the sow becoming less active in the last hour before the first piglet. Intermittent abdominal straining occurs before the birth of the first piglet, but straining is usually mild thereafter except at the moment of fetal expulsion. A prelude to farrowing is the presence of a viscous, blood-tinged secretion from the vulva that appears within 30 minutes of the first piglet. Once farrowing commences, the average interval between the births of piglets is 15–20 minutes. The entire parturition process is usually less than 3 hours. Fetal membranes are typically expulsed from 20 minutes to 12 hours after birth of the last piglet. Piglets can be presented cranially or caudally.

Signs of dystocia in a sow can include an abnormally prolonged gestation, blood-tinged vulvar discharges, meconium without straining, straining without delivery of piglets, cessation of labor after straining, cessation of labor after delivery of one or more piglets, exhaustion of the sow, and foul-smelling and discolored vulvar discharge. Primary uterine inertia associated with a decreased contractile activity of the myometrium is probably not as common as secondary uterine inertia resulting from uterine and maternal exhaustion associated with fetal malposition, fetopelvic disproportion, or obstruction.

From an obstetrical point of view, the causes of dystocia are classified into two categories, fetal and maternal, based upon the origin. Fetal causes include fetal malpositions such as a breech, simultaneous presentation of two fetuses into the birth canal, and fetal congenital malformations. Maternal causes include uterine inertia, deviation of the uterus, fetopelvic disproportion, and maternal excitement. Dystocia may also occur as a result of the misuse of exogenous prostaglandin and oxytocin use to induce and/or control farrowing.

Intervention for dystocia must be in a timely fashion. In a successful farrowing program, sows are optimally assessed at 30 minute intervals to be aware of the sow's interval between the births of piglets once parturition has commenced. If over 1 hour has lapsed since the last piglet has farrowed (and no placenta has been passed), then a clean vaginal examination should be performed. Correction of dystocia due to obstructions or malpositioned fetuses is achieved by manual vaginal examination and requires strict hygiene, obstetrical gloves, and lubricant. Manual extraction is usually the safest technique to extract fetuses. Caution must be exercised when using forceps, blunt hooks, or cable snares due to the risk of trauma to the fetus and the sow's reproductive tract. After removal of the malpositioned piglet, the birth canal should be digitally reexamined prior to the administration of oxytocin. High doses (>20 IU) of oxytocin may create a refractory period (3 hours) in which endogenous and exogenous oxytocin fails to stimulate contractions. In some cases where oxytocin does not stimulate contractions, calcium preparations may be used successfully prior to oxytocin treatment. In other cases, animals may continue farrowing after being treated with a combination of an analgesic and spasmolytic drug. Farrowing should be completed as soon as possible, as a prolonged farrowing can have negative effects on colostrum yield, involution of the uterus, and subsequent fertility and predisposes the animal for the development of postpartum dysgalactia syndrome (Peltoniemi et al. 2016).

Injectable antibiotics are warranted if sufficient contamination of the uterus occurs during farrowing management. Intrauterine infusions of antibiotics or iodine solutions are usually not effective in promoting uterine involution or preventing uterine infections in swine.

Hemorrhage may occur postpartum as a result of uterine, vaginal, or vulvar lacerations. Lacerations of the vagina and vulva can be sutured externally, whereas severe uterine lacerations or uterine ruptures are difficult to repair without conducting a laparotomy. Oxytocin treatment promotes uterine contractions and may be beneficial with minor uterine lacerations. Hematomas of the vulva are resolved as the blood and fluid are resorbed; however, sharp projections in farrowing crates increase the danger of lacerating the hematomas.

Vaginal and uterine prolapses are often seen shortly before, during, or up to several days after farrowing. Factors that have been suspected to increase the risk of vaginal or uterine prolapse in sows are genetics, housing, physical trauma to the genital tract following parturition, older parity, nutrition, and exposure to estrogenic mycotoxins, but neither etiology nor pathogenesis is documented. Vaginal prolapses can be surgically repaired using a purse-string suture with good success. Uterine prolapse repair typically has a very poor prognosis.

Reproductive problems in the boar

Reproductive disease in a boar can have a direct effect on the animal's well-being, breeding behavior, semen quality, and subsequent herd fecundity. The broad use of AI in the global swine industry today further facilitates a boar's impact on herd health through the dissemination of infectious pathogens through extended semen into the sow herd. As with other body systems, disease can be noninfectious or infectious in origin.

In today's commercial herds a large percentage of reproductive problems appear to be secondary to issues related to improper management, irrespective of whether boars are housed with the sow herd or in dedicated boar studs (Althouse 2014). Management-related diseases in the boar negatively impact their semen quality, whose breeding outcomes may be high return rates, low farrowing rates, decreases in average total born per litter, and/or increases in litter scatter.

Heat stress or pyrexia

One of the more common insults associated with reproductive failure in confined boars is exposure to high ambient or "heat stress" temperatures. Under heat stress-induced conditions, normal thermoregulatory mechanisms for the boar's testis are compromised, leading to increased testis temperatures and subsequent disruptions in spermatogenesis (McNitt and First 1970; Wettemann et al. 1976; Althouse 1992). Considerable variation also appears to exist between boars in their individual susceptibility and response to heat stress. Variables such as the duration and intensity of the elevated temperatures, relative humidity (RH), and adequacy of housing ventilation can further complicate the issue. In general, the risk of heat stress in boars is present when ambient temperatures are at or above 27 °C with ≥50% RH (Figure 20.3). The detrimental effects of heat stress on the spermiogram (i.e. reduced sperm viability, low sperm motility, increased abnormal sperm morphology, decrease in total sperm output) begin to appear 7–14 days post-insult (Figure 20.4) and usually remain present for 5 weeks or longer based upon the scope of the heat stress event (Althouse 1992).

Extreme heat Stress | Probable heat Stress | Possible heat Stress

Figure 20.3 Risk of a heat stress event in boars based upon ambient temperature and relative humidity.

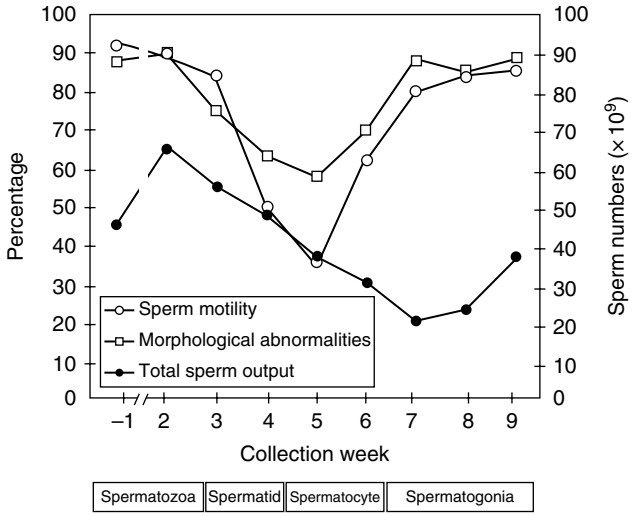

Figure 20.4 Effect of heat stress on boar sperm quality and time for recovery. Open circle points and line = sperm motility. Open box points and line = morphological abnormalities; Blackened round points and line = Total sperm output. *Source:* Adapted from Althouse (1992).

In similar mode to a heat stress event, an infectious challenge or even a routine vaccination to a boar can elicit an increase in core body temperature (e.g. pyrexia). The increased body temperature causes a concomitant increase in testis temperature that disrupts the spermatogenetic process. In addition and because of the critical role the scrotum plays in regulating testis temperature in most mammals, any trauma or abnormal condition to the scrotal area (and underlying testis) can have an adverse effect on spermatogenesis. In general, the changes to semen quality after scrotal/testis trauma or pyrexia are similar to those that occur after boars are exposed to environmental heat stress conditions. To reduce the negative semen quality effects on a boar exhibiting fever, antipyretic medication should be administered to keep body temperature below 39.5 °C.

Mycotoxins

Cereal grains contribute substantially to a typical boar diet; hence continued vigilance in minimizing the risk of mycotoxicosis from mycotoxins in feedstuffs is critical to boar health and normal spermatogenesis. Mycotoxins are products of fungi and mold that colonize cereal crops and can be produced in crops either pre- or postharvest. Factors that favor mycotoxin formation include crop stress, weather conditions, and production practices. Mycotoxicosis in a boar is dependent upon the type of mycotoxin(s), amount consumed, and duration of exposure. Specific mechanisms of mycotoxin impact on boars are not well understood, but general loss of vigor and reproductive compromise can be associated with their presence. Mycotoxins of current concern to boar health include aflatoxins, ergot, fumonisin, trichothecene toxins (e.g. ochratoxin, T-2 toxin), vomitoxin (deoxynivalenol), and zearalenone (Althouse 2014). Prudent mycotoxin screening of boar diets is recommended with a strong preference not to use grains in which mycotoxins are present. If exclusion is not an option, then selective inclusion of effective mold inhibitors, binders, absorbents, and denaturants, specific to the mycotoxin(s) found, to the diet may be of benefit.

Boar overuse

Many factors such as available boar power, genotype, libido, season, animal age, and health may drive how frequently a boar is used in a breeding program. If a boar's ejaculate frequency is too high (e.g. overuse) over several weeks, a concomitant decrease in total sperm numbers,

Table 20.2 Suggested semen collection frequencies by age for AI boars used at stud.

Boar age	Ejaculate collection frequency
<8 mo	1×/7–10 days
8–10 mo	1×/7 days
10–12 mo	≤3×/2 weeks
12+ mo	≤2×/week

Table 20.3 Minimum requirements for use of fresh boar semen for artificial insemination.

Semen variable	Descriptor/value
Appearance	Milky to creamy consistency
Color	Gray – white to white
Gross motility (unextended)	≥70% (if used by 48 hours)
	≥80% (if used after 72 hours)
Abnormal morphology	<25% (includes cytoplasmic droplets)
Cytoplasmic droplets	<15% (proximal and distal droplets)

semen quality, and subsequent fertility can be expected (Swierstra and Dyck 1976; Hemsworth et al. 1983). Young boars (<8 months of age) exposed to overuse conditions early in their careers tend to develop chronic subfertility problems, leading to premature culling (Leman and Rodeffer 1976). To avoid boar overuse, active boar management and ejaculate monitoring is essential. Table 20.2 provides suggested semen collection frequencies based upon boar age for boars used in AI programs and standing at stud. For boars used in natural mating conditions, a male–female ratio of 1 : 15–1 : 25 should be available. To avoid semen quality issues related to boar underuse, breeding boars should be ejaculated at least once every 10–14 days.

Semen quality

Achievement of herd fecundity goals is dependent, in part, upon the delivery of good quality extended boar semen. Standard tests in evaluating boar semen include a subjective visual inspection for normal appearance and color, along with more detailed objective analysis of sperm motility, sperm morphology, sperm concentration, volume, and total sperm numbers (Althouse 2007). Minimum requirements of fresh boar semen for intended AI use are listed in Table 20.3. In addition to acceptable spermiogram parameters, the source stud should confirm that any materials used in the direct production of extended semen (i.e. semen extender, plastics, gloves, etc.) are obtained from AI material suppliers that abide by acceptable supply chain practices that support product safety, quality, consistency, and traceability.

Infectious pathogens

Numerous infectious pathogens can cause reproductive problems in the boar and/or appear to play an epidemiological role in the transmission of the disease in swine (Guerin and Pozzi 2005; Althouse and Rossow 2011; Maes et al. 2016). Certain infectious agents (e.g. *Brucella*, *Chlamydophila/Chlamydia*, cytomegalovirus, Japanese B encephalitis virus [JEV], rubulavirus) can directly infect the testis and/or epididymis, eliciting an inflammatory response that disrupts sperm cell development in addition to promoting the shedding of the pathogen through the semen. Other pathogens (i.e. African swine fever [ASF], Aujeszky's/pseudorabies, classical swine fever [CSF], FMD, *Leptospira*, parvovirus, PCV2, PRRS) appear to disseminate and infect tissues throughout the body, including the boar's genital tract. Once seeded, the pathogen is shed in the seminal fluids of the boar ejaculate, facilitating the transmission of the disease to the female bred with infected semen. Currently known pathogens that have been identified in boar semen and have been transmitted through AI are listed in Table 20.4. Lastly, any pathogen in the boar that elicits a febrile response has the undesirable side effect of increasing core body and testis temperature, leading to disruption in spermatogenesis with a similar outcome to that which occurs with heat stress exposure.

Many bacterial species have been identified in fresh boar ejaculates (Althouse et al. 2000; Althouse and Lu 2005; Gączarzewicz et al. 2016). Contribution of other bacterial contaminants can occur to semen during processing for use in AI programs (Althouse and Lu 2005; Payne et al. 2008). Several bacterial species present as contaminants have been found to thrive under the cooling and storage conditions of extended boar semen in the days prior to insemination use (Althouse 2008), with the effect of damaging the sperm and affecting sow reproductive performance upon use (Althouse et al. 2000; Maroto-Martin et al. 2010; Kuster and Althouse 2016). To minimize this risk, implementation of effective bacterial control strategies during semen collection and processing should be followed (Table 20.5).

Diagnosis of abortion and reproductive diseases

The root cause of abortion lies in the loss of progesterone provided by the CL. Loss of the CL terminates pregnancy. The release of cortisol by sows and/or fetuses

Table 20.4 Selected swine diseases that have been identified in boar semen and spread through artificial insemination (AI).

Disease	Demonstrated transmission via AI
African swine fever	
Aujeszky's disease (pseudorabies)	
Brucellosis	
Chlamydophilosis/ chlamydiosis	
Circovirus type 2 (PCV2)	Yes (Madson et al. 2009; Sarli et al. 2012)
Classical swine fever (hog cholera)	Yes (De Smit et al. 1999; Hennecken et al. 2000)
Foot-and-mouth disease	
Japanese encephalitis	
Leptospirosis	
Malignant catarrhal fever	
Parvovirus	Yes (Lucas et al. 1974)
Reproductive and respiratory syndrome	Yes (Prieto et al. 1997; Nathues et al. 2016)
Rubulavirus	
Vesicular disease	

initiates a hormonal cascade, resulting in prostaglandin release from the pregnant uterus, lysis of the CL, and pregnancy loss. Infectious agents and noninfectious events can interrupt the endocrine equilibrium of pregnancy.

Diagnosis of fetal death is challenging due to the broad array of processes that have been associated with *in utero* mortality, including genetic, hormonal, nutritional, toxic, traumatic, metabolic, hypoxic, and infectious causes (Christianson 1992).

The goal of abortion diagnosis is the same as for any diagnostic investigation, which is to identify the etiology and associated epidemiology. The diagnostic process differs because clinical signs (abortion) may occur well after the inciting cause; therefore the veterinarian and producer, blinded to the initiating event, must try to retrospectively determine the event or events resulting in pregnancy loss. Infectious agents may cause fetal death shortly before the abortion or well before the abortion. An intimate knowledge of the pathogenesis of the agent or agents causing abortion is required. For example, knowing that the viremia of PRRSV in sows with preexisting immunity is much shorter than in PRRSV, naïve sows will influence the types of samples to collect, the best time for sample collection, and the number of samples required to have confidence in results of virus detection tests. The detailed pathogenesis of the specific pathogenic agents is discussed in their respective chapters.

Table 20.5 Boar and laboratory management to minimize semen contamination.

Boar preparation/semen collection

1. Hair should be kept trimmed around the preputial opening.
2. Use double gloving, with the outer glove discarded after preparation of the boar, allowing for a clean gloved hand for grasping of the penis.
3. Disposable gloves or a hand disinfectant should be used during semen collection to minimize contamination of semen and reduce risk of cross-contamination between boars.
4. Clean preputial opening and surrounding area (if needed) with a single- use disposable wipe.
5. Manually evacuate preputial fluids prior to exteriorizing penis for semen collection.
6. Hold penis horizontally to minimize preputial fluid contamination of the semen and semen collection vessel.
7. Divert initial jets of an ejaculate (i.e. presperm fraction) and gel fraction from the semen collection vessel.
8. Dispose of rubber band and filter/gauze before passing collected semen to the laboratory for further processing.

Semen processing/laboratory and barn sanitation

1. Encourage single-use disposable products when economically feasible to minimize cross-contamination.
2. If using reusable laboratory materials that cannot be heat/gas sterilized or boiled, clean initially using a laboratory-grade detergent (residue free) with water, followed by a distilled water rinse, and lastly, a 70% alcohol (nondenatured) rinse. Allow enough time and proper ventilation for complete evaporation of residual alcohol. Rinse with semen extender prior to their first use of the day.
3. Disinfect countertops and contaminated lab equipment at the end of the processing day with a moist residue-free detergent and rinse.
4. Floor should be mopped at the end of the day with a disinfectant.
5. Break down bulk products into smaller, daily use quantities immediately after opening.
6. Ultraviolet lighting can be installed to aid in sanitizing reusables and lab surfaces; however, safety precautions need to be integrated to prevent exposure of personnel.
7. Boar housing should be on a maintenance schedule that minimizes buildup of organic material and surface moisture.
8. The semen collection area and collection dummy should be thoroughly cleaned and disinfected at the end of the collection day.

In swine, the most common mechanisms of infectious abortion are infection of one or more fetal–placental units or the systemic effects of maternal illness. Clinical signs observed and the selection of appropriate specimens and diagnostic tests differ depending on the mechanism of abortion. In abortions due to infection of the fetus or placenta, the sow may have seroconverted by the time of abortion and may no longer be viremic or bacteremic, but will be seropositive for the offending

agent. The organism may or may not be detected in placenta or in one or more of the aborted fetuses. Diagnostic efforts need to focus on the placenta, fetuses, and seroconversion of dams. Abortion due to maternal illness usually happens during the acute phase of the disease at which time the sows typically exhibit signs of systemic illness such as fever, inappetence, lethargy, respiratory disease, or enteric disease. The sows usually have not had time to seroconvert or have an anamnestic response to the causative infectious agent. With acute maternal infections, there is an opportunity to detect the causative agent in clinical or postmortem specimens (i.e. serum, nasal swab, tonsil scraping, tissues) from the sow. Fetal infection may or may not be present; therefore collection of specimens from sows and fetuses from acute maternal illness will optimize the likelihood of diagnosing the causative agent.

The initial step in investigating an abortion outbreak is to assess whether aborting sows have clinical signs of systemic illness either at or near the time of abortion. If the aborting dam is clinically ill, then specimens from both the dam and fetuses should be submitted for diagnostic testing. The nature of the sow's illness will dictate the appropriate specimen collection strategy. For example, influenza A virus (IAV) can cause sows to become febrile, lethargic, and inappetent and develop signs of respiratory disease such as coughing and dyspnea. Since IAV infection does not cause viremia, abortions result from the maternal inflammatory response that then initiates the disruption of the pregnancy endocrine equilibrium. A fetus is not an acceptable specimen for identifying IAV but may prove valuable in identifying a secondary sow bacteremia. A diagnosis of IAV as the initiating cause of the abortion is then dependent on identifying the virus in nasal swabs, bronchial swabs, and lung or oral fluids of sick or dead sows. Demonstrating seroconversion to SIV with paired serum samples may be problematic considering the myriad of influenza viruses circulating in pigs.

Infectious agents that can infect and replicate in fetuses are detectable in fetal tissues and/or placenta if a sufficient number of specimens are examined and the diagnostic tests are capable of detecting live pathogens or their residual specific antigens or nucleic acids. Studies have demonstrated that maternal bacteremia or viremia may result in infection of one to several fetuses, with later *in utero* spread from fetus to fetus (Nielsen et al. 1991). What is important about this observation is that not all fetuses in a litter are infected at the time of abortion; therefore diagnosis of the causative agent may be missed if only a few fetuses are evaluated. A general recommendation is to sample 4–6 fetuses per litter from at least 3 litters. This is based on a calculation to achieve 90–95% confidence that at least one infected fetus is represented in a submission, assuming a fetal infection rate of 50% and a litter size of 12 (Benson et al. 2002). For most diagnostic tests, pooling of samples from several fetuses generally has limited impact on diagnostic sensitivity. The stage of gestation and *in utero* spread of pathogens influence the clinical presentation of reproductive disease with fetal or placental infection. Infection of a fetus can result in a range of outcomes, including embryonic death and resorption, fetal death and mummification, abortion of fresh or autolyzed fetuses, stillborn pigs, or weak-born pigs with increased neonatal mortality (Christianson 1992). Infection early in gestation may lead to embryonic death and resorption of some but not all fetuses, resulting in decreased litter size. Complete resorption of fetuses indicates fetal death occurred prior to 35 days' gestation. After 35 days, fetal bone mineralization occurs; therefore fetuses that die become mummified. Progressive *in utero* spread of a pathogen between fetuses may lead to fetal death and mummification, with variation in the size of mummified fetuses. Fetuses infected after 65–70 days of gestation can mount an immune response to a number of agents. These fetuses may be live born yet seropositive to the pathogen (Nielsen et al. 1991). Clinically, this sequential infection scenario may manifest as multiple variable-sized mummified fetuses with a few apparently normal live-born piglets at parturition.

Porcine abortion: Serology

Serology remains a useful tool in diagnosing infectious agents of abortion. The greatest value of serology is either to confirm the presence of an agent previously absent from the herd or to verify that the agent in question is still not present in the herd. Accumulating negative results for different agents is a valuable part of the diagnostic effort. Diagnosis by opinion and strict reliance on agent detection tests or on single test types (e.g. polymerase chain reaction [PCR], IHC) rather than pursuing a complete, proper, and objective diagnostic investigation leads to prolonged clinical disease and inappropriate or delayed interventions.

With an acute infectious event, the affected sow likely has not yet seroconverted. Specific antibody detection via acute and convalescent samples from several acutely affected or sick sows is quite valuable to demonstrate seroconversion and/or increasing antibody titer. Serum samples from acutely affected animals can be split, with one portion used for agent detection testing and the remainder retained for paired serology if needed. These samples can later be discarded if they are not needed, but they are invaluable for investigation of abortion events that continue to be undiagnosed over time. Seroconversion to a known pathogen and temporal association with an abortion event is strong evidence for a role in the clinical process. If abortion rate is increasing and sows are not

clinically ill, then serum collected from sows that have aborted and a few herd mates can identify seroconversion to the causative agent. Samples consistently negative for antibody for the suspected agent will help rule out a role for that agent in abortion.

The detection of serum antibodies to known endemic infectious agents can be difficult to interpret. That frustration is a common reason serology has become less a part of abortion diagnostic investigations. However, antibody detection with appropriate serology tests remains an important diagnostic tool. Serology performed on a few animals of known clinical status for diagnostic reasons can be very insightful, and sampling utilized for this type of diagnostic investigation should not be confused with the more generic epidemiology-based sampling protocols used for detection and prevalence studies in subclinical populations or animals of unknown clinical status.

Agent-specific antibody detection performed on fetal thoracic fluid is not generally reliable due to both a lack of sensitivity and specificity. IgG/IgM identified in fetal thoracic by agar-gel immunodiffusion (AGID) is a reliable method to indicate *in utero* antigen exposure after 65 days' gestation. A positive result is not specific for a causative agent but is an indication of an infectious event prompting additional submissions.

Tissue sampling guidelines

The most important part of a diagnostic investigation is a thorough review and evaluation of the clinical problem by the veterinarian and producer prior to sample selection and submission. The decision may be straightforward in cases of acute abortion events. Chronic or recurring events causing different stages of fetal death or pregnancy loss can be especially challenging. These events may require multiple submissions or the collection of samples from multiple animals over time with a single submission. In the absence of lesions or detection of offending etiology, the diagnosis is idiopathic with cause unknown. The relative frequency of identified causes reported from diagnostic laboratories should not be considered as true prevalence or a complete data set, as that data is a tiny fraction of the abortions occurring day to day and is strongly influenced by selection bias in sampling and test selection.

A summary of preferred specimens for porcine abortion laboratory examinations is listed in Table 20.6. Collection and submission of chilled or frozen fetuses and placenta, along with dam sera, is the most common type of diagnostic specimen submitted to laboratories as caretakers can then collect and submit directly from the farm with guidance from the herd veterinarian. Diagnosticians can then sample and select appropriate tests using hygienic techniques. Intact fetuses are expected to be sterile or devoid of infectious agents, so identification of an agent is usually a significant finding. Whole fetus submissions give the pathologist or diagnostician the opportunity for gross examination (gross lesions are infrequent), crown-to-rump measurements for determining fetal age, and separation of fetuses used for testing by size/age and condition (mummified, partially autolyzed, or fresh). Contamination of samples with agents normally found in feces such as PPV, PCV2, and a host of endemic bacterial flora is not uncommon; mere detection is not causation, so care in interpretation is warranted before assigning cause. Histopathology is a very useful tool for routine diagnostic investigation as it can link an agent to a typical or expected lesion. Histopathology can also identify tissue lesions of unknown origin, leading to more in-depth analysis.

Table 20.6 Fetal tissue sampling guidelines in cases of porcine abortion.

Formalin-fixed tissues	Fresh/chilled tissues
Brain	Brain
Heart	Heart
Lung	Lung
Liver	Liver
Spleen	Spleen
Kidney	Kidney
Placenta	Placenta
Skeletal muscle	Fetal thoracic fluid
	Fetal stomach contents[a]
	Serum ± nasal swab, other specimens from aborting sows

[a] Fetal stomach contents are a minimally contaminated specimen for bacterial culture and can easily be harvested by puncturing a syringed needle through the wall of the stomach and aspirating.

Viruses affecting reproduction

Viruses, of which many are known, are considered the most economically significant infectious cause of pregnancy loss in swine. A large portion of viral reproductive losses is associated with maternal infections rather than direct fetal infection; hence careful observation of sows and appropriate sampling strategies are a critical part of all abortion investigations. Viruses found in the United States related to pregnancy loss include PRRSV, PCV2, PPV1, PPV2, IAV, encephalomyocarditis virus (EMCV), porcine enteroviruses (PEV), porcine teschoviruses (PTV), atypical porcine pestiviruses including bovine viral diarrhea virus (BVDV)/border disease virus (BDV), swine vesicular disease, porcine cytomegalovirus (PCMV), and the potential for pseudorabies virus (PRV)

from feral pigs. Outside of the United States, pregnancy loss occurs by infection with JEV, CSF, ASF, Menangle virus, and rubulavirus, which is also known as blue-eyed pig disease.

Diagnosis of viral abortion

Gross lesions that may indicate viral-induced reproductive disease include an increased number of mummified fetuses, the presence of fetal anomalies in multiple litters (e.g. cerebellar hypoplasia, arthrogryposis), and multiple pinpoint foci of necrosis (PRV). The most common observation with fetal viral infection is "no gross lesions." Microscopic lesions are valuable indicators of viral abortion and are present more frequently than gross lesions. Microscopic lesions that suggest viral involvement include nonsuppurative encephalitis, myocarditis, vasculitis, and necrotizing lesions in multiple tissues.

The advent of PCR for the identification of fetal viral infections has remarkably enhanced abortion diagnostic investigations. PCR tests can be designed to identify a broad range of genetic variations within a group of viruses such as PRRSV and to also have applications across a broad range of sample types including autolyzed tissues or tissues from mummified fetuses. The application of next-generation sequencing (NGS), a method to screen for and identify unknown RNA or DNA in a sample for abortion diagnosis, will increase the number of viruses detected in fetal tissues and be able to rule out the presence of infectious agents so that negative results will have diagnostic value as well. No longer are diagnosticians reliant on insensitive use of virus isolation for the discovery of unknown viruses. Submission of whole fetuses gives the pathologist or diagnostician the option of specific tissue selection for NGS investigations.

Bacterial and fungal abortion

A wide variety of bacteria and fungi have been isolated from porcine abortions (Kirkbride and McAdaragh 1978; Eustis et al. 1981), but most are not commonly thought of as herd problems. Fungal infections are only reported to account for roughly 0.3% of porcine abortions (Kirkbride and McAdaragh 1978). A maternal bacteremia that causes fetal and/or placental infection may originate from exposure to newly introduced bacteria or more commonly from endemic opportunists that may also be involved in pneumonia, pericarditis, and toe or joint infections. The herd impact of various bacterial species causing abortion varies considerably with the size of the herd (large herds increase opportunities for expansion/spread and can provide an increasing challenge dose) and the degree of preexisting individual immunity to the bacteria. Abortions associated with the most common maternal bacterial infections occur in clusters lasting several weeks or possibly longer (i.e. *Erysipelothrix rhusiopathiae, Actinobacillus* spp., *E. coli*) and are occasionally of economic significance.

Leptospira spp. and *Brucella suis* are bacteria in swine that can contribute to higher morbidity, mortality, and herd persistence. *Leptospira* spp. pregnancy loss in sows is currently uncommon in the United States because of vaccination and diminished exposure to the organism (in addition to eliminating access to wildlife reservoirs and untreated surface waters). Regulatory programs using serologic testing and animal removal in infected herds have led to the virtual elimination of *B. suis* from domestic populations in the United States, Northern Europe, and Australia. However, there is the potential for reintroduction of *B. suis* into commercial populations from feral swine.

Diagnosis of bacterial abortion

Gross lesions indicative of bacterial abortion are uncommon but may include fetal icterus, splenomegaly, fibrinous exudate on the surface of abdominal or thoracic viscera, or gross placental hemorrhage, necrosis, or exudates. Gross placental lesions are difficult to identify as most are fecal contaminated. Microscopic lesions identified are most commonly pneumonia and placentitis. Preferred fetal tissues for bacterial culture are lung and stomach contents. Assigning causal roles of bacteria isolated from the placenta as the causative agent of abortion is dependent on both confirming a compatible lesion (e.g. acute placentitis) by microscopy and by a bacterial culture result indicating a relatively heavy growth.

Toxins associated with abortion and infertility

Abortion and infertility associated with exposure to toxins can impact multiple animals in breeding herds and, to a degree, mimic infectious and contagious abortions. The two most common toxins associated with reproductive wastage in swine are carbon monoxide and zearalenone.

Carbon monoxide (CO) poisoning is usually the result of incomplete combustion and inadequate removal of fossil fuel by-products in heated facilities. Cherry red discoloration of fetal subcutaneous tissue, muscle, abdominal, and thoracic viscera is a hallmark for carbon monoxide poisoning, confirmed by detection of carboxyhemoglobin levels >2% in fetal thoracic fluid (Carson 1990). A carbon monoxide detector would give a more rapid diagnosis.

Experimental evidence does not support a direct role for any particular mycotoxin as cause of abortion in swine; abortion as a direct result of mycotoxin ingestion in an otherwise asymptomatic sow is rare. On the

Table 20.7 Some infectious and toxic diseases causing abortion, stillbirth, and mummification in swine.

Disease	Signs in sow	Reproductive manifestations	Gross fetal lesions	Diagnosis
PRRSV	Mild depression, anorexia, fever	Late-term abortion, stillbirths, weak-born pigs	Meconium staining of fetal skin; umbilical cord edema and segmental hemorrhage	PCR: pooled fetal thoracic fluid and/or tissues; PCR on serum from acutely ill dams
PCV2	None	Weak births, stillbirths, fetal mummification	Dilated and hypertrophied heart; fluid in the body cavities; enlarged, congested liver	PCR on fetal heart/lung; IHC on fetal heart
Parvovirus (PPV)	None	Embryonic death and resorption (small litter size), fetal mummification	Fetal mummification (3–16 cm crown-rump length)	FA/PCR mummified fetal tissues (lung)
Psuedorabies virus (PRV); Aujeszky's disease	Generally none	Embryonic death, fetal mummification, abortion, stillborn, and weak-born pigs	Multifocal; random; pinpoint white foci (necrosis) in liver, spleen, and possibly lung	FA, PCR, VI on fetal lung, liver, spleen, brain, and kidney
Influenza virus A (IAV)	Fever, lethargy, coughing, dyspnea	Infertility, decreased litter size, abortion, and stillbirths	None	IAV not found in fetuses; PCR, VI, AgELISA on nasal swabs or lung from sick sows; paired serology
Encephalomyocarditis virus (EMCV)	None	Decreased farrowing rates, abortion, mummification, stillbirths, weak-born pigs	Chalky white foci in the heart, hydrothorax, hydropericardium, ascites	VI, PCR on heart, lung, spleen, kidney, and brain
Enterovirus, teschovirus	None	Infertility, embryonic death, mummification, stillbirths, neonatal mortality	None	VI, FA, PCR on lung, spleen, kidney, and heart
Classical swine fever (CSF); Hog cholera	Fever, reduced feed intake, depression, ataxia, conjunctivitis, constipation, cachexia, and cutaneous erythema	Embryonic death and resorption, abortion, mummification, stillbirths, fetal malformations, and increased neonatal mortality	Ascites, widespread petechiation, pulmonary hypoplasia, malformations, micrognathia, cerebellar hypoplasia, microcephaly	PCR on tonsil, kidney, spleen, lung, and placenta
Atypical pestiviruses (APPV, BVD, BDV)	None	Decreased conception, abortions, stillbirths, congenital anomalies, increased neonatal mortality	Cerebellar hypoplasia	VI, FA, PCR on brain, spleen, lung, and kidney
Japanese encephalitis virus (JEV)	None	Abortion, fetal mummification, stillborn or weak piglets	Subcutaneous edema, hydrocephalus, cerebellar hypoplasia, cavitary effusions, serosal petechia	VI, FA, IHC, PCR brain, liver, spleen, lung, and placenta
Porcine cytomegalovirus (PCMV)	None	Decreased litter size, fetal mummification, stillbirths, neonatal mortality	Interlobular pulmonary edema	VI, FA, PCR on fetal lung, spleen, and kidney
Rubulavirus	Transient anorexia, occasional corneal opacity	Infertility, stillbirths, fetal mummification, infrequent abortion	Fetal mummification	VI, FA, PCR on brain, lung, liver, and placenta
Menangle virus	None	Infertility, decrease live-born piglets, fetal mummification, stillborn fetuses, congenital anomalies	Malformation: brachygnathia arthrogryposis, kyphosis, pulmonary hypoplasia, CNS abnormalities	VI on brain, lung, and heart; serology

(*Continued*)

Table 20.7 (Continued)

Disease	Signs in sow	Reproductive manifestations	Gross fetal lesions	Diagnosis
Leptospira	Transient fever, anorexia, and depression	Infertility, fetal mummification, abortion, stillbirths, and weak-born pigs	Occasional fetal jaundice	PCR, IHC, FAT on fetal kidney; dam serology
Brucella suis	None	Infertility, abortion, stillborn and weak-born pigs	Placentitis	Bacterial culture: liver, placenta, stomach content, lung; dam serology
Chlamydia spp.	None	Abortion, infertility	None	IHC, PCR, antigen-capture ELISA on placenta, liver
Carbon monoxide	Typically none	Abortions, stillbirths, weak-born piglets	Cherry red subcutaneous tissue, muscle, abdominal and thoracic viscera	Carboxyhemoglobin levels on fetal thoracic fluid
Zearalenone	Infertility, anestrus, pseudopregnancy, swollen mammae and vulvas, anestrus	Infertility, embryonic death, small litter size, small pigs, piglets with hyperestrogenism	None	Feed analysis

other hand, zearalenone is an estrogenic mycotoxin produced by *Fusarium roseum*, and to a lesser extent *Fusarium moniliforme*, that has a well-known influence on reproductive function. Zearalenone infection occurs most commonly in corn, but other feedstuffs may also be infected. Zearalenone fed during pregnancy may interfere with early fetal development, resulting in reduced litter size (Kirkbride and McAdaragh 1978; Osweiler et al. 1985) or pseudopregnancy, but not abortion. A summary of infectious and toxic causes of reproductive wastage in swine is found in Table 20.7.

Respiratory System

Michael J. Yaeger and William G. Van Alstine

Introduction

The average adult pig-sized mammal breathes 7,000–12,000 L of air every day. The combined area of the air passages and alveolar surface of the respiratory tract represents the largest epithelial surface exposed to the outside environment in the mammalian body. The interaction of the massive respiratory surface with the enormous volumes of air, containing potentially harmful gases, particles, and pathogenic microorganisms, has necessitated the development of robust respiratory defenses.

The increased pressures of rearing pigs in modern-day confinement systems have the potential to overcome these robust defenses and lead to the development of respiratory disease. In most swine-producing areas, large groups of pigs are housed under intensive conditions, often in geographical regions with a dense pig population. Respiratory disease may result when the respiratory defenses are compromised by exposure to fine particulates, such as dust, and volatile chemicals, such as ammonia from animal waste (Michiels et al. 2015). The high stocking density in a closed environment also facilitates transmission of airborne pathogens within a herd (Buddle et al. 1997; Donham 1991) and between herds (Christensen et al. 1993; Stark et al. 1992). Many of these primary respiratory pathogens adversely impact respiratory defenses, leading to the development of costly secondary bacterial bronchopneumonia.

Worldwide, respiratory disease continues to cause substantial losses to the swine industry (Bak et al. 2008; Grandia et al. 2010; Jager et al. 2010; Neumann et al. 2005; Sales et al. 2010). Results from the 2012 National Animal Health Monitoring System (NAHMS) study showed that respiratory infections were the main cause of nursery deaths (47.3%) and grower/finisher pig mortality (75.1%) (United States Department of Agriculture 2015). Two large surveys identified pneumonia lesions in an average of 55.9–59.6% of slaughtered pigs (Hillen et al. 2014; Ostanello et al. 2007). Financial losses associated with respiratory disease are due to increased mortality, decreased weight gain, increased feed costs, increased condemnation at slaughter, and increased costs for treatments, vaccination, and labor. Consequently, respiratory disease is regarded as one of the most serious health problems in modern swine production.

Normal structure and function

The respiratory system is broadly divided into the upper and lower respiratory tract. The upper respiratory tract is the portion of the respiratory tract external to the chest and consists of the nasal cavity, sinuses, nasopharynx, larynx, and trachea. The primary functions of the upper respiratory tract are to condition incoming air (warm, humidify, cleanse), sample antigens to initiate an adaptive immune response, and conduct air to the lower respiratory tract. Many of these functions also occur in the lower respiratory tract, where air is ultimately delivered to the alveoli for efficient gas exchange.

Upper respiratory tract

The nasal cavity has a large, moist, highly vascularized, and convoluted mucosal surface that conditions incoming air by removing particulates, warming, humidifying, and uniformly mixing the air (Figure 21.1). The upper respiratory tract, including the majority of the nasal cavity and continuing through the pharynx, larynx, trachea, and bronchi, is lined by a mucus-coated ciliated epithelium that forms the mucociliary apparatus – one of the most important respiratory defenses.

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Lower respiratory tract

The lungs are divided into seven lobes: the right lung is composed of the cranial, middle, and caudal and accessory lobes; the left lung is composed of the cranial, middle, and caudal lobes (Figure 21.2). Lobes vary in size. The lobes are subdivided by solid interlobular septa into separate lobules, each served by a bronchiole. Collateral ventilation between lobules is minimal. As a result of this complete lobulation, exudate within alveoli, as seen with a bronchopneumonia, is often retained within lobules, giving the lungs a sharp line of demarcation between affected and unaffected lobules.

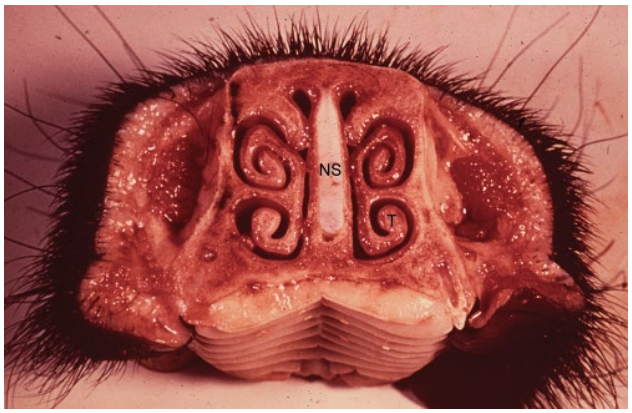

Figure 21.1 Normal turbinates from a normal pig. The nasal septum (NS) is straight, and the turbinates (T) fill the nasal cavity.

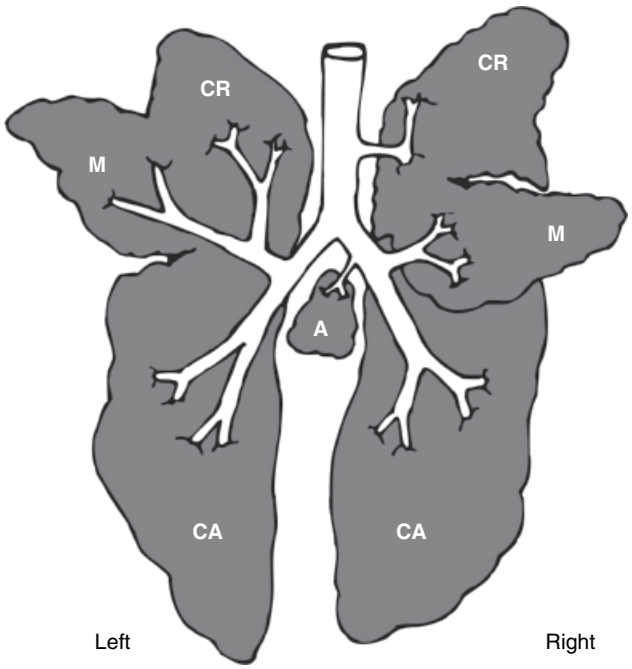

Figure 21.2 Schematic diagram of the lung lobation with branches of the bronchial tree. CR, cranial lobe; M, middle lobe; CA, caudal lobe; A, accessory lobe.

The lower respiratory tract consists of the bronchi, bronchioles, terminal and respiratory bronchioles, and alveoli. At the level of the terminal and respiratory bronchioles, lung function transitions from cleansing and conducting incoming air to the region where gas is exchanged. The terminal air passages and alveoli are no longer protected by a mucus layer, since mucus would slow the diffusion of oxygen and carbon dioxide. Blood in alveolar capillaries is separated from luminal air by three extremely compact tissue layers measuring only 0.22–0.55 µm in thickness (Bradley and Wrathall 1977), allowing for efficient gas exchange. A drawback of this design is that this very large and fragile surface lacks the protective components of the mucociliary apparatus and is vulnerable to infectious agents should they penetrate deep into the lung.

Respiratory defenses

Mucociliary apparatus

Throughout much of the respiratory tract, extending from the nasal cavity to the bronchioles, the mucosal surface is protected by the mucociliary apparatus. In this system, mucus coats the epithelial surface. High air velocity in the nasal cavity coupled with marked air turbulence around nasal turbinates results in impaction and trapping of larger airborne particles (>30 µm) onto the mucus bilayer lining the nasal mucosa (Bustamante-Marin and Ostrowski 2017). Particles greater than 10 µm diameter are mostly removed before reaching the bronchial tree (Baskerville 1981). Particles are trapped in the mucus, and the rhythmic beating of the cilia results in the delivery of mucus from the nasal cavity, trachea, and bronchi to the pharynx where it is subsequently swallowed.

The particle-trapping surface mucus of the mucociliary apparatus is not simply a passive layer of viscous liquid. The mucus gel acts as a mechanical barrier for bacteria. The surface mucus also contains specific immunoglobulins, primarily immunoglobulin A (IgA), and many antimicrobial substances, including antimicrobial peptides (defensins), lysozyme, surfactant, opsonins, lactoferrins, and complement factors, all of which aid in the neutralization and removal of pathogens, further bolstering the effectiveness of the mucociliary apparatus (Nicod 2005).

Alveolar defenses

Particles less than 5 µm in diameter may be able to reach the alveoli. The primary defense against particulates in the alveolus is the alveolar macrophage. Additionally, pneumocytes produce surfactant proteins, which are

members of the collective family of mammalian lectins that enhance the phagocytosis and killing of microbes by alveolar macrophages (Nicod 2005).

Phagocytes

Phagocytic cells in the respiratory tract include dendritic cells (DCs), macrophages, and neutrophils. In general, macrophages and neutrophils are key components of the innate immune system, while the primary role of DCs is to interface with the adaptive immune system and modulate immune responses.

The basal layers of the respiratory mucosa in the nose and the conducting airways contain a tight network of phagocytic DCs that capture invading organisms and present them to the draining lymph nodes (Nicod 2005). They form a network optimally situated to sample inhaled antigens. After antigen uptake, airway DCs migrate to the paracortical T-cell zone of the draining lymph nodes of the lung, where they interact with naive T cells to generate adaptive immunity (Nicod 2005).

Macrophages play a key role in defense against respiratory infection. They are important in both innate and acquired immunity of the respiratory tract. Pulmonary macrophages remove foreign material that escapes the mucociliary defense mechanism, process antigens, and modulate the immune response. Alveolar macrophages provide the first line of defense against organisms or particles reaching the lower airways. They either neutralize the invading pathogens or recruit neutrophils and other mononuclear cells. Nonpathogenic particles and microbes are phagocytized and removed in the mucus flow or through the lymphatic system. Pigs also have intravascular macrophages that reside within the vascular lumen and likely contribute to defense against pathogens through uptake of pathogen products and enhancement of immune responses (Ohgami et al. 1989).

In healthy pigs the normal ratio between the cellular elements in the bronchoalveolar mucus is 70–90% alveolar macrophages, 5–18% lymphocytes, 4–12% neutrophils, and up to 5% eosinophilic granulocytes (Jolie et al. 2000; Neumann et al. 1985). Inflammation can lead to the recruitment of neutrophils into the alveolus to augment the phagocytic activity of macrophages. Neutrophils are phagocytic and have a potent array of pathogen killing enzymes. The recruitment of neutrophils is a major component of the protective host response to acute bacterial infections (Mizgerd 2002).

If the invading agents are not neutralized by the alveolar macrophages, the activity of the phagocytes is highly accelerated and inflammation or tissue damage can result. Proinflammatory cytokines produced by macrophages play an important role in porcine respiratory disease by coordinating and activating the adaptive immune response, which enables the host to eliminate pathogens (Thanawongnuwech et al. 2004). This adaptive immune response ideally ends in cell-mediated immunity and local and systemic production of specific antibodies.

Immunoglobulins

The production of specific antibodies is crucial in the defense of the respiratory tract. IgA is the predominant antibody in mucus of the conducting airways. Immunoglobulins in the mucus bilayer act primarily to prevent the initial establishment and penetration of pathogens. IgG antibodies, which originate in the blood, are the predominant immunoglobulin in mucus of the lower respiratory tract near the alveoli. Regardless of location, acute inflammation leads to serum transudation and allows circulating antibodies to aid in protecting the respiratory mucosa. IgE antibodies contribute to the immune response against parasites such as lungworms (*Metastrongylus* sp.) and migrating ascarid larvae.

Cell-Mediated immune response

Immunity is divided into a humoral immune response, in which the immunoglobulins play an essential role, and a cell-mediated immune (CMI) response based on antibody-independent components. However, immunity cannot be separated into two distinct components because many mechanisms are interdependent. The CMI response is particularly important in viral infections such as influenza A virus (IAV), porcine reproductive and respiratory syndrome (PRRS), porcine circovirus type 2 (PCV2), and pseudorabies (PRV) (Aujeszky's disease), but is also assumed to play an important role in *Mycoplasma hyopneumoniae* (MHP) infection (Fort et al. 2008; Lowe et al. 2005; Maes 2010; Tsai et al. 2010). Included in this response are interferons that activate antiviral responses in epithelial and other cell types.

Factors that impair or overwhelm respiratory defenses

The previously described respiratory defenses are robust. Respiratory disease in swine typically occurs when adverse environmental and management conditions or primary and opportunistic infectious agents conspire to impair and/or overwhelm these defenses.

Mucociliary apparatus impairment

The mucociliary apparatus is designed to trap, neutralize, and remove particulate material and infectious agents from the respiratory tree. Interference with this vital defense mechanism by adverse environmental

conditions or by primary respiratory pathogens has the potential to allow bacteria to reach the deeper, more vulnerable portions of the lung, leading to the development of bacterial bronchopneumonia.

Mucociliary clearance can be negatively impacted by a variety of environmental influences including temperature, dust, gases, pollutants, and dehydration. Excessive cold leads to increased viscosity of the mucus and the cilia becoming sluggish, resulting in reduced mucous velocity (Giesbrecht 1995). High temperatures in a low humidity environment, especially in an animal that is dehydrated, can lead to diminished hydration of the mucus layer and decreased clearance. Ammonia in concentrations of 50–100 ppm depresses normal mucociliary function (Curtis et al. 1975; Neumann et al. 1987), and epidemiologic studies demonstrate that higher ammonia concentrations are associated with a higher incidence of respiratory disease (Pointon et al. 1985). Dust decreases mucociliary clearance, resulting in increased mortality and an increased severity of lung lesions (Michiels et al. 2015; McClendon et al. 2015).

Several primary respiratory pathogens negatively impact the mucociliary apparatus. IAV, PCV2, PRV, and porcine respiratory coronavirus (PRCV) can all cause necrosis of the airway epithelium, destroying cells that produce and maintain the mucociliary apparatus (Brockmeier et al. 2002). *M. hyopneumoniae* damages the mucociliary apparatus by binding to cilia, causing ciliostasis, clumping and loss of cilia, and loss of airway epithelial cells (Brockmeier et al. 2002). The adverse effects of each of these primary pathogens on the mucociliary apparatus have the potential to increase the incidence and severity of secondary bacterial bronchopneumonia.

Pulmonary macrophages

Innate immunity, including the maintenance of pulmonary macrophage health and function, is an important defense mechanism against respiratory pathogens. Alveolar macrophage activity can be negatively impacted by both environmental influences and primary pathogens. Organic dust extract exposure negatively affects pig macrophage activation and function, potentially enhancing host susceptibility to a variety of respiratory infections (Knetter et al. 2014). PRRSV infection results in destruction and decreased function of pulmonary alveolar macrophages and pulmonary intravascular macrophages (Gómez-Laguna et al. 2013). PRRSV, *M. hyopneumoniae*, and PCV2 all adversely affect macrophage function, and there is abundant clinical evidence that all three are associated with the development of secondary bacterial bronchopneumonia (Brockmeier et al. 2002).

Stress

A variety of stresses, including excessive heat, cold, crowding, mixing, weaning, limit feeding, shipping, noise, restraint, nutritional status (macronutrients and micronutrients), and concurrent infections, can suppress innate and adaptive immune function and have the potential to contribute to the development of respiratory disease.

Overwhelming of respiratory defenses

Outbreaks of respiratory disease may be facilitated by overwhelming the respiratory defenses. For example, *Actinobacillus pleuropneumoniae* may be carried by pigs in their tonsil and upper respiratory tract asymptomatically because a fully functional mucociliary apparatus generally prevents this organism from reaching the alveoli and causing disease. Impairment of the mucociliary apparatus by excessive dust or *M. hyopneumoniae* infection can lead to the development of pleuropneumonia in an index animal (Gottschalk 2012). An outbreak of *A. pleuropneumoniae* may ensue when massive numbers of finely atomized bacteria are aerosolized into the environment of neighboring pigs overwhelming their respiratory defenses (Gottschalk 2012). This process is exacerbated by overcrowding, poor ventilation, and failure to utilize sick pens.

Primary and secondary pathogens in the lung

Pathogens can be categorized as either primary or opportunistic (secondary) pathogens. Although primary respiratory infectious agents can cause serious disease on their own, particularly when introduced to immunologically naïve herds, uncomplicated infections with these agents are more often mild and transient. More serious and economically important chronic respiratory disease results when these primary infections become complicated by concurrent infection with multiple agents, including opportunistic bacterial infections.

Primary respiratory pathogens include a number of viruses and several bacteria, including *Mycoplasma*, while secondary invaders are potential bacterial pathogens that frequently reside in the nasopharynx. Primary bacterial and viral pathogens have virulence factors that allow them to overcome natural defenses in the respiratory tract and to cause disease acting alone. Primary pathogens involved in porcine respiratory disease complex (PRDC) vary tremendously between countries, regions, and farms. The most common viral agents involved with PRDC include PRRSV, classical swine fever virus (CSFV), IAV, PRV, and PCV2 (Brockmeier

et al. 2002; Thacker et al. 2010). *M. hyopneumoniae* and *A. pleuropneumoniae* are the most common primary bacterial pathogens.

The commensal bacterial flora of the respiratory tract may have a favorable competitive effect for the host by outnumbering pathogenic agents, stimulating immunity, and inducing the production of innate defense factors. However, many of the bacteria that colonize the tonsil and nasal cavity of live healthy pigs are considered to be potential or secondary pathogens. Secondary bacterial pathogens readily colonize the tonsil and nasal cavity of healthy pigs and are in position to replicate to a greater extent and infect deeper tissues when adverse environmental conditions or primary pathogens adversely impact the respiratory defenses. Potential secondary bacteria include *Mycoplasma* spp., streptococci, staphylococci, *Escherichia coli*, *Klebsiella*, *Trueperella pyogenes*, *Bordetella bronchiseptica*, *Haemophilus parasuis*, and *Pasteurella multocida* (Amass et al. 1994; Castryck et al. 1990; Ganter et al. 1990; Hansen et al. 2010; Møller and Kilian 1990).

Interaction between infectious agents

PRDC was coined to emphasize the complexity of events leading to the development of pneumonia, including the involvement of viral and bacterial pathogens as well as the environmental, management, and genetic factors (Brockmeier et al. 2002). Four or more infectious agents are commonly identified in cases of PRDC, resulting in complex and potentially synergistic interactions that can increase the severity and duration of respiratory disease and lesions.

Diagnostic laboratory data, which typically represents pigs that died or were euthanized due to illness, provides insight into the most deleterious forms of respiratory disease in swine (Table 21.1). It is commonly recognized in such diagnostic investigations that severe disease is typically polymicrobial, opportunistic bacterial infections enhance the severity of primary disease insults, and opportunistic bacteria are rarely isolated alone, but are recovered in combination with one or more primary pathogens.

Because of the complicated nature of mixed infections, studying their interactions can be challenging, and the pathogenesis of mixed respiratory infections in swine is still somewhat speculative. Some of the known mechanisms by which primary pathogens can diminish respiratory defenses and lead to secondary bacterial infections include damaging the mucociliary apparatus (IAV, PCMV, PRCV, PCV2, PRV, *M. hyopneumoniae*, *B. bronchiseptica*) (Loving et al. 2010; Pol et al. 1997), inducing immunosuppression (PCV2, PRRSV, PRV) (Renukaradhya et al. 2010), altering cytokine responses (*M. hyopneumoniae*, PRRSV, IAV, PCV2) (Thanawongnuwech et al. 2004), or affecting macrophage function (*M. hyopneumoniae*, PRRSV, PCV2) (Chiou et al. 2000).

Table 21.1 Frequency (percent) of common agents of porcine pneumonia.

Agent	Frequency[a] (% of cases)
	1429 (40.8)
PRRS	1362 (38.9)
Pasteurella multocida	576 (16.5)
Mycoplasma hyopneumoniae	513 (14.7)
Streptococcus suis	456 (13.0)
Haemophilus parasuis	267 (7.6)
Actinobacillus suis	188 (5.4)
Trueperella pyogenes	101 (2.9)
Bordetella bronchiseptica	96 (2.7)
Actinobacillus pleuropneumoniae	94 (2.7)
PCV2	87 (2.5)
Salmonella spp.	44 (1.3)
Ascarid migration	37 (1.1)

[a] Cases often have more than one diagnosis; mixed infections are common in outbreaks of respiratory disease.
Data from derived from microbiologic testing and histopathology of 3512 cases of porcine pneumonia submitted to the Iowa State University Veterinary Diagnostic Laboratory in 2016.

Bacteria including *P. multocida*, *Streptococcus suis*, *H. parasuis*, and *B. bronchiseptica* are some of the most common agents isolated from cases of swine pneumonia. Attempts to experimentally induce bronchopneumonia by aerosolizing these organisms into the respiratory tract of healthy pigs rarely result in pulmonary infection (Amass et al. 1994; Reams et al. 1994; Vahle et al. 1995). These agents typically colonize the tonsil and nasal cavity of pigs without causing disease until an insult allows them to replicate to a greater extent and infect deeper into the respiratory tract. Though both *S. suis* and *H. parasuis* can behave as primary pathogens resulting in septicemia and/or polyserositis, when limited to lung involvement, they are generally considered to be opportunistic or secondary causes of bacterial bronchopneumonia.

Respiratory pathology

Respiratory lesions can be categorized into three main disease entities: rhinitis, pneumonia, and pleuritis. For each of these entities, pathognomonic gross lesions (lesions uniquely associated with a specific disease or agent) are uncommon; however, the character of any

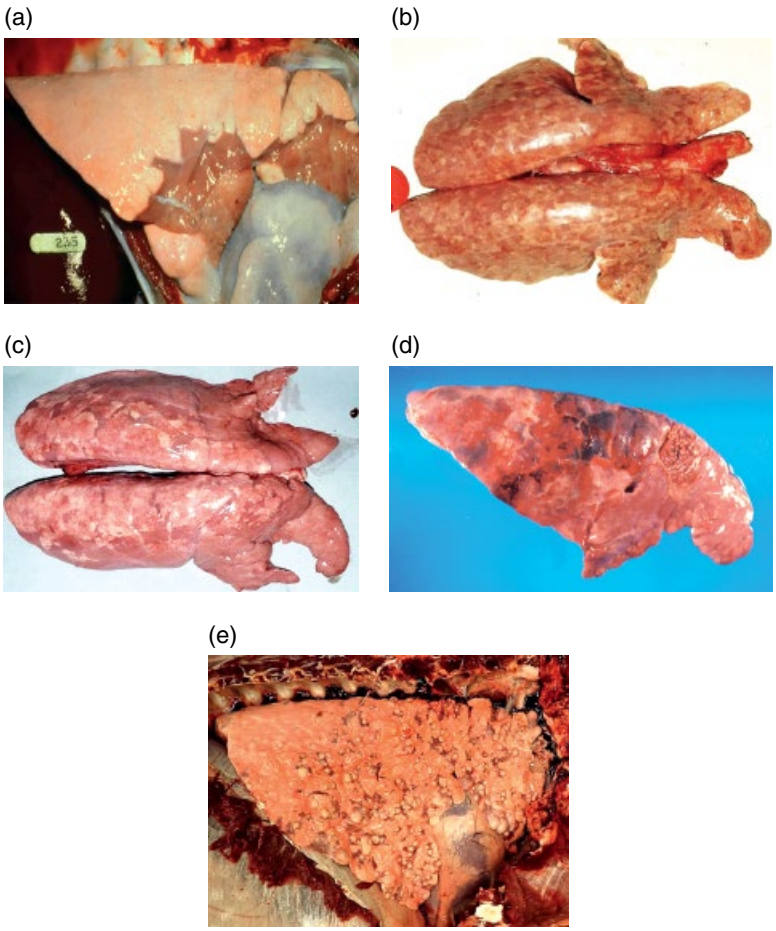

Figure 21.3 Patterns of pneumonia in swine. (a) Suppurative bronchopneumonia with cranioventral consolidation. (b) Diffuse interstitial pneumonia with diffusely tan mottled, non-collapsing lungs. (c) Bronchointerstitial pneumonia with diffusely tan mottled, non-collapsing lungs accompanied by cranioventral consolidation. (d) Hemorrhagic bronchopneumonia and fibrinous pleuritis. (e) Embolic pneumonia with variably sized abscesses in many lobes.

gross lesions that are present can assist in narrowing the list of differentials and aid in the selection of appropriate laboratory tests.

Pneumonia (inflammation of the lungs) can be categorized based on gross morphologic patterns to help predict cause or insult type (e.g. viral, bacterial, parasitic, intoxication, degenerative, or neoplastic) (López 2007). Figure 21.3 illustrates examples of the common grossly identifiable morphologic patterns of pneumonia. Table 21.2 lists some of the common respiratory pathogens associated with these patterns of pneumonia.

Rhinitis and tracheitis

Inflammation of the nasal mucosa is common in young animals. Many agents that affect the ciliated nasal epithelium can also affect the tracheal ciliated epithelium. Sneezing is a common clinical sign of rhinitis, along with serous or purulent discharge (Table 21.3). The cause is often infectious (PRV, IAV, cytomegalovirus, *B. bronchiseptica*, toxigenic strains of *P. multocida*, *Mycoplasma hyorhinis*), but air pollution, such as elevated ammonia and dust, can initiate nasal mucosal inflammation (Hamilton et al. 1998). *P. multocida* can colonize even a slightly damaged mucosa and induce progressive atrophic rhinitis with permanent distortion and shrinkage of turbinates (Figure 21.4). The structural changes in atrophic rhinitis are the result of the elaboration of cytotoxins by *P. multocida* types A and D, which disrupt osteogenesis of the turbinate bone (Foged 1992). *B. bronchiseptica* can also contribute to atrophic rhinitis through colonization of the ciliated epithelium with release of dermonecrotic and other toxins (Horiguchi 2012).

Bronchopneumonia

Bronchopneumonia results from the deposition of infectious agents, typically bacteria, at the level of the terminal bronchioles and/or alveoli, leading to the accumulation of exudate within the lumens of alveoli and small airways. This process results in several characteristic gross features. Because the alveoli and small airways are filled with an exudate, bronchopneumonia has the most firm/solid consistency of any of the broad classes of pneumonia, leading to the use of terms such as consolidation (the process of becoming solid) or hepatization (the consistency of liver) to describe their texture. When

Table 21.2 Classification of pneumonia based on gross morphology.

Type of pneumonia	Distribution of lesions	Texture of lungs	Grossly visible exudate	Potential causes[a]
Suppurative bronchopneumonia	Cranioventral consolidation	Affected portion of lung is firm	Exudate in bronchi of affected lung	Bacteria (Pm, Ss, Hps, Bb, Tpyo) often follow 1^0 insults (*M. hyopneumoniae*, IAV)
Interstitial pneumonia	Diffuse	Diffusely rubbery	Not visible	Viruses (PRRSV, PCV2), Gm– sepsis (Sal, Hps), ascarid migration
Bronchointerstitial pneumonia	Cranioventral consolidation while remaining lung is non-collapsing	Cranioventral lung is firm; caudal lung is rubbery	Exudate in bronchi of cranioventral lung	Combinations of bronchopneumonia and interstitial agents of pneumonia
Hemorrhagic bronchopneumonia and fibrinous pleuritis	Region of hilus or cranioventral	Areas of necrosis or hemorrhage are very firm	Fibrin on pleural surface; exudate in bronchi of affected lung	*A. pleuropneumoniae*, *A. suis*, *Bordetella* (in very young pigs)
Embolic pneumonia	Multifocal and random	Nodular	Abscesses or granulomas	Streptococci, Tpyo, pyogenic bacteria, tuberculosis

[a] Pm, *P. multocida*; Ss, *S. suis*; Hps, *H. parasuis*; Bb, *B. bronchiseptica*; Tpyo, *T. pyogenes*; Sal, *S. choleraesuis*.

the affected lung is sectioned, exudate can typically be expressed from small airways. Because alveolar air has been replaced by exudate, the affected lung will typically sink when placed in water or formalin. The vast majority of true bronchopneumonia cases will have a cranial and ventral pattern of distribution. *A. pleuropneumoniae* is a notable exception; often this bacterial bronchopneumonia is characterized by consolidation and hemorrhage involving the dorsal portions of the caudal lung lobe in the region of the hilus (Gottschalk 2012).

Bronchopneumonia is most commonly caused by bacteria that reside as normal flora in the upper respiratory tract, such as *P. multocida*, *S. suis*, *H. parasuis*, *T. pyogenes*, and *B. bronchiseptica*, all of which are typically secondary invaders that opportunistically colonize the lung as a result of adverse environmental influences or primary pathogens diminishing the respiratory defenses.

Table 21.3 Respiratory disease entities and agents associated with sneezing.

Disease	Agents
Rhinitis	*Bordetella bronchiseptica*, cytomegalovirus, IAV, PRV, hemagglutinating encephalomyelitis virus, dust, ammonia, and others
Progressive and atrophic rhinitis	*B. bronchiseptica* and toxigenic *Pasteurella multocida* (usually type D)

Interstitial pneumonia

Interstitial pneumonia is characterized by an inflammatory process focused on the alveolar walls and adjacent interstitium. Interstitial pneumonias are typically diffuse because they commonly result from blood-borne dissemination of infectious agents including bacteria (e.g. *Salmonella choleraesuis*) and viruses (e.g. PRRSV, PCV2). Diffuse inflammation of the pulmonary interstitium results in several characteristic gross features. Lungs are typically diffusely tan mottled, heavy, and rubbery, do not fully collapse, and may have rib imprints on the pleural surfaces. The interstitium is expanded by inflammation, but alveoli still contain air, so affected lungs will be spongy, will float when placed in formalin, and are palpably less firm than lungs with a bronchopneumonia. Migration of *Ascaris suum* through the lung results in small hemorrhages in many lobes and, if sufficiently severe, will resemble an interstitial pneumonia (Liljegren et al. 2003). Certain intoxications (e.g. paraquat or fumonisin) as well as heart failure or valvular endocarditis can cause gross appearance similar to interstitial pneumonia.

Embolic pneumonia

Embolic pneumonia is characterized by randomly scattered hemorrhagic foci, discolored firm foci, or small abscesses in multiple lung lobes. These lesions result from hematogenous dissemination of bacteria from lesions elsewhere in the body. The presence of an embolic

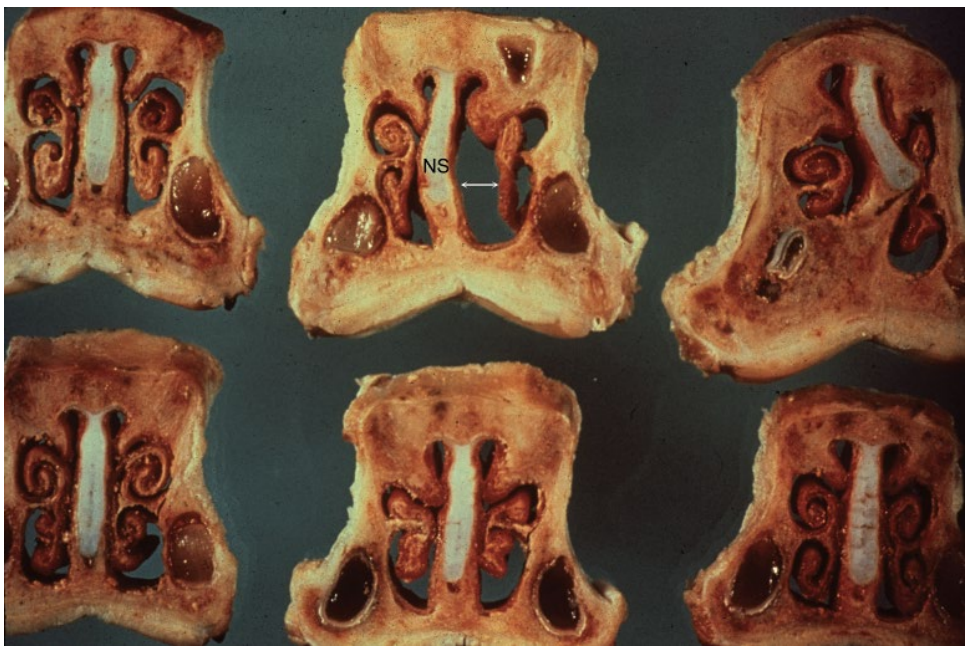

Figure 21.4 Gross lesions of atrophic rhinitis in swine. The nasal septum (NS) is distorted, and turbinates are shrunken and misshapen, resulting in increased airspace (arrow) in the nasal cavity.

pneumonia suggests that there is or was a bacterial septicemia. Acute sepsis is not uncommon with bacteria such as *Actinobacillus suis*, where multifocal hemorrhages and necrosis are suggestive of acute embolic pneumonia. Subacute and chronic lesions are often the result of bacterial infection and emboli arising from another location, and attempts should be made to identify the initial sources of infection, which may include navel infections, skin infections (ear or tail necrosis), abscesses from other sites (liver, subcutaneous, joints), and vegetative valvular endocarditis.

While most of the lung abscesses in pigs are due to pyogenic bacteria (e.g. streptococci, staphylococci, *Trueperella*), mycobacteriosis (*Mycobacterium tuberculosis* complex and *Mycobacterium avium* complex) is a recognized cause of nodular lesions in the lung and thoracic lymph nodes in some parts of the world (Gómez-Laguna et al. 2010; Mohamed et al. 2009).

Healing of pneumonia

The healing, repair, and restitution period, and probability of complete resolution, depends greatly on the agents involved. Uncomplicated viral diseases such as swine influenza can cause bronchiolitis and a mild interstitial pneumonia that can heal in 2–3 weeks with complete resolution (no visible lesions) remaining in the lung. Bronchopneumonia usually takes much longer to heal and may result in lung fibrosis or pleural adhesions to the chest wall or both. In specific-pathogen-free (SPF) pigs inoculated with *M. hyopneumoniae*, lung lesions were healed after 2 months, but pleural adhesions and fissures persisted for more than 3 months (Kobisch et al. 1993; Sørensen et al. 1997). Pattison (1956) identified lesions of pneumonia up to 25 weeks after inoculation with *M. hyopneumoniae*, presumably due to secondary bacterial infection.

Pleuritis

In swine, pleuritis is most commonly associated with hematogenous dissemination of bacteria to serosal surfaces, such as *H. parasuis*, *S. suis*, or *M. hyorhinis* (Kim et al. 2010; Palzer et al. 2015), or an extension from an underlying bacterial bronchopneumonia or abscess. Hematogenous dissemination of bacteria to serosal surfaces can lead to an acute diffuse fibrinous pleuritis, as well as polyserositis. Often, this can be without an accompanying frank pneumonia and may result in acute mortality. If the animal survives, fibrin deposited on serosal surfaces will gradually become organized, leading to the development of chronic fibrous adhesions between the lung and chest wall, which is one of the most frequent lesions observed in swine at slaughter. If fibrous adhesions are extensive to diffuse at slaughter and are accompanied by epicardial/pericardial fibrosis or fibrous adhesions between abdominal viscera, pleuritis/polyserositis likely resulted from hematogenous dissemination of bacteria and implicates agents such as *H. parasuis*, *S. suis*, *and M. hyorhinis*. If the chronic fibrous adhesions are confined to the cranioventral portions of the lung or are associated with abscesses or underlying sequestered or encapsulated foci of necrosis, these chronic lung lesions are likely secondary to a prior bronchopneumonia. Enoe et al. (2002) demonstrated that herds seropositive for *A. pleuropneumoniae* serotype 2 and *M. hyopneumoniae* had chronic pleuritis and pneumonia in 51 and 29% of the pigs at slaughter, respectively.

Control

PRDC results from a combination of primary and opportunistic infectious agents, often facilitated by adverse environmental and management conditions. The primary principles for herd-level control of respiratory diseases are to (1) eliminate or reduce pathogen load (diminish the infection pressure), (2) minimize negative influences on the pig's respiratory defenses, and (3) maximize the pigs' resistance. Issues to consider to accomplish these goals include (1) the environment; (2) pig flow, age segregation, and commingling; (3) biosecurity; (4) pathogen elimination; and (5) vaccination.

Environment

Dust and gases inside swine buildings can contribute to the development of respiratory disease by negatively impacting the respiratory defenses. Dust is made up primarily of feed particles, but dried fecal material, containing bacteria and bacterial toxins such as lipopolysaccharide (LPS), also contributes, along with hog dander, molds, pollen, insect parts, mineral ash, and bedding material in certain housing systems. Ammonia is released by bacterial action on urine and feces. Studies have documented that the level of air contaminants, including dust, ammonia, and microbes, correlated with pneumonia and pleuritis in swine (Donham 1991; Michiels et al. 2015).

Since dust is made up largely of feed particles, liquid feeding has the potential to reduce dust during handling and feeding. Removal of particulates by electrostatic particle ionization has been shown to reduce the quantity of airborne infectious agents, significantly improve average daily gain, and decrease mortality (Alonso et al. 2016; Rademacher et al. 2012). Good ventilation and robust cleaning practices can improve indoor air quality by reducing exposure to air pollutants and respiratory pathogens (McClendon et al. 2015). As expected, low ventilation rates are negatively correlated with the concentration of indoor gases, while gaseous contaminants decrease as

the ventilation rates increase (Kim and Ko 2007). Dust levels in excess of 3.7 mg m^{-3} for pigs are reported to have a negative health impact on both humans and pigs in swine production facilities (Donham et al. 2002; Schenker et al. 1998). Maximal safe concentrations of airborne pollutants have been proposed on the basis of dose–response correlation to swine and human health problems: dust 2.4 mg/m^3, ammonia 7 ppm, LPS (endotoxin) 0.08 mg/m^3, total microbes 105 cfu/m^3, and carbon dioxide 1540 ppm (Donham 1991).

Airflow and climate

The goal of good ventilation is to achieve an effective compromise between removal of airborne pollutants and pathogens without inducing stress caused by drafts and chilling. Cold drafts and wide temperature differentials stress the immune system, increasing susceptibility to disease. When weaned pigs were exposed to cold drafts, their immune response was significantly reduced (Scheepens et al. 1988). Prolonged cold stress in suckling piglets experimentally infected with *P. multocida* resulted in lowered levels of serum IgG, lowered phagocytic activity of the polymorphonuclear granulocytes, and delayed local cellular reaction in the lungs of some of the piglets compared with controls (Rafai et al. 1987).

A higher incidence of pneumonia occurs in pigs during cold seasons than summer months, indicating that climatic factors can influence respiratory disease (Agostini et al. 2014; Bille et al. 1975; Maes et al. 2001a). Season of the year can also influence the prevalence of specific primary pathogens. A low minimum outdoor temperature was positively associated with the probability of being *M. hyopneumoniae* positive at the piglet level (Segalés et al. 2012; Vangroenweghe et al. 2015).

Management

Management practices can influence the development of respiratory disease by impacting stress levels, pathogen exposure and dose, and the transmission of primary respiratory pathogens. Identification of potential environmental or management problems may by themselves control the transmission or susceptibility to disease. Problems with overcrowding, ventilation, or temperature control need to be addressed because they cause stress or damage the respiratory tract. Filling barns with pigs from a single source helps eliminate the introduction of new pathogens that often occurs when pigs from different sources are mixed. Optimally, herd management practices should be implemented that decrease the transmission of pathogens. Practices such as multisite production (separating pigs by stage of production), all-in/all-out production (moving pigs in and out of a building as a group with disinfection between groups), isolation and acclimatization of new breeding stock (isolation to avoid bringing new diseases in and acclimatization to expose animals to agents already on the farm), segregated early weaning with or without the addition of medication (diminish transfer of agents from dam to offspring), and basics in biosecurity have helped control infectious disease outbreaks and led to the establishment of higher health herds. Management practices that keep a herd relatively free from pathogens do carry an inherent risk. Lack of adaptive immunity makes these animals more vulnerable to the introduction of new diseases.

Management factors including increased herd size, increased stocking density, and farrow-to-finish operations have been associated with an increased risk of lung lesions at slaughter, while implementing an all-in-all-out system has been associated with a decreased risk of lung lesions at slaughter (Cleveland-Nielsen et al. 2002; Enoe et al. 2002; Meyns et al. 2011; Stärk et al. 1998).

Control of primary respiratory pathogens

Respiratory disease in pigs is a complex multifactorial disease associated with respiratory pathogens that are often found in combination in pneumonic lungs (Palzer et al. 2008). Methods used to reduce or eliminate primary respiratory pathogens vary widely and are covered in individual pathogen chapters. The spread of respiratory diseases from herd to herd involves two potentially distinct mechanisms. First, respiratory pathogens may be disseminated through infectious contacts (purchase of pigs, incoming and outgoing vehicles, birds, rodents, persons, flies, semen, etc.) (Schurrer et al. 2004; Swenson et al. 1994). Second, airborne pathogens can spread over long distances, resulting in rapid and widespread exposure among individual pigs and between farms.

Airborne transmission of respiratory diseases between herds

Respiratory pathogens in swine that can be transmitted over distances up to several kilometers include *M. hyopneumoniae* (Dee et al. 2010b; Goodwin 1985; Stark et al. 1992), PRCV (Henningsen et al. 1988), foot-and-mouth disease virus (Gloster et al. 2003), PRRS (Dee et al. 2010; Mortensen et al. 2002), and PRV (Mortensen et al. 1990). Airborne transmission between small pig units at close range can be experimentally induced with PRRSV, *A. pleuropneumoniae*, and *B. bronchiseptica* (Brockmeier and Lager 2002; Kristensen et al. 2004a,b; Torremorell et al. 1997). The typical pattern of simultaneous influenza outbreaks in many herds is highly suggestive of the airborne transmission of this virus (Madec et al. 1982). Factors affecting the risk of a

herd contracting an airborne infection are increasing herd size (Anderson et al. 1990; Flori et al. 1995; Mortensen et al. 1990), short distances between herds and large-sized neighboring herds (Flori et al. 1995; Stark et al. 1992), high regional pig density (Stark et al. 1992), and herds infected with *A. pleuropneumoniae* (Anderson et al. 1990).

Viruses can be labile and susceptible to varied environmental conditions (Jacobs et al. 2010; Van Alstine et al. 1993). However, airborne spread of disease between herds may be facilitated by several meteorological factors – most significantly the direction and velocity of the prevailing winds. Factors such as cloud cover, turbulence, and topography are also important. Overcast skies, night (when the turbulence is often low), and high relative humidity facilitate airborne transmission (Gloster et al. 1981).

Long-distance aerosol transmission of primary respiratory pathogens may render routine biosecurity measures ineffective. However, filtering incoming air has the potential to diminish this method of transmission. High-efficiency particulate air (HEPA) filtration has been shown to reduce or prevent long-distance transmission. Though airborne pathogens should be able to pass through HEPA filters, the particulates on which they are carried are removed by HEPA filtration, eliminating long-distance aerosol transmission (Dee et al. 2010).

Transmission of infection between age groups

Although most large swine production facilities use all-in/all-out and multisite systems, farrow-to-finish operations still exist. Commingling age groups, continuous flow of animals through the system, or even holding a few animals over between groups can lead to a steady transmission of primary respiratory pathogens from older to younger pigs. Replication of respiratory pathogens may concentrate in the facilities for growing pigs, which act as "pathogen generators" in the herd. From here the breeding animals can be periodically infected.

Commingling and new introductions to a herd

The mixing of two pig populations carrying different pathogens results in a sudden rise in infectious disease pressure, jeopardizing the established herd balance between infection and immunity. The risk of a herd contracting respiratory problems increases with the number of animal groups introduced and the number of different sources (Agostini et al. 2014; Castryck et al. 1990; Jorsal and Thomsen 1988). Documenting a herd's health status regarding respiratory pathogens, in particular the presence or absence of PRRSV, *A. pleuropneumoniae*, and *M. hyopneumoniae*, and assuring acquisition of pigs of a similar status can help prevent outbreaks of respiratory disease. Establishment of quarantine facilities for new breeding animals may help reduce pathogen exposure by identifying carrier or diseased animals prior to actual entry into the herd. Biosecurity is essential to prevent unwanted respiratory pathogens from entering the facilities by other routes.

Biosecurity

Biosecurity is paramount to sustaining healthy pigs (Amass 2005a,b). Strict hygiene and disinfection controls over vehicles, equipment, and personnel entering the farm will help reduce the introduction of pathogens and minimize transmission between herds. Barn workers should understand that some bacterial and viral diseases may spread from humans with respiratory illnesses to healthy pigs (Keenliside et al. 2010; Nielsen and Frederiksen 1990). Breeding stock should be quarantined, tested, and treated or vaccinated appropriately for respiratory pathogens prior to introduction to the herd.

Other factors that are important in maintaining a clean herd include personnel training to identify the earliest signs of respiratory disease, proper nutrition, reduction of nonrespiratory pathogens, separating pigs with solid barriers between different age groups if housed in the same airspace, maintaining appropriate stocking density to avoid overcrowding, maintaining proper temperature and airflow in the barn, minimizing ammonia and dust in the air, and ensuring appropriate sanitation between groups of pigs.

Pathogen elimination

Different techniques are used to eliminate specific diseases and can be found under specific disease sections. In general, methods include depopulation/repopulation or modified depopulation techniques; segregated early weaning; strict age segregation, especially with multisite separation of ages; medicated early weaning; test with removal of sick/infected pigs; and strategic vaccination and medication.

Vaccination

Studies have demonstrated that vaccination against a variety of primary respiratory pathogens, including *M. hyopneumoniae*, PRRSV, PCV2, and IAV, alone or in combination, can decrease the incidence and severity of gross and microscopic lung lesions, increase average daily gain, decrease tissue pathogen load, reduce mortality rate, and reduce time to market (Bourry et al. 2015; Fachinger et al. 2008; Jeong et al. 2016; Vincent et al. 2010). Harnessing the pigs' adaptive immune response to

enhance host defenses against these agents can diminish the negative impact of these organisms on respiratory defenses and decrease the incidence and severity of PRDC. Conversely, vaccination induces stress, which can be detrimental to the pig. A thorough understanding of the primary pathogens that are involved in each herd, when lactogenic immunity has waned sufficiently to allow for an active immune response, the time during which these pathogens impact the population, and the efficacy of various vaccines are vital in determining the most effective way to utilize vaccination to enhance pig health.

Diagnosis and monitoring of respiratory disease

The purpose of diagnosing and monitoring respiratory diseases is to identify clinical and subclinical infections that can affect production. Farm inspections, routine slaughter checks, serosurveys, and postmortem examinations of dead or euthanized animals are often the basis for diagnosing and estimating the severity of respiratory disease. A haphazard approach to diagnostics is typically inefficient and ineffective. Diagnostics should be undertaken with clear objectives, and a testing strategy developed to accomplish these goals.

If addressing underlying environment and management issues does not successfully bring respiratory disease under control, identifying the primary pathogens that are involved can assist in developing targeted control strategies. Since there is great overlap in clinical signs and pathologic lesions in PRDC, diagnosing the causes of respiratory disease is based on herd history, clinical observations, necropsies, gross and microscopic lesions, and laboratory testing (Andrews et al. 1986).

Monitoring of respiratory disease

Once the primary underlying agents have been identified and an intervention strategy devised (see individual disease sections), a monitoring plan should be implemented to measure the impact. This can be challenging as most systems are plagued by a high degree of normal variation, including seasonal variation. Statistical analysis, charting performance trends, and multiple replications are often necessary to properly determine the impact of an intervention strategy.

Slaughter checks of market weight pigs can identify chronic lung lesions or respiratory diseases that are active in the late stages of production. Labor concerns, including the fast line speed of modern slaughter facilities, have made slaughter inspections less practical. Cross-sectional and longitudinal serology and, sometimes, nasal swabs have increasingly replaced slaughter checks to determine the incidence, prevalence, and location of specific pathogens on farms (Andreasen et al. 2000, 2001; Chiers et al. 2002; Maes et al. 2001b). Serosurveys may be more effective than slaughter checks to detect subclinical infections that may affect some production parameters (Regula et al. 2000). Oral fluids (saliva and mucosal transudate) obtained from cotton ropes suspended in pens has been successfully used to detect agents and antibodies to some respiratory pathogens (Kittawornrat et al. 2010; Prickett et al. 2008; Strait et al. 2010). These minimally invasive techniques may be easy and efficient ways to monitor several respiratory diseases.

Slaughter checks: Examining the snout for atrophic rhinitis

Slaughter checks for atrophic rhinitis are usually performed by examining a transverse section of the snout (see Figures 21.1 and 21.4). Optimal results are obtained if the cut is placed between premolars 1 and 2 (Martineau-Doizé et al. 1990). Several methods of scoring atrophic rhinitis have been used (Bäckström et al. 1985; Straw et al. 1983). These methods are based on subjective and visual assessment of structures. Results from different slaughter checks should be compared with caution, as demonstrated by D'Allaire et al. (1988). Comparisons should be performed by the same experienced observer using the same scoring system. Morphometric techniques to quantify the degree of atrophic rhinitis have been developed (Gatlin et al. 1996). These yielded highly reproducible results but may be less practical for field use.

Slaughter checks: Examining thoracic viscera (plucks)

The progression and regression of pneumonia in growing pigs is highly dependent on the type and severity of pneumonia (Morrison et al. 1985; Noyes et al. 1988; Wallgren et al. 1994). Slaughter examinations of the respiratory tract may not detect subclinical diseases or diseases affecting young pigs that heal without scarring (Regula et al. 2000). Careful slaughter checks of thoracic viscera cannot normally be performed at the slaughter line. The material needs to be transferred to an appropriate location for thorough visual examination and palpation.

Slaughter checks supply useful information on the prevalence and severity of chronic lung lesions in a group, and the pattern of lesions provides insight into presumed underlying causes. Chronic consolidation and/or pleuritis of the cranioventral lung is presumed to represent enzootic pneumonia associated with *M. hyopneumoniae* infection and a secondary bacterial bronchopneumonia (Garcia-Morante et al. 2016). Fibrous

pleural adhesions in the dorsocaudal lung correlate with herd *A. pleuropneumoniae* seropositivity (Merialdi et al. 2012). Diffuse pleural adhesions identified in conjunction with epicardial/pericardial adhesions are indicative of a prior bacterial polyserositis due to agents such as *H. parasuis*, *S. suis*, and *M. hyorhinis*.

The percentage of pneumonia is usually based on the percentage of lung surface that is abnormally firm and discolored or has fibrous adhesions (Garcia-Morante et al. 2016) and can be given a numeric score (Christensen et al. 1999; Madec et al. 1982) or sketched onto a standard diagram of the lung followed by image analysis of the diagrams to determine the overall lung score. Some slaughter-check diagrams include more detailed information about the lung, such as the type of pneumonia, pleuritis, and adhesions, plus evaluations of the liver and heart (Christensen et al. 1999). Visual-only evaluations of digital images of lungs obtained at slaughter may be an effective alternative to drawings (Baysinger et al. 2010). In most situations slaughter checks should be performed on at least 30 pigs (with similar or known age if possible) to get a reliable picture of the herd problem (Straw et al. 1989). Chronic lung and pleural lesions present at the time of slaughter can provide valuable information regarding the health conditions on the farm and the effectiveness of intervention strategies.

Urinary System

Richard Drolet

Anatomy

The kidneys of swine are bean shaped, smooth, brown, elongated, flattened dorsoventrally, and at least twice as long as wide. At the middle of the medial border of each kidney is an indentation, the hilus, where the vessels, nerves, and ureter communicate with the organ. The kidneys are located ventral to the psoas muscles at the level of the first four lumbar vertebrae. Contrary to most species, the left kidney of pigs usually is situated cranially to the right. In the adult, the ratio of the combined weight of the kidneys to that of the body is about 0.50–0.66% (Sisson 1975).

The kidneys are enveloped by a rather thin fibrous capsule that can be easily peeled off. In a kidney section, the relative surface occupied by the cortex and the medulla is readily apparent (Figure 22.1). Pigs have multipyramidal or multilobar kidneys but without the external lobation typically found in the bovine species. The medullary portion of each lobe is called a pyramid; some are simple, whereas others are compound, that is, formed by the fusion of two or more primitively separate pyramids. The pale apical portion of a pyramid, called the papilla, projects into the renal pelvis or its ramifications; the latter are referred to as calyces. Papillae of simple pyramids are generally narrow and conical, whereas those of compound pyramids, often located in the area of the renal poles, are broad and flattened. There are 8–12 papillae per kidney. Collecting ducts of the kidneys have their openings at the tips of the papillae.

The ureters, which are continuous with the renal pelvis, leave the kidneys in a sharp caudal curve and reach the dorsolateral sides of the bladder neck area. In newborn piglets, the length of the portion of the ureter running beneath the bladder mucosa is about 5 mm, whereas it reaches a mean length of about 35 mm in the adult (Carr et al. 1990). The intravesical portion of the ureters acts as a valve that prevents vesicoureteral reflux of urine.

The urinary bladder of the pig is large and has a long neck. When full, it lies well down into the abdominal cavity. The bladder is supported by one median (ventrally located) and two lateral ligaments. The urethra of the adult female is about 7–8 cm long, and its external ostium is located ventrally, at the junction of the vagina and vestibule; beneath it is a small depression, the suburethral diverticulum. In the male, a urethral recess is present near the ischial arch in the area where the ducts of the bulbourethral glands empty into the urethra (Garret 1987). These fold-like structures represent a significant barrier to urethral catheterization. The urethra finally opens into a slit-like structure at the tip of the penis.

Physiology

Histophysiology

The kidney is involved in many vital functions: the elimination of waste products from the body, the conservation of water, and the regulation of the acid–base balance and electrolyte composition. In addition, it has an endocrine function, producing a variety of hormones including erythropoietin, renin, prostaglandins, and vitamin D_3. The function units of the kidney are called nephrons, each consisting of a renal corpuscle, proximal tubule, loop of Henle, and distal tubule, which form the bulk of the renal parenchyma. The renal corpuscle comprises the glomerulus, a tuft of arterial capillaries, and Bowman's capsule. The kidney of a pig contains well over 1 million nephrons. Newborn piglets have immature kidneys, and nephrogenesis continues during the first 3 months of life (Friis 1980).

The first mechanism used to accomplish renal function is glomerular filtration, where the volume of plasma filtered depends on the renal perfusion, blood pressure, and integrity of the glomerulus itself. The glomerular filtrate is an ultrafiltrate of blood plasma that contains

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

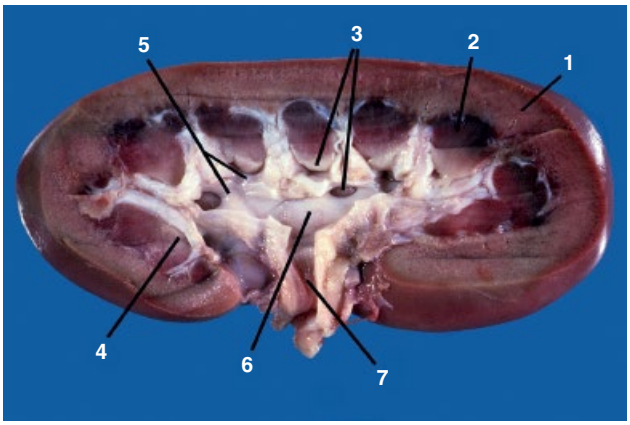

Figure 22.1 Section of the kidney from a feeder pig. (1) Cortex, (2) medulla, (3) papillae, (4) compound papilla, (5) calyces, (6) pelvis, and (7) ureter.

water, glucose, salts, ions, amino acids, and small amounts of protein of low molecular weight. The tubular components of the nephron modify glomerular filtrate as homeostasis processes dictate. The proximal tubules are lined by well-developed and metabolically active epithelial cells that can actively reabsorb 100% of the filtered glucose and many other substances, such as water, sodium, amino acids, albumin, and bicarbonate, in significant amounts (Banks 1993). Pigs reabsorb very few urates from glomerular filtrate compared with most other species. Tubular secretion complements glomerular filtration in clearance of certain waste products. The filtrate finally enters the collecting ducts, where it may be further concentrated. Urine expelled into the pelvis normally is not modified as it travels through the rest of the lower urinary tract, which is lined with transitional epithelium (urothelium).

Urine

The volume of urine produced daily depends on several variables, including diet, fluid intake, ambient temperature and humidity, and the size and weight of the animal. Accurate data on the normal ranges of the amount of urine excreted per day in pigs are limited. Salmon-Legagneur et al. (1973) reported a mean urinary output of 9 L and 5.3 L/day in gestating and lactating sows, respectively. Other factors, such as the water distribution system used, may also affect the production of urine if they influence drinking behavior.

The mean specific gravity of urine in adult swine is about 1.020 (plasma >1.010), one of the lowest found in domestic animals (Ruckebusch et al. 1991). Young animals have even lower values. Specific gravity of urine is usually inversely related to urine volume. Urinary pH is usually between 5.5 and 7.5. It is influenced by the metabolism and the composition of the feed; starvation or a high protein intake lowers urinary pH. Urinary infection with urea-splitting bacteria (e.g. *Actinobaculum suis*) may result in a significant alkalinization of urine.

A small amount of protein passes through the glomeruli and is usually reabsorbed by proximal tubules. The presence of proteinuria is of diagnostic significance but should be interpreted in conjunction with the specific gravity. Significant proteinuria occurs with glomerulonephritis (GN) (increased permeability to protein), tubular necrosis (decreased reabsorption of protein), pyelonephritis (inflammation), and lower urinary tract inflammation. The presence of protein in the urine is, however, not always pathologic because transient physiological or functional proteinuria also occurs in some instances. Proteinuria is expected in the first few days of life because glomeruli are permeable to colostral proteins found in high levels in the blood. Transient proteinuria can occur following excessive physical activity (e.g. transport) or intense stress or when excessive amounts of protein are ingested.

The color of urine is usually yellow to amber depending on the concentration of urochromes. Abnormal coloration of urine is observed with some underlying urinary tract diseases. Urine sediment examination can be informative, particularly for inflammatory diseases.

Impaired renal function

In some pathological situations, renal function is impaired so much that renal failure ensues. Renal failure may have a prerenal (e.g. any condition that reduces renal blood flow), postrenal (e.g. obstructive uropathy), or primary renal origin (e.g. extensive renal parenchymal disease).

Renal failure can cause metabolic acidosis, electrolyte imbalances, and intravascular accumulations of various metabolic waste products, including blood urea nitrogen (BUN) and creatinine. Determination of both BUN and serum creatinine concentration may be used to assess the renal function. The serum creatinine concentration is a more accurate index of the glomerular filtration rate than the BUN because it is less dependent on nonrenal factors. Concentrations of BUN may rise in animals with high dietary protein intake or in any conditions resulting in increased protein catabolism. Friendship et al. (1984) reported normal range values for BUN and serum creatinine in weaned and feeder pigs, gilts, and sows. In sows, for example, the mean BUN concentration has been reported as 5.3 mmol/L (n = 102) (Friendship et al. 1984) and 5.0 mmol/L (n = 120) (McLaughlin and McLaughlin 1987), whereas the mean serum creatinine concentrations reported in the same two studies are 160 and 186 µmol/L, respectively.

Developmental anomalies

Anomalies of development occur in all body systems, and the urinary tract is no exception. These anomalies may involve the kidneys as well as the lower urinary tract. Many of these conditions in swine are relatively rare and of little economic significance. Few of these malformations in pigs are common, and only rarely are they associated with clinical signs. In some instances, developmental anomalies have been shown to be inherited.

Malformations of the kidneys

Most of the well-characterized renal anomalies of development occurring in domestic animals have also been documented in pigs. Depressions of the external surface and partial persistence of fetal lobation of the kidneys have been reported to be relatively common in Norwegian slaughtered pigs (Jansen and Nordstoga 1992). Unilateral renal agenesis (aplasia) occurs sporadically in pigs and is relatively common compared with other domestic animals (von Höfliger 1971). Bilateral renal agenesis is incompatible with life and would be encountered in the fetus or stillborn piglet. Cases of bilateral renal agenesis and renal hypoplasia have been described in pigs and linked to a genetic cause (Cordes and Dodd 1965; Mason and Cooper 1985). Malposition of the kidneys (renal ectopia) is not rare and is often characterized by caudal displacement of one kidney, often the left, to the pelvic area (Sisson 1975). Duplication of one kidney has been observed on a number of occasions in pigs (Nieberle and Cohrs 1967). Horseshoe kidney, rarely observed in swine, is a condition in which the kidneys have fused at either the cranial or the caudal poles, resulting in a horseshoe-shaped organ (Nieberle and Cohrs 1967). Renal dysplasia, a disorganized development of renal parenchyma due to anomalous differentiation, also is relatively rare. Some cases have been attributed to hypovitaminosis A (Cianciolo and Mohr 2016).

Congenital renal cysts are frequent in various species but are more common in swine (Figure 22.2). The presence of one or a few cysts in the kidney is a common incidental finding at abattoirs, and the affected organs are generally condemned. The cystic cavities are filled with serous fluid and vary from a few millimeters in diameter to larger than the organ itself. They are commonly found in the cortex and often protrude from the surface of the organ, where they may appear translucent or opaque depending on the amount of fibrous connective tissue present in the cyst wall. Histologically, these cysts are lined with a layer of tubular epithelial cells surrounded by a fibrous capsule.

Polycystic kidney disease, another form of congenital cysts, occurs far less frequently. It is characterized by the presence of numerous smaller cysts that occupy a large portion of the renal parenchyma; cystic bile ducts may be found in the liver as well. Affected piglets usually die from renal failure during the neonatal period (Webster and Summers 1978). The distinction between simple renal cysts and polycystic kidney disease is not always clear. Wells et al. (1980) reported a prevalence of renal cysts of nearly 50% from a single herd that experienced an abnormally high rate of kidney condemnations at the abattoir where affected kidneys had extremes in variation of numbers and sizes of cysts. Further investigation showed that affected animals were the progeny of a Landrace boar and disease was found to be inherited as an autosomal dominant trait, the number of cysts being determined by polygenic inheritance (Wijeratne and Wells 1980).

Figure 22.2 Congenital renal cyst in a slaughtered sow.

Malformations of the lower urinary tract

Developmental anomalies of the lower urinary tract appear to be rare in swine. Cases of duplication of the ureter (Benko 1969), persistent urachus (Weaver 1966), and congenital ureteral occlusion (Nieberle and Cohrs 1967) have been reported in pigs. A case of congenital urethral stenosis has also been described recently (Pouleur-Larrat et al. 2014).

Circulatory disturbances

Circulatory disturbances may occur in the urinary tract as well as in any other tissues of the body. Some of these disturbances of the circulation produce lesions that may be of diagnostic significance on postmortem inspection.

Hemorrhage

Hemorrhages, in the form of widespread petechiae or less commonly ecchymoses, may be found in any part of the kidney or lower urinary tract in various septicemic

Figure 22.3 Widespread petechiae in the kidney of a piglet with *Streptococcus suis* septicemia.

illnesses (Figure 22.3). Bacterial infections commonly associated with these lesions include septicemia due to *Salmonella*, streptococci, *Erysipelothrix rhusiopathiae*, and *Actinobacillus* spp. These lesions are also seen in acute viral diseases such as classical swine fever, African swine fever, or systemic cytomegalovirus infection (Orr et al. 1988). Petechiation of the renal cortex is also observed occasionally in acute GN, in some acute intoxications, and in electrocuted animals. Neonates normally have dilated, congested glomerular tufts within an otherwise normal renal cortex that erroneously can be interpreted as petechiae.

Larger intrarenal or subcapsular hemorrhages are usually caused by trauma, necrosis, or clotting defect, including poisoning by anticoagulant rodenticides. They may also occur in some cases of disseminated intravascular coagulation. Widespread hemorrhages in almost all body systems, including the urinary tract, are a striking pathologic feature in suckling piglets with isoimmune thrombocytopenic purpura due to passively transferred antiplatelet antibody from the dam's colostrum (Andersen and Nielsen 1973; Dimmock et al. 1982). In this relatively common disease, affected piglets appear normal at birth but eventually die between 1 and 3 weeks of age from hemorrhagic diathesis.

Infarction

Renal infarcts, infrequently found in the kidneys of swine, are localized areas of ischemic coagulative necrosis produced by the occlusion of the renal artery or one of its tributaries. The localization and size of the infarct reflect the area vascularized normally by the involved blood vessel. The occlusion is usually due to thrombosis or aseptic emboli (the consequences of septic emboli are discussed under embolic nephritis). In some instances, infarction of the renal parenchyma is primarily associated with renal vasculitis (Jansen and Nordstoga 1992), including polyarteritis nodosa (Nieberle and Cohrs 1967). Bilateral renal cortical necrosis is seen on rare occasions in pigs and is considered to be the result of an infarct of a major part of the cortex of both kidneys (Häni and Indermühle 1980). The reaction is characterized by disseminated intravascular coagulation with a marked tropism for the small arterial blood vessels of the renal cortex. The etiopathogenesis of these lesions remains unclear, but the condition has been associated with septicemia, endotoxemia, and hemorrhagic shock due to bleeding gastric ulcers.

Glomerular diseases

Renal diseases that involve primarily the glomeruli include amyloidosis and GN. Renal amyloidosis has been rarely reported in pigs (Cianciolo and Mohr 2016; Jakob 1971). GN represents an important category of renal diseases in animals, and in recent years this condition has been recognized with increasing frequency in swine.

Glomerulonephritis

Inflammatory changes in renal glomeruli may take place via a number of mechanisms, including immunologic, thrombotic, toxic, and as yet uncharacterized mechanisms. Most cases of GN in humans and animals are thought to be immune mediated. The main types of glomerular immunologic injury recognized are trapping of circulating antigen–antibody complexes, *in situ* immune complex formation, activation of the alternate pathway of complement, and cell-mediated processes (Spargo and Taylor 1988). Because immunoglobulins and complement components are frequently found in inflamed glomeruli, antibody-mediated injury has received the most attention. In veterinary medicine, the various morphologic types of immune-mediated GN are commonly classified as membranous, proliferative, mesangioproliferative, membranoproliferative, and exudative.

Although the pathogenesis of GN is now reasonably well understood, knowledge of the etiology or triggering event is still unknown in most cases (idiopathic immune-mediated GN). Theoretically GN may be triggered by a variety of factors including drugs, chemicals, food allergens, endogenous antigens, and infectious agents (Drolet et al. 1999).

GN is not often diagnosed in swine but does occur occasionally as a sporadic event (Bourgault and Drolet 1995; Cianciolo and Mohr 2016; Nieberle and Cohrs 1967; Slauson and Lewis 1979). It has also been reported as a sequel to chronic infectious diseases such as classical swine fever, African swine fever (Choi and Chae 2003; Hervas et al. 1996; Martin-Fernandez et al. 1991),

systemic cytomegalovirus infection (Yoshikawa et al. 1988), and group A streptococcal abscesses (Morales and Guzman 1976). In these cases, the resulting GN appears to be caused by the presence of glomerular immune complexes in which the antigen is related to the agent responsible for the underlying disease (Slauson and Lewis 1979). Nutritionally induced GN has also been reported, the apparent result of ingestion of a protein-rich by-product (Elling 1979) and ingestion of "smut fungus" contained in the feedstuff (Müller 1977).

An inherited renal disease, classified morphologically as membranoproliferative GN type II, has been described in Yorkshire piglets from Norway (Jansen and Nordstoga 1994). It is caused by an autosomal recessive deficiency of the complement inhibitory protein "factor H" (Hegasy et al. 2002; Jansen et al. 1995). Deficiency of factor H ultimately provokes activation of the alternate pathway of complement, with subsequent massive deposition of complement in renal glomeruli, large intramembranous dense deposits, and mesangial hypercellularity (Jansen et al. 1998).

In many species, generalized or focal GN is also observed in some cases of systemic vasculitis (mainly immune-mediated vasculitis). In pigs, the best example of this certainly is porcine dermatitis and nephropathy syndrome (PDNS). The condition, first described in the United Kingdom in 1993 (Smith et al. 1993; White and Higgins 1993), has been subsequently observed in most parts of the world. The disease affects nursery and growing pigs and, less commonly, breeding animals (Drolet et al. 1999). The prevalence of the syndrome in affected herds is usually less than 1% although higher prevalences have been detected in the United Kingdom and other countries, with case mortality in affected herds ranging from 0.25 to over 20% (Segalés et al. 2005).

Affected animals present a systemic necrotizing vasculitis with marked tropism for the skin and kidneys (Hélie et al. 1995; Smith et al. 1993; Thibault et al. 1998). Vascular lesions in the skin provoke a conspicuous dermatopathy (Figure 22.4). Kidney lesions in acute cases include exudative and occasionally necrotizing GN with or without cellular crescent formation (crescentic GN). Interstitial nephritis and renal vasculitis are also commonly observed. Vascular lesions in other tissues vary considerably in frequency and distribution in individual pigs (Thomson et al. 2002). In some atypical cases, there may be cutaneous lesions without renal lesions and vice versa. An animal with GN without any other vascular lesions elsewhere should probably not be diagnosed as PDNS since other glomerular diseases not related to this syndrome are known to occur in pigs.

In PDNS, the glomerular and systemic vascular damages are thought to be immune mediated, possibly through a type III hypersensitivity reaction, which is characterized by deposition of antigen–antibody aggregates or immune complexes within these sites (Hélie et al. 1995; Sierra et al. 1997; Smith et al. 1993; Thibault et al. 1998; Thomson et al. 2002; Wellenberg et al. 2004). Over the years several bacterial and viral pathogens, including porcine reproductive and respiratory syndrome (PRRS) virus and porcine circovirus type 2 (PCV2), have been incriminated as possible etiologies for PDNS (Opriessnig et al. 2007). Observations from the last decade support an association between PCV2 and PDNS. The precise way by which this virus promotes directly or indirectly the development of PDNS remains unknown at this time. It has been shown that animals with PDNS often have relatively low PCV2 viral loads (Olvera et al. 2004) but very high PCV2 antibody titers (Wellenberg et al. 2004). However, PDNS has been observed recently in a pig challenged with PCV2 during a vaccination trial, and the animal had low IgG titers against PCV2, but the IgM response was not measured (Opriessnig et al. 2017). Other hypotheses on the role of PCVs in triggering PDNS include PCV3 infection and a misdirected excessive immune response toward a decoy epitope called CP (169–180) located in ORF2 of PCV2 (Opriessnig et al. 2017).

Figure 22.4 A white sow affected with PDNS. Note multifocal to coalescent erythematous macules and typical caudal distribution.

Other examples of glomerular disease/lesion in swine have been reported in the literature in recent years (Carrasco et al. 2003; Jansen and Nordstoga 1992; Pace et al. 1998; Shirota et al. 1984, 1995; Tamura et al. 1986; Vezzali et al. 2011; Yoshie 1991).

The clinical significance of GN is highly variable, with a spectrum ranging from a subclinical condition to a fulminating and rapidly fatal disease (Bourgault and Drolet 1995; Shirota et al. 1986). Mortalities are commonly recorded in pigs affected with PDNS (Hélie et al. 1995; Kavanagh 1994; Segalés et al. 1998; Smith et al. 1993; Thomson et al. 2002; White and Higgins 1993). In this latter condition, the survival of the affected pigs depends

on the extent and severity of the vascular lesions in the internal organs, particularly within the kidneys. The hereditary GN of Norwegian Yorkshire pigs appears to be invariably fatal; affected piglets die of renal failure within 11 weeks of birth (Jansen et al. 1995).

Unlike most other domestic animals affected with GN (with the exception of the familial glomerulopathies), pigs appear to be affected at a relatively young age. The condition has been described most commonly in weaned and feeder pigs (1.5–6 months old), occasionally in breeding animals, and rarely in nursing piglets. Clinical signs, when present, may include anorexia, lethargy, unwillingness to move, subcutaneous edema, rapid loss of condition, and death.

GN is rarely recognized clinically because most of the signs are nonspecific, and analysis of urine and blood from an individual is rarely considered of practical value in the herd medicine approach applied in our large units of production. Pigs affected with PDNS are often easier to detect clinically because of the presence of hemorrhagic and necrotizing skin lesions, mainly located on the hind limbs and perineal area (Segalés et al. 2003). Pigs with GN may show concomitant hypoproteinemia, hypoalbuminemia, and persistent proteinuria, which are highly suggestive of a protein-losing glomerulopathy. The urine protein/creatinine ratio may also be increased (Hélie et al. 1995). Proteinuria, hematuria, and pyuria, which are usually compatible with lower urinary tract lesions, may also occur in severe types of GN, namely, in acute exudative GN. Blood of affected animals may also reveal elevated urea and creatinine levels suggestive of renal failure (Drolet et al. 1999; Hélie et al. 1995; Jansen et al. 1995; Thomson et al. 2002; White and Higgins 1993).

The gross lesions of GN will depend largely on the severity of the glomerular lesions and the stage (acute vs. chronic) of the disease process. In acute GN, the kidneys may be slightly to markedly enlarged, pale, and edematous, often with cortical petechiation (Figure 22.5). The most important differential diagnoses to consider for such acutely affected kidneys are bacterial septicemia, acute viremia, and intoxications. With time, the surface of the kidneys may become finely granular, and in the chronic phase of the disease, the organs may appear shrunken and contracted due to progressive cortical fibrosis, which is difficult to distinguish from other chronic renal diseases. Perirenal and subcutaneous edema and serous effusions in body cavities may be observed in some cases of GN, and high prevalence of gastric ulcers has been reported with GN (Bourgault and Drolet 1995; Jansen 1993; Kavanagh 1994; White and Higgins 1993).

Treatment of GN is usually symptomatic since disease is not often diagnosed in live animals under normal farm-raising conditions. Pigs affected with PDNS have been treated with various antimicrobial agents, anti-inflammatory drugs, and multivitamin supplements with no significant effect (Segalés et al. 2003).

Tubular diseases

Renal diseases characterized primarily by degenerative changes of the tubular epithelium of the nephrons may occur under certain circumstances, where the epithelial lining cells of the tubules undergo degeneration, necrosis, and sloughing of the cells into the lumen. Acute tubular necrosis is termed nephrosis, which represents an important cause of acute renal failure in animals. The epithelial cells of the proximal tubules, because of their high metabolic activity, are especially susceptible to damage caused by prolonged ischemia or nephrotoxins, the two main causes of this type of nephropathy.

Ischemic tubular necrosis

Ischemic tubular necrosis is generally the result of a severe and prolonged period of hypotension associated with shock of endotoxic, hypovolemic, cardiogenic, or neurogenic origin (Cianciolo and Mohr 2016). These renal lesions are potentially life threatening, and the clinical signs of the resulting renal failure are often hidden by the marked systemic effects of the primary disease responsible for the state of shock.

Nephrotoxic tubular necrosis

Nephrotoxic tubular necrosis has been documented in domestic animals in association with a wide variety of exogenous natural and synthetic compounds. These toxic substances may affect tubular function and ultimately cause cellular damage by several mechanisms,

including metabolic alterations affecting cellular respiration, interference with the tubular transport system, and damage to specific organelles (Brown and Engelhardt 1987). Plants, mycotoxins, antimicrobial drugs, heavy metals, ethylene glycol, and some other industrial compounds are potential nephrotoxins in swine, covered elsewhere in this book.

Several species of pigweed, particularly redroot pigweed (*Amaranthus retroflexus*), may cause acute renal failure in pigs, clinically characterized by weakness, incoordination, posterior paresis, and death (Osweiler et al. 1969).

Fungi of some species of *Aspergillus* and *Penicillium* produce nephrotoxins that can contaminate grains used as feedstuff. Ochratoxin A and citrinin are the most common nephrotoxic mycotoxins. Monogastric animals, particularly pigs, may develop significant disease when moldy feed containing ochratoxin A is ingested. Acute clinical signs are relatively rare; a subacute to chronic wasting disease is more commonly associated with this poisoning (Osweiler 1996).

Antibiotic-associated nephropathies are well documented in domestic animals. Classes of antibiotics considered potentially nephrotoxic include aminoglycosides, tetracyclines (or their degradation products), and sulfonamides. Predisposing factors associated with the toxicity of these agents include the dosage and the route of administration, the duration of the treatment, the solubility of the products, and the general health status (dehydration, shock, preexisting renal disease) of the animal.

Ethylene glycol, found in high concentration in older antifreeze solutions, is ingested, absorbed from the gastrointestinal tract, enzymatically oxidized in the liver, and successively transformed into several nephrotoxic compounds and finally to oxalate. Poisoning occurs in swine with the ingestion of 4–5 mL of ethylene glycol/kg of body weight (Carson 2006).

Outbreaks of melamine- and cyanuric acid-associated nephrotoxicity have been reported in recent years in animals, mainly dogs and cats, and human infants. In these cases, feedstuffs were adulterated with melamine and its analogues, including cyanuric acid, to falsely elevate their protein concentrations. A syndrome characterized by progressive weight loss, pallor, and high mortality rate due to renal failure has been reported in pigs with this intoxication (Nilubol et al. 2009). Many metallic compounds are nephrotoxic, including inorganic mercury, arsenic, cadmium, lead, thallium, and bismuth. Cases of poisoning with these products are relatively rare in pigs.

Gross renal lesions observed in acute cases of nephrotoxic tubular necrosis are not always conspicuous, but the kidneys may appear slightly swollen, pale, and moist (Figure 22.6). In pigweed (A. retroflexus) poisoning, these renal lesions are often accompanied by a marked perirenal edema that may contain blood and possibly by serous effusions elsewhere in the body (Osweiler et al. 1969). In severe acute tubular necrosis, death from acute renal failure may ensue. Animals that survive the acute phase of the disease either recover or develop progressive fibrosis of the kidneys that may or may not lead to chronic renal failure. This chronic evolution appears relatively common in pigs with ochratoxin A toxicosis (Cook et al. 1986; Krogh 1977; Rutqvist et al. 1978).

Figure 22.6 Pale and swollen kidney associated with acute tubular necrosis in a sow dead of ethylene glycol poisoning. A leaking valve on the water heating system was responsible for the poisoning of several animals.

Acute tubular necrosis is characterized histologically by swelling and necrosis of the lining epithelial cells of the proximal and distal tubules, the presence of granular casts in the tubular lumen, dilated tubules, and mild interstitial edema. Abundant calcium oxalate crystals within tubules are a characteristic finding in ethylene glycol poisoning, whereas round, yellow-brown crystals with radiating striations within tubules and collecting ducts are the hallmark of melamine and analogue poisoning. Subacute or chronic changes are epithelial regeneration and eventually, at least in some cases, interstitial fibrosis accompanied by focal loss of nephrons and a mild interstitial inflammatory infiltrate.

Tubulointerstitial diseases

Tubulointerstitial diseases include a relatively large group of conditions characterized primarily by interstitial inflammation and tubular damage, namely, interstitial nephritis (such as that occurring from leptospirosis), embolic nephritis, and pyelonephritis (one of the most significant urinary tract diseases in swine). Immunologically mediated tubulointerstitial disease as occurs in humans has only rarely been documented in domestic animals.

Interstitial nephritis

Many serovars of *Leptospira*, especially those of the serogroups Pomona and Australis for which pigs act as maintenance hosts, cause reproductive disturbance in swine including infertility, abortion, and birth of weak or dead piglets. The pathogenesis of the disease involves preferential localization and persistence of the organisms at sites physically protected from antibodies, such as in the ocular vitreous humor, the cerebrospinal fluid, the genital tract, and the lumen of the renal proximal tubules (Cianciolo and Mohr 2016). The passage of the leptospires from the bloodstream to the interstitial tissue of the renal parenchyma and finally to the tubular lumen elicits multifocal lesions of interstitial nephritis (Cheville et al. 1980). The severity of the interstitial nephritis varies and ranges from grossly undetectable to extensive lesions, particularly when serovars of the Pomona serogroup are involved. The lesions are randomly distributed and appear as poorly circumscribed whitish foci of various shapes and sizes, becoming confluent in severe cases. Histologically these foci correspond to the infiltration of lymphocytes, plasma cells, and macrophages in the interstitial tissue, along with some degenerative changes of the surrounding nephrons. In chronic cases, interstitial fibrosis occurs. In most cases these lesions are not extensive enough to cause renal failure, so the generally asymptomatic animal may shed the leptospires in urine for a relatively long period of time (Mitchell et al. 1966).

The association between lesions of interstitial nephritis in pigs and the detection of leptospires within these kidneys are highly variable among studies (Baker et al. 1989; Boqvist et al. 2003; Hunter et al. 1987; Jones et al. 1987; McErlean 1973). Factors that may influence these results include the serovar of *Leptospira* spp. involved, the methods of leptospiral detection used, the phase of the infection, and also the prevalence of leptospirosis and of other infectious causes of interstitial nephritis in swine in a given geographical area. For instance, the prevalence of leptospirosis in fattening pigs and sows in southern Vietnam was found to be high (Boqvist et al. 2002, 2003), whereas similar studies conducted in slaughtered pigs in southwestern Quebec have shown a very low prevalence of this infection (Drolet et al. 2002; Ribotta et al. 1999).

Severe multisystemic disease from PCV2 infection can and often does cause lymphohistiocytic to granulomatous lesions involving multiple tissues, including kidney (Segalés and Domingo 2002). The interstitial nephritis is in some cases grossly detectable as patchy pallor or obvious white foci within renal parenchyma (Figure 22.7). Histologic examination of these affected kidneys by Sarli et al. (2008) revealed tubulointerstitial nephritis with lymphocytes, plasma cells, macrophages, and multinucleated giant cells in variable proportions.

Figure 22.7 Interstitial nephritis in a pig naturally infected with porcine circovirus type 2.

Using an *in situ* hybridization technique, they also found that PCV2 nucleic acid detection was in general more frequent in tubular epithelial cells than in interstitial inflammatory cells. Renal lesions characterized by widespread necrosis and PCV2 infection of renal tubular epithelium with accompanying interstitial edema and hemorrhage (turkey-egg kidneys) have also been described (Imai et al. 2006).

Multifocal lesions of interstitial nephritis also occur in swine with other bacterial (see section "Embolic Nephritis") and viral hematogenous infections. Although lesions may not impair renal function, they are of diagnostic significance because they are suggestive of a systemic disease. Lesions of interstitial nephritis caused by systemic viral infections are often visible only by microscopy and are characterized by the presence of foci of nonsuppurative inflammation. Viral infections that may produce these lesions include cytomegalovirus (Kelly 1967), adenovirus (Nietfeld and Leslie-Steen 1993; Shadduck et al. 1967), PRRS virus, and possibly others. Multifocal lesions have been reproduced experimentally in PRRS virus-infected piglets examined 2–3 weeks post inoculation (Cooper et al. 1997; Rossow et al. 1995) and are also frequently found in naturally infected pigs.

Gross lesions of multifocal interstitial nephritis, often called white-spotted kidneys, represent a common cause of kidney condemnation at the slaughterhouse in some areas (Drolet et al. 2002). Lesions generally appear either as few randomly distributed or numerous widely disseminated whitish foci, 1–3 mm in diameter (Figure 22.8). Histologically these foci are composed of mononuclear inflammatory cells that often have a distinct lymphofollicular pattern (follicular nephritis) corresponding to the development of tertiary lymphoid structures within the kidneys. This type of interstitial reaction probably represents a nonspecific immunological response to prolonged local antigenic stimulation. In one study there

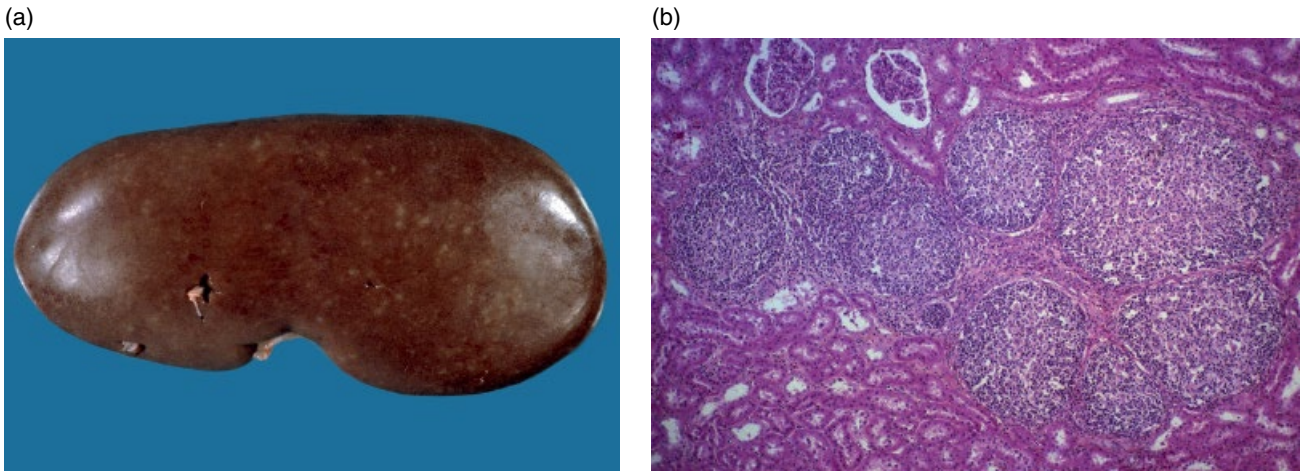

Figure 22.8 (a) Kidney from a slaughtered pig with multifocal interstitial nephritis. Note the relatively well-demarcated white dots randomly distributed throughout the cortex. (b) Well-demarcated focal areas of interstitial nephritis showing a distinct lymphofollicular pattern (follicular nephritis).

was a statistically significant association between the lesions and the presence of porcine parvovirus and PCV2, with a stronger association when both viruses were identified in the same kidney (Drolet et al. 2002). These renal lesions have also been observed in some cases of chronic leptospirosis (Pezzolato et al. 2012).

Embolic nephritis

Embolic nephritis may occur with bacteremia or septic thromboembolism when any of various species of bacteria is seeded within the vasculature of the kidneys. In bacteremia, small aggregates of microorganisms localizing in the renal microcirculation (particularly in the interstitial and glomerular capillaries) cause the formation of small suppurative foci. Early lesions appear grossly as small hemorrhagic foci bilaterally scattered throughout the renal cortex. They gradually form small (1–3 mm) whitish to yellowish abscesses that may be surrounded by a hyperemic rim (Figure 22.9). These lesions, although more numerous in the cortex, may also be found in the medulla. The finding of such renal lesions when performing a necropsy strongly suggests the possibility of a septicemia. In swine, infections with *Actinobacillus suis*, *Streptococcus* spp., *E. rhusiopathiae*, *Escherichia coli*, *Staphylococcus* spp., *Trueperella pyogenes*, and, more recently, *Actinobacillus equuli* (Benavente and Fuentealba 2012; Thompson et al. 2010) must be considered.

Septic thromboembolism occurs when fragments of a septic thrombus enter the bloodstream and occlude the arterial vasculature of the kidneys, resulting in necrosuppurative foci of variable sizes (Figure 22.10). Such renal lesions, if disclosed during a postmortem examination, should prompt a careful examination of the left cardiac valves (mitral and aortic) for the presence of vegetative

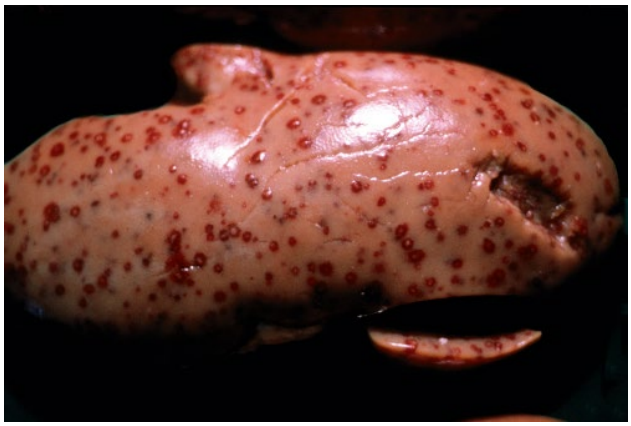

Figure 22.9 Embolic nephritis caused by *Actinobacillus suis*. Scattered suppurative foci are surrounded by a hemorrhagic rim.

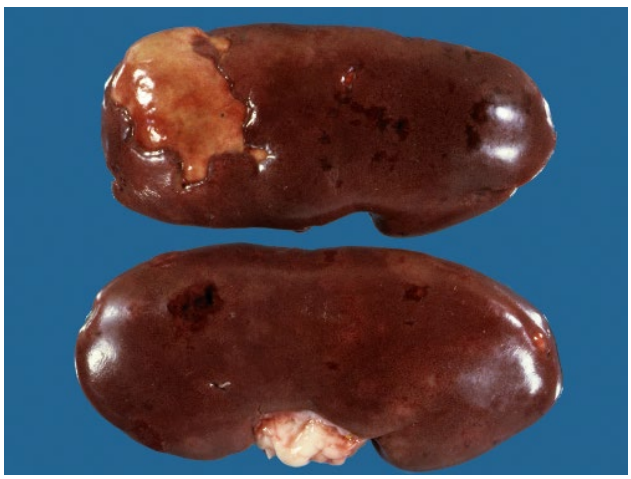

Figure 22.10 Septic thromboembolic nephritis secondary to *Streptococcus suis* endocarditis.

endocarditis. In these cases, bacteria most often involved include *Streptococcus* spp., *E. rhusiopathiae*, and *E. coli*.

Cystitis–pyelonephritis complex

Urine is formed by the kidneys and stored in the bladder by way of the ureters. Ascending infection from vagina and distal urethra to the sterile portions of the urinary tract may lead to cystitis and pyelonephritis. The cystitis–pyelonephritis complex has been documented as a leading cause of mortality in sows (D'Allaire and Drolet 2006). Porcine cystitis–pyelonephritis has been reported throughout the world, and the increased incidence appears to be correlated with changes in management, particularly the adoption of confinement housing for gestating sows.

A wide variety of bacteria have been isolated from cases of porcine cystitis and pyelonephritis, including *E. coli*, *T. pyogenes*, *Streptococcus* spp., and *Staphylococcus* spp. (Carr and Walton 1993). These endogenous and opportunistic organisms typically inhabit the lower urinary tract and are often referred to as being responsible for "nonspecific" urinary tract infections, which are reviewed in their respective chapters. *A. suis*, a specific urinary pathogen, is also an important cause of ascending infection in swine. Infection with *A. suis* frequently results in elevated sow mortality, and *A. suis* has been isolated, either alone or in combination with other bacteria, from nearly half of the reported cases of cystitis and pyelonephritis reviewed by Carr and Walton (1993).

The pathogenesis of the cystitis–pyelonephritis complex begins with the infection of the lower urinary tract. The normal complete voiding of urine is a major mechanism in maintaining sterility of the bladder; any factor that causes stasis of urine (decreased water intake, decreased urination, incomplete emptying of bladder, etc.) should be considered important in the development of this condition (Cianciolo and Mohr 2016). Environmental risk factors including the reduced availability of water, reduced consumption of poor quality water, high water pH, increased fecal contamination of the perineal area, excessive weight gain, or leg injuries all can result in a reduction in the frequency of urination and enhanced bacterial establishment in the urogenital tract. Advanced-parity sows are considered more susceptible to ascending infections possibly in part because older animals are more prone to obesity, limb injuries, and lack of exercise (D'Allaire and Drolet 2006). Once infection is established in the bladder (cystitis), deformation of the intravesical portion of the ureter and of ureteric orifices may facilitate vesicoureteral reflux, which is the retrograde flow of infected urine up the ureters and into the kidney (Cianciolo and Mohr 2016).

Clinical signs associated with infections of the urinary tract vary from asymptomatic, revealed only by urinalysis, to acute and severe cases of cystitis–pyelonephritis where affected animals may be found dead, probably from acute renal failure. Symptomatic animals are usually afebrile and may show anorexia, hematuria, and pyuria. The urine is often reddish brown in color with a strong odor. With *A. suis* infection, urinary pH may increase from normal values of 5.5–7.5 up to 8–9 due to the cleavage of urea into ammonia through the use of urease enzyme of the bacteria. Animals that survive the initial infection frequently experience weight loss and reduced productivity secondary to end-stage renal disease, resulting in premature removal from the breeding herd.

Grossly, the inflammatory reaction on the mucosal surface of the bladder may be catarrhal, hemorrhagic, purulent, or necrotic, and the bladder wall may be thickened. Struvites can also be found in the lumen. The ureters, often filled with exudate, may increase to as much as 2.5 cm in diameter.

Unilateral or bilateral pyelonephritis or pyelitis is the primary lesion detected in the kidneys. The pelvic region frequently distended with blood, pus, and foul-smelling urine often shows irregular ulceration and necrosis of the papillae. These suppurative lesions may eventually extend irregularly through the renal medulla and even into the cortex, causing exophytic and discolored deformations of the renal surface (Figure 22.11). These foci of cortical inflammation, when present, seem to occur more frequently at the renal poles (Isling et al. 2010). Compound papillae that are mainly located in these latter areas are considered more susceptible to intrarenal reflux of septic urine because of the inability of their papillary ducts to close under intrapelvic pressure (Carr et al. 1991; Carr and Walton 1993; Ransley and Risdon 1974). In long-standing cases of pyelonephritis, fibrosis ultimately replaces inflammation (Figure 22.11).

Microscopically, necrotizing ureteritis and pyelitis with accumulation of bacterial colonies can be seen (Woldemeskel et al. 2002). Renal tubules may contain protein casts, bacteria, and purulent exudate. The interstitium contains mononuclear inflammatory cells, neutrophils, and possibly some fibrosis. Examination of the ureteric valves may reveal inflammation, necrosis, and fibrosis.

Presumptive diagnosis of cystitis and pyelonephritis in live animals is best achieved when frequent micturition of bloodstained and cloudy urine can be observed. Examination of the urine sediments may also be very informative, because it may reveal the presence of inflammatory cells, erythrocytes, granular renal casts, bacteria, and crystals (Carr and Walton 1992). Blood concentrations of urea and creatinine may indicate renal failure. Due to the striking gross lesions, confirmatory diagnosis of the condition is usually not difficult.

Determination of urea concentration in ocular fluids can be a useful aid in diagnosing cystitis–pyelonephritis

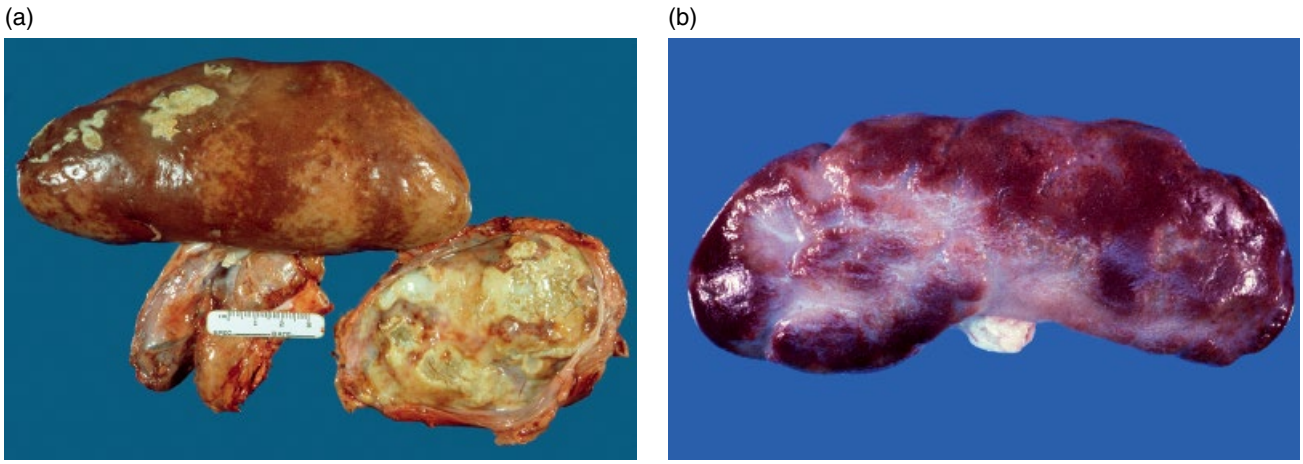

Figure 22.11 (a) Acute pyelonephritis due to *Actinobaculum suis* in a sow. Note the cortical foci of suppurative inflammation that have extended through the renal capsule (removed on the right). (b) Chronic pyelonephritis in a sow.

in dead animals, particularly when a complete necropsy is not possible or when it is difficult to ascertain that the lesions found in the urinary tract are responsible for death (Drolet et al. 1990). A significantly higher aqueous humor urea concentration was found in sows dead of cystitis–pyelonephritis (45–92 mmol/L) than in those dead of other causes (9–10 mmol/L) (Arauz and Perfumo 2000; Chagnon et al. 1991).

Treatment of urinary tract infections may be successful if the correct antibiotic is administered early in the course of the disease. Prevention of urinary tract infections should include the maintenance of a high degree of hygiene during breeding and parturition, as well as throughout the gestation period. Facilities need to be properly designed to reduce the spread of pathogens within the breeding herd and allow efficient removal of feces from the environment. It is recommended that free-choice water be available at all times to reduce the possibility of water deprivation and its sequels. Because a higher degree of urinary tract infection can be seen in older sows, proper culling procedures are important to ensure that an optimal parity distribution is maintained within the breeding herd.

Neoplasia

Neoplasms are infrequent in pigs because of the low average age of the population. However, those most often recorded have been from young animals (Nielsen and Moulton 1990). Tumors of the urinary tract in swine involve mainly the kidneys. Neoplasms of the lower urinary tract, although they have been reported (Nieberle and Cohrs 1967), are generally considered exceedingly rare.

Embryonal nephroma, also named nephroblastoma, is one of the most common neoplasms of swine and is certainly the most common primary renal tumor observed in this species, although its relative prevalence varies from one region to another. As its name implies, this neoplasm appears to originate from the embryonic renal blastema. The tumor arises from the kidney or, rarely, from the perirenal tissues (probably from remnants of embryonic renal tissues). Affected animals are typically young, and most of them reach market age without significant clinical signs, the tumor being discovered at postmortem inspection. Embryonal nephroma is most commonly found as a single mass involving one kidney, but it may be multiple or bilateral (Nielsen and Moulton 1990). The tumor, which can reach impressive size, often appears firm, pale, and nodular. Metastasis infrequently occurs in swine compared with other mammals affected with embryonal nephroma. Histologically, this tumor is very peculiar and resembles disorganized embryonic renal tissue. The primitive tissue from which it arises is pluripotent and accounts for the presence of neoplastic epithelial and mesenchymal elements simultaneously observed within the tumor. Hayashi et al. (1986) classified porcine nephroblastomas into four types according to their contents: nephroblastic, epithelial, mesenchymal, and miscellaneous. Only a few of the nephroblastic tumors described in their case series had metastasized.

Other primary renal tumors are believed to be uncommon in swine. Renal carcinomas have been occasionally reported (Anderson et al. 1969; Sandison and Anderson 1968). Neoplasms originating from the renal pelvis are very rare (Vitovec 1977).

Secondary renal involvement may occur with some multisystemic or generalized cancers such as the malignant lymphoma (lymphosarcoma). In pigs, this relatively common neoplasm occurs predominantly as multicentric and thymic forms. In advanced cases of multicentric

and thymic lymphomas, which involve primarily the lymph nodes and the thymus, respectively, infiltration of the liver, spleen, kidneys, and other organs may occur. Renal involvement is diffuse or more often nodular so that the organs appear either enlarged and pale or dotted with pale nodules often protruding from the cortical surface (Figure 22.12). During the disease, some animals may develop a leukemic phase. Renal lesions in some of these cases appear rather hemorrhagic (Marcato 1987; Stevenson and DeWitt 1973) and may be confused with some systemic infectious diseases (Figure 22.13). The precise pathogenesis of these latter lesions is uncertain but may involve either a coagulation defect or a phenomenon of acute infarction caused by the presence of intravascular neoplastic cells.

Figure 22.12 Lymphoma in a fattening pig. Multiple tumoral nodules in the kidney.

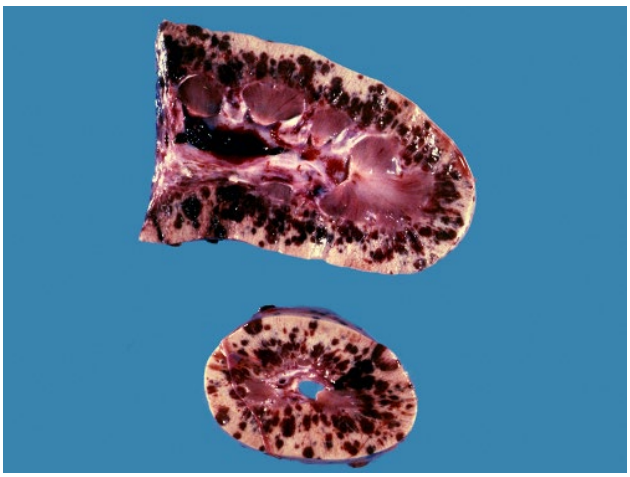

Figure 22.13 Leukemic lymphoma in a gilt showing multiple renal hemorrhagic foci. Histologically, these focal interstitial hemorrhages also contain neoplastic lymphoid cells.

Miscellaneous conditions

Urolithiasis

Urolithiasis is the presence of calculi, or uroliths, in the urinary passages. Uroliths are macroscopic mineral (polycrystalline) concretions that may contain small quantities of organic material; the term crystalluria is used for abnormal microscopic crystalloid precipitates in urine. Reports on the mineral composition of calculi found in pigs and their relative importance are relatively scarce (Osborne et al. 2009). Nevertheless, various types of calculi can be found, including calcium apatite (calcium phosphate), struvite (magnesium ammonium phosphate hexahydrate), calcium carbonate, and uric acid and urate. Factors known to predispose to the formation of uroliths include the diet, urinary pH, reduced water intake, urinary stasis, and preexisting urinary tract diseases.

Swine are rarely afflicted with urolithiasis in comparison with other domestic animals. The condition is sporadically found in pigs of all ages and is also occasionally observed as incidental findings in slaughtered pigs. Outbreaks of obstructive urolithiasis have been reported on some occasions (Inoue et al. 1977; Sim 1978; Smyth et al. 1986). In these outbreaks, which involved weaned and feeder pigs as well as breeding animals, the predisposing cause for the condition was not elucidated. Animals affected with obstructive urolithiasis may demonstrate decreased appetite, oliguria or anuria, abdominal distension and pain, and death from postrenal uremia. Ruptured bladder may also occur in some cases. Treatment of pigs with obstructive urolithiasis is theoretically feasible but is generally not considered cost effective.

The bladder of sows sometimes contains yellowish sediments that do not seem to be of clinical significance. On postmortem examination, such sediments, admixed with desquamated epithelial cells, may give the false impression of cystitis because of the turbidity of the urine. Infection-induced calculi are also observed occasionally in sows with cystitis and pyelonephritis (Figure 22.14).

Uric acid and urate uroliths are frequently found in the kidneys of newborn piglets (Figure 22.15). These often appear as fine orange precipitates in the medulla and pelvis. This peculiar form of urolithiasis is observed mainly in piglets that have no access to the sow's milk (which contains both fluids and nutrients) or are afflicted by a debilitating disease associated with anorexia and diarrhea (e.g. transmissible gastroenteritis), thus contributing to dehydration. Accelerated catabolism of tissue proteins and purines to supply energy needs and decreased kidney function related to dehydration are responsible for the high levels of blood urea and uric acid

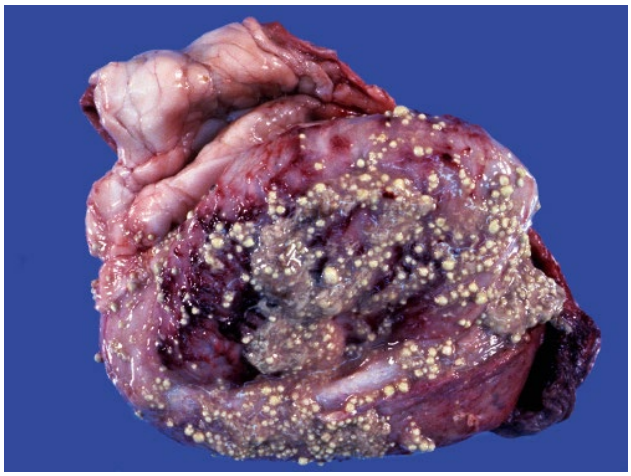

Figure 22.14 Infection-induced calculi in the bladder of a sow with a chronic suppurative cystitis.

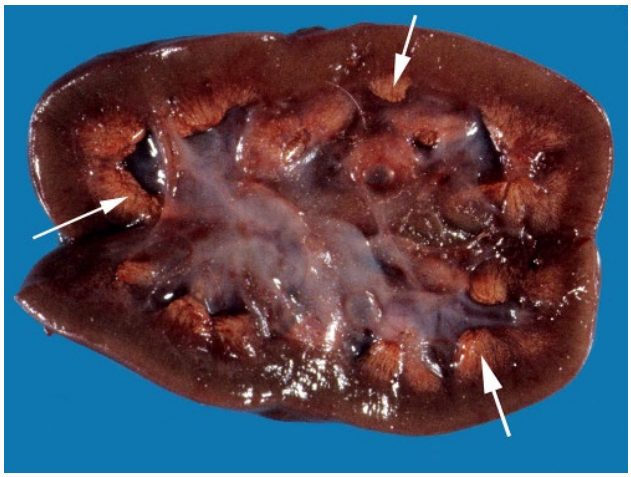

Figure 22.15 Urate calculi in the medulla (arrows) of a dehydrated suckling piglet.

found in these piglets. The excess solute, poorly reabsorbed from the glomerular filtrate, is ultimately deposited in the inner medulla and pelvis (Cianciolo and Mohr 2016).

Hydronephrosis

Distension of the renal pelvis and calyces with urine, associated with progressive atrophy of the kidney parenchyma, is the hallmark of hydronephrosis, which is uncommon and sporadic in swine. The pathogenesis of this condition always involves some form of obstructive impediment to the normal passage of urine within the lower urinary tract, anywhere from the pelvis to the distal urethra. The causes of the obstruction include urinary calculi, exudate within urinary passages, ureteral kinking, focal external compression (abscesses, tumors), and posttraumatic or postinflammatory strictures.

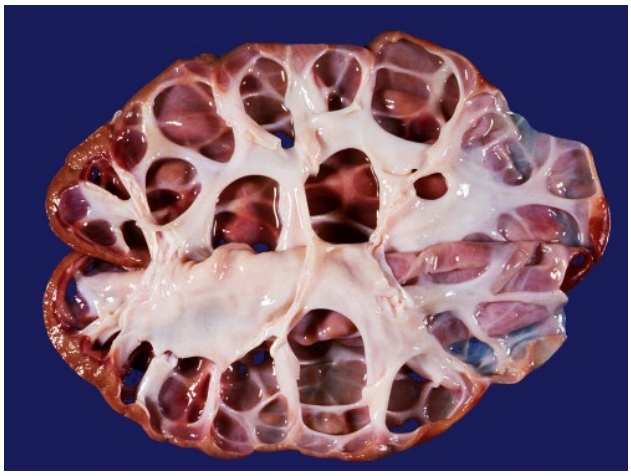

Figure 22.16 Chronic unilateral hydronephrosis.

Severe unilateral hydronephrosis (Figure 22.16) may develop unnoticed since the remaining kidney, if normal, may compensate adequately. In these cases, the affected kidney shows extensive dilation of the pelvis and calyces at the expense of the renal parenchyma, which may appear as a thin layer of cortical tissue. Depending on the location of the obstruction, hydroureter may also develop. In long-standing cases, the kidney may be virtually transformed into a large fluid-filled sac delimited by a severely distended renal capsule. These extreme lesions may take months to develop. Since stagnation of urine predisposes to infection, the urine may be transformed into a purulent exudate in some instances. In cases of bilateral hydronephrosis, affected animals usually die from uremia before renal lesions get fully developed.

Parasitic infections

The pig is the final or intermediate host of a number of parasitic helminths. Compared with some other body systems, the urinary tract is the niche of very few of these parasites. Renal infections with *Dioctophyma renale*, the giant kidney worm, and with larval stages of certain tapeworms may occur on rare occasions. The most significant helminth with tropism for the urinary system of swine is the nematode *Stephanurus dentatus*, the so-called kidney worm of swine.

Stephanurus dentatus is a widely distributed strongyloid worm and is most prevalent in warm climates, including the Southern United States. In endemic areas, this parasitic infection may have significant economic impact since it is associated with deaths, retarded growth, decreased feed efficiency, and condemnations at the abattoir (Batte et al. 1960). Larvae of this nematode need moisture and shade for optimal survival, so pigs raised on soil in this type of environment are the most prone to the disease. Infective larvae penetrate the skin

Table 22.1 Differential diagnosis of some renal diseases based on gross findings at necropsy.

Gross findings	Differential diagnosis
Normal size kidneys with widespread petechiae	• Bacterial septicemia (Figure 22.3) • Acute viremic diseases: classical swine fever (CSF), African swine fever (ASF), cytomegalovirus • Electrocution • Some intoxications
Enlarged and edematous kidneys with widespread petechiae	• Acute glomerulonephritis[a] (GN) including PDNS (Figure 22.5)
Enlarged, pale, and edematous kidneys	• Acute GN[a] • Acute tubular necrosis[a]: various toxic agents (Figure 22.6) Note: Occasionally with perirenal edema (pigweed, GN)
Multiple renal hemorrhages (larger than petechiae)	• Trauma • Necrosis • Clotting defects: anticoagulant poisoning, isoimmune thrombocytopenia
One or both kidneys with red or white foci of necrosis (often wedge shaped and cortical)	• Acute or subacute infarcts: thrombosis, vasculitis, emboli
Kidneys with patchy pallor or obvious white foci within renal parenchyma	• Interstitial nephritis: circovirus, leptospirosis, undetermined cause (Figure 22.7) Note: Kidneys may also be enlarged with circovirus
Kidneys with multiple microabscesses	• Suppurative embolic nephritis: *Erysipelothrix rhusiopathiae*, *Actinobacillus suis* (Figure 22.9)
One or both kidneys with exudate within dilated pelvis and possibly papillary necrosis and asymmetric foci of parenchymal suppurative inflammation	• Acute pyelonephritis[a]: various bacteria including *Actinobaculum suis* (Figure 22.11) Note: Often accompanied with ureteritis and cystitis
Kidneys diffusely pale, firm, and fibrotic with generalized fine granularity of the capsular surface	• Chronic GN[b] • Chronic tubular necrosis[b]: some toxic agents including ochratoxin A • Chronic generalized interstitial nephritis (uncommon in pigs)
One or both kidneys with large irregular fibrous bands with intervening areas of normal parenchyma; dilation of pelvis and deformities of papillae	• Chronic pyelonephritis (Figure 22.11)
One or both kidneys with large irregular fibrous bands with intervening areas of normal parenchyma; normal pelvis	• Chronic infarcts (septic or not) • Renal dysplasia (rare)
One or both kidneys with one to several fluid-filled cysts that do not communicate with the pelvis	• Congenital renal cysts (Figure 22.2)
One or both kidneys with dilation of the pelvis and calyces associated with atrophy and cystic enlargement of the kidney	• Hydronephrosis[b] (obstructive nephropathy) (Figure 22.16)
One or both kidneys with multiple exophytic nodules of various sizes	• Lymphoma (often bilateral) (Figures 22.12 and 22.13) • Embryonal nephroma (often unilateral) • Other neoplasms (rare)

[a] Acute renal failure possible.
[b] Chronic renal failure possible.

or are ingested by the pigs. Transplacental fetal infection is also possible (Batte et al. 1966).

After being introduced into the host, the larvae molt and migrate to the liver, where they remain for several months, causing severe hepatic damage and inflammation. The presence of the parasite within the hepatic parenchyma is often responsible for extensive liver condemnation in some herds (Hale and Marti 1983). Eventually some larvae escape from the liver and migrate to the abdominal cavity and potentially to various ectopic sites, eliciting a severe inflammatory reaction. To complete the cycle, some adults establish themselves in the

perirenal tissues or, more rarely, within the kidney. At that site, the worms, measuring about 3 cm in length, are found in cystic inflammatory nodules that communicate with either the pelvis or the ureter in order to shed their eggs successfully into urine. The prepatent period in most cases is at least 9 months, and adults may shed ova in urine for over 2 years (Batte et al. 1960, 1966). Preventive and curative measures for the control of parasites are addressed in detail elsewhere in this book.

Other conditions

Urethral polyps causing local obstruction have been reported on several occasions in male Vietnamese potbellied pigs (Helman et al. 1996). These inflammatory polyps have all occurred at the level of the urethral recess (see section "Anatomy"). The precise cause of the lesions could not be determined, but traumatic injuries secondary to urinary catheterization have been strongly suspected in some cases. Urethral catheterization should be performed with great care in male pet breeds of swine to avoid potential damage to the urethral recess.

Mineralization of the kidneys occurs in swine with acute vitamin D toxicosis. This poisoning is usually observed when excessive amounts of vitamin D_3 are inadvertently added to their feed (Kurtz and Stowe 1979; Long 1984). Affected pigs show lethargy, vomiting, diarrhea, respiratory distress, and death. Salient gross necropsy findings include hemorrhagic gastritis or gastroenteritis, myocardial necrosis, and pulmonary edema and congestion. Histologically, besides the gross lesions described above, there is widespread mineralization accompanied by degenerative changes of varying severity in the kidneys, myocardium, lungs, gastrointestinal tract, and blood vessels.

Chronic salt intoxication has been reported recently in growing pigs (Alonso et al. 2010). This poisoning was associated with a severe bilateral diffuse interstitial fibrosis in the middle and deep area of the renal cortex with loss of glomeruli and glomerulosclerosis.

Mucinous metaplasia of the epithelial cells lining the renal pelvis, ureter, and urinary bladder is occasionally observed in pigs. This rather nonspecific lesion, of uncertain pathogenesis, has been reported in pigs with various conditions, including exudative epidermitis, *E. coli* enteritis, classical swine fever, and suppurative arthritis (Brobst et al. 1971), as well as in urinary tract infections.

Ossification of the renal pelvis of unknown etiology has been reported in slaughtered pigs (Bundza 1990).

Differential diagnosis

Main differential diagnoses based on gross renal findings are presented in Table 22.1.

Overview of Viruses

Jianqiang Zhang, Kyoung-Jin Yoon, and Jeffrey J. Zimmerman

Characteritics of viruses

Historically, a virus was defined as a "filterable agent" (Hughes 1977) because filtration (<300 nm pore size) would separate viruses from most bacteria and other microorganisms. However, some mycoplasmas and chlamydia may be <300 nm in diameter (MacLachlan and Dubovi 2011), and "giant" viruses have been identified, such as mimiviruses (750 nm in diameter) and pandoraviruses (up to 1000 nm in diameter) (MacLachlan and Dubovi 2017) (Table 23.1).

Viruses are very distinct from other microorganisms. Viruses are obligate intracellular parasites. They cannot be cultivated on nonliving (i.e. artificial) medium because they only replicate within living cells. Indeed, they rely on the host cell to provide many of the resources required for their replication. Viruses also have other unique properties: they do not reproduce by binary fission, they contain DNA or RNA genomes (but not both), and they are not sensitive to antibiotics but to interferons (Table 23.1).

Compositions of virions

A virion is a complete virus particle consisting of the genomic RNA or DNA surrounded by a protein shell (sometimes with an external envelope as well) and is the infective form of a virus (Figure 23.1). The genome can be single stranded or double stranded, can be linear or circular in form, and can contain one or more segments (Table 23.2). If single stranded, the virion genome can be positive sense, negative sense, or ambisense (Table 23.2).

Genomic RNA or DNA encodes various viral proteins. Generally speaking, viral proteins produced in the process of virus life cycle, but not physically incorporated into the virion, are referred to as "nonstructural proteins." Viral proteins incorporated into the virion are "structural proteins." However, some virions include a small amount of nonstructural proteins (e.g. viral polymerase) used at the initiation of the next cycle of replication. Whether some viral polymerases are packaged into virions or not depends on virus replication/transcription strategies and subcellular sites (cytoplasm and/or nucleus) of viral replication (Table 23.2).

Within a virion, the viral genome is surrounded by a protein coat ("capsid") composed of viral protein subunits ("capsomere"). Together, the viral genome and capsid form the nucleocapsid. For some viruses, the nucleocapsid is "naked" (non-enveloped viruses). For some viruses, the nucleocapsid is covered by an outer structure ("envelope") that is acquired as the nucleocapsid passes ("buds") through a cell membrane, i.e. cytoplasmic, intracytoplasmic, or nuclear membrane. Due to the nature of the budding process, the major constituent (lipid bilayer) of the viral envelope is structurally identical to the cell membrane from which it was derived. An enveloped virion also has additional virus-encoded proteins on the surface of envelope. These proteins are attached to the matrix protein (or the tegument in the case of herpesviruses) located between the envelope and the nucleocapsid. These envelope proteins, sometimes called envelope glycoproteins or envelope-associated proteins, play a critical role in the process of virus life cycle. For example, they are involved in virus attachment (receptor binding), membrane fusion and uncoating, and release of progeny virus (receptor destruction).

Viral morphology

Viruses vary in size and morphology (Figure 23.2 and Table 23.2). Nucleocapsid symmetry and virion morphology are two important aspects of viral morphology (Condit 2013; MacLachlan and Dubovi 2011). Nucleocapsid symmetry is often described as icosahedral (isometric), helical, or complex. Descriptions of virion morphology are not standardized, and various descriptors may be seen in the literature (e.g. icosahedral, spherical, complex, pleomorphic, bullet shaped, and others).

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

Table 23.1 Comparison of basic properties among unicellular microorganisms.

Property	Bacteria	Mycoplasma	Rickettsia	Chlamydia	Virus
Size >300 nm[a]	Yes	Yes	Yes	Yes	No
Grow on artificial media	Yes	Yes	No	No	No
Divide by binary fission	Yes	Yes	Yes	Yes	No
Contain both DNA and RNA	Yes	Yes	Yes	Yes	No
Sensitive to antibiotics	Yes	Yes	Yes	Yes	No

Source: Adapted from Murphy et al. (1999).
[a] Some mycoplasmas and chlamydia are <300 nm in diameter. Some viruses, e.g. mimiviruses and pandoraviruses, are >300 nm in diameter.

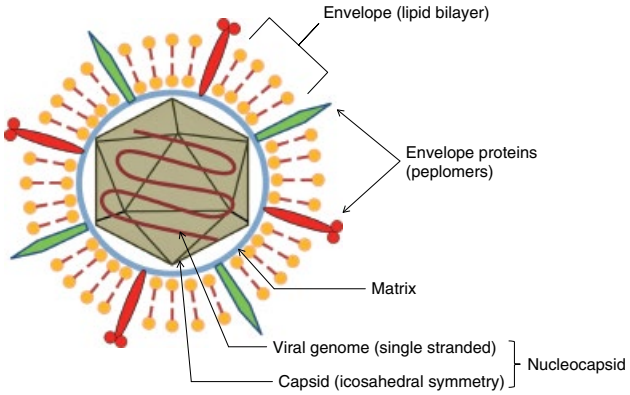

Figure 23.1 Schematic diagram of an enveloped virion with a single-stranded genome surrounded by an icosahedral capsid.

Virus taxonomy

Basis of taxonomy

Initially, viruses were named or categorized on the basis of (1) the disease or pathology associated with the virus (e.g. foot-and-mouth disease virus, hepatitis virus), (2) the geographic location where the virus was found (e.g. Rift Valley fever virus), (3) transmission vectors (e.g. arthropod-borne viruses or arboviruses), and (4) other overt characteristics. As more viruses were discovered and the scientific basis of characterizing viruses expanded, this system became inadequate. Therefore, the International Committee on Taxonomy of Viruses (ICTV) was established in 1966 with the objective of developing an internationally recognized taxonomy and nomenclature for viruses.

The current virus taxonomy system classifies viruses on the basis of specific characteristics: (1) genome characteristics (RNA vs. DNA, strandedness, segmentation, circular vs. linear, polarity, haploid vs. diploid), (2) virion structure (morphology, envelope, nucleocapsid symmetry, capsomere number), (3) genome organization and viral replication and transcription strategies, and (4) other features.

Hierarchy and nomenclature

Virus taxonomic classification is an ongoing process and evolves as new information is brought to light. *Diseases of Swine* (11th edition) relied on the information in the 10th Report of the ICTV (2017). Updates and new information on virus taxonomy may be found on the ICTV website https://ictv.global/report.

The ICTV has adopted a universal system to describe the hierarchical taxonomic levels of viruses: order, family, subfamily, genus, and species. Within this system, a virus species is defined as "a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche." A type species is defined for each genus, but the type species is not necessarily the most well-characterized virus in the genus. Rather, it is the virus that initially necessitated the creation of the genus. A genus is a group of virus species sharing some common characters, a subfamily is a group of genera sharing some common characters, a family is a group of genera or subfamilies sharing some common characters, and an order is a group of families sharing some common characters. However, not all families have a defined higher taxonomic level "order," and, in fact, only a few families have been grouped into orders. In addition, not all families include subfamilies; for most cases, species are grouped into genera and genera directly into families.

The ICTV has defined specific naming conventions for the taxa in this system. The names of orders end with the suffix "*-virales*," families with the suffix "*-viridae*," subfamilies with the suffix "*-virinae*," and genera with the suffix "*-virus*." In formal nomenclature, order, family, subfamily, and genus names are a single word in italics with the first letter capitalized, for example, the order *Herpesvirales*, the family *Herpesviridae*, the subfamily *Alphaherpesvirinae*, and the genus *Varicellovirus*. Taxonomic species name is written in italics as well, but there is no specific suffix for species. In addition, the species name can be more than one word. For a species name, the first word begins with a capital letter, and other words only begin with a capital letter if they are

Table 23.2 Viral families containing animal and human pathogens and their virion and genome properties.

		Virion			Genome					
Family[a]	Nucleocapsid symmetry[b]	Diameter (nm)	Envelope	Morphology[d]	Type	Structure[e]	Segment	Size (kb)	Virion Polymerase[f]	Virus replication and assembly[c]
Adenoviridae	I	80–110	–	I	DNA	Linear, ds	1	32–40	–	Nu
Anelloviridae	I	30–32	–	I	DNA	Circular, ss(–)	1	2–4	–	Nu
Asfarviridae	I	175–215	+[g]	I	DNA	Linear, ds	1	170–190	+	Cy
Circoviridae	I	17–24	–	I	DNA	Circular, ss(– or ±)	1	1.7–2.3	–	Nu
Hepadnaviridae	I	40–48	+	S	DNA	Circular, ds	1	3–3.3	+	Nu/Cy
Herpesviridae	I	150–200	+	S	DNA	Linear, ds	1	120–235	–	Nu
Iridoviridae	I	160–350	±	I	DNA	Linear, ds	1	150–300	–	Nu/Cy
Papillomaviridae	I	40–55	–	I	DNA	Circular, ds	1	5.3–8	–	Nu
Parvoviridae	I	18–26	–	I	DNA	Linear, ss(– or +)	1	5	–	Nu
Polyomaviridae	I	40–55	–	I	DNA	Circular, ds	1	5.3–8	–	Nu
Poxviridae	C	250–300 × 200	+	C	DNA	Linear, ds	1	130–375	+	Cy
Arenaviridae	H	100–300	+	S	RNA	Circular, ss(±)	2	10–14	+	Cy
Arteriviridae	I	50–70	+	S	RNA	Linear, ss(+)	1	13–15	–	Cy
Astroviridae	I	27–30	–	I	RNA	Linear, ss(+)	1	6.8–7.9	–	Cy
Birnaviridae	I	60	–	I	RNA	Linear, ds	2	7	+	Cy
Bornaviridae	I	50–60	+	S	RNA	Linear, ss(–)	1	8.9	+	Nu
Bunyaviridae	H	80–120	+	S	RNA	Linear, ss(– or ±)	3	11–22.7	+	Cy
Caliciviridae	I	35–39	–	I	RNA	Linear, ss(+)	1	7.4–8.3	–	Cy
Coronaviridae	H	80–160	+	S	RNA	Linear, ss(+)	1	20–33	–	Cy
Filoviridae	H	800–950 × 80	+	P	RNA	Linear, ss(–)	1	18.9–19.1	+	Cy
Flaviviridae	I	40–60	+	S	RNA	Linear, ss(+)	1	9.5–12.5	–	Cy
Hepeviridae	I	27–34	–	I	RNA	Linear, ss(+)	1	7.1–7.2	–	Cy
Orthomyxoviridae	H	80–120	+	P,S	RNA	Linear, ss(–)	6–8	10–14.6	+	Nu
Paramyxoviridae	H	150–600	+	P,S	RNA	Linear, ss(–)	1	15–18	+	Cy
Picornaviridae	I	22–30	–	I	RNA	Linear, ss(+)	1	7–8.5	–	Cy
Reoviridae	I	60–80	–	I	RNA	Linear, ds	10–12	16–27	+	Cy
Retroviridae	I	80–100	+	S	RNA	Linear, ss(+) dimer	1	7–11	+	Cy/Nu
Rhabdoviridae	H	180 × 75	+	Bullet shaped	RNA	Linear, ss(–)	1	13–16	+	Cy
Roniviridae	H	150–200 × 40–60	+	S	RNA	Linear, ss(+)	1	26.2	–	Cy
Togaviridae	I	65–70	+	S	RNA	Linear, ss(+)	1	9.7–11.8	–	Cy

[a] Families are listed in the alphabetical order of family names but with DNA viruses first followed by RNA viruses.
[b] Nucleocapsid symmetry abbreviation: I, icosahedral; C, complex; H, helical.
[c] Location where virus replication takes place: Cy, cytoplasm; Nu, nucleus.
[d] Virion morphology abbreviation: I, icosahedral; S, spherical; C, complex; P, pleomorphic.
[e] ds, double stranded; ss, single stranded; –, negative sense; +, positive sense; ±, ambisense.
[f] Viral polymerase packaged into virion: – No; + Yes.
[g] Intracellular virion is not enveloped.

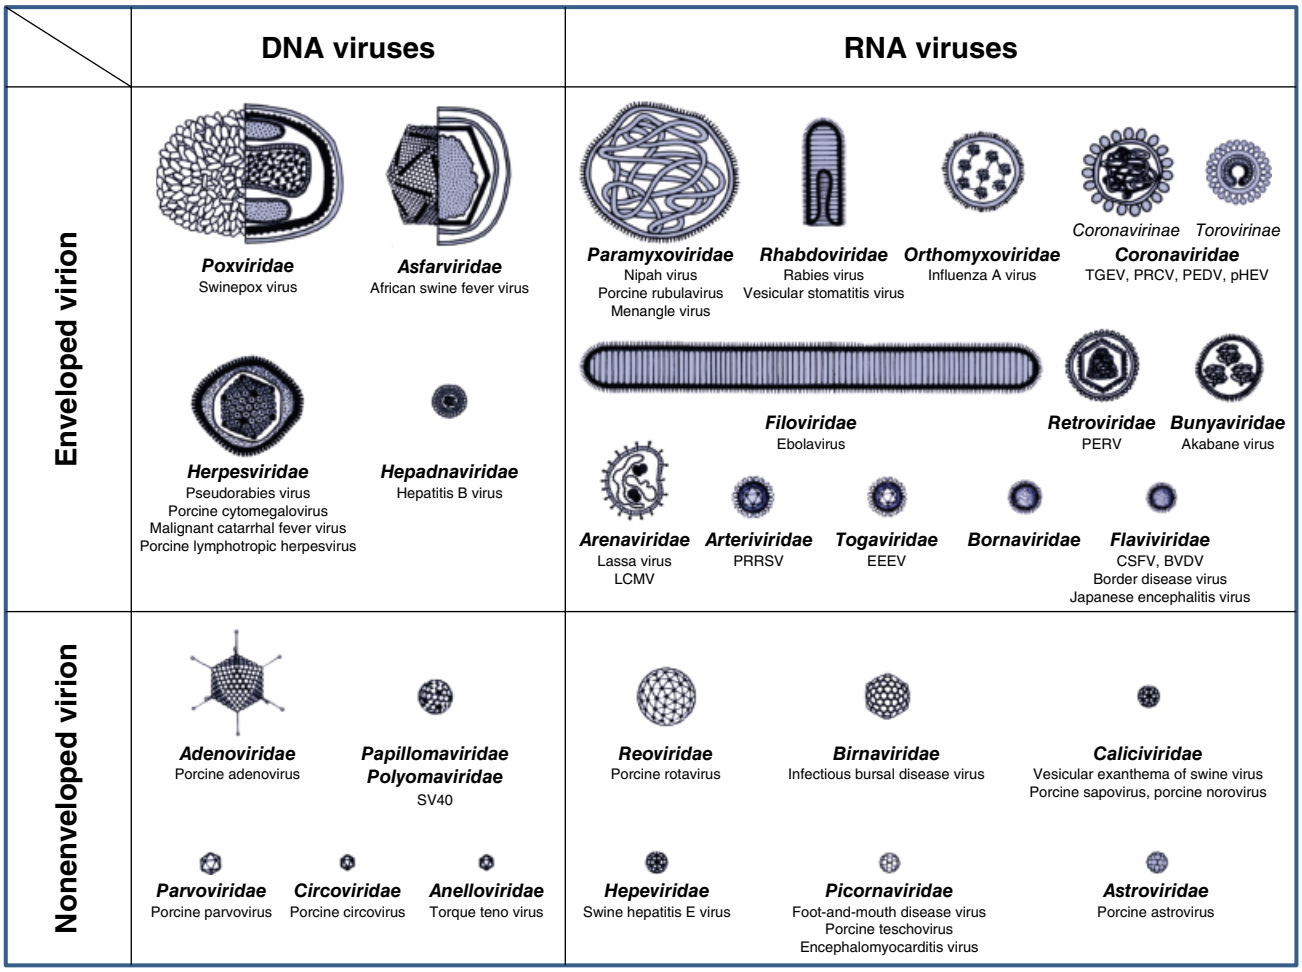

Figure 23.2 Grouping of animal viruses based on morphological characteristics and composition of nucleic acid. *Source:* Adapted with permission from Murphy et al. (1999). Reproduced with permission of Elsevier. LCMV, lymphocytic choriomeningitis virus; EEEV, Eastern equine encephalitis virus; CSFV, classical swine fever virus; BVDV, bovine viral diarrhea virus; PEDV, porcine epidemic diarrhea virus; PERV, porcine endogenous retrovirus; pHEV, porcine hemagglutinating encephalomyelitis virus; PRCV, porcine respiratory coronavirus; PRRSV, porcine reproductive and respiratory syndrome virus; TGEV, transmissible gastroenteritis virus.

proper nouns or alphabetical identifiers, for example, the species *Suid alphaherpesvirus 1*, the species *Vesicular exanthema of swine virus*, the species *West Nile virus*, and the species *Teschovirus A*. A species name should not be abbreviated.

Taxonomic levels lower than species are not officially specified by the ICTV. For that reason, there are no formal rules of naming members of a virus species, although recommendations are provided on the ICTV website. A virus name should not be italicized and should be written in lowercase. Words in a virus name, including the first word, should only begin with a capital letter when these words are proper nouns or when a sentence starts with a virus name. Virus names may be abbreviated. Some examples are given below:

- "Porcine epidemic diarrhea virus (PEDV) was detected in the fecal samples."
- "Fecal samples tested positive by a porcine epidemic diarrhea virus (PEDV)-specific real-time RT-PCR."
- "Detection of West Nile virus (WNV) can be achieved using a virus-specific RT-PCR."

Sometimes the common virus name is the same as the species name, e.g. the virus name is "porcine epidemic diarrhea virus" and the species name is "*Porcine epidemic diarrhea virus*." Sometimes the common virus name is different from the species name, e.g. the virus is named "Seneca Valley virus," and the species is named "*Senecavirus A*."

A species may consist of just one virus or a species can include multiple virus members. For example, the species *Alphacoronavirus 1* includes virus members, such as transmissible gastroenteritis virus, porcine respiratory coronavirus, canine coronavirus, feline infectious peritonitis virus, and feline enteric coronavirus.

Occasionally a collective name is used to describe a group of viruses belonging to a genus, a family, or an order. Under such a circumstance, the collective name is neither italicized nor capitalized. For example, the

collective name "nidoviruses" is used to describe viruses in the order *Nidovirales*. However, collective names must be used carefully to avoid miscommunication. For example, does "flaviviruses" represent viruses in the genus *Flavivirus* or all viruses in the family *Flaviviridae*? Does the collective name "picornaviruses" represent all viruses in the family *Picornaviridae* or all viruses in the order *Picornavirales*?

Utility of taxonomy

Virus classification provides useful information. For example, DNA viruses tend to be more genetically stable (lower rate of genetic change) than RNA viruses during the process of genome replication. Enveloped viruses are more susceptible to environmental stresses than nonenveloped viruses and lose their infectivity easily when exposed to lipid solvents or detergents. Most importantly, virus taxonomy provides a standard framework for properly classifying viruses and comparing viruses between different groups. When a newly identified virus is classified into a given family, some basic information on its properties and certain viral characteristics can be inferred.

Detection of viruses

The technology for virus detection continues to evolve, but current methods for detecting viruses fit into five categories (MacLachlan and Dubovi 2017; Storch and Wang 2013): (1) detection of infectious virus (virus cultivation), (2) electron microscopy (EM), (3) viral antigen-based detection methods, (4) viral nucleic acid-based detection methods, and (5) detection of virus antibodies. These detection methods can be agent dependent, agent independent, or both.

Virus cultivation

Initially, propagation of animal viruses was limited to live animals, either their natural animal hosts or laboratory animals. In the 1930s, some avian and animal viruses were successfully propagated using embryonated chicken eggs (Goodpasture et al. 1932) and embryonated chicken eggs are still widely used for the isolation and propagation of influenza viruses and many avian viruses. In 1948, the growth and maintenance of mammalian cells *in vitro* became possible (MacLachlan and Dubovi 2017). This led to the development of *in vitro* cell culture systems, including organ cultures, primary explant cultures, primary cell cultures, and cell lines. In particular, continuous cell lines are routinely used for virus cultivation. Although virus cultivation in animal hosts has largely been replaced by cell culture and embryonated chicken eggs, not all viruses can be cultivated *in vitro*, and inoculation of animals (bioassays) is sometimes necessary to assess the viability of some viruses in samples.

Electron microscopy

EM enables direct visualization of virus particles. The virus of interest is then assigned to the appropriate family on the basis of the morphology and size of the viral particles. In disease outbreak investigations, EM is particularly useful in identifying previously unrecognized viruses or uncultivable viruses. In addition to the need for expensive equipment and a highly skilled microscopist, another limitation of EM is its low analytical sensitivity; that is, the agent needs to be present in abundance. However, immunoelectron microscopy can enhance sensitivity to some extent.

Viral antigen-based detection methods

Several methods can be used for the direct detection of viral antigens in clinical specimens or virus-infected cells. These include fluorescent antibody (FA) staining, immunohistochemical (immunoperoxidase) staining, solid-phase enzyme immunoassays (e.g. antigen-capture enzyme-linked immunosorbent assay [ELISA]), and lateral flow immunochromatographic assays (e.g. strip test). These assays detect viral antigens in clinical specimens by reacting with virus-specific antibody. Thus, these viral antigen-based detection methods are agent specific. FA staining and immunohistochemistry (IHC) are extremely useful in establishing a diagnosis because they are able to identify viral antigens in a tissue specimen in the context of microscopic lesions. Solid-phase enzyme assays or lateral flow chromatographic assays are useful for a liquid specimen (e.g. feces).

Viral nucleic acid-based detection methods

Nucleic acid-based methods for virus detection and discovery include sequence-dependent approaches, sequence-independent metagenomics approaches, and next-generation sequencing (NGS).

Nucleic acid sequence-dependent approaches

Polymerase chain reaction (PCR) assays are generally agent specific and require virus-specific sequence information to design primers and/or probes. Development of consensus, degenerate, or pan-family PCRs partially overcomes this limitation, but degenerate PCRs lack analytical sensitivity and are still highly dependent on prior sequence information on the virus genera/families being investigated.

Microarrays are another nucleic acid sequence-dependent approach for virus detection. Microchips consist of hundreds to thousands of oligonucleotide probes bound to a solid matrix. Virus detection and identification is based on hybridization of viral nucleic acids to specific probes. Microarrays have the potential to simultaneously detect multiple viruses in one sample. However, the current microarrays are not as sensitive as real-time PCRs and are not routinely used for virus detection in diagnostic laboratories (MacLachlan and Dubovi 2017).

In situ hybridization (ISH) utilizes a virus-specific probe to directly detect a virus present in clinical samples, especially tissues. Similar to FA or IHC, ISH is able to correlate the presence of virus with lesions observed in tissues. ISH is particularly useful for those viruses against which a validated antibody reagent is not available to conduct FA staining or IHC but whose nucleotide sequences are known.

Nucleic acid sequence-independent approaches

Nucleic acid sequence-dependent approaches efficiently detect known viruses but have limitations in discovering previously unrecognized viruses. Metagenomics is a technique that detects the totality of genetic material present in one sample (Handelsman 2004). A number of viral metagenomics approaches based on random amplification techniques have been utilized to amplify viral genetic materials for cloning and sequencing, including sequence-independent single-primer amplification, virus discovery cDNA-AFLP, and rolling circle amplification (Bexfield and Kellam 2011; Delwart 2007; Thurber et al. 2009). These approaches have allowed for the discovery of new viruses, but they have been mainly replaced by NGS-based metagenomics approaches.

NGS technologies became commercially available in 2005 and many different platforms of NGS have been developed since then. One common feature of NGS platforms is "massive parallel sequencing," an approach that generates millions of sequence reads in a single run, thereby producing sequences at a lower cost and faster speed. In addition, the hypothesis-free basis of NGS provides an unbiased approach for detecting multiple agents in a sample and for discovering new microorganisms (Datta et al. 2015; Temmam et al. 2014).

Detection of virus antibodies

Unless the antibody is maternally acquired, detection of virus-specific antibodies in a bodily fluid provides evidence that an animal has previously been exposed. This may be particularly useful in the case of viruses that are rapidly cleared by the animal. Classically, antibody-based detection of a viral infection was based on testing paired samples (2–4-week interval) from the same animal(s), with significant increases in antibody levels indicative of active viral infection. Likewise, detection of virus-specific IgM antibody in a single acute-phase serum sample can also indicate active viral infection. In contemporary production systems, collection and testing of serum, oral fluid, or other clinical specimens at 2- to 4-week intervals either for antibody or viral nucleic acid is used to detect infections prior to the appearance of clinical signs or disease outbreaks.

Depending on the clinical specimen and the viral pathogen, a variety of assays are available for detecting virus antibodies, including ELISA, virus neutralization, indirect FA, immunodiffusion, hemagglutination inhibition, and fluorescent microsphere immunoassay (FMIA). In particular, the differentiation of infected and vaccinated animals (DIVA) using vaccines and antibody ELISAs specifically designed for this purpose has improved the success of disease control and elimination programs, as in the case of Aujeszky's disease (pseudorabies) virus.

Characterization of viruses

Characterization of virion structure

EM is the most direct way to determine the morphology and size of a virus particle. Conventional transmission EM is generally used for detecting and characterizing virus particles in fluid matrices (negative stain EM) and cells/tissues (thin-section positive stain EM). Only the surface topography of virus particles can be imaged by transmission EM.

Some advanced techniques can be used to further characterize virion structures (Mateu 2013) although they are not used in diagnostic medicine. For example, cryo-electron microscopy (cryo-EM) together with three-dimensional reconstruction techniques can determine the three-dimensional structural model of virus particles by averaging the images of many individual virus particles. Cryo-EM is best applied to symmetric viruses and is not suitable for pleomorphic viruses because the procedures involve image averaging. Cryo-electron tomography (cryo-ET) can image an individual particle from various angels of view and, thus, can determine the three-dimensional structure of a single virus particle including symmetric and pleomorphic viruses. X-ray crystallography can be used to determine the crystal structures of virus particles or individual viral proteins, but crystals must be obtained first.

Ultrafiltration can be used to estimate the virion's size. In this procedure, a concentrated purified virus suspension is passed through a series of membrane filters with different pore sizes (10–300 nm). The presence and quantity of virus are then established for each filtrate.

Table 23.3 Taxonomy of the main viruses infecting pigs (based on ICTV Virus Taxonomy released in 2017).

Order	Family	Subfamily	Genus	Species	Virus common name
Bunyavirales	*Peribunyaviridae*		*Orthobunyavirus*	*Akabane orthobunyavirus*	Akabane virus
				?	Oya virus, Lumbo virus, Tahyna virus
			Herbevirus	*Herbert herbevirus*	Herbert virus
	Phenuiviridae		*Goukovirus*	*Gouleako goukovirus*	Gouleako virus
Herpesvirales	*Herpesviridae*	*Alphaherpesvirinae*	*Varicellovirus*	*Suid alphaherpesvirus 1*	Pseudorabies virus (PRV) or Aujeszky's disease virus
		Betaherpesvirinae	?	*Suid betaherpesvirus 2*	Porcine cytomegalovirus (PCMV)
		Gammaherpesvirinae	*Macavirus*	*Suid gammaherpesvirus 3*	Porcine lymphotropic herpesvirus 1 (PLHV-1)
				Suid gammaherpesvirus 4	PLHV-2
				Suid gammaherpesvirus 5	PLHV-3
				Ovine gammaherpesvirus 2	Ovine herpesvirus 2 (OvHV-2)
Mononegavirales	*Filoviridae*		*Ebolavirus*	*Reston ebolavirus*	Reston virus (RESTV)
				Zaire ebolavirus	Ebolavirus (EBOV)
	Paramyxoviridae		*Rubulavirus*	*Menangle rubulavirus*	Menangle virus
				Porcine rubulavirus	Blue eye paramyxovirus (BEPV) or La Piedad-Michoacan virus (LPMV)
			Henipavirus	*Nipah henipavirus*	Nipah virus (NiV)
				Hendra henipavirus	Hendra virus (HeV)
			Respirovirus	*Porcine respirovirus 1*	Porcine parainfluenza virus 1 (PPIV-1)
	Rhabdoviridae		*Vesiculovirus*	*Indiana vesiculovirus*	Vesicular stomatitis Indiana virus (VSIV)
				New Jersey vesiculovirus	Vesicular stomatitis New Jersey virus (VSNJV)
			Lyssavirus	*Rabies lyssavirus*	Rabies virus
Nidovirales	*Arteriviridae*		*Porartevirus*	*Porcine reproductive and respiratory syndrome virus 1*	Porcine reproductive and respiratory syndrome virus 1 (PRRSV-1)
				Porcine reproductive and respiratory syndrome virus 2	Porcine reproductive and respiratory syndrome virus 2 (PRRSV-2)
	Coronaviridae	*Coronavirinae*	*Alphacoronavirus*	*Alphacoronavirus 1*	Transmissible gastroenteritis virus (TGEV); porcine respiratory coronavirus (PRCV)
				Porcine epidemic diarrhea virus	Porcine epidemic diarrhea virus (PEDV)
			Betacoronavirus	*Betacoronavirus 1*	Porcine hemagglutinating encephalomyelitis virus (pHEV)
			Deltacoronavirus	*Coronavirus HKU15*	Porcine deltacoronavirus (PDCoV)
		Torovirinae	*Torovirus*	*Porcine torovirus*	Porcine torovirus (PToV)
Ortervirales	*Retroviridae*	*Orthoretrovirinae*	*Gammaretrovirus*		Porcine endogenous retrovirus (PERV)

Picornavirales	*Picornaviridae*	*Aphthovirus*	*Foot-and-mouth disease virus*	Foot-and-mouth disease virus (FMDV)
		Cardiovirus	*Cardiovirus A*	Encephalomyocarditis virus (EMCV)
		Enterovirus	*Enterovirus B*	Coxsackievirus B4 (including swine vesicular disease virus 2 [SVDV-2]); coxsackievirus B5 (including SVDV-1)

Virion size is based on the pore sizes of two filters – one allowing virus to pass and the other not allowing virus to pass or substantially reducing the amount of viruses passing. While EM estimates the size of the dehydrated virion, ultrafiltration gives an estimate of the hydrated virion.

The presence of a viral envelope can usually be determined by exposing the virus to a lipid solvent (ether, chloroform) or detergent (sodium deoxycholate, Triton® X). The infectivity of enveloped virions is easily destroyed by these reagents, whereas non-enveloped viruses retain their infectivity.

Characterization of viral genome

Compositions of viral genome

Either enzymatic or chemical methods can be used to determine the type of viral nucleic acid in a virus. In the enzymatic method, virus material is digested with RNase or DNase and then subjected to gel electrophoresis to determine which enzyme digested the genetic material. Chemical determination uses the diphenylamine reaction for DNA or the orcinol reaction for RNA to characterize the makeup of the genome.

Acridine orange staining can be used to differentiate double-stranded DNA or RNA viruses from single-stranded DNA or RNA viruses in infected cells. Double-stranded DNA or RNA is visualized as a yellow-green fluorescence, whereas single-stranded RNA or DNA is orange-red. In combination with the location of fluorescence in cells (nucleus vs. cytoplasm), both the nucleic acid composition (DNA vs. RNA) and the strandedness of the virus can be determined.

Electrophoretic techniques can be used to determine if a virus has more than one molecule of double-stranded RNA or DNA. For certain viruses (e.g. rotaviruses), electrophoretic typing based on migration pattern of RNA segments has been used to determine groups. The polarity (sense) of viral nucleic acid can be determined through transfection or *in vitro* translation studies with a extracted viral genome. Appropriate cells transfected with positive-sense viral genome will produce virions because the genomic material serves as mRNA and is translated into proteins. Under specific conditions, an *in vitro* translation study can demonstrate the same effect.

Virus genetic diversity and relatedness

Viruses can sometimes be divided into different types, subtypes, serotypes, or genotypes. For example, influenza viruses can be classified into different types (A, B, C, and D); influenza A virus (IAV) can be classified into different subtypes (e.g. H1N1, H1N2, H3N2) based on the hemagglutinin (HA or H) and neuraminidase (NA or N); rotaviruses can be classified into different serogroups (based on the VP6 protein) or G genotypes/serotypes (based on the VP7 protein) and P genotypes (based on the VP4 protein). Determination of subtypes and/or genotypes of viruses can be achieved using subtyping PCRs or genotyping PCRs. However, genomic sequences can more definitely determine the subtypes and genotypes. In addition, sequences can be analyzed in depth to fulfill other purposes.

From the 1970s to the early 2000s, Sanger sequencing was the primary method for DNA/cDNA sequencing. This method is still used by many diagnostic and research laboratories, but is being replaced by NGS technologies. Virus sequences can be used in comparative sequence analyses (sequence homology), phylogenetic analyses, and recombination analyses to determine the genetic diversity and genetic relatedness of viruses. If collection dates of the samples containing the virus are available, molecular clock phylogenetic analyses can be conducted to establish the evolutionary relationship of viruses. For those viruses in which genetic sequences have been associated with certain phenotypes, determination of virus sequences can predict the corresponding phenotypes. For example, sequencing the HA gene of avian influenza viruses can predict whether the virus will be highly pathogenic.

Quantitation of viruses

The concentration (titer) of infectious virus in a sample can be determined using a dose–response curve, with the results expressed as infectious dose 50 (ID_{50}) (i.e. the dilution at which 50% of the population becomes infected). For viruses that can be cultivated in cell culture or embryonated chicken eggs, wells of susceptible cells or individual eggs are inoculated with sequential dilutions of the virus. Data (positive or negative for virus replication) are then analyzed using one of several possible statistical procedures (Finney 1978) to estimate the 50% infectious dose (e.g. tissue culture infectious dose [$TCID_{50}$] or egg infectious dose [EID_{50}]). For cytopathic viruses that produce clear plaques in cell culture, the concentration of infectious virus can also be estimated in terms of plaque-forming units (PFU). For viruses with hemagglutinating activity, a hemagglutination (HA) test can be performed to determine HA titers.

Real-time PCR has the capability to quantitate genomic copies of a virus in a sample (quantitative real-time PCR), but unlike the infectivity assays described above, PCR detects both infectious and noninfectious virus. In order to accurately quantitate virus in a sample, two criteria should be met: (1) control samples with known genomic copies of the virus should be included in the quantitative PCR to generate a standard curve, and (2) the suspension of test samples should be treated with nucleases to degrade all non-virion nucleic acids. However, in a diagnostic laboratory, it is impractical to treat every clinical

sample with nucleases before testing by a quantitative real-time PCR; thus, under diagnostic setting, quantitative real-time PCR just estimates the genomic copies of a virus in a sample based on standards.

Characterization of specific viral phenotypes

Some viruses cause cytopathic effect (CPE), inclusion bodies, and hemadsorption. For cytopathic viruses, CPE is characterized by morphological changes of cells infected with viruses. Inclusion bodies are alterations to the intracellular architecture induced by virus infection and can be observed after infected tissues/cells are fixed and treated with cytological stains. For example, paramyxoviruses, reoviruses, rabies virus, and poxviruses can induce cytoplasmic inclusion bodies, whereas herpesviruses, adenoviruses, and parvoviruses can induce intranuclear inclusion bodies. However, not all viruses produce obvious inclusion bodies. Hemadsorption refers to adsorption of erythrocytes to the surface of virus-infected cells. Examples of hemadsorbing viruses include some parainfluenza viruses and coronaviruses.

Viral susceptibility to temperature, pH, disinfectants, and other factors can be assessed by comparing the infectious titers of untreated with treated viruses.

Virulence phenotypes, pathogenicity, pathogenesis, and immunity of a virus can be determined by inoculating test animals followed by assessment of appropriate parameters such as clinical signs (including morbidity and mortality), viral shedding, gross lesions, microscopic lesions, immune responses, and so on. For novel or previously uncharacterized viruses, detection of the virus in a sample (especially by molecular methods) does not necessarily mean the virus is the causative agent of a disease. In order to establish causality between a previously unrecognized virus and disease, animal inoculation studies may be required to determine whether Koch's postulates can be fulfilled.

Viral phenotypes and their genetic determinants

Even if well-characterized viral phenotypic and genetic data are available, it is often difficult to identify the genetic determinants of some phenotypes. However, advancements in recombinant DNA and reverse genetics technologies have revolutionized virus studies. Construction and genetic manipulation of full-length cDNA clones (RNA viruses) and DNA clones (DNA viruses) have become important tools in the study of the biology, pathogenesis, and virulence determinants of viruses. After introducing the defined nucleotide changes into the gene(s) of interest in a cDNA/DNA clone, phenotypes of the recombinant progeny virus can be compared with those of the parental viruses. Thus, reverse genetics systems make it possible to achieve functional characterization of genes of interest and their association with viral phenotypes and genetic determinants.

Swine viruses

The taxonomy of the principal viruses infecting swine is summarized in Table 23.3. The detailed descriptions of each virus and its consequences of infecting swine are provided in Chapters 24–46.

Adenoviruses

David A. Benfield and Richard A. Hesse

Relevance

Adenoviruses have been isolated from pigs with diarrhea (Coussement et al. 1981; Haig et al. 1964; McAdaragh et al. 1980), encephalitis (Kasza 1966), nephritis (Nietfeld and Leslie-Steen 1993), respiratory disease (Hirahara et al. 1990), aborted fetuses (Dee 1995), and pigs with no clinical signs (Clarke et al. 1967; Sharpe and Jessett 1967). In general, porcine adenoviruses (PAdVs) produce subclinical infections and rarely cause disease of economic significance in swine herds.

Etiology

PAdVs are classified in the genus *Mastadenovirus* in the family *Adenoviridae*. There are three species (*Porcine mastadenovirus A*, *Porcine mastadenovirus B*, and *Porcine mastadenovirus C*) and five serotypes identified by virus neutralization assays (Clarke et al. 1967; Haig et al. 1964; Hirahara et al. 1990; Kadoi et al. 1995; Kasza 1966). The species *Porcine mastadenovirus A* includes PAdV serotypes 1, 2, and 3; the species *Porcine mastadenovirus B* includes serotype 4, the most commonly isolated serotype; and the species *Porcine mastadenovirus C* includes serotype 5 (Büchen-Osmond 2003).

Serotype 1 was isolated from a rectal swab from a pig with diarrhea (Haig et al. 1964), types 2 and 3 were isolated from pigs with normal feces (Sharpe and Jessett 1967), type 4 was isolated from the brain of a pig with neurological signs and enteritis (Kasza 1966), and type 5 was isolated from nasal secretions of pigs with respiratory disease (Hirahara et al. 1990) and the brain of a newborn piglet (Kadoi et al. 1995). In a study of 24 pools of swine fecal samples, 17/24 pools from pigs 3 to 18 months of age were positive for PAdV with serotype 3 most commonly detected (Maluquer de Motes et al. 2004). Recently, a new serotype of PAdV (WI) was isolated from the wash water in a swine facility (Sibley et al. 2011), and another novel serotype (SVN1) from urinary bladder urothelial cell cultures prepared from the bladders of normal pigs (Jerman et al. 2014). Infections of porcine urinary bladder cells with PAdV had not been previously reported, although bladder tissue did not show visible signs of infection (Jerman et al. 2014).

The morphology, structure, and physical properties of PAdVs are similar to other adenoviruses. Virions are nonenveloped icosahedra 80–90 nm in diameter with a capsid consisting of 240 hexon capsomeres, and 12 penton capsomeres (pentamers) that occupy the 12 corners of the virion. A fiber protein 20–50 nm in length with a terminal knob projects from each pentamer. The adenovirus genome is double-stranded linear DNA approximately 32–34 kilobases in length (Kleiboeker et al. 1993; Nagy et al. 2001; Reddy et al. 1998). The genome contains sufficient genetic information to code for 10 proteins, but actually encodes up to 40 proteins due to a complex RNA splicing mechanism (Kleiboeker 2005). Viral replication of PAdV is similar to other adenoviruses, with early protein expression needed for viral replication and late proteins consisting of structural components of the virion. Adenoviral virions are very stable, resisting heat inactivation at room temperature for up to 10 days, but readily inactivated by bleach, formaldehyde, alcohol, and phenolic compounds (Derbyshire and Arkell 1971).

PAdVs can be isolated and amplified in primary porcine kidney, continuous porcine kidney cells (PK-15), primary thyroid (Dea and El Azhary 1984), and primary testicular cell cultures (Hirahara et al. 1990). Replication in cell cultures produces a cytopathic effect (CPE) 2–5 days after inoculation. CPE is characterized by rounding and swelling of infected cells into aggregates of "grape-like" clusters that eventually detach from the substrate (Derbyshire et al. 1968). The most notable morphologic feature of adenovirus replication is the presence of Cowdry type A intranuclear inclusions that represent crystalline arrays of viral proteins in the cell nucleus (Koestner et al. 1968). These inclusions have been

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

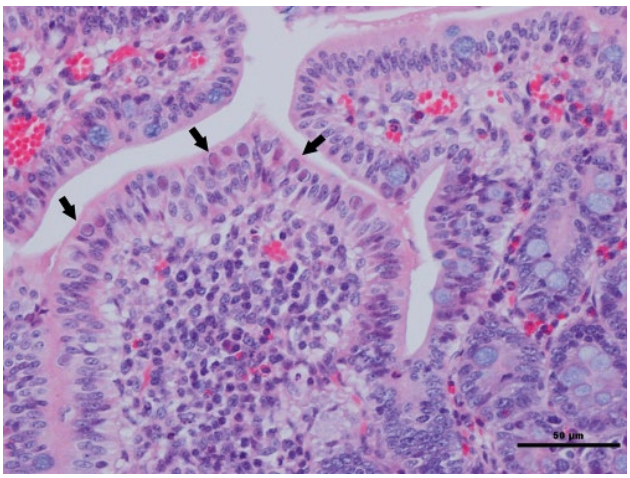

Figure 24.2 Intranuclear porcine adenovirus inclusions (arrows) in the follicle-associated epithelium of a small intestinal dome of a naturally infected pig (hematoxylin and eosin stain). Bar = 50 µm. *Source:* Courtesy of Jerome Nietfeld.

observed in cell cultures (Derbyshire et al. 1968) and in several tissues, most notably the kidney (Figure 24.1) and intestinal epithelium in the distal jejunum and ileum (Figure 24.2) of naturally and experimentally infected pigs (Coussement et al. 1981; Ducatelle et al. 1982; Sanford and Hoover 1983).

Public health

PAdVs are not known to have public health significance.

Epidemiology

Adenoviruses tend to be host specific and swine are the only known species susceptible to PAdV. While PAdV does not infect humans, swine can be experimentally infected with human adenoviruses (Betts et al. 1962). Cross-species infection between human adenoviruses and swine has been useful in that replication-defective human adenovirus type 5 vectored vaccines have been successfully developed and used to immunize swine against swine influenza (Braucher et al. 2012; Wesley and Lager 2005, 2006; Wesley et al. 2004).

Serological surveys indicate that most adult animals have antibodies to adenoviruses, but in the context of the low incidence of clinical disease, the data suggest that most infections are subclinical. The present incidence of PAdV in swine populations is unknown because most of the serological surveys were done in the 1960s–1970s. These studies indicated 26–53% of the swine population in southwest England had adenovirus group-specific antibodies (Darbyshire 1967; Darbyshire and Pereira 1964). Other reports from England indicated that 50–60% of adult swine had antibodies to adenovirus, as determined by virus neutralization and immunodiffusion tests (Darbyshire 1967; Kasza et al. 1969). The prevalence of adenovirus type 4 in Quebec was found to be considerably lower, with 83/540 (15.2%) of swine seropositive in one study (Dea and El Azhary 1984) and 64/350 (18.3%) in another (Elazhary et al. 1985).

Most PAdVs are transmitted via fecal–oral route or possibly by aerosol exposure (Benfield 1990). Vectors are not known to be involved, but the stability of PAdVs in the environment makes transmission possible via fomites, e.g. boots, clothing, bedding, transport vehicles, and feed utensils.

Most outbreaks of adenoviral diarrhea occur in pigs 1–4 weeks of age (Abid et al. 1984; Coussement et al. 1981; Sanford and Hoover 1983). PAdVs are most frequently isolated from rectal swabs of weaned pigs and rarely from adult animals (Derbyshire et al. 1966). The presence of high antibody titers in adults may prevent active replication of virus. Shedding of PAdV in feces has been reported up to 14 weeks post weaning (Derbyshire et al. 1966), and PAdV has been isolated from brain, nasal tissue, pharynx, lungs, and intestines up to 48 days after experimental inoculation (Kasza 1966). Viral antigen has also been observed in enterocytes by fluorescent antibody (FA) staining up to 45 days after infection, suggesting that long-term fecal shedding may occur (Kleiboeker 2005).

Pathogenesis

PAdVs are most commonly associated with gastrointestinal disease in swine (Abid et al. 1984; Coussement et al. 1981; Derbyshire et al. 1966, 1975; Ducatelle et al. 1982; Haig et al. 1964; Sanford and Hoover 1983). Respiratory (Hirahara et al. 1990), reproductive (Dee 1995), and neurological (Edington et al. 1972; Kasza 1966; Shadduck

et al. 1967) signs have been associated with PAdV infection, but rarely reported as the principal pathogen in pigs with these clinical presentations.

Infection of swine with PAdV occurs via ingestion and/or inhalation. Primary replication occurs in the tonsil and villous enterocytes and lymphoid tissue in the distal small intestine (Coussement et al. 1981; Ducatelle et al. 1982; Sanford and Hoover 1983; Shadduck et al. 1967; Sharpe and Jessett 1967). In all experimental studies, independent of the route of inoculation, virus replication is always demonstrated in the short blunt villi overlying lymphoid tissue or Peyer's patches in the ileum (Figure 24.2).

Piglets inoculated orally with PAdV-4 developed a watery diarrhea 3–4 days post inoculation (DPI) that lasted for 3–6 days. Adenoviral particles were demonstrated in intestinal contents up to 9 DPI. Antigen was detected in villous epithelial cells of the distal jejunum and the ileum as early as 24 hours after inoculation and for at least 15 DPI and, in one pig, up to 45 DPI (Ducatelle et al. 1982). In another study, diarrhea was induced in 8-day-old gnotobiotic piglets within 48 hours post inoculation, and adenovirus inclusions and antigens were demonstrated by light microscopy and immunofluorescence in the short blunted villi overlying lymphoid aggregates or Peyer's patches in the ileum (McAdaragh et al. 1980).

Infection of colostrum-deprived pigs causes pneumonia and lesions in the kidney, thyroid, and lymph nodes (Shadduck et al. 1967). Inoculation of pregnant swine can result in abortion, with virus replication demonstrated in fetal tissues (Dee 1995). Adenoviruses may also play a role in coinfections. Serotype 4 adenovirus in combination with *Mycoplasma hyopneumoniae* produced a more severe pneumonia (Kasza et al. 1969), and adenovirus inclusion bodies are more commonly observed in the kidneys of pigs with porcine circovirus-associated disease (J. Nietfeld, 2010, personal communication).

Common histological lesions include villous blunting and the presence of intranuclear basophilic inclusion bodies in enterocytes of the distal jejunum and ileum (Coussement et al. 1981; Ducatelle et al. 1982). In naturally infected pigs, affected enterocytes are usually present along the sides and tips of villi or on the apical border of the short blunt villi over Peyer's patches. These enterocytes appear to be desquamating and the nuclei contain large eosinophilic-to-amphophilic inclusion bodies (Sanford and Hoover 1983) (Figure 24.2). Intranuclear inclusion bodies are also commonly observed in the lung, kidney (Figure 24.1), and occasionally brain following experimental inoculation (Shadduck et al. 1967).

Shadduck et al. (1967) induced encephalitis only when pigs were inoculated via the intracerebral route; intranasal/oral inoculation produced a nonsuppurative pneumonitis. Intranuclear inclusions were observed in a variety of organs including the lung, kidney, and brain. Virus was isolated from these tissues for several weeks after inoculation.

Interstitial nephritis has also been described in a pig naturally infected with adenovirus. Kidney lesions included inflammation and intranuclear inclusion bodies in cells lining the tubules of the medulla. These cells were confirmed to be adenovirus-infected by direct FA staining, electron microscopy, and virus isolation from kidneys (Nietfeld and Leslie-Steen 1993). An unusual disseminated adenovirus infection in a nursing pig with cutaneous and visceral hemorrhages has also been described (Tang et al. 1995).

Clinical signs

Watery to pasty diarrhea is the most consistent clinical sign observed in pigs naturally or experimentally inoculated with PAdV. Diarrhea is typically observed 3–4 days after oronasal inoculation of Cesarean-derived colostrum-deprived piglets and persists for 3–6 days. Pigs may present with mild dehydration and reduced weight gain, but mortalities are rare (Coussement et al. 1981; Derbyshire et al. 1969, 1975; Ducatelle et al. 1982; Sanford and Hoover 1983). Respiratory signs and abortion are also rare clinical presentations.

Diagnosis

Adenovirus infection should be considered in the differential diagnosis of gastrointestinal and possibly respiratory diseases of pigs. PAdV can be detected by negative stain electron microscopy of feces or intestinal contents, detection of viral antigens in tissue by FA, or immunohistochemistry (IHC) staining of infected cells. FA staining using frozen sections is rapid, and results may be available the day of sample submission. IHC also offers rapid and specific identification of adenoviruses, but usually requires 1–2 days processing time. Although intranuclear inclusion bodies may be detected by light microscopy in histological samples of tissues, definitive diagnosis of PAdV should be confirmed by FA, IHC, or virus isolation.

PAdV can be readily isolated in cell culture from fecal samples or homogenates of lung or kidney. PAdV replicates and induces CPE in primary swine kidney cells, PK-15 cells, primary pig thyroid, and pig testicular cells. PAdV is frequently isolated from the kidneys, spleen, or testes harvested for the production of primary cell cultures (Hirahara et al. 1990). Thus, interpretation of virus isolation results can be complicated by the ubiquitous presence of adenoviruses in swine herds. This becomes an adventitious agent "problem" when primary pig kidney cells are used as vaccine substrate or in xenotransplantation procedures where pig tissues are used in

humans. Once isolated, the serotype of adenoviruses can be determined by virus neutralization assays with type-specific antisera, but this is rarely done because such reagents are not readily available.

PAdV infection can be serologically diagnosed by demonstrating a rising antibody titer in the presence of clinical disease. Serological diagnosis is done by either viral neutralization assays or an indirect FA test with adenovirus-infected cells as substrate to detect antibodies (Dea and El Azhary 1984).

Polymerase chain reaction (PCR) and quantitative polymerase chain reaction (qPCR) assays have been developed for the detection of PAdV serotype 3 in feces (Hundesa et al. 2006; Maluquer de Motes et al. 2004). To date, PCR has not been evaluated as a diagnostic tool for the detection of PAdV in clinical samples.

Immunity

Since most PAdV infections are either asymptomatic or cause moderate disease, there is little information on immunity. Most adult swine are seropositive to adenovirus. Colostrum-deprived and conventional newborn piglets are free of adenovirus antibodies prior to nursing. After nursing, antibody titers peak within a few days and persist for 8–9 weeks after weaning. Presumably, antibodies are protective, or at least moderate adenovirus infection, because the frequency of adenovirus shedding increases after weaning as colostral antibody titers decline (Derbyshire et al. 1966).

Prevention and control

PAdVs are stable for up to 10 days in the environment (Dee 1995) and are reported to remain viable for 18 days downstream of the site of a manure spill (Haack et al. 2015). Control and prevention is dependent on practicing sanitation procedures that reduce environmental fecal contamination. Due to the mild nature of adenovirus infections, there is little incentive for the production of vaccines. PAdVs have proven to be potential vectors for veterinary vaccines incorporating antigens from transmissible gastroenteritis and African swine fever viruses (Bangari and Mittal 2004; Ferreira et al. 2005).

African Swine Fever Virus

José Manuel Sánchez-Vizcaíno, Alberto Laddomada, and Marisa L. Arias

Relevance

Historical overview

African swine fever (ASF) was first described in 1921 in Kenya when the virus (ASFV) was transmitted from wild African suids to domestic pigs, causing a disease with 100% mortality (Montgomery 1921). Since this discovery, ASFV has left Africa on three occasions. The first incursion occurred in 1957 from Angola to Lisbon (Manso-Ribeiro et al. 1958). The second (1960) was from Africa to Lisbon and then to Spain and other European countries, including France (1964), Italy (1967, 1969), the island of Sardinia (1978), Malta (1978), Belgium (1985), and the Netherlands (1986). From Europe, ASFV spread to Latin America, including Cuba (1971, 1980), Brazil (1978), the Dominican Republic (1978), and Haiti (1979). Subsequently ASFV was eradicated from all of these countries, except Portugal and Spain, where it remained endemic until 1995, and Sardinia, where it remains endemic today. A third ASFV incursion from Africa occurred in 2007, when it entered the Caucasian region and spread to the Russian Federation (2007), Ukraine (2012), Belarus (2013), reaching the Baltic regions and Poland in 2014, and spreading westward to Central and Western Europe in 2017 and 2018. In August 2018 ASF was reported for the first time in China. All of these countries remain infected with ASFV at present.

The current ASFV epidemiological situation poses a serious threat to animal health, pig production, and therefore the economies of affected and neighboring countries. ASFV remains endemic in many sub-Saharan countries on the African continent.

Public health

ASFV is not infectious to humans and does not directly affect public health (EFSA 2009). However, ASFV has a serious social and economic impact on the trade of swine, pig by-products, and food security, particularly in countries in which pigs are an important source of protein.

Etiology

ASFV is a large, icosahedral, linear double-stranded DNA virus and the only member of the family *Asfarviridae*, genus *Asfivirus* (Dixon et al. 2005). The virion is composed of four concentric layers and an external hexagonal membrane (Figure 25.1) acquired by budding through the cell plasma membrane (Salas and Andrés 2013). ASFV replication occurs mainly in the cytoplasm of infected macrophages, though an early stage of replication has also been described in the nucleus.

The viral genome varies in length from 170 to 193 kb and contains 150–167 open reading frames. The genome consists of a conserved central region of approximately 125 kb and two variable ends containing five multigene families (MGFs) (Yañez et al. 1995). Deletions and insertions of copied regions as long as 20 kb occur within the MGF genes, suggesting that these regions may help generate antigenic variability and therefore help ASFV evade the host immune system.

The virus is genotyped and subtyped on the basis of small variations in a central variable region (CVR) within the conserved central region. Complete genome sequences are available for 15 African and European ASFV isolates to date, coming from different regions and hosts (domestic pigs, warthogs, and ticks). These isolates display different levels of virulence and significant genomic diversity (De Villiers et al. 2010). Sequence variation within MGF regions has been associated with the degree of virulence in macrophages and with tick host range (Burrage et al. 2004; Zsak et al. 2001).

ASFV particles are extremely complex: two-dimensional electrophoresis indicates at least 28 structural proteins

Diseases of Swine, Eleventh Edition. Edited by Jeffrey J. Zimmerman, Locke A. Karriker, Alejandro Ramirez, Kent J. Schwartz, Gregory W. Stevenson, and Jianqiang Zhang.

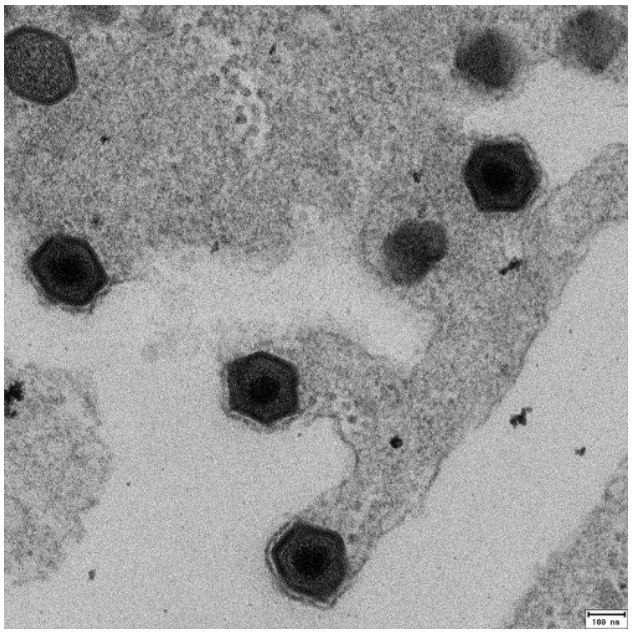

Figure 25.1 Electron micrograph of an ASFV particle. *Source:* Courtesy of CBM-CSIC-UAM.

in particles within the cell and 54 in purified extracellular particles. More than 100 virus-induced proteins have been described in infected porcine macrophages (Esteves et al. 1986). Attachment proteins p12 and p24 can be found in the external membrane of extracellular particles, while proteins p150, p37, p34, and p14 localize to the virus core. The external envelope also contains the hemagglutinin (HA) protein (virus homologue of cellular CD2), the only known glycoprotein in the viral particle.

Several ASFV proteins are highly antigenic, including the major structural component of the viral capsid (p72) as well as the membrane proteins p54, p30, and p12. More than 50 viral proteins induce an antibody response in infected or recovered pigs. They are useful as antigens in serological diagnosis, although their role in inducing protective immunity is unclear (Neilan et al. 2004).

ASFV does not induce a full neutralizing antibody immune response, preventing the development of a serotyping classification scheme. Instead, a genotyping strategy has been used to define 24 ASFV genotypes based on partial nucleotide sequencing of the p72 gene (Achenbach et al. 2017; Quembo et al. 2017). Subtyping is performed based on sequence analysis of tandem repeat sequences in a CVR within the B602L gene (Nix et al. 2006) as well as in the region between the I73R and I329L genes on the right end of the genome (Gallardo et al. 2014). Genome regions encoding p54, p30, or HA have also proven useful for virus tracking.

All 24 known ASFV genotypes have been identified in sub-Saharan Africa (Achenbach et al. 2017; Quembo et al. 2017). ASFV isolates detected in Europe and the Western Hemisphere before 2006 were limited to genotype I from West Africa. In 2007, a new ASFV isolate with genotype II from southeast Africa was detected throughout the Caucasian region in Europe (EFSA 2010).

ASFV particles remain stable in serum-free culture medium at pH 4–10, but they are inactivated in minutes at pH below 4 or higher than 11.5 (EFSA 2010). Particles in serum can remain infectious for 6 years at 5 °C (41 °F) and can remain infectious for days at pH 13.4 in medium containing 25% serum. ASFV is inactivated by heating at 60 °C (140 °F) for 30 minutes (Plowright and Parker 1967) or 56 °C (133 °F) for 70 minutes (Mebus 1988). Many organic solvents can inactivate the virus by disrupting the lipid envelope, but ASFV is resistant to proteases and nucleases (Plowright and Parker 1967).

ASFV field isolates must be recovered in porcine monocytes and macrophages because they do not replicate in conventional cell culture. For research purposes, several ASFV isolates have been adapted to grow in African green monkey kidney stable cell lines such as VERO, MS, and CV-1 cells. More recently, several porcine cell lines of monocyte origin have been developed for research purposes (Chitko-McKown et al. 2013; Hurtado et al. 2010). For example, the COS-1 cell line is used for detection, growth, and titration of field isolates, as well as for generation of laboratory-engineered ASFV. Despite this progress, a suitable cell line has yet to be identified or developed in which the virus isolates or potential vaccine candidates can replicate without undergoing genomic changes that alter its immunogenicity. This remains a significant obstacle to ASFV research and vaccine development.

Epidemiology

ASF has been described in 25 countries in sub-Saharan Africa, where different epidemiological patterns and scenarios are present. In Europe, ASF is endemic in Sardinia (Italy) and in some areas of Eastern Europe (Gogin et al. 2013). In June 2007, ASF was recognized in the Caucasian region following an outbreak in Georgia. Subsequently the outbreak spread to Armenia, Azerbaijan, and the Russian Federation, reaching the border with Ukraine and northwest Russia near the Baltic Sea and Barents Sea. Since 2011, ASF has spread to the northwest, reaching new territories in the Russian Federation (around Moscow), Ukraine (2012), Belarus (2013), Estonia (2014), Latvia (2014), Lithuania (2014), Poland (2014), Moldova (2016), Czech Republic (2017), Romania (2017), Hungary (2017), Bulgary (2018), Belgium (2018). From August 2018, ASF has rapidly spread to many provinces and municipalities in China. The Eastern European outbreaks resulted from a single introduction of a southeast African genotype II ASFV isolate into Europe in 2007. Two genetic variants have been identified so far

among isolates from the various Eastern European countries affected (Gallardo et al. 2014). The mortality associated with these outbreaks has decreased over time, while the rates of surviving animals positive for antibodies or with unspecific clinical signs have increased. This fact could be related at least in part to the presence of moderate virulent viruses that have been recently identified in certain regions of Europe (Gallardo et al, 2018).

The natural hosts of ASFV are wild and domestic suids. European wild boars are susceptible to ASFV infection and present clinical signs and mortality rates similar to those observed in domestic pigs (McVicar et al. 1981; Sánchez-Botija 1982). In contrast, ASFV usually produces subclinical infection in the three African wild suid species that serve as reservoirs: warthogs (*Phacochoerus aethiopicus*), giant forest hogs (*Hylochoerus meinertzhageni*), and bushpigs (*Potamochoerus porcus*) (De Tray 1957).

ASFV is maintained in Africa via a complex transmission cycle involving African wild suid species, soft ticks, and domestic pigs. In eastern and southern regions, the virus follows an ancient sylvatic cycle involving soft ticks and asymptomatic infected warthogs and bushpigs. Two additional cycles have been described in endemic areas: a domestic pig/tick cycle without warthog involvement and a domestic pig/pig cycle.

ASFV is transmitted within Europe most often directly via contact between sick and healthy animals, including domestic pigs and wild boar. ASFV spreads among domestic pigs via oral and nasal routes (Colgrove et al. 1969). Pigs can also be infected by other routes, including tick bite (Plowright et al. 1969), cutaneous scarification, and injection (intramuscular, subcutaneous, intraperitoneal, or intravenous) (McVicar 1984).

Natural infection in the European wild boar has been described in the Iberian Peninsula, Sardinia, and Eastern Europe. For reasons that remain unclear, the wild boar currently plays a significant role in ASFV spread and persistence in Eastern Europe (EFSA 2015). In contrast, in Spain and Portugal, the wild boar was not a major ASFV reservoir and did not pose a major obstacle to eradication. The difference may be that the wild boar population density is much higher now than in the past (Arias and Sánchez-Vizcaíno 2002a). Evidence in Sardinia suggests that ASFV naturally disappears from wild boar populations if the disease is eradicated from domestic pigs in the same area (Laddomada et al. 1994).

Several species of soft ticks are ASFV reservoirs and vectors, including *Ornithodoros moubata* in Africa (Plowright et al. 1969) and *Ornithodoros erraticus* on the Iberian Peninsula (Sánchez-Botija 1963). Indirect transmission by biological vectors such as *O. erraticus* occurs on the Iberian Peninsula, especially in outdoor pig production. The role of these vectors in Eastern Europe is unknown. In Africa, both transovarial and transstadial transmissions of ASFV have been described involving *O. moubata* (Plowright et al. 1970), while in Europe, only transstadial transmission involving *O. erraticus* has been observed. *O. savignyi*, present in Africa, can transmit ASFV to domestic pigs in the laboratory (Mellor and Wilkinson 1985), although this has not been described in the field. Several other tick species widely distributed in North and South America are capable of harboring and transmitting ASFV (Groocock et al. 1980). All *Ornithodoros* spp. tested to date are susceptible to ASFV infection (EFSA 2010).

The ASFV incubation period varies from 4 to 19 days, depending on the ASFV isolate and route of exposure. Domestic pigs infected with virulent isolates begin shedding virus during the incubation period, prior to the observation of clinical signs. After the onset of clinical signs, ASFV is shed at high levels in all secretions and excretions, including nasal secretions, saliva, feces, urine, conjunctival exudate, genital discharges, and bleeding wounds. Surviving pigs show high antibody titers and long-term viremia; virus may be recovered from tissues for weeks or months. Consequently, once ASFV is established in domestic pigs, carrier pigs become an important ASFV reservoir and therefore must be a focal point of ASF eradication strategies.

Infection in wild African suids typically results in low virus titers in tissues and low or undetectable viremia (Plowright 1981). Genetic factors and immunologic responses in the host that may be associated with low viral load remain unclear. These levels of virus are sufficient for transmission to domestic pigs through tick vectors, but usually not through direct contact between animals. This transmission cycle makes ASFV eradication in Africa extremely difficult.

ASFV is very stable in the environment and can remain infectious for more than 3 days in contaminated pens and for up to several weeks in pig feces. After storage at room temperature, ASFV can be isolated from sera or blood after 18 months and from putrefied blood after 15 weeks (EFSA 2009). ASFV persists for weeks to months in frozen or uncooked meat. In cured or processed products, such as Parma ham, infectious virus was not found after 300 days of processing and curing (McKercher et al. 1987). Spanish cured pig meat products, such as Serrano hams and shoulders, were free of viable ASFV by day 140 and Iberian loins by day 112 (Mebus et al. 1993). No infectious ASFV was found in cooked or canned hams heated to 70 °C (158 °F). Infectious ASFV was undetectable by 110 days in chilled deboned meat, bone-in meat, or ground pork and by 30 days in smoked deboned meat (Adkin et al. 2004).

ASFV is inactivated by organic solvents, detergents, oxidizing agents such as hypochlorite and phenol, and commercial disinfectants as a function of exposure time and temperature. For example, ASFV is inactivated in 30 minutes by exposure to 2.3% chlorine, 3% orthophenylphenol, or iodine-containing compounds. Other effective virucidal treatments include formalin, sodium

hydroxide, beta-propiolactone, glyceraldehydes, or acetyl-ethyleneimine (EFSA 2010). In general, soaps, detergents, and alkalis are effective for disinfecting animal housing, machinery, clothing, vehicles, and areas of human habitation. Disinfectants such as Virkon® are recommended for use in aircraft. Virus-contaminated feed, effluents, and manure may be buried or burned. ASFV-contaminated pig slurry can be treated at 4 °C (39 °F) with 1% sodium or calcium hydroxide for 3 minutes or with 0.5% sodium or calcium hydroxide for 30 minutes (Turner and Williams 1999). Insecticides (organophosphates and synthetic pyrethroids) are recommended for tick eradication.

Pathogenesis

The sites of primary ASFV replication are the monocytes and macrophages of the lymph nodes nearest the point of virus entry. In the case of oral exposure, the monocytes and macrophages of the tonsils and mandibular lymph nodes are the first involved. Subsequently the virus spreads via the blood and/or lymphatic system to sites of secondary replication: lymph nodes, bone marrow, spleen, lung, liver, and kidney. Viremia usually begins 4–8 days postentry and, because of the absence of fully neutralizing antibodies, persists for weeks or months.

While ASFV replicates mostly in monocytes and macrophages (Mínguez et al. 1988), it also replicates in endothelial cells (Wilkinson and Wardley 1978), hepatocytes, renal tubular epithelial cells (Gómez-Villamandos et al. 1995), and neutrophils (Carrasco et al. 1996). No infection has been observed in T or B lymphocytes (Mínguez et al. 1988). The virus particle enters susceptible cells by receptor-mediated endocytosis (Alcamí et al. 1989) and replicates in distinct areas of the cytoplasm close to the nucleus. Studies on the interaction of ASFV with monocytes and derived macrophage subsets showed that virulent isolates have evolved mechanisms to counteract activated macrophage responses, thereby promoting viral survival, dissemination in the host, and ASF pathogenesis (Franzoni et al. 2017).

Most ASFV isolates bind to red blood cell membranes (Quintero et al. 1986) and platelets (Gómez-Villamandos et al. 1996) and cause hemadsorption in affected pigs. Some isolates, however, do not induce hemadsorption.

The hemorrhaging observed in the final stages of the ASF acute form is believed to reflect phagocytosis of the endothelial cells in which the virus is replicating. In contrast, hemorrhaging in ASF subacute form reflects mainly an increase in vascular permeability (Gómez-Villamandos et al. 1995). Lymphopenia in ASF acute form is associated with lymphocyte apoptosis, mainly in the T area of lymphoid organs (Carrasco et al. 1996). This apoptosis does not appear to involve viral replication, since no evidence of replication in T or B cells has been reported; instead, other processes are likely to be involved, perhaps triggered by cytokines or apoptotic mediators released by ASFV-infected macrophages (Oura et al. 1998).

ASF subacute form is characterized by transitory thrombocytopenia (Gómez-Villamandos et al. 1996). The alveolar edema observed in the final stages of acute and subacute forms of ASF is the primary cause of ASF-related death. This edema results from the activation of pulmonary intravascular macrophages (Sierra et al. 1990).

Clinical signs

Wild African pigs are extremely resistant to clinical disease and do not generally present lesions. Domestic pigs and European wild boars exhibit a wide range of clinical signs from acute to chronic. ASF may resemble several other pig diseases, especially classical swine fever (hog cholera) and erysipelas.

The incubation period ranges from 4 to 19 days in natural infections but only 2–5 days in experimental infections, depending on the virus dose and inoculation route (Mebus et al. 1983). Clinical manifestations of ASF depend on the virulence of the isolate, exposure dose, and route of infection. Highly virulent ASFV isolates are mainly involved in the peracute and acute forms of the disease. Moderately virulent isolates can generate a wide range of clinical forms: acute, subacute, and chronic or inapparent. Low virulent isolates may induce subacute, chronic, or inapparent disease.

Morbidity ranges from 40 to 85%, depending on whether the virus isolate causes acute or subacute disease, the virulence of the isolate, the route of exposure, and the presence or absence of bleeding (epistasis or hemorrhagic diarrhea). Highly virulent isolates may cause 90–100% mortality, moderately virulent isolates cause 20–40% mortality in adult animals and 70–80% in young animals, and lowly virulent isolates produce 10–30% mortality.

Peracute form

The peracute form of ASF is characterized by loss of appetite, body temperature >41 °C, depression, and cutaneous hyperemia. Death usually follows 1–4 days after clinical signs appear. The peracute form is usually reported in ASF-naïve areas.

Acute form

The acute form of disease is characterized by loss of appetite, elevated body temperature (40–42 °C, 104–108 °F), inactivity, early leukopenia, pulmonary edema,

Figure 25.2 Purple marks on the ears of a pig with acute ASF because of intense hyperemia.

extensive necrosis and hemorrhage of lymphoid tissue, hemorrhages in skin (especially the skin of ears and flanks), splenomegaly, and high mortality (Mebus et al. 1983). In the final stages, rapid, labored breathing may be observed, as well as serous or seromucous nasal secretions caused by pulmonary edema.

In some cases there may be nasal hemorrhaging, constipation, vomiting, and, to a lesser extent, diarrhea. Hemorrhagic discharge from the anus (melena) is sometimes observed. Obvious signs of disease are exanthemas, in which the skin turns pinkish and nearly purple because of intense hyperemia, and/or cyanotic foci, which appear as irregular purple marks on the skin of the extremities, ears, chest, abdomen, and perineum (Figure 25.2). Hematomas and necrotic areas may be observed, although these lesions are more intense in pigs infected with moderately virulent isolates. Abortion frequently occurs in gestating females and is sometimes the first clinical sign of an outbreak. Mortality rates range from 90 to 100% at 7 days after the appearance of clinical signs. This clinical form is observed mainly in ASF-naïve areas.

Subacute form
